Abstract. *The effectiveness of simplified nonlinear models for seismic assessment of steel moment frames using single and multi-mode nonlinear static methods compared to nonlinear response history analysis is discussed in this paper. Results of studies of different steel arch-type buildings with perimeter steel moment resisting frames are compared with those from nonlinear response history analysis (NRHA). Simplified modeling of gravity systems is also discussed. It is demonstrated that the nonlinear static procedure (NSP) has many limitations for quantitative assessment of moment frame demands even for relatively low-rise structures. But it has much value in understanding important behavior characteristics that are not being explored in a NRHA in which engineers usually focus on a “blind” demand/capacity assessment rather than interpretation and visualization of behavior. The conclusion is that both NSP and NRHA have intrinsic value and that it is advisable to employ a combination of both to understand seismic performance and quantify important engineering demand parameters. This study is part of a recent National Institute of Standards and Technology (NIST) funded project through a joint venture partnership of the Applied Technology Council (ATC) and Consortium of Universities for Research in Earthquake Engineering (CUREE) on improvement of nonlinear multiple-degree-of-freedom modeling for design decisions of regular and irregular structural systems (NIST GRC 10-917-9).*

1 INTRODUCTION

Performance Based Earthquake Engineering (PBEE) concepts have been adopted by a number of engineering guidelines such as [1-7] for seismic evaluation and rehabilitation of steel and reinforced concrete structures. A common procedure for a structural engineer to conduct such an evaluation is to utilize nonlinear static procedure (NSP), which is also referred in the literature as pushover analysis. In U.S. practice, a pushover analysis is typically based on an invariant lateral load pattern that is applied along the height of a structure, which is pushed to a pre-defined target roof displacement. Many researchers have conducted extensive research on the evaluation of seismic demands of structural systems with nonlinear static procedures based on invariant load patterns, e.g., [8-12]. In these studies major drawbacks of these procedures to predict seismic demands of structures have been summarized. Others [13-16] have conducted research on enhanced NSPs that account for higher mode effects and either retain the simplicity of invariant load patterns or employ adaptive procedures in which the lateral load pattern varies during the nonlinear analysis. Typically, these methods improve the prediction of engineering demand parameters compared to the single mode PA. The value of NSP is in the fact that this procedure permits inspection of response and is a relatively simple approximate tool to identify critical regions of a structural system in which the potential for significant strength or stiffness discontinuities is relatively high.

In FEMA-440 [5] the major differences between results obtained from nonlinear static and nonlinear response history analysis (NRHA) were attributed to a number of reasons such as the effect of component deterioration on the seismic response of a structural system [6]. Other reasons for differences between NRHA and NSP in prediction of seismic demands of a structural system are (1) P-Delta effects, (2) inaccuracies in the prediction of target roof displacement at which structural response is to be evaluated, and (3) multi-degree-of-freedom (MDOF) effects. In order to improve nonlinear MDOF modeling for structural engineering design practice for better estimation of the seismic response of structural systems such as steel and reinforced concrete moment resisting frames (MRFs) and reinforced concrete and masonry shear walls, the National Institute of Standards and Technology (NIST) initiated a program of focused studies [18]. This paper summarizes one of the analytical studies conducted as part of this program, which addressed the minimum level of MDOF modeling sophistication and appropriateness of nonlinear methods for seismic evaluation of special steel MRFs. This study investigates the effect of higher modes and gravity system as part of the lateral resisting system on engineering demand parameters (EDPs) of steel MRFs such as story drift ratios, story shear forces, overturning moments, residual story drift ratios and absolute floor accelerations along the height of steel MRFs. The investigation is based on simplified nonlinear models of steel MRFs.

2 ARCHETYPE STEEL BUILDINGS

The steel buildings used for evaluation of EDPs predicted with NRHA and NSP procedures are two-, four- and eight-story special MRFs. The structural systems are perimeter moment frame systems of a set of archetype steel buildings designed as part of the NIST [19] project. These structures comprise 3-bay steel MRFs with Reduced Beam Sections (RBS) designed in accordance with AISC 358-05 [20]. A plan view of a typical archetype is shown in Fig. 1. The three steel buildings that are utilized in this study are designed based on Response Spectrum Analysis (RSA) for seismic design category D_{max} . This corresponds to a design spectral acceleration at short period, S_{DS} , and at a period of 1 second, S_{D1} , equal to 1.0g and 0.60g, respectively. More details on the design of the archetype steel buildings are summa-

rized in [19, 21]. In the subsequent discussion and figures, the two-, four- and eight-story steel MRFs are denoted as 2-RSA- D_{\max} , 4-RSA- D_{\max} and 8-RSA- D_{\max} , respectively.

Figure 1: Plan view of typical archetype building with perimeter moment resisting frames.

3 MODELING OF ARCHETYPE STEEL MOMENT RESISTING FRAMES

In order to model the seismic response of the perimeter steel MRFs discussed in Section 2, two analytical models are utilized. Both models are two-dimensional (2-D). In the first analytical model all components (beams, columns and panel zones) of the steel MRF are modeled explicitly. The second model is a single bay simplified frame whose properties are tuned to represent the detailed steel MRF. In both models P-Delta effects are simulated with a leaning column that is connected to the steel MRF with axially rigid links. These links have hinges at their ends. The subsequent sections discuss details of these two analytical models.

3.1 Three-bay steel moment resisting frame model

The steel MRF in the East-West loading direction (see Fig. 1) is modeled in a customized version of DRAIN-2DX (Prakash et al. [22]). This numerical model consists of elastic beam-column elements with concentrated plastic hinge springs at their ends. These springs simulate the hysteretic response a steel component (beam or column) subjected to cyclic loading including strength and stiffness deterioration based on the modified Ibarra-Krawinkler (IK) deterioration model [23, 24]. Panel zones are modeled with the model discussed in [25], which explicitly represents panel zone shear distortions including the possibility of nonlinear behavior during an earthquake. The exact location of the RBS section is also incorporated in the model. The deterioration parameters of beams with RBS and steel columns are determined by multivariate regression equations that have been developed based on information retrieved from a recently developed database for deterioration modeling of steel components [24, 26]. These analytical models were used extensively for quantification of building seismic performance factors using the FEMA P-695 methodology [19].

3.2 Simplified single-bay frame model

To reduce the computational effort in estimating seismic demands of the steel MRFs with NRHA and evaluate the effectiveness of simpler representations of the 3-bay steel MRFs discussed in Section 3.1, a simplified model as shown in Fig. 2 is developed. In this model a single bay frame in a manner represents the three-bay moment-resisting frame so that overturning moment and column axial deformation effects are adequately represented. Luco et al. [27] developed similar models for computing the seismic inelastic demands of steel MRFs. P-Delta effects are simulated with a leaning column that is always present in the nu-

merical model. Strength and stiffness properties of the gravity framing that is not part of the moment resisting frame can be represented with the fishbone model shown at the right of Fig. 2. Lumping together multi-bay frames into a single bay frame can be accomplished by the following rules:

$$\sum EI_i/L_i = EI/L \quad (1)$$

$$\sum M_{p,i} = M_p \quad (2)$$

in which I_i and L_i is the moment of inertia and length of the i -th beam in a story, respectively, and EI/L and M_p are the stiffness and plastic moment of the single bay beam. For steel columns,

$$\sum EI_i = 2EI \quad (3)$$

$$\sum M_{pc,i} = 2M_{pc} \quad (4)$$

in which $M_{pc,i}$ is the plastic moment of the i -th column of the multi-bay frame and M_{pc} is the plastic moment of the single bay column in the presence of an axial load. For taller steel MRFs in which overturning moment and axial deformations in columns are important, these effects can be approximated by setting L of the single bay frame equal to the distance between end columns of the multi-bay frame, and setting the area of the single bay column equal to the area of the end column of the multi-bay frame. This simplification is based on the assumption that overturning effects are resisted mostly by the exterior columns of a steel MRF. The approximations summarized herein are reasonable if all bays of the steel MRFs are of about equal width, and become more approximate when spans of the steel MRF vary considerably. Ignoring panel zone shear deformations and using centerline dimensions for beams and columns introduce additional approximations to the analytical models.

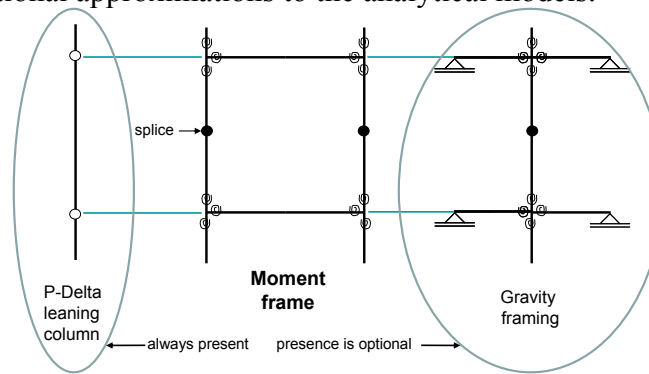

Figure 2: Simplified model with P-Delta column and gravity framing fishbone model.

Figure 3a shows a comparison between the pushover curves of the 3-bay four-story steel MRF and the simplified 1-bay model. In this figure, the base shear V is normalized with respect to the seismic weight W of the steel MRF. The base shear V is computed from the inertia forces only (V_I). The roof drift θ_r is defined as roof displacement δ_r over the total height H of the steel MRF. As seen from this figure, the response of the 1- and 3-bay models is almost identical. The 1-bay models are implemented in the OpenSees [28] simulation platform whereas the 3-bay models are implemented in Drain-2DX [22]. The base shear histories for a single ground motion obtained from the 3-bay model developed in Drain-2DX (ATCW 3-Bay)

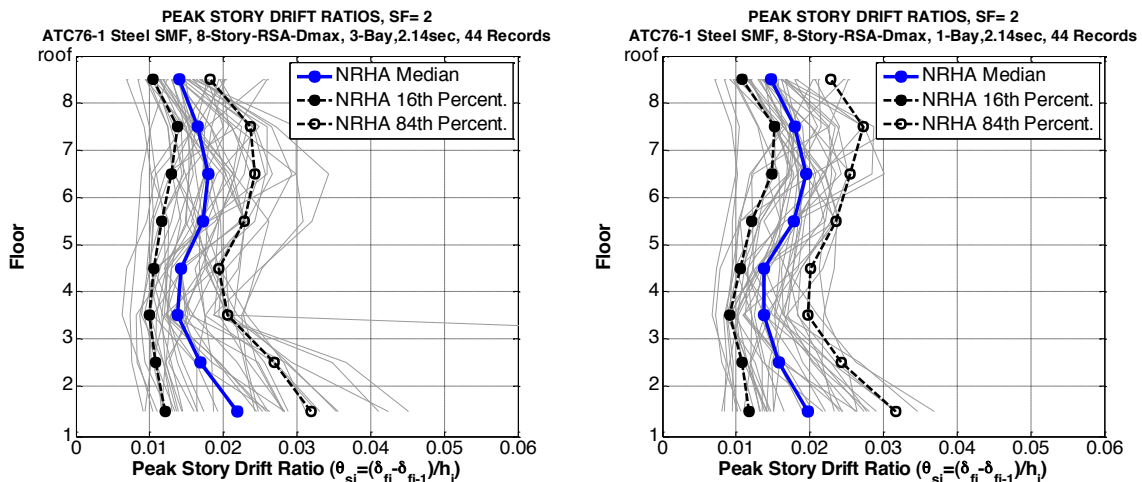

and the 1-bay model developed in OpenSees are shown in Fig. 3b. . Simulations are carried out for the FEMA P-695 [7] set of 44 ground motions for three scale factors (0.5, 1.0 and 2.0). Note that a scale factor $SF=2.0$ corresponds to approximately a maximum considered event (MCE) in California. A comparison between absolute peak overturning moments (OTM) obtained for the eight-story 3-bay and 1-bay frames is shown in Fig. 3c. In both static and dynamic analysis the seismic response based on the 1-bay and 3-bay models is almost identical, providing confidence in both the simulation platforms and in the ability of the simplified model to represent the response of the 3-bay steel MRF.

4 SEISMIC ASSESSMENT OF STEEL MOMENT RESISTING FRAMES

This section focuses on evaluating the seismic response of steel MRFs with simplified models discussed in Section 3.2. The assessment is based on a comparison between NSP and NRHA results. Feasibility and limitations of the NSP is illustrated with the case studies that were investigated. Since the emphasis is on simple methods that can assess multi-mode effects on the seismic response of steel frame structures the modal pushover analysis (MPA) [13] is also evaluated. Two main options are used for modeling the components of the steel MRFs discussed in Section 3. These options are summarized as follows:

- **ASCE41:** all the steel components are modeled in accordance with ASCE/SEI 41-06 [3] utilizing the component model shown in Fig. 4a. Note that a post-capping stiffness obtained by linearly connecting peak point C and point E of the generic ASCE/SEI 41-06 model is used. This modification is made in order to provide a better match with data and analysis models developed in the past decade [23, 24] and also to avoid numerical stability problems in the analysis.
- **Analyt.M1:** all the steel components are modeled with the modified IK component model [24]. For this purpose, a monotonic backbone curve is used as shown in Fig. 4b. This option is the same as the ATC-72-1 [29] analysis Option 1. Cyclic deterioration is not reflected in the component model for monotonic response and subsequently in the NSP. However, in the NRHA the component model deteriorates cyclically based on rules discussed in [23, 24]. For comparison purposes in the same figure we have superimposed the modified backbone curve based on the IK model (see Fig. 4b) based on the ATC-72 [29] analysis option 3.

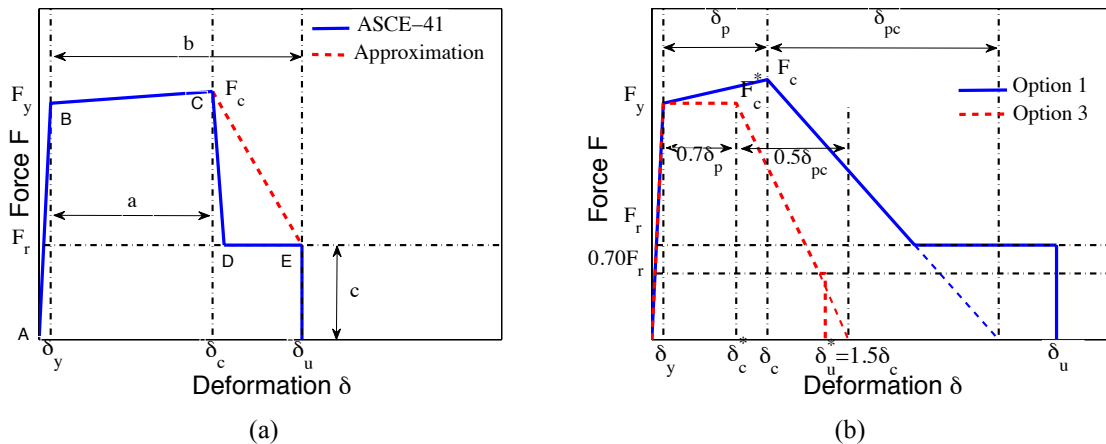

Figure 4: Steel component models; (a) ASCE 41; (b) Modified IK model, Options 1 and 3.

The following two options are used to determine the target roof displacement for the NSP:

- **ASCE41:** Target displacement obtained from ASCE/SEI 41-06 [3] coefficient method.
- **EqSDOF:** Target displacement based on median displacement obtained from NRHA of the first mode equivalent Single-Degree-Of-Freedom (SDOF) system using the 44 ground motions of the FEMA P-695 [7] set and the analysis tool IIIDAP (Lignos [30]). Equivalent SDOF properties are obtained from the base shear without P-Delta V_I – roof displacement pushover curve (not the base shear including P-Delta $V_{I+P-\Delta}$ – roof displacement pushover curve), which implies that P-delta effects are accounted for approximately in the properties of the equivalent SDOF system.

Note that for the MPA procedure only the Analyt.M1-EqSDOF option was explored. This implies that the pushover analysis is conducted with the Analyt.M1 model, and the target displacement for the individual modes is determined from an equivalent SDOF analysis with the analysis tool IIIDAP [30], which computes inelastic response of SDOF systems with due consideration given to deterioration. The cyclic deterioration parameter λ [26] is set equal to the median value for steel components obtained from a steel database for deterioration modeling (Lignos and Krawinkler [26]).

4.1 Single mode nonlinear static analysis procedure

Figures 5a and 5b show the pushover curves with ($V_{I+P-\Delta}$) and without P-Delta (V_I) effects for the four-story steel MRF based on the ASCE-41 and Analyt.M1 component models, respectively. In the same figures we have superimposed the idealized trilinear curve based on the ASCE-41-06 [3] criteria. These figures show that the NSP based on the ASCE41 component model underestimates the post-yield strength and deformation capacities compared to the Analyt.M1 model. The implication is that the target roof displacements predicted from the equivalent SDOF systems shown in Fig. 5c and 5d are different for large ground motion demands.

Figure 5: Single mode pushover curves and equivalent SDOF systems for the 4-story-RSA-Dmax steel MRF.

The use of the pushover curve based on the ASCE-41 component model (see Fig. 5a) together with the equivalent SDOF model for target displacement prediction (ASCE41-EqSDOF) may provide performance estimates that are lower than might be justifiable. For a scale factor $SF = 2.0$ the EqSDOF leads to 33 collapses, which are a direct consequence of the relatively short yield plateau obtained from using ASCE41 component models in the pushover analysis. For all options, NSP story drift predictions show a significant deviation from median NRHA values (Fig. 6a, 6b). In the inelastic range ($SF = 2.0$) drifts in the lower stories are overestimated and drifts in the upper stories are underestimated. Results are illustrated for the two- and four-story steel MRFs but the same observation applies for the eight-story MRF.

Nonlinear static procedure story shear predictions for the four-story steel MRF show poor correlation with NRHA results in the inelastic range ($SF = 2.0$). This can be seen in Fig. 6c and 6d. Story shears are consistently underestimated, particularly in the upper stories. The reason is dynamic redistribution, which amplifies story shear forces compared to those obtained from a predetermined lateral load pattern. If story shears are an important performance consideration, then the validity of quantitative values obtained from a pushover analysis diminished for this 4-story steel SMF. Similar observations apply to floor OTMs, which control axial forces in columns of frame structures. In the upper stories, the NSP predictions are less than half those obtained from NRHA (see Fig. 6e and 6f). The situation is better at the base, because absolute maximum shear forces in individual stories occur at different times. The outcome is that even for relatively low-rise steel MRF structures NSP predictions may provide misleading quantitative information, particularly for force quantities.

The all-important issue of lateral load pattern is not explored here. Previous work [5] has addressed this issue and came to the conclusion that variations in invariant lateral load patterns do not improve the accuracy of EDP predictions. The load pattern applied in all cases discussed here is the pattern structured after the elastic first mode deflected shape, as recommended in [3].

4.2 Incorporation of gravity system in analysis model

Gravity system components must have sufficient strength and deformation capacity to resist tributary gravity loads at the maximum drifts computed for the lateral load resisting system. The structural engineer typically decides whether or not to include contributions of the gravity system to lateral stiffness and strength of a building. It is recommended to incorporate the gravity system in the analytical model of the structural system because the analysis might expose weaknesses that are not evident from inspection. An incentive for incorporating the gravity system is its potential benefit in decreasing drift demands and increasing collapse capacity. This might be particularly attractive if the pushover curve exhibits an early negative tangent stiffness that may lead to large displacement amplification or even collapse. The negative stiffness will be reduced potentially by incorporating the gravity system or might even turn into a positive stiffness (Gupta and Krawinkler [31]).

A simple way to incorporate the gravity framing is by means of the “fishbone” arrangement shown earlier in Fig. 2. In order to prevent accumulation of large axial force in the column of the fishbone, an arrangement with two beams is preferred. In this arrangement all beams are lumped into a single beam (I/L of beam = $\sum EI_i/L_i$ of all beams), all columns are lumped into a single column (I of column = $\sum I_j$ of all columns), and all gravity connections are lumped into two connections represented by rotational springs.

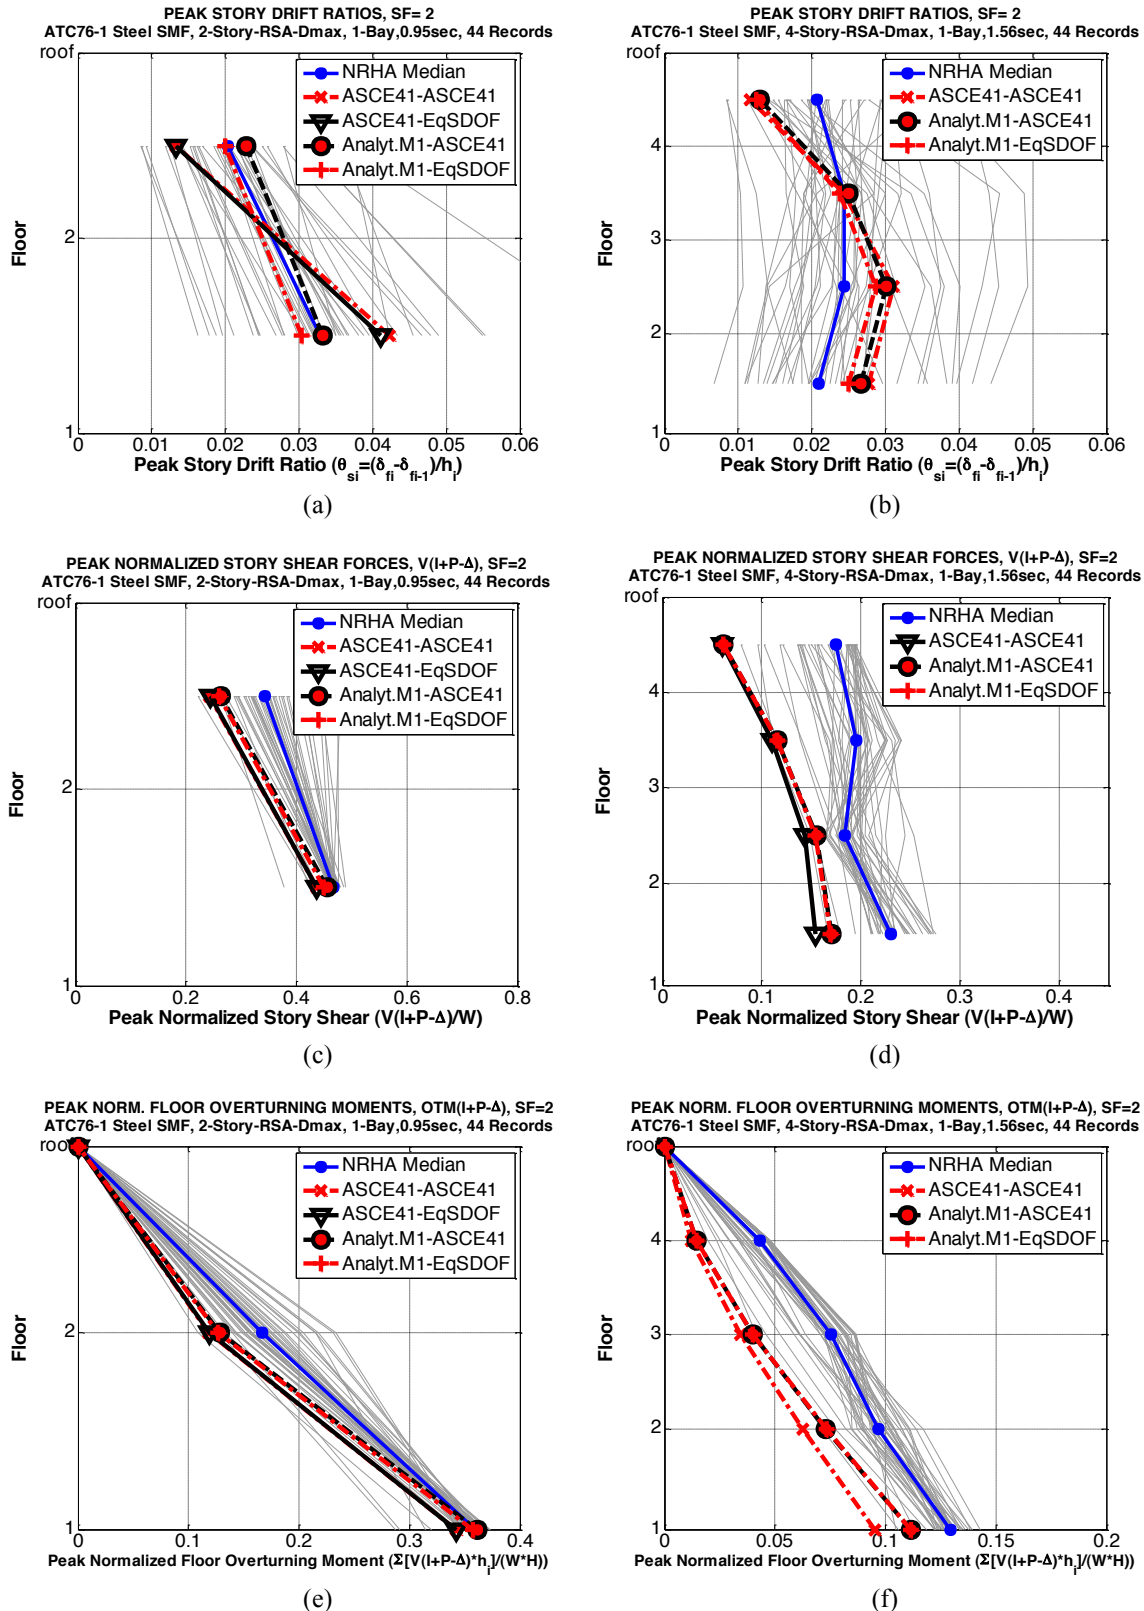

Figure 6: Comparison between NSP and NRHA predictions for EDPs of the two and four-story steel MRFs for SF=2.0.

Beams can be represented usually by elastic elements, provided the connections of beams to columns are weaker than the beams. Column bending strength should include the effects of

tributary axial forces due to gravity loads. Post-yield properties of the columns should be based on average plastic hinge properties of the column sections. For modeling of the 4-RSA- D_{\max} gravity system, a preliminary design of the gravity beams and columns is performed using tributary areas deduced from the plan view shown in Fig. 1. Since only half of the structure is modeled, the spine (column) of the “fishbone” represents 6 gravity columns and four moment frame columns bending about the weak axis. The beam represents 7 gravity beams.

Connection properties were estimated from tests summarized in Liu and Astaneh-Asl [32, 33]. The cyclic behavior of a typical steel shear tab connection is shown in Fig. 7a. From this figure, the hysteretic response of the gravity connection is pinched. Utilizing the pinching04 model in OpenSees [28] the simulated response of this connection matches the experimental results fairly accurately. However, because of the complex behavior of these connections, greatly simplified and generally conservative models can also be employed that are easily utilized by the engineering profession; thus, a simple elastic-perfectly plastic spring model superimposed on the experimental results is also used. The yield rotation for this spring is 0.008, which is about the same as the yield rotations of the beams of the steel MRF. Pre-capping plastic rotation θ_p is 0.10 and post-capping θ_{pc} is assumed as 0.15. The yield strength is a compromise between positive and negative strength values that can be sustained at very large inelastic rotations. This model ignores the additional strength at relatively small rotations. A comparison of pushovers without and with gravity system is presented in Fig. 7b. In this example not much is gained in pushover strength and deformation capacity by incorporating the gravity system in the analysis model.

Figure 7: Effect of gravity system on global pushover of the four-story steel MRF.

The gain in peak story drift ratios when incorporating the gravity system in this example is seen in Fig. 8, which show NRHA and NSP results for a ground motion scale factor $SF = 3.0$. For this large ground motion scale factor the maximum response is mostly in the negative tangent stiffness region of the pushover (roof drift $> 3\%$ as seen from Fig. 7b). Figure 8a shows the median story drift ratios along the height of the bare four-story steel MRF for the set of 44 ground motions for $SF=3.0$. This scale factor represents the median collapse capacity of this steel MRF, because collapse occurred under 22 of 44 ground motions. Incorporation of the gravity system reduced the number of collapses from 22 to 11, which has a significant effect on the probability of collapse. The median roof drift is reduced from 0.049 to 0.034, and the effect of the gravity system on peak story drifts can be inspected from the figure. The ob-

servations made here are case specific, and the benefit gained from incorporating the gravity system may depend strongly on the structural configuration.

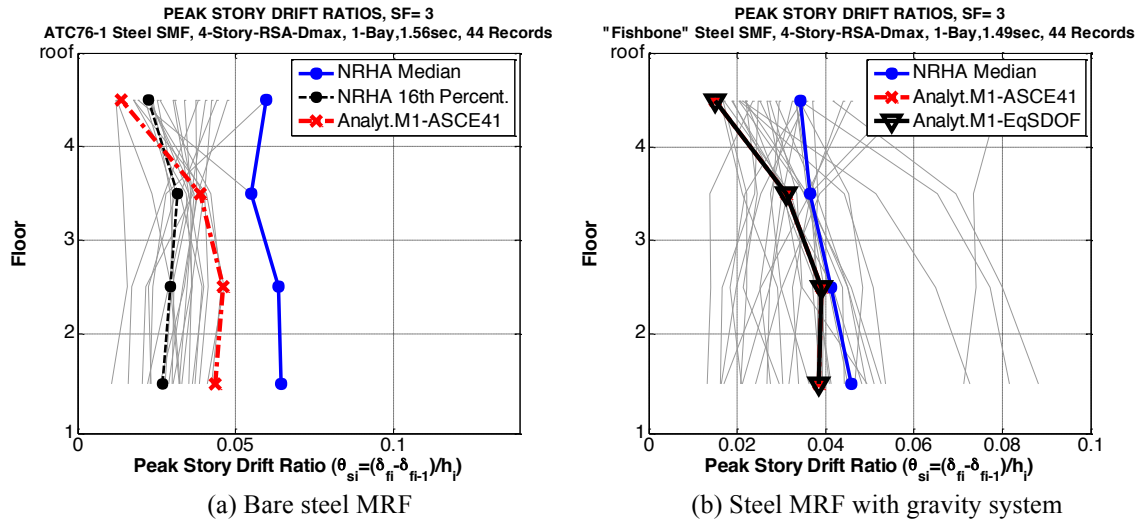

Figure 8: Effect of gravity system on story drift ratios of the four-story MRF for SF=3.0.

4.3 Multi mode nonlinear static procedures

In this section, the assessment of the four- and eight-story steel MRF based on the MPA procedure is discussed. The basic steps for seismic evaluation of the peak response of a structural system using MPA are summarized in [13,18]. Figures 9a and 9b show the pushover curves of the four-story steel MRF using the 1st and 2nd mode lateral load pattern. The idealized equivalent SDOF systems based on the Analyt.M1 component model are shown in Fig. 9c and 9d for the 1st and 2nd mode load pattern, respectively. The IIIDAP program was used to compute median displacements for the equivalent modal SDOF systems using the 44 FEMA P695 ground motions.

Based on Goel and Chopra [34] an improved estimate of plastic hinge rotations and member forces using MPA into the inelastic range can be obtained by computing plastic hinge rotations from the total story drifts [36]. However, this will require an additional nonlinear static analysis. For simplicity purposes, this approach was not implemented in the results presented in this section. But in many cases, particularly for low-rise regular structure, the higher mode target displacement obtained from the equivalent SDOF system is less than the yield displacement, which implies that the higher mode contribution is elastic. If this is the case, all deformations and forces obtained from the MPA are modal combinations of inelastic first mode contributions and elastic higher mode contributions. In general, this is a preferred procedure compared to the elastic response spectrum analysis (RSA) in which all modal contributions are assumed to be elastic up front [18].

The results presented in this section are for the four- and eight-story steel MRFs. Note that their seismic response has not entered the negative tangent stiffness region. The following summary observations are made on the benefits of MPA predictions for steel SMFs compared to single mode NSP predictions:

1. In all cases investigated the MPA led to improved EDP predictions compared to the single mode NSP options. The MPA employed here is based on the component model used in the NRHA (Analyt.M1) and on predicting modal target displacements from NRHA of equivalent modal SDOF systems.

Figure 9: Pushover curves for 1st and 2nd lateral load pattern of the 4-story-RSA-Dmax steel MRF together with equivalent SDOFs.

2. Incorporation of the second mode led to considerable improvement in EDP predictions. Consideration of the 3rd mode did not change the results by much even for the eight-story steel MRF (see Fig. 10).
3. In the case of the four-story steel MRF (see Fig. 10a, 11c, 10e) the improvement of all story-based EDP predictions compared to NSP predictions is remarkable. In the eight-story steel MRF the MPA significantly improved story drift ratios (Fig. 10b), shear force (Fig. 10d), and overturning moment predictions in the upper stories (Fig. 10f), compared to NSP. But predicted drifts based on MPA in the lower stories are more than 50% larger than those obtained from NRHA for a ground motion scale factor of 2.0. The reason is that for this scale factor the first mode pushover shows large amplification of story drifts in the lower stories, which is not present in the NRHA. This shows the sensitivity to invariant load patterns, which is present as much in the MPA as it is in a single mode NSP.
4. The second mode contribution was elastic, which simplifies the modal combination and avoids ambiguities that might be caused by displacement reversals sometimes observed in inelastic higher mode pushover analyses.

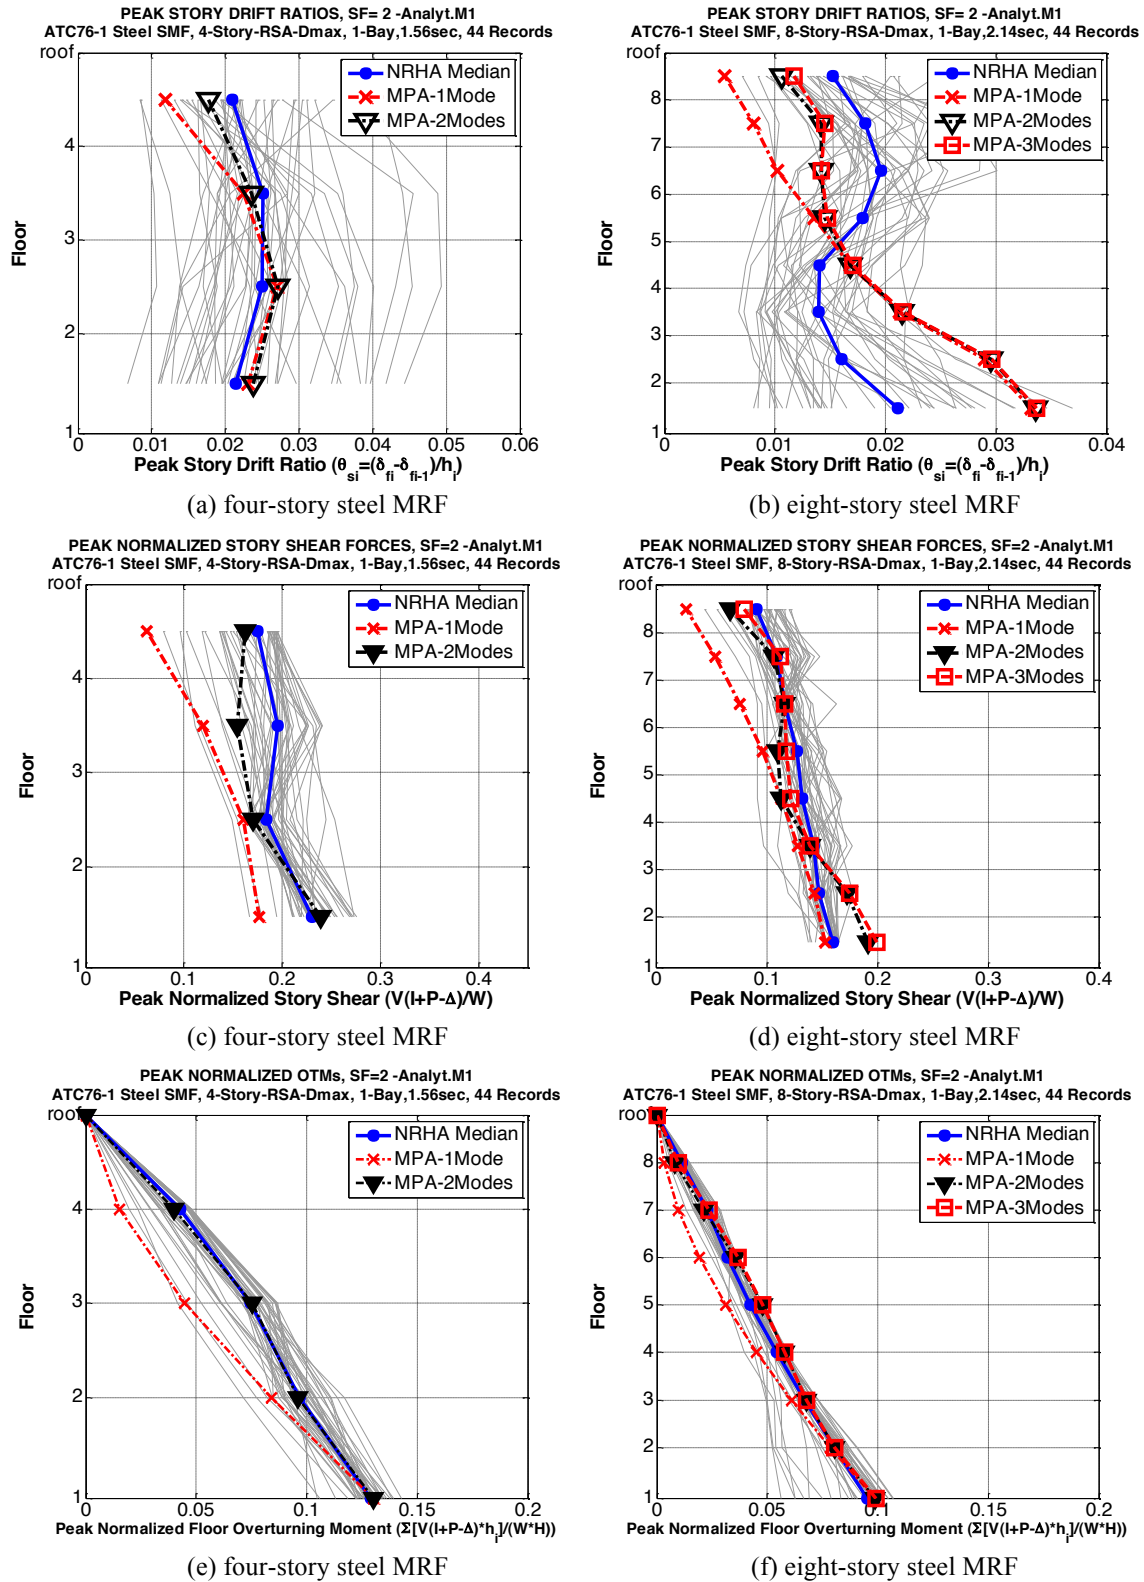

Figure 10: Peak EDPs for the four and eight-story steel MRF as predicted with NRHA and MPA for SF=2.0.

4.4 Residual deformations and absolute acceleration demands

Figure 11 shows residual story drift ratios and peak absolute floor accelerations along the height of the four-story steel MRF for SF=1.0 and 2.0. It is noteworthy that the maximum ab-

solute floor acceleration does not vary radically over the height of the four-story MRF, and that it is distributed almost uniformly over the height for a ground motion scale factor of 2.0 at which the structure responds in the highly inelastic range. Similar observations are made for all structures in this study. It is a shortcoming of the NSP that it does not provide any estimation of these two important EDPs, considering the increasing importance of floor acceleration and residual drift in loss assessment of structures [37-39], and the importance of floor accelerations in estimating diaphragm forces.

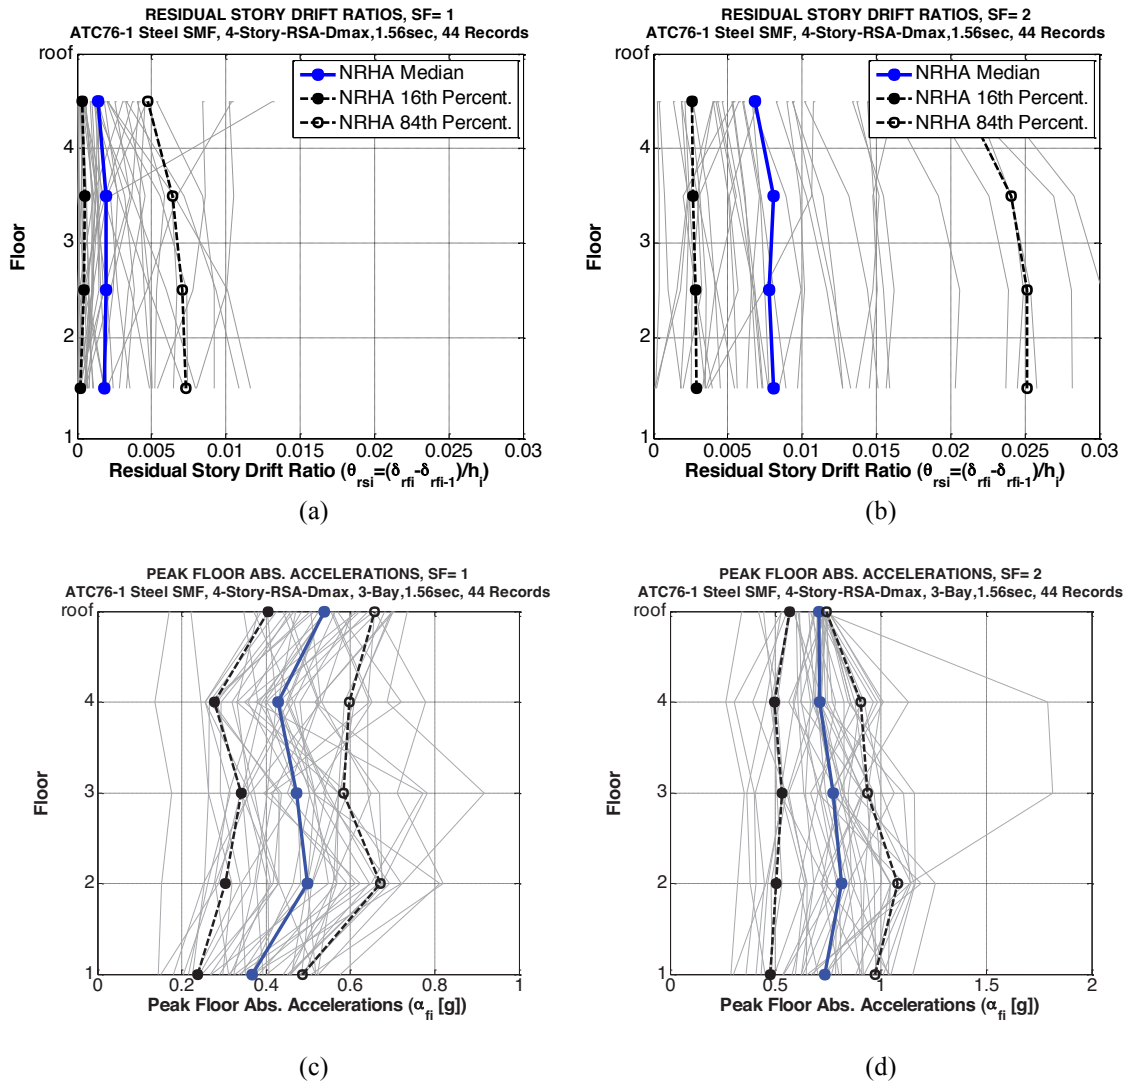

Figure 11: Residual story drift ratios and peak floor accelerations for the four-story MRF for SF=1.0 and 2.0.

5 CONCLUSIONS

This paper presents an assessment of simplified techniques for the seismic evaluation of steel moment resisting frames. This assessment is based on direct comparison of engineering demand parameters such as story drift ratios, story shear forces and overturning moments as predicted with nonlinear single and multi mode static procedures and nonlinear response history analysis. The analytical models employed in this study are 2-dimensional models of two, four and eight-story archetype steel buildings designed as part of NIST [19]. Detailed 3-bay models and simplified 1-bay “models of the steel MRFs of these buildings are utilized, with

the results being almost identical. Modeling of gravity framing can be achieved by means of a simple fishbone model. The main findings from the results presented here, which are representative for regular moment frames only, are summarized as follows:

- For regular frames of 4 and more stories, results from a single mode pushover analysis with an invariant load pattern do not correlate well with median results from nonlinear response history analysis. This holds true for story drifts, shear forces, and overturning moments.
- Modal Pushover Analysis leads to improved EDP predictions compared to the single mode NSP options by incorporating the second mode in the analysis in addition to the first mode. The second mode contribution is elastic for the cases evaluated in this study, which simplifies the modal combination.
- The sensitivity to invariant load patterns in single mode NSP and MPA typically leads to amplification of story drifts in lower stories compared to NRHA.
- Incorporating the effect of gravity system into the analytical model of the structural system typically leads to a reduction in story drift ratios compared to the bare frame only. This reduction may not be very important, except when the ground motion intensity is large and collapse becomes an issue. Further studies need to be conducted to address in detail the effect of gravity system on the seismic response of steel MRFs.
- Nonlinear static analysis procedures are not capable of providing relevant information on residual drifts and floor accelerations. These two EDPs are very important in loss assessment of buildings; the former for nonstructural acceleration sensitive damage, and the latter for assessing the need for demolition.
- In the authors' opinion, the main value of a nonlinear static (pushover) analysis is to inspect the load-deformation response at a global and local level for the purpose of evaluating behavior characteristics such as importance of P-Delta effect, global yielding, and post-yield and post-capping strength and stiffness characteristics, and for detection of potential strength and stiffness discontinuities that might adversely affect dynamic response. Quantification of demand parameters from pushover results is questionable for structures that have considerable higher mode effects and/or significant strength or stiffness discontinuities. Such quantification can be obtained, approximately, from NRHA using simple component models such a bilinear hysteresis model, and a small set of spectrum-matched ground motions. More accurate assessment of demand parameters, including measures of uncertainties, will necessitate more accurate structural modeling for NRHA and ground motions that represent the intensity characteristics and record-to-record variability inherent in seismic hazard.

Keywords: Skewed Bridges, Response History Analysis, Structural Dynamics, Earthquake Engineering.

Abstract. *Damage and seismic movements observed in bridges in recent earthquakes have indicated that the response and failure modes of bridges with skew-angled abutments are significantly different from those of bridges with normal abutments. One significant manifestation of this difference is the inherent tendency of skewed bridges to rotate about their vertical axes under seismic excitation. In this study, with the aforementioned field observations in mind, we have conducted parametric response-sensitivity analyses in an effort to identify the key parameters that control the seismic behavior of skewed bridges. This paper describes our simplified modeling technique, which takes bridge-abutment interaction into account, along with the analysis results. Three short bridges located in California were used as subjects. These bridges have different arrangements of number of spans and number of columns per bent; and through nonlinear time-history analyses, we investigated the sensitivity of their various responses to variations in parameters such as torsional stiffness, span arrangement, column height, abutment skew angle, and ground motion characteristics.*

1 INTRODUCTION

Bridge with skew-angled abutments (“skewed bridges”) are constructed to accommodate geometry constraints resulting from the alignment of a waterways or roadway crossing that occurs at an angle that is different from 90 degrees. In the present study we consider only “seat-type” abutments, which are very common in construction practice in California. A seat-type abutment is simpler to construct compared to an “integral abutment.” It reduces service and seismic demands on foundations and allows the superstructure to move freely under thermal, and low-intensity mechanical (service or seismic) loads [1]. Despite having a fair amount of knowledge on the response of bridges with normal abutments [2], the engineering community still lacks quantitative knowledge on the seismic performance of skewed bridges with adequate certainty. As a result, somewhat gross approximations are employed in their design, and the implications of these approximations are not completely understood [3]. There has been a recent surge of studies that were aimed at providing guidelines for nonlinear seismic response-history analysis of regular bridges, primary motivated by developments in performance-based earthquake engineering (PBEE) [4-8]. The present study follows in the footsteps of these efforts, and provides an initial attempt at applying PBEE concepts to skew-angled bridges.

In a seat-type abutment (Figure 1), exterior shear keys are used to counter the deck movement along the transverse direction. They are proportioned and detailed to act as fuses that will break off under the design earthquake [9]. In the longitudinal direction, a backwall that holds an engineered backfill in place is designed to break off and allow the mobilization of the soil mass, which, in turn, generates passive resistance. Observations from past earthquakes indicate [10-12] that one of the primary causes of unseating of the skewed bridges is the pronounced in-plane rotation caused by the eccentric passive resistance of the backfill [13-16]. Post-earthquake reconnaissance reports also suggest that this rotational mode of response is exacerbated once the bridge is subjected to near-field motions [17]. However, there still remains significant uncertainty in predictive models that needs to be alleviated and addressed in order to better quantify such behavior.

In the present study, we adopt a performance-based seismic assessment approach, which starts with the selection of a representative suite of critical ground motions and repeated nonlinear response-history analyses of models with varied parameters. The output is a statistically scattered collection of response metrics. The trends in these measures are what we seek to identify. In what follows, we first describe the details of our modeling approach and the ground motion selection procedures. We then summarize and discuss the results.

Figure 1: Configuration of typical seat-type abutment (adopted from [2]).

2 ANALYTICAL MODEL

For the present study, we have selected three actual bridges as seeds for our parametric response-sensitivity analyses. These bridges are recently designed and built (ca. 2000) in Southern California, at regions with high seismicity. The first bridge is the *Jack Tone Road Overcrossing*, which over-crosses Route 99 at the City of Ripon. It has a typical configuration encountered frequently in California. Its total length is 67.2 m, consisting of two (33.1m and 34.1 m) spans with a single column. It has seat-type abutments with four elastomeric bearing pads on each seat. The superstructure is a three-cell continuous reinforced concrete box-girder. The bent-cap is integral with the deck and the concrete column. The column has a 1.68-m diameter and is supported on steel piles. Its longitudinal reinforcing steel ratio is approximately 2%.

The second bridge is the *La Veta Avenue Overcrossing*. It is also a two-span structure; but it is supported on a multi-column bent. As such, it has a larger global torsional stiffness than the single-column Jack Tone Road Bridge. The third bridge is the *Jack Tone Road Overhead*. It is a three-span and multi-column bridge, and has the largest global torsional stiffness among the three bridges studied here.

A representative analytical model used in the parametric studies is displayed in Figure 2. The modeling platform is OpenSees [18], which provides an adequate element and material response library, and enables scripted execution of repetitive nonlinear response-history analyses in which the model parameters and input ground motions can be systematically varied. The present modeling assumptions follow the general guidelines suggested in Caltrans' Seismic Design Criteria document [3], and the studies by Aviram *et al.* [6] and Kaviani *et al.* [19-20].

The superstructure is modeled as a three-dimensional spine that follows the alignment of the bridge with line elements located at the centroid of the cross-sections. The model features various nonlinear elements, which capture the behavior of components that significantly impact the response. These include column plastic hinges, transverse and longitudinal springs that mimic passive abutment reaction, and abutment gap elements. As no damage or significant nonlinear behavior is expected within the superstructure and the foundation system, the superstructure elements, the cap beam, and the foundation springs are all considered as linear elastic elements.

2.1 Column Bent Modeling

Progression of column yielding and damage is expected under strong ground motions, and thus nonlinear fiber-based force-based beam finite elements are used to represent the columns (Figure 3). In order to achieve a more realistic representation of their response, the beam finite elements representing them are endowed with the ability to respond inelastically at every quadrature point. All fiber sections are assigned with the *UniaxialMaterial* model tag of OpenSees [18]. Three different constitutive rules are used depending on which material a given fiber of the cross-section represents—*viz.*, (i) confined concrete, (ii) unconfined concrete, and (iii) steel rebar.

The specific beam finite element of the OpenSees library used in the simulations is the *NonlinearBeamColumn*, which has a force-based formulation that enables a more accurate accounting of the moment distribution within the element [21]. A single force-based element with 10 quadrature points is used per column, and this is usually deemed to provide adequate accuracy. In order to model the portion of the column-bent embedded in the superstructure, a rigid element is attached to the top of the nonlinear beam-column element. The length of this

rigid element was set equal to the distance between the centroid of the soffit-flange of the superstructure box-girder and the column top.

Figure 2: Typical analytical model used for nonlinear time-history analysis of skewed bridges.

Figure 3: Column analytical modeling scheme.

2.2 Abutment Modeling

The model of the abutments is adopted from a simplified modeling technique (Figure 4) as recommended by Priestley et al. [22] and Aviram et al. [6]. Each abutment is modeled with a massless rigid element of length equal to the superstructure width, connected through a rigid joint to the superstructure centerline, and with a zero-length element at each.

In the longitudinal direction, the response is governed by a zero-length, tension-free (gap)

element. In compression, it behaves as an elastic-perfectly-plastic material once the gap is closed. The gap size is proportional to the expansion joint detail as shown on the bridge as-built plans. The stiffness and the equivalent yield strength are defined according to Section 7.8 of Caltrans SDC [3]. The rotation about the longitudinal direction is not allowed.

In the transverse direction, the behavior is characterized as elastic compression-only response. The abutment stiffness and the backwall strength for the longitudinal direction are modified by corresponding wall effectiveness factor (C_L) of 2/3 and participation factor (C_w) of 4/3. The wingwall length is assumed to be 1/3 times the back wall length.

In the vertical direction, only simple elastic material properties associated with the bearing pads are included upon assuming that the response in this direction does not significantly impact the horizontal movements,

Figure 4: Simplified abutment model

3 GROUND MOTIONS

To investigate the sensitivity of bridge responses to a sufficiently diverse range of ground motions that are representative of those recorded in California, three sets of ground motions were selected from the “EQ Library” that was developed as part of the *PEER Transportation Research Program* [23]. These sets are denoted as “Soil,” “Rock,” and “Pulse.” Each set comprises forty ground motions. Figures 5, 6, and 7 show the fault-normal and fault-parallel spectra for these three ground motion sets, respectively. The EQ Library motions do not represent motions that are specific to the site of the bridges considered in this study; they are generic and are merely used to observe the general trends within the seismic responses. The ground motions in the EQ Library are originally selected from a subset of the PEER NGA Project ground motion library [24] representing mid- to large-magnitude earthquakes occurring at close distances. Selected motions have a variety of spectral shapes, durations, and directivity periods. For each set, the mean and variance of the natural logarithm of spectral acceleration match the generic $M_w = 7$ and $R = 10$ km scenario for California.

4 OBSERVATIONS

We investigated the sensitivities of seismic responses of the specimen skewed bridges to variations in their structural properties by analyzing each instance of the models under each ground motion. The four response measures—henceforth referred to as *Engineering Demand Parameters* (EDPs)—that we selected were the maximum values of deck rotation, column drift ratio, abutment unseating, and transverse abutment displacement.

4.1 Deck Rotation

The results indicate that deck rotation is highly sensitive to bridge structural properties and ground motion characteristics. Figure 8 shows the variation of deck rotation as a function of abutment skew angle of the Jack Tone Road Overcrossing for different types of ground motion. The solid lines show the estimated median, and the individual data points are depicted with solid dots on the plot. Figures 8(a) and 8(b) show deck rotation variation due to the abutment skew angle increment; however, they differ in span arrangement. In the asymmetrical span arrangement of the bridge (Figure 8(b)), the span lengths differ by 20%.

Results in Figures 8(a) and 8(b) indicate that by increasing the abutment skew angle from 0° to 30° , the median estimate of deck rotation increases, regardless of the type of applied ground motion or span configuration. However, for higher skew angles ranging from 30° to 60° , the deck rotation increases for the symmetric-span configurations (i.e., Jack Tone Overcrossing); whereas the increasing trend continues on for the asymmetrical one. This behavior is particularly pronounced for pulse-like ground motions.

Figure 8: Deck Rotation Sensitivity to span arrangement: (a) Symmetrical spans, (b) Asymmetrical spans

The effect of abutment gap-size variation on the selected EDPs is shown in Figure 9. Four abutment gap-sizes (0.25, 0.5, 1.0, and 2.0 in.) are investigated. For deck rotation, it is observed that for skew angles less than 40° , the curves corresponding to different abutment gap-sizes are approximately matched. However, for larger skew angles the bridge with the 0.25-in. gap distance rotates more, in comparison to that with a 2-in. gap. This trend indicates that with reducing gap-distance, the bridge rotates more for higher skew angles. Less gap-distance between the deck and the backwall results into more effective impact forces impose to the superstructure by backfill soil.

Figure 9: Deck rotation sensitivity to abutment gap size

Considering the variations in column height, the general observation is that for a given skew angle, bridges with taller and more flexible columns tend to have larger deck rotations. Figure 10 shows this general trend.

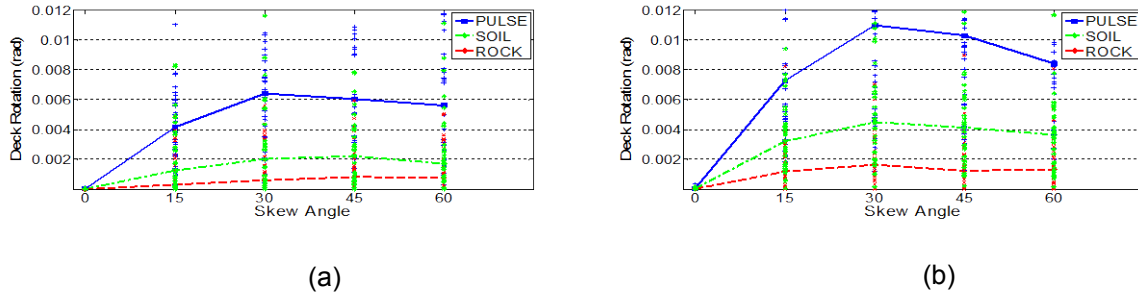

Figure 10: Deck rotation sensitivity to column bent elevation: (a) Lower column, (b) Higher column

4.2 Column Drift Ratio

Results for the two-span single-column bridge (i.e., Jack Tone Overcrossing) indicate that the column drift ratio (CDR) for smaller values of column height is insensitive to abutment skew angle (Figure 11). This behavior is likely due to the particular mode shape of vibration for the single column bridge in which the rotation of the deck increases as the skew angle increases, but the column usually remains near the center of rotation. However, for higher columns (Figure 12), CDR increases with increasing skew angle. For instance, for lower values of column height (the actual height of the Jack Tone Overcrossing), the CDR varies smoothly around 4%. However, for higher values (as a common assumption in design practice, we considered higher-level height of the columns as eight times its diameter), the CDR ranges from 2.5% to more than 4%; and it has greater values for the 60° skew angle. This trend demonstrates that if column stiffness is decreased, then the sensitivity of CDR to abutment skew angle increased.

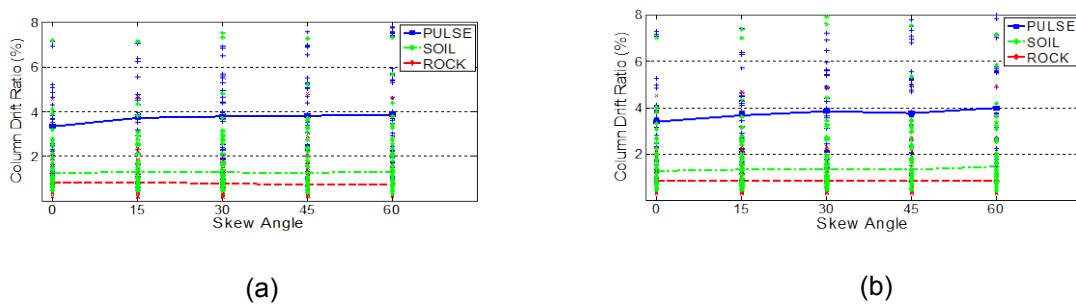

Figure 11: Column drift ratio sensitivity (lower column) to span arrangement:
(a) Symmetrical spans, (b) Asymmetrical spans

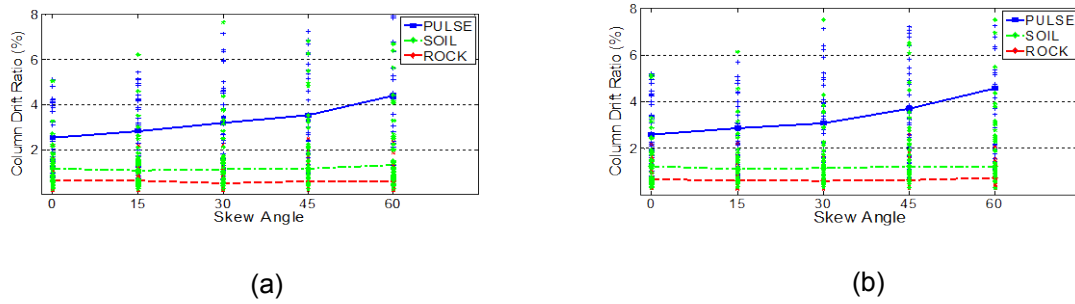

Figure 12: Column drift ratio sensitivity (higher column) to span arrangement:
(a) Symmetrical spans, (b) Asymmetrical spans

4.3 Abutment Unseating

As displayed in Figure 13, incidence of the unseating of abutment is increased by skew angle, particularly for the higher range of skew angles. As expected, the abutment unseating increases with increasing skew angles, because the effective stiffness of the abutment in the longitudinal direction is reduced for larger skew angles.

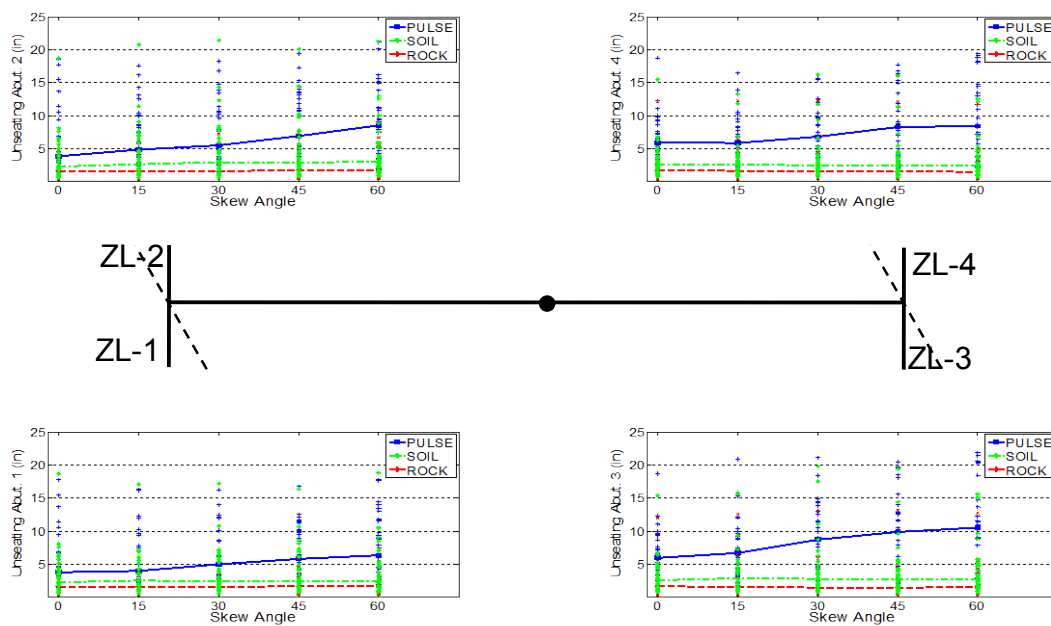

Figure 13: Abutment unseating for symmetrical span arrangement (recorded from the ZeroLength elements, located at each abutment corner)

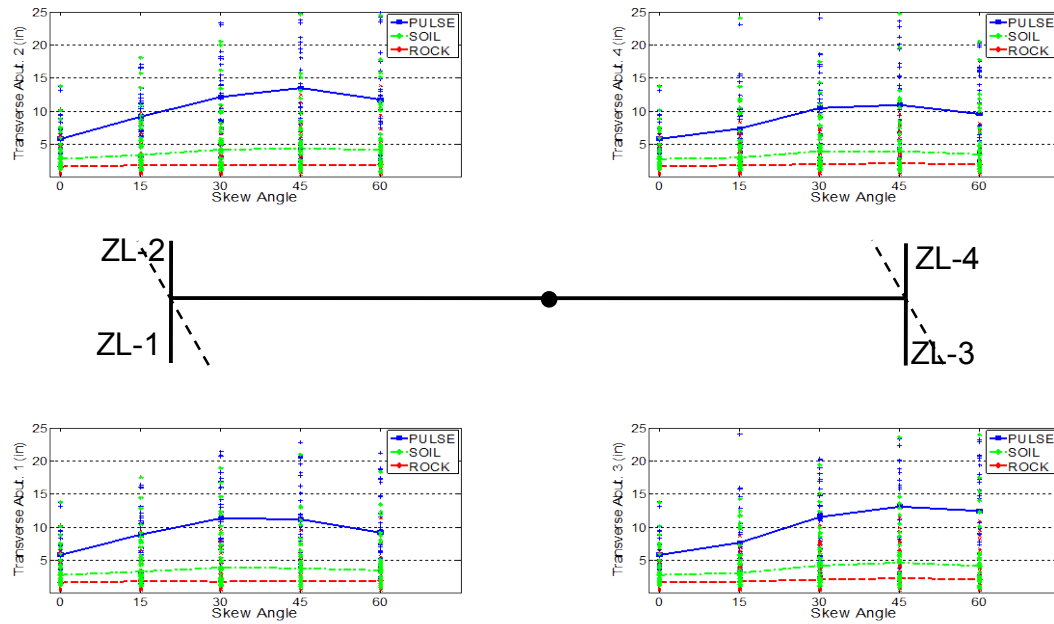

Figure 14: Transverse abutment displacement for symmetrical span arrangement (recorded from the ZeroLength elements, located at each abutment corner)

4.4 Transverse Abutment Displacement

As the deck rotational response here is calculated by dividing the difference between abutment transverse displacements at both ends of the bridge to the bridge length, the abutment transverse displacement is expected to follow a similar trend as the deck rotation. As expected, the transverse abutment displacement increases with increasing skew angle from 0° to 30° , but slightly decreases thereafter, particularly for symmetrical span arrangements (Figure 13).

5 SUMMARY

In this study, we investigated the sensitivity of seismic response of skewed bridges to variations in critical parameters using simulations carried out as nonlinear time-history analyses. Seismic response parameters that we looked into include deck rotation, column drift ratio, abutment unseating, and transverse displacement of abutment. We used three bridges located in California as seeds for our parametric study. These bridges mainly differ in their global torsional resistance. Multiple analytical bridge models were generated from each of three seed bridges by varying the original bridges' geometrical properties, which included abutment skew angle, span arrangement, and column height. In addition, we studied effects of ground motion characteristic on the seismic response of skewed bridges by introducing three types of ground motions into our response-sensitivity analyses. These were soil-site, rock-site, and pulse-like ground motions. We observed that less gap size between the deck and the backwall results in more effective impact forces that mobilize the backfill soil and leads to higher deck rotation; especially when the bridge is subjected to pulse-like ground motions. Column drift ratio is significantly sensitive to the column height, abutment skew angle, and number of columns in each bent. Abutment unseating increases by increasing skew angle, particularly for bridges with tall columns.

Abstract. *Traditional seismic assessment is based on a simple comparison of estimated base shear capacity and base shear demand specified by a seismic code. The required code base shear is found by reducing the elastic base shear force corresponding to the elastic stiffness of the structure, by a code-specified force-reduction or behaviour factor. The problems with this approach are that no assessment is made of the actual collapse mechanism, inelastic deformed shape and ductility demand of the structure. In recognition of the limitations of force-based design and assessment methods, several researchers have started proposing displacement-based approaches for earthquake engineering evaluation and design, with the aim of providing improved reliability in the engineering process by more directly relating computed response and expected structural performance. The need for accurate seismic assessment methods is particularly important for bridges, due to the crucial role that some bridges (especially highway bridges) have after an earthquake, for allowing the civil protection interventions and first aid organizations. In Italy, many of these “strategic” bridges have been built without antiseismic criteria and, therefore, they need to be assessed against seismic risk. In this extent, the development of an assessment procedure which gives reliable results and, at the same time, is sufficiently simple to be applied on a large population of bridges in a short time is very useful. In this paper a Direct Displacement-Based Seismic Assessment (DDBA) procedure satisfying the aforesaid requirements is proposed. In the paper, the proposed DDBA procedure is applied to a number of bridge configurations derived from a 4-span reinforced concrete simply-supported deck bridge of the A16 Italian highway. Some analyses are also repeated following the traditional force-based seismic assessment approach. Finally, the predictions of the proposed DDBA procedure are compared to the results of nonlinear time history analyses.*

1 INTRODUCTION

Recent earthquakes have repeatedly demonstrated the seismic vulnerability of existing bridges, due to their design based on gravity loads only or inadequate levels of lateral forces [1]. Many bridges are of great importance after an earthquake for guaranteeing civil protection interventions and first aid organizations. As a consequence, they have to be in service immediately after the earthquake. In Italy, as well as in other seismic countries, many bridges have been built before the '80s, without antiseismic criteria. Therefore, they must be seismically assessed and, if needed, retrofitted. From this point of view, the development of seismic assessment procedures which give reliable results and, at the same time, are sufficiently simple to be applied to a large stock of bridges could be very useful.

In recognition of the limitations of force-based design and assessment methods, several researchers have started proposing displacement-based approaches for earthquake engineering evaluation and design, with the aim of providing improved reliability in the engineering process by more directly relating computed response and expected structural performance. A rather complete literature review of the subject is reported in Calvi [2], where most displacement – based approaches proposed in the literature, are summarized, critically reviewed and compared, to favour code implementation and practical use of rational and reliable methods. One of the most developed displacement-based methods is the Direct Displacement-Based Design (DDBD) approach proposed by Priestley et al. [3]. A Model Code for the DDBD of structures has been recently published [4], as part of the 2005-2008 RELUIS project.

In this paper, a Direct Displacement-Based seismic Assessment (DDBA) procedure is presented and applied to a number of bridge configurations derived from a multi-span reinforced concrete bridge of the A16 Italian highway. The predictions of the proposed procedure are then compared to the results of nonlinear time-history analysis carried out using a set of seven accelerograms compatible with the Eurocode 8 [5] response spectrum. In addition, a comparison with the traditional force-based approach has been made for a number of selected case studies.

2 DIRECT DISPLACEMENT BASED ASSESSMENT PROCEDURE (DDBA)

The fundamentals of proposed DDDBA procedure are derived from previous studies by Petrini et al [6]. In particular, the proposed procedure is based on an Iterative Eigenvalue Analysis (IEA) to obtain the target displacement profile of the bridge, corresponding to a selected Performance Level (i.e. target displacement) of the structure. The Multi Degree of Freedom (MDOF) model of the structure is then converted into an equivalent Single Degree of Freedom (SDOF) system, according to the principles of the DDBD [7], [8]. Hence, the Peak Ground Acceleration (PGA_{PL}) corresponding to the selected Performance Level (PL) is evaluated.

In this paper, the proposed DDDBA procedure is specialised to multi-span reinforced concrete simply-supported deck bridges. In particular, the influence of the bearing devices placed between pier/abutment and decks is taken into account. At this stage of the study, the attention is focused on the transverse response of the bridge.

The proposed DDDBA procedure can be summarized in three main steps:

- (i) Structural modelling, through the acquisition of structural information;
- (ii) Derivation of the bridge target displacement profile associated to a selected performance level of the structure, through an Iterative Eigenvalue Analysis (IEA);
- (iii) Evaluation of the corresponding PGA value, based on the comparison between the seismic capacity of an equivalent SDOF model of the structure and the seismic demand

of the expected ground motions represented by an overdamped elastic response spectrum.

2.1 Structural Modelling and Damage States

The bridge model has been purposely kept as simple as possible in order to reduce the complexity of the analysis. In accordance with the structural component modelling approach [1], the bridge structure has been divided in a number of independent rigid diaphragms, modelling the bridge decks, mutually connected by means of a series of nonlinear springs, modelling bearing devices and piers (see Fig. 1). Obviously, different modelling strategies can be pursued without influencing the core of the proposed DDBA procedure. Table 1 summarises the basic modelling assumptions adopted in this study for each bridge component, to describe their monotonic and cyclic behaviour, within modal and nonlinear dynamic analysis, respectively.

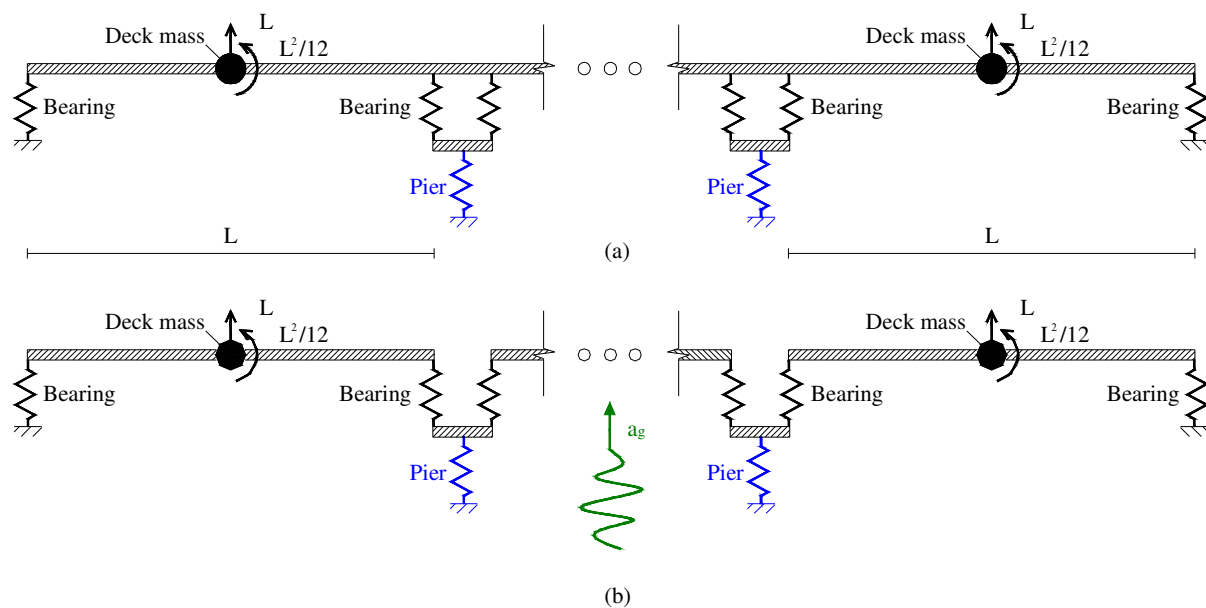

Figure 1: Schematization of multi-span simply supported (a) continuous and (b) isostatic deck bridges.

COMPONENT	MODELLING ASSUMPTIONS	DAMAGE STATES
Foundations/ Abutments	Infinitely rigid and resistant.	-
Deck	Diaphragm behaviour. Lumped translational and rotational masses.	-
Piers	Nonlinear force-displacement behaviour. Flexural behaviour based on moment-curvature analysis. Shear strength, lap-splice effects, buckling of bars and P-Δ effects considered.	Plastic hinge formation. Ultimate rotation capacity. Shear failure.
Bearing devices	Mechanical behaviour described by means of nonlinear force-displacement relationships.	Device failure. Post-failure sliding.

Table 1: Types of bridge components and basic modelling assumptions considered in the procedure.

The translational and rotational mass of each deck have been lumped as shown in Figure 1. Decks and foundations have been considered as infinitely rigid and resistant. Piers have been modelled with nonlinear springs characterized by a bilinear backbone curve. In this study, the

lateral force-displacement relationships of the piers have been derived based on preliminary elasto-plastic pushover analyses of the piers, schematized as elastic beams with plastic hinges at the end(s). The plastic hinge behaviour has been derived from a moment-curvature analysis of the critical cross section(s) of the pier, considering the axial force due to gravity loads and the effects of concrete confinement and steel strain-hardening. In this study, reference to the models by Mander et al. [9] and Menegotto-Pinto [10] has been made for confined/concrete and steel, respectively. Lap-splices and buckling effects have been also considered in the moment-curvature analysis (see Fig. 2(a)). The moment-curvature relationship thus obtained has been properly bilinearized (see Fig. 2(a)) and then converted in the moment-rotation behaviour of the plastic hinge, whose length has been evaluated according to the formula proposed by Priestley et al. [1]. P- Δ effects due to gravity loads and premature shear failure have been considered in the pushover analysis (see Fig. 2(b)). As far as the cyclic behaviour of the piers is concerned, reference to the Takeda degrading-stiffness-hysteretic model has been made [11] (see Fig. 2(c)).

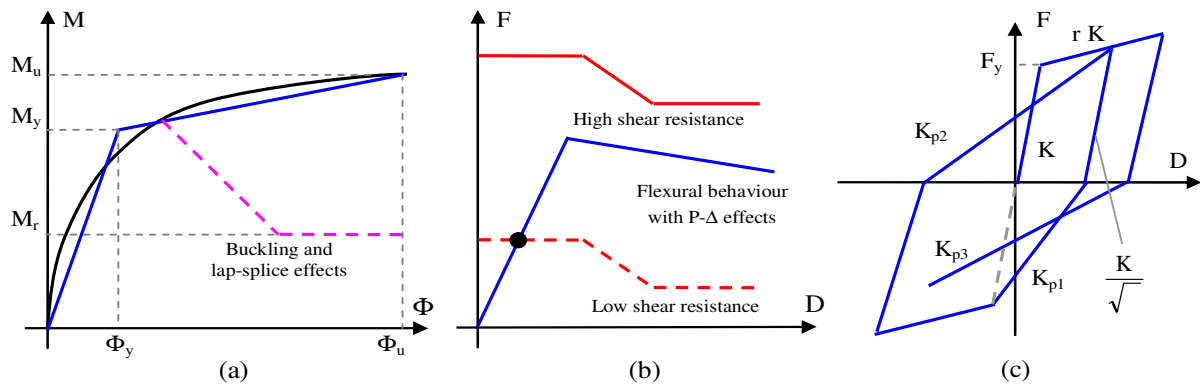

Figure 2: Pier modeling: (a) Moment-curvature analysis of the critical section, (b) force-displacement behaviour taking into account possible shear failure, (c) Takeda degrading-stiffness-hysteretic cyclic model.

The nonlinear behaviour of the bearing devices has been defined based on a comprehensive survey of the Italian highway bridge inventory. In particular, two different types of bearing devices have been considered, i.e.: (i) steel hinges and (ii) neoprene pads.

Steel hinges have been assumed to remain linear elastic up to failure (Fig. 3(a)), which is usually brittle, being due to the attainment of the shear strength (F_u) of the device. The shear stiffness has been estimated based on the geometric details available. During the analysis, the maximum shear force has been monitored. When the shear strength was prematurely exceeded, a post-failure frictional behaviour, corresponding to sliding between deck and pier cap, has been considered (Fig. 3(a)).

A linear visco-elastic behaviour has been considered for neoprene pads (Fig. 3(b)), whose shear stiffness (K) has been evaluated based on the dimensions (cross section area and thickness) of the pads and shear modulus (G) of neoprene. In this study, a shear modulus of 1 MPa and a viscous damping ratio (ξ) of 6% have been assumed for neoprene pads. The horizontal strength of the bearing system has been computed as the lowest between the shear resistance of the neoprene pads and the friction resistance between neoprene and concrete sliding surfaces. The shear resistance of neoprene pads has been associated to the attainment of a shear strain of 150%. The friction coefficient between neoprene and concrete has been taken equal to 70%.

Figure 3: Force-displacement behaviour of (a) steel hinges, (b) neoprene pads.

A number of Damage States (DSs) have been defined for piers and bearing devices. The DSs have been grouped in three different Performance Levels (PLs) (see Tab. 2), based on the consequences in terms of damage that the attainment of each DS can produce. Obviously, this division is only formal and it is made only for the sake of clarity. The first Performance Level (PL1) includes post-earthquake Damage States in which only very limited structural damage has occurred (e.g. pier yielding, attainment of the horizontal strength in neoprene pads,...). The second Performance Level (PL2) includes post-earthquake Damage States in which significant damage to some structural elements has occurred but large margin against either partial or global collapse still remains (e.g. 50% of the ultimate ductility demand in piers, large post-failure displacements in neoprene pads,...). The third Performance Level (PL3) includes post-earthquake Damage States in which the structure continues to support gravity loads but retains no margin against collapse (e.g. collapse of steel hinges, pier collapse due to the attainment of ultimate ductility or shear strength, ...).

PL1 (Slight Damage State)	PL2 (Moderate Damage State)	PL3 (Severe Damage State)
<ul style="list-style-type: none"> ○ Pier yielding ○ Neoprene pad failure 	<ul style="list-style-type: none"> ○ 50% ultimate ductility of piers ○ Large post-failure displacements in neoprene pads 	<ul style="list-style-type: none"> ○ Pier collapse ○ Steel hinge failure

Table 2: Performance Levels of the structure and Damage States of piers and bearing devices.

2.2 Iterative Eigenvalue Analysis (IEA)

An eigenvalue analysis is initially performed assuming the elastic stiffness of piers and bearings. The resultant mode shape in the transverse direction is recorded as the displacement pattern of the bridge. Next, in order to obtain the target displacement profile, the displacement pattern is scaled, based on the displacement corresponding to the attainment of a given DS in a (trial) critical element (pier or bearing) of the bridge. The element that first reaches a predefined target displacement amplitude in the current displacement pattern is recognized as the critical element of the bridge and its displacement is the critical displacement Δ_{cr} . The displacements of the other piers and bearings are obtained from Δ_{cr} in proportion to the mode shape (ϕ_i):

$$\Delta_i = \frac{\Delta_{cr} \phi_i}{\phi_{cr}} \quad (1)$$

where ϕ_i is the component of the mode shape vector related to the i -th pier or bearing, ϕ_{cr} is the component of the mode shape vector related to the critical pier, Δ_i is the displacement of the i -th structural element.

Next, the secant stiffness of each element corresponding to the displacements Δ_i are found:

$$K_i = \frac{F_i}{\Delta_i} \quad (2)$$

where F_i is the force value corresponding to the pier displacement Δ_i found on each force-displacement curve. New secant stiffness values are used in the next eigenvalue analysis and a new displacement shape is obtained. The iterative procedure continues till there is no significant change in the displacement shape. The iterative procedure normally converges in 3-5 iterations.

At this point, the effect of higher modes must be checked and if needed the bridge displacement shape must be revised. If the mass participation ratio at the end of the IEA process is lower than 65-70% of the total mass, higher mode effects shall be considered. To this end, reference has been made to the so-called Effective Mode Shape (EMS) method [12], in which the displacement of each element (piers and bearings) is calculated with the following equation:

$$\Delta_{i,j} = \phi_{i,j} \cdot PF_j \cdot S_{d,j} \quad (3)$$

where the index i represents the element number and the index j represents the mode number, $\Delta_{i,j}$ is the displacement of the i -th element for the j -th mode, $\phi_{i,j}$ is the modal displacement of i -th element for the j -th mode, PF_j is the participation factor of the j -th mode and $S_{d,j}$ is the spectral displacement for the j -th mode obtained by entering the 5% damped elastic displacement spectrum with the modal period of the j -th mode. The final displacement shape of the bridge, considering the higher mode effects, is calculated by any appropriate modal combinations (SRSS, CQC etc.) of these displacements.

2.3 Evaluation of the PGA associated to given Damage States of the structure

The equivalent SDOF displacement of the bridge (Δ_e) is derived, from the displacement profile obtained at the end of the IEA, through the following equation:

$$\Delta_e = \frac{\sum_j (m_j \cdot \Delta_j^2 + I_j \cdot \delta_j^2)}{\sum_j m_j \cdot \Delta_j} \quad (4)$$

where m_j and Δ_j are the translational mass (μL) and the horizontal displacement of the centre of mass of the j -th deck, respectively, I_j and δ_j are the rotational mass ($\mu L^3/12$) and the rotation around the vertical axis of the j -th deck, respectively. The force level associated to Δ_e is given by the global base shear (V_b) obtained at the end of the IEA.

The equivalent SDOF mass (m_e) is then given by:

$$m_e = \frac{\sum_j m_j \cdot \Delta_j}{\Delta_e} \quad (5)$$

The next step of the procedure is to determine the seismic demand associated to each DS, represented by a reference over-damped elastic response spectrum. This step requires the evaluation of the equivalent viscous damping of the bridge by the combination of the damping

contributions of each structural member (piers and bearings). The equivalent damping of the bearing devices can be calculated through the well-known Jacobsen approach [13]:

$$\xi_{b,j} = \frac{E_{visc} + E_{hyst} + E_{fr}}{2\pi \cdot F_{b,j} \cdot \Delta_{b,j}} \quad (6)$$

in which E_{visc} , E_{hyst} and E_{fr} identify the energy dissipated by the device, through its viscous, hysteretic or frictional behaviour, in a cycle of amplitude $\Delta_{b,j}$, being $\Delta_{b,j}$ the displacement of the device and $F_{b,j}$ the corresponding force level.

As far as piers are concerned, reference has been made to the following relationship:

$$\xi_{p,k} = 0.05 + \frac{1}{\pi} \left(1 - \frac{(1-r)}{\sqrt{\mu}} - r \right) \quad (7)$$

which relates the equivalent hysteretic damping of the pier to its displacement ductility (μ) and post-yield hardening ratio (r). The aforesaid relationship has been derived by Kowalski et al. [14], by applying the Jacobsen's approach to the Takeda degrading-stiffness-hysteretic model.

The global equivalent damping of the bridge ξ_e is calculated by weighting the damping contributions based on the energy dissipated by each structural element:

$$\xi_e = \frac{\sum_{j=1}^{nb} \xi_{b,j} F_{b,j} \Delta_{b,j} + \sum_{k=1}^{np} \xi_{p,k} F_{p,k} \Delta_{p,k}}{\sum_{j=1}^{nb} F_{b,j} \Delta_{b,j} + \sum_{k=1}^{np} F_{p,k} \Delta_{p,k}} \quad (8)$$

Once the equivalent damping of the bridge has been determined, the corresponding demand spectrum can be derived from the reference 5%-damping normalized response spectrum, using a proper damping reduction factor [15].

The final step of the procedure is to determine the PGA value associated to the selected DS.

From a graphical point of view, the PGA associated to a selected Performance Point (PP) can be evaluated through a translation of the over-damped Normalized Response Spectrum (NRS in Fig.4) to intercept the selected PP, whose coordinates are the equivalent SDOF displacement Δ_e and the spectral acceleration:

$$S_e = \frac{V_b}{m_e} \quad (9)$$

where V_b is the total base shear of the structure corresponding to the deformed shape resulting from IEA

From an analytical point of view, the PGA associated to a selected Performance Point (PP) can be determined as the ratio between the spectral acceleration S_e corresponding to the selected PP and the normalized spectral acceleration at the effective period of vibration (T_e) and global equivalent damping (ξ_e) of the structure:

$$PGA = \frac{S_e}{S_{e1}(T_e, \xi_e)} \quad (10)$$

being:

$$T_e = 2\pi \cdot \sqrt{\frac{m_e}{K_e}} \quad (11)$$

and K_e is the equivalent SDOF stiffness given by:

$$K_e = \frac{V_b}{\Delta_e} \quad (12)$$

Figure 4: Evaluation of the PGA associated to a selected PP.

3 COMPARISON WITH NTHA RESULTS

3.1 Case Studies

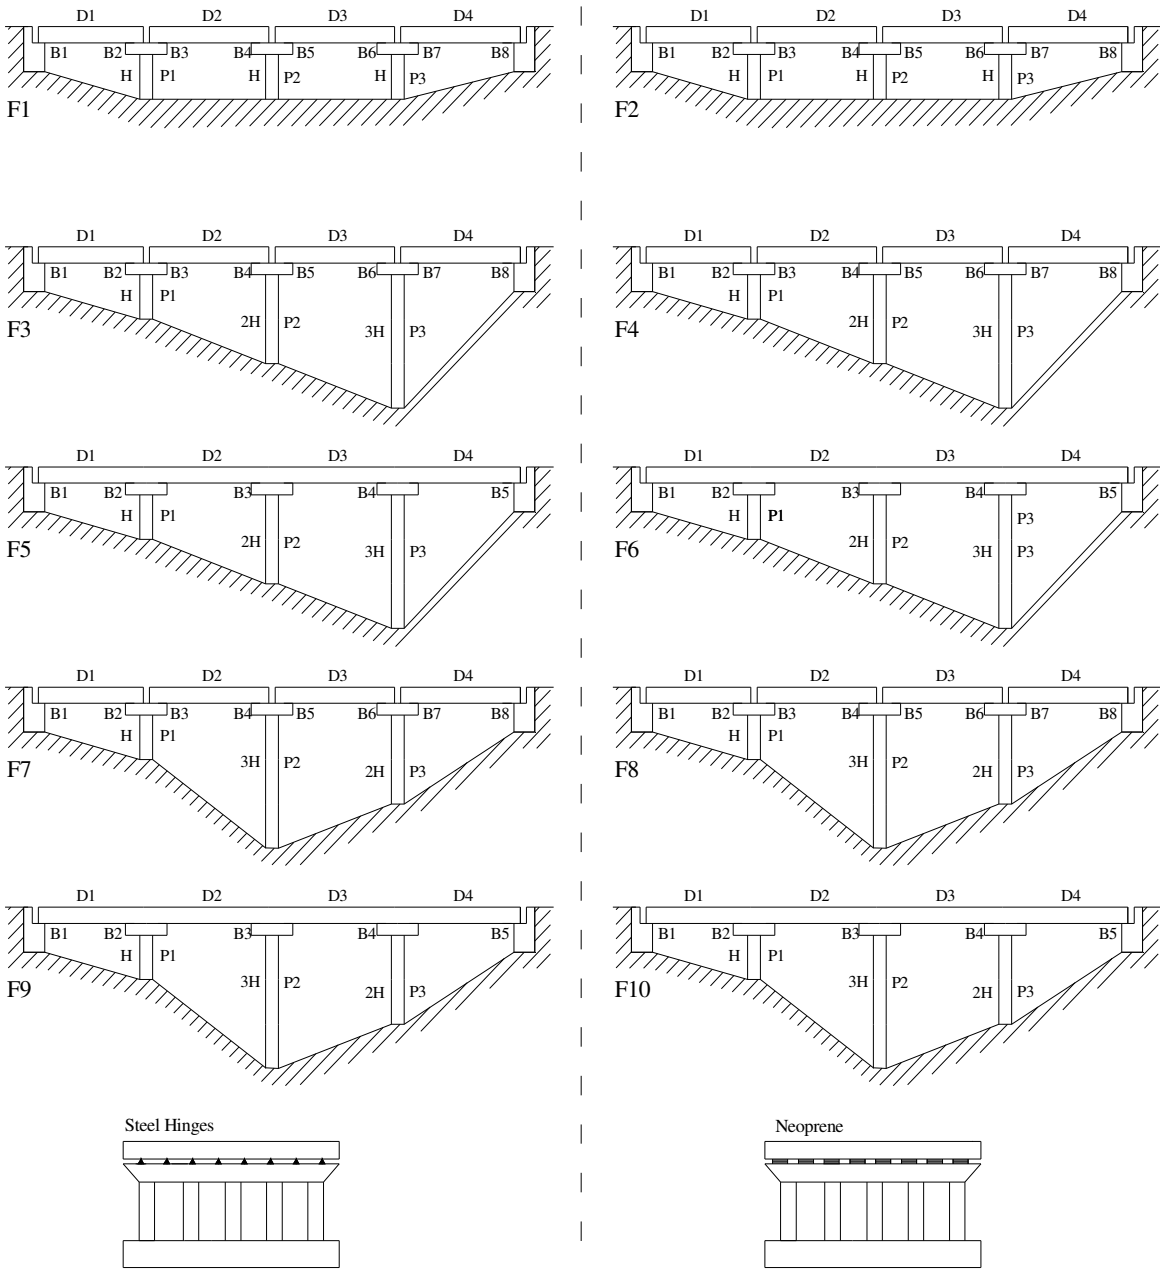

The proposed DDBA procedure has been applied to a number of bridge configurations derived from a Reinforced Concrete (RC) bridge of the A16 Italian highway (Fiumarella viaduct). The Fiumarella viaduct is a 4-span simply-supported isostatic deck bridge of 135m total length, featuring two seat-type abutments and three identical frame-type piers characterised by five RC columns with 1.2m diameter circular cross section and 3.2m effective height. The longitudinal reinforcement ratio of each column is equal to 0.44%. The transverse reinforcement is realised by 10mm diameter hoops at 20mm spacing. The bridge presents steel bearings acting as a pendulum in the longitudinal direction and as a fixed steel hinge in the transversal direction. The yield strength of the reinforcing steel (type AQ50-60) is equal to 270 N/mm². As far as concrete is concerned, a compression strength of 35 N/mm² has been assumed, based on the design data available.

A set of nine bridge configurations have been derived from the real bridge configuration (F1 in Tab. 3). They are summarized in Table 3. The schematic layout of the ten bridge configurations is shown in Fig. 5. In the bridge configuration F2 neoprene pads have been considered in place of steel hinges. The stiffness of each line of neoprene pads has been assumed equal to 35000 KN/m, based on a comprehensive survey of similar Italian highway viaducts. The configurations from F3 to F10 have been derived from the configurations F1 and F2 by changing the pier layout (pier heights equal to H-2H-3H or H-3H-2H, with H = 3.20 m) and considering both isostatic and continuous decks.

BRIDGE CONFIGURATION	DECK	PIER LAYOUT ^(*)	BEARINGS
F1	Isostatic	H-H-H	Steel Hinges (SH)
F2	Isostatic	H-H-H	Neoprene (N)
F3	Isostatic	H-2H-3H	Steel Hinges (SH)

Table 3: Main characteristics of the analyzed bridges

3.2 Application of the DDBA procedure

Figure 6 shows the displacement profiles obtained at each step of the IEA for the bridge configurations with irregular pier layouts. As can be seen, the displacement profile considerably changes considering the inelastic behaviour of the bridge elements, since plastic deformations are mainly concentrated in a few elements, due to the irregular bridge configuration. The most significant changes, however, take place in the first 2-3 steps of the analysis. The comparison between the initial and final displacement profile emphasizes the differences between the traditional force-based approach, based on the elastic response of the structure reduced by a proper behaviour factor, and the proposed DDBA procedure, based on the use of an inelastic displacement profile scaled at a given target displacement amplitude.

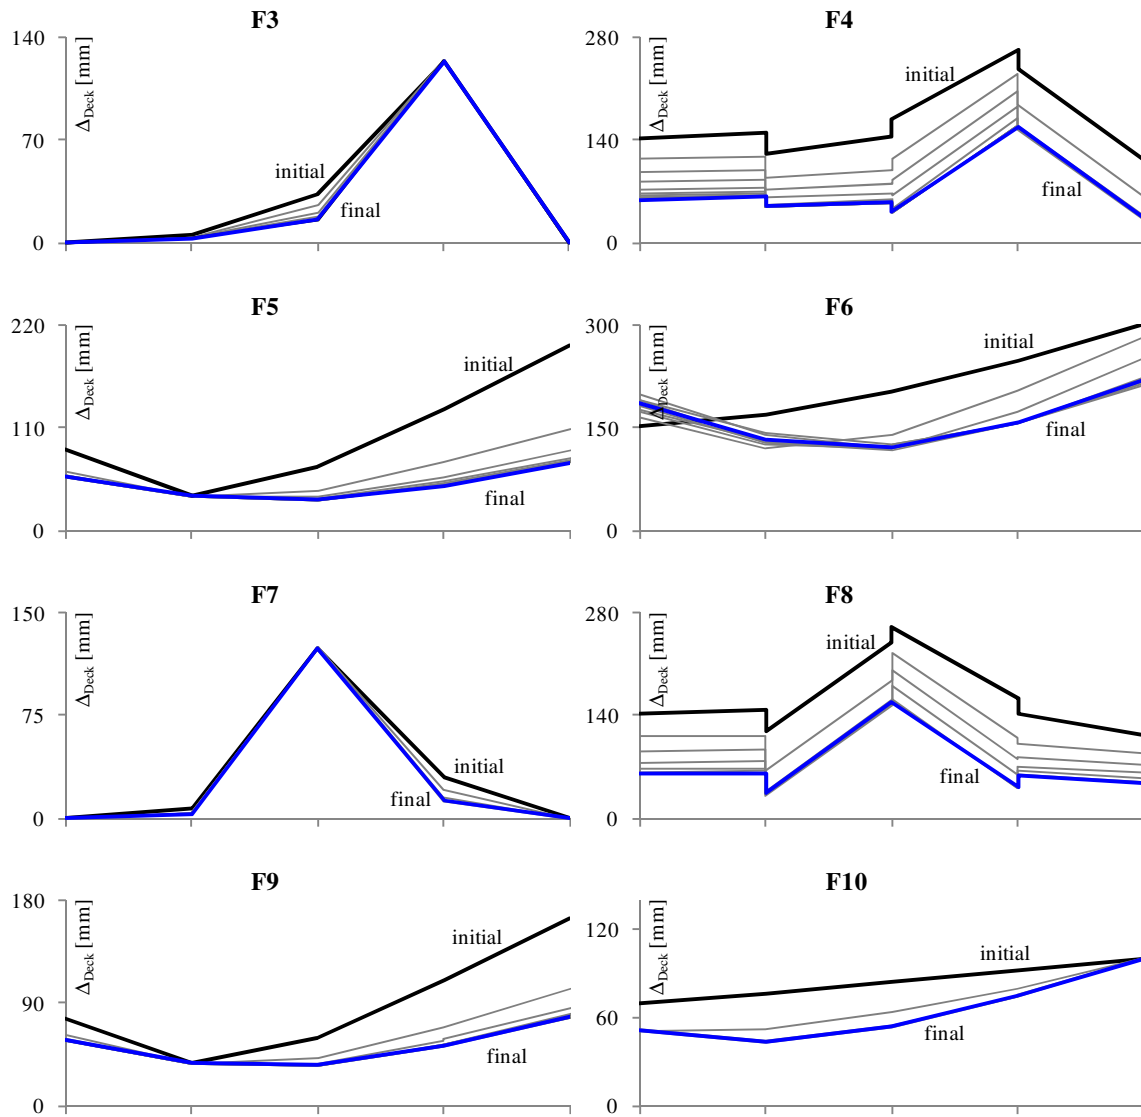

Figure 6: Displacements profiles of the bridge configurations with irregular pier layouts at each step of the IEA.

Table 4 summarizes the results obtained from the application of the DDBA procedure to the case studies described in the paragraph 3.1. The results are expressed in terms of PGA values associated to a number of PLs, corresponding either to pier collapse or failure of neo-prene pads. The critical element of the bridge, where first the selected damage state is reached, is also specified in Tab. 4. The PGA values listed in Tab. 4 have been used to scale the accelerograms for nonlinear time-history analysis.

BRIDGE CONFIGURATION	DECK	PIER LAYOUT*	BEARINGS	PERFORMANCE LEVELS	PGA VALUES
F1*	Isostatic	H-H-H	SH	PL3: collapse of P2	0.565 g
F2	Isostatic	H-H-H	N	PL1: elastic limit of B4 PL2: Large displacement on B4	0.206 g 0.538 g
F3	Isostatic	H-2H-3H	SH	PL3: collapse of P3	0.447 g

* H=3.20 m

Table 4: Performance levels, damage states and corresponding PGA values for the examined bridges.

3.3 Comparison with NTHA results

Comprehensive nonlinear response Time-History Analyses (NTHA) have been carried out to assess the accuracy of the proposed DDBA procedure. The bridge models for NTHA have been implemented in SAP2000_Nonlinear [16], adopting the same modelling assumptions made in the IEA within the proposed DDBA procedure. The NTHA have been performed using a set of 7 artificial accelerograms strictly compatible, on average, with the 5%-damped acceleration response spectrum provided by Eurocode 8 for soil type B [5]. The input ground motions have been scaled to the PGA values provided by DDBA for the calculated PLs (see Tab. 4). A total of 77 NTHA (10 bridges * 7 accelerograms * 1-2 damage states) have been carried out. The accuracy of the proposed procedure has been evaluated by comparing the bridge displacement profile expected based on DDBA with the envelope of the maximum bridge displacements (averaged on 7 accelerograms) obtained from NTHA.

A preliminary comparison between DDBA predictions and NTHA results has been made considering an elastic performance level of the structure (corresponding to the shear failure of neoprene pads at 0.206g for the bridge configuration F2 of Tab. 4), in order to select the best modal combination rule between SRSS and CQC. The comparison is shown in Figure 7. As can be seen, the CQC combination rule leads to errors less than 10% while the SRSS combination rule leads to errors up to 30%.

In Figure 8, DDBA predictions and NTHA results are compared for the PL3 of the bridge configuration F1 (regular pier layout and isostatic decks supported by steel hinges in the transverse direction), representing the real Fiumarella viaduct. Based on the DDBA outcomes, the critical pier, where collapse first takes place, is the pier P2 at 0.565g PGA. Piers P1 and P3, on the contrary, undergo negligible plastic deformations. The comparison between expected and ‘actual’ deformed shapes clearly points out the great accuracy of the DDBA in the prediction of the PGA values associated to severe damage states. Indeed, the percent errors in the evaluation of the ‘actual’ maximum deck displacements do not exceed 14% and, on average, they result of the order of 9%. The NTHA results also confirm that pier P2 is the critical element of the bridge with ductility demands that differ from those derived from DDBA less than 8%. It is worth to observe that in Figures 7-17 displacement profiles and bridge coordinates are reported in two different scales. From a graphical point of view, this determines a distortion of the deformed shape of the bridge that considerably amplifies the rotations of the decks.

Figure 7: Comparison between NTHA results and DDBA predictions using the CQC and SRSS combination rule.

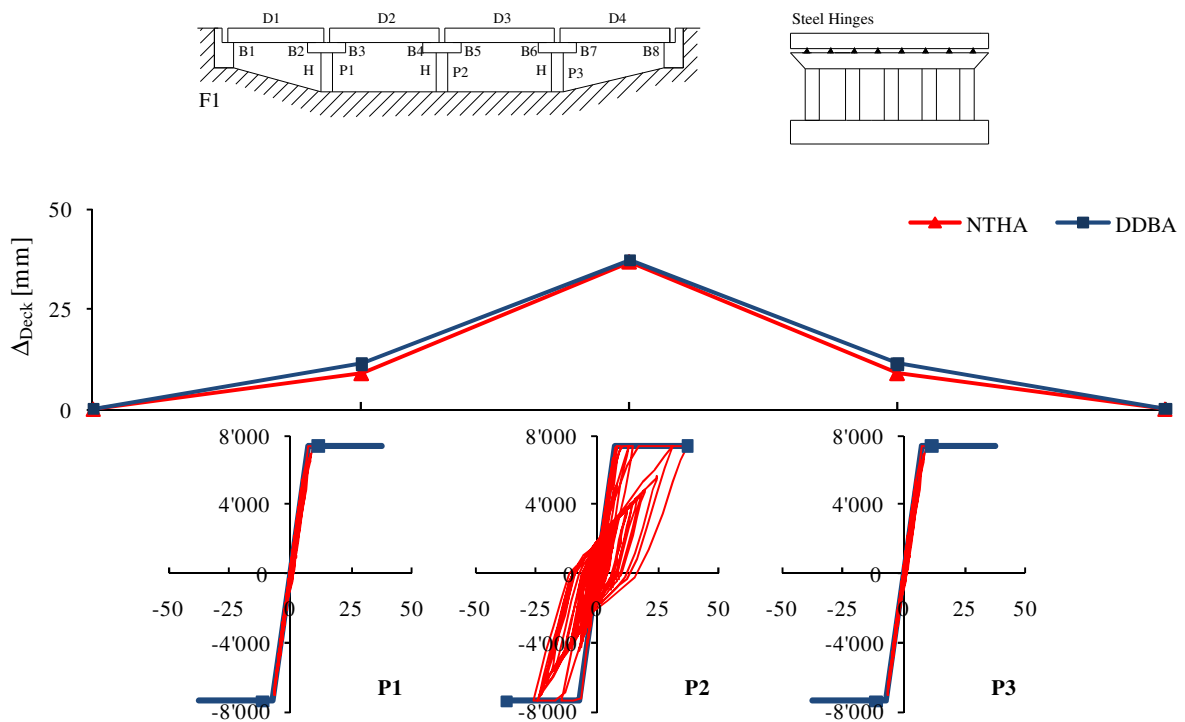

Figure 8: Comparison between DDBA predictions and NTHA results (average maximum values) in terms of deformed shape of the bridge and cyclic behaviour of some structural elements (F1 bridge configuration at PL3, PGA = 0.565 g).

Similar observations can be made examining the seismic response of the bridge configuration F2 (see Fig.9), differing from the bridge configuration F1 for the pier-deck connections (neoprene pads instead of steel hinges). A moderate damage state (PL2), corresponding to a post-failure displacement of 100 mm in the bearing devices B4 and B5, occur at 0.538g. No plastic deformations are registered in the piers. The percent errors between DDBA predictions and NTHA results do not exceed 14% and, on average, result of the order of 9%.

The same level of accuracy in the prediction of the ‘actual’ maximum deformed shape of the bridge is found considering irregular pier layout and multi-span simply-supported continuous deck (Figs. 9-17). As a matter of fact, indeed, the percent errors between DDBA pre-

dictions and NTHA results never exceed 20% and, on average, result lower than 15%. Also the critical element of the bridge is always captured correctly.

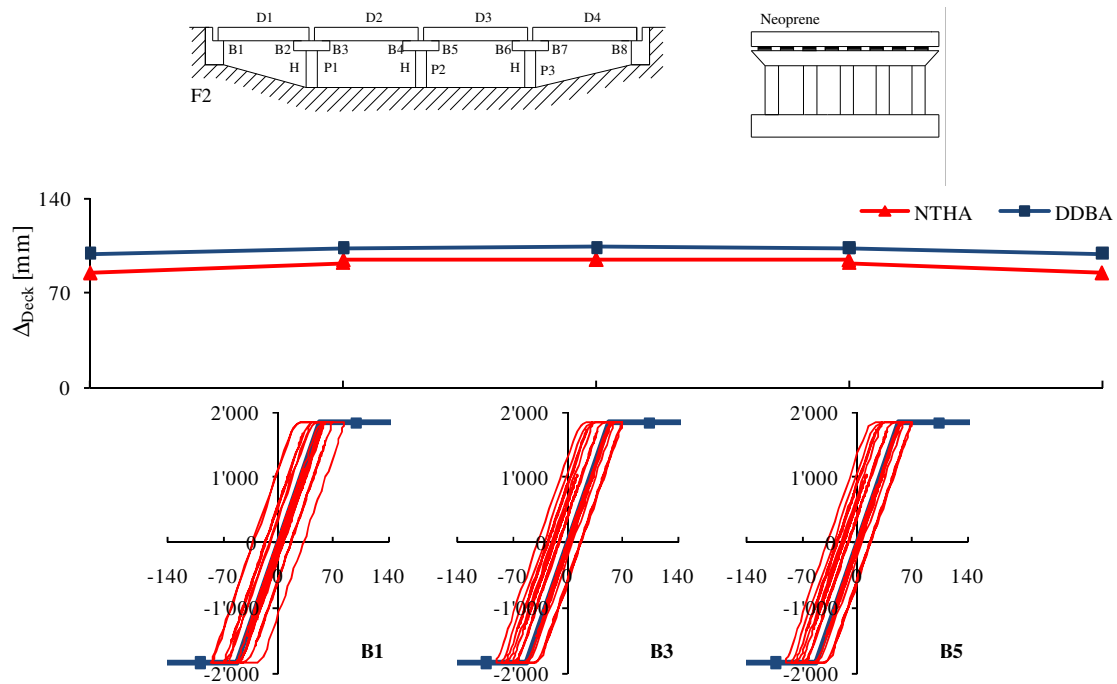

Figure 9: Comparison between DDBA predictions and NTHA results (average maximum values) in terms of deformed shape of the bridge and cyclic behaviour of some structural elements (F2 bridge configuration at PL2, $\text{PGA} = 0.538\text{g}$).

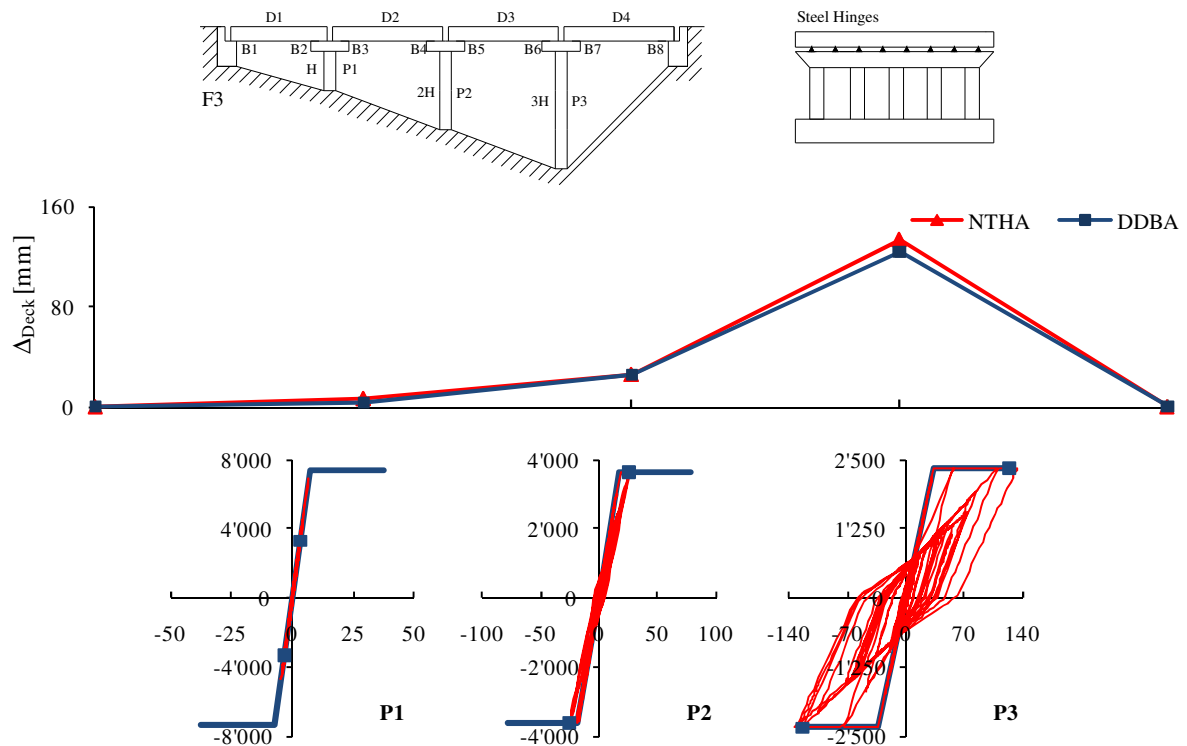

Figure 10: Comparison between DDBA predictions and NTHA results (average maximum values) in terms of deformed shape of the bridge and cyclic behaviour of some structural elements (F3 bridge configuration at PL3, $\text{PGA} = 0.447\text{g}$).

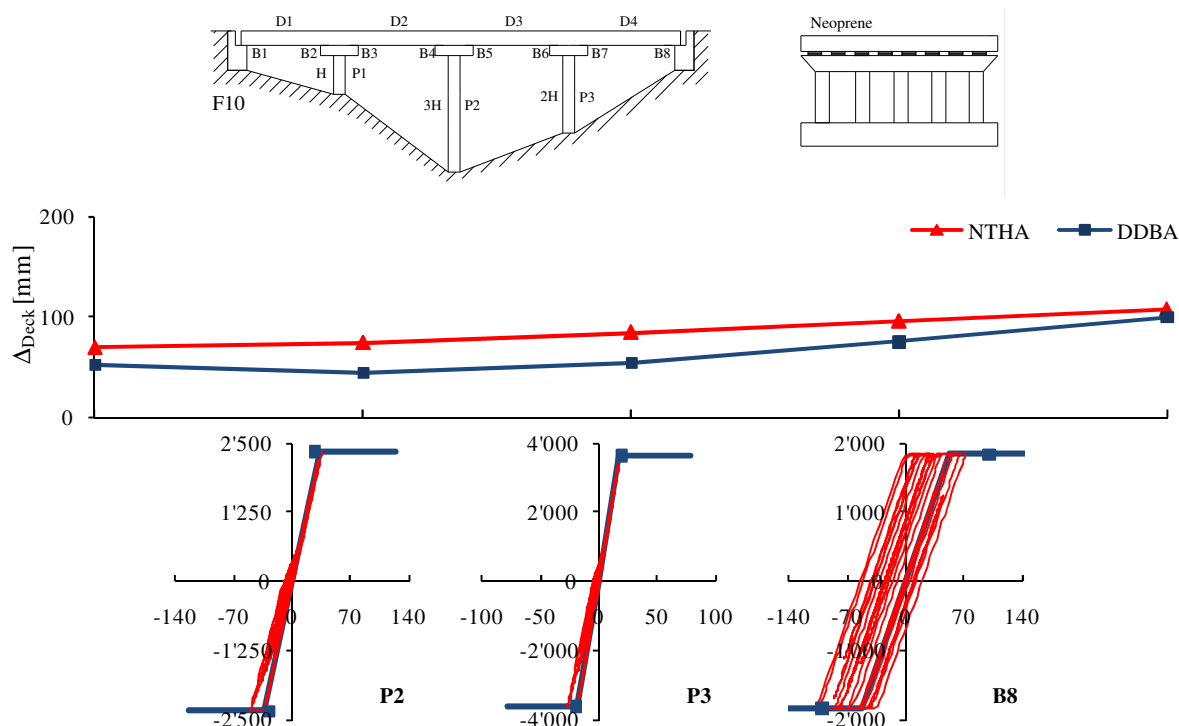

Figure 17: Comparison between DDBA predictions and NTHA results (average maximum values) in terms of deformed shape of the bridge and cyclic behaviour of some structural elements (F10 bridge configuration at PL2, PGA=0.405 g).

For more clarity, in Table 5 the average errors (ERR_{av}) between DDBA and NTHA results, computed based on the deformed shape of the entire bridge, and the error relevant to the critical element of the bridge (ERR_{cr}) are summarised for the ten bridge configurations considered.

BRIDGE CONFIGURATION	DECK	PIER LAYOUT (*)	BEARINGS	PL	PGA	ERR_{av}	ERR_{cr}
F1	Isostatic	H-H-H	SH	PL3-P2	0.565 g	5.01%	1.44%
F2	Isostatic	H-H-H	N	PL1-B4 PL2-B4	0.206 g 0.538 g	5.79% 8.64%	9.86% 9.69%
F3	Isostatic	H-2H-3H	SH	PL3-P3	0.447 g	0.72%	7.19%

* H=3.20 m

Table 5: Comparison between DDBA and NTHA results: average error and error relevant to the critical element.

In Figure 18 the results derived from DDBA are compared to those obtained applying the traditional Force-Based seismic Assessment (FBA) approach, consisting in a Response Spectrum analysis, considering three different behaviour factors, equal to 1 (elastic behaviour), 1.5 and 3.5, respectively. The comparison is made for two different bridge configurations (F4 and F6 respectively) in terms of base shear of each pier and abutment. As can be seen, the accu-

racy of the FBA approach is very sensible to the definition of an appropriate behaviour factor and, in the investigated cases, is rather low. Assuming $q = 1.5$, for instance, the FBA approach captures with good accuracy the maximum base shear of the piers P1 and P2 while it considerably overestimate (by 90%) the maximum base shear of the pier P3. On the contrary, assuming $q = 3.5$ the FBA approach captures with good accuracy the maximum base shear of the pier P3 while it largely underestimate (by 40%) the maximum base shear of the piers P1 and P2.

Figure 18: Comparison between DDBA, FBA and NTHA results (average maximum values) in terms of base shear of piers and abutments.

4 CONCLUSIONS

A Direct Displacement-Based Assessment (DDBA) methodology for the seismic evaluation of multi-span simply-supported deck bridges has been proposed. The proposed DDBA procedure provides the PGA values associated to given Damage States (DS) of the critical elements of the bridge (piers, bearing devices,...). The target displacement profile of the bridge corresponding to the selected DS is determined through an Iterative Eigenvalue Analysis (IEA).

In the paper, the proposed DDBA procedure has been applied to a set of ten multi-span simply-supported deck bridges, differing in pier layout (regular or irregular), bearing type (neoprene pads or steel hinges) and deck type (isostatic or continuous). The predictions of the DDBA procedure have been compared to the results of Nonlinear response Time-History Analyses (NTHA), carried out using a set of seven accelerograms, compatible with the EC8-soilB response spectrum, scaled to the PGA values provided by DDBA procedure for selected DSs. The comparison between DDBA predictions and NTHA results confirms the good accuracy of the proposed procedure in predicting the PGA values associated to slight-to-severe Damage States, regardless pier layout, bearing type and deck type. In all the examples of application considered, indeed, the DDBA correctly identify the critical element of the bridge, where first a given DS is reached. The displacement profile of the bridge predicted by the DDBA (including joint displacements, top pier displacements, bearing device displacements

and deck rotations) is in good agreement with the maximum deformed shape of the bridge found with NTHA, with errors that do not exceed 15 %. Meanwhile, the accuracy of the traditional force-based seismic assessment approach is very sensible to the definition of an appropriate behaviour factor and, in the investigated cases, rather low.

Although the proposed methodology appears very promising, there are a number of aspects that require further investigation. Works are still in progress and additional numerical studies are being to be carried out, in order to fully verify the proposed procedure. Future research shall focus also on the influence of different modelling assumptions and modelling approaches.

Finally, considering that the proposed DDBA procedure for multi-span reinforced concrete bridges is very simple and it can be applied to bridges with different typologies with small revisions, the use of this procedure is recommended when the time and conditions are limited to perform more detailed nonlinear analyses.

5 ACKNOWLEDGEMENTS

This work has been carried out within the RELUIS 2010-2013 research program, Project AT1_L2_Task7, funded by the Italian Civil Protection Department.

Abstract. *Multispan simply supported concrete and steel girder bridges are common bridge types in Central and Southeastern United States. Probabilistic seismic risk assessment of these bridge classes is essential due to an increased awareness of the seismic hazard in the region. This study focuses on developing and comparing fragility curves for seismically and non-seismically designed bridges that are common in the region. Detailed three dimensional nonlinear analytical models, which account for the nonlinear behavior of the columns, girders and abutments, are developed in OpenSEES platform. Unlike most previous studies, the fragility curves are developed considering a wide range of material and geometric uncertainties in the stochastic analyses coupled with considerations of vulnerability of multiple components in defining bridge system performance. The results provide insight into the level of uncertainty introduced in the analysis of fragility curves for portfolios of bridges with the use of three dimensional analytical models and nonlinear time history analyses. Component and system fragility curves are obtained and are compared for the case of non-seismically and seismically designed bridge classes and with those currently used in HAZUS-MH.*

1 INTRODUCTION

Fragility curves, which are conditional probability statements that give the likelihood that a structure will meet or exceed a specified level of damage for a given ground motion intensity measure, have found widespread use in probabilistic seismic risk assessment of highway bridges. The conditioning parameter is typically a single intensity measure such as peak ground acceleration (PGA) or spectral acceleration at the geometric mean of the longitudinal and transverse periods (S_{a-gm}). They are a fundamental building block used in multiple (current and potential future) applications including emergency response, design support such as performance based earthquake engineering, planning support involving assessment of traffic impacts and possible economic losses post a seismic event, and policy support.

The earliest attempt to formalize seismic risk assessment procedures is found in the seminal work by Whitman et al. [1]. Since then several attempts have been made to quantify the risk to highway infrastructure systems. The Applied Technology Council took the first step in performing seismic risk assessment [2] of infrastructure for the state of California using damage probability matrices and restoration functions. Since then several committees constituted by ATC have been solely devoted to the risk assessment of lifelines. The ATC 25 report [3] introduced the concept of continuous fragility functions for lifeline systems including bridges by performing regression on the discrete values of damage probability matrices. Further attempts to push forward the seismic risk assessment methods were made by the Federal Emergency Management Agency (FEMA) by the constitution of a committee of experts and introduction of a Geographic Information Systems (GIS) based risk assessment software, Hazards United States [4] in 1997. Since then HAZUS has undergone several improvements and revisions and now includes models for estimating potential losses from a variety of natural disasters like earthquakes, floods and hurricanes.

Over the years, structural fragilities have been determined in a variety of ways. The ATC 13 Report documents risk assessment of the infrastructure stock in California essentially based on expert opinion. A panel of 42 experts was assembled to develop damage probability matrices for bridge infrastructure based on their expertise. This technique has several major concerns since the procedure is totally subjective and depends on the number of experts queried and therefore is based on expertise and experience of the individuals with little correlation to actually observed earthquake damage. The 1989 Loma Prieta, 1994 Northridge and 1995 Kobe earthquakes were watershed events for fragility research. Several researchers [5, 6, 7, 8, 9, 10] developed empirical fragility curves based on actual damage data observed in these earthquakes. Although the adopted procedure differed slightly among the researchers, the general essence was the same. Basoz and Kiremidjian [5] assembled damage frequency matrices and performed a logistic regression analysis to develop fragility curves while Shinozuka et al. [9] used the Maximum Likelihood Method to estimate the parameters of a lognormal probability distribution describing the fragility curves. Der Kiureghian [7] employed a Bayesian approach in order to develop fragility curves. However, lack of sufficient damage data, discrepancies in the damage assessments in the aftermath of a seismic event, variation in the ground motion intensities at the damage sites depending on the earthquake source are some of the limitations of this technique for developing fragility curves.

Advances in modeling capabilities coupled with lack of sufficient earthquake damage data drove the development of fragility curves using analytical methods. Yu et al. [11] used simple single-degree-of-freedom models and elastic response spectrum analysis to develop fragility curves for highway bridges in Kentucky while Hwang et al. [12] furthered this approach with slight modifications. Dutta [13] and Basoz and Mander [14] used the Nonlinear Static Procedure commonly referred to as the Capacity Spectrum Method (CSM) to develop fragilities for

highway bridge classes in the United States. Currently these values are employed in HAZUS-MH for seismic risk assessment of highway infrastructure systems. Several researchers resorted to more reliable yet computationally expensive techniques like Nonlinear Time History Analysis (NLTHA) and Incremental Dynamic Analysis (IDA) to develop fragility curves. Mackie and Stojadinovic [15] employed NLTHA and IDA to develop fragility curves. These formed the basis of a rational methodology to evaluate damage potential and to assess probable highway bridge losses for critical decision making regarding post earthquake safety and repairs to highway networks. Nielson et al. [16], Padgett et al. [17], Ramanathan et al. [18] employed NLTHA to develop fragility curves for as-built and retrofitted bridge classes in Central and Southeastern United States (CSUS) accounting for multiple component vulnerability.

This study develops analytical fragility curves for seismically (S-) and non-seismically (NS-) designed multispan simply supported (MSSS) bridge classes in the CSUS to provide new insight on the relative vulnerability of these classes of bridges considering distinct levels of seismic design. The following eleven states are considered in the analysis: Arkansas, Alabama, Georgia, Illinois, Indiana, Kentucky, Missouri, Mississippi, North Carolina, and South Carolina. A detailed review of bridges in the NBI [19] in the CSUS region shows MSSS concrete and steel girder bridge classes account for approximately 20% of the bridges in the region. In 1990, bridges in the CSUS began incorporating seismic details. The bridges in the CSUS built prior to 1990 have several known seismic deficiencies which include non-ductile steel bearings, short seat widths, non-ductile columns, high pounding potential and the increased potential for the toppling of rocker bearings [20]. Some of the changes post-1990 included the component design forces, design of columns and foundation, bearing types, and treatment of liquefaction and liquefaction induced ground movement. A review of the evolution in seismic design practices in the region reveals that the predominant difference between seismically and non-seismically designed bridges is associated with the detailing aspects in the columns and the replacement of the steel rocker bearings with elastomeric bearing pads with steel dowels, as presented in detail in the next section of the paper. Bridge piers designed in the CSUS after 1990 have greater splice lengths and transverse reinforcement ratios in the longitudinal and transverse directions, when compared to the respective values in columns designed prior to 1990. The steel rocker bearings are often replaced with elastomeric bearing pads with steel dowels. Their flexibility allows the superstructure to be decoupled from the substructure yet they may also render susceptibility to large deck displacements as well as the potential for bearing walk out from under the girders.

While previous studies [16, 21, 12] have evaluated the seismic response and fragility of various bridge classes common to the CSUS, there is very little research that explores the differences in performance of typical CSUS bridge classes built with and without seismic detailing. This paper addresses this gap by investigating the influence of seismic detailing of the two multispan bridge classes on the seismic performance, as well as the failure probability through the development and comparison of fragility curves.

2 PRE- AND POST-SEISMIC DESIGN CONSIDERATIONS IN CSUS

This paper assesses the effect of seismic design detailing on typical MSSS concrete and steel girder bridge classes in the CSUS through the development of analytical fragility curves. As previously stated, the predominant difference between the non-seismically (NS-MSSS) and seismically (S-MSSS) designed bridges considered in this study is associated with the enhanced ductility characteristics of the columns in terms of detailing aspects and the replacement of non-ductile steel bearings with elastomeric bearing pads having steel dowels. Bridges constructed prior to 1990 in the CSUS region are typically not designed for the adequate

seismic hazard in the region. Non-seismically designed bridges with steel girders in their superstructure typically use one of the two general classes of steel bearings, viz. high type and low type. Both of these bearing types include a fixed or pinned type bearing and an expansion type bearing with the difference being the type of motion associated with the latter. In the case of high type bearings, the motion associated with the expansion bearing is based on a rocking mechanism while it is characterized by sliding in the case of the low type bearing. In the case of MSSS steel girder bridge class, these bearing types are replaced by elastomeric bearing pads with steel dowels in addition to the reduced transverse reinforcement spacing in the columns. The relative flexible nature of these elastomeric bearings allows the superstructure to be decoupled from the substructure, and hence these bearings are susceptible to large deformations, which will be illustrated in subsequent sections of the paper. However, these large deformations could cause unseating of the bridge girders and may also result in bearings walking out from under the girders. In case of both NS- and S-MSSS concrete girder bridges, the bearings adopted were elastomeric bearing pads with steel dowels.

The reduced spacing of the transverse reinforcement in the columns is the primary difference considered between seismically and non-seismically designed columns in both bridge class columns. It is well known that column transverse reinforcement has a major impact on the shear resistance, and ductility capacity of bridges. Prior to 1990, bridge columns in the CSUS typically had transverse reinforcement which consisted of #13 bars at a spacing of 305 mm on center. Whereas, in case of the seismically designed bridges, the spacing of the #13 stirrups is as close as 76 mm on center thereby making flexure the predominant behavioral mode. In either case, the bridges have multi column bents often consisting of a rectangular reinforced concrete bent beam (Figure 1) supported by 914 mm diameter circular columns. The effect of closely spaced transverse reinforcement is incorporated by an increase in the confined compressive strength of concrete and ductility by specifying higher ultimate strain using the concrete model proposed by Mander et al. [22]. Further details can be found in [18]. In the case of the seismically designed columns, the confined compressive strength, f_{con} is approximately 33% larger than characteristic concrete strength, f'_c and the ultimate strain, ϵ_{cu} is approximately 0.05. Whereas, in the case of the non-seismically designed bridge columns, f_{con} is approximately 7.1% larger than f'_c and ϵ_{cu} is only about 0.012. Other column details such as lap splices in plastic hinge regions are not considered explicitly in the current study's column models.

3 SEISMICALLY AND NON-SEISMICALLY DESIGNED BRIDGE CLASS CASE STUDIES

The following sections present detailed information on the bridge class characteristics, analytical modeling procedures and provide some insight on the change in dynamic characteristics with the incorporation of seismic design principles. It moves on with the development of PSDMs and having characterized damage, demonstrates the development of component level fragility curves, which provides a means to look at the relative vulnerability of components in the seismic and non-seismically designed bridges.

3.1 Bridge Class Characteristics

Basic geometric characteristics of the bridge, such as number of spans, span length, deck width, and column height are analyzed and empirical cumulative density functions (CDF) are developed for each of these parameters. Twelve representative bridge configurations are generated using Latin Hypercube sampling from these empirical CDFs for the geometric parameters. The distributions are consistent with those presented in [16] to facilitate comparison.

Based on the inventory analyses, analytical bridge models are created with three spans and zero skew across all bridge classes as these were the most likely bridge configurations. Typical details for these bridge classes can be found in [21, 16], and these are consistent with [12] for Memphis, TN and [23] for Southern IL. The pre- and post-seismic design considerations for the respective bridge classes were discussed in the preceding section.

3.2 Analytical Bridge Models

The typical layout of a three span zero skew bridge is shown in Figure 1. The bridges are modeled in three dimensions using the finite element platform OpenSEES [24] incorporating both geometric and material nonlinearities. The superstructure is modeled using elastic beam-column elements with mass lumped along the centerline. This is typical as the composite slab and girder generally behave linearly. Pounding between the decks is considered using the contact element approach developed by Muthukumar and DesRoches [25]. This approach explicitly accounts for the effects of loss of hysteretic energy. Rayleigh damping is used in the model but is treated as a random variable. Nonlinear beam column elements with fiber defined cross sections are used to model the columns. The nonlinear hysteretic behavior of these columns is captured using a distributed plasticity element. Fiber defined cross sections enable specifying different properties for cover concrete and confined concrete. The differences in the modeling of the seismically and non-seismically designed columns are incorporated using the concrete model. The effect of the closely spaced transverse reinforcement in the case of the seismically designed bridge columns is accounted for by using the confined concrete model discussed in the previous section.

The bearings, both steel and elastomeric bearing pads with steel dowels, are modeled using nonlinear translational springs. In case of the elastomeric bearings, this accounts for the contribution of the elastomeric pads in addition to the steel dowels in the bearing elements. The behavior of steel bearings in both longitudinal and transverse directions is modeled according to the recommendations of Mander et al. [26] stemming from an experimental study. Abutments provide both longitudinal and transverse restraint to the bridge superstructure under loading in both directions. The longitudinal resistance is comprised of both passive and active components. The former is partially provided by soil and by the piles while the latter is provided only by the piles. This study adopts the recommendations of Caltrans [27] in estimating the stiffness of the abutments which are modeled using nonlinear translational springs. Further, the Caltrans recommendations [27] suggests that the effect of wing-walls decreases as the width of the abutment increases and therefore the transverse resistance is conservatively assumed to be provided solely by the piles. The foundation system of most of the highway bridges in CSUS consists of piles [12] which are modeled using nonlinear translational and rotational springs. The stiffness used here is the average stiffness by considering both rigid and flexible nature of the piles. The composite behavior is then computed following some basic geometry based equations presented in [28].

3.3 Deterministic Bridge Responses

In order to understand the effect of seismic detailing principles on the dynamic characteristics of the bridge, one sample set of responses from the NLTHA is compared prior to presenting the PSDMs. In this sample, identical geometries of seismically and non-seismically designed bridges with all the variables set to their median values are subjected to the same ground motion with geometric mean of the PGA of two orthogonal components equal to 0.62g . Therefore, the only distinction rests with the incorporation of seismic provisions viz.,

enhanced ductility in the columns in all bridge classes and replacement of steel bearings with elastomeric bearing pads in the steel bridge classes.

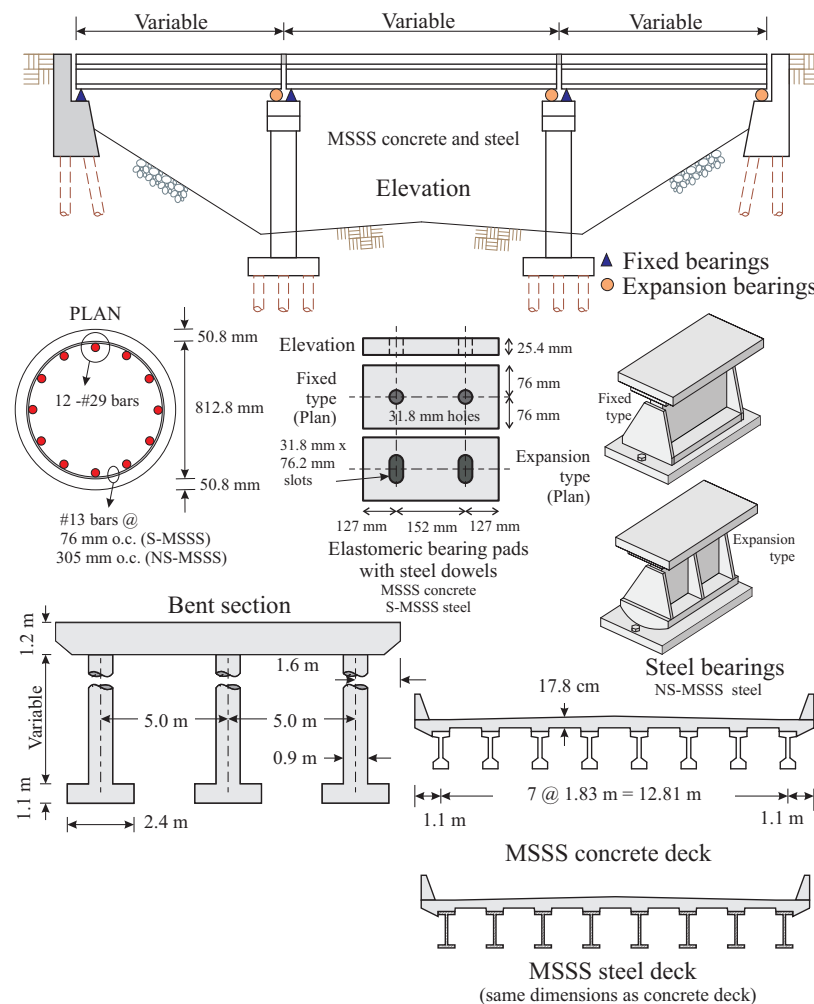

Figure 1: Configuration details of seismically and non-seismically designed bridge classes.

Figure 2 shows various component responses in the MSSS steel girder bridge. Figures 2(a) shows that the column demand is substantially greater in non-seismically designed bridge when compared to its seismic counterpart. In the transverse direction, the seismically designed column experiences a slightly higher moment demand but by far the non-seismically designed column has a much higher curvature demand. The reduced demand on the columns in the seismically designed bridge is due to the increased demand on the bearings. As seen in Figures 2(b) and 2(c), the elastomeric bearing pads in the seismically designed bridge experiences a large force and displacement demand when compared to the brittle steel bearings in the non-seismically designed bridge. The elastomeric bearings have a well defined hysteresis as seen in the figures thereby causing much of the seismic energy to dissipate through enhanced displacement capabilities. It must be noted that in case of steel bearings the internal hysteresis loop captures the frictional component of its response and this frictional force is a function of the normal force that it experiences. In this bridge type, the fixed bearings are typically located at the abutments and the end span, in this case is shorter than the middle span, thereby having a smaller mass and producing smaller reactions leading to narrow hysteresis

loops as depicted in Figure 2(b). This leads to difference in the demand models for these components, as will be shown subsequently in this section. In this case, the abutment response in longitudinal direction is seen to be dominated by passive action as shown in Figure 2(d). The transverse response is characterized by piles alone and in this case, although not shown here, it is seen that the pile action of the abutments never exceeded the linear range with maximum deformations less than 6 mm in either case of seismic and non-seismically designed bridges. Greater pounding action was seen in the non-seismically designed bridge when compared to the seismically designed bridge. Pounding typically causes the passive action of abutments to engage while doing very little to engage the active action. This is depicted in Figure 2(d) where the non-seismically designed bridge has a very dominant passive response (negative quadrant) when compared to the seismically designed bridge. Further, the seismically designed bridge shows very little active response (positive quadrant) which is absent in the case of the non-seismically designed bridge. The transverse load path does not interfere much with pounding and hence very little force gets transmitted to the abutments thereby resulting in the linear response of the abutment piles as seen in this case.

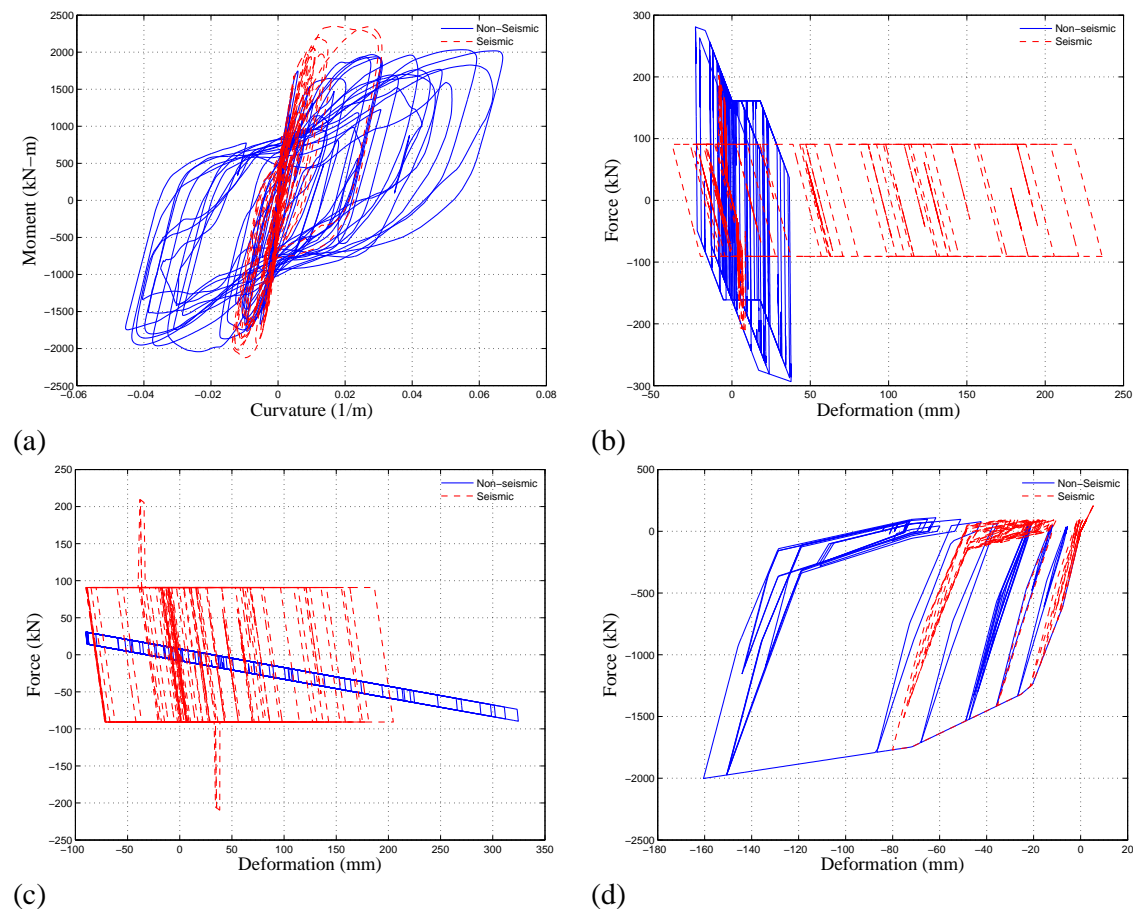

Figure 2: MSSS steel girder bridge component responses for (a) transverse column response, (b) transverse fixed bearing response, (c) longitudinal expansion bearing response, and, (d) longitudinal abutment response.

The component responses from seismically and non-seismically designed MSSS concrete girder bridges with identical geometries and median parameters is shown in Figure 3. As seen in almost all figures 3(a) through 3(d), there is no major difference in demand in the seismically and non-seismically designed bridge. Seismically designed column is seen to have a

slightly greater demand in the transverse direction although both the columns have almost similar demands in the longitudinal direction. The elastomeric bearing pads in the seismically designed bridge were observed to have slightly larger displacement demands when compared to their presence in the non-seismically designed bridge maintain the same force demands. Passive action dominated the abutment response in the longitudinal direction as in the case of steel girder bridges, with the abutments in the seismically designed bridge experiencing slightly greater demands when compared to non-seismically designed bridge. The abutment piles were seen to respond in the elastic range in both the bridges considered similar to steel girder bridges. Therefore, it can be concluded that in case of concrete girder bridge class, the seismic design does not lead to a significant change in the demands and this is reflected in the PSDMs developed subsequently in this section. Instead the change in capacity due to seismic detailing of components is more critical for the concrete bridges.

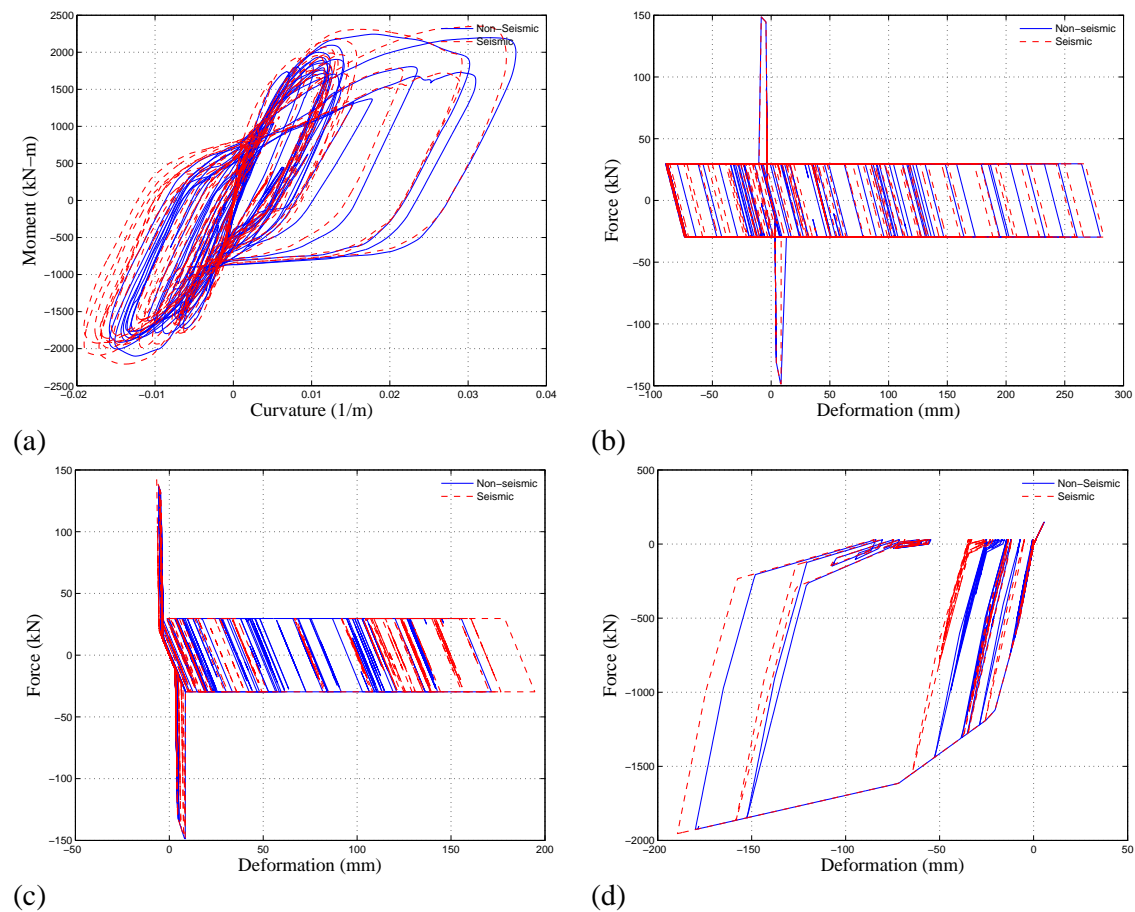

Figure 3: MSSS concrete girder bridge component responses for (a) transverse column response, (b) longitudinal fixed bearing response, (c) transverse expansion bearing response, and, (d) longitudinal abutment response.

3.4 Ground Motion Suite

240 ground motions developed by Fernandez and Rix [29] are used to perform NLTHA. These are probabilistic ground motions developed for selected cities within the Upper Mississippi Embayment including Memphis, TN; Jonesboro, AR; Jackson, TN; Blytheville, AR; Paducah, KY; Cape Girardeau, MO, and Little Rock, AR. Ground motions developed for

Memphis, TN included both Lowlands and Uplands soil profiles since portions of the city are in each soil type. The CSUS ground motions in this database were generated by scaling recorded ground motions for Western United States (WUS). Thus this process provides CSUS ground motions with realistic phase, amplitude relationships between components and frequency-to-frequency variability [29]. The ground motions are probabilistic motions consistent with hazard levels of 10%, 5% and 2% probability of exceedance in 50 years, corresponding to return periods of 475, 975 and 2475 years. 10 motions for each intensity level were generated for every city making it 240 in total. The suite of ground motions is intended to represent the epistemic and aleatoric variability characterized in the soil attenuation relationships developed for the region. Each of the synthetic ground motion was used to generate two orthogonal components following the procedure outlined by Baker and Cornell [30]. The geometric mean of the PGA values of the orthogonal components varies between 0.08g and 1.46g.

3.5 Probabilistic Seismic Demand Models (PSDM)

A PSDM is a conditional statement of the probability that a component experiences a demand for a given IM level, illustrating the importance of the IM as a conditional parameter in the probabilistic model. Hence, the choice of ground motions, definition of the class of structures, formulation of a nonlinear analysis model, and choice of IM and demand measure (DM) pairs form the key aspects of the approach. Padgett et al. [31] and Shafieezadeh et al. [32] explored IMs for portfolios of bridges with geometric variation and concluded that PGA is an optimal IM for probabilistic seismic demand analysis of classes of bridges. This study uses PGA as the IM to develop PSDMs and fragility curves subsequently. The estimation of the median demand, expressed in Equation (1) is based on a power-law model proposed by Cornell et al. [33].

$$S_D = a(IM)^b \quad (1)$$

where, S_D is the median demand, IM is the intensity measure chosen, a and b are the power-law model parameters. By expressing the median demand in logarithmic space, the variation of S_D with the IM takes a linear form and this facilitates the evaluation of the parameters a and b using a simple linear regression analysis. In order to describe the uncertainty about the demand, the logarithmic standard deviation, commonly referred to as the dispersion, $\beta_{D|IM}$, needs to be evaluated, which is expressed in Equation (2). Having estimated, S_D and $\beta_{D|IM}$, the PSDM can be formulated as shown in Equation (3):

$$\beta_{D|IM} = \sqrt{\frac{\sum_{i=1}^N (\ln d_i - \ln a(IM)^b)^2}{N-2}} \quad (2)$$

$$P[D \geq d | IM] = 1 - \Phi\left(\frac{\ln(d) - \ln(S_D)}{\beta_{D|IM}}\right) \quad (3)$$

where, $\Phi(\bullet)$ is the standard normal cumulative density function and S_D is shown in Equation (1).

This study considers various geometric and material variabilities in the fragility analysis. As stated previously, twelve representative bridge realizations are created by sampling on the geometric variables obtained from the inventory analyses. In addition to these geometric variations, several other uncertainties are propagated as listed in Table 1. The bridge realizations together with the uncertainties presented in Table 1 are used to create 240 bridge models

which are then randomly paired with 240 Rix ground motions to create 240 bridge – ground motion pairs which are statistically significant and nominally identical.

Uncertainty parameter	Units	Sampling distribution	Distribution parameters	
Concrete compressive strength	MPa	Normal*	$\mu = 33.5$	$\sigma = 4.3$
Reinforcing steel yield strength	MPa	Lognormal†	$\lambda = 6.14$	$\zeta = 0.03$

*Normal distribution is characterized by the mean, μ , and standard deviation, σ .

†Lognormal distribution is characterized by the parameters, λ and ζ , which are the mean and standard deviation, respectively, of the associated normal distribution.

‡Uniform distribution is characterized by the lower, α , and upper bound, β .

Table 1: List of uncertainties considered in fragility analysis.

A full NLTHA is performed for each bridge – ground motion pair and the maximum demand placed on various components is recorded. In total, 1920 NLTHA are performed for the seismically and non-seismically designed bridges in the four bridge classes considered. Researches in the past [16, 17, 18] have indicated the necessity to consider the vulnerability of several key components to assess system level performance and hence this study considers multi-component vulnerability. Table 2 details the demand parameters used to assess component demands for various bridge components considered in this study. Having performed NLTHA and recorded peak component demands, PSDMs are determined according to the procedure described in the previous section, according to the formulations in Equations (1), (2) and (3).

Demand measure	Abbreviation	Units
Column curvature ductility demand	μ_ϕ	
Longitudinal fixed bearing deformation	δ_{fl}	mm
Transverse fixed bearing deformation	δ_{ft}	mm
Longitudinal expansion bearing deformation	δ_{el}	mm
Transverse expansion bearing deformation	δ_{et}	mm
Passive abutment deformation	δ_p	mm
Active abutment deformation	δ_a	mm

Transverse abutment deformation	δ_t	mm
---------------------------------	------------	----

Table 2: Bridge component demand measures.

Figure 4 illustrates a few sample PSDMs for S-MSSS and NS-MSSS concrete and steel girder bridge classes for the columns and bearings. There is a very minor difference in demand in S-MSSS and NS-MSSS concrete bridges as seen in Figures 4(a) and 4(b). This is expected since the initial stiffness for both cases is identical, and the maximum compressive strength only shows in small difference between the seismically and non-seismically designed bridge columns. The critical effect of the non-seismically designed column is not necessarily an effect on the demand but rather a reduction in capacity. Hence, limit states are most critical when considering changes only in column detailing. However, in the case of the steel bridges, an appreciable difference in demand curves is observed as shown in Figures 4(c) and 4(d) for MSSS steel girder bridges. The difference in the dynamic characteristics of the bridge and the change in load path, as explained in the early parts of this section, are the predominant reasons for the difference in demand models.

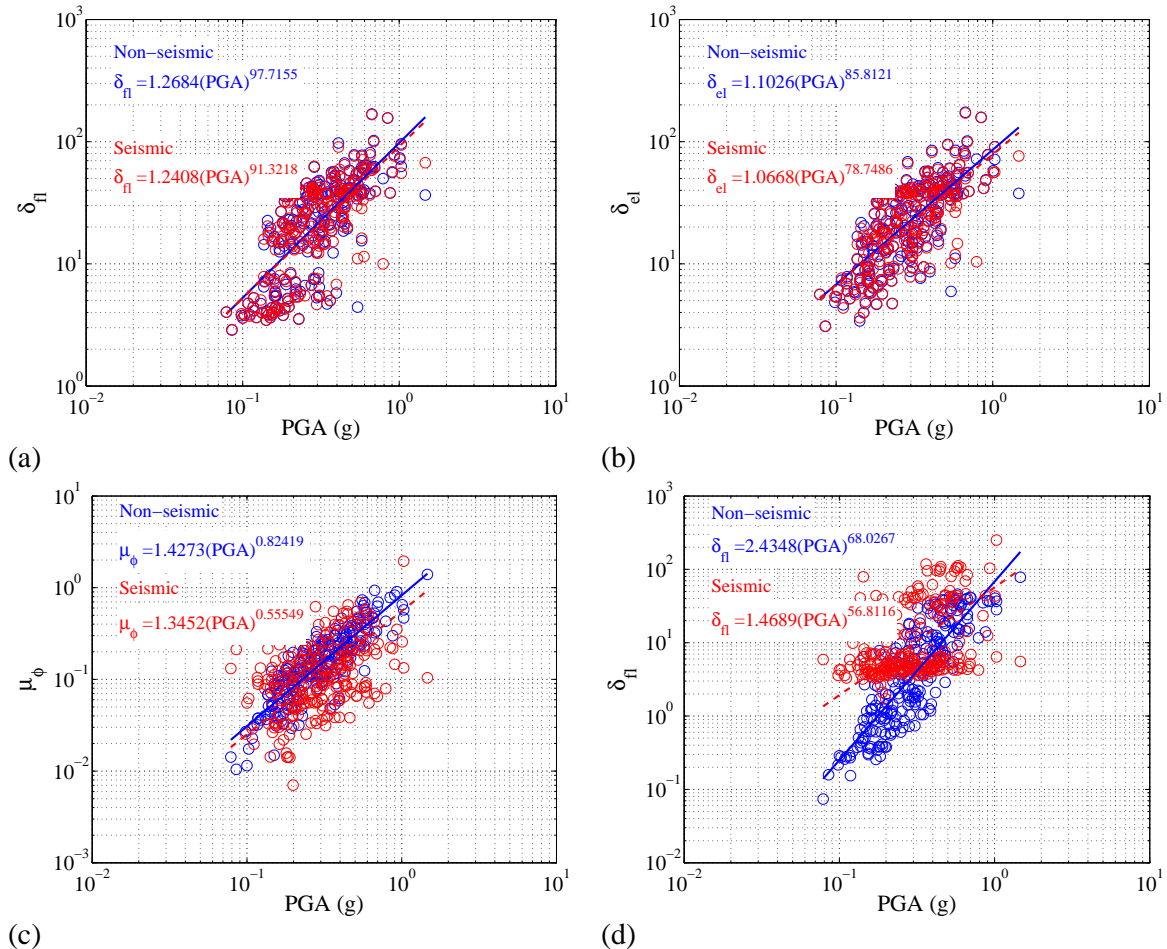

Figure 4: Probabilistic seismic demand models for (a) longitudinal fixed bearing response in MSSS concrete, (b) longitudinal expansion bearing response in MSSS concrete, (c) columns in MSSS steel, and (d) longitudinal fixed bearing response in MSSS steel.

3.6 Component Damage States

The components considered in this study are columns, fixed and expansion elastomeric bearings and abutments (active and passive as well as transverse). The component limit states are also assumed to be lognormally distributed. The median, S_c and the dispersion, β_c values of the capacity limit states are obtained from experimental results and are truly prescriptive. The study uses four damage states; slight, moderate, extensive and complete, comparable to those found in HAZUS-MH. Table 3 summarizes the limit states adopted for the various bridge components. The damage state definitions provided in Table 3 stem from recommendations from previous studies [12, 21, 16, 18] and results from experimental tests. The damage states for columns are quantified using curvature ductility and the results presented in the table below for seismically and non-seismically designed columns stem from the recommendations of [12] and the Pacific Earthquake Engineering Research (PEER) Center's column structural performance database [34]. Steel fixed and expansion bearings have damage states prescribed in terms of displacements and the values shown in Table 3 are obtained from experimental tests conducted on similar bearings [26]. The bearing damage states for elastomeric bearing pads and those for the abutments are consistent with those presented in [16].

Component	Slight		Moderate		Extensive		Complete	
	S_c	β_c	S_c	β_c	S_c	β_c	S_c	β_c
Columns								
Non-seismically designed	1.0	0.25	1.58	0.25	3.22	0.47	4.18	0.47

Table 3: Prescriptive bridge component limit states.

3.7 Component Fragility Curves

Fragility curves at the component level are derived based on the formulation presented in Equation (4) to provide a basis of comparison for the effect of seismic detailing on component vulnerability for the various bridge classes.

$$P[D > C | IM] = \Phi \left(\frac{\ln(S_D/S_c)}{\sqrt{\beta_{D|IM}^2 + \beta_c^2}} \right) \quad (4)$$

Figure 5 plots the component fragilities for the S-MSSS concrete and steel girder bridges at the two intermediate limit states. In the case of the S-MSSS steel bridge class, the elasto-

meric expansion bearings are the most vulnerable component at the slight damage state whereas the elastomeric fixed bearings tend to be the most vulnerable component at all the other damage states as shown in Figures 5(a) and 5(b). This should be expected as there was considerable demand imposed on the bearings as illustrated in Section 3.5 and Figure 2. In the case of NS-MSSS steel, the columns tend to be the most vulnerable component at lower damage states while the longitudinal expansion bearing response dominates the system fragility at higher damage states. This shift in vulnerability may be attributed to the change in dynamic characteristics and resulting demands imposed on the components due to the consideration of seismic design principles. In the case of the S-MSSS concrete bridge class, as shown in Figures 5(c) and 5(d), the expansion bearings tend to dominate the vulnerability in the slight and moderate damage states but the fixed bearings dominate the vulnerability in the case of the extensive and complete damage states. In contrast, columns tend to dominate the vulnerability of the system at all damage states.

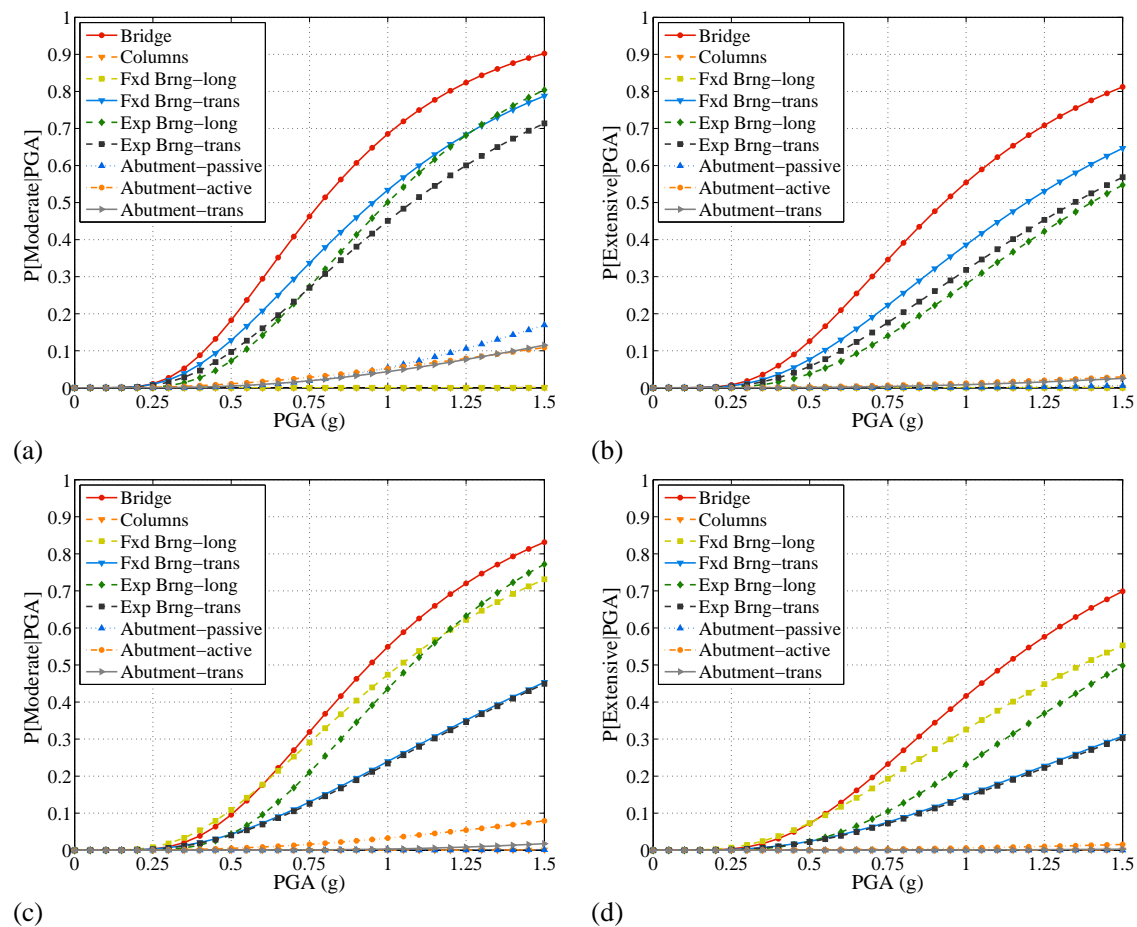

Figure 5: Bridge and component fragility curves for S-MSSS steel girder bridge class for (a) moderate, and (b) extensive limit states, and for S-MSSS concrete girder bridge class for (c) moderate, and (d) extensive damage states.

4 BRIDGE SYSTEM FRAGILITY CURVES

4.1 Comparison of System Fragility for Seismically and Non-seismically Designed Bridge Classes

The logical step that succeeds the determination of component fragilities is to integrate these to enable the macroscopic view of the bridge as a system. Several researchers [16, 35, 21] have proposed techniques to develop fragility curves for the bridge as a system. Mackie and Stojadinovic [35] used the first order reliability method in developing fragility curves while Choi et al. [21] considered first order bounds for series systems. The present study uses the approach developed by [16]. The estimate of system fragility curves is facilitated through the development of joint probabilistic seismic demand model (JPSDM), recognizing that the demands on various components have some level of correlation. A Monte Carlo simulation is then used to compare realizations of the demand (using the JPSDM defined by a conditional joint normal distribution in the transformed space) and statistically independent component capacities to calculate the probability of system failure. Samples (10^6 in this case) are drawn from both the demand and capacity models and the probability of demand exceeding the capacity is evaluated for a particular IM value. The procedure is repeated for increasing values of the IM. Regression analysis is used to estimate the lognormal parameters, median and dispersion, which characterize the bridge system fragility. The methodology presented in this section is used to develop system fragility curves for seismically and non-seismically designed bridges within the fore mentioned bridge classes by considering multiple component vulnerability. The CDFs that define the probabilities of exceeding a limit state, LS, can then be plotted based on the Equation (5), where λ_i and ζ_i are the median and dispersion, respectively, of the i^{th} limit state.

$$P[LS | IM] = \Phi\left(\frac{\ln(IM) - \ln(\lambda_i)}{\zeta_i}\right) \quad (5)$$

Figure 6 shows the system fragility curves for seismic and non-seismically designed MSSS concrete and steel girder bridge classes. In the case of the MSSS concrete bridge class, a very minor difference is seen in the curves at slight damage state. This is because the elastomeric expansion bearings dominate the vulnerability at this limit state followed by elastomeric fixed bearings. Hence, a significant improvement is not seen due to seismic detailing of the columns which has little effect on the demand and more effect on the capacity. On the contrary, in case of the MSSS steel bridge class, significant differences are observed in the curves at all damage states as shown in Figure 6(b). These differences may be attributed predominantly to the replacement of the non-ductile steel bearings with elastomeric bearing pads. This is not the case in their concrete bridge counterparts as the only difference between seismic and non-seismic design is with respect to the column ductility enhancement. Steel bearings are the most vulnerable components in case of NS-MSSS steel bridge class and hence their replacement along with seismic detailing of columns produces a significant reduction in the vulnerability of the system as a whole. This is seen in Figure 6(b).

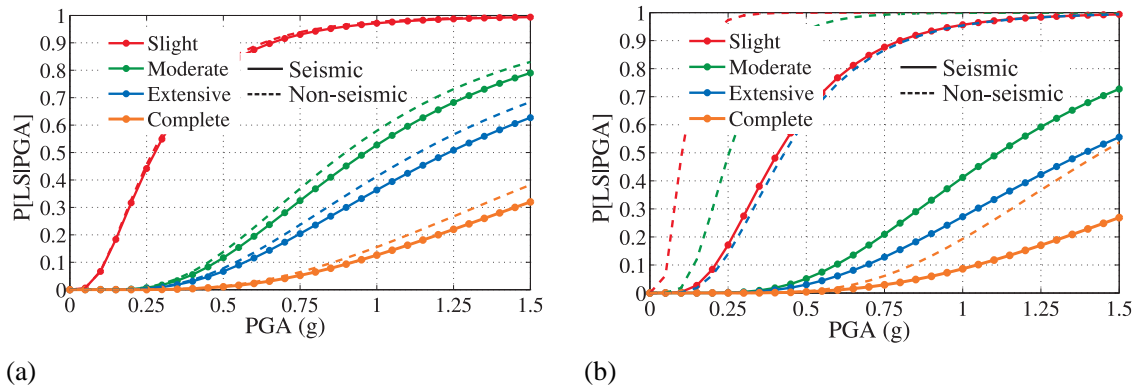

Figure 6: Bridge system fragility curves for seismically and non-seismically designed (a) MSSS concrete girder bridge class, and (b) MSSS steel girder bridge class.

In the case of all the bridge classes, with and without seismic design, the dispersions associated with various limit states fall in a narrow range and hence a single constant dispersion value is chosen to characterize the bridge fragility curves. For example, in the case of the S-MSSS concrete girder bridge class, the dispersion values for slight, moderate, extensive and complete damage states are 0.50, 0.56, 0.52, and 0.55 respectively. In this case, a constant dispersion equal to the mean value, 0.53 in this case, is chosen for the curves corresponding to all the limit states. The median values of fragility curves for the bridge system for various bridge classes along with the dispersions is tabulated in Table 4. It can be seen that incorporation of seismic design principles tends to increase the dispersion about the median fragility. In this study, the parameters included in the uncertainty analysis are the same for both seismic and non-seismically designed bridges, and these were obtained from a sensitivity study presented in [16] that was primarily aimed as non-seismically designed bridge classes. The dispersions associated with the various damage states are similar for seismically and non-seismically designed bridge classes.

Bridge class	Seismically designed*					Non-seismically designed					Percent change in λ			
	λ_s^\dagger	λ_m	λ_e	λ_c	ζ	λ_s	λ_m	λ_e	λ_c	ζ	λ_s	λ_m	λ_e	λ_c
MSSS concrete	0.37	0.94	1.12	1.66	0.53	0.34	0.84	0.99	1.41	0.46	8.8	11.9	13.1	17.7
MSSS steel	0.41	1.12	1.39	2.09	0.52	0.10	0.26	0.43	1.45	0.46	310	331	223	44.1

*The subscripts s, m, e, c for the median values denote slight, moderate, extensive and complete damage states, respectively.

† Median values are reported as proportions of acceleration due to gravity, g .

Table 4: Median and dispersion values for bridge class fragility and percentage change in median values of between seismically and non-seismically designed bridge classes.

A simple technique to compare differences in the fragility curves is to evaluate the relative change in the median value of the fragility curves. This facilitates comparison between the bridge classes as well as for seismic and non-seismic detailing of a given bridge type. A positive change indicates a less vulnerable structure while a negative change indicates a more vulnerable structure. The percentage change in median values for the seismically designed bridges with respect to their non-seismic counterparts is also reported in Table 4. As mentioned previously, significant improvements in the median values are seen in case of the steel bridges in comparison to the marginal improvements in case of concrete bridges. The higher percentage increase in case of steel bridges can be attributed to the seismic detailing provisions in the columns and replacement of the steel bearings with the elastomeric bearing pads.

The results show that the difference in the median values is well pronounced at higher damage states when compared to lower states. This can be attributed to the fact that the actual distinction in performance is predominant when significant nonlinearity occurs and this is seen typically at higher damage states. Hence, the effect of seismic design is well pronounced at the higher damage states.

4.2 Comparisons with HAZUS

As mentioned in Section 1 of the paper, the fragility curves currently used in the risk assessment software, HAZUS, were developed by Basoz and Mander [14] using the nonlinear static procedure, commonly referred to as the Capacity Spectrum Method. These fragility curves, akin to the ones developed in this study are applicable to a class of bridges. The dispersions for the system fragility curves obtained in this study are in the range of 0.5-0.6 (see Table 4) and this is in good agreement with the value of 0.6 proposed by Basoz and Mander [14]. Table 5 shows the median value of fragilities obtained from this study along with the values used in HAZUS-MH. The percentage change in the median values of the present study with respect to those in HAZUS-MH is also presented. A positive change in the median values indicates a less vulnerable structure while a negative change indicates a more vulnerable structure.

Bridge class	Source	Median (g) values				Percentage change (%)			
		λ_s	λ_m	λ_e	λ_c	λ_s	λ_m	λ_e	λ_c
S-MSSS concrete	Proposed	0.37	0.94	1.12	1.66	-17.8	23.7	6.7	8.50
	HAZUS	0.45	0.76	1.05	1.53				
NS-MSSS concrete	Proposed	0.34	0.84	0.99	1.41	30.8	14.0	25.0	16.9
	HAZUS	0.26	0.35	0.44	0.65				
S-MSSS steel	Proposed	0.41	1.12	1.39	2.09	-8.9	47.4	32.4	36.6
	HAZUS	0.45	0.76	1.05	1.53				
NS-MSSS steel	Proposed	0.1	0.26	0.43	1.45	-61.5	-25.7	-2.3	23.1
	HAZUS	0.26	0.35	0.44	0.65				

Table 5: Median values of fragility curves obtained in this study and those from HAZUS.

For the seismically and non-seismically designed bridge classes, this study shows that the bridges are much less vulnerable in the complete damage state. The difference in median values proposed in this study to those reported in HAZUS-MH could be attributed to a variety of reasons. This study adopts nonlinear time history analyses while the fragilities reported in HAZUS-MH are derived using nonlinear static procedure. The differences are also attributed to the consideration of multiple components in estimating the overall system vulnerability and differences in the limit state values. Further, this study considers a much broader list of geometric and material variables in the fragility framework in addition to inclusion of key bridge class attributes based on a detailed NBI bridge inventory. The hallmark of this study is that it also includes considerations of seismic, non-seismic, and general design features exclusive to bridge classes predominant in CSUS making these fragility estimates more suitable to this region.

5 CONCLUSIONS

This study presents an analytical method for the development of fragility curves for seismically and non-seismically designed bridge classes in the central and southeastern United States. Two typical multispan bridge classes are considered that include simply supported

concrete and steel girder bridges. Detailed three dimensional finite element models which account for the nonlinear behavior of the column, girders, and abutments, are developed in the OpenSEES platform. Fragility curves are developed from nonlinear time history analyses using a suite of 240 ground motions developed by Fernandez and Rix [29] for selected cities within the Upper Mississippi Embayment. The uncertainty analysis includes a range of material and geometric parameters and the fragility curves are developed considering multiple component vulnerability using the joint probabilistic seismic demand model approach developed by Nielson and DesRoches [16]. The predominant difference between seismically and non-seismically designed bridges is associated with enhanced ductility characteristics of the column in all the bridge classes considered. In the case of steel girder bridge class, the non-ductile steel bearings prevalent in non-seismically designed bridges are replaced with elastomeric bearing pads with steel dowels in bridges designed post 1990.

The following are some of the important conclusions that can be drawn from the present study. Significant reduction in the vulnerability is seen in both the bridge classes considered in this study with seismic design principles used in their design. The percentage change in the median values is as high as 300% for almost all damage states in the case of steel girder bridges and it is to the order of 15% in the case of their concrete counterparts. The big increase in steel bridges may be attributed to enhanced column ductility performance and replacement of non-ductile steel bearings with elastomeric bearing pads. Comparisons are made between the proposed fragility curves and with those presently adopted by HAZUS-MH. For the seismically and non-seismically designed bridge classes, this study yields significantly fewer vulnerable bridge classes at the complete damage state. The results from this study yield significantly less vulnerable seismically designed bridge fragilities in comparison to HAZUS-MH. The differences in median fragilities may be attributed to the difference in the adoption of analyses techniques, definition of system vulnerability, range of parameters considered in the stochastic analysis at the least. This study considers seismic, non-seismic, and general design features exclusive to bridge classes predominant in CSUS making these fragility estimates more suitable to this region.

AN IMPROVED DISPLACEMENT-BASED SEISMIC DESIGN METHODOLOGY FOR BRIDGES ACCOUNTING FOR HIGHER MODE EFFECTS

Andreas J. Kappos¹, Konstantinos I. Gkatzogias¹, and Ioannis G. Gidaris¹

Keywords: Displacement-Based Seismic Design, Bridges, Reinforced Concrete, Higher Mode Effects.

Abstract. *Weaknesses of existing methods for direct displacement-based design (DDBD) of bridges are pointed out and an improvement is suggested to account for higher mode effects, the key idea being not only the proper prediction of a target-displacement profile through the effective mode shape (EMS) method (wherein all significant modes are considered), but also the proper definition of the corresponding peak structural response. The proposed methodology is then verified by applying it to an actual bridge wherein the different pier heights and the unrestrained transverse displacement at the abutments result in an increased contribution of the second mode. A comparison between the extended and the 'standard' DDBD is conducted, while further issues such as additional design criteria leading to optimum design, the proper consideration of the degree of fixity at the pier's top, and the effect of the deck's torsional stiffness are also investigated. The resulting designs are evaluated using nonlinear response-history analysis (NLRHA) for a number of spectrum-compatible motions. Unlike the 'standard' DDBD, the extended procedure adequately reproduced the target-displacement profile providing at the same time a good estimate of results regarding additional design quantities such as yield displacements, displacement ductilities etc., closely matching the results of the more rigorous NLRHA. However, the need for additional iterations clearly indicates that practical application of the proposed procedure is feasible if it is fully 'automated', i.e. implemented in a software package.*

1 INTRODUCTION

Although force-based design methods still remain the norm in existing national seismic codes, during the past decade several research groups have developed alternative, performance-based, evaluation and design procedures [1], based directly on displacements and/or deformations. In this context, Moehle [2] proposed a general framework for earthquake-resistant design of structures based on drift control, with the seismic demand given by displacement response spectra, while Priestley and co-workers proposed the so-called direct displacement-based design (DDBD) for the design of fundamental mode dominated structures, which may be reduced to 'equivalent' linear single-degree-of-freedom (SDOF) systems [3 - 6]. The DDBD procedure starts from a target displacement, consistent with a deformation capacity ensured by an appropriate detailing of the structure. Estimating a reasonable value for the yield displacement, the target displacement translates into a displacement ductility demand and a corresponding equivalent damping ratio, which is used to reduce the selected displacement spectra, to account (indirectly) for non-linear hysteretic behaviour. Entering this response spectrum with the aforementioned target displacement (expressed in terms of the displacement of the equivalent SDOF system) the effective period (secant value at target displacement) of this system is determined; subsequently, the yield strength corresponding to the previously defined peak displacement and the secant stiffness calculated from the effective period, are found and used to apply a 'traditional' equivalent lateral force design of the structure. Calvi and Kingsley [7] were the first to extend this methodology to multi-degree-of-freedom (MDOF) structures which can be reduced to an equivalent SDOF system using an assumed deformed configuration of the structure. For buildings, this deformed configuration is that corresponding to a predefined plastic mechanism and is dominated by the fundamental mode. This version of the DDBD methodology, accompanied with tables for easier implementation of the procedure for different performance levels, was incorporated in the SEAOC [8] recommendations (referring only to buildings).

As far as bridges are concerned, the early work by Kowalsky et al. [5] dealing with isolated columns modelled as SDOF systems was later extended by Kowalsky [9] and Dwairi and Kowalsky [10], who introduced the effective mode shape (EMS) method to identify the displacement pattern and hence the displacement profile of a bridge at the beginning of the design process. Displacement pattern scenarios for continuous bridge structures subjected to transverse seismic excitation were also investigated in the latter study [10] through the use of nonlinear response-history analysis, while the recent study by Kappos et al. [11] identified required extensions and/or modifications of the aforementioned DBD procedure (see next section), for it to be applicable to actual bridges wherein the simplifying assumptions made at various stages of the procedure do not really hold. Finally, the book by Priestley et al. [12] presents a detailed treatment of the DBD procedure and its application to different structural types, mainly focussing on buildings, but also addressing bridges.

So far, the vast majority of the work performed on this topic does not consider higher mode effects, given the procedure's inherent limitation (resulting from the equivalent SDOF approach) to structures wherein the fundamental mode dominates the response. In a recent study, Adhikari et al. [13] introduced some additional considerations to account for higher mode effects on flexural strength of plastic hinges in the case of long-span concrete bridges with limited-ductile piers. Following the suggestion of Priestley et al. [12], Adhikari et al. used a response-spectrum analysis (RSA), after completion of the DDBD procedure, with two different design spectra (a 5%-damped design spectrum and a design spectrum with damping value obtained from the DDBD procedure) to determine the design responses (elastic and inelastic) at critical locations of the bridge as combinations of several modes.

In view of the aforementioned limitations of DDBD and the fact that bridges are structures wherein higher modes usually play a more critical role than in buildings, the present study attempts to refine and extend the procedure for bridges proposed by Dwairi and Kowalsky [10] and extended by the writers [11], to account for higher mode effects, not only regarding the proper definition of a target-displacement profile (comprising non-synchronous displacements, since all significant modes are considered), but also the proper definition of the corresponding peak structural response. The extended modal procedure proposed herein follows the general framework introduced in previous studies of Chopra and Goel [14] on buildings and Paraskeva et al. [15] on bridges, noting that these studies deal with the pushover procedure, rather than with design based on elastic analysis. The efficiency of the proposed methodology is then assessed by applying it to an actual bridge, whose different pier heights and the unrestrained transverse displacement at the abutments result in an increased contribution of higher modes. Some additional issues such as the proper consideration of the degree of fixity at the pier's top and the effect of the deck's torsional stiffness are also investigated, and comparisons between the extended modal and the 'standard' DDBD method are made. Design results are finally evaluated with the aid of nonlinear response-history analysis.

2 LIMITATIONS OF THE EXISTING DIRECT DBD PROCEDURE

The direct DBD method of Kowalsky [9] and Dwairi & Kowalsky [10] aims at designing a bridge to achieve a prescribed limit state that may be defined directly from displacements or derived from strain criteria under the selected design earthquake. The procedure utilizes the elastic displacement spectra reduced for an equivalent damping value, and the secant stiffness at the selected design displacement. Hence the stiffness of the bridge is not fixed at the beginning of the procedure (as in force-based design, FBD) but is derived in the process through the effective period (secant value). This is achieved by reducing the multi degree of freedom (MDOF) structure to an equivalent single degree of freedom (SDOF) system. The equivalent SDOF inelastic response is represented by the secant stiffness at peak response and equivalent damping, meant to account for hysteretic energy dissipation.

The crucial assumption involved in the above procedure is that this SDOF system suffices for capturing the displacement response of the bridge (which is typically inelastic, for all limit states beyond that corresponding to full serviceability); this implies that a single mode (which might, in fact, be a fictitious one, see subsequent sections) is used for deriving the properties of the equivalent SDOF system. The idea of the 'effective mode shape' (EMS) proposed in [9], building on concepts previously put forward by Calvi & Kingsley [7], is a useful one in this respect; it involves the estimation of a fictitious mode shape of the (inelastically responding) bridge by a statistical combination of individual modes. It is important to note that these modes are also fictitious ones, since they are not the (elastic) normal modes of the bridge but they are derived by eigenvalue analysis of a bridge model wherein yielding members (such as piers and, wherever applicable, abutments) are modelled with their secant stiffness at the intended displacement that generally exceeds the yield displacement, hence inelastic response is foreseen. It is clear from the foregoing summary of the procedure that, in general, a substantial number of iterations would be required to define effective mode shapes consistent with the inelastic response of the bridge to the design earthquake, even more so when multiple earthquake intensities are considered for checking multiple limit states (performance requirements). This important limitation of the method has been remedied to a certain extent by the 'calibration' of inelastic displacement patterns carried out by Dwairi & Kowalsky [10] who performed response-history analyses of four-span bridges with regular and irregular pier configurations, and with different support conditions at the abutments, for a set of 12 recorded motions from all over the world.

To simplify things and improve convergence of the procedure, the existing DDBD methodology assumes that the transverse response of single-column piers monolithically connected to the superstructure is that of a simple cantilever. This simplifying assumption can lead to conservative design of the piers, since the consideration that pier behaviour is that of a simple cantilever usually results to significant increase in the required steel ratio at the base of the pier. Additionally, the assumption of the simple cantilever implies that the superstructure has zero or significantly small torsional stiffness; in the common case of box-girder type decks this situation can be realistic only in the case of yielding of the superstructure's transverse reinforcement (Katsaras et al. 2009). However, this situation is not permitted by current seismic codes, wherein the superstructure is required to remain (essentially) elastic under the design earthquake. Moreover, proper consideration of the expected moment pattern in the piers has a significant importance in the case of the DBD procedure, as it affects the yield displacement (hence the displacement ductility demand) and the flexural stiffness of the piers. Although the previous aspects are identified by Priestley et al. [12], no specific guidelines are given for taking into account the degree of fixity at the pier's top.

A more general limitation of all DBD procedures is the (hardly ever mentioned in the previously cited publications on DBD) fact that not all bridges are, or should be made, displacement-controlled. There are two typical 'scenarios' wherein DBD is meaningless:

First, the case of regions of low, moderate, and even moderate-to-high seismic hazard, where the maximum displacement defined by the pertinent design spectrum is too low, even when no additional viscous damping (accounting for inelastic response) is introduced. Just as an example, seismic Zone I in Greece (which is the country with the highest seismicity in the European Union) is characterized by a design $PGA=0.16g$ and a design spectrum, according to Eurocode 8 (CEN, 2005) for the common case of ground *C*, that results in a maximum elastic displacement (for 5% damping) of only 119 mm at a period $T_D=2.0$ sec (the Eurocode 8 recommended value for the threshold of the constant displacement branch of the spectrum). This is lower than the yield displacement of the pier of even a bridge with relatively short piers like the overpass reported later in the paper. In fact, to make DBD relevant to the common bridge configurations studied by the authors, higher seismic hazard (Zones II and III) and more conservative assumptions ($T_D=4.0$ sec) for the displacement spectrum had to be used. For bridges with (relatively) tall piers even these conservative assumptions cannot lead to meaningful DBD.

Second, the configuration of the bridge, including support conditions, which must also account for soil-structure interaction (SSI), should be such as to permit substantial displacements, accompanied by inelastic action. The case of bridges with tall piers has been mentioned previously, another case is that of bridges with transverse displacement blocked at the abutments. For instance, in the bridge studied in a later section, which is a typical overpass structure, blocking of transverse movement through stoppers at the (seat-type) abutments leads to very small displacements of the piers subsequent to their yielding, as most of the base shear developed after that stage goes to the abutments.

Last and not least, for DBD procedures for bridges to be suitable for practical design, they should be enriched with additional design criteria that would avoid the situation (that the authors have encountered on several occasions in their case-studies) wherein the advantages of DBD (with respect to FBD) are lost when minimum requirements for dimensioning and detailing of reinforced concrete (R/C) members are applied, in line with current practice.

The extensions to the Kowalsky et al. method introduced by the authors in [11] and here aim at remedying some of the aforementioned limitations.

3 PROPOSED EXTENSIONS TO THE 'STANDARD' DDBD

Various design criteria (complementary to those already included in the procedure of Kowalsky et al. and recently proposed by the authors [11]) are briefly reviewed herein; they can be deemed as guidelines that can assist the practicing engineer to achieve an efficient design, regarding both performance and economy. The extension (to account for higher-mode effects) of the displacement based design procedure for bridges with monolithically connected single-column piers to the superstructure, is then proposed, wherein the degree of fixity to pier top provided by superstructure rigidity is taken into consideration.

It is clear that not only the complexity but also the challenge of the design procedure derives from the multiplicity of 'solutions' to the design 'problem'. An ideal solution would satisfy all design criteria; nevertheless such an outcome (if at all feasible) would require numerous iterations. Therefore, the pragmatic approach is to meet as many criteria as possible with the least number of iterations. The additional design criteria proposed herein for the 'standard' DDBD method are as follows:

- i. $V_{pier} \geq V(\rho_{req} = \rho_{min})$: The shear carried by each pier (V_{pier}) should exceed, for the sake of economical design, the shear (and hence the moment) that corresponds to the minimum required longitudinal reinforcement ratio, $V(\rho_{req} = \rho_{min})$. Otherwise, code minimum requirements will prevail and any benefits of DDBD will probably vanish.
- ii. $V_{Abt} \leq V_u$: The shear carried by each abutment (V_{Abt}) should not exceed the ultimate shear (V_u), which is directly related to the 'weakest link' of the superstructure-abutment-backfill (SAB) system. For instance, in the case of a bearing-supported superstructure (with or without seismic links), it can be assumed that the SAB system will respond quasi-elastically ($K_{SAB} = K_{Bearings}$) until the closure of the gap between the deck and the abutment or seismic link; thus, V_u can be calculated from the ultimate force that can develop in the elastomeric bearings placed at the abutment, or the resistance of the seismic link. Activation of the abutment-backfill system can in turn determine V_u ; this is also the 'weakest link' in the case of a monolithic superstructure-abutment connection.
- iii. $k_{eff} \geq k(T_{eff} = T_D)$: Calculated supporting member (pier/abutment) secant stiffnesses (corresponding to the target-displacement profile), and hence the secant stiffness (k_{eff}) of the equivalent SDOF system (see Step 3 in next section) should not correspond to an effective period (T_{eff}) longer than the threshold (T_D) of the constant displacement branch of the design spectrum (see next section and Figures 2, 4). For very long T_{eff} the target displacement has to be reduced, which generally results in a longitudinal reinforcement increase and hence in less economical design. It should be stressed here that the choice of a proper T_D is essential for DDBD to be meaningful (see also section 'Evaluation of the proposed procedure in the case of an existing bridge').
- iv. $\Delta_{pier} \leq \Delta_D$ and $\mu_{pier} \leq \mu_u$: The pier target-displacements should not exceed the corresponding 'damage-based' displacements (Δ_D), determined either from strain-based criteria [16] or drift-based criteria. P- Δ effects should also be considered. In addition, an ultimate displacement ductility value, determined by the designer (taking into account the detailing rules used in dissipating zones), should specify the upper limit in pier displacement ductilities.
- v. $\Delta_{Abt} \leq \Delta_D$: As in design criterion (ii), the abutment target-displacements should not exceed the corresponding 'damage-based' displacements (Δ_D), defined with due consideration of the SAB system configuration. Referring to the common case of a bearing-supported superstructure, Δ_D is calculated in terms of the maximum acceptable shear strain ratio (γ_u), given the bearing horizontal stiffness.

In the extensions of the 'standard' DDBD method presented herein, the parameter of the equivalent cantilever length (h_{eq}), which is the distance from the pier base to the contraflexure point (see Fig. 1), is introduced to take into account the degree of fixity at the top of the pier.

Figure 1 represents the modelling of a pier with a rigid base and monolithically connected to the deck, whereas possible moment diagrams under transversal loading are also illustrated. It is obvious that a pier moment diagram consists of two different components; the bending moment derived from the inertial horizontal forces F , acting on the mass centroid (G), and the bending moment induced from the eccentricity of the latter forces with respect to the shear centre, in the usual case wherein the shear centre does not coincide with the mass centroid. The final moment diagram depends on the cracked torsional stiffness of the bridge deck, the superstructure-abutment connection and the pier-superstructure relative stiffness; likewise it is required to properly account for the degree of fixity at pier's top and hence for the pier's transverse response regarding its flexural stiffness (k_{pier}) and yield displacement ($\Delta_{y,pier}$), according to Equations (1) and (2), (referring to case (b) in Figure 1, similar relations can be derived for the other cases).

$$x_k = \frac{h_{eq}}{h} = \frac{h_{eq}}{h_{clear} + h_G}, \quad k_{eq} = \frac{3EI}{h_{eq}^3}, \quad k_{pier} = x_k k_{eq} \quad (1)$$

$$x_{\Delta y} = \frac{L_{eq}}{L_{eff}} = \frac{h_{eq} + 0.022f_y d_{bl}}{h_{clear} + h_G + 0.022f_y d_{bl}}, \quad \Delta_{y,eq} = \frac{\phi_y L_{eq}^2}{3}, \quad \Delta_{y,pier} = \frac{1}{x_{\Delta y}} \Delta_{y,eq} \quad (2)$$

Figure 1: Pier modelling and transverse response accounting for the deck's torsional stiffness.

In Equations (1) and (2) E is the elasticity modulus of concrete and I is the moment of inertia of the pier cross-section (modified for cracking effects wherever necessary), ϕ_y is the yield curvature, f_y is the longitudinal bar yield stress and d_{bl} is the longitudinal bar diameter.

4 A MODAL DDBD PROCEDURE FOR BRIDGES

An extension of the DDBD methodology to bridge structures, wherein consideration of higher mode effects is deemed indispensable, is proposed herein. Procedures supplementary and/or alternative to those included in the 'standard' DDBD, are presented in this section, while an application of the suggested methodology to an actual bridge is given in the following section. For the sake of completeness (and the benefit of the reader) all steps of the procedure (including those that are essentially the same as in the 'standard' method [9, 10, 11]) are summarized in the following.

Step 0 - Definition of initial input parameters: General input parameters concerning the geometry (e.g. column height and diameter in piers with cylindrical columns), the mass properties (e.g. translational mass and mass moment of inertia), and material properties are defined. An initial estimate of the column cross-section is required. As a starting point, the output of the dimensioning of the deck and the piers for the Ultimate and Serviceability Limit States under the pertinent combinations of permanent and transient actions can be used. Then, single or multiple performance levels are set as design objectives, by designating the targeted damage states ('damage-based' displacements) for selected seismic hazard levels (elastic displacement response spectra).

Step 1 – Selection of the displacement pattern: The step prescribed in the 'standard' DDBD procedure, involves the computation of the relative pier-deck stiffness (RS) and the determination of whether the bridge has a rigid or a flexible displacement pattern, as suggested by Dwairi et al. [10]. Given that the procedure proposed here is intended for bridges where higher mode contribution should not be ignored, the flexible displacement pattern scenario is adopted, disregarding the relative stiffness parameter. This means that this step is essentially redundant, nevertheless it is deemed advisable to retain it, as it is always useful for the designer to have a proper indication of the relative stiffness of the deck.

Step 2 – Definition of target-displacement profiles: The iterative effective mode shape (EMS) method is followed, according to the following steps:

i. Evaluation of mode shapes (Φ_j): Due to the unavailability of the member effective properties at the start of the process a first estimation is required. Based on current seismic design practice for bridges it can be assumed that the superstructure will respond essentially elastically, regarding its flexural stiffness, while for its torsional stiffness it is proposed to assume 20% of the uncracked value, based on the ratios (10÷30%) of cracked-to-uncracked torsional stiffness just after concrete cracking, estimated by Katsaras et al. [17]. On the other hand, it is suggested that a secant flexural stiffness equal to 10% EI_g be applied to columns expected to deform inelastically, while 60% of the uncracked section stiffness is suggested for columns that are expected to remain elastic. The reduction in the effective axial [18] and shear [19] stiffness of the column(s) can be considered proportional to the reduction in the effective flexural stiffness. Once the structure properties have been established, the eigenvalue problem can be solved, hence the mode shapes Φ_i can be obtained.

ii. Evaluation of modal participation factors (Γ_j): The modal participation factors can be computed using standard procedures, i.e. Equation (3), where \mathbf{m} represents a diagonal mass matrix and $\mathbf{1}$ is a unit vector.

$$\Gamma_j = \frac{\Phi_j^T \mathbf{m} \mathbf{1}}{\Phi_j^T \mathbf{m} \Phi_j} \quad (3)$$

iii. Evaluation of peak modal displacements ($u_{i,j}$): The peak modal displacements are computed according to Equation (4), where index i represents the joint number associated with a lumped mass, as per the inertial discretization, index j represents the mode number, $\Phi_{i,j}$ is the modal factor of joint i and mode j , and S_{dj} is the spectral displacement for mode j obtained by entering the 5%-damped design spectra with the period obtained from modal analysis.

$$u_{i,j} = \Gamma_j \Phi_{i,j} S_{dj} \quad (4)$$

iv. Evaluation of expected displacement pattern: The displacement pattern (δ_i) is obtained by an appropriate combination of the peak modal displacements, such as the SRSS combination given by Equation (5); CQC combination is expected to yield better results when the natural frequencies of the participating modes in the response are closely spaced.

$$\delta_i = \sqrt{\sum_j u_{i,j}^2} \quad (5)$$

It is noted that a displacement pattern derived from the above procedure accounts for the effect of all significant modes (e.g. those needed to capture 90% of the total mass in the transverse direction); therefore, it does not correspond to an actual inelastic deformed shape of the bridge, particularly so in the case of asymmetric systems. To obtain the target displacement profile (Δ_i), the displacement pattern given by Equation (5) is scaled such that none of the member (pier or abutment) displacements exceed the target displacements obtained based on strain or drift criteria:

$$\Delta_i = \delta_i \frac{\Delta_{D,c}}{\delta_c} \quad (6)$$

where $\Delta_{D,c}$ and δ_c are the 'damage-based' displacement and the modal value at the critical mass c (whose displacement governs the design), respectively. Finally, peak modal displacements ($u_{i,j}$) are scaled to N modal target-displacement profiles ($U_{i,j}$) utilizing the same scaling coefficient as that used to obtain the target-displacement profile in Equation (6):

$$U_{i,j} = u_{i,j} \frac{\Delta_{D,c}}{\delta_c} \quad (7)$$

An immediate consequence of the aforementioned procedure is that the combination of the N modal target-displacement profiles ($U_{i,j}$) yields the target-displacement profile (Δ_i); hence, in the case the SRSS combination rule is used:

$$\Delta_i = \sqrt{\sum_j U_{i,j}^2} \quad (8)$$

Step 3 – Definition of $N+1$ equivalent SDOF structures: These structures are established based on equal work done by the MDOF bridge and the equivalent SDOF structure, according to Calvi & Kingsley [7]. Each of the N SDOF structures is related to the corresponding modal target-displacement profile ($U_{i,j}$), whereas the additional SDOF is related to the target-displacement profile (Δ_i). Utilizing Equations (9) and (10), an equivalent system displacement (Δ_{sys} , $U_{sys,j}$), mass (M_{sys} , $M_{sys,j}$) and location (x_{sys} , $x_{sys,j}$) of the SDOF across the MDOF bridge deck is computed for each of the $N+1$ SDOF structures. In Equations (9) and (10), m_i is the mass associated with joint i , and n is the number of joints as per the inertial discretization.

$$U_{sys,j} = \frac{\sum_{i=1}^n m_i U_{i,j}^2}{\sum_{i=1}^n m_i U_{i,j}}, \quad M_{sys(j)} = \frac{\sum_{i=1}^n m_i U_{i,j}}{U_{sys,j}}, \quad x_{sys,j} = \frac{\sum_{i=1}^n (m_i U_{i,j} x_i)}{\sum_{i=1}^n (m_i U_{i,j})} \quad (9)$$

$$\Delta_{sys} = \frac{\sum_{i=1}^n m_i \Delta_i^2}{\sum_{i=1}^n m_i \Delta_i}, \quad M_{sys} = \frac{\sum_{i=1}^n m_i \Delta_i}{\Delta_{sys}}, \quad x_{sys} = \frac{\sum_{i=1}^n (m_i \Delta_i x_i)}{\sum_{i=1}^n (m_i \Delta_i)} \quad (10)$$

Step 4 – Estimation of equivalent viscous damping levels: Utilizing the target displacement (Δ_i) and the modal target-displacement profiles ($U_{i,j}$), the ductility level is calculated for each member (for each of the $N+1$ profiles), according to Equation (11) and in line with the equivalent cantilever concept (Equation (2)). The height of the equivalent cantilever cannot be determined at the initial stage of design, therefore either preliminary structural analyses should be performed for each of the $N+1$ equivalent structures under lateral loads compatible with the corresponding profile, or an assumption that the height of the equivalent cantilever equals the height of the pier, should be made during the first iteration. The first approach is strongly recommended for the case of significant higher mode effects, since it reduces the number of iterations required to achieve convergence.

$$\mu_{\Delta_i} = \Delta_i / \Delta_{yi}, \text{ (or } \mu_{\Delta_i} = U_{i,j} / \Delta_{yi,j} \text{)} \quad (11)$$

Yield curvatures in Equation (2) are estimated using Equation (12), where ε_y is the reinforcement yield strain and D is the diameter of a circular section; similar equations are provided for different section shapes [12, 19].

$$\phi_y = 2.25\varepsilon_y / D \quad (12)$$

The displacement ductility ($\mu_{\Delta,i}$) of each pier should be compared with μ_u , (see design criterion iv). If any $\mu_{\Delta,i}$ exceeds μ_u , the designer should revise either the target-displacement profile (by reducing the pier limit-state displacements) or the yield displacements (by reducing the pier cross-section).

Several relationships [20 - 23] between hysteretic damping and ductility have been proposed. The one obtained by Dwairi [20] based on Takeda's hysteretic model [24], given by Equation (13), is used here. Additional elastic viscous damping (ζ_v) up to 5% should be added to the hysteretic damping in line with the approach proposed by Grant et al. [25].

$$\zeta_i = \zeta_v + \frac{50}{\pi} \left(\frac{\mu_{\Delta} - 1}{\mu_{\Delta}} \right) \% \quad (13)$$

These damping values need to be combined in some form to obtain system damping for each of the $N+1$ equivalent SDOF structures. A weighted average can be computed, as given by Equation (14), where $W_i / \sum W_k$ is a weighting factor, based on the work (W_i) done by each member (Equation (15)), according to the Kowalsky [9] approach.

$$\zeta_{sys} = \sum_{i=1}^n \left(\frac{W_i}{\sum_{k=1}^n W_k} \zeta_i \right), \quad \zeta_{sys(j)} = \sum_{i=1}^n \left(\frac{W_{i,j}}{\sum_{k=1}^n W_{k,j}} \zeta_{i,j} \right) \quad (14)$$

$$W_i = V_i \Delta_i, \quad W_{i,j} = V_{i,j} U_{i,j} \quad (15)$$

Calculation of the weighting factors obviously requires the knowledge of member forces (V), which are not known at the current step. As a starting point, it can be assumed that the seismic force carried by the abutments is equal to 30% of the total seismic force carried by the bridge and column shears are inversely proportional to column heights, as illustrated by Equation (16) [9], where μ is less than one for elastic columns and equal to one for columns that have yielded. In subsequent iterations, system damping is computed in proportion to the member forces obtained from structural analyses.

$$W_i = \mu_{\Delta_i} \Delta_i / h_{eq,i}, \quad W_{i,j} = \mu_{\Delta_i} U_{i,j} / h_{eq,ij} \quad (16)$$

Step 5 – Determination of the equivalent structures effective periods: Utilizing the $N+1$ system target-displacements (Δ_{sys} , $U_{sys,j}$), levels of system damping (ξ_{sys} , $\xi_{sys,j}$), and elastic response spectra for the chosen seismic demand, the effective periods (T_{eff} , $T_{eff,j}$) of the equivalent structures are determined from the design spectrum as shown in Figure 2.

Figure 2: Effective period evaluation based on DDBD procedure.

Once again, revision of the target-displacement profile is required when the calculated target displacements exceed the displacement that corresponds to the corner period (T_D) (see design criterion iii). Once the effective periods have been determined, effective stiffnesses (k_{eff} , $k_{eff,j}$) and design base shears (V_B , $V_{B,j}$) are computed by Equations (17) and (18), respectively.

$$k_{eff} = 4\pi^2 M_{sys} / T_{eff}^2, \quad k_{eff,j} = 4\pi^2 M_{sys,j} / T_{eff,j}^2 \quad (17)$$

$$V_B = k_{eff} \Delta_{sys}, \quad V_{B,j} = k_{eff,j} U_{sys,j} \quad (18)$$

Step 6 – Verification of design assumptions: Design base shears (V_B , $V_{B,j}$) are distributed in proportion to the inverse of the column height according to Equation (19), which is based on the simplifying assumption that all columns have the same diameter and longitudinal reinforcement steel ratio, zero post-elastic slope of the force-displacement response, mass small enough such that inertia forces due to self-weight can be neglected, and the same end-fixity conditions. In Equation (19) μ_i and μ_k are less than one for elastic columns and equal to one for columns that have yielded and F_{Abt} represents the total force carried by the abutments. Member cracked section stiffnesses are computed for each of the $N+1$ profiles, using Equations (20) and are compared to assumed values of Step 2. If the values related to the target-displacement profile (Δ_i) differ significantly, computed secant stiffnesses ($k_{eff,i}$) are utilized in the EMS to obtain revised target-displacement profiles (Δ_i , $U_{i,j}$). Steps 2 to 6 are repeated by changing column secant stiffnesses until the target profile (Δ_i) stabilizes. Although a strict approach requires iteration within Steps 2 to 6 until all profiles (Δ_i and $U_{i,j}$) stabilize, the implementation of the proposed methodology in the next section indicates that whenever Δ_i stabilizes, $U_{i,j}$ are also practically stabilized, hence Δ_i can be used as the sole convergence criterion.

$$V_{B,k} = (V_B - F_{Abt}) \frac{\mu_{\Delta,k}}{h_k} \bigg/ \sum_{i=1}^n \frac{\mu_{\Delta,i}}{h_i}, \quad V_{B,kj} = (V_{B,j} - F_{Abt,j}) \frac{\mu_{\Delta,kj}}{h_k} \bigg/ \sum_{i=1}^n \frac{\mu_{\Delta,ij}}{h_i} \quad (19)$$

$$k_{eff,i} = V_{B,i} / \Delta_i, \quad k_{eff,ij} = V_{B,ij} / U_{i,j} \quad (20)$$

Step 7 - Structural analysis: Once the target-displacement profile (Δ_i) stabilizes, base shears ($V_{B,j}$) are distributed as inertia forces to the masses of the MDOF structure in accordance with the modal target-displacement profiles ($U_{i,j}$), as given by Equation (21) [7]. In this equation $F_{i,j}$ are the bent inertia forces, $V_{B,j}$ are the design base shears, indices i and k refer to joint numbers, and n is the number of joints.

$$F_{k,j} = V_{B,j} \left(m_k U_{i,j} \right) / \sum_{i=1}^n (m_i U_{i,j}) \quad (21)$$

N structural analyses (as many as the significant modes) are performed on the bridge under the inertia loads, to obtain the 'modal' base shear for each column. Secant stiffnesses $k_{eff,i,j}$ obtained from the iteration within Step 6, at which stabilization of Δ_i (hence stabilization of $U_{i,j}$ as mentioned in Step 6) was observed, should be used in each of the N structural model analyses, in order to be consistent with the DDBD philosophy. Afterwards, displacements derived from the N structural analyses are compared with the corresponding profiles $U_{i,j}$. In the case of significantly different displacements, reasonable values for column secant stiffnesses are assumed and analyses are conducted until convergence is achieved. Once the displacement profiles obtained from structural analyses converge to the assumed modal target-displacement profiles, column secant stiffnesses and abutment forces from each analysis are compared with the values assumed at Step 6, at which stabilization of $U_{i,j}$ was achieved. It is reminded that during the first loop of iterations the seismic force carried by the abutments is assumed equal to 30% of the total seismic force carried by the bridge for all the $N+1$ cases. In case of significant discrepancy, the target-displacement profile is revised utilizing the EMS method and forces from structural analyses. Steps 2 to 7 are repeated, until column secant stiffnesses and abutment forces converge.

In order to perform the new loop of iterations and the new EMS in particular, previous loop secant stiffnesses ($k_{eff,i}$) (Step 6) can be assumed as a starting point. Furthermore, revised equivalent cantilever heights are computed according to the results of the N structural analyses, which were previously performed, as far as the modal target-displacement profiles ($U_{i,j}$) are concerned, whereas in the case of the target-displacement profile (Δ_i), proper values of the equivalent cantilever heights can be approximately determined by combining the peak 'modal' responses (N structural analyses). Following the same approach, the force carried by the abutments and the base shear distribution for each of the $N+1$ cases required in the subsequent steps are determined from analysis results, instead of utilizing Equation (19), which, given the diversity of the column end-fixity conditions, is not accurate.

Step 8 - Design of the MDOF structure: The MDOF bridge is designed in accordance with capacity design principles and also design criterion (i), such that the desired failure mechanism, as well as economical design are achieved. The response quantities of design interest (displacements, plastic hinge rotations, internal pier forces) are determined by combining the peak 'modal' responses (the N structural analyses), using an appropriate modal combination rule (e.g. SRSS or CQC), superimposed with the pertinent combinations of permanent and transient actions. To meet design criterion (i) the target-displacement profile and/or the pier cross section are revised and Steps 1 to 8 are repeated.

5 EVALUATION OF THE PROPOSED PROCEDURE IN THE CASE OF AN EXISTING BRIDGE

5.1 Description of studied bridge

To investigate the accuracy, efficiency, and also the practicality, of the proposed procedure it was deemed appropriate to apply it to an actual bridge structure, whose different pier heights and the unrestrained transverse displacement at the abutments result in an increased contribution of the second mode. The selected structure (known as the T7 Overpass), is quite common in modern motorway construction in Europe. The 3-span structure of total length equal to 99 m (see Figure 3), is located in northern Greece and is characterized by a significant longitudinal slope (approximately 7%). The deck consists of a 10 m wide prestressed concrete box girder section with a variable geometry across the longitudinal axis of the bridge (see Figure 3). The two piers have a cylindrical cross section, a common choice for bridges both in Europe and in other areas, while the pier heights are unequal (clear column height of 5.94 and 7.93 m), due to the deck's longitudinal inclination. The deck is monolithically connected to the two piers, while it rests on its abutments through elastomeric bearings; movement in both the longitudinal and the transverse direction is initially allowed at the abutments, but transverse displacements are restrained in the actual bridge whenever the 15 cm gap shown in Figure 3 is closed. In applying the proposed design procedure to this bridge, the gap size, as well as the characteristics of the bearings are treated as design parameters. The piers and the abutments are supported on surface foundations (footings) of similar configuration.

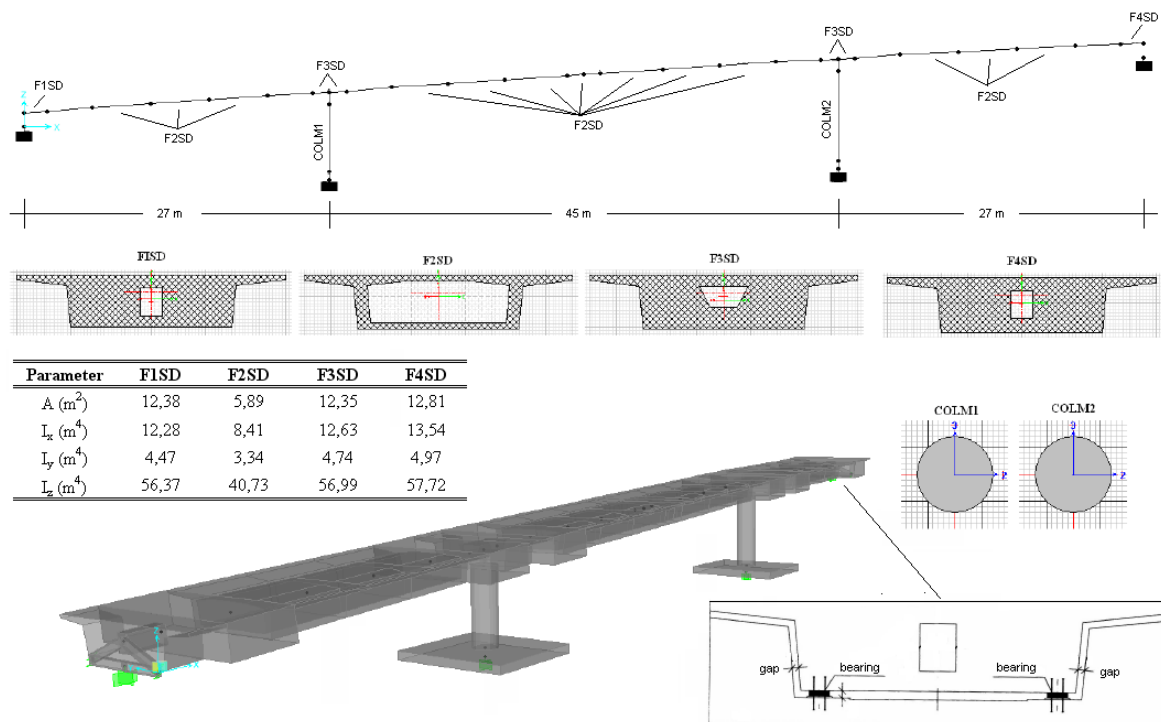

Figure 3: Layout of the bridge configuration and finite element modelling.

T7 Overpass was designed using DDBD, both in the form proposed by Dwairi and Kowalsky [10], and its modified version proposed herein, for two different seismic zones. The Greek Seismic Code (EAK2000) elastic spectrum [26] for Zone II (PGA of 0.24g) and III (PGA of 0.36g) was the basis for seismic design; it corresponded to soil conditions category 'B' of the Code, which can be deemed equivalent to subsoil class 'B' of older drafts of Eurocode 8-2 and

closer to 'C' in the final version of the Eurocode [27]. The bridge was designed as a ductile structure implying that plastic hinges are expected to form in the piers, while P- Δ effects were taken into consideration. A further parameter that was investigated in applying the DDBD was the effect of the girder's torsional stiffness.

In the analyses presented in the following, the focus is on the transverse response of the bridge, as it is well known (e.g. Reference [28]) that this is the response most affected by higher modes; additional analyses in the longitudinal direction were also conducted [29], however due to space limitations and the fact that longitudinal design was found to be less critical, these analyses are not presented herein. The analysis was carried out using the SAP2000 software [30]; the reference finite element model (Fig. 3) involved 32 non-prismatic 3D beam elements. Preliminary analyses accounting for soil-structure interaction (SSI) effects, using an appropriate foundation compliance matrix, have shown that due to the relatively stiff soil formations underneath the studied bridge, SSI had little effect on the response; hence these effects were subsequently ignored in the design (and assessment) of the bridge.

5.2 'Standard' direct displacement-based design (DDBD)

A 'standard' DDBD [9, 10, 11] was first performed, mainly to show the inefficacy of the procedure, which arises from its inherent restriction to structures wherein the fundamental mode dominates the response, as previously pointed out by Calvi & Kingsley [7]. In the case of T7 Overpass, the transverse response is determined by two dominant modes (see Figure 5). A 'damage control' limit state that corresponds to a drift ratio of 3%, was considered; qualitatively, 'damage control' implies that only repairable damage occurs in the columns. The design displacement spectrum was derived from the pertinent elastic acceleration response spectrum (see Figure 4), using the well-known equation $S_d(T) = S_a(T)/\omega^2$

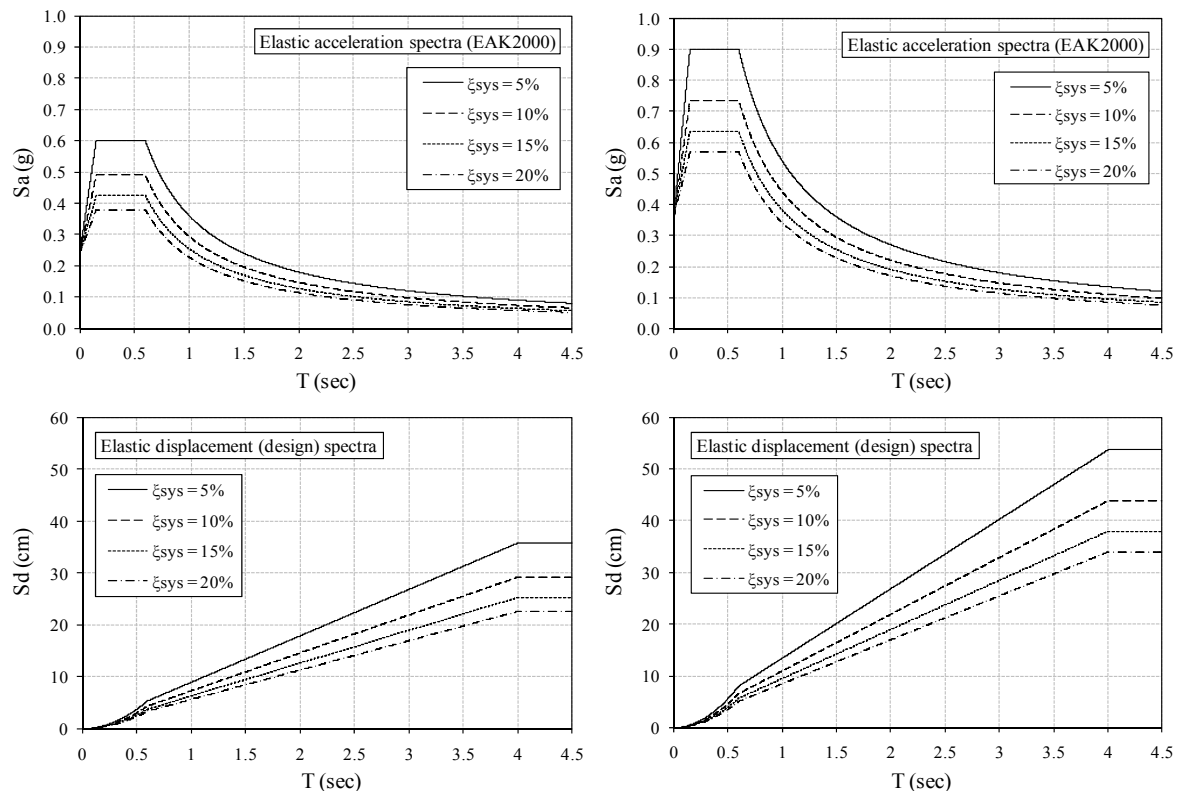

Figure 4: Elastic acceleration (according to EAK2000, Soil Type B) and displacement response spectra; left: Zone II (PGA=0.24g), right: Zone III (PGA=0.36g).

A significant modification was made to the spectrum used for design, i.e. the corner period in S_d was taken equal to 4.0 sec, according to SEAOC's [8] recommendations, which is substantially higher than the values of 2.5 and 2.0 specified by EAK2000 and EC8, respectively. This modification is not only in line with recent research findings, but also necessary for DDBD to be meaningful (short corner periods lead to small displacement values in the period range that is common to DDBD, which relies on secant stiffness values at the maximum displacement). Moreover, the modification to the elastic acceleration spectrum, required to account for ductile response through an increased effective damping ratio, was made using the damping modifier (η) adopted in the final version of EC8, i.e. Equation (22) below, where ξ_{sys} is the viscous damping ratio of the structure, expressed as a percentage.

$$\eta = \sqrt{10/(5 + \xi_{sys})} \quad (22)$$

As previously mentioned, the mechanical characteristics of the elastomeric bearings are a design parameter, hence an initial estimate is required. A rational choice of the elastomer (rubber) cross-sectional area can be made from the design for axial loading, while, regarding the transverse modes of the bridge (Figure 5), the total thickness (t_r) of the elastomer should provide the target-displacement profile with adequate displacements at the abutments, so that the 'damage-based' displacements (Δ_D) of each column, related to the acceptable drift ratio, could be attained, and a reasonable longitudinal reinforcement ratio could be obtained for the pier. The elastomeric bearings chosen herein are rectangular in shape (350 · 450 mm) with t_r of 88 mm, horizontal stiffness of 2506 kN/m and equivalent viscous damping ratio equal to 5%; two bearings are placed at each abutment, as shown in Figure 3. The maximum acceptable shear strain ratio (γ_u), from which the 'damage-based' displacements of the bearings are derived, is taken equal to 2.0. Introducing the 3% drift ratios for the columns, the 'damage-based' displacements of all members (piers or abutments) were calculated and are shown in Table 1; a diameter of 2.0 m was initially assumed for the two columns.

Damage-based displacements				
Member	Abt ₁	Col ₁	Col ₂	Abt ₂
Δ_D (m)	0.176	0.218	0.278	0.176

Table 1: 'Damage-based' displacements related to the 'damage control' limit state.

In order to obtain the target-displacement profile for the inelastic system, the EMS method was utilised. It was assumed that the superstructure will respond essentially elastically, as far as its flexural stiffness is concerned, while its torsional stiffness was set equal to 20% of the uncracked section torsional stiffness [17]. A secant flexural stiffness equal to 10% the gross value was applied to the columns (both of them are expected to deform inelastically), while the reduction in the effective axial and shear stiffness was considered to be proportional to the reduction in flexural stiffness. Figure 5 illustrates the target-displacement profile derived from applying the EMS repeatedly until convergence was achieved (four iterations were needed in total); displacement patterns, peak modal displacements and modal mass participation factors for each mode are also shown. Convergence was checked with regard to stabilization of the target-displacement profile or the column secant stiffness from one iteration to the next. Discrete dots on the graphs represent the points of the deck's axis passing from its mass centroid, corresponding to the centres of elastomeric bearings and columns.

Figure 5: Displacement profile: Peak modal displacements u_{ij} , displacement pattern δ_i and target-displacement profiles Δ_i , estimated iteratively from EMS method.

The next step of the 'standard' DDBD method involves structural analysis of the bridge under the inertia loads given by Equation (21), (where, in the 'standard' procedure U_{ij} corresponds to Δ_i), to obtain the design base shear of each column. In Figure 6 the displacement profile derived from structural analysis Δ_i (SA1), is compared with the target-displacement profile Δ_i (EMS4). The discrepancy between the two profiles reveals one of the main deficiencies of the standard DDBD, i.e. its inability to predict the peak structural response (in terms of displacements and hence internal member forces), on the basis of which design will be carried out.

Figure 6: Structural analysis displacement profile (SA1) compared with target-displacement profile (base shear distribution (F_i) as inertia forces to the masses of the MDOF structure is also illustrated).

The target-displacement profile, which generally reflects the ultimate limit state (in terms of displacements) of the structural members, was constructed from the combination of the peak modal displacements (according to the SRSS rule), and then scaled in such a way that none of the member displacements exceeds the 'damage-based' design values. By following this procedure, the target-displacement profile never reflects an actual deformed shape of the structure; instead, it represents a fictitious deformed shape comprised of non-simultaneous displacements, which is deemed to reflect the peak (and non-simultaneous) structural member response. Therefore, in cases (like here) where more than one mode dominates the response, a static structural analysis under a modal combination of seismic lateral forces such as those

given by Equation (21) (whose distribution is also shown in Figure 6), cannot, under any circumstances, produce the target-displacement profile.

A final remark regarding the above, is that the above discrepancy in the displacement profiles is due neither to errors in the estimation of the equivalent cantilever heights nor to the approximate base shear distribution according to Equation (19). In fact, additional iterative structural analyses wherein secant stiffnesses are modified, as required by the DDBD, in this case can only lead to convergence in terms of one critical member displacement (the first member that reaches its limit state) rather than in terms of the entire target-displacement profile, which is determined from the contribution of all significant modes.

5.3 Modal direct displacement-based design (MDDBD)

The proposed extended DDBD procedure was applied to the T7 Overpass as follows.

Step 0: As in the 'standard' DDBD, a 2.0 m column diameter was assumed as a starting point. However, seismic design for Zone II resulted in column longitudinal reinforcement ratios less than the minimum required by E39 [18] and other codes. Due to the fact that providing the minimum required ratio, would obscure the concepts of DDBD (regarding the target profile, displacement ductilities etc.) and aiming at an optimum design (see design criterion i), a 1.5 m column diameter was subsequently used. Preliminary structural analyses were performed for each of the three equivalent SDOF systems (N+1, considering the first 2 modes), under lateral loads compatible with the modal profiles and their SRSS combination, to obtain the equivalent cantilever heights and the uncracked stiffnesses ($K_{g,i}$), according to Equation (1). The assumed characteristics of the elastomeric bearings, the design spectrum and the 'damage-based' displacements were determined as in the standard DDBD.

Steps 2 to 6: The previously described EMS methodology was applied. In order to establish the initial displacement profiles, a modal analysis was conducted where member stiffnesses were set as in the standard DDBD. The peak modal displacements ($u_{i,j}$), the displacement pattern (δ_i), the target-displacement profile (Δ_i) and the modal target displacements profiles ($U_{i,j}$) were determined by Equations (4 to 7) respectively, and presented herein in Figure 7, and it is clear that the abutments are the critical elements. The three equivalent SDOF systems were defined in accordance with Equations (9) and (10).

Once the target-displacement profiles were established, the individual member ductility values (Equations (11)) were calculated along with the corresponding equivalent viscous damping values (Equation (13)), where elastomeric bearings were assumed to respond elastically ($\xi_{Abt}=5\%$). Assuming that 30% of the total shear is carried by the abutments (in all 3 cases), the equivalent system damping values were obtained from Equations (14) and (16) for the first iteration and Equation (15) thereafter. The effective periods at maximum response were then obtained from Figure 4. This was then followed by the calculation of secant stiffnesses at maximum response (Equation (17)). Design base shears were calculated from Equation (18) and member shear forces from Equation (19). It is noted, that in the case of modal target-displacements with different signs, Equation (23) was used in lieu of (19).

$$V_{B,j} - F_{Abt,j} = V_{B,lj} + V_{B,lj}, \quad V_{B,lj} / V_{B,2j} = - \left(\frac{\mu_{\Delta,lj}}{h_{eq,lj}} / \frac{\mu_{\Delta,2j}}{h_{eq,2j}} \right) \quad (23)$$

As soon as base shears for the SDOF systems are defined, the fraction of the shear carried by the abutments can be recalculated using the following equation

$$x_{Abt}(\%) = F_{Abt}/V_B = \sum F_{Abt,i}/V_B = \sum (2k_h \Delta_{Abt,i})/V_B$$

$$x_{Abt,j}(\%) = F_{Abt,j}/V_{B,j} = \sum F_{Abt,ij}/V_{B,j} = \sum (2k_h \Delta_{Abt,i})/V_{B,j}$$
(24)

In Equation (24), k_h represents the bearing's horizontal stiffness (for one bearing). If the revised fractions differ significantly from the assumed values (30%), Steps 4 and 5 are repeated until fractions of x_{Abt} stabilize. It is clear than in the case of seat-type abutments with bearings the design is simplified on the grounds that the shear carried by the abutment is known from the first iteration. The column secant stiffness values can be recalculated at this point since column forces and member displacements are now known (Equation (20)). This is then followed by a revised modal analysis with the new secant stiffness properties resulting into new target-displacement profiles (Δ_i , U_{ij}). In total, four iterations were needed until Δ_i stabilized. The finally derived (from all iterations) profiles are illustrated in Figure 7. It is evident (from Iterations 3 and 4), that whenever Δ_i stabilizes, U_{ij} also stabilize.

Step 7: Once the target-displacement profile (Δ_i) stabilized, two structural analyses of the MDOF structure were performed under the inertia forces of Equation (19), utilizing the secant stiffnesses ($k_{eff,ij}$) from the 4th Iteration. Due to the inconsistency of the derived displacements ($U_{an,ij}$) with the corresponding modal target-displacements (U_{ij}), the two analyses were repeated with revised secant stiffnesses until convergence was achieved. Since the final secant stiffnesses of columns differed significantly from the assumed ones, Steps 1 to 7 were repeated, so long as new equivalent cantilever heights and column shear distribution were defined from the results of the structural analyses.

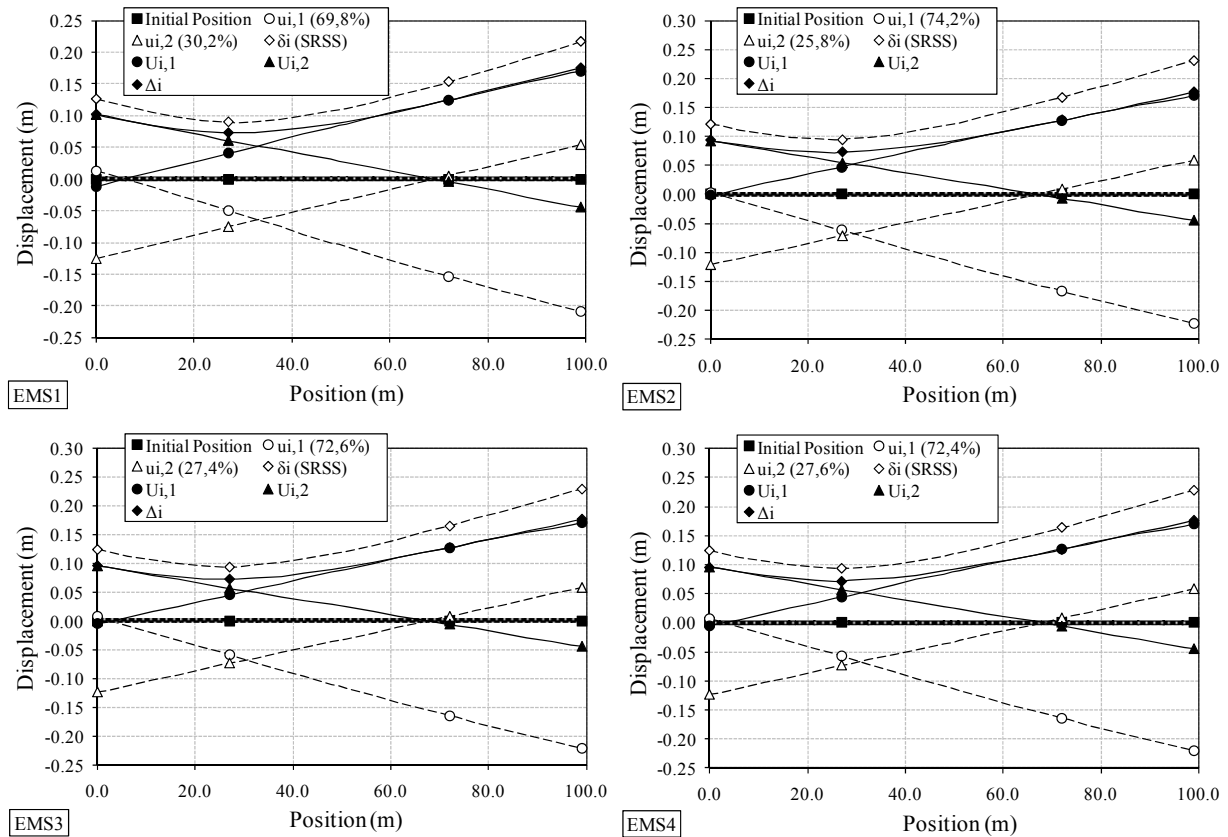

Figure 7: Displacement profiles: Peak modal displacements $u_{i,j}$, displacement pattern δ_i , modal target-displacement profiles $U_{i,j}$ and target-displacement profiles Δ_i , successively derived from EMS.

The new loop of iterations attempts to reduce the discrepancy resulting from the equivalent cantilever height updating (which does not change much the initially assumed value), and the shear distribution effect according to Equation (19), but not the fraction of the shear carried by the abutments, since this is considered known, as already discussed. The results from the final iterations are summarised in Figure 9(a) in the next section, where the target-displacements profiles (Δ_i) and the profiles derived from structural analysis ($\Delta_{i,an}$) are shown. It is noted that $\Delta_{i,an}$ is derived from the SRSS combination of $U_{ij,an}$.

Step 8: The response quantities of design interest (rotations, pier forces) are determined by combining the peak 'modal' responses (from the two structural analyses), using the SRSS combination rule, superimposed with the pertinent combinations of permanent and transient actions. P- Δ effects were also taken into account, and it is verified that the stability index satisfied $\theta_A \leq 0.20$. Finally, the design procedure yielded a longitudinal steel ratio of 9.8‰ and 12.4‰ for Col₁ and Col₂, respectively. The ratio of Col₁ is just slightly less than the minimum required ratio (1%), according to E39 and the Eurocode.

The whole procedure was repeated for the case of Zone III, (PGA of 0.36g), in which case a 2.0 m column diameter was selected. The target-displacements profiles (Δ_i) and the profiles derived from structural analysis ($\Delta_{i,an}$) are shown in Figure 9(b). In this case the design procedure yielded a longitudinal steel ratio of 11.5‰ and 19.0‰ for Col₁ and Col₂, respectively.

Furthermore, the effect of the girder's torsional stiffness throughout the suggested methodology was investigated. The design procedure was repeated assuming zero deck torsional stiffness, which results to cantilever action of the columns (see Figure 1(a)), and using a simplified stick model of the deck, supported on elastic translational spring elements, representing the abutments and the piers. It is clear, that such an approach simplifies the design procedure, since iterations with respect to the equivalent cantilever heights are no longer required. In Figure 8, the derived target-displacement profile (Δ_i) is compared with the corresponding profile of the previous (general) case, where deck torsional stiffness was set equal to 20% of the uncracked value. Despite the slight discrepancy in column displacements (ascribed to the different participation factors of the first two modes), the simplified design procedure yielded a longitudinal steel ratio of 42.2‰ and 62.3‰ for Col₁ and Col₂, respectively, attributed mainly to the increased required ratios of the secant-to-uncracked column stiffnesses ($K_{eff,i}/K_{g,i}$) (resulting from the significant reduction of $K_{g,i}$). It is seen that despite the fact that a zero torsional stiffness assumption simplifies the design procedure, it also overestimates the required longitudinal steel ratios and leads to uneconomical design.

Figure 8. Target-displacement profile (Δ_i) in the case of finite and zero deck's torsional stiffness (GI_r), (Zone II, $D = 1.5$ m, in both cases).

5.4 Assessment of MDDBD by NLRHA

The proposed DDBD procedure was assessed using nonlinear response-history analysis (NLRHA) for artificial records closely matching the design spectrum. The artificial records were generated with the computer program SIMQKE [31], while nonlinear analyses were carried out using the SAP2000 software [30]; appropriate nonlinear links were introduced in the finite element model (Figure 3) for response-history analysis, in line with the well-known lumped plasticity approach. The assessment focussed mainly on the target-displacement profiles and on design quantities such as yield displacements, displacement ductilities, stiffnesses, and magnitude of forces developed in critical members of the bridge.

Since the primary objective of the assessment was the study of the transverse bridge response under a seismic excitation which matches as closely as feasible the 'design excitation' (i.e. the design spectrum), one set of NLRHAs was performed for each case (Zone II, III), using artificial records compatible with the design spectra (Figure 4). The set consisted of seven artificial records that fitted the linear design S_a spectra of Figure 4. The Hilber et al. $\alpha = -0.1$ integration method was selected in SAP2000 [28], which utilises lumped plasticity elements (NLLinks) with rotational spring. Herein, the Takeda degrading-stiffness model [22], also assumed for design (to estimate ξ_i), was adopted. Moment-rotation (M- θ) relationships, assigned to NLLinks used in the finite elements models, were defined from moment-curvature analyses performed for each pier section, utilizing the computer program RCCOLA-90 [32].

Figure 9: Nonlinear response history maximum displacements: (a) Zone II (PGA=0.24g), (b) Zone III (PGA=0.36g), compared with target-displacements profiles (Δ_i) and displacement profiles obtained from structural analyses (Δ_{ani}) of Modal DDBD.

In Figure 9 the target-displacement profiles and the displacement profiles obtained from structural analyses within the MDDBD procedure are compared with the displacement envelopes from NLRHA; it is noted that the deck displacements shown in the figures as the NLRHA case are the average of the maximum displacements recorded in the structure during the seven RHAs of each set. It is observed that the target-displacement profiles derived from MDDBD tend to match that obtained from NLRHA, more so in the case of Zone II. The main difference between MDDBD and NLRHA is noted towards the abutments of the bridge (critical members of design), with differences diminishing in the area of the piers. These differences may be attributed to a higher mode contribution (modes not taken into account in the MDDBD) and/or to the contribution of the first two modes with different participation factors than those obtained from the EMS method. However, the displacement demand in the critical member (the one that governs the design – herein Abutment 2) obtained from NLRHA, never

exceeds the design displacement, indicating a safe design. A minor exceedance was only observed in the case of Col₁ (see also Figure 10).

Similar conclusions are drawn with respect to the other design quantities; yield displacements, displacement ductilities, bearing shear strain and column drift ratios obtained from NLRHAs were compared with those estimated at the design stage. Figure 10 (supplemented by Table 2) illustrates the correlation in the above quantities, in the case of Zone II. Again, curves shown in the figures as the NLRHA case are the average of the quantities recorded in the structure during the seven RHAs (either at the time step each member enters the inelastic range or at the time step of maximum response), whereas curves shown as MDDBD were computed from the results of structural analyses. It is clear that MDDBD predicts very well, (i.e. matches closely the values from the NLRHA approach), the quantities related to member yielding, which implies the effectiveness of the equivalent cantilever approach in capturing the degree of fixity at the top of the piers, despite the fact that during the design procedure the equivalent cantilever heights are computed according to moment diagrams at maximum response (and not the response at the time of yielding). Finally, difference in member shear force at maximum response is mainly attributed to the consideration of strain hardening in $M-\theta$ relationships used in the assessment, whereas MDDBD assumes zero post-elastic slope of the member force-displacement response. In conclusion, the overall agreement between MDDBD and NLRHA is deemed satisfactory.

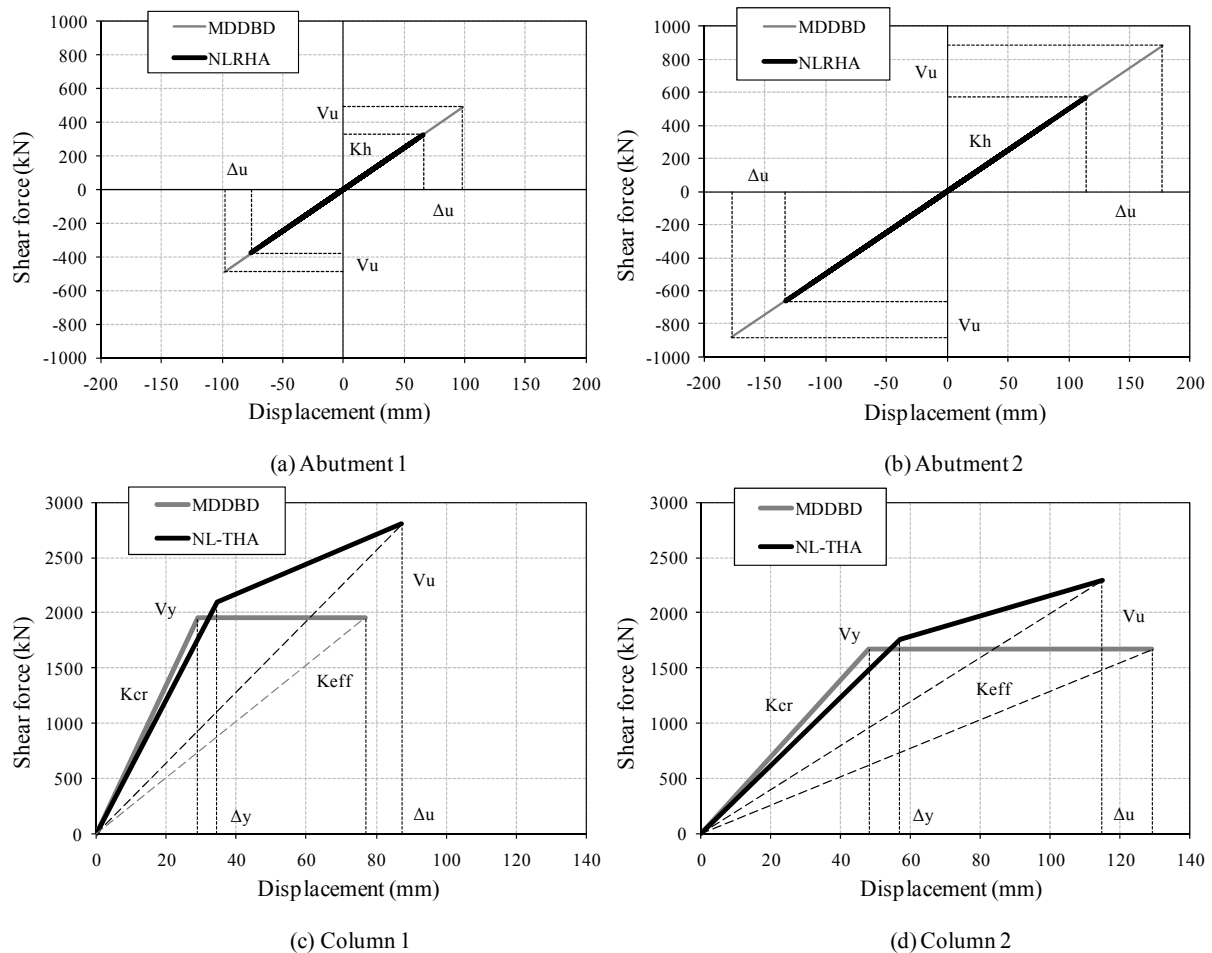

Figure 10: Member shear force-displacement curves derived from modal direct displacement-based design (MDDBD) and nonlinear response history analyses (NLRHA) in the case of artificial records and Zone II (PGA=0.24g).

Member	Abutment 1		Abutment 2		Column 1		Column 2

6 CONCLUSIONS

An existing displacement-based methodology (DDBD) was extended here to account for higher mode effects in the case of bridges. Its feasibility and accuracy were evaluated by applying it to an actual bridge wherein the first two modes dominate the transverse response. The key issue in this extension was the proper definition of N+1 target-displacement profiles and equal in number equivalent SDOF structures for performing the EMS and estimating the peak 'modal' earthquake forces; the peak 'modal' response was then obtained by conducting N structural analyses, (as many as the significant modes), on the MDOF. Additional issues addressed included the columns' degree of fixity, introducing the concept of the equivalent cantilever heights, and the base shear distribution according to the results of structural analysis. The significance of a rational consideration of the superstructure torsional stiffness throughout the design procedure was also underlined.

By applying DDBD and MDDBD, as well as NLRHA, to the aforementioned bridge, it was concluded that:

- The DDBD method failed to reproduce, through the structural analysis, the target-displacement profile (Δ_i), which was anticipated given the fact that the latter represents a fictitious profile consisting from non-synchronous displacements, and eventually reflects the peak (and non-synchronous) structural member response. On the contrary, MDDBD is intrinsically capable of meeting this goal, by producing the target-displacement-profile (Δ_i) and hence the peak structural response.
- The MDDBD provided also a good estimate of results regarding not only the displacement profile but also additional design quantities such as yield displacements, displacement ductilities, values of stiffness and magnitude of member forces, closely matching the results of the more rigorous NLRHA, and indicating at the same time the validity of the equivalent cantilever concept.
- Investigation concerning the effect of the girder's torsional stiffness throughout the suggested methodology revealed the significance of a properly selected value according to the current bridge design philosophy. In contrast, the simplified design procedure, based on the assumption of a simple cantilever column behaviour under lateral earthquake forces, resulted in significantly overestimated longitudinal steel ratios.
- On the basis of the results obtained for the studied bridge, MDDBD can be further simplified, as far as the required iterations in the EMS methodology (Steps 2 to 6) are con-

cerned. Given that whenever the target-displacement profile Δ_i stabilized, the modal target-displacement profiles U_{ij} also stabilized, Δ_i (and hence the characteristics of the corresponding SDOF) should be used as the sole convergence criterion during Steps 2 to 6. U_{ij} and hence the remaining SDOFs should be used only in the last iteration (i.e. during the 4th iteration of Figure 7, instead of the 1st, 2nd, 3rd and 4th) in order to define the peak 'modal' earthquake forces (base shears of Equation (18)). This simplification reduces the amount of required calculations.

- More work is clearly required, to further investigate the effectiveness of MDDBD by applying it to bridge structures with higher mode contribution (even more significant than in the bridge studied here), since MDDBD is expected to be even more valuable for the proper estimation of the actual inelastic response and hence for the efficient design of bridges with significant higher modes. Further investigation is also required in the case of different abutment type configuration (i.e. superstructure's transverse displacement restrained at the abutments through seismic links – activation of the abutment-backfill system), where the shear carried by the abutment is not known during the design procedure.
- The MDDBD method proposed herein, as a rule requires a substantial number of iterations; therefore an implementation of the proposed procedure in a software package would significantly increase its usefulness in practical design.

Abstract. *The definition of appropriate modelling approaches combined with a consistent software framework is a topic of major importance in the present days for structural engineering in general and, particularly, for earthquake engineering. The accuracy of the results obtained in the recent “Concrete Column Blind Prediction Contest 2010” for a full-scale reinforced concrete bridge column tested on the NEES Large High-Performance Outdoor Shake Table, seems to indicate that current modelling strategies are on the right track. The 1.2 m diameter cantilevered column spans 7.2 m from the footing. A massive 230 tonne reinforced concrete block supported by the column generates the inertial forces to mobilize the column capacity. Seismic performance was investigated under 6 ground motions, starting with low-intensity shaking and bringing the column progressively to near-collapse conditions. Based on the obtained results from the pre-contest simulation, as well with the post-contest analysis, it was possible to extract some important conclusions regarding the application of several strategies, namely the use of different type elements, element discretization, constitutive laws for materials.*

1 INTRODUCTION

In 2010 a blind prediction contest was announced and sponsored by PEER and NEES. The aim of the contest was to predict failure mode and several response quantities for a full-scale reinforced concrete bridge column. The specimen, subjected to six uniaxial earthquake ground motions, was tested in September 2010 on the NEES Large High-Performance Outdoor Shake Table located at UCSD's Englekirk Structural Engineering Center, starting with low-intensity shaking and bringing the column progressively to near-collapse conditions.

In order to prepare the analytical model, the organizing committee provided all the relevant input data, such as construction details, material properties and base excitation records. Based on the obtained informations, the FE model of the bridge column was prepared using a fiber-based Finite Elements computer program. Several modelling strategies (e.g. different type elements, element discretization, constitutive laws for materials, damping, etc.) were studied in order to obtain the best representation of the real structure. A nonlinear dynamic time-history analysis was performed for predicting the failure mode of the structure. Because the actual loadings were determined during the course of the testing, after the pre-test the organizing committee provided each participant with the registered records. The analytical model was thus updated and another nonlinear dynamic time-history analysis was carried out considering the actual loading.

The analytical results, in terms of displacements at the top of the column and base shear, were compared with experimental ones to assess the nonlinear response prediction capabilities of the adopted modelling strategy.

2 DESCRIPTION OF THE SPECIMEN

The test specimen is a full-scale RC bridge column (see Figure 1) [1] which details are consistent with current Caltrans design practice. The 1.2 m diameter cantilevered column spans 7.2 m from the footing, as shown in Figure 2. A massive 230 tonne reinforced concrete block supported by the column generates the inertial forces to mobilize the column capacity.

Figure 1: Full-scale reinforced concrete bridge column tested on the NEES Large High-Performance Outdoor Shake Table at UCSD's Englekirk Structural Engineering Center [1].

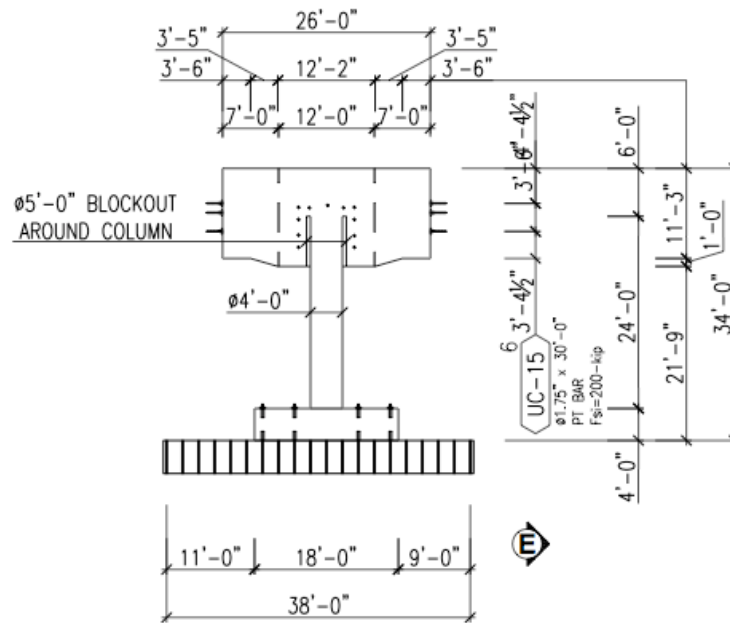

Figure 2: RC bridge column specimen configuration [1].

The concrete used for the construction of the column was normal-weight with a cylinder compressive strength of 41500 kPa.

The reinforcement of the column consisted of eighteen No. 11 continuous bars (see Figure 3), as longitudinal reinforcement and butt-welded No. 5 double hoops, spaced at 152-mm on-center (see Figure 3), as transverse reinforcement. The steel was A706 grade 60 for both longitudinal and transverse reinforcement.

Figure 3: Reinforcement details for the RC bridge column [1].

3 FINITE ELEMENTS MODELLING OF THE RC BRIDGE COLUMN

3.1 Selection of the Finite Elements computer program

The software employed in this work for modelling the behavior of the RC bridge column is SeismoStruct [2], a fiber-based Finite Elements computer program for seismic analysis of framed structures, which is freely downloadable from the Internet. The program is capable of predicting the dynamic behavior of any framed type of structural configuration, accounting both for geometric nonlinearities and material inelasticity.

In the following paragraphs, a description of the constitutive laws for materials, type elements and element discretization is given.

3.2 Section and materials

In the model, the column cross-section was defined through a 1.22 m diameter reinforced concrete circular section with a concrete cover of 0.06667 m and the longitudinal reinforcement which reproduces the layout of the test specimen, as shown in Figure 3.

The stress-strain behavior of the reinforcing steel (see Figure 4(left)) was described by the nonlinear model of Menegotto and Pinto [3], as modified by Filippou *et al.* [4] including isotropic strain hardening effects.

The constitutive law employed for defining the concrete material is a nonlinear constant confinement concrete model that follows the relationship proposed by Mander *et al.* [5], later modified by Martinez-Rueda and Elnashai [6] for numerical stability reasons under large displacements/deformations (see Figure 4(right)). This is a uniaxial model in which a constant confining pressure is assumed through the entire stress-strain range.

Figure 4: Menegotto-Pinto steel model, with Filippou isotropic hardening (left) and nonlinear constant confinement concrete model (with $k_c = 1.2$) (right).

Some mechanical characteristics of the materials, such as yield strength, ultimate stress and strain for the steel, cylinder compressive strength and strain at peak stress for the concrete, were provided by the organizing committee. The other model parameters were calibrated and set as shown in Table 1 and 2.

Parameter	Steel
Modulus of elasticity (kPa)	2.00E+008
Yield strength (kPa)	518500
Strain hardening parameter	0.008
Transition curve initial shape parameter (default value)	20
1 st transition curve shape coefficient (default value)	18.5
2 nd transition curve shape coefficient (default value)	0.15
1 st isotropic hardening coefficient	0
2 nd isotropic hardening coefficient	1
Specific weight (kN/m ³)	77

Table 1: Parameters for Menegotto-Pinto steel model.

Parameter	Concrete (conf)	Concrete (unconf)
Cylinder compressive strength (kPa)	41500	41500
Tensile strength (kPa)	0	0
Strain at unconfined peak stress (m/m)	0.0028	0.0028
Constant confinement factor	1.2	1
Specific weight (kN/m ³)	23.6	23.6

Table 2: Parameters for the nonlinear constant confinement concrete model.

The tensile strength of the concrete was ignored for the numerical stability of the analysis.

3.3 Element type and discretization

Two different FE formulations can be selected within the software for implementing distributed inelasticity frame elements, the classical displacement-based (DB) formulation (e.g. Hellesland and Scordelis [7], Mari and Scordelis [8]) and the more recent force-based formulation (e.g. Spacone *et al.* [9], Neuenhofer and Filippou [10]).

In the present study, a 3D inelastic beam-column element with displacement-based (DB) formulation and capable of capturing both geometric and material nonlinearities was selected for modelling the cantilevered column. The number of fibers used in section equilibrium computations was set to 300, in order to guarantee an adequate reproduction of the stress-strain distribution across the element cross-section, considering the shape and material characteristics of the latter and the degree of material inelasticity that is likely to be reached.

The structural member was appropriately subdivided into eight elements of different length (see Figure 5), in order to accept the assumption of a linear curvature field inside each of the sub-domains.

3.4 Applied mass and boundary conditions

In order to perform the nonlinear dynamic time-history analysis required for the blind prediction, it was necessary to define the mass elements. The mass of the column was automatically computed by the program knowing the material's self weights, while the additional mass coming from the reinforced concrete block supported by the column, was applied in a lumped fashion at the top node (see Figure 5). The applied values are summarized in Table 3.

Lumped mass	Concrete block
Translational mass (tonne)	228
Rotational mass (tonne \times m ²)	885

Table 3: Computed masses.

Modelling of the footing under the column was ignored; hence the column base node was considered as fully restrained against rotations and translations (see Figure 5).

Figure 5: Bridge column FE model with finite element discretization.

3.5 Applied dynamic loading

For post-test response prediction, the actual ground motions were applied as dynamic loading. Time history analysis was carried out for a single input record consisting of an assemblage of the six accelerograms provided by the organizing committee. Ten seconds of delay were left between one motion and the one immediately after (see Figure 6) in order to damp out the structure motion.

Figure 6: Actual acceleration records.

The time step for the dynamic analysis was set as 0.00390625 s, coincident with the input record sampling time step.

3.6 Damping, Integration Algorithm and Convergence Criterion

In addition to the hysteretic damping, which was implicitly accounted for by the cyclic material relationships, a small amount of non-hysteretic equivalent viscous damping (1%) was also introduced in order to improve the numerical stability of the dynamic nonlinear analyses. A tangent stiffness-proportional viscous damping model was employed, as suggested by Priestley and Grant [11] and Hall [12].

Regarding the numerical integration scheme, the Hilber-Hughes-Taylor algorithm (Hilber *et al.* [13]), with an alpha coefficient equal to -0.1, was adopted.

Finally, the displacement/rotation based scheme was selected as convergence criterion.

4 COMPARISON BETWEEN NUMERICAL AND EXPERIMENTAL RESULTS

After the submission of the post-test analytical results, the organizing committee provided all the responses of the column, in terms of maximum/minimum values and time histories, for each ground motion.

The experimental time histories of column top displacement and base shear were compared with the numerical ones; they are presented in the following figures. It is observed that the numerical predictions matched relatively well the experimental results. In particular, there is a good agreement between both the amplitude and the frequency content of the response when the column is subjected to earthquake 1, 3, 5 and 6 (see Figures 7, 8, 9 and 10, respectively).

Figure 7: Top displacements (left) and base shear during earthquake 1

Figure 8: Top displacements (left) and base shear during earthquake 3

Figure 9: Top displacements (left) and base shear during earthquake 5

Figure 10: Top displacements (left) and base shear during earthquake 6

5 CONCLUSIONS

This work described the blind prediction of the dynamic response of a full-scale RC bridge column tested on the NEES Large High-Performance Outdoor Shake Table located at UCSD's Englekirk Structural Engineering Center. The results show that the definition of appropriate modelling approaches combined with a consistent software framework led to a relatively accurate prediction of the global nonlinear dynamic response of the column.

GENERALIZED FRAGILITY CURVES FOR BEARING-SUPPORTED SKEW BRIDGES, FOR ARBITRARY ANGLE OF INCIDENCE OF THE SEISMIC ACTION

Ioannis F. Moschonas¹, Andreas J. Kappos¹

Keywords: Bridges, Vulnerability assessment, Fragility curves, Pushover analysis, Damage states, Angle of Incidence.

Abstract. *In a previous work by the authors and their co-workers an analytical methodology for the derivation of seismic fragility curves for bridges was proposed. Bridges were classified into three main categories according to their seismic energy dissipation mechanism: bridges with yielding piers of the column type, bridges with bearings and non-yielding piers of the wall type, and bridges with bearings and yielding piers of the column type. Then, damage states were defined using deck displacement at characteristic points of ‘typical’ bridge pushover curves, which are related to the seismic energy dissipation mechanism, consistently with the proposed classification scheme. Only one horizontal component of the seismic action was considered to act along the principal directions of the bridge. This methodology was subsequently extended by the authors to take into account the angle of incidence of the seismic action, considering only the single-component case. In the present work the methodology is further extended to the general case wherein the minor principal horizontal component of the earthquake is also taken into account (dual-component seismic action). Furthermore, damage states for bridges with bearings are redefined in a broader manner, to take into account biaxial shear effects, and all possible failure mechanisms of the bearings. The methodology is applied here to a skew bridge, subjected to either single- or dual-component seismic action. The main difference between straight and skew bridges is that the modal principal bridge directions are rotated with respect to the geometric principal bridge directions, for a specific angle of incidence. The proposed methodology is formulated in terms of modal principal directions. The CQC rule is used for the combination of the projections of the control point displacement and of the base shear in the single-component case, while in the dual-component case the SRSS rule is used and it is found adequate for all excitation angles. From the derived generalized fragility curves it is concluded that when the minor principal horizontal component of the earthquake is taken into account, bridge fragility is significantly increased, while it remains practically unaffected by the angle of incidence.*

1 INTRODUCTION

Various analytical methodologies proposed in the past for the vulnerability/fragility assessment of bridges in Europe [8], the US [6, 9, 10, 13], and Japan [4], address only one horizontal component of the seismic action (single-component seismic action) acting along the longitudinal or transverse direction of the bridge. Hence, an issue that has to be addressed is the assessment of bridge vulnerability/fragility in the general case where the seismic excitation acts at an arbitrary angle. The first attempt in this direction was made by Shinozuka et al. [12] who proposed an analytical methodology based on dynamic inelastic analysis for single-component seismic action. Damage states were defined only for bridges with inelastic piers, in terms of displacement ductility of pier critical sections.

Recently the authors have developed a methodology for the derivation of fragility curves for arbitrary angle of incidence of the seismic action [7] extending their previously proposed methodology [8], which is based on static nonlinear (pushover) analysis. At first, static nonlinear analysis was extended to take into account the angle of incidence of the seismic action; it is noted that on this topic only two previous attempts have been made in [14] and [15], both of them focusing on the estimation of the critical angle of incidence of the seismic action, rather than on the derivation of pushover curves. Two methodologies were proposed for deriving pushover curves for arbitrary angle of incidence of the single-component seismic action. According to the first one, an effective mode shape is determined in the direction of the seismic action, while according to the second one the response along the principal bridge directions is combined in order to derive the response in the direction of the earthquake. The two methods were both applied to a symmetric overpass bridge and the results were evaluated against those from nonlinear response-history analysis (NLRHA). It was concluded that the first method is valid only in the period range where the equal displacement approximation is valid, while the second one is valid for all periods. Besides the extension of static nonlinear analysis, damage state definitions were also extended to take into account the effect of the angle of incidence of the seismic action.

In the work presented herein, the methodology for the derivation of static pushover curves and fragility curves for arbitrary angle of incidence of the seismic action is extended to account for dual-component seismic action. Static nonlinear analysis for arbitrary angle of incidence is carried out using the second of the previously proposed methods [7], due to its broader range of application; the method is further extended to account for biaxial bending effects in critical pier sections and for biaxial shear effects in the bearings. Regarding damage state definitions, in particular for bearing-supported bridges, damage states are defined taking into account the biaxial deformation of the bearings. Furthermore, the last damage state is defined on the basis of the ultimate shear deformation, as it is derived considering all possible failure mechanisms of the bearings. Finally, the proposed methodology is applied to a skew bearing-supported bridge and conclusions are drawn regarding the effect of dual-component action and of angle of incidence.

2 METHODOLOGY FOR THE DERIVATION OF FRAGILITY CURVES

2.1 Modelling of the seismic action

The earthquake ground motion is analyzed into three principal components E_I , E_{II} and E_{III} linearly independent (or statistically linearly uncorrelated) directed along a set of principal axes $O-I-II-III$. Components E_I and E_{II} are the horizontal ones, with the first one having the maximum intensity (E_I = major horizontal component, E_{II} = minor or secondary horizontal component).

The simpler approach is to consider only the major horizontal earthquake component (single-component seismic action) acting at an angle α with respect to the bridge longitudinal axis (Fig. 1). Thus, the axis system $O-I-II-III$ is considered identical with system $O\xi\eta\zeta$ which is rotated by an angle α with respect to the bridge axes $Oxyz$. Thus, the major earthquake component E_I acts along $O\xi$ axis and for this reason it will be referred to as E_ξ .

The proposed methodology for deriving pushover curves for arbitrary angle of incidence of the seismic action described in the following paragraphs is based on the combination of longitudinal and transverse responses. Therefore, it is more convenient to analyse the major earthquake component into two components $E_x=E_{\xi}\cos\alpha$ and $E_y=E_{\eta}\sin\alpha$ (Fig. 1) acting along the longitudinal and transverse direction, respectively. Components E_x and E_y have identical time-histories (accelerograms), thus they are linearly dependent or statistically linearly fully correlated.

Figure 1: Single-component seismic action acting at an arbitrary angle of incidence.

Figure 2: Dual-component seismic action acting at an arbitrary angle of incidence.

In the general case the minor horizontal earthquake component, $E_{II} \equiv E_{\eta}$, is also considered (dual-component seismic action) (Fig. 2) and it is normal to the major horizontal component E_I , which acts at angle α with respect to the longitudinal bridge axis X (i.e. the minor component acts at an angle α with respect to the Y-axis). The components acting along the longitudinal and the transverse bridge directions are $E_x = E_{\xi} \cos \alpha - E_{\eta} \sin \alpha$ and $E_y = E_{\xi} \sin \alpha + E_{\eta} \cos \alpha$. These components are a linear combination of E_{ξ} and E_{η} , thus they are linearly dependent or statistically linearly correlated. For excitation angles 0° , 90° , 180° and 270° components E_x and E_y become identical with the principal horizontal components $E_I \equiv E_{\xi}$ and $E_{II} \equiv E_{\eta}$, thus they have quite different time-histories, i.e. they are linearly independent or statistically linearly uncorrelated.

Only natural earthquake records can be analyzed into principal components. Hence, in the case where a code-type response spectrum, or spectrum-compatible artificial accelerograms are utilized, a proper value for their intensity ratio is required; based on the available literature [5] a value of 0.70 can be reasonably adopted.

2.2 Derivation of pushover curves

Having modelled the seismic action appropriately, i.e. analyzing it into the components acting along the longitudinal and transverse directions, the next step for the derivation of pushover curves for arbitrary angle of incidence of the seismic action is to take into account the interaction between biaxial bending moments and axial force (PMM interaction) at critical pier sections and/or the interaction between biaxial shear forces and axial force (PFF interaction) in the bearings.

In the first step of the method, the bridge is analyzed for a low earthquake intensity level (e.g. 0.1g) for which the response along both principal bridge directions remains within the elastic range. Then, the displacements of the selected control point along the longitudinal and transverse bridge directions, $u_{L,el}$ and $u_{T,el}$, are calculated using elastic response spectra, and from them the corresponding rotations ($\theta_{x,el}$ and $\theta_{z,el}$) and moments ($M_{x,el}$ and $M_{z,el}$) of the critical pier sections, as well as the corresponding shear deformations ($\gamma_{x,el}$ and $\gamma_{z,el}$) and forces ($F_{x,el}$ and $F_{z,el}$) in the bearings along their principal axes, are estimated. The moment ratio $M_{x,el}/M_{z,el}$ (Fig. 3) and the bearing shear force ratio $F_{x,el}/F_{z,el}$ remains constant also for higher earthquake intensity levels so long as the loading is monotonically increasing and the response along both principal bridge directions remains elastic. For a certain earthquake intensity level the pier critical section, or an individual bearing, yields under a moment M_{int}^y (Fig. 3) or force F_{int}^y , respectively (the subscript *int* indicates that the point lies on the interaction curve). This means that the critical section or the bearing yields under biaxial conditions earlier than in the case where the moment vector is normal, or the force vector is parallel, to one of the principal directions. Then, the (idealised as bilinear) M - θ or F - γ diagrams along the principal directions of critical pier sections or bearings are modified using the reduced values of yield moments or yield forces, respectively.

Finally, the selection of an appropriate axis to project the displacement of the control point and the base shear force of the bridge along the longitudinal and the transverse direction is needed, so that the pushover curve can be plotted. An obvious choice is the axis $O\xi$ of the major earthquake component $E_I \equiv E_{\xi}$. From the two approaches proposed in [7] the one based on the combination of responses along the bridge's principal directions is used here, for the reasons explained earlier in the paper. The successive steps of the methodology proposed for deriving the pushover curve are the following:

Figure 3: Elliptically idealised moment interaction diagram of a critical R/C pier section.

- Step 1:* For a given dual-component seismic action E (code-type spectra or natural records) whose major component acts at an angle α , the corresponding component response spectra E_x and E_y (Fig. 2) are calculated and are scaled to increasing levels of earthquake intensity (0.1g, 0.2g, ..., $A_{g,u} \cdot g$) until the bridge reaches its ultimate point (bridge failure) at the intensity level $A_{g,u}$.
- Step 2:* For a low earthquake intensity level (e.g. 0.1g), for which bridge response along both its principal directions remains elastic, the moments $M_{x,el}$ and $M_{z,el}$ of critical pier sections and the shear forces $F_{x,el}$ and $F_{z,el}$ of bearings along their principal directions are calculated. The resulting moment ratios $M_{x,el}/M_{z,el}$ and shear force ratios $F_{x,el}/F_{z,el}$ are subsequently used in the corresponding interaction diagrams (Fig. 3) to reduce yield moments of critical pier sections and/or yield shear forces of bearings; the reduced values are introduced in the $M-\theta$ or $F-\gamma$ diagrams for the principal directions of critical pier sections and of individual bearings.
- Step 3:* A ‘standard’ pushover analysis is performed separately along the longitudinal (0°) and the transverse direction (90°), for lateral force patterns compatible with the corresponding prevailing mode. Then, the derived pushover curves are idealised as bilinear ones [11] and they are converted to spectral pushover curves (‘capacity curves’ [3]) of the inelastic equivalent SDOF corresponding to the prevailing mode of each principal bridge direction.
- Step 4:* At each earthquake intensity level the displacement $u_{L,max}$ along the longitudinal direction and $u_{T,max}$ along the transverse direction are calculated using inelastic spectra. Then, the corresponding base shears V_{bL} and V_{bT} are extracted from the database of each individual pushover analysis and the projections of these two quantities on the axis of earthquake action (Fig. 2) are taken, i.e.

$$u_{L,proj} = u_{L,max} \cdot \cos \alpha, \quad V_{bL,proj} = V_{bL} \cdot \cos \alpha \quad (1)$$

$$u_{T,proj} = u_{T,max} \cdot \sin \alpha, \quad V_{bT,proj} = V_{bT} \cdot \sin \alpha \quad (2)$$

Then, the projections are combined using the SRSS rule, the CQC rule or the ABS rule, since these response quantities are not simultaneous, for the calculation of the displacement u_ξ and the base shear force $V_{b\xi}$ in the earthquake direction. In case of the SRSS rule, u_ξ and $V_{b\xi}$ are calculated using the following relationships:

$$u_\xi = \sqrt{u_{L,proj}^2 + u_{T,proj}^2} = \sqrt{u_{L,max}^2 \cdot \cos^2 \alpha + u_{T,max}^2 \cdot \sin^2 \alpha} \quad (3)$$

$$V_{b\xi} = \sqrt{V_{bL,proj}^2 + V_{bT,proj}^2} = \sqrt{V_{bL}^2 \cdot \cos^2 \alpha + V_{bT}^2 \cdot \sin^2 \alpha} \quad (4)$$

Step 5: Step 4 is repeated for all earthquake intensity levels ($0.1g, 0.2g, \dots, A_{gu} \cdot g$) until the bridge reaches its ultimate point in either principal direction. The pushover curve referring to the earthquake direction is plotted using $u_{\xi}-V_{b\xi}$ points.

2.3 Definition of damage states

The first step for defining damage states is their qualitative (descriptive) definition. Here the corresponding definitions of HAZUS [3] are adopted which are based on bridge damage data from the Loma Prieta and Northridge earthquakes [1]. Thus, four damage states, in addition to the No-Damage state (DS0), are defined: Minor/Slight Damage (DS1), Moderate Damage (DS2), Major/Extensive (DS3) Damage, and Failure/Collapse (DS4).

Then, damage state descriptive definitions are quantified in terms of bridge deck displacement δ_{ξ} (global damage parameter) along the earthquake direction. Apart from bridge damage, i.e. damage developed due to plastic hinge formation in the piers and/or yielding of bearings, damage developed at the abutment-backfill system due to its activation after the longitudinal gap closure is also taken into account. Damage states due to bridge damage are defined using bridge deck displacement δ_{ξ} at characteristic points of ‘typical’ bridge pushover curves for a given earthquake direction α , which are defined on the basis of the seismic energy dissipation mechanism consistently with the classification scheme proposed in [8]. Damage states due to damage developed at the abutment-backfill system are also defined using bridge deck displacement, and complement the corresponding damage state definitions referring to bridge damage. The final threshold value of displacement for each damage state is taken as the minimum of the two threshold values for damage to the bridge (piers, bearings) and damage to the abutment-backfill system.

2.3.1 Bridges with yielding piers of the column type

In bridges with inelastic piers of the column type the ‘typical’ pushover curve for seismic action acting at an angle α along the axis $O\xi$ is shown in Fig. 4. The first branch of the pushover curve corresponds to all the seismic intensity levels for which the response in both bridge directions remains in the elastic range, and terminates at the first plastic hinge formation (Point A). The second branch of the pushover curve corresponds to the successive plastic hinge formation (development of plastic mechanism) and terminates at the intensity level for which the last plastic hinge forms (Point B). The third branch of the pushover curve terminates at the first failure of a pier (Point C). Subsequent to this point progressive failure of the bridge occurs, with successive pier failures, as shown in Fig. 4.

Idealizing the pushover bridge curve as bilinear, the second branch corresponding to the plastic hinge formation stage (branch AB) is reduced to a single point (named conventional yield point) and the branch after Point C corresponding to the failure mechanism is reduced to another single point (named bridge ultimate point) using a strength drop criterion for the bilinearization and the assumption of equal areas between the initial and the idealised pushover curves [11]. The four damage states are then defined on the bilinearised bridge pushover curve as described in Table 1. The first damage state (DS1: Minor Damage) is defined at the elastic branch (at 70% of conventional yield displacement, since, as described previously, actual yielding occurs before the conventional yield point), while the last damage state (DS4: Failure/Collapse) is defined at the ultimate bridge point, defined as previously. The two intermediate damage states (DS2: Moderate Damage and DS3: Major/Extensive Damage) are defined differently for high ductility bridges ($\mu_u \geq 3.0$) and for low-to-moderate

ductility bridges ($\mu_u < 3.0$). More specifically, in high ductility bridges intermediate damage states are defined at bridge displacements corresponding to ductility levels 1.5 and 3.0, while in low-to-moderate ductility bridges are defined at displacements equally spaced (1/3 and 2/3) along the post-yield branch.

Figure 4: 'Typical' pushover curve of bridges with yielding piers of the column type.

a/a	Damage State	Threshold values of δ_ξ^z	
		$\mu \geq 3.0$	$\mu < 3.0$
DS1	Minor/Slight	$> 0.7 \cdot \delta_{\xi,y}^z$	$> 0.7 \cdot \delta_{\xi,y}^z$
DS2	Moderate	$> 1.5 \cdot \delta_{\xi,y}^z$	$> \delta_{\xi,y}^z + (1/3) \cdot (\delta_{\xi,u}^z - \delta_{\xi,y}^z)$
DS3	Major/Extensive	$> 3.0 \cdot \delta_{\xi,y}^z$	$> \delta_{\xi,y}^z + (2/3) \cdot (\delta_{\xi,u}^z - \delta_{\xi,y}^z)$
DS4	Failure/Collapse	$> \delta_{\xi,u}^z$	$> \delta_{\xi,u}^z$

Table 1: Damage state definitions for bridges with yielding piers of the column type.

2.3.2 Bridges with bearings and non-yielding piers of the wall type

In this type of bridge the shape of the 'typical' pushover curve is similar to that of the previous type, replacing yielding and failure of critical pier sections with yielding and failure of bearings (or groups of bearings in the common case where more than one bearings are placed at the top of a pier) (Fig. 5-solid line). Whenever seismic links (stoppers) are present at the top of the piers an apparent hardening-softening is noticed due to their successive activation and failure, respectively (Fig. 5-dotted line, see discussion in [8]).

Damage states for this bridge type are defined as follows: Firstly, damage states for a single bearing are defined (Table 2) using shear deformation, γ_{bi} , as damage parameter. Then, the deformation of the equivalent single bearing, γ_{eq} , is calculated as the average of the deformations of all bridge bearings, i.e.

$$\gamma_{eq} = \frac{\sum_{i=1}^N \gamma_{bi}}{N} \quad (5)$$

where: γ_{bi} = shear deformation of single bearing i
 γ_{eq} = shear deformation of the equivalent single bearing and
 N = total number of bridge bearings

hence damage state definitions for the single bearing (Table 2) can be used also for the entire bridge. Alternatively, the corresponding bridge displacement δ_ξ (Table 2) can be used for damage state definitions. More specifically, the first damage state is defined using the yield shear deformation γ_{int}^y , which lies on the interaction curve and is derived for low earthquake intensity level. The other three damage states are defined reducing the threshold values for the uniaxial shear deformation of bearings (1.5, 2.0 and γ_u) using the minimum of the ratios $\gamma_{x,int}^y / \gamma_x^y$ and $\gamma_{z,int}^y / \gamma_z^y$ (Table 2).

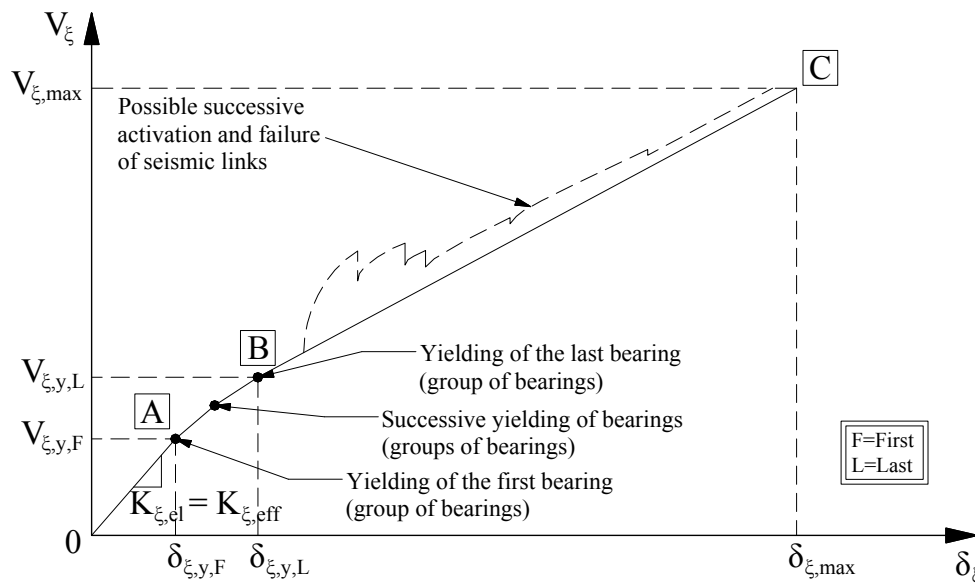

Figure 5: ‘Typical’ pushover curve of bridges with bearings and non-yielding piers of the wall type.

a/a	Damage State	Threshold values of γ_{bi}, γ_{eq}	δ_ξ
DS1	Minor/ Slight	$> \gamma_{int}^y$	$> \delta_\xi(\gamma_{eq,DS1})$
DS2	Moderate	$> 1.5 \cdot \min \left[\gamma_{x,int}^y / \gamma_x^y, \gamma_{z,int}^y / \gamma_z^y \right]$	$> \delta_\xi(\gamma_{eq,DS2})$

Table 2: Damage state definitions for bridges with bearings and non-yielding piers of the wall type

2.3.3 Bridges with bearings and yielding piers of the column type

In this bridge typology the seismic energy is dissipated due to the inelastic behaviour of both piers and bearings. Thus, the shape of a ‘typical’ bridge pushover curve (Fig. 6) is similar to the previous bridge types. Here, the second branch represents both the successive plastic hinge formation and yielding of bearings. In addition, the slope of the first branch is smaller than in the case of bridges with yielding piers of the column type due to the significantly lower stiffness of pier-bearings systems, thus ultimate displacement ductility in

bridges with yielding piers of the column type is usually small, but is also a rather inappropriate indicator of the bridge's response. Damage states are defined using the corresponding definitions of bridges with yielding piers of the column type (Table 5, typically the $\mu_u < 3.0$ case applies).

Figure 6: 'Typical' pushover curve of bridges with bearings and yielding piers of the column type.

a/a	Damage State	Threshold values of δ
DS1	Minor/Slight	$> 0.7 \cdot \delta_{\xi,y}$
DS2	Moderate	$> \delta_{\xi,y} + (1/3) \cdot (\delta_{\xi,u} - \delta_{\xi,y})$
DS3	Major/Extensive	$> \delta_{\xi,y} + (2/3) \cdot (\delta_{\xi,u} - \delta_{\xi,y})$
DS4	Failure/Collapse	$> \delta_{\xi,u}$

Table 3: Damage state definitions for bridges with bearings and yielding piers of the column type.

2.3.4 Damage due to abutment-backfill system activation

In case the abutment-backfill system is taken into account in the analysis model ('full-range analysis') the typical bridge pushover curve in the longitudinal direction has the shape shown in Fig. 7 (a bilinear force-displacement, V - δ , diagram is assumed for the abutment-backfill system). For deck displacements smaller than the longitudinal gap, δ_{gap} , the pushover curve is derived on the basis of bridge response. After the activation of the abutment-backfill system, its response is combined with bridge response and the pushover curve is derived adding the corresponding shear forces of bridge and abutment-backfill system for each value of bridge displacement.

Damage states are defined differently in the case where the abutment-backfill system is modelled (full-range analysis) and in the case where the abutment-backfill system is not directly included in the model (approximate analysis). In the former case (full range analysis) the first damage state is defined on the basis of the displacement at the longitudinal gap closure, δ_{gap} , the last damage state is defined on the basis of the ultimate displacement of the abutment-backfill system, if it is smaller than the ultimate bridge displacement δ_{max} , and the two intermediate damage states are defined at displacements equally spaced along the post-yield branch of the 'typical' bridge pushover curve after the activation of the abutment-backfill system. In the latter case (approximate analysis) the first damage state initiates at the gap closure, δ_{gap} . The two intermediate damage states are defined increasing the threshold

value of the first damage state by 10% and 20%, while the last damage state is defined as the maximum of $a \cdot \delta_u$ (which is an estimate for the ultimate displacement of the abutment-backfill system, see [8]) and $1.1 \cdot \delta_{DS3}$. When bridge ultimate displacement is smaller than these two values, δ_u is used to define the threshold of the final damage state.

Figure 7: 'Typical' pushover bridge curve (here bridge with yielding piers of the column type) taking into account the abutment-backfill system.

a/a	Damage State	Threshold values of <i>Full range analysis</i>	<i>Approximate analysis</i>
DS1	Minor/Slight	$> \delta_{gap}$	$> \delta_{gap}$
DS2	Moderate	$> \delta_{y,ab} + (1/3) \cdot (\delta_{u,ab} - \delta_{y,ab})$	$> 1.1 \cdot \delta_{gap}$
DS3	Major/Extensive	$> \delta_{y,ab} + (2/3) \cdot (\delta_{u,ab} - \delta_{y,ab})$	$> 1.2 \cdot \delta_{gap}$
DS4	Failure/Collapse	$> \delta_{u,ab}$	$> \begin{cases} \delta_u, & \text{when } \delta_u < 1.1 \cdot \delta_{\Sigma B3} \\ \max \{ a \cdot \delta_u, 1.1 \cdot \delta_{\Sigma B3} \} \end{cases}$

Table 4: Damage state definitions for damage developing at the abutment-backfill system.

The effect of the angle of incidence of the seismic action is taken into account by modifying bridge deck displacements estimated from static nonlinear analysis. More specifically, bridge displacement δ_ξ in the earthquake direction a , is firstly projected on the longitudinal bridge direction ($\delta_\xi \cos a$ – Fig. 8a) and then it is increased by the displacement caused by the rotation of the bridge deck ($B \cdot \sin \theta$ – Fig. 8b). Hence, the bridge displacement $\delta_{\xi,Br}$, used in order to take into account the damage caused by the activation of the abutment-backfill system is

$$\delta_{\xi,Br} = \delta_\xi \cdot \cos a + B \cdot \sin a \quad (6)$$

Figure 8: Calculation of bridge displacement for the activation of the abutment backfill system.

2.4 Derivation of fragility curves

The starting point for the derivation of fragility curves is the quantification of the exceedance of a given damage state, which is materialized using damage parameters, here bridge displacement δ_ξ along the axis $O\xi$ (Fig. 2) of the major horizontal component of the earthquake. Peak ground acceleration A_g is selected as the earthquake intensity parameter, but other quantities could also have been used (e.g. spectral displacement S_d).

The available bridge capacity that corresponds to the threshold of damage state i ($i=1,2,3,4$) is quantified through the bridge displacement δ_ξ used for the damage state definitions (Tables 1 to 4). Correspondingly, bridge response for a given earthquake intensity level A_g is quantified through bridge displacement $\delta_{\xi,Br|A_g}$, as it is calculated from bridge analysis for earthquake intensity A_g . Thus, the exceedance of a damage state can be represented by the following relationship

$$\delta_{\xi,Br|A_g} \geq \delta_{DSi} \quad (7)$$

and the probability of exceedance is written

$$P(\delta_{\xi,Br|A_g} \geq \delta_{DSi}) = P_f \quad (8)$$

In order to derive a fragility curve quantification of the total uncertainty is also needed. Here, since the probability density function is idealised as lognormal (as in most previous studies on bridge fragility), the total uncertainty is represented by the total lognormal standard deviation β_{tot} , which is assumed equal to 0.6 in line with previous studies [3]. The probability of exceedance using the median values of damage parameter (bridge displacement in the earthquake direction δ_ξ) can be written as:

$$P_f = \Phi \left[\frac{1}{\beta_{tot}} \cdot \ln \left(\frac{\delta_{\xi,Br,m|A_g}}{\delta_{DSi,m}} \right) \right] \quad (9)$$

The next step is the correlation of damage parameter (δ_ξ) with earthquake intensity parameter (A_g), which is achieved through the median damage evolution curve (or primary fragility curve, Fig. 10), which is the plot of the median value of bridge deck displacement versus the corresponding earthquake intensity parameter (here A_g). Fig. 9 shows the estimation of bridge displacement for increasing earthquake intensity levels using inelastic demand spectra in the region where the equal energy approximation is valid (i.e. for $T \leq 0.5-0.6$

sec) and elastic demand spectra in the region where the equal displacement approximation is valid (i.e. for $T > 0.5-0.6$ sec). From the median damage evolution curve, given the threshold value of bridge deck displacement for a specific damage state, the corresponding median value of A_g can be estimated (Fig. 10). For example, the median threshold value of A_g for damage state DS2 for bridges with bearings and elastic piers of the wall type is the direction of the piers is that corresponding to $\delta_{DS2} = \delta(\gamma_{eq} = 1.5)$.

Hence, the damage state probability can be written in terms of peak ground acceleration A_g as follows:

$$P_f = \Phi \left[\frac{1}{\beta_{tot}} \cdot \ln \left(\frac{A_{g,m}}{A_{g,DSi,m}} \right) \right] \quad (10)$$

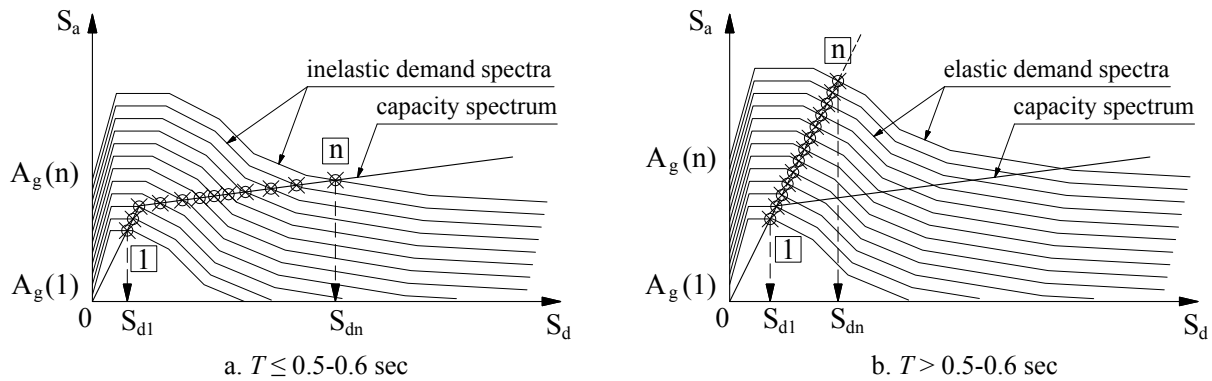

Figure 9: Estimation of target displacement for increasing earthquake intensity levels

Figure 10: Median damage evolution curve (primary vulnerability curve) and fragility curve.

The plot of equation (10) is the fragility (probabilistic vulnerability) curve, of the specific damage state (Fig. 10). For the derivation of generalized fragility curves the proposed methodology is applied for various values of the angle of incidence of the seismic action between 0° and 180° .

3 APPLICATION OF THE PROPOSED METHODOLOGY TO SKEW BRIDGES

In a previous study by the authors [7] the proposed methodology was applied to a straight overpass bridge subjected to single-component seismic action. Here, the methodology is applied to a skew bridge subjected to either single- or dual-component seismic action.

3.1 Description and modelling of the selected bridge

The selected bridge is a 5-span bridge of 180m total length (5×36) that crosses Kosynthos River in North-Eastern Greece (Thrace), and is part of the Egnatia Motorway. The deck consists of a system with 6 simply-supported precast-prestressed beams connected through a continuous R/C slab (Fig. 11) and rests through common elastomeric bearings $400 \times 500 \times 181$ (elastomer thickness 77mm) on four piers of the wall type with rectangular solid cross section 1.2×14.7 m (Fig.12). Piers are inclined at an angle of 110° with respect to the bridge's longitudinal axis, i.e. there is a skew of 20° (Fig. 13).

Figure 11: Deck section of Kosynthos bridge

Figure 12: Wall-type pier section of Kosynthos bridge

Figure 13: Inclination of pier in Kosynthos bridge with respect to the geometric longitudinal axis (Plan View)

The bridge deck rests on the abutments through common elastomeric bearings $400 \times 600 \times 226(110)$. The deck movement along the longitudinal direction is permitted up to the closure of a 100mm gap, while in the transverse direction it is unrestrained.

The Kosynthos bridge was modelled using the software package SAP2000 Nonlinear [2] (Fig.14a). Precast deck beams and piers are modelled with frame elements, while the

continuous deck slab is modelled with shell elements. Bridge bearings are modelled with Link elements with length equal to the total thickness of rubber in each bearing. The base of Link elements is connected through rigid-arms to the top of piers (Fig. 14b). The behaviour of bearings is considered as linear, which is a reasonable and common assumption for low-damping bearings (here the equivalent viscous damping is only about 5%).

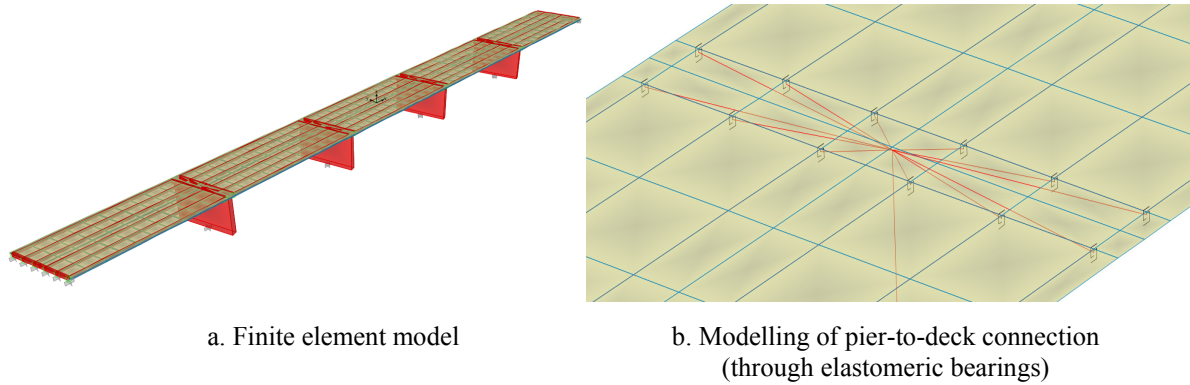

Figure 14: Modelling of Kosynthos bridge.

3.2 Application of the proposed methodology

The proposed methodology is applied twice, considering the seismic action either as single- component or as dual-component, for three different greek earthquakes using the records described in Table 5. For each of the three pairs, principal horizontal components are derived. The corresponding response spectra are shown in Fig. 15 for the case of Thessaloniki earthquake; it is worth pointing out that due to its different frequency content the minor component has larger spectral displacement values than the major one.

Place	Station	Date	Time	M	R [km]	Orientation	A_g [g]
Thessaloniki	City Hotel	20/6/78	08:03:21	6.1	29	N-S	0.139
						E-W	0.146

						N10W	0.272
Athens	Sepolia (Garage)	7/9/99	11:56:50	5.8	21	LONG	0.326
						TRANS	0.310

Table 5: Selected greek earthquakes.

Figure 15: Elastic response spectra of principal horizontal components of Thessaloniki earthquake.

For the derivation of pushover curves for arbitrary angle of incidence of the seismic action, the modal characteristics of the bridge have to be determined. The prevailing mode in the longitudinal direction is translational and the bridge deck moves as a rigid body at an angle of 20° with respect to the longitudinal axis (Fig. 16). The transverse prevailing mode is also translational but the deck moves as a rigid body at an angle of 110° with respect to the longitudinal axis (Fig. 17) or at an angle of 20° with respect to the geometric transverse axis, i.e. normal to the longitudinal prevailing mode. The two prevailing modes define the modal principal axes of Kosynthos bridge (Fig. 18, system $O-M1-M2$), which are rotated at an angle of 20° with respect to the geometric principal axes (Fig. 18, system Oxy). The rotation of the modal principal axes with respect to the geometric principal axes is due to the bridge skewness.

Figure 16: Prevailing longitudinal mode of Kosynthos bridge

Figure 17: Prevailing transverse mode of Kosynthos bridge

Figure 18: Geometric and modal principal axes of Kosynthos bridge

Regarding the periods of the two prevailing modes it is noticed (Table 6) that they differ only by 6.4%, something that is usual for bearing-supported bridges [8]. In addition, modal participating mass ratios are 100% for both prevailing modes along the corresponding modal principal axes, while with respect to the geometric principal axes they are $\varepsilon_x = \varepsilon_{M1} \cdot \cos^2 20^\circ = 88.3\%$ and $\varepsilon_y = \varepsilon_{M1} \cdot \sin^2 20^\circ = 11.7\%$ for the longitudinal prevailing mode and $\varepsilon_x = \varepsilon_{M2} \cdot \sin^2 20^\circ = 11.7\%$ and $\varepsilon_y = \varepsilon_{M2} \cdot \sin^2 110^\circ = 88.3\%$ for the prevailing transverse mode.

Prevailing mode	T [sec]	ε_x [%]	ε_y [%]	ε_{M1} [%]	ε_{M2} [%]
Longitudinal	1.376	88.3	11.7	100	0
Transverse	1.288	11.7	88.3	0	100

Table 6: Modal characteristics of the two prevailing modes of Kosynthos bridge

For force distribution consistent with the longitudinal and the transverse prevailing mode the bridge deforms only along the direction of modal principal axis $O-M1$ and $O-M2$, respectively. Thus, in order to apply the proposed methodology the modal principal directions are used instead of the corresponding geometric ones. Biaxial effects in the bridge bearings are ignored to simplify the procedure, keeping the modal principal axes constant; it is also noted that no information on shear and axial force interaction in bearings is available in the literature. The derived pushover curves, using the deck mass centre as control point, along the

modal principal directions are linear because the behaviour of common elastomeric bearing is considered as linear.

Then, the proposed methodology is applied for excitation angles from 0° to 110° , and the results are evaluated against those from linear dynamic analyses. In the single-component case the CQC rule is used for the combination of the projections of displacements of the control point and of base shears, because the earthquake components acting along the modal principal directions have identical accelerograms, hence identical response spectra, and the correlation of modal responses is significant (the modal correlation coefficient [16] is $\rho_M = 0.696$). Conversely, for the dual-component case the SRSS rule is adopted, ignoring the correlation of the earthquake components acting along the modal principal directions and the correlation of modal responses.

The key results from the application of the proposed methodology, i.e. displacement δ_ξ of the control point (deck mass centre) along the earthquake direction and the shear deformation of the equivalent single bearing γ_{eq} along the geometric principal directions, against the corresponding ones from the dynamics analyses, are shown in Tables 7 and 8 for single- and dual-component seismic action, respectively.

Focussing first on the results for the simpler case of the single-component seismic action, it is seen from Table 7 that the differences for δ_ξ are small for all excitation angles and vary from 0.0% for $\alpha=110^\circ$ to 7.3% for $\alpha=60^\circ$. With respect to γ_{eq} , differences are similar to those for δ_ξ , varying from 0.0% for $\alpha=110^\circ$ to 5.5% for $\alpha=60^\circ$.

When the minor principal horizontal component of the earthquake is also taken into account, differences are larger than in the single-component case, still small enough to be acceptable, varying from 0.1% for $\alpha=110^\circ$ to 15.5% for $\alpha=45^\circ$ for the displacement of the control point, and from 0.2% for $\alpha=110^\circ$ to 13.1% for $\alpha=30^\circ$ for the deformation of the equivalent shear bearing. Furthermore, differences are maximized for excitation angles $\alpha=30^\circ$, 45° and 60° , i.e. the region where correlation between the earthquake components acting along the modal principal bridge directions is maximized, something anticipated due to the use of the SRSS rule where the aforementioned correlation is ignored.

α [$^\circ$]	δ_ξ [m]		Difference [%]	$\gamma_{eq}=\max[\gamma_{eq,x}, \gamma_{eq,y}]$		Difference [%]

Table 7: Comparison between static and dynamic analysis results – Single-component seismic action.

The derived pushover curves for various excitation angles between 0° and 110° with a step of 15° (including the directions of modal principal directions) are also linear since the behaviour of common elastomeric bearings is considered as linear for both the single- and dual-component case. The most critical and least critical directions regarding bridge failure (bridge ultimate point) are for $\alpha=90^\circ$ ($A_{g,u,min}=2.80g$) and $\alpha=45^\circ$ ($A_{g,u,max}=3.80g$) for single-component seismic action, and for $\alpha=30^\circ$ ($A_{g,u,min}=1.80g$) and $\alpha=75^\circ$ ($A_{g,u,max}=2.02g$), i.e. for

the excitation angles where the maximum and the minimum value of the shear deformation of the equivalent single bearing is reached, for the dual-component action (Tables 7 and 8).

Table 8: Comparison between static and dynamic analysis results – Dual-component seismic action.

Finally, generalized fragility curves for various excitation angles are derived (Figures 19 to 26) for both the single- and the dual-component case. The corresponding median damage state threshold values of peak ground acceleration are shown in Table 9. It is observed that in the case of single-component seismic action, for all damage states, the critical bridge direction is $\alpha=90^\circ$, while the less critical direction is $\alpha=45^\circ$. When the minor principal earthquake component is also taken into account the critical direction is $\alpha=30^\circ$ while the least critical one is $\alpha=75^\circ$. It is also observed that for both in single- and dual-component seismic action the most critical and the least critical directions are similar with those resulting from the pushover curves, because the ultimate bridge point and the damage state definitions are based on the shear deformation of the equivalent single bearing.

Figure 25: Generalized fragility curves of Kosynthos bridge for single-component seismic action, DS4: Failure/Collapse.

Figure 26: Generalized fragility curves of Kosynthos bridge for dual-component seismic action, DS4: Failure/Collapse.

It is important to point out that when the minor principal component is considered in the analysis, median threshold values of A_g are reduced by 41.6%, indicated a significant increase in bridge fragility, for all excitation angles. Finally, the maximum and the minimum median threshold values of A_g differ by 25.7% in the single-component case, while in the dual-component case the difference is reduced to 10.5%. This suggests that bridge fragility remains practically insensitive to the earthquake direction when the minor principal component of the earthquake is taken into account.

4 CONCLUDING REMARKS

A methodology for bridge fragility analysis under arbitrary angle of incidence of the earthquake, previously proposed by the authors [7], was extended here to take into account the minor principal horizontal component of the earthquake (dual-component seismic action). Furthermore, damage states for the case of bearing-supported bridges were redefined in a broader manner in order to take into account the interaction between biaxial shear and axial load, as well as all possible failure mechanisms, of the bearings. The proposed methodology was applied to an actual skew bridge for both single- and dual-component seismic action.

In skew bridges modal principal directions are not identical to geometric principal bridge directions, as in straight bridges, but they are rotated at a specific angle. According to the proposed methodology standard pushover analyses are performed for force distributions consistent with each of the prevailing bridge modes (longitudinal-transverse). Thus, modal principal bridge directions are used for the application of the proposed methodology. In the single-component case the CQC rule is used for the combination of the projections of the control point displacement and of the base shear, due to the significant correlation of modal responses in bearing-supported bridges. Conversely, in the dual-component case the SRSS rule is used, ignoring the correlation between the modal responses and also the earthquake components acting along the modal principal bridge directions. The expected differences in the range of excitation angles wherein the correlation between the earthquake components acting along modal principal direction is maximized are reasonably small (15%), showing the validity of the use of the SRSS rule in the dual-component case, for all excitation angles.

From the derived generalized fragility curves for arbitrary angle of incidence of seismic action it was seen that when the minor principal horizontal component is taken into account bridge fragility is significantly increased (more than 40% in the studied skew bridge), whereas it remains almost unaffected by the angle of incidence of the seismic action.

Keywords: bridges; seismic isolation; knowledge-based systems; software; preliminary design; testing of elastomeric bearings

Abstract. *The preliminary design of seismically isolated R/C highway overpasses is the target of a software based on the current design provisions of Eurocode 8 (Part 2) as well as on engineering decisions included in the expert system. The features of this expert system, which is aimed to facilitate the design of a highway overpass by isolating its deck with the inclusion of elastomeric bearings, are presented and discussed. For such an upgrade scheme a number of successive checks is necessary in order to select an optimum geometry of the bearings. The developed software includes a series of checks provided by Eurocode 8 (Part 2), in order to ensure the satisfactory seismic performance of the selected upgrade scheme. In doing so, the software accesses a specially created database of the geometrical and mechanical characteristics of either cylindrical or prismatic elastomeric bearings which are commercially available; this database can be easily enriched by relevant data from laboratory tests on isolation devices. The basic assumptions included in the software are (a) modeling the seismic response of the bridge overpass as a SDOF system, and (b) only the longitudinal direction response is considered; it is common practice for seismically isolated bridge systems to restrain the transverse movement of the deck by stoppers. Moreover, the results form a number of tests performed in the Laboratory of Strength of Materials and Structures of Aristotle University, verified the quality of the production process of a local producer of elastomeric bearings subjecting production samples to the sequence of tests specified by International Standard ISO 22762-1 (2005). Strain amplitudes larger than 250% resulted in the debonding of the elastomer from the steel plating. Artificial aging resulted in a small increase of the axial (vertical) stiffness and a small decrease of the shear (horizontal) stiffness of the tested bearings. More specimens must be tested to validate further these findings.*

1 INTRODUCTION

Seismic design of structures, in general, involves the conceptual, preliminary and final design [1], the latter being typically prescribed in detail, for most conventional structures, by the existing seismic code requirements. The conceptual design, however, is not, and cannot easily be, encapsulated in codes' provisions; hence, it relies heavily on engineering judgment, expertise and experience. It is therefore quite often the case that the final design, although completely covered by detailed seismic code provisions, is essentially driven by the choices initially made. The same design process described above is also followed in the case of bridge structures, independently of whether they are typical, short highway overpasses or more complex, long and/or curved bridges. Such bridges, although appearing to be relatively simple structures compared to some irregular buildings, may be designed with numerous different configurations depending on a set of performance (in terms of safety and serviceability), economic (including maintenance), constructability or even aesthetic criteria [2]. This gives the designer the flexibility to choose among various structural configurations, and especially among different strategies for the support of the deck on the abutments and piers; a decision related to the use of monolithic or bearing-type connections. On the other hand, the process to select the desired dimensions and the number of the bearings to be used at each support is often time consuming, as it commonly leads to iterative calculations and numerical analyses [3] and multiple design checks against target code-based criteria concerning both the maximum bearing strain and the overall performance of the bridge structure [4][5].

In general though, it can be claimed that no comprehensive procedure has been presented to this date for the optimal (i.e., cost-effective), preliminary design of seismically isolated highway overpasses and bridges. To this end, the present study aims to facilitate the designer of typical overpass configurations [6] in selecting from a smaller, filtered sample of "eligible" bearing sections, and quickly spot the preferable combination of bearing size, type, number, location and cost at minimal computational effort. The decision-making system developed is based on multiple code-based performance criteria [4][5], statistics arising from the construction of 40 km of bridges along the 680 km, newly built, Egnatia Highway in northern Greece [7], engineering judgment and recent research findings as well as ad-hoc laboratory testing, conducted for the purpose of this study. The particular process is also integrated and implemented in a user-friendly software, which permits the quick selection of the bearing scheme for given structural systems and seismic conditions. An effort was made to cover the majority of realistic overpass and simple bridge configurations, and a wide variety of steel laminated elastomeric bearing sections which are most commonly adopted for practical purposes [8][9][10]. The structure of both the Knowledge-Based Expert System (KBES) and the software developed for preliminary design of base-isolated overpasses, together with their validation against more rigorous numerical analysis procedures, is presented in the following.

2 PRINCIPLES OF SEISMIC ISOLATION OF BRIDGE SYSTEMS AND CURRENT CODE PROVISIONS

2.1 Preliminary design

In Europe, seismic isolation of bridges is performed according to the Eurocode 8 - Part 2 [4] and more specifically according to clause 7, which refers to the basic requirements and compliance criteria, analysis procedures and the verification of the isolating system. Annexes J and K of the Eurocode 8-Part 2 also make reference to the laboratory tests required in order to determine the variation of the design properties of the seismic isolator units and to verify the elastomeric bearings under seismic design situations. Similar provisions exist in the

United States. [5]. The Bridge Engineer is also given the choice between commercially available bearings or any other, experimentally tested, rubber bearing suitable for seismic isolation.

In most practical cases, the preliminary design of seismically isolated bridges can be performed using the response spectrum analysis framework prescribed by Eurocode 8, for a simple rigid deck finite element model which adequately provides a first estimate of the bearings' size, number and configuration. It is noted herein, that the rigid deck model is valid for most of the straight isolated bridges with continuous deck, at least in the longitudinal direction, in which the deck actually "floats" along the isolation pier-deck interface. In the transverse direction, however, the deck is in most cases restrained by stoppers (i.e., seismic links) which prevent excessive transverse deck displacements. In both cases though, as long as the displacements are kept below a prescribed magnitude, the system can be reliably assumed to be a single degree of freedom (SDOF).

The process for the design of the seismic isolation of the above bridges, considering a SDOF response, usually follows a series of simple steps, which are not prescribed by most codes [4][5] with the exception of the Indian code specifications [11], but results from fundamentals of the dynamics of structures:

a) calculation of the weight of the bridge per unit length according to the code provisions for the combination of the dead and permanent loading of the bridge (i.e., according to [12] and partly from the variable vertical loading (i.e., 0.2 for highway or 0.3 for railway bridges according to [4],

b) initial selection of the bearings' cross section, the total height of the elastomer and the number of the bearings per support,

c) calculation of the total effective stiffness K_{tot} of the isolation system in the longitudinal direction of the bridge,

d) calculation of the effective longitudinal period of the bridge as $T_{eff} = 2 \cdot \pi \cdot \sqrt{\frac{m_{tot}}{K_{tot}}}$,

where m_{tot} is the total mass of the bridge,

e) calculation of the seismic displacement $d_{Ed,x}$ of the deck in the longitudinal direction, by using the elastic spectrum of the code, according to Eurocode 8 specific guidance for seismically isolated bridges and

f) performing a final check to judge the bearing adequacy according to code-based performance criteria.

The most common engineering practice for the final design of the aforementioned bridge systems is given in the following with emphasis on the commonly used Low Damping Rubber Bearings (LDRB).

2.2 Final design

The techno-economical selection of an LDRB bridge isolation system is made so as to satisfy all the design constraints arising from safety-oriented code provisions, but also to maximize performance at the lowest possible cost. This is a complicated problem, and depending on the structural configuration of the bridge, the designer has many design alternatives which require an iterative procedure, involving the repeated analysis and the design of the bridge isolation system until both criteria, i.e. code requirements that ensure both safety and cost-effectiveness, are simultaneously satisfied. Typically, the designer selects an acceptable isolation system for the bridge without considering all the possible combinations of bearing type, size and configuration, and without knowing whether the system selected was the best possible balance between cost and performance. Furthermore, most bridge isolation systems use

bearings that are manufactured by international companies. In addition, due to the complexity of the above process and although permissible according to the codes, in most cases the designers are reluctant to use experimentally tested products of the local industry, hence, they lean primarily towards commercially manufactured products of the international market.

3 THE PROPOSED KNOWLEDGE-BASED DECISION MAKING SYSTEM

The methodology presented herein for the preliminary design of base isolated bridges is described in detail. The methodology applies to all bridges isolated with low damping steel laminated elastomeric bearings (LDRBs), with the exception of cases where monolithic pier-deck or abutment-deck connections are combined with bearing-type pier-deck connections. The verification of the methodology is given in section 6 of the paper and shows satisfactory results in straight bridges. The structure of the KBES can be summarized in the following three steps, which also conceptually comply with those proposed by [13].

3.1 Step 1: User Input

A database of commercially available and experimentally tested elastomeric bearings is first compiled consisting of bearings' properties, (i.e. shear stiffness G), shape (i.e., rectangular or circular), rubber and steel plate thickness, height, and width, overall area (A) and dimensions (B_x , B_y or D). Possible bridge structural systems, characterized by different number and length of middle and central spans (L_1 or L_2), that define the total bridge length (L_{tot}) and the mass per unit length (m), as well as initial configurations of n bearings are herein defined by the designer. Seismic hazard is also considered with the most commonly used parameters in mind, i.e. the design seismic acceleration (S_a), soil type and the importance factor of the bridge under study.

3.2 Step 2: Decision process

The second step of the methodology includes the necessary and basic calculations and checks for the seismically isolated bridge. The designer decides the acceptable range for bearing compression (σ_e) where a minimum of 2.0 MPa and a maximum value of 5.0 MPa are proposed by the system itself according to [14]. The limit for the bearing's compression ensures that friction will be adequate to avoid the sliding of the bearing during seismic shear loading, whereas the upper limit is given to ensure that the shear strain due to the interaction between the neoprene and the steel plates under compression will remain at acceptable limits (i.e., $\epsilon_{c,d} \leq 2.5$ according to Eurocode 8 Part 2). It is noted that this limitation is optional, in the sense that it is not explicitly imposed by the codes, however, it is good common practice. For instance, the vast majority of the bearings used in isolated bridges built along the Egnatia Highway have been designed not to exceed 5.0 MPa in compression. As such, the compression criterion is adopted as the first filter applied to all the bearings checked.

Based on the mass of the bridge, the compression stress (σ_e) is derived as a ratio of the total vertical load acting on each bearing (P_i) over its own area (A). The criterion proposed by Eurocode 8-Part 2 for the calculation of the maximum effective normal stress of the bearing is herein adopted:

$$\sigma_e \leq \frac{2 \cdot b_{min}}{3 \cdot t_t} \cdot G \cdot S_{min} \quad (1)$$

where σ_e is maximum effective normal stress of the bearing, b_{min} is the minimum dimension of the bearing, t_t is the total thickness of the elastomeric, G the shear modulus of the elastomer and S_{min} the minimum shape factor of the bearing layers.

It is noted that this criterion has to be applied to every single eligible bearing, in this case, stored in an external database as will be described in Section 4.1. All bearings that pass this filter are marked as “potentially eligible” and proceed to the next check.

By respecting the desired configuration of the bearings as set by the designer at the beginning of the process, for each bearing that has passed the previous check, the total isolation system stiffness (K_{tot}), its effective period (T_{eff}) and spectral displacement (d_{Ed}) are defined and each bearing is separately checked against seismic actions. The criterion used herein is strain-based, checking the horizontal shear deflections of the bearing given the computed level of vertical loading.

All the bearings that passed the above initial screening process are checked against a set of code-prescribed criteria, involving the normalized shear strain of the bearing due to (a) seismic loading, (b) vertical loading and (c) rotation. Herein, the criterion prescribed in Eurocode 8 is adopted, according to which the maximum total shear strain ϵ_{td} of the equivalent single degree of freedom system of the seismically isolated bridge should not exceed:

$$\epsilon_{t,d} \leq 6.0 \quad (2)$$

where:

$$\epsilon_{t,d} = \epsilon_{s,d} + \epsilon_{c,d} + \epsilon_{a,d} \quad (3)$$

and $\epsilon_{s,d}$ is the shear strain due to the total design seismic displacement, $\epsilon_{c,d}$ is the shear strain due to compression and $\epsilon_{a,d}$ is the shear strain due to angular rotation. The latter is clearly the less critical [4]. Shear strain due to the vertical load combination $\epsilon_{c,d}$ is of the order of 0.70 for a maximum effective normal stress of the bearing that remains below 5.0 MPa as described above.

The second criterion [4] is that the seismically induced shear strain $\epsilon_{s,d}$ should be limited to:

$$\epsilon_{s,d} \leq 2.0 \quad (4)$$

The shear strain of the bearing due to seismic load is computed again for the equivalent single degree of freedom system of the isolated bridge based on its dynamic characteristics and seismic response. Equation (4) can be written in terms of the displacement d_{Ed} of the system under study as:

$$\epsilon_{s,d} = \frac{d_{Ed}}{t_t} \quad (5)$$

where t_t is the total thickness of the elastomeric and $d_{Ed} = \sqrt{d_{Ed,x}^2 + d_{Ed,y}^2}$ $d_{Ed} = \sqrt{d_{Ed,x}^2 + d_{Ed,y}^2}$

the SRSS combination of the two horizontal components of seismic displacement. It is noted that, in many practical cases, $d_{Ed,y}$ is negligible, as the transverse movements of the deck are restrained by seismic links. Moreover, it was found that the shear strain due to the total design seismic displacement expressed in eq. (5) is more critical than the $\epsilon_{t,d} \leq 6.0$ criterion of eq. (2) at least for cases where the compressive stress σ_e is kept within the proposed limits, (i.e., $2.0 < \sigma_e < 5.0$ MPa).

4 EXPERIMENTAL TESTING

An experimental investigation was carried out aiming at establishing the mechanical characteristics of elastomeric bearings locally produced. For this purpose a series of standard tests were performed at the Laboratory of Strength of Materials and Structures of Aristotle University according to the International Standard ISO 22762-1 (2005). Initially, these tests were used as qualification tests for the materials used in the production; that is the neoprene, the steel plates and the adhesion materials and processes. These tests are presented in a summary form and discussed in what follows. Next, in an effort to study the influence of certain parameters in the mechanical characteristics of these elastomeric bearings, the vulcanization process was investigated. Finally, compression and shear tests were also conducted with elastomeric bearings as will be presented in the following subsections.

Figure 1a. Tensile cyclic tests with 200% strains

Figure 1b. Tensile cyclic tests with 400% strains that lead to the fracture of the specimen

4.1 Tensile cyclic tests of the neoprene

Eleven tests were performed with frequencies varying from 0.25Hz to 4.0Hz. At the end of the series the specimens failed at maximum axial strain 400% and maximum axial stress 8MPa. At fracture the specimen underwent approximately 500 cycles. The approximate Young's modulus was found to be equal to 0.75MPa. At high levels of axial strain (more than 100%) this value was more than double. At even higher levels of strain this value was further increased. At the initial static load-unload cycles there was a considerable difference in the load-unload path that tended to become less pronounced when the loading cycles increased in numbers. There was no noticeable influence on the behavior of the specimen arising from the frequency of the loading. The cyclic loading was introduced from an initial condition that was the result of preloading it with 50% of the target maximum strain level. Figure 1a depicts the test results for maximum target strain 200% whereas figure 1b depicts similar results for maximum target strain 400% which resulted in the fracture of the test specimen.

4.2 Shear cyclic tests of unit slices of elastomeric bearings

Shear cyclic tests of a specimens made of two unit slices were performed according to the International Standard ISO 22762-1 (2005). For the prismatic specimens each unit slice included a layer of elastomer and two steel plates from a bearing with plan dimensions 200mm x 200mm. The dimensions of each slice of elastomer were 200mm x 200mm and 7.62mm thickness for the orthogonal specimens (figure 2a); for the cylindrical specimens the diameter of the elastomer was 250mm and its thickness 7.62mm (figure 2b) with the appropriate steel plating. Thus, the tested specimens were formed by two slices of elastomer and four steel plates. Each steel plate had a thickness of 2.94mm and sufficient dimensions in plan to have

the elastomer attached and to provide enough room for the loading arrangement. Figure 2b and 3a depicts the used loading arrangement. The final slice-specimen was of relatively large dimensions as to be in plan a one to one representations of elastomeric bearings produced by the same process; that is employing identical unit slices and building it up at the desired height with the appropriate number of such unit slices [14]. A dynamic actuator of considerable displacement and force capability was utilized to introduce a series of cyclic shear strain imposed loading sequences to the specimens (see figures 3b). Initially, the series of tests did not exceed a maximum strain level of 100%. Next a series of similar tests introduced maximum shear strain levels larger than 100% up to the failure of the specimen that appeared in the form of debonding of the elastomer from the steel plating. In what follows typical tests results are presented in brief.

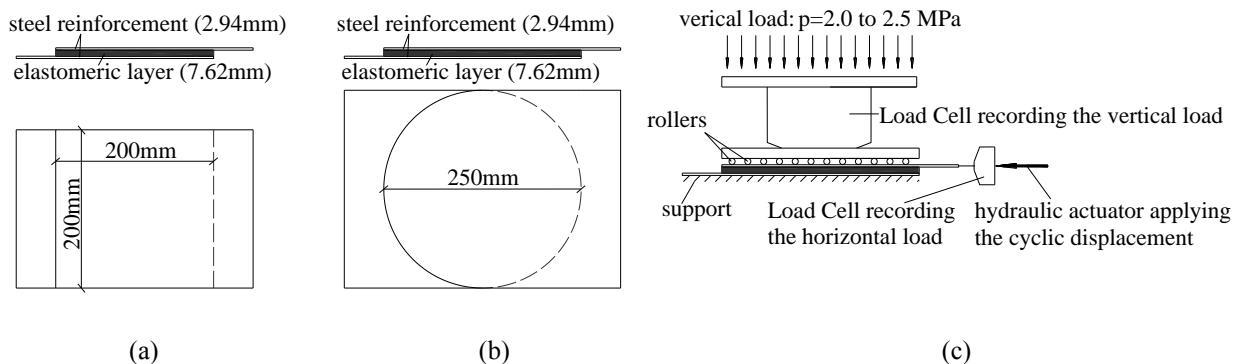

Figure 2: Cross sections and plan views of: (a) Rectangular specimens (200x200x13.5(7.62)mm) and (b) cylindrical specimens (Ø250x13.5(7.62)mm), (c) testing arrangement.

Figure 3a. Loading arrangement of a unit slice.

Figure 3b. Loading arrangement of a unit slice with the simultaneous application of a compressive stress field.

4.2.1. Shear cyclic tests with strain amplitude lower than 100%

Both orthogonal as well as cylindrical geometry elastomeric specimens were tested during this sequence. Throughout all the tests the applied load producing the shear strains was monitored together with the corresponding displacements of the specimen that were utilized to deduce the applied shear stress and shear strain levels to the specimen. At the same time the applied vertical load, normal to the slices of neoprene, was recorded and checked for any significant variations; the objective in this case being to keep the vertical load almost constant at the range of 2.0 to 2.5 MPa throughout all tests. These cyclic tests were performed for the following combinations: 3-11 cycles for each test, with temperature 23 degrees Celsius and cyclic loading varying with frequency 0.2Hz. The shear strain amplitude was varied from 5% to

75% in the following steps: 5% (0.38mm), 10% (0.76mm), 25% (1.91mm), 50% (3.81mm), and 75% (5.72mm). An increase in the shear stiffness was observed when the cyclic shear strain became larger than 75%. Subsequent tests that followed the initial tests with shear strain amplitudes varying again in the range from 5% to 75% exhibited an increase in the shear stiffness when they are compared with the results of the initial shear tests. Again, the specimen exhibited a stable performance throughout the increasing shear strain amplitude from 5% to 75% during these subsequent tests. Additional tests were also performed with the same specimens whereby the studied variable this time was the frequency of imposing the shear strain, keeping the maximum target strain amplitude constant and equal to 75%. The corresponding results are depicted in figure 4a. In this case the specimen's performance was examined for loading frequencies equal to 0.1Hz, 0.5Hz and 1.0Hz. As can be seen from this figure no significant variation in the performance of the specimen could be observed from the obtained response whereby the loading frequency was varied from 0.1Hz to 1.00Hz. An additional specimen of the same geometry and produced by the same process was tested by the loading arrangement shown in figure 3b. This time, apart from imposing the shear strain levels of continuously increasing amplitude, the specimen was placed under a constant compressive stress field normal to the horizontal plane of the elastomer. This stress field corresponded to an equivalent compressive stress equal to 2.4MPa. The frequency of the cyclic load was equal to 0.5Hz and the shear strain amplitude was continuously increasing from 10% to 75%. The summary results of this test are depicted in figure 4b. An increase in the stiffness and a decrease in the equivalent damping ratio is evident when the specimen is subjected to the previously described compressive stress field of 2.4MPa equivalent uniform stress normal to the elastomer. However, this observation should not be generalized; as was shown from the measurements of another investigation (Ryan et. al. 2004, Manos et. al. 2007) further increase in this compressive stress field has the opposite effect.

Figure 4a. Shear cyclic test results for shear strain amplitude 75% and frequencies 0.1Hz, 0.5Hz and 1.0Hz

Figure 4b. Shear test results for frequency 0.5Hz and shear strain amplitude from 5% to 75% slice with the simultaneous application of a compressive stress field.

Similar observations can be drawn from the shear test results obtained from the cylindrical geometry specimens. Typical shear test results are depicted in figure 5 whereby a cylindrical bearing slice specimen $d=250\text{mm}$ with a variation on the shear strain amplitude up to 90% and the normal stress amplitude (σ) from 0 to 2.0 MPa.

Figure 5: cylindrical bearing slice specimen $d=250\text{mm}$ with a variation on the shear strain amplitude up to 90% and the normal stress amplitude (σ) from 0 to 2.0 MPa.

4.2.2. Shear cyclic tests with strain amplitude higher than 100%

The previously described loading sequences were repeated again with unit slice elastomeric specimens of the orthogonal and cylindrical geometry being loaded this time with shear strain amplitudes higher than 100% up to the failure of the specimen. Two distinct loading arrangements were again adopted. First, the shear strains were introduced without the application of compressive load normal to the horizontal plane of the elastomer (figures 2c and 6a) whereas in the second case a vertical load was applied and kept constant producing an equivalent uniform compressive stress normal to the plane of the elastomer in the range of 2.0 to 2.5 MPa (figure 2c and 3b). Figure 6b depicts a typical failing mode during this loading process without the presence of the compressive stress field. Figure 7a depicts the load-unload behavior of this test with large shear strains without the application of compressive normal stress; figure 7b shows the resulting debonding of the elastomer from the steel plating at the end of this loading sequence. The levels of shear strain ranged from 100% and gradually increased to 275%. It can be observed that for shear strain levels lower than 200% the specimen's behavior remains stable even for this demanding test that corresponds to an elastomeric bearing that does not have the beneficial stabilizing effect of the compressive stress field normal to the slices of the elastomer within the bearing.

Figure 6a. Loading the unit slice specimen without the presence of the compressive stress field.

Figure 6b. Failing mode of the unit slice specimen without the presence of the compressive stress field.

The maximum shear stress capacity reached for this specimen a value equal to 1.7MPa; this occurred for a maximum strain level equal to 275%. The load-unload behavior of the specimen

with the simultaneous application of continuously increasing shear strains and an imposed compressive stress field normal to the elastomer equal to 2.0MPa is shown in figure 7c; figure 7d shows the resulting debonding of the elastomer from the steel plating at the end of this loading sequence. When no compressive field was applied, the level of shear strain reached first a maximum strain equal to 250% whereby the maximum shear stress was observed equal to 1.6Mpa; then for larger shear strain amplitudes the bearing capacity degrades and the specimen reaches its debonding failure mode. The maximum shear stress, when the 2.0Mpa compressive field was applied, reached a maximum value equal to 2.4Mpa for a shear strain level equal to 275%. Then for higher shear strain levels the bearing capacity degrades and the specimen reaches its debonding failure mode. From the comparison of the performance of the specimens with and without the compressive stress field (figures 7c and 7a) it can be seen that the most severe test is that without the normal compressive stress field. It corresponds to an elastomeric bearing that does not have the beneficial stabilizing effect of the compressive stress field normal to the slices of the elastomer.

Figure 7a. Shear stress-strain response of the sliced elastomeric specimens up to failure for strains in the region of 300%. ($\sigma=0.0$ Mpa)

Figure 7c. Shear stress-strain response of the sliced elastomeric specimens up to failure for strains in the region of 300%. ($\sigma=2.0$ Mpa)

Figure 7b. The debonding of the elastomer from the steel plating at the end of this loading sequence.

Figure 7d. Failing mode of the unit slice specimen with the presence of the compressive stress field.

4.3 Tests with elastomeric bearings

After completing an extensive sequence of tests with the slices of the elastomeric bearings, that tried to improve and validate the production process, another sequence of tests was conducted with elastomeric bearings of certain geometry as will be described in the following

subsection. This series of tests had as an objective to study the compression and shear behavior of these elastomeric bearings in time and examine the influence on the behavior of an artificial aging process that these bearings were subjected to by keeping them in specific heating conditions for a certain time. Two different elastomeric bearings were examined; the first was a square bearing with dimensions 150mm x 150mm in plan and a height of 95mm. The clear thickness of the elastomer was 70mm with two layers of elastomer and a thickness of the steel plating equal to 10mm for the outer plates and 5mm for the middle plate. The second elastomeric bearing was again of orthogonal geometry with dimensions 200mm x 250mm in plan having six layers of elastomer. All the steel plating was 3.5mm thick. Two specimens of this bearing were examined; the first had a thickness of the elastomer equal to 72mm (thick) whereas the second specimen had a thickness of the elastomer equal to 57mm. These specimens were subjected to vertical loading tests as well as to test that combined a vertical pre-loading condition, that resulted to an axial compressive field of approximately 2.0MPa, with a horizontal dynamic load, which produced the desired level of shear strain. The loading arrangement that was utilized is in accordance with the International Standard ISO 22762-1.

4.3.1. Tests with elastomeric bearings 150mm x 150mm

Initially, this elastomeric bearing specimen was tested in compression and then in combined pre-compression of 2.0 MPa and in shear without any artificial aging (23rd September 2008). Then the same specimen was heat treated for 20 days in a temperature equal to 80 C and after cooling it was subjected again to the same loading sequence; e.g. in combined pre-compression of 2.0 MPa and in shear (11th November 2008). During the shear tests, cyclic load was applied with varied frequencies in the range of 0.1 Hz to 1.0Hz. Figures 8a and 8c depict the vertical stress-strain diagram for this specimen before and after the heat treatment whereas figures 8b and 8d depict the shear stress-strain diagram for the same specimen that was first subjected to pre-compression of 2MPa and then to shear strain; again this test was conducted before (figure 8b) and after (figure 8d) the described heat treatment.

Figure 8a.

Figure 8b.

Figure 8c.

Figure 8d.

Figure 8. Results from compression as well as from combined pre-compression and shear for the elastomeric specimen 150mm x 150mm before and after the artificial aging.

Figure 9. Comparison of the vertical stress-strain response before and after artificial aging.

In figure 9 the comparison of the vertical stress-strain response for this elastomeric bearing specimen before and after artificial aging is shown. As can be seen, this artificial aging process resulted in a small decrease in the vertical stiffness for this elastomeric bearing. In figure 10 the effect of the artificial aging is depicted by comparing the cyclic shear stress-strain response before and after the heat treatment. As can be seen in this figure, this artificial aging process resulted in a very small increase in the shear stiffness for this bearing.

Figure 10. Comparison of the shear stress-strain response before and after artificial aging.

4.3.2. Tests with elastomeric bearings 250mm x 200mm

All the tests for this elastomeric bearing were conducted at the “new” strong reaction frame of the Laboratory of Strength of Materials and Structures of Aristotle University which houses a dynamic actuator with capabilities of $\pm 1000\text{KN}$ in load and $\pm 250\text{mm}$ in displacement and includes servo-electronic control in order to perform dynamic tests in real-time. Figure 11a illustrates a view of this strong reaction frame whereas figure 11b depicts the placement of the elastomeric bearing in this loading arrangement being supported by a special sliding device with very low coefficient of friction.

Figure 11a. The strong reaction frame of Aristotle University.

Figure 11b. The 250mm x 200mm elastomeric bearing at the strong reaction frame

Figure 12. Comparison of the vertical stress-strain response before and after artificial aging.

Initially, this elastomeric bearing specimen was tested in compression and then in combined pre-compression of 6.0 MPa and in shear without any artificial aging. Then the same specimen was heat treated for 21 days in a temperature equal to 75 C and after cooling it was subjected again to the same loading sequence; e.g. in combined pre-compression of 6.0 MPa and in shear. During the shear tests, cyclic load was applied with varied frequencies in the range of 0.1Hz to 0.2Hz. Figures 12 and 13 include summary results of these tests for the specimen with the relatively thick layers of the elastomer (72mm total elastomer thickness). In figure 12 the comparison of the vertical stress-strain response for this elastomeric bearing specimen before and after artificial aging is shown. As can be seen, this artificial aging process resulted in a small decrease in the vertical stiffness for this bearing. In figure 13 the ef-

fect of the artificial aging is depicted by comparing the cyclic shear stress-strain response before and after the heat treatment. As can be seen in this figure, this artificial aging process resulted again in a small decrease in the shear stiffness for this bearing.

Figure 13. Comparison of the shear stress-strain response before and after artificial aging.

5 SOFTWARE STRUCTURE AND FLOW

5.1 Database structure

The above decision-making system was integrated and implemented in a computer software in order to facilitate the process and visualize the results in a way useful to the designer. As already mentioned, a database of 260 commercially available bearings is developed in Microsoft Access using three distinct relational tables containing the aforementioned necessary fields to describe the bearing geometry and capacity.

5.2 Embedment of non-commercial bearings after laboratory testing

It is noted that the database, which is part of the software, has the ability to be enriched by experimentally verified bearings. This was done for three additional bearings, produced by a local industry, which have been subjected to an extensive testing performed at the Laboratory of Strength of Materials of Aristotle University Thessaloniki. As already mentioned, the experimental study of the present investigation followed the specifications of the International Standards [15], which refer to the properties of the materials of which the elastomeric bearing are composed. These tests involved quality control, vulcanization procedures and construction guidelines and were performed with samples of elastomeric slices taken from the production process. Then, a sequence of prototype tests according to [4] were applied to a series of steel laminated elastomeric bearings produced by the local industry.

The influence of the normal stress level, shear strain amplitude, frequency of shear stress loading and artificial aging was investigated. From such tests the effective shear stiffness and the equivalent effective damping can be deduced together with their variation; the measured values can become input parameters for the developed software [14] [16] [17]. A complete set of the experimental campaign results can be found in [18] [19].

5.3 User input

The main input of the software refers to Step 1 of the proposed methodology and is made through a user-friendly interface which manages previous and new bridge seismic isolation alternative solutions as these are progressively created by the user. A new project, i.e. a new preliminary design of isolation system requires the following input parameters:

(a) **Selection of structural system and bearing type:** The software developed provides for four different bridge structural systems of up to four spans as is illustrated in Figure 6. The first system (Type 1) corresponds to a single span bridge with a length equal to L that is typical for a highway overpass. Type 2 corresponds to an overpass of a higher class of highway with two spans of equal lengths and a middle pier between the lanes of a two-way highway. Types 3 and 4 are alternatives of longer highway bridges. The weight of the superstructure, which essentially controls the vertical load on the bearings, is given by the designer as it is quite possible that the deck section has been selected prior to the selection of the isolation system. A commonly used value of 200 KN/m, is also proposed for cases for which more detailed geometrical data are not available.

The screenshot shows the 'Bearing test' software interface. At the top, there is a 'New input' button and an 'Exit' button. Below this is a table with columns 'Code', 'Description', and 'Date'.

Code	Description	Date
1	bridge isolation 1	27/5/2010
2	bridge isolation 2	28/5/2010
3	BRIDGE KNIDIS	26/5/2010
4	ARAXTHOS PERISTERI BRIDGE	1/6/2010

Below the table, the 'Code' is set to 4, 'Description' is 'ARAXTHOS PERISTERI BRIDGE', and 'Date' is '27/5/2010'. The 'Selection of Bridge Type and Span Lengths' section shows four diagrams: Type 1 (One span), Type 2 (Two spans), Type 3 (Three spans), and Type 4 (Four spans). Type 4 is highlighted with a green box. The 'Selection of Bearing shape' section shows a 3D diagram of a rectangular bearing with dimensions 'a' and 'b'. The 'Shape' is set to '01 Rectangular'. The 'Bearings / Support' section shows '03 3 bearings'. The 'Soil Type' is '02 B', 'Seismic Zone' is '01 Zone I', and 'Importance Factor' is '03 $\gamma_I=1.30$ '. The 'Max Compression (Mpa)' is '5.00', 'Min Compression (Mpa)' is '2.00', 'Shear Modulus G (Mpa)' is '1.00', and 'Deck Mass (KN/m)' is '308.40'. At the bottom, there are buttons for 'Save', 'Cancel', 'Delete', and 'Check'.

Figure 14: Typical overpass configurations supported by the software developed and overview of the user's interface of the software developed for the preliminary design of bridge isolation system.

(b) **Desirable bearing type and configuration:** The cross-section of the bearing (i.e., rectangular and/or circular) can also be selected at this stage. In case of pre-stressed and precast I-beam bridge decks, the number of bearings on each support (pier or abutment) is based on the

number of the longitudinal beams. In the case of a cast-in-situ box girder or slab-type bridge deck, the number of bearings per support can be decided by the designer as a function of the dimensions of the pier's cap and the anticipated response of the isolated deck as well as making use of the software. As already mentioned, the user can define a minimum and a maximum value for the compression of the bearings or confirm the default range between 2.0 to 5.0 MPa. The shear modulus of the bearings is automatically set by the program based on the manufacturer's specifications or any other experimentally justified value for the case of non-commercial bearings after appropriate testing, as described in section 4.2. It is noted that the value generally suggested by Eurocode 8 [4] is 1.0 MPa. However, Eurocode 8 also provides a lower limit of 0.9 MPa and upper limit of 1.5 MPa to be used in two successive analyses that can lead to the maximum displacements or the maximum forces of the isolating system and the bridge piers respectively.

(c) Level of seismic demand: The user defines the level of seismic demand, based on the elastic response spectrum of Eurocode 8-Part 1, the relevant soil classification and importance factor and a peak ground acceleration of 0.16, 0.24 and 0.36 that corresponds to the seismic zonation of Greece; the latter being an open parameter to potentially comply with different levels of seismic hazard in other countries.

5.4 Decision process

The system automatically checks all bearings stored in the database against compression (through the resulting shear strain in the bearing) and the shear strains produced by the earthquake loading based on the compression and shear strain criteria described in Sections 3.2.1 and 3.2.2 and then ranks all eligible bearings that have passed the above checks according to the Optimal Performance criterion. The results are illustrated in a graph, of the $OP_{(i)}$ ratios with the section geometry. The same graph also illustrates the individual safety criterion value ($SC_{(i)}$) and total costs ($CC_{(i)}$) in order to facilitate the designer when making selections based on purely safety or cost criteria. The software also provides in a tabular form the following summary results: (a) the maximum displacement of the deck subjected to the design seismic action, and (b) the aforementioned safety criterion values, cost ratios and optimal performance indicators. Apart from the graph and the table, the software provides an output interface for each eligible bearing, showing the main dynamic characteristics of the analyzed bridge system, i.e. the effective stiffness of the resulting isolating system, the total weight of the superstructure, the effective period of the bridge, the design acceleration at the specific period, the design seismic displacement and finally, a video representation illustrating the fundamental mode of the bridge along the longitudinal direction.

5.5 Assumptions and limitations

The simplified analysis performed in the software considering the rigid deck model for the bridge, is applicable when the total mass of the piers is less than 20% of the total bridge mass, as prescribed by Eurocode 8. The bridges under design should also be straight or have small curvature in plan and small longitudinal inclination. The developed software is not limited by the choice of the deck cross section. The user can employ a default vertical deck load value equal to 200 KN/m, considering that the used combination of loads includes earthquake loading. Otherwise, the user should input an appropriate vertical deck load value if the particular deck does not correspond to the default value. The software can be used in all isolated bridges with elastomeric bearings. However, the software cannot be used in cases when monolithic pier-deck or abutment-deck connections are combined with seismic isolation in the bridge. This structural scheme represents a design alternative implemented in case of

long cast, in situ bridge decks or in irregular bridges, which have short piers and are usually protected from the deck's movements through isolation bearings.

As already mentioned, the software is designed for the preliminary design of the isolation of bridges with up to four spans. This restraint is not related with the seismic action, but mostly with the in-service induced movements of the deck, which become significant in bridges with total lengths greater than 150 m according to the limits imposed by various transportation agencies also described by [20]. It was finally decided that the work should be restricted to overpasses and typical small, and intermediate span continuous deck bridges, i.e. with a total length up to, say, 150m.

The bearings are assumed to be actually fixed in their feet, which means that the flexibility of the longitudinal seismic resisting system of the bridge is determined by the flexibility of the isolation. The piers with their foundations were considered to be quite stiff, as compared with the corresponding stiffness of the isolation interface. Therefore, the piers are not considered to participate in the seismic resisting system and they only receive the seismic actions of the bearings supporting the deck. It follows that the software is not recommended to be used in bridges with a flexible pier-foundation system, i.e. in bridges with slender and/or tall piers with flexible foundations. However, it can be underlined that seismic isolation with elastomeric, i.e. LDRB, bearings does not seem to be a design alternative for bridges with flexible pier-foundation systems.

Another assumption of the software concerns the bearings used for the support of the deck to the piers and abutments. The software has the ability to consider a number of bearings per support. This number does not have a restraint due to the calculation procedure used in the software. The software, however, considers that the number of bearings used for the isolation of the bridge deck is the same in all supports, and these bearings are all of the same type, e.g. they have the same cross section area and the same total thickness of the elastomer layers along deck. This assumption is considered to be rational as most bridge structures up to 150m, typically do not use an escalation of either bearings' areas or total thickness of the elastomer.

As far as the seismic action is concerned, the software considers that the isolation system is activated only during the longitudinal design earthquake. The response of the bridge in the transverse direction was assumed to be restrained by seismic links, which join the deck with the piers' heads. This assumption is deemed to be rational, since most bridges with isolated decks use seismic links [4] in the transverse direction, in which the in-service movements, due to creep and/or shrinkage [21] and pre-stressing [22], are negligible. Under the above assumptions, the longitudinal seismic action is transferred to the piers of the bridge through the isolating interface. In the transverse direction, capacity design stoppers transfer the total seismic action directly to the supporting piers without the interjection of the flexible isolation.

6 CONCLUSIVE REMARKS

The knowledge-based methodology developed for the preliminary design of the seismic isolation of bridges is presented in this paper. The proposed methodology is based on the current design provisions of Eurocode 8, but is also complemented by additional criteria set according to expert judgment, laboratory testing and recent research findings, while using a combined cost/performance criterion to select from a database of commercially available bearing products. It also offers the advantage that all possible selections of bearing sections can be considered as potential design solutions as opposed to the common preliminary design procedure, which due to time and complexity constraints investigates a limited number of design alternatives. The methodology is also implemented in a software whose efficiency is validated through more rigorous MDOF parametric numerical analyses as well as by using the case of a real bridge.

It is evident that the prediction success of the preliminary design process, that is proposed here, heavily relies on the extent of the contribution of the fundamental mode in the longitudinal direction, which, when dominant, yields the SDOF simplification as reasonable assumption. To sum up, it is believed that: a) the criteria imposed regarding compression stress limits, which are complementary to the ones prescribed in the codes, b) the automation of the process achieved through the developed software, which permits the investigation of hundreds of different bearing solutions, and c) the eligible bearing hierarchy provided through the proposed safety over cost (Optimal Performance) criterion, provide a significantly large number of potential design alternatives to be considered for the final selection. In this way, the proposed process can be seen as an effective preliminary design tool which is believed to lead to the quicker and more reliable estimate of the optimal bearing selection and seismic response of a highway overpass bridge either in the stage before its final design or when such an existing bridge is checked for upgrading its seismic performance utilizing such an isolation scheme.

The extensive experimental sequence verified the quality of the production process of a local producer of elastomeric bearings by subjecting slices of these bearings, being sampled during production, to the loading sequence specified by the International Standard ISO 22762-1 (2005). As can be concluded from these tests, for shear strain amplitudes lower than 250%, the variation of the frequency and shear strain amplitude did not influence the stiffness and strength properties of the tested specimens. For strain amplitudes larger than 250% the prevailing mode of failure was that of the debonding of the elastomer from the steel plating. Next, the experimental investigation examined the cyclic shear strain performance of locally produced prototype elastomeric bearings by subjecting samples of such bearings to the test sequence specified by the same International Standard ISO 22762-1. This time, the influence of aging was also investigated. As can be deduced from the measured behavior, aging resulted in a small increase of the axial (vertical) stiffness and a small decrease of the shear (horizontal) stiffness of the tested elastomeric bearings. More specimens must be tested to validate further these findings.

7 ACKNOWLEDGEMENTS

This research was conducted in the framework of the Regional Innovation Pole of the Region of Central Macedonia in northern Greece which was established in 2006, in the city of Thessaloniki. The project was funded by the General Secretariat of Research and Technology of the Greek Ministry of Development; its support is gratefully acknowledged. Ms. M. Geraiki's contribution in the parametric validation of the software and the help of the personnel of the Laboratory of Strength of Materials and Structures of Aristotle University of Thessaloniki during the experimental tests are also acknowledged. The authors also wish to thank P. Skalkos for his contribution to the development of this specific software.

Abstract.

The Evripos bridge in central Greece, connects the island of Evia to the mainland. The cable-stayed section of the bridge is 395m in length, with a central span of 215m and side-spans of 90m each. The deck, 13.5m in width, is at 40m above sea-level, suspended by cables from two, 90m high pylons. A permanent accelerometer special array of 43 sensors was installed on the bridge in 1994 by the Institute of Engineering Seismology and Earthquake Engineering. Two triaxial sensors have been monitoring the free-field (near pier M4) and pier M5 base response on the mainland (Boeotean) coast and two others the respective locations (pier base M6 and free-field near pier M7) on the Euboean coast. Since then the bridge's behaviour to seismic excitations has been continuously monitored and investigated. From various earthquake events recorded at the site, it became obvious that the excitation at each of the aforementioned locations differs, with the lowest peak acceleration values observed at site M7 for all three components, independently of magnitude, azimuth and epicentral distance of the earthquake, a fact that can be attributed to local site conditions. In the present research effort, an investigation of the dynamic response of the Evripos bridge due to the asynchronous base excitations along its supports is carried out. Comparisons are made with the conventional design procedure of assuming a common (synchronous) base excitation at all the supports and interesting conclusions are drawn regarding the impact of spatially variable ground motion on the seismic response of the particular bridge.

1 INTRODUCTION

During the last decade, time history analyses have become increasingly popular both for design and research purposes, especially for the case of complex and/or important bridges. This trend has significantly improved the analysis rigor and facilitated the consideration of various physical phenomena that were too complicated to be taken into account in the past. One of those issues, is the identification of a realistic, spatially variable earthquake ground

motion (SVEGM) which can be used for the excitation of the bridge for design or assessment purposes. As it is well known, this phenomenon may affect the seismic response of long bridges, or of bridges crossing abruptly changing soil profiles; however, its potentially beneficial or detrimental impact on the final bridge performance cannot be easily assessed in advance ([1]-[5] among others).

One major difficulty in assessing the spatially variable patterns of earthquake ground motion is the complex wave reflections, refractions and superpositions that take place as seismic waves travel within inhomogeneous soil media. Different analytical formulations have been proposed in the past, but the inherent multi-parametric nature of wave propagation and soil-structure interaction makes it practically impossible to predict the spatially varying earthquake input along the bridge length in a deterministic manner. Dense seismograph arrays, primarily in Taiwan, Japan and the U.S., have contributed in shedding some light into this problem which can be primarily attributed to four major factors that take place simultaneously, i.e., wave passage effect, the extended source effect, wave scattering and attenuation effect [6]. The operation of these arrays, also led to the development of numerous empirical, semi-empirical and analytical coherency models, fit to represent the decaying signal correlation with distance and frequency.

Despite the significant impact of the aforementioned analytical approaches and experimental evidence, a reliable and simple methodology for the prediction of the effects of asynchronous motion on bridges is still lacking. Even modern seismic codes like Eurocode 8 deal with the problem through either simplified code-based calculations or indirect measures involving larger seating deck lengths [7].

An interesting case for the study of this phenomenon using recorded data is the Evripos cable-stayed bridge, which has been permanently monitored by an accelerometer network since 1994 [8], [9]. A series of minor to moderate intensity seismic events have been recorded by this network, providing a useful set of motions recorded both in the vicinity of the structure and on specific locations on the structure and its foundation. Scope of this study therefore, is to:

- (a) Make use of the recorded data in order to investigate the nature of earthquake ground motion and the effects of its spatial variation on the dynamic response (in terms of forces and displacements) of the particular cable-stayed bridge.
- (b) Attempt to correlate the beneficial or detrimental effect of asynchronous motion with the excitation of higher structural modes observed under multiple-support earthquake input.

The description of the bridge, its monitoring system as well as its response under various asynchronous ground motion records, is presented in the following.

2 DESCRIPTION OF EVRIPOS CABLE-STAYED BRIDGE

The Evripos bridge, a 694.5m R/C structure, connects the Euboean coast in the island of Evia to the Boeotean coast in continental central Greece (Figure 1). It is composed of three parts, the central cable stayed section and two side (approaching) parts made of pre-stressed R/C beams that rest on elastomeric bearings. The central section of the bridge is divided into three spans of length 90m, 215m and 90m respectively, while the deck (of 13.50m width) is suspended by the 90m height pylons M5 and M6 with cables. The displacements of the deck along the longitudinal direction are permitted in piers M4 and M7 while those in the trans-

verse direction are blocked [8], [9]. In the present study, it is only the central cable-stayed section that is examined.

As already mentioned, the Evripos cable-stayed bridge behavior is constantly monitored through a special accelerometer array installed by the Institute of Engineering Seismology and Earthquake Engineering (ITSAK). The network is composed by four triaxial accelerometers installed at the base of the bridge, in particular, on the pile caps of piers M5 and M6 and on soil surface in areas adjacent to piers M4 and M7. There are also 31 additional uniaxial accelerometers installed on the superstructure, for system identification purposes. It is noted that all sensors have common time and common trigger settings [8],[9] thus permitting signal processing and correlation. The Finite Element model of the bridge is illustrated in Figure 2.

Figure 1: The central section of the Evripos cable-stayed bridge.

Figure 2: Finite model of the Evripos cable-stayed bridge.

3 EARTHQUAKE STRONG MOTION DATA AVAILABLE ON SITE

Due to the significant overall length of the central section of the bridge that is almost 400m in total, an effort is made to process specific groups of records available on-site in order to investigate the impact of spatial variability of seismic ground motion. For this purpose, a set of four ground motions was used, as recorded during the Athens earthquake, that occurred on 7/9/1999 at a source-to-site distance of approximately 50km with a surface Magnitude $M_s=5.9$. The recorded time histories are presented in Figure 3 where the longitudinal, transverse and vertical component is illustrated in different rows for each location. Having ensured that the common time and common trigger condition was fulfilled, the records were first filtered in the frequency range 0.65-25Hz in order to remove the influence of the vibration of the superstruc-

ture which was transmitting waves back to the soil due to inertial soil-structure interaction. Then, the coherency between all pairs of records was computed using a GUI-based, Matlab script written for this purpose. For each individual record, the power spectrum was computed after appropriate smoothing using an 11-point Hamming window as proposed by Abrahamson for 5% structural damping [10], [11]:

$$\bar{S}_{jj}(\omega_n) = \sum_{m=-M}^{+M} W(m\Delta\omega) \hat{S}_{jj}(\omega_n + m\Delta\omega) \quad (1)$$

where ω_n is the discrete frequency, $W(m\Delta\omega)$ the (Hamming) spectral window and \hat{S}_{jj} the unsmoothed power spectra.

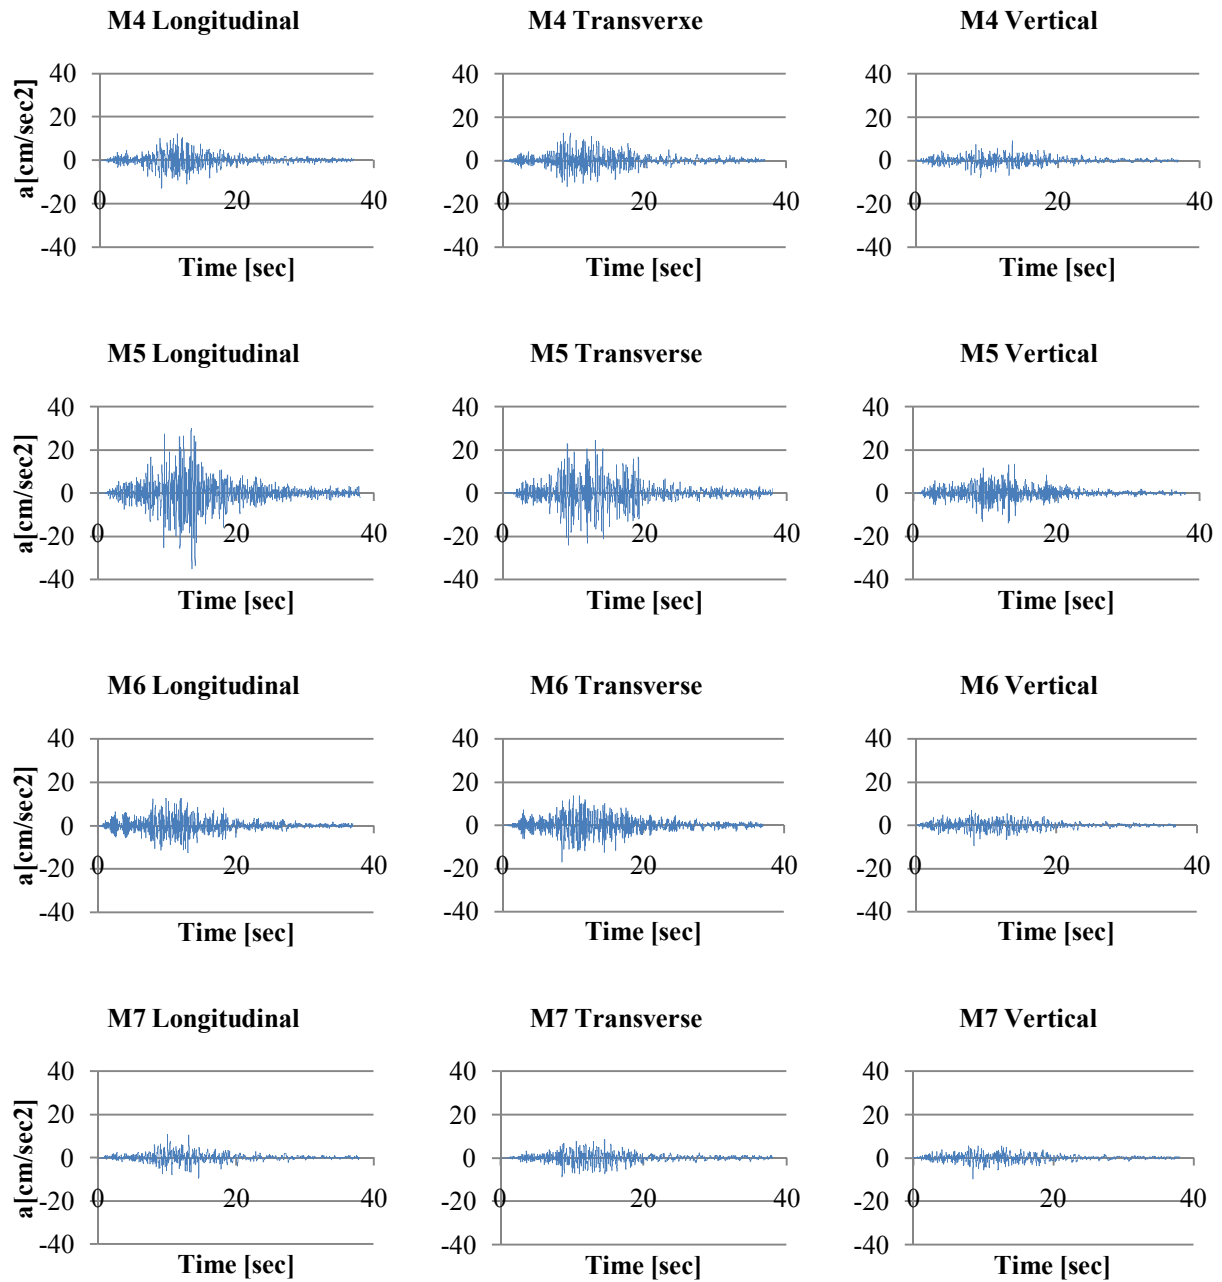

Figure 3: Horizontal and Vertical components of the strong ground motions recorded at the base of piers M4, M5, M6 and M7 due to the 1999 $M_s=5.9$ Athens earthquake.

Similarly, the smoothed cross spectral densities were calculated for all six pairs of records M_{jk} (i.e., M4-M5, M4-M6, M4-M7, M5-M6, M5-M7, M6-M7) according to the following expression:

$$\bar{S}_{jk}(\omega_n) = \frac{2\pi}{T} \sum_{m=-M}^{+M} W(m\Delta\omega) \Lambda_j(\omega_n + m\Delta\omega) \Lambda_k(\omega_n + m\Delta\omega) \exp \{i[\Phi_k(\omega_n + m\Delta\omega) - \Phi_j(\omega_n + m\Delta\omega)]\} \quad (2)$$

where Λ_j and Λ_k is the Fourier amplitude in stations j and k respectively and Φ_j , Φ_k is the corresponding phase. The lagged coherency, expressing the correlation of the records among all stations, can then be calculated as:

$$|\bar{\gamma}_{jk}^M(\omega)| = \frac{|\bar{S}_{jk}^M(\omega)|}{\sqrt{\bar{S}_{jj}^M(\omega) \cdot \bar{S}_{kk}^M(\omega)}} \quad (3)$$

The diagrams of lagged coherency in the frequency range 0-10Hz, where the frequencies of all significant modes of a structure are expected to be, computed individually for the longitudinal, transverse and vertical component of the recorded motions are illustrated in Figure 4 for pairs M4-M5, M4-M6 and M4-M7, in Figure 5 for pairs M5-M6 and M5-M7 and in Figure 6 for pair M6-M7. As anticipated, the coherency loss increases with increasing separation distance and frequency.

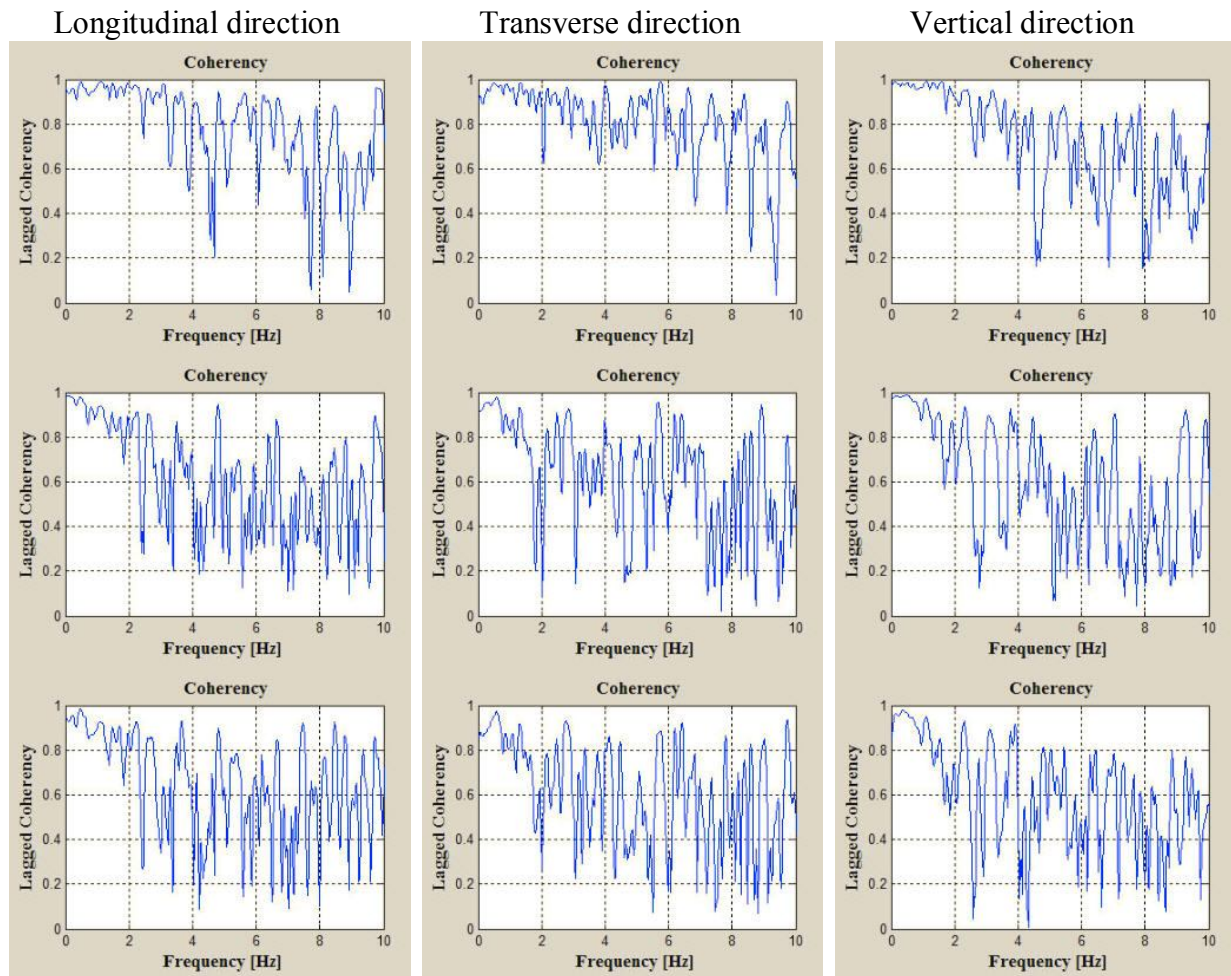

Figure 4: Lagged coherency of motions recorded between piers M4-M5 (at distance $l=90\text{m}$, top), M4-M6 (at distance $l=305\text{m}$, middle) and M4-M7 (at distance $l=395\text{m}$, bottom).

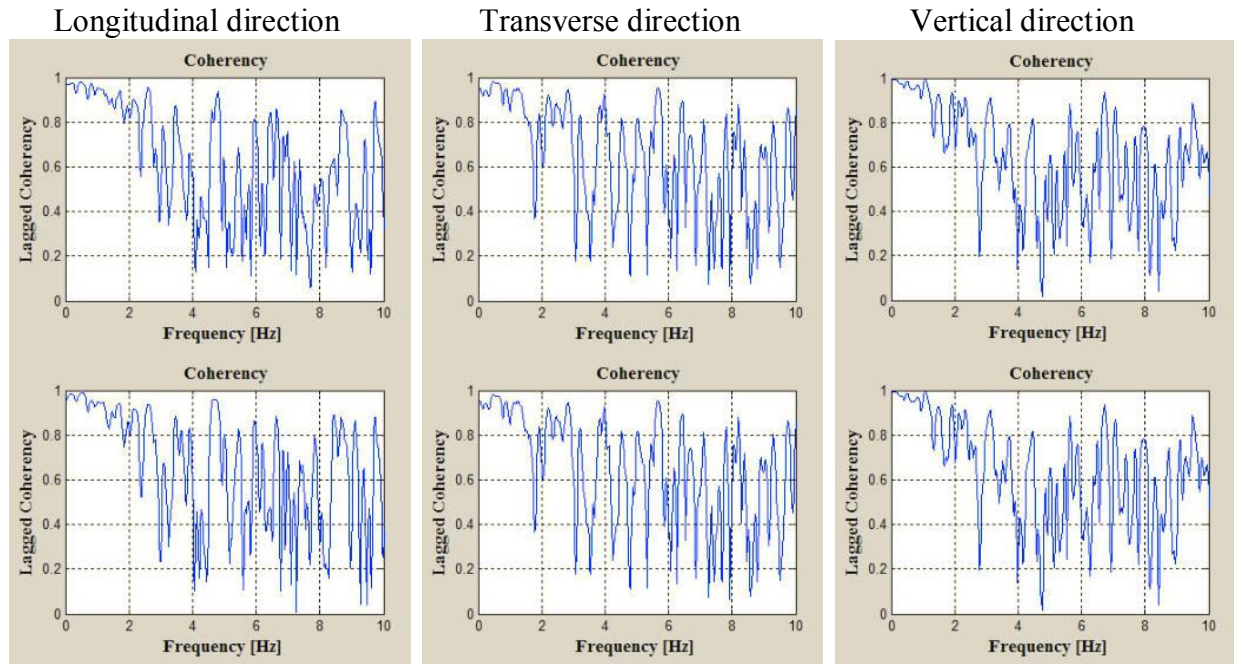

Figure 5: Lagged coherency of motions recorded between piers M5-M6 (at distance $l=215\text{m}$, top), and M5-M7 (at distance $l=305\text{m}$, bottom).

Figure 6: Lagged coherency of the motions recorded between piers M6-M7 (at distance $l=90\text{m}$).

The comparison of the computed incoherencies with one of the most commonly used patterns proposed by Luco and Wong [12] is made in Figure 7, where the lagged coherency is given by the following expression:

$$|\gamma(\xi, \omega)| = e^{-\left(\frac{v\omega\xi}{v_s}\right)^2} = e^{-a^2\omega^2\xi^2} \quad (4)$$

In eq. (4), the coherency drop parameter a controls the exponential decay and ξ is the distance between the two stations examined. Typically, a is taken equal to $2.5 \times 10^{-4} \text{sec/m}$; however, comparison for the case of motions recorded along the longitudinal direction at the bases of the piers M4 and M7 (i.e., at separation distance $\xi=395\text{m}$) reveals that a value of a equal to $0.5 \times 10^{-4} \text{sec/m}$ leads to better matching with the observed incoherency.

Figure 7: Comparison between observed and predicted coherency loss for different values of the Luco and Wong model [12].

4 ANALYSES PERFORMED

Most analytical or numerical studies investigating the effects of spatial variability of earthquake ground motion on the response of bridges compare the results of multiple-support excitation analysis with those of a reference condition which typically assumes synchronous excitation among all bridge supports. The comparison can then be made in terms of a ratio of the action effects (forces or displacements) of specific structural components over the response under synchronous conditions.

In the case examined herein though, the fact that the ground motions have been recorded at the bases of the four bridge piers leads to a realistic excitation scenario with respect to the actual seismo-tectonic and soil conditions of the site under study but at the same time makes it difficult to assume the corresponding compatible “synchronous” excitation conditions. One option would have been to pick one of the recorded motions and apply it synchronously at all pier supports; however, this option is limited by the fact that the available records show significant discrepancy in terms of both their PGA and spectral amplification, primarily due to local site effects at the location of pier M5 (Figure 8).

In order to overcome this difficulty, it was decided to adopt the following procedure: as the strongest component of the motions recorded is in the longitudinal direction, all records (in all components) are scaled (Table 1) to the average spectral acceleration of all records at period $T=1.64\text{sec}$, which is the period of the highest contributing mode, activating 76% of the mass in the longitudinal direction (Table 2). Then, four different “synchronous” excitation scenarios are developed, assuming each time that the scaled motions in piers M4, M5, M6 and M7 respectively, are applied uniformly at all supports. Given the aforementioned scaling, it is deemed that the four different versions of uniform excitation are compatible in terms of spectral amplification (at least at the period of vibration that is affected by the dominant earthquake component), while the fact that all the resulting scaling factors are close to unity, guarantees that the scaling-induced dispersion is limited.

Based on the above, five non-linear dynamic analyses of the Evripos cable-stayed bridge are performed using the computer program SAP2000 [13], that is one using the recorded set of motions and four considering the aforementioned compatible “synchronous” excitation

scenarios. All three components of the motions were applied simultaneously. The geometrical non-linearity induced by the bridge cables was considered assuming tension-only capabilities and the initial cable stress state due to dead loading was applied through non-linear staged-construction static analysis.

Beam elements were used to model the piers, while the bridge deck was simulated by shell elements. Piers were assumed fixed at their bases while the supporting conditions at the two bridge edges were considered as rolled in the longitudinal direction and pinned in the transverse.

Table 2: Dynamic characteristics (eigenfrequencies and corresponding modal contribution) of the Evripos cable-stayed bridge.

The amplitude of the seismic moments (i.e., the earthquake-induced bending moments at the bases of piers M4 and M7 and at one of the two columns at each pier M5 and M6), the displacements at the top of each pier and the displacements in the middle of the deck are examined for all asynchronous and synchronous excitation cases previously presented.

Figure 9 presents the comparison between the computed seismic moments at the base of pier M6 using the Athens 1999 (asynchronous) recorded motions, and those computed through the four “synchronous” excitation scenarios, that is, by the uniform application of records M4, M5, M6, and M7 respectively. The comparison of the maxima among all cases are summarized in Table 3. It can be seen that the moments M_2 developed at the base of pier M6 transversely to the bridge plane, due to the asynchronous recorded ground motions is systematically lower regardless of the “synchronous” excitation pattern adopted. As anticipated, this is more intense (approximately 32%) for the synchronous case involving the uniform application of record M5, which, despite of the scaling to a common level of spectral amplification, still corresponds to the highest PGA among the records at all locations. On the other hand, the situation reverses for the bending moments M_3 within the bridge plane and the asynchronous excitation results in higher levels of stress in all cases, reaching 43% increase in the extreme case of applying record M7 uniformly at all support points. The respective results for pier M5 are also summarized in Table 3. It can be seen that seismically-induced bending moments in both directions are decreased when assuming uniform excitation conditions independently of the scenario adopted.

As far as the displacements are concerned, the corresponding time histories are plotted in Figures 10, 11 and 12 for the middle of the central span and the top of the pylons M5 and M6 respectively, while the maximum in time displacements are compared in Tables 4, 5 and 6. More specifically, asynchronous excitation is systematically favorable for the span middle deck displacements which are decreased up to 36%, 45% and 63% along the three principal direction U_x , U_y and U_z . The same trend is also observed for the case of the top of the M5 pylon - though to a lesser degree - and with the exception of a minor (6%) increase in vertical displacements for one of the scenarios studied. In contrast to the above, the displacements at the top of pylon M6 derived under the asynchronous recorded ground motions are generally increased compared to the synchronous case and are almost double (increased by 82%) when compared to the uniform application of record M4. Vertical displacements are also increased up to 11% due to asynchronous motion.

Table 6: Maximum absolute values of displacements [cm] which developed due to asynchronous and synchronous (M4, M5, M6, M7) excitation at the pier M6 top. In last row is presented the rate of increase or decrease.

These results indicate that the complex inherent nature of ground motion incoherency are strongly correlated to the dynamic characteristics of the excited structure and do not systematically lead to uniform increase or decrease of the corresponding action effects. For this reason, it was deemed useful to investigate further the significance of the potential excitation of higher structural modes for which there are strong indications ([2], [7], [14]) that it is one of the key features of multiple support excitation.

It has to be noted that due to the cable suspension of the Evripos bridge, the associated geometrical non-linearities make it difficult to spot specific, load independent, modes of vibration. However, it was computationally verified that the low level of excitation of the event considered in this work (which does not exceed 0.032g) does not lead to any untensioning of the suspension cables, thus ensuring that at least for the particular earthquake intensity, the eigen-frequencies summarized in Table 2 still hold.

In order to examine the higher modes excitation, the Fourier spectra of the accelerations were plotted at the same points as for the displacements (Figures 13 and 14). As the analysis is in fact linear elastic, (since the dynamic characteristics remain constant during the studied excitation), the frequencies where the peaks of the Fourier spectra are observed coincide with the eigen-frequencies of the structure. In principle, one would expect that the decreased response due to asynchronous excitation observed in Figures 9-12 should correlate well with the decrease of the Fourier amplitudes at the corresponding frequencies of the associated modes.

Indeed, Figure 13 shows a clear reduction in the Fourier amplitudes of acceleration at the middle of the central span, at the period of 1.64 sec, which corresponds to the 4th mode activating 76% of mass in the longitudinal direction when the response under the recorded asynchronous excitation is compared to that of the uniform application of the M5 record. This is in good agreement with the decrease in both bending moments and displacements summarized in Table 4. The same correlation is observed with respect to the vertical direction where the Fourier amplitudes are decreased at periods 1.30 sec and 1.06 sec corresponding to the 5th

mode (activating 6.5% of mass in the vertical direction) and 9th mode (activating 37% of mass in the vertical direction) respectively; a fact that is also in line with the favorable effect of asynchronous excitation in Table 4.

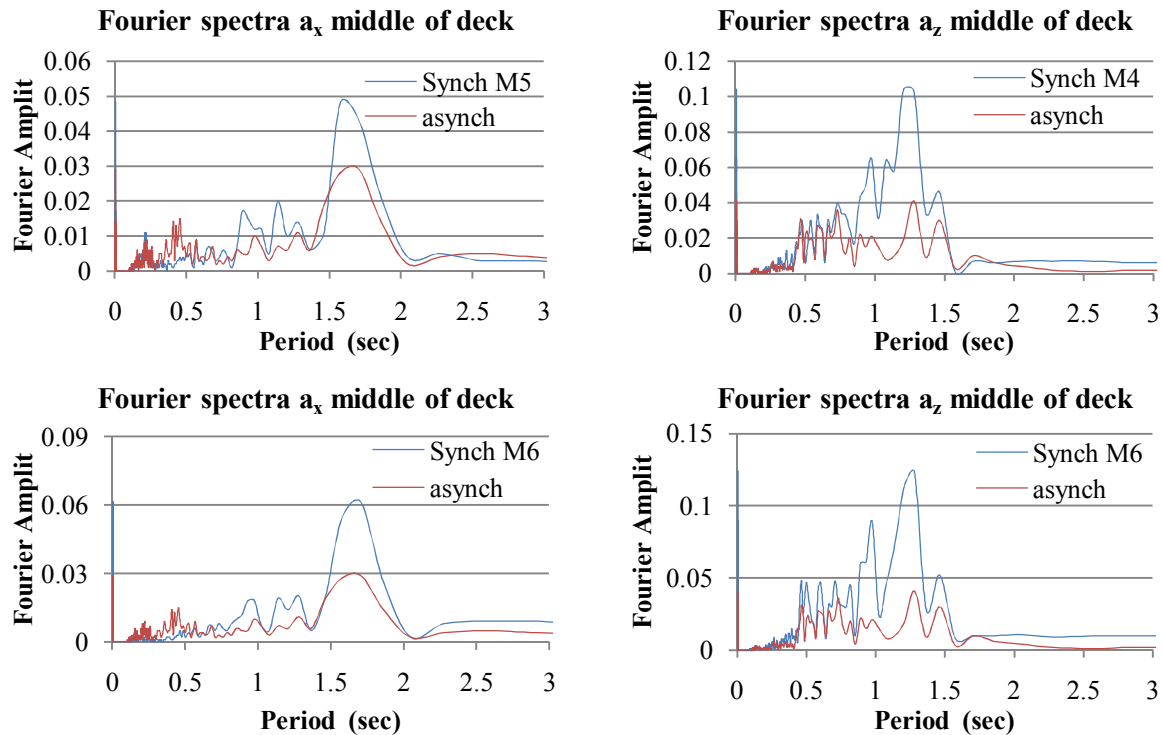

Figure 13: Comparison of the Fourier spectra of the accelerations computed in the longitudinal and vertical direction at the middle of the deck using the Athens 1999 (asynchronous) recorded motions, with those computed by the four “synchronous” excitation scenarios (uniform application of records M4, M5, M6, M7 respectively).

Similarly to the above, when the comparison is made on the basis of the uniform application of record M5, the reduction of the Fourier amplitudes at periods 2.38 sec (2nd mode-activating 20% in the longitudinal direction) and 1.64 sec (4th mode-activating 76% in the longitudinal direction) is confirmed with the response reduction in Table 4. Again, good correlation is observed for the vertical direction, where the reduction of the Fourier amplitudes takes place at periods 1.3 sec (5th mode-activating 6.5% in the vertical direction), 1.06 sec (9th mode-activating 37% in the vertical direction) and 0.82 sec (15th mode-activating 68% in the same direction) and the comparison of the maxima in the time domain depicted in Table 4. It is noted that the same trend is also observed in numerous locations of the bridge.

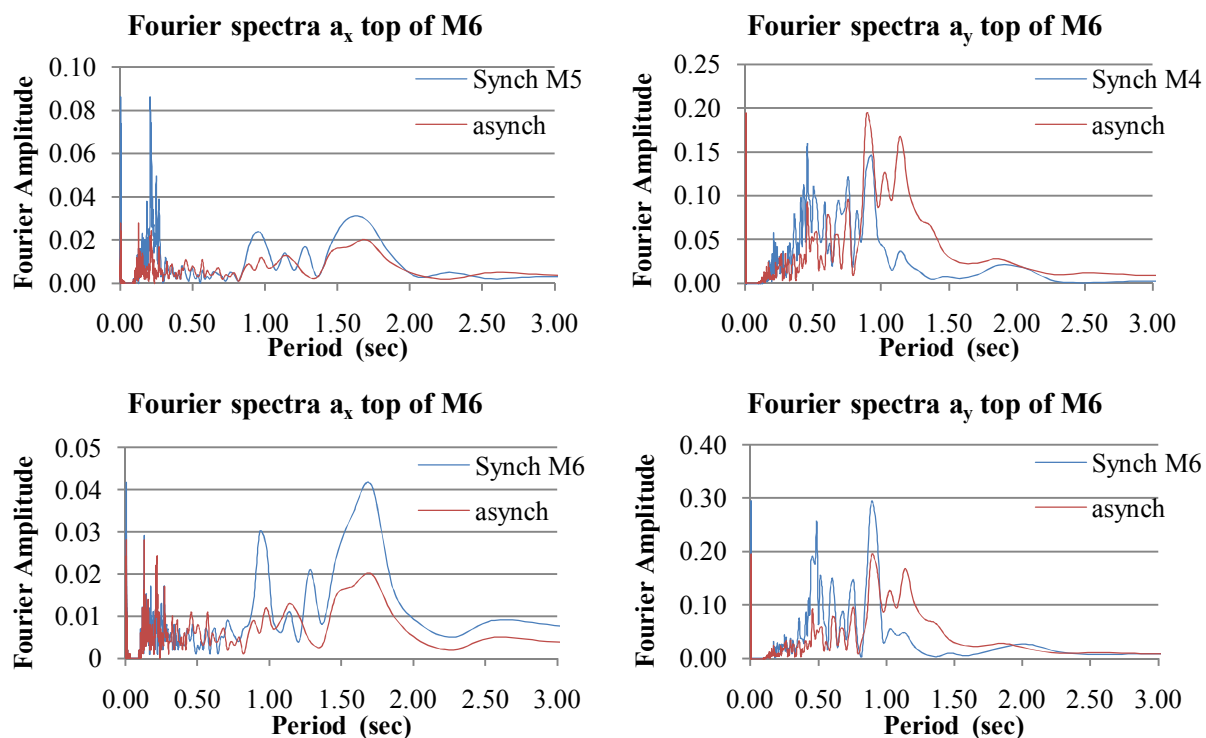

Figure 14: Comparison of the Fourier spectra of the accelerations computed in the longitudinal and vertical direction at the top of the pylon of M6 using the Athens 1999 (asynchronous) recorded motions, with those computed by the four “synchronous” excitation scenarios (uniform application of records M4, M5, M6, M7).

Figure 15: Characteristic antisymmetric (mode 8: $T=1.11\text{sec}$, $R_z=10\%$, middle) and symmetric (mode 11: $T=0.89$, $U_y=10.7\%$, left) mode shapes, excited due to asynchronous excitation.

Figure 14 presents the Fourier spectra of the accelerations in the longitudinal and transverse directions at the top of the M6 pylon. When the comparison is made on the basis of the uniform application of the M5 record, a reduction of the Fourier amplitudes is first observed at periods 2.38 sec (corresponding to the 2nd mode, activating 20% of the mass in the longitudinal direction) and 1.64 sec (4th mode, activating 76% of the mass in the same direction), which justifies the reduction of the displacements documented in Table 6. On the other hand, when the transverse direction is examined, a remarkable amplification is observed at period 0.89 sec corresponding to the symmetric 11th mode, activating 10.7% of the mass in the trans-

verse direction, while significant amplification is also depicted at period $T=1.11$ sec which corresponds to the antisymmetric 8th mode (activating 9.8% of the mass around the z axis). Both mode shares are illustrated in Figure 15 where it is clearly seen that the transverse displacement of the top of the M6 pylon is very much affected by the excitation of the particular modes. As a result, the good correlation between the excited higher modes of vibration due to asynchronous earthquake motion and the corresponding impact of the latter on the overall bridge response is also confirmed for the case of the particular cable-stayed bridge. This observation is deemed interesting, especially bearing in mind that it has been made for the case of a real bridge using recorded earthquake ground motions.

5 CONCLUSIONS

The scope of this study was to examine the effects of asynchronous excitation on the Evripos cable-stayed bridge, utilizing the recorded response at four locations of the accelerometer network maintained by ITSAK, due to the $M_s=5.9$, 7/9/1999 Athens earthquake. The records were filtered to remove inertial interaction effects and their coherency was computed for all available record pairs. A detailed finite element model of the cable-stayed bridge was developed and its response was computed using both the recorded motions and four synchronous excitation scenarios. The comparative study of the results indicates that:

- For the particular bridge studied, spatial variability of seismic ground motion has a generally favorable effect, at least on the pier base bending moments and the displacements middle of the central span deck. Apparently, the extent of this beneficial phenomenon is very much dependent on the assumptions made regarding the definition of the “synchronous” excitation, which, in contrast to the actual, recorded asynchronous case, is not obvious.
- There are specific cases (i.e., out-of-plane bending moments and displacements at the top of the two bridge pylons) where the asynchronous excitation has a clearly critical effect.
- In all cases, the observed deamplification or amplification of the bridge displacements was verified by the reduced or increased amplitude of the Fourier spectra respectively, at selected frequencies, which correspond to specific modes that have a strong impact on the vibration of the structure along the directions examined. It is believed that, given the complexity of the problem studied, the potential excitation of higher modes due to asynchronous excitation may be a key tool for understanding the role of spatial variability of earthquake ground motion on the overall seismic response of bridges.

Abstract. *The paper presents experimental and analytical studies on developing high-performance (i.e., high-energy absorption) BRBs for steel bridge structures. Low-cycle fatigue tests of four BRB's specimens with different constant strain amplitudes and with different constraints on the core brace were conducted as benchmark experiments in order to evaluate the results of the simulations. Both half and whole models of beam elements are proposed with and without taking into account the symmetry of the brace member. Experimental and analytical results show that the BRB's specimens with the stoppers possess better low-cycle fatigue performance than the specimens without the stoppers. The CID performance of steel BRBs with the stoppers even under the strain amplitude, larger than 3%, can meet the requirements of High-performance BRBs but the CID performance of steel BRBs without the stoppers cannot meet the requirements of High-performance BRBs. The friction coefficient of 0.075 is regarded as the right value for the simulations and half and models can effectively simulate the mechanical behavior of the BRB with or without the stoppers.*

1 INTRODUCTION

In the last few decades, the recent trend of seismic design methodology for steel building structures is that the primary members of building structures almost remain elastic and most of the inelastic deformations are enforced to occur in some energy absorption members, such as bracing members. Residual deformations of building structures after a severe earthquake could be reduced based on this design philosophy because most of main members have not been damaged during the earthquake excitation.

This design philosophy has been gradually implemented and refined in steel bridge structures. Developing a reliable method of designing the energy absorption equipment is indispensable. One way is to utilize some lateral or diagonal bracing members in a bridge structure as energy absorption members. Members in the lateral bracing system will be performed under cyclic compression and tension so that they should have high energy absorption capacity. Therefore, in order to obtain a stable performance, the global buckling of bracing members must be restrained by restraining cover members. This is the buckling-restrained brace (BRB), which attracts more and more attentions, because it does not buckle in compression but yield in both tension and compression and represents an effective energy absorption mechanism for damping of engineering structures with low cost.

As an axial-type damping device, BRBs are widely studied on component behavior and system applications in building [1, 2] and bridge engineering [3]. Test results in references[4, 5] show that BRBs process good cumulative inelastic ductility capacity before failure of the core segment, larger than the minimum required value of 200 by AISC seismic provisions[6]. It has been indicated from recent research series by the authors[3, 7] that light weight BRBs were employed to replace insufficient lateral braces and cross diagonal braces for retrofiting an existing steel arch bridge, which leads to damage concentration in sacrificing damping devices and mitigates damage of main structures.

Based on authors' past researches, the concept of high-performance BRBs (HPBRBs) is proposed that no replacement is needed during the lifecycle of bridges and it is likely to suffer three times of strong earthquakes without severe damage[8]. Therefore, besides general performance requirements for BRBs used in building engineering, additional special performance requirements for HPBRBs in bridge engineering are summarized as follows [8]: (1) Stable hysteretic characteristics and high energy dissipation capacity; (2) High deformation capacity; (3) High low-cycle fatigue strength; (4) Easy fabrication and construction with low cost; (5) High durability; (6) No need of replacement. Moreover, two performance indices for high-performance BRBs under strong earthquake excitations, the target maximum strain and cumulative inelastic strain, are recommended as 3% and 70%, respectively.

In order to meet the requirements of HPBRBs, series of low-cycle fatigue tests are performed to evaluate the light-weight bolt-assembled steel BRBs proposed by authors[9, 10]. During the experiment, the constraints of the flat core brace, such as the stopper pins used to prevent the relative displacement between the core brace and the restraining members, attracted our attentions and obviously affected the low-cycle fatigue performance verified by the contrastive low-cycle fatigue tests.

In this paper, the experiment, including four steel BRB's specimens looked as the benchmark tests, is firstly presented. These specimens are selected from a series of low-cycle fatigue tests[11] and used to validate both half and whole models of beam elements, considered with and without taking into account the symmetry of the brace member. Details of the experimental and analytical results are given as follows. All the tests were performed at the Advanced Research Center for Seismic Experiments and Computations (ARCSEC) at Meijo University.

2 TEST SPECIMENS AND PROGRAM

As shown in Figure 1, light-weight steel BRBs mainly consist of a steel plate brace member (BM), a pair of restraining members (RMs) connected by high-strength bolts through two filler members, and unbonding material stuck to the brace member as the isolation material in order to reduce the friction between the BM and RMs.

Figure 1: Assemblage of steel BRBs.

2.1 Brace member

The full view of the BM is shown in Figure 2, geometric dimensions and structural properties are listed in Table 1. A flat steel plate is used as the BM, and aiming at well connection to the test equipment, cruciform sections at both ends are expanded by welding 12mm thick rib stiffeners to each side of the plate. The BM is made of SM400A mild steel. Three JIS No.1-typed test pieces for each series are made from the same steel of the BM and average values tested as material constants are listed in Table 2, respectively. At the center of FE-4.0 and FT-3.5 specimens' BMs, two welded stoppers of 9 mm in diameter and 30 mm in height are used to prevent the relative movement between the BM and RMs in the longitudinal direction. But there are nothing at the center of FT-3.5(NS) and FT-4.0(NS) specimens.

Figure 2: Dimensions of brace member.

Series	Specimen	Steel Type	L	B	t	$A(\text{mm}^2)$	λ	δ_y	Stopper
S-I	FE-4.0	SM400A	1375	99.8	10.3	1028	457	1.91	Yes
	FT-3.5			100.2	10.6	1060	438	1.91	Yes
S-II	FT-3.5(NS)			100.3	10.2	1026	461	1.91	No
	FT-4.0(NS)			100.0	10.6	1060	438	1.91	No

Note: L = length of brace member without cruciform part; B = width; t = thickness; A = sectional area; λ = slenderness ratio on weak axis; P_y = yield axial load; δ_y = Nominal axial yield displacement. Unit: mm.

Table 1: Geometric dimensions and structural properties of BMs.

2.2 Restraining member

Figure 3 gives cross-sectional details of the BRB. The BM is sandwiched by a pair of RMs, and small gaps, d and d_0 , are provided between the BM and RMs or filler members. Geometric dimensions and structural properties of RMs are listed in Table 3. The same SM400A mild steel is used for RMs and filler members made of flat steel plates. Nominal values of gap widths are given in Table 3, together with measured material properties of RMs.

Figure 3: Cross-sectional details of BRB.

Series	Steel Type	E (GPa)	σ_y (Mpa)	ε_y (%)	σ_u (Mpa)	ε_u (%)	ν
S-I	SM400A	210	291	0.139	433	30.2	0.285
S-II		209	251	0.130	409	29.2	0.280

Note: E = Young's modulus; σ_y = yield stress; ε_y = yield strain; σ_u = tensile strength; ν = Poisson ratio.

Table 2: Material constants of brace members.

Table 3: Geometric dimensions and structural properties of restraining members.

2.3 Testing setup

As shown in Figure 4, the specimen is horizontally pinned by high-strength bolts between two rigid pillars while the BM is horizontally placed. The loading is applied by two jacks parallelly arranged in the vertical direction. The edge of specimens is well treated to avoid eccentric axis load. Before installing specimens, the initial deflection of the specimen is measured in the direction perpendicular to the plate plane so that the initial deflection could direct downward. During a typical experiment, axial displacements of the restrained yielding segment were monitored using eight displacement gauges. These gauges were mounted on both ends of the specimen and displacements were collected by a digital data acquisition system.

2.4 Loading patterns

In the present study, a tensile and compressive alternative cyclic loading controlled by the axial strain of specimens is illustrated in Figure 5. Two cycles of the axial loading of the yield strain amplitude are firstly imposed as an evaluated procedure for testing the specimen and system. For this reason, counting of the cycles starts subsequently. As shown in Figure 5, the constant strain amplitude specified in Table 4 is imposed cyclically until the failure of the BM in the tests. When the loading displacement becomes steady, the strain control equals to the

displacement control. Therefore, we conducted the present fatigue tests by controlling the axial displacement.

Figure 4: Testing setup

Table 4: Test results of BRB's specimens.

3 TEST RESULTS

3.1 Experimental stress-strain relations

Overall experimental stress-strain curves of the BRBs' specimens are given in Figure 6. The tensile state of BRBs is displayed in the positive direction. The abscissa is the engineering strain, ϵ , defined as the relative displacement divided by the original length of both ends of the core plate, while the ordinate is the engineering stress, σ , defined as the axial force di-

vided by the original cross-sectional area of the core plate. The core plate indicates the portion of the BM where it behaves plastically. Test results of all the specimens are summarized in Table 4. In addition, stable stress-strain curves were obtained without overall buckling occurrence in the whole loading history of all the specimens even though the maximum strain amplitude was as large as 4%.

Figure 6: Stress-strain relations.

It is shown in the hysteretic curve of the FT-3.5 specimen with the constant strain amplitude that the first loop is hardly affected by the strain hardening effect while the others are remarkably influenced by the strain hardening effect. At the last loop, the strength decreases rapidly in the tensile state of the BM and then unloading is applied when the axial force falls down by over 10% of the maximum axial force. The same results can be observed in other specimens with the constant strain amplitude.

Hysteretic behaviors of BRB's specimens are unsymmetric in tension and compression, and the maximum absolute compressive stress is 21% to 37% larger than the maximum tensile stress. The reason for this behavior is explained as follows: with the strain amplitude increasing in the compressive state, the contact force and the friction between RMs and the BM increased under the multi-wave deformation.

As listed in Table 4, the failure cycle number N_f of the FT-3.5 specimen with the stopper under the same 3.5% strain amplitude decreased from 9 to 5 in contrast with the FT-3.5(NS) specimen without the stopper, while N_f of the FE-4.0 specimen with the stopper under the same 4.0% strain amplitude decreased from 7 to 4 in contrast with the FT-4.0(NS) specimen without the stopper. It is concluded that the stopper used to prevent the relative displacement obviously affects the low-cycle fatigue performance of steel BRBs.

3.2 Failure mode

Failure modes of the BMs are presented in Figure 7, while failure positions of all the test specimens are sketched out in Figure 7(e). It is clear that crack initiating from the mid-span of the BMs induced the failure of specimens. From the failure modes of the FT-3.5 and FE-4.0 specimens with the stoppers, crack began to appear on the side of the BM and propagate in the transversal direction, but from the failure modes of the FT-3.5(NS) and FT-4.0(NS) specimens without the stoppers, crack began to develop in the middle of the BM and the fold deformations were observed after the failure of the BRB's specimens. So, it is concluded that the stoppers have a noticeable impact on the failure of the BRB, and then the analytical models are proposed to simulate the behaviors of the BRB with or without the stoppers.

Figure 7: Failure modes of BRB's specimens

3.3 Cumulative inelastic deformation

A measure used in practice to describe the plastic demand on a BRB element is the cumulative inelastic strain, or alternatively, the cumulative inelastic deformation (*CID*). The *CID*, which is expression of the cumulative plastic deformation, is defined by

$$CID = \sum_i \Delta\beta_p^i \quad (1)$$

where, $\Delta\epsilon_p^i$ = plastic strain during each visit i into the inelastic range, as shown in Figure 8.

The *CID* values of all test specimens are summarized in Table 4. The calculation of the *CID* was achieved with an algorithm that detects local peaks and valleys in the strain history. *CID* values indicate that the *CID* performance of steel BRBs with the stoppers even under the strain amplitude, larger than 3%, can meet the requirements of high-performance BRBs but *CID* performance of steel BRBs without the stoppers cannot meet the requirements of high-performance BRBs.

Figure 8: Stress-strain loop.

4 PROPOSED MODELS

Figure 9: Analytical models based on beam element.

In order to simulate the mechanical behaviors of the BRBs with or without stoppers, two analytical models built in ABAQUS[12] are given as follows.

Considering that stoppers are welded on the BM, the mechanical behavior of the BRB is symmetric. So an elastic-plastic 2D model simulating the BRB with the stoppers is proposed and illustrated in Figure 9(a), where half a BRB is modeled under the symmetry condition. A pair of RMs is simulated as two 2D beams equally divided into 54 segments and the BM is also simulated using two 2D beams considering that it is easy to accurately simulate the contact between the BM and RMs. A number of rigid elements between the BM beams are used

to satisfy the linear plane assumption. The same elements are applied between the RMs to simulate high-strength bolts. Initial deflection of a sinusoidal pattern is considered with the maximum value of a , which is set to one thousandth of the length of the BM without cruciform part. The constant gap d between the RMs and the BM is assumed.

The unbonding material was stuck to the BM as the isolation material in order to reduce the friction between the BM and RMs. So, the rigidity of the unbonding material is neglected in this model. However, when one of the BM beams comes into contact with a RM beam, friction effects will exist between them. As shown in Fig. 6, the compressive force is over 20% larger than the tensile force, and therefore the static friction coefficient μ is considered in the model.

Moreover, the horizontal displacement and the rotation are restrained at the mid-span nodes due to symmetry conditions, the vertical displacement is restrained at the right end nodes and the rotation is restrained at the BM's end where the force is applied. A general purpose finite element analysis software ABAQUS is used with 2D Timoshenko beam element (B21) considering shear deformation[12]. The modified two surface model developed by the authors [13] is used for the constitutive law in the analysis.

Figure 9: Nonlinear spring force-relative displacement relation.

Because the stoppers were not welded in the FT-3.5(NS) and FT-4.0(NS) specimens' tests, the RMs of the steel BRB, were driven by the friction at the beginning of low-cycle fatigue tests, and were stopped because of the interaction between the RMs and the cruciform section part of the BM in the axial direction. Therefore, the second elastic-plastic model of a whole BRB is presented in Figure 9(b) and the different boundary conditions of the RMs are given. The four nonlinear springs are used to simulate this movement and the force-relative displacement relation of nonlinear springs is given in Figure 9. As shown in Figure 9, the nonlinear spring behavior is defined by a group of the stiffness coefficient and the displacement. The value of k_1 , about one thousandth of the axial stiffness of the RM, makes the RM free and the value of k_2 , equal to the axial stiffness of the RM, prevents the RM's movement. The displacement u_1 is decided by the gap between the RM and the cruciform section part of the BM, so u_1 is set to 32.5mm. The elements, initial deflection, friction coefficient and material constants are same to the first elastic-plastic model. In order to compare with each other conveniently, the first model is called *Half Model*, and the second model is called *Whole Model*.

5 COMPARISON WITH TEST RESULTS

5.1 Experimental data

In this section, low-cycle fatigue test results of the FT-3.5 and FT-3.5(NS) specimens will be conducted to evaluate the proposed analytical models. As shown in Figure 10, the maximum absolute compressive stress at the first loop of the FT-3.5(NS) specimen is about 5% larger than the FT-3.5 specimen, but it is nearly the same as the FT-3.5 specimen. It is considered that the difference of the first loop is affected by the constraint of the RM. However, the indifference of the last loop is considered to affect by two factors: one is that the stoppers of the FT-3.5 specimen had broken at last, and another is that the residual deformation of the previous loops had an effect on the last loop. So in the next section, we will only use the data of the first loop as the criteria to check the analytical results.

Figure 10: Stress-strain relations ($\mu=0.0$).

Figure 11: Stress-strain relations ($\mu=0.0$).

Figure 12: Stress-strain relations of *Half Models* ($\mu=0.0, 0.075, 0.1$).

Figure 13: Stress-strain relations of *Whole Models* ($\mu=0.0, 0.075, 0.1$).

Figure 14: Stress-strain relations ($\mu=0.075$).

5.2 Stress-strain relation

Stress-strain relations of *Half Model* and *Whole Model* are given together with the experimental data in Figure 11. Stress-strain relations of two analytical models are identical and symmetric in tension and compression when the friction between the BMs and the RM is neglected. However, the maximum absolute compressive stress of the first loop of the FT-3.5(NS) specimen is about 13% larger than the results of *Half Model* or *Whole Model*. It can be seen that if the friction is neglected in the analytical model, *Half Model* and *Whole Model* cannot simulate the experiment accurately, but from nearly the same hysteretic behavior, *Half Model* and *Whole Model* are proper.

Stress-strain relations of *Half Model* and *Whole Model* with different friction coefficients are given together with the experimental data in Figures 12 and 13. It is clear that with the friction coefficient increasing, *Half Model* and *Whole Model* can effectively simulate the mechanical behavior of the FT-3.5 and FT-3.5(NS) specimens. As shown in Figure 14, the friction coefficient of 0.075 is regarded as the right value for the following simulations.

5.3 Deformation of BM

The BM's deformations of *Half Model* and *Whole Model* with the same 3.5% compressive strain amplitude are compared in Figure 15. The multi-wave deformation of the *Half Model* is symmetric because of the symmetry conditions. It can be seen that the BM of *Half Model* has fifteen peaks and fifteen valleys, while the BM of *Whole Model* has seventeen peaks and seventeen valleys. So, some of wave peaks of *Whole Model* is sharper than the peaks of *Half Model*. It is considered to be one of the reasons why the failure life of the FT-3.5(NS) specimen is shorter than the failure life of the FT-3.5 specimen.

Figure 15: Deformation of brace member.

6 CONCLUSION

In this study, low-cycle fatigue tests of benchmark specimens with or without the stoppers were carried out to evaluate the proposed analytical models. The main results are summarized as follows:

- 1) Low-cycle fatigue tests were conducted to verify that the BRB's specimens with the stoppers possess better low-cycle fatigue performance than the specimens without the stoppers.
- 2) It was experimentally indicated that the *CID* performance of steel BRBs with the stoppers even under the strain amplitude, larger than 3%, can meet the requirements of HPBRBs but the *CID* performance of steel BRBs without the stoppers cannot meet the requirements of HPBRBs.
- 3) It is clear that the friction coefficient of 0.075 is regarded as the right value for the simulations and *Half Model* and *Whole Model* can effectively simulate the mechanical behavior of the BRB with or without the stoppers.

Abstract. *This work consists on the seismic analysis of the Talübergang Warth bridge studied within the framework of the European research project entitled VAB - Vulnerability Assessment of Bridges [1]. This case-study bridge was built in Austria during the 70's, designed to a very low seismic level, consisting of a seven span continuous deck supported on two abutments and six rectangular hollow section piers, the latter with some peculiar characteristics concerning the reinforcement detailing whose modeling is quite demanding for cyclic response simulation. Still in the VAB project context, a physical scaled model of the bridge was also experimental tested under pseudo-dynamic conditions at the JRC-Ispra [2] and the results were compared against numerical simulations carried out by the FEUP team involved in the project.*

The non-linear behavior is considered concentrated in the piers, which are discretized with (i) a re-fined constitutive model or (ii) a Plastic hinge type model for the nonlinear material behavior simulation. For the numerical prediction of the seismic performance of the Talübergang Warth bridge these methodologies were adopted with the seismic action taken as an asynchronous and synchronous ground motion induced along the transverse direction only.

The main results of the seismic analyses will be presented focusing on the essential role that the longitudinal reinforcement curtailment plays on macro-crack localization, which leads to a shift of the plastic hinge (usually at the base of piers) up to the elevation where a significant reduction of the longitudinal reinforcement takes place. From the comparison of the numerical predictions with the experimental results, as recorded during the pseudo-dynamic tests performed at the JRC, the capability from the damage model to provide accurate simulations of the seismic performance of the bridge was brought into evidence, even when the piers are difficult to simulate due to the concrete hollow section geometry and to the unusual reinforcement layout adopted in the design (as in this case).

1 INTRODUCTION

Recent earthquake effects on reinforced concrete bridges have shown that many behave poorly and some possess very low levels of safety, to the extent that they are at risk of collapse, especially those built according to outdated seismic codes. Thus, efforts must be made to develop and apply accurate bridge assessment methodologies that will assist in the determination of failure probability in order to evaluate the need for retrofiting and to improve seismic safety levels.

The difficulties of carry out analyses with methodologies that adopt hysteretic non-linear material behavior increase significantly with the complexity degree of the model, involving a compromise between the accuracy and time computer consuming, and with the several parameters that is necessary to define. In the current work a comparative study with several strategies to evaluate the seismic behavior of bridges was intended to carry out. Therefore, two numerical models were used:

- (i) PNL [3] –non-linear behavior lumped in plastic hinges.
- (ii) Damage Model [4] – refined constitutive model for the nonlinear material behavior.

The numerical prediction of the seismic performance of this bridge adopts a peculiar two-dimensional modeling of the entire bridge [3, 5] consisting of a simplified plane model with easy practical application and involving reduced calculation efforts while maintaining adequate accuracy. The bridge structural modeling is carried out with plane elements, bars or 2D finite elements, maintaining the essential features of the 3D transverse response through an appropriate plane structural simulation. This is achieved by considering the deck and piers in the same plane, while the top pier horizontal displacement and the correspondent horizontal transversal deck displacement are constrained by uniaxial tie elements in order to have the same value. The comparative analyses were carried out with increasing seismic action level, in order to show the sensibility of the results with the different non-linear levels. Finally, the performances and solutions of the different methodologies are compared and discussed.

2 DESCRIPTION OF STUDIED BRIDGE

The Talübergang Warth bridge was studied within the framework of the European research project entitled VAB - Vulnerability Assessment of Bridges [1, 2], and is illustrated in Figure 1. This bridge, at about 63 km to the south of Vienna, is formed by a deck with 7 spans and a total length of 459m, and it is supported by 6 piers and 2 abutments. Piers' nomenclature is also indicated in Figure 4, to ensure a clear identification.

Figure 1: Talübergang Warth bridge and piers' nomenclature.

The geometry of the bridge piers was defined on the basis of the design drawings documented in Talübergang Warth Bridge Drawings (1975). Figure 2 and Table 1 reproduce the basic geometry of the piers, both for the concrete section and for the footings (piers height L refers to the distance between the top of the footing and the base of the deck bearings.). All the piers have $6.8 \times 2.5 \text{ m}^2$ concrete hollow sections.

In what concerns the curtailment of the longitudinal reinforcement, involving bars of different diameters, 4 regions are depicted in Figure 2. Details about the reinforcement layout are referred in previous publications [1, 6]. For piers P2, P3 and P4 the first interruption of the longitudinal rebars occurs close to the foundation, leading to a reduction of about 50% on the amount of steel reinforcement.

Transversal reinforcement is provided by a single rectangular stirrup on each wall of the hollow section [1, 6], according to the following distribution: (i) $A_{sw} = \phi 12 // 0.20 \text{ m}$ on the first 1m layer close to the piers footing, and (ii) $A_{sw} = \phi 8 // 0.20 \text{ m}$ elsewhere.

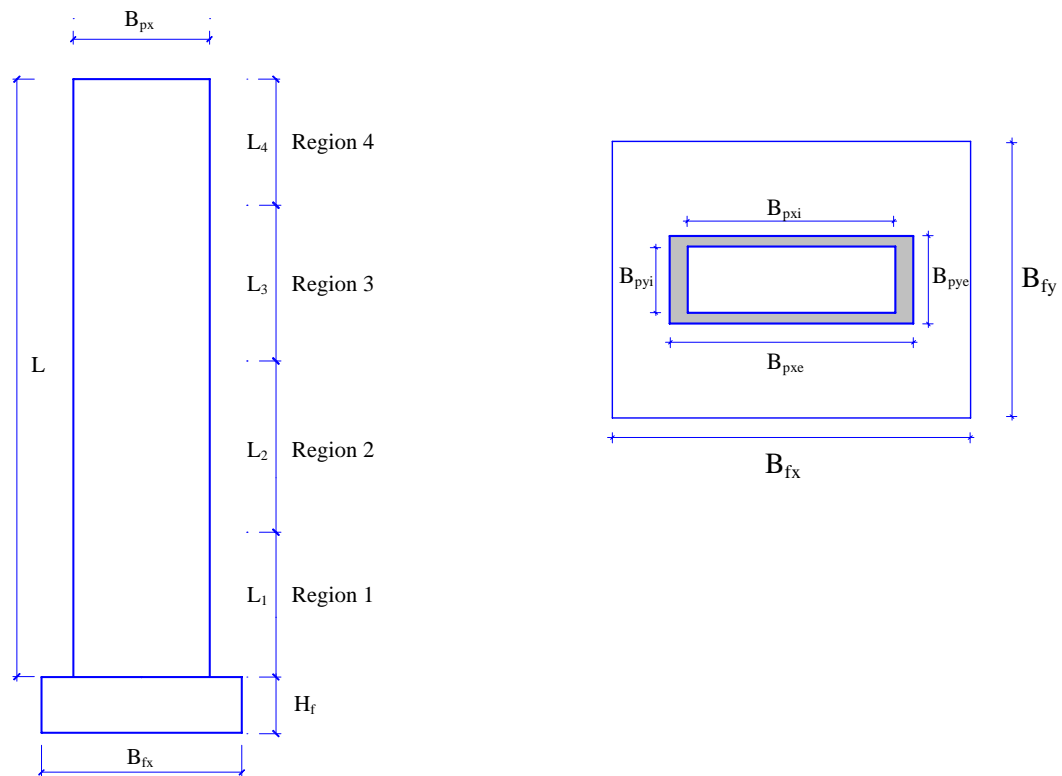

Figure 2: Basic geometry nomenclature.

Pier	L (m)	L/B _{pxe}	L/B _{pye}	Hollow section	Foundation		
					B _{fx}	B _{fv}	H _f
P1 (A20)	29.8	4.4	11.9	B _{pxe} = 6.8m B _{pxi} = 5.8m B _{pye} = 2.5m B _{pyi} = 1.9m	10.8	10.1	3.45
P2 (A30)	38.9	5.7	15.6		10.2	8.0	2.80
P3 (A40)	37.8	5.6	15.1		10.2	8.0	2.80
P4 (A50)	36.0	5.3	14.4		10.2	8.0	2.80
P5 (A60)	30.0	4.4	12.0		10.5	9.0	3.20
P6 (A70)	16.9	2.5	6.8		10.4	9.5	3.20

Table 1: Basic geometry.

Taking into consideration the stirrup arrangement documented in the design drawings, it is doubtful that concrete could benefit from any significant effect of confinement. Accordingly, for Talübergang Warth bridge piers the class B400 concrete was assumed as under unconfined conditions, with the material properties reproduced in Table 2 (average values).

E (GPa)	f_{co} (MPa)	ε_{co}	f_o^+ (MPa)	f_{cm} (MPa)	ε_{cm}	Z
33.5	43.0	2.0‰	3.1	—	—	100

Table 3 resumes the average material properties assumed for the longitudinal and transversal rebars, defined as corresponding to a class RT50 steel.

f_{sv} (MPa)	f_{su} (MPa)	ε_{su}	ε_{sh}	E_h/E	R_o	a_1	a_2
545	611	100‰	5.0‰	0.0034	20	18.5	0.15

f_{su} and ε_{su} are the ultimate strength and strain for the steel.

Table 3: Steel properties (class RT50).

3 SIMULATION OF THE PSD TEST (ASYNCHRONOUS MOTION)

The Talübergang Warth bridge was tested on the ELSA Laboratory (Joint Research Centre, at Ispra) under pseudo-dynamic conditions and asynchronous ground motion induced along the transverse direction only, being all the experimental results described in the reference Pinto et al. [2].

The non-linear behavior is considered concentrated in the piers, which are discretized with a refined constitutive model for the nonlinear material behavior simulation. The refined numerical model combines a 2D plane-stress finite element discretization for the concrete with 2-noded truss elements to include the steel reinforcement. The concrete behavior is simulated resorting to a constitutive model based on Continuum Damage Mechanics, involving two independent scalar damage variables to account for degradation under tensile and compressive stress conditions. The cyclic response of steel is simulated via the Giuffré-Menegotto-Pinto model [7].

The numerical analysis were performed in a sequential way, where the accelerograms were inputted according to increasing intensities, in order to better reproduce the experimental tests; when a given seismic action is considered the structure has already been modified due to the non-linear effects induced by the previous one.

Figure 3 illustrates the comparison of the pier P3 top displacement responses obtained numerically (using the Damage Model) and experimentally (pseudo-dynamic test performed at the JRC), for three different intensity level earthquakes. These three responses are in general very close as much in frequency as in maximum values, except for the high level earthquake where some differences can be found on the response last part.

From the comparison of the numerical simulations with the experimental results, the capability from the damage model to provide accurate simulations of the seismic performance of the bridge was brought into evidence, even when the piers are difficult to simulate due to the concrete hollow section geometry and to the unusual reinforcement layout adopted in the design. In fact, the longitudinal reinforcement curtailment represents an important influence on macro-crack localization, which leads to a shift of the plastic hinge up to the elevation where a significant reduction of the longitudinal reinforcement takes place.

a) Low level earthquake

b) Moderate level earthquake

c) High level earthquake

Figure 3: Top horizontal displacement history of pier P3.

4 SYNCHRONOUS NUMERICAL ANALYSIS

In this section, the numerical analyses were carried out assuming synchronous ground motion in the transverse direction, being considered the pier P3 accelerogram as the reference.

Again the numerical analysis were performed in a sequential way, where the accelerograms were inputted according to increasing intensities, therefore; when a given seismic action is considered the structure has already been modified due to the non-linear effects induced by the previous one. The non-linear behavior was considered concentrated in the piers, which are discretized with (i) the Damage model, a refined constitutive model or (ii) the PNL model [3, 8], a plastic hinge type model for the nonlinear material behavior simulation.

Once the capability from the damage model to provide accurate simulations of the bridge seismic performance was brought into evidence from previous asynchronous responses, it is reasonable to assume that accurate response simulations are expected for synchronous input motion.

Figure 4 illustrates the comparison of the pier P3 top displacement responses obtained numerically, using the Damage Model and the plastic hinge model, for three different intensity level earthquakes. The first response, for low level earthquake, has similar results for both models in the initial seconds, but after half time the frequencies become different and higher maximum displacement values were achieved for the plastic hinge model. For subsequent responses of the numerical simulations, it was difficult to achieve accurate results for the plastic hinge model due to the unusual reinforcement layout adopted in the design, the longitudinal reinforcement curtailment represents an important influence on crack localization and plastic hinge formation, which leads to a shift of the plastic hinge up to the elevation where a significant reduction of the longitudinal reinforcement takes place.

For this assumption of consider the bridge synchronous ground motion as the pier P3 accelerogram (used in asynchronous analysis), the comparison between the asynchronous and synchronous response obtained with the damage model, Figure 3 and Figure 4, allows to verify that maximum peak displacement is reasonable similar, for moderate and high level earthquake. Both responses are similar for initial seconds, however with some differences for final seconds of the accelerograms.

After these first results and conclusions obtained with the plastic hinge modeling, a second set of simulations was carried out assuming the longitudinal reinforcement reduction at the pier base and therefore the corresponding decrease on the yielding moment, but keeping the plastic hinges in the same place (near the foundation), although the referred longitudinal reinforcement curtailment takes place in region 2 (see Figure 2). Figure 5 illustrates the comparison of the pier P3 top displacement responses obtained numerically with the referred plastic hinge model modifications, for three different intensity level earthquakes.

Generically, as is possible to see from Figure 5, the results for the plastic hinge model considering the longitudinal reinforcement reduction improve the quality of the responses, once both damage model and PNL model are now more similar responses. In fact, regarding frequencies and maximum displacement values, both responses are now significantly closer.

5 CONCLUSIONS

- The Talübergang Warth bridge, studied in the VAB project context, was experimental tested under asynchronous pseudo-dynamic conditions at the JRC and the results were compared against numerical simulations carried out with the damage model.
- Displacement responses obtained numerically and experimentally, for three different intensity level earthquakes, are in general very close as much in frequency as in maximum values, being highlighted the capability from the damage model to provide accurate simulations of the seismic performance of the bridge even when the longitudinal reinforcement curtailment represents an important influence on macro-crack localization.
- Once the capability from the damage model to provide accurate simulations of the bridge seismic performance was brought into evidence from asynchronous responses, it is reasonable to assume that accurate response simulations are expected for synchronous input motion.
- The comparison between the asynchronous and synchronous response obtained with the damage model allows to conclude that maximum peak displacement is reasonable similar, for moderate and high level earthquake.
- For the synchronous numerical simulations with damage model and a plastic hinge model, it was difficult to achieve accurate results for the plastic hinge model due to the longitudinal reinforcement curtailment, which leads to a shift of the plastic hinge up to the elevation where a significant reduction of the longitudinal reinforcement takes place.
- The results for the plastic hinge model considering the longitudinal reinforcement reduction improve the quality of the responses, once both damage model and PNL model are now closer responses. Therefore, a significant importance must be given to the simulations with plastic hinge model regarding the aspects and singularities of the structures that are likely to affect the seismic response.

Abstract. *The lifetime seismic performance of a typical segmental three-span (75+120+75) Egnatia Odos Highway bridge is assessed, considering the corrosive action of chloride ions that leads to pier strength degradation over time. The aim is to show the influence of corrosion on the seismic demand and capacity over the entire design life of the bridge, as well as the usefulness of simplified single-degree-of-freedom (SDOF) models to minimize the computational cost to non-prohibitive levels for contemporary capabilities. Five different time instants are chosen within the 120 year design life of the bridge. For each instant, the piers' reinforcement steel loss is calculated via a probabilistic model using Monte Carlo simulation to account for the uncertainty in the factors that affect the corrosion. While incremental dynamic analysis (IDA) of the complex model would be the method of choice for a comprehensive evaluation, we employ instead approximate IDA of equivalent SDOF systems with capacity curves derived by static pushover analysis. Such analyses are efficiently executed for different time moments of the design life of the bridge, taking into account the active pier rebar diameter due to corrosion effects. Thus, the usefulness of the equivalent SDOF system concept combined with nonlinear dynamic analysis or a powerful R- μ -T relationship such as SPO2IDA is shown. This usefulness turns to a necessity when more factors of epistemic uncertainty beyond the corrosion process are added in this already complex problem, disproportionately magnifying the required computational load.*

1 INTRODUCTION

In bridge design, the seismic load often constitutes the most critical loading case. Still, even though there is a relatively long inventory of bridges in Greece designed according to older guidelines, no significant damages have ever appeared due to earthquakes. On the contrary, the most common damage found can be attributed to the environmental conditions. Moisture, chlorides and CO_2 can impact the mechanical properties of structural materials, most importantly of structural steel, through the process of corrosion. Thus, the topic of ageing bridges subject to corrosion is a potentially dangerous situation in a seismically active region. The main question is whether, and at to extent, corrosion influences the seismic performance over the lifetime of a bridge.

Corrosion is a complex process that may affect a concrete bridge in a variety of ways, including, among others, cover spalling, loss of prestress, loss of steel-concrete bond strength and loss of steel itself. Since the seismic response is our topic of interest, we will focus exclusively on the effect of steel loss for the longitudinal and transverse pier reinforcement, while ignoring the potentially important impact of debonding. The reinforcement area losses lead to a direct decrease in the shear and moment capacity and secondarily in a reduction of the stiffness of piers. All the above contribute to a degradation of the bridge seismic performance. We aim to calculate this degradation over the 120 year lifetime of a well-designed modern bridge.

The corrosion in the case of reinforced concrete (RC) structures is a phenomenon that has received wide attention. Of immediate interest for the present study is the work of Stewart and Rosowsky [1] and Vu and Stewart [2] who have calculated RC bridge deck strength degradation against static loads as a function of time and distance from sea. More recently, Celarec et al. [3] have employed simplified single-degree-of-freedom models to calculate the increase of seismic risk in RC buildings due to corrosion. Finally, Ghosh and Padgett [4] have offered a holistic picture of ageing effects on the seismic fragility curves of bridges through time. Most importantly, researchers tend to agree that corrosion phenomena are subject to severe uncertainties thus necessitating the use of probabilistic models.

2 CASE STUDY BRIDGE

The G7 bridge is part of the Egnatia highway. It has a total length of 270m (Figure 1). The longitudinal axis of the bridge is shaped as a circular arc both in the horizontal and in the vertical plane, having radii of curvature equal to +320m and -1000m, respectively. For the construction of the bridge the segmental cantilever method has been chosen, where the piers function temporarily as pure cantilevers. These support the construction of the deck, short segments of which are extended in alternation or simultaneously from the two opposite sides of the piers to maintain a balanced load. Due to the specifics of the construction method, it is often the case that earthquakes do not constitute the critical loading for such bridges. Combined with the curvature of the bridge and the height of the piers which favor non-seismic loading cases, we do not expect to see integrity-threatening situations due to the combined corrosion and earthquake effect. Nevertheless, the relative change in the performance will help us understand the effect of corrosion for bridges where earthquake loads are dominant.

The bridge deck has a heavily post-tensioned single-cell box section (Figure 2a). The two piers M1 and M2 have box cross sections of 4.0x7.35m (Figure 2b) with a height of 41.70m and 49.50m, respectively. They are connected monolithically with the superstructure. At the abutments A1 and A2 the deck is supported on bearings of the elastic single-point type (pot bearings) moving freely. The mobility of the deck in the transverse direction is restrained by shear keys up to the point of the earthquake design loads (Figure 3). The pier foundations are deep, situated within the rocky substrate.

Figure 1. (a) plan view and (b) Longitudinal section.

Figure 2. (a) Deck cross section and (b) Pier cross section.

Figure 3. Deck support conditions.

A three dimensional finite-element model (Figure 4a) has been developed using the Open-sees platform [5]. It is a powerful program that offers the possibility to create realistic nonlinear models with elements that approach with accuracy the real behavior of reinforced concrete structures. In addition it allows reliable analyses even under numerically unstable conditions that approach global collapse.

The bridge deck has been modeled with linear beam-column elements, closely following the centroidal axis of the tapering cross sections. The superstructure and the abutments are connected to the bearings via stiff zero-mass elements. The piers are modeled using force-based beam-column elements with fiber sections. Therein, different material properties have been used (Figure 4b) to distinguish the confined core concrete from the unconfined cover and the steel reinforcement. The effect of confinement allows higher strength and ductility at the core, an effect that is taken into account according to the Mander et al. [6] model.

For the pot bearings, a set of one-dimensional non-interacting springs have been grouped into a single macroelement. They simulate accurately the freedom of the horizontal movement under friction and the transverse connection of the bridge with the central shear key up to the load of 250 tn by employing a bilinear force-deformation relationship. Still, they do not take into account the possibility of a contact with the side walls of the abutments when the shear key collapses. At the two outer bearings of each abutment, a link with stiffness of 1MN/m has been used in the vertical direction to reduce the deck uplift during earthquake loading.

The first two mode shapes of the bridge are mainly translational for the deck (Figure 5). The first is a displacement along the longitudinal axis; the second is a displacement along the transverse axis; the third is a symmetric deformation in the vertical direction. The corresponding periods are $T_1=1.59s$, $T_2= 1.48s$ and $T_3= 0.85s$. It must be noted that due to the curvature of the bridge and the existence of transverse links at the abutments, the transverse and longitudinal displacements are partially interacting [7]. As a result, the two prime mode shapes combine both transverse and longitudinal displacement of the piers.

3 PIER DEGRADATION DUE TO CORROSION

Corrosion may be initiated either due to carbonation in dry-air conditions or due to the action of chlorides and moisture. The latter constitute the main corrosive hazard for this bridge, arising from the application of de-icing salts and due to sea spray exposure in a coastal environment. Reinforcement corrosion is a complex process that can attack the pier integrity via multiple vectors, e.g. spalling, debonding and steel material loss. In our case, we will only focus on the latter and will assume that corrosion leads to a uniform reduction in reinforcing steel along the pier height, equally affecting the entire external row of longitudinal and transverse reinforcement bars. A probabilistic model is used to take into account the aleatory and epistemic uncertainty inherent in the process while Monte Carlo simulation is performed to propagate the effects to the estimated structural performance.

3.1 Corrosion Model

The aim is to estimate the corrosion initiation time T_i and the respective rebar diameter loss ΔD_b for every time instant. The corrosion deterioration model proposed by Stewart and Rosowsky [1], as amended later by Vu and Stewart [2], is used as our basis. It leads to a uniform reduction in the bar diameter of the reinforcing steel due to general (non-pitting) corrosion. For reasons of completeness, the fundamentals of the model are repeated here.

First of all, chloride content $C(x,t)$ at a distance x from the concrete surface at time t follows Fick's second law:

$$C(x,t) = C_o \left[1 - \operatorname{erf} \left(\frac{x}{2\sqrt{tD}} \right) \right] \quad (1)$$

where C_o is the surface chloride content (kg/m^3), D is the chloride diffusion coefficient (cm^2/sec) and erf is the error function. The surface chloride concentration C_o is the sum due to the application of de-icing salts $C_{oi} = 3.5$ and air-born chlorides C_{od} . The latter is assumed to depend only on the distance from the coastline:

$$C_o = C_{oi} + C_{od} \quad (2)$$

The surface chloride concentration C_{od} as a function of distance from the coast (d in km) is:

$$C_{od} = \begin{cases} 2.95 & d \leq 0.1 \text{ km} \\ 1.15 - 1.81 \log_{10}(d) & 0.1 \text{ km} < d \leq 2.84 \text{ km} \\ 0.03 & d > 2.84 \text{ km} \end{cases} \quad (3)$$

The chloride diffusion coefficient (D) is influenced mainly by the mix proportions (water-cement ratio):

$$D = D_{H_2O} 0.15 \frac{1 + \rho_c \frac{c}{w}}{1 + \rho_c \frac{w}{c} + \frac{\rho_c}{\rho_a} \frac{a}{c}} \left(\frac{\rho_c \frac{w}{c} - 0.85}{1 + \rho_c \frac{w}{c}} \right)^3 (\text{cm}^2 / \text{sec}) \quad (4)$$

The terms $\rho_a = 2.7 \text{ g/cm}^3$ and $\rho_c = 3.12 \text{ g/cm}^3$ are the mass densities of cement and limestone aggregates, respectively. The ratio $a/c = 0.66/0.11$ is the aggregate-cement ratio, $D_{H_2O} = 1.6 \times 10^{-5} \text{ cm}^2/\text{sec}$ is the chloride diffusion coefficient in an infinite solution and the water-cement ratio is estimated as

$$w / c = \frac{27}{f'_{cyl} + 13.5} \quad (5)$$

where f'_{cyl} is the mean concrete compressive strength in MPa, assumed to be approximately 7.5MPa above the characteristic strength.

The corrosion rate is a function of concrete quality, cover thickness and time. The time-dependency appears due to the formation of rust on the steel surface, which tends to reduce the corrosion rate:

$$i_{corr}(t_p) = \frac{32.13}{b} (1 - w / c)^{-1.64} t_p^{-0.29} \quad (\mu A / cm^2) \quad (6)$$

where the concrete cover b is given in cm and t_p is the time since corrosion initiation.

The corrosion initiation time T_i is calculated from Equation (1) to coincide with the time that the chloride concentration reaches a critical value C_r of $0.9kg/m^3$ on average. Thus, if the inverse of the error function is erf^{-1} , we have:

$$T_i = \frac{b^2}{4D} [\text{erf}^{-1}(1 - C_r / C_0)]^{-2}. \quad (7)$$

Finally the deterioration process caused by reinforcement corrosion will lead to a uniform reduction $\Delta D_b(t_p)$ in the bar diameter of the reinforcing steel as follows:

$$\Delta D_b(t_p) = \min \left(0.0232 \int_{T_i}^{t_p} i_{corr}(\tau) d\tau, D_{b0} \right). \quad (8)$$

The reduction is zero for times earlier than T_i , D_{b0} is the initial bar diameter and the instantaneous corrosion rate (at the surface) in mm/yr is taken as $\lambda(\tau) = 0.0116 \cdot R \cdot i_{corr}(\tau)$, where $R=1$ for general corrosion. The parameters f'_{cyl} , C_{od} , C_{oi} , C_r , D and i_{corr} are randomly distributed as described in [2]. The latter two quantities, in addition to the randomness induced by their parameters, also incorporate model epistemic uncertainty.

3.2 Impact of corrosion on the longitudinal pier reinforcement

The effects of corrosion on the longitudinal reinforcement are presented in Figure 6. The rebar diameter decreases throughout the lifetime of bridge from 25 mm to a median value of 22.7 mm which corresponds to a 9% reduction. At each of the five time instants selected, Monte Carlo simulation is performed for 100 realizations of the bridge. Since nonlinear dynamic analysis is prohibitive for such numbers, we instead chose to employ static pushover analysis (SPO). Thus, the bridge is pushed along its longitudinal axis where it is most vulnerable to collapse. Figure 7 shows the resulting 500 SPO curves together with their corresponding medians. Although the effect is not overwhelming, there is still a 10% median reduction in terms of the maximum base shear capacity after 120 years; it drops from 17720 kN to 15880 kN. The low impact of corrosion is mainly attributed to the large diameter bars, the sufficient concrete cover and the good quality of the concrete. While the latter two factors are intuitive, the former is perhaps slightly more difficult to understand. The reason is that corrosion uniformly attacks the entire surface area of the rebars. At least for general corrosion, the diameter reduction is the same under the same conditions, regardless of the bar size. Thus, if the same amount of steel is distributed among few large diameter bars or many small diameter ones, corrosion will always impact more heavily the latter configuration. For the above reasons, the longitudinal reinforcement will not suffer much from the chloride attack.

Figure 6. Boxplots of the longitudinal rebar diameter at 25 year intervals. The three horizontal lines defining each box represent the 25, 50 and 75% values of the sample while the whiskers show the gross extent of the sample distribution, out of which the outliers (red crosses) are.

Figure 7. (a),(b),(c),(d),(e) SPOs of 100 samples (blue) at 25 year intervals together with their median (red); (f) the median SPOs for every time instant.

3.3 Impact of corrosion on the transverse pier reinforcement

While longitudinal reinforcement is well protected from corrosion, the same is not true for transverse reinforcement. Actually, the shorter distance to the surface and the significantly smaller bar diameter are both heavily aggravating factors that work against the integrity of the stirrups.

The shear strength of concrete members is given by

$$V_R = V_s + V_c \quad (9)$$

where V_c and V_s are the nominal strength of concrete and transverse reinforcement shear-resisting mechanisms, respectively. According to Directive E39/99 [8], within the plastic end regions the concrete contribution is removed from the shear strength. The reinforcement contribution (truss mechanism) according to DIN1072 is given by

$$V_s = \frac{A_{sv}}{s} f_y \frac{7}{8} d \quad (10)$$

where A_{sv} is the total area of transverse reinforcement in a layer in the direction of the shear force, s is the spacing along the member axis of the layers of stirrups or hoops, and d the effective depth of the section.

The results of corrosion impact to the transverse reinforcement and finally to the piers' shear strength are presented in Figure 8. The base shear strength throughout the lifetime of the bridge decreases from 21770 kN to 17140 kN. This corresponds to a 21% reduction in the median value, most of which happens at an early stage: After the first 20 years of the bridge's life, shear strength decreases from 21770 kN to 18950 kN, having a 13% median reduction. While still not threatening for the bridge, which retains enormous amounts of shear capacity due to the overdesign mandated by the code minima for reinforcement, such reductions are not to be ignored.

Figure 8. Boxplots of the pier shear strength at 25 year intervals. The three horizontal lines defining each box represent the 25, 50 and 75% values of the sample while the whiskers show the gross extent of the sample distribution, out of which the outliers (red crosses) are.

4 DYNAMIC PERFORMANCE OF CORRODED BRIDGE

Perhaps the most comprehensive method for estimating seismic performance is Incremental Dynamic Analysis (IDA) [9]. It utilizes numerous nonlinear time-history analyses of the system under a suite of multiply-scaled ground motion records. In our case the aim is to produce the distribution of seismic demand and capacity, ideally represented by summarized 16, 50 and 84% IDA curves, for each of the five time instants (20, 45, 70, 95 and 120 years) within the 120 years design life of the bridge. The seismic performance of the bridge is investigated for loads mainly along its longitudinal axis, where it is most vulnerable to collapse. In this direction, the bridge has a general elastoplastic response as shown by the SPO curve (Figure 7). For every time instant 100 model realizations are used in a Monte Carlo simulation in order to take into account the epistemic uncertainty inherent in corrosion.

Assuming that 30 records are used at seven intensity levels for IDA for each corroded bridge realization, then $30 \times 7 \times 5 \times 100 = 105,000$ dynamic time-history analyses should be executed on a multi-degree-of-freedom (MDOF) model, requiring unreasonable computational resources. In order to reduce the computational load to realistic levels, simplified methods must be employed. Thus, following the example of Celarec et al. [3], we will use a suitable equivalent SDOF instead of the MDOF model, and replace the expensive IDA with an SPO analysis together with SPO2IDA [10,11]. The latter is a powerful R - μ - T (reduction factor-ductility-period) relationship which allows instantaneous estimation of summarized IDA curves of SDOF systems, offering significant savings in computations at the cost of a small error. Thus, weeks of analysis are reduced to less than 48hrs on a single computer.

4.1 Simplified single-degree-of-freedom (SDOF) models

The applicability of equivalent SDOF models to estimate the MDOF response largely depends on the regularity of the structure (Isakovic et al. [12]). In irregular structures such a substitution may underestimate significantly the seismic response. According to the eigenvalue analysis, the studied bridge responds in each direction predominantly in a single mode. Moreover the primary mode shapes are mainly translational with only low coupling between them. On the contrary the rotational mode shapes are of secondary importance. Thus, the bridge can be characterized as regular and the use of equivalent SDOF models is appropriate.

Figure 9. The SPO curve and its trilinear approximation.

Figure 10. The summarized IDA curves as predicted by SPO2IDA for the adopted trilinear fit to the SPO.

4.2 Approximate Incremental Dynamic Analysis via SPO2IDA

The Static Pushover to IDA (SPO2IDA) software [10,11] is used to approximate the IDA 16, 50 and 84% curves by taking advantage of the results of the static pushover (SPO). In our case, the capacity curves are closely approximated with a trilinear shape. This starts elastically, followed by a hardening positive-stiffness part and then by a lightly negative-stiffness segment that we choose to terminate at a reasonable maximum attainable displacement dictated by the abutment geometry (Figure 9).

The SPO2IDA software is based on the fitted response of multiple SDOF systems with a wide range of periods, moderately pinching hysteresis and 5% viscous damping. It can effortlessly generate the statistics of the normalized intensity R versus normalized response μ curves (Figure 10) for complex quadrilinear force-deformation backbone shapes, unlike simpler R - μ - T relationships that are restricted to the simplest of shapes and just the mean response. R is the reduction factor, defined as the ratio $S_a(T_1, 5\%) / S_a^{\text{yield}}(T_1, 5\%)$ of the spectral acceleration over its value at yield. Similarly, μ is the ductility, i.e., the ratio of displacement response over the displacement at yield δ / δ^y .

To obtain proper IDA curves in terms of $S_a(T_1, 5\%)$ and for any desired structural response, a denormalization must take place. We employ the procedure described by Vamvatsikos and Cornell [12] but allowing for the simplifications of Fragiadakis and Vamvatsikos [13]. Thus, the initial elastic slope of the IDA fractile curves for the deck displacement is set to $4\pi^2 / (C_0 T_1^2 g)$, where C_0 is the first-mode participation factor, e.g., as defined by FEMA-356 [14]. The approximate 16, 50 and 84% IDA curves are then produced for every realization of the bridge and every time instant considered, shown in Figure 11. According to the results, the corrosion causes the displacement of bridge deck to increase by 10% on average for any given level of $S_a(T_1, 5\%)$, closely following our earlier SPO-based conclusions for this simple SPO shape. While not a threatening condition for this bridge, where seismic loads were not critical for design, it still provides a useful standard of comparison for other, less-protected cases.

Figure 11. (a),(b),(c),(d),(e) 16, 50 and 84% fractile IDA curves for 100 samples together with the overall median curve for each fractile (in black) ; (f) the overall median IDA curves for all time instants and each fractile.

5 CONCLUSIONS

The seismic performance of a typical cantilever-construction three-span bridge under the effect of corrosion has been examined. Instead of performing IDA on the MDOF bridge model, we produce instead the 16, 50 and 84% IDA capacity curves approximately, for each of the five time instants within the 120 years design life of the bridge, using the SPO2IDA software on the equivalent SDOF bridge model. The latest simplification is generally applicable as the examined structure is a first-mode dominated system as most similar bridges tend to be. Thus, the equivalent of almost 100,000 dynamic time-history analyses can be executed in less than two days rather than several weeks. This allows us to consider a fully probabilistic model of steel reinforcement corrosion and accurately assess its effects on the seismic response of the bridge. It is a general method that can be efficiently applied to reinforced concrete structures and leads to useful, quantifiable results.

In the case examined, since only the external layer of pier reinforcement is exposed to corrosion, a median degradation of 10% for flexural capacity and 20% for shear capacity is expected to occur within the design life of 120 years. In both cases, the degradation rate is at its highest at the initiation of corrosion and it slowly declines with time. Thus, more than half of the reduction is typically reached within the first twenty years. Still, the effects are not overwhelming for this bridge. For example, although the shear capacity loss seems substantial, it poses no threat for the bridge as the code-minimum transverse reinforcement has led to large amounts of reserve shear capacity.

Bridge G7 is a contemporary bridge designed by the latest codes. It enjoys good quality concrete and a thick reinforcement cover which are the principal factors acting against corrosion. Added to the fact that earthquakes are not the critical loading case, it becomes clear that corrosion will never be catastrophic for the piers. This conclusion might be very different for older or contemporary bridges where earthquake loads are dominant. In such cases, performing assessment or design while neglecting the substantial effect of corrosion may not be a wise choice.

Abstract. *Seismic response of extended structures, such as bridges, must take into account spatial variability of earthquake ground motion (SVGM). Models that describe SVGM have been developed during last decades and structural analyses have been performed on numerous structures. Based on these studies, simplified approaches have been developed. The new Algerian bridge seismic regulation code proposes a simplified approach that takes into account SVGM. This paper aims at performing preliminary studies on the accuracy of this method. This is performed through comparison with more refined approaches. Bridges, with different overall lengths and seating on different types of site conditions, are considered. The results show that this simplified method overestimates the response of the analyzed bridges .*

1 INTRODUCTION

Seismic analysis of extended structures, such as bridges, must take into account spatial variability of earthquake ground motion (SVGM) which can induce significant additional forces. In fact, it has been recognized that space-time variability of the seismic of ground motion is the results of three distinct effects [2]: (1) loss of coherence of the seismic movement due to multiple refractions and reflexions of the seismic waves along their paths, named incoherence effect, (2) difference in arrival times of the seismic waves at the various recording stations due to the variation of their apparent propagation velocity, named wave passage effect, (3) space variation of the geotechnical properties, named site effect.

During last decades, models that describe SVGM have been developed based on either empirical or analytical approach (as e.g., [3, 4]) and it is now widely accepted that the coherence function describes the SVGM. Using these models, structural analyses have been performed on numerous structures and show the importance of taking into account SVGM as, e.g., among many others, in references: [5, 6, 7, 8, 9, 10]. Based on these studies, simplified approaches have been introduced in regulation codes to take into account SVGM. The Algerian bridge seismic regulation code (RPOA) [1] has been recently lunched.

This paper aims at performing preliminarily studies on the accuracy of the simplified approach proposed by the RPOA. For the purpose of the study, seismic motion is simulated using time domain segmentation and the well-established method of Deodatis [11]; SVGM is described by the empirical model of Harichandran and Vanmarcke [3]. The simulated time histories are used as input excitations at bridge supports. The time-history analysis results are compared to those obtained by the simplified method of RPOA for different bridges. Results are presented in terms of internal forces.

2 SIMULATION OF SPATIALLY VARYING GROUND MOTIONS

In order to study the effect of SVGM on bridges responses, it is necessary to generate acceleration and displacement time-histories at several locations on the ground surface, corresponding to the bridge supports. In this study, the seismic ground motions are simulated as non stationary from predefined time history, using time domain segmentation method [12, 13, 14]. The predefined time histories are divided into nearly stationary segments with different durations. Then, each segment is used as a reference time series and stationary conditional simulations are carried out for each segment, using the simulation technique proposed by Deodatis [11]. The simulated segments are joined together to obtain the entire non stationary and spatially variable acceleration time-histories, after the incorporation of a time shift to account for the wave passage effect.

The generated acceleration time histories are further corrected and integrated in order to obtain the corresponding displacement time-histories. The properties of each set of simulated time-histories are the same in terms of target power spectral density function, peak of displacement and response spectrum compatibility.

3 OVERVIEW OF THE RPOA PROVISIONS REGARDING SVGM

RPOA [1] is the first Algerian code established for the seismic design of bridges. RPOA clearly recognizes that, since the differential ground motion induces significant internal forces, the seismic action cannot be based only on the characterization of uniform motion, and proposes a simplified approach to take into account SVGM effects. According to RPOA, the effects of differential displacements between supports are generally negligible for current structures, except when: (a) the structure crosses an active fault, (b) the soil properties vary along the bridge, (c) the length of the bridge is very important.

According to RPOA, designers must perform, firstly, a dynamic analysis of the structure under uniform seismic excitations, and secondly, a pseudo-static analysis based on pattern of prescribed differentials displacements at the bridge supports. Finally, the dynamic response is combined with the pseudo-static response using the SRSS rule.

On a ground site without significant mechanical discontinuity, the design differential displacement d , between two points separated by a distance X , is given by [1]:

$$d = \eta AgX; \text{ for } X < L_M \quad (1)$$

$$d = AgD_M\sqrt{2}; \text{ for } X \geq L_M \quad (2)$$

With:

$$\eta = \frac{D_M}{L_M}\sqrt{2} \quad (3)$$

Ag : is the design seismic acceleration; g is the acceleration of gravity.

L_M : is the distance beyond which the motions of the two supports can be regarded as independent.

D_M : are absolute displacements; they are given for unit acceleration (1m/s^2).

The values of D_M and L_M are given in Table 1 for the four ground types in RPOA, S1 to S4, which are classified on the basis of the shear wave velocity V_s .

Ground Type	S1	S2	S3	S4
V_s (m/s)	$V_s \geq 800$	$400 \leq V_s \leq 800$	$200 \leq V_s \leq 400$	$V_s \leq 200$
L_M (m)	600	500	400	300
D_M (m)	0.03	0.05	0.07	0.09

Table 1. Values of L_M and D_M [1]

RPOA do consider two special situations. If two support points are located on both sides of a significant topographic discontinuity (valley), and in absence of a better approach, the value of d is raised by 50%. In case they are located on both sides of a mechanical discontinuity (fault), design differential displacement d is given by:

$$d = Ag\sqrt{D_{M,1}^2 + D_{M,2}^2} \quad (4)$$

Where:

$D_{M,1}$ and $D_{M,2}$ are the absolute displacements at points 1 and 2.

4 EVALUATION OF THE SIMPLIFIED APPROACH OF RPOA

4.1 Bridge model

In order to quantitatively assess the simplified method of RPOA, two bridges are selected (Bridge A and Bridge B). They have different overall lengths (i.e.400m and 600m, respectively); they have the same configuration (Figure 1) which is taken from design example No. 1 from the Federal Highway Administration seismic design examples [15]. The span length is constant and equal 50 m; the respective numbers of spans are 8 and 12.

The finite element models use six equal-length 3-D elastic beam elements per spans and four beam elements per pier. The superstructure and the columns are connected by rigid elements. The shear stiffness of the bearings is assumed to provide no restraint in the longitudin-

al direction. In the vertical direction, the bearings are considered fully restrained due to the gravity forces of the superstructure. The rigid element at each end of the bridge is restrained in the transverse direction by springs, which represent the effect of the girder stops at both ends of the bridge. The stiffness of each bent foundation is modeled by six springs at the lower end of the footing elements, which were determined using an elastic half-space approach [15]. Finally, 5% Rayleigh damping is utilized.

Figure 1. Girder cross-section.

4.2 Support motions

In this study, uniform soil conditions are assumed and only the longitudinal component of the excitation is considered. The accelerograms used for the conditional simulation of support motions are compatible with RPOA's response spectrum. Two ground types S1 (firm soil) and S3 (soft soil), 5% damping and 0.4g peak ground acceleration are selected to describe the ground motion at piers. The Harichandran and Vanmarcke model [3] is chosen to model the coherence loss between pair of bridge supports:

$$|\gamma_{jk}(\omega, d_{jk})| = A \cdot \exp\left(-\frac{2(1-A+\alpha A)|d_{jk}|}{\alpha\theta(\omega)}\right) + (1-A) \cdot \exp\left(-\frac{2(1-A+\alpha A)|d_{jk}|}{\theta(\omega)}\right) \quad (5)$$

$$\theta(\omega) = k \left[1 + \left(\frac{\omega}{2\pi\omega_0}\right)^b\right]^{-\frac{1}{2}} \quad (6)$$

The following parameters of the model are used: $A = 0.736$, $\alpha = 0.147$, $k = 5210 \text{ m}$, $\omega_0 = 6.85 \text{ rad/s}$ and $b=2.78$, which correspond to data recorded during Event 20 at the SMART-1 array, Lotung, Taiwan. Since the span length is the same for all bridges, it was decided to simulate stationary SVGM every 50 m. In this study, an apparent propagation velocity $v = 750 \text{ m/s}$ was used.

For Monte Carlo simulation needs, the procedure of simulation is repeated 10 times. Fig. 2 gives one set of non stationary SVGM displacements corresponding to ground types S1 and S3 which were simulated for the longest bridge (600 m, i.e., 13 support points).

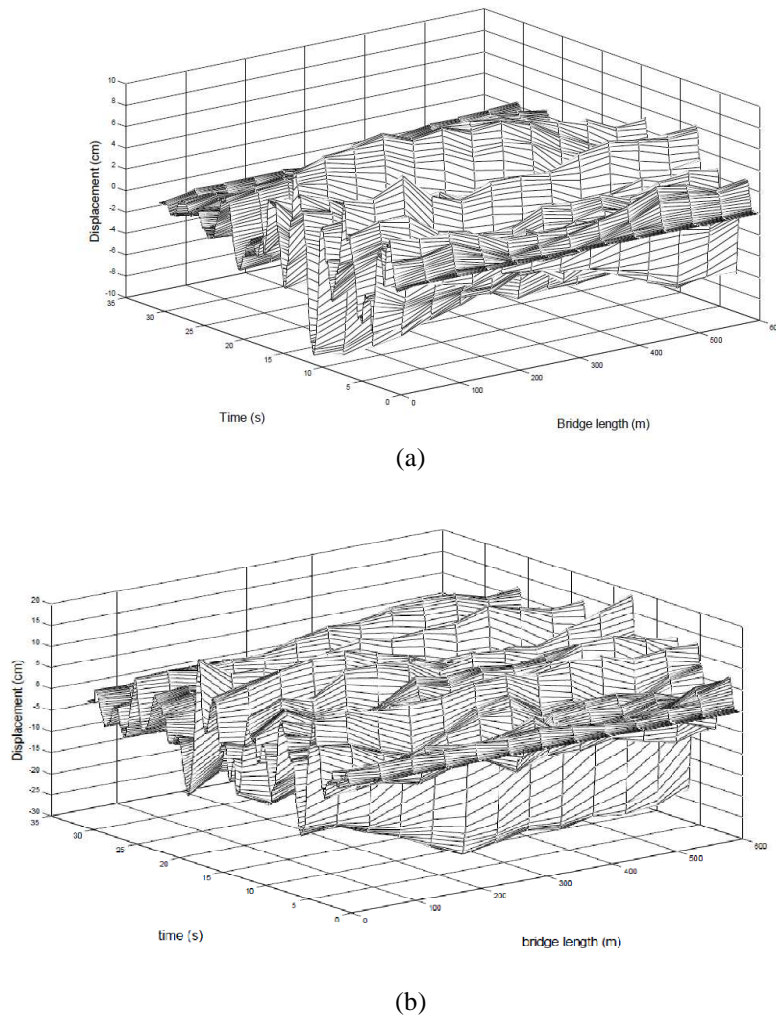

Figure 2. One sample of non stationary SVGM displacements for ground types (a) S1 and (b) S3.

4.3 Analysis Results

In order to evaluate RPOA's simplified approach, the bridges presented in section 4.1 are analyzed three times, using the following three cases of analysis:

- URSA:** Conventional response spectrum analysis, i.e., which assumes uniform ground motion, using RPOA's response spectrum.
- VTHA:** Time-history analysis using the asynchronous displacements simulated in section 4.2.
- VRPA:** RPOA's simplified analysis for SVGM (see section 3) using RPOA's response spectrum. The prescribed differential displacements are calculated using Eqs. (1) to (3) and are presented in Table 2.

Tables 3 and 4 present comparisons of the bending moment demand envelopes at the extreme column of each bent of Bridge A. It should be noted that VTHA results are the mean values obtained from 10 time-history analyses. These tables show that VTHA results remain equal or lower than those obtained using conventional response spectrum analysis (URSA). Consequently, in this case, the effect of SVGM is negligible (i.e. lower than 5%), and to a certain degree, it is even beneficial (i.e. a reduction in the resulting bending moments is observed). The latter is an observation in agreement with the findings of previous studies [16], for the symmetric bridge configuration and uniform soil condition. However other studies as, e.g., [17, 6, 8], observed that this findings cannot be generalized, and concluded that, depend-

ing on the characteristics of the SVGGM, the bridge configuration and its boundary conditions, spatially variable ground motions can induce a higher or lower response in the structure than the response resulting from uniform ground motions.

<i>Site</i>		<i>S1</i>	<i>S3</i>
η		0.7×10^{-4}	2.5×10^{-4}
L_M		600	400
<i>d (m)</i>			
	Abut A X=0	0	0
	Pier 1 X=50m	0.013	0.049
	Pier 2 X=100m	0.027	0.098
	Pier 3 X=150m	0.041	0.147
	Pier 4 X=200m	0.055	0.196
	Pier 5 X=250m	0.068	0.245
	Pier 6 X=300m	0.082	0.294
	Pier 7 X=350m	0.096	0.343
	Pier8 X=400m	0.11	0.388
	Pier9 X=450m	0.123	0.388
	Pier10 X=500m	0.137	0.388
	Pier11 X=550m	0.151	0.388
	Abut BX=600m	0.165	0.388

Table 2. Differential displacements for Bridge A and Bridge B, according to RPOA.

In addition, tables 3 and 4 suggest that VRPA and VTHA give comparable results: they reduce the seismic demand in the central piers and increase it in piers close to abutments. However it is found that VRPA amplify the results and the differences are more pronounced in the lateral piers. VRPA can amplify the results by 20% for the firm soil and 50% for the soft one.

Table 5 presents ratios between pier top displacements given by VRPA and VTHA. It is found that VRPA displacement amplification is as high as 1.44 and 1.82, for ground types S1 and S3, respectively

The results for Bridge B are presented in Tables 6-7. Once again, it is observed that VRPA overestimates the seismic demand. It reaches 37% for the firm ground type and 55% for the soft one, which is higher than those observed for Bridge A.

5 CONCLUSIONS

RPOA gives a simplified approach to introduce the effect of the SVGM in the design of bridges. In this paper, the accuracy of this method is evaluated through comparison with a more refined approach. Two bridges, having different lengths and seating on different types of ground conditions, are considered. For each bridge/site case, three types of linear analyses are conducted. Based on this study, the following conclusions can be done:

The spatial variability of earthquake ground motion can significantly change the structural response. SVGM increases seismic demand in some cases and reduces it in others. The present study clearly demonstrates that the simplified method does not give satisfactory results and overestimates the seismic demand, especially for laterals piers. In order to reduce those results it is suggested to decrease the differential displacement given by RPOA code.

It should be noted that the present analysis correspond only to one model of bridge with different overall lengths. However, additional research needs to be conducted in this area for enrichment of the presents study.

Abstract. *During mid-2010, the PEER (Pacific Earthquake Engineering Research Center) and NEES (George E. Brown, Jr. Network for Earthquake Engineering Simulation) institutions co-sponsored a shaking table test on a full-scale reinforced concrete bridge pier that was carried out at the UCSD Large High-Performance Outdoor Shake Table. This experimental initiative was encompassed by a worldwide blind prediction contest (Concrete Column Blind Prediction Contest – CCBPC 2010) with over 40 participant teams seeking for the best numerical simulation results. The authors of this paper have participated in that contest and managed to achieve very good results as recognized by an “Award of Excellence” by the contest judges.*

The tested pier was included in a 10.50m high structure, comprising a 5.50m wide footing, a pier body 7.30m high with 1.20m diameter solid circular section. A 250ton reinforced concrete block was placed on the top of the pier in order to drive inertia forces large enough to mobilize the pier capacity, under increasing intensity uniaxial ground motions derived from real earthquake records. The blind numerical analyses were performed knowing only the specimen geometry, reinforcement detailing, material characteristics and the actual ground motions recorded during the testing.

In this context and, in view of the author's participation success, the present paper mainly aims at presenting several aspects of the adopted numerical methodology (and related difficulties) which proved to yield good results, while also providing some insight regarding key problems in numerical simulations of bridge pier seismic behavior. The main numerical and experimental results are compared and a brief discussion is included concerning the reasons for mismatching of some results.

1 INTRODUCTION

Understanding seismic performance of constructions, in general, has been a concern of the scientific community for quite long. That knowledge has met great advances over the last three decades but many problems of earthquake engineering are still difficult to assess in an easy and straightforward way. As an example, most code recommendations are based on reduced scale experimental validation, which for large structures such as bridges, is not easy to accomplish due to a need of considering heterogeneous multi-support excitation [1]. Aiming at providing ever more insight to this particular area, several methodologies and techniques were developed. Such example is the shaking table test, which allows imposing ground motions on structures, attempting to reproduce real earthquake-induced behaviour.

On that particular subject, notable cases can be referred such as the very large E-Defense [2] facility in Japan (some recent works related to it by Yu *et al.* [2010] or Chung *et al.* [2010], ([3,4])), or the NEES [5] equipment sites network of University of Buffalo, SUNY, University of California at San Diego and University of Nevada at Reno (most recent works from NEES@UCSD by Moaveni *et al.* [2010], or NEES@UNR by Johnson *et al.* [2009], ([6,7])). Other smaller scale equipments can be found for example in European facilities such as the Italian EUCENTRE [8], or the French CEA laboratory [9], and even the Portuguese LNEC [10]. Moreover, other relevant testing facilities have been in preparation in the last few years, such as the large shaking table array at Tongji University in Shanghai, China, the Korean laboratory network, and the advanced testing facility currently being developed in the European EFAST program [11].

In the context of scientific testing works carried out resorting to shaking tables, which usually happens with the objective of providing additional information not available from simpler experimental tests, blind numerical prediction initiatives have also been held in the past like SMART 2008 [12], UCSD Englekirk Structural Research Centre's full scale 7 story RC building test [13], or the CAMUS International Benchmark [14,15], the later where some of this paper authors have also participated with great success [16,17,18]. Those simulations are always dependent on deep understanding of the phenomena associated with the seismic behavior of the structures at hand. Besides that, a well-thought methodology needs to be devised in order to adequately address modeling issues without a thorough experimental knowledge.

In light of the documented experience and taking into account the recent results at the Concrete Column Blind Prediction Contest 2010 [19], this paper aims at describing the adopted analysis strategy and, therefore, discussing a number of aspects which are both critical and difficult to evaluate, regarding a given bridge pier seismic behaviour and a correct assessment of its numerical simulation.

2 EXPERIMENTAL CAMPAIGN (CCBPC 2010)

The experimental program associated with the Concrete Column Blind Prediction Contest 2010 initiative was devised by PEER (Pacific Earthquake Engineering Research Center) and NEES (George E. Brown Jr. Network for Earthquake Engineering Simulation) and is briefly described in this chapter. It basically involved of a full-scale reinforced concrete column tested at the UCSD Large High-Performance Outdoor Shake Table [20,21], under uniaxial ground motions with increasing intensity.

2.1 Specimen and material properties

The specimen was a large circular bridge column, bearing a massive concrete block (250 ton) on the top. Figure 1 illustrates its schematic layout and dimensions.

Figure 1 – Column model and dimensions (in meters)

The column was built on the UCSD shaking table, together with two steel-based restraint towers installed around it, in order to prevent excessive (and potentially dangerous) concrete block lateral movements, as depicted by Figure 2 .

Figure 2 – Restraint towers

The pier's reinforcement steel layout was based on 18 equally spaced No. 11 continuous bars ($\phi \approx 36$ (35.81mm)). The transverse reinforcement consisted of butt-welded double No. 5 ($\phi \approx 16$ (15.875mm)) hoops, roughly spaced at 0.15m. The longitudinal bars and circular stirrups development is constant throughout the pier height, both of them penetrating inside the column footing. The properties of the construction materials used in the aforementioned test column were available to all the participant teams and are briefly addressed in the Table 1.

Concrete		Longitudinal Steel		Transverse Steel	
σ_c (21 days)	36.96 MPa	σ_{sy}	518.5 MPa	σ_{sy}	453.7 MPa
σ_c (29 days)*	40.33 MPa	σ_{su}	706.0 Mpa	σ_{su}	592.0 Mpa
σ_c (45 days)	41.85 Mpa				

* - Tests started more than 28 days after concrete casting.

Table 1 – Material Properties

2.2 Instrumentation and Result Demands

The prototype column was densely instrumented in order to obtain good quality results. Specifically, several Linear Voltage Displacement Transducers (LVDTs) were mounted on rods that were rigidly fixed to the concrete column at multiple height levels and accelerations were recorded, using a 16-bit data acquisition system. All the quantities requested in the contest were taken from the resulting data, by direct measurement or implied calculation. Figure 3 describes the aforementioned quantities and the instrumentation layout as used in the tests.

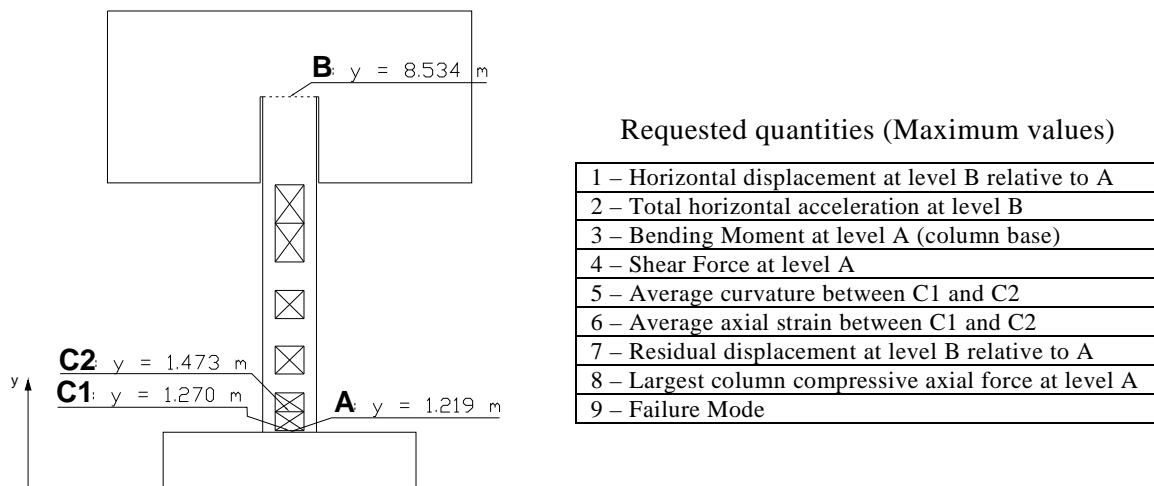

Figure 3 – Instrumentation layout and Contest requested response parameters

2.3 Ground Motions and Test Sequence

Since the experimental programme aimed at assessing the adequacy of design procedures developed by Caltrans to deal with seismic-based structural problems, real earthquake records were used to test the prototype column. Four different acceleration time histories were chosen from Loma Prieta (3 records) and Kobe (1 record) seismic events.

The complete test sequence was performed as described in Table 2, where the really applied seismic events are numbered by even numbers; before each of these six events, a white noise ground motion was applied in order to perform dynamic identification of the system throughout the whole response range.

Event	Ground Motion	Earthquake	Station Name	Scale	Target drift
2	EQ1	Loma Prieta	Agnews State Hospital	1.0 (PGA=4.00 m/s ²)	1%
4	EQ2	Loma Prieta	Corralitos	1.0 (PGA=4.38 m/s ²)	2%
6	EQ3	Loma Prieta	LGPC	1.0 (PGA=4.99 m/s ²)	4%
8	EQ4 = EQ2	Loma Prieta	Corralitos	1.0 (PGA=4.38 m/s ²)	2%
10	EQ5	Kobe	Takatori	0.8 (PGA=5.27 m/s ²)	N/A
12	EQ6 = EQ3	Loma Prieta	LGPC	1.0 (PGA=4.99 m/s ²)	4%

Table 2 – Testing Sequence covering only recorded seismic events

3 MODELLING STRATEGY

This participation in the CCBPC 2010 contest was based in numerical modeling carried out with the Seismostruct analysis software [22]. Since the behavior of the column (due to the uniaxial nature of the table movements) was expected to be dominated by its first vibration mode (because no other significant mass is involved apart from the concrete block), the column was modeled as a simple cantilever structure built upon a sequence of beam elements. Although inelastic force-based elements were used (which helps on reducing the need of a very refined mesh for this type of motion) several finite elements were adopted in order to facilitate the result analysis process, by choosing control sections at appropriate height levels.

The massive concrete block on top of the full-scale column was modeled as a simple lumped mass element at the height level B ($y = 8.534\text{m}$), with corresponding translational mass of 236.15 ton and zero rotational mass moments of inertia.

Figure 4 – Numerical finite element model representation

The column cross-section was considered with two distinct zones having different characteristics that were taken into account resorting to the fiber model implemented in Seismostruct. Table 3 includes the parameters used to describe the column behavior of the different types of fibers, while elastic behavior was assumed for the column footing.

A cover band was defined for the peripheral concrete ring, with the remaining cross-section area associated with confined core behavior. Material properties of both zones were defined according to the compressive test results, but an improved scheme was used to simulate the beneficial effect of transverse reinforcement on the core concrete confinement. Thus, Mander's constitutive relations and confinement effects simulation rules [23] were adopted, coupled with cyclic rules proposed by Martinez-Rueda and Elnashai [1997] ([24]), as documented in the adopted software manual.

Cover concrete		Confined Concrete		Longitudinal Steel	
Compressive strength (f_c)	41 MPa	Compressive strength (f_c)	41 MPa	Elastic Modulus (E_s)	200 GPa
Tensile strength (f_t)	3 MPa	Tensile strength (f_t)	3 MPa	Yield Strength (f_y)	520 MPa
Strain at peak stress (ϵ_c)	0.0028	Strain at peak stress (ϵ_c)	0.0028	Strain hardening parameter (μ)	0.011
Confinement factor (k_c)	1.0	Confinement factor (k_c)	1.296	R_0^*	20
Unit weight (γ) (kN/m^3)	23.6	Unit weight (γ)	23.6	Unit weight (γ)	77 kN/m^3

Table 3 – Model Properties (*: notation as adopted in [22])

Steel was simulated using the Menegotto-Pinto model [25] implemented in Seismostruct, which also considers isotropic hardening [26]. Default code parameters were used for that purpose, as well as for describing the transition curve.

The above referred modeling aspects are associated with either geometrical or material behavior description issues of an experimental test numerical simulation. However, the most important modeling decisions are strongly related with the seismic loading applied to the structure and to an accurate representation of its effects on the column, because they reflect the dynamic nature of the interaction between the inertia forces (generated by the imposed ground motions) and the non-linear material behavior associated with the accommodation of the developed deformations. Thus, an accurate simulation requires thorough evaluation of the characteristics of both the loading and the structure, in order to understand the influence of some phenomena on the overall column behavior (crack development, stiffness reduction, resonance effects, etc).

The modal analysis of the structural model showed a first vibration mode frequency of 1.46 Hz which is inherently associated with an undeformed state. When drift movements reach a certain level and pier cracks start to develop, the column stiffness drops. This means that the interaction between the loading pattern and the structural response is not constant and can change over time, according to the increasing damage imposed to the column.

The second step in this process consisted on the evaluation of the frequency content of the ground motion signals by means of FFT analyses. Figure 5 displays the FFT amplitude results obtained for each ground motion and a vertical line represents the aforementioned first mode frequency of the structure. Horizontal lines refer to the PGA level of each record adopted.

Figure 5 – FFT results for the testing ground motions.

In the previous figure it can be seen that ground motions 2 and 3 have more significant frequency contents around 1.50 Hz (i.e., near the structural frequency). However, once the frequency drops to values slightly smaller than 1.00 Hz, EQ5 can be seen also to have larger significance. In order to better evaluate the inherent consequences, elastic displacement spectra regarding each of the four ground motions were developed for a damping range of 0-2% of the corresponding critical damping. A sound interpretation of such results shown in Figure 6, regarding the experimental sequence which is known beforehand, is very important to understand how the column is likely to perform.

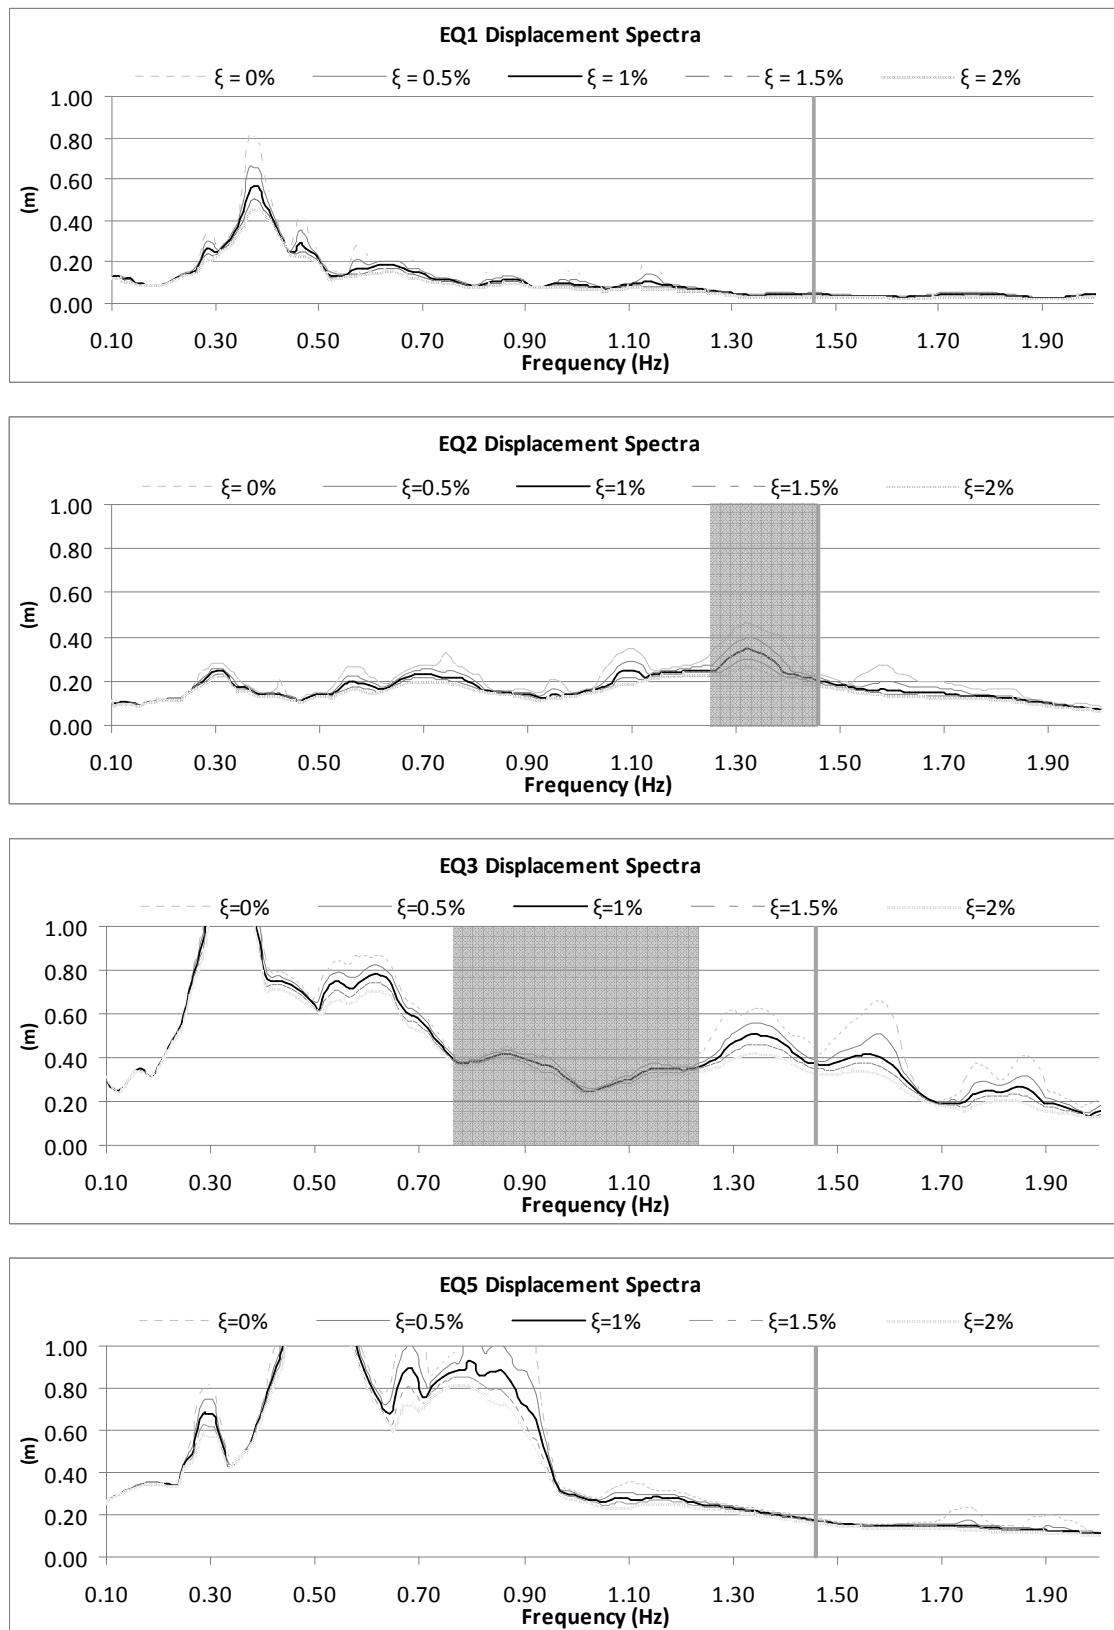

Figure 6 – Elastic displacement spectra due to the imposed ground motions, for several damping ratios

According to Figure 6, the displacement spectra for EQ1 shows low impact for the first vibration mode frequency and also no severe displacement peak in the near range; therefore, it sounds reasonable to assume that the damage imposed to the column during that event was minimal. However, due to low tensile strength of concrete, the column was expected to exhibit cracking on early stages (during EQ2 or even EQ1) leading to stiffness reduction which shifts down the fundamental frequency whose exact range is hard to predict (for that reason, shadow bands are included in the displacement spectra to provide an estimate of the frequency range for the damaged structure). That reduction increases as the concrete cracks develop in size and number, which is consistent with a damage state indicative of moderate non-linear incursion.

As shown in Figure 6, EQ3 ground motion displacement spectra shows relatively uniform values for a wide range of frequencies (within the shadow band) onto which the fundamental frequency is likely to drop. Thus, it is reasonable to assume that important drift values could be reached (say between 200mm and 400mm), regardless of the actually observed column stiffness despite its progressive reduction due to accumulated damage. If the ground motion was shown to be strong enough to induce yielding of the longitudinal rebars, a plastic-hinge mechanism would be due to form, which was further likely to occur because the peak ground acceleration (PGA) was higher for EQ3 than for EQ2.

This reasoning also raises another important point relative to the adopted damping scheme. It is known that viscous damping is especially relevant until the development of a clear hysteretic mechanism, after which the energy dissipation due to hysteretic behavior is much larger than that assumed from viscous damping alone. Therefore, accurate calibration of a numerical model for earthquake simulation requires good viscous damping representation until the plastic-hinge formation and, essentially, good non-linear material behavior description from then onwards. With that in mind, and attempting to reduce the viscous damping impact on the column response after EQ3, the methodology herein adopted was the consideration of a Rayleigh damping matrix matching $\xi = 1\%$ for target frequencies of 1.46 Hz and 0.67 Hz using the tangent stiffness instead of the initial elastic one.

Finally, beyond an effective representation of the interaction between loading, structural properties, viscous damping and hysteretic mechanisms, the time-history analyses of structures subjected to earthquake motions require also an adequate time-step. Thus, in order to correctly represent the loading and to capture its effects on the structure, the time-step of 0.05s was used, which allows vibration components to be adequately described for frequencies of up to 2 Hz.

It should be mentioned that, unlike the experimental activity, no white-noise simulations were made in this work; the ground motions were applied sequentially from EQ1 to EQ6.

4 NUMERICAL SIMULATION RESULTS

The results achieved with the modeling strategy herein presented were generally very good. Although depending on the testing stage, some very significant quantities like top displacement, acceleration or base shear were quite accurately captured, while mainly strains and curvatures exhibited clear deviations from the experimental results. Some of the numerical results are shown in the next paragraphs, generally plotted together with the corresponding experimental results for comparison purposes.

One first issue to be addressed relates to residual displacements that can reach important figures but may not be easily captured in numerical analyses. In order to identify the performance of numerical simulations on this particular issue, shows the complete sequential re-

sponse of the numerical model in terms of top displacement; horizontal lines corresponding to the numerical and experimental residual displacements are also included in order to compare permanent deformation levels captured with this modeling strategy and those recorded in the experimental test.

Figure 7 – Complete series of numerical top displacement time-histories with residual displacements (numerical and experimental).

Results show that residual deformations were quite accurately captured except for EQ5, where the difference was larger. It indicates that the overall column stiffness level and material properties were adequately simulated, since each ground motion was able to reproduce the same deformation levels on both the experiment and its numerical model. Non-linear progression might have been similar, although this argument needs further support in view of the difference shown for EQ5 where plastic hinging was due to be established.

A more in-depth, motion by motion, analysis can provide additional information regarding this modeling strategy's adequacy to the blind prediction problem.

Taking for example the horizontal acceleration time histories represented in -a) for the first stage (EQ1), both experimental and numerical curves seem to be in good agreement, with slight numerical overestimation of peak values, until approximately 23s. From then on, i.e., after the peak displacement values, the experimental period elongation was more evidenced than in the numerical response, which might have been due to more damage in the real test. This effect contributes, not only for the period elongation, but also to the increase of damping which is reflected in lower experimental displacements (than the numerical ones) around the 30s time instant.

Similar conclusions are drawn for the corresponding displacement time histories -b) and it is worth mentioning that, by the end of this test (EQ1) when displacements become smaller, the numerical response shows lower values than the experimental one. This modification of the relative magnitude of experimental and numerical response might be explained by the difficulties on achieving a robust simulation of damping that is able to follow adequately the response both in the large and small amplitude cycles.

This issue was also observed for other earthquake motions but, unlike EQ1 where the post-peak differences were mild, larger discrepancies were observed between numerical and experimental curves for the other earthquakes, on the post-peak range, as shown for instance in the top horizontal acceleration time-history for EQ2 (see Figure 9).

a)

b)

Figure 8 – Numerical vs. Experimental time histories of horizontal a) acceleration and b) displacements (EQ1).

Figure 9 – Numerical vs. Experimental horizontal acceleration time-history (EQ2).

In contrast however, EQ3 showed remarkable results for a blind prediction, with almost all parameters simulated with quite good accuracy (as globally depicted in Figure 10).

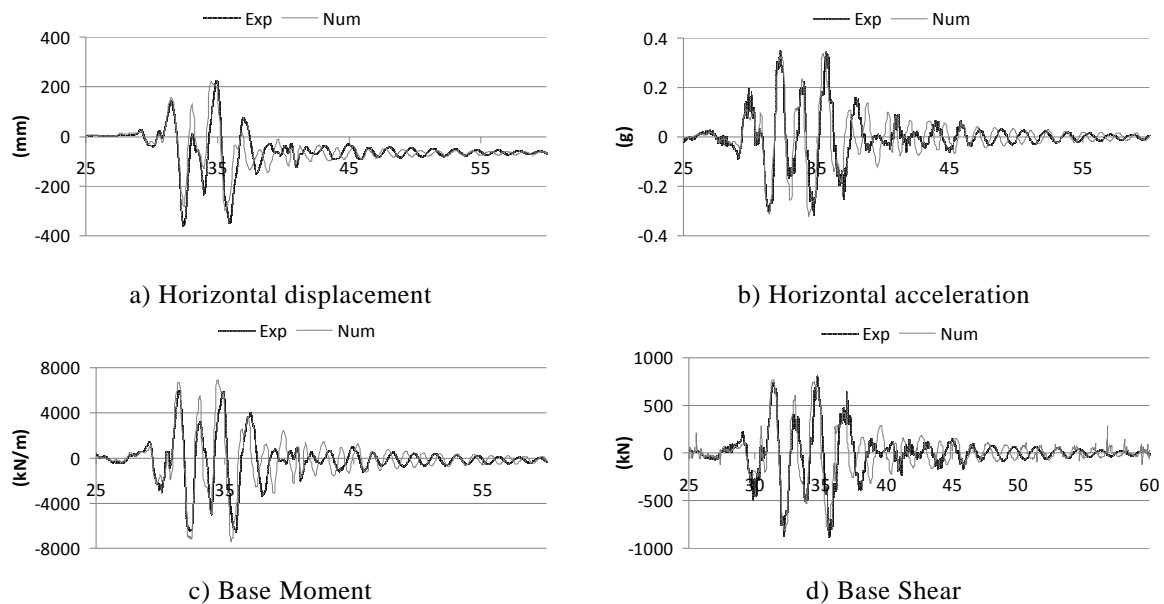

Figure 10 – Numerical vs. Experimental horizontal results (EQ3).

This was especially important because EQ3 was the first ground motion to clearly push the column into plastic behavior of the longitudinal reinforcement as it was predicted (see Figure 11, where the complete time history of longitudinal reinforcement stress is compared against the yielding threshold). Therefore, the plastic hinge formation was adequately captured by the numerical model.

Figure 11 – Complete longitudinal reinforcement stress time-history.

Since the numerical simulation was so similar to the experimental results for this specific ground motion, it follows that the adopted damping was probably accurate enough to provide a good balance between viscous damping during EQ1 and EQ2 (especially concerning peak response values), while making sure the plastic hinge contribution was the main dissipation mechanism once it formed.

It is noteworthy that, for plastic behavior clearly installed (as for EQ3), the influence of viscous damping, adopted to simulate (essentially) the cracking stage preceding the yielding

threshold, becomes less important in global response, particularly in what concerns peak values.

This is further confirmed with the response simulation for EQ5 earthquake, which has exhibited quite satisfactory agreement between numerical and experimental results (Figure 12) for the same parameters as for EQ3, notwithstanding the fact (already stated before) that deformation measures (axial strain and curvature) were not accurately simulated in the post-peak behavior.

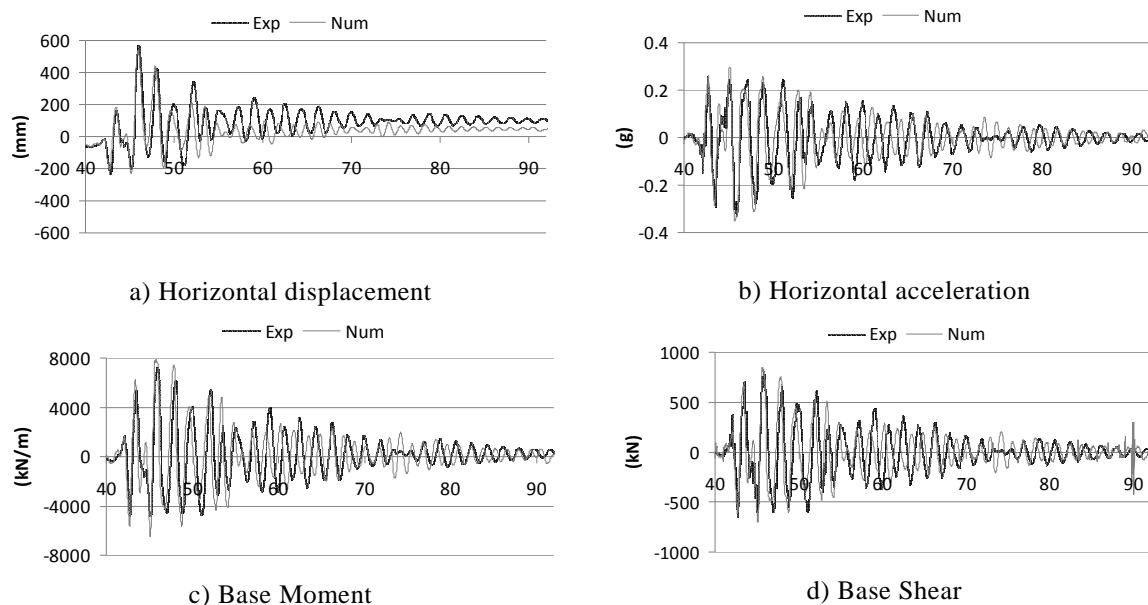

Figure 12 – Numerical vs. Experimental horizontal results (EQ5).

From the above described, an overall observation allows confirming that very satisfactory results were obtained. Differences focused mainly on the column post-peak behavior for each time-history, encompassed by slight out-of-phase response records due to difficulties on simulating accurately the cracking (thus affecting the fundamental period of vibration). Inaccurate residual deformations in the numerical modeling were also identified, although mainly for the EQ5 motion.

5 CONCLUSIONS

This paper described the work carried out by the authors in the framework of their participation in the Concrete Column Blind Prediction Contest 2010 sponsored by PEER and NEES. The blind numerical analyses were presented, preceded by a brief description of the strategy upon which the modeling decisions were made. That was based in simple procedures to evaluate the impact of the seismic loading (such as FFT analyses) and a refined characterization of the structural model using well proven constitutive relations, wherein confinement effects were also considered. The interaction between the seismic loading and the resulting structural degradation was addressed as being of key importance. The former directly increases the latter which, in turn, influences the intensity of the structural response. An adequate representation of the energy dissipation mechanisms was devised for this case, namely by adopting a suitable compromise between structural viscous damping and non-linear material behavior. As expected, the influence of the former was found of greater importance up to the plastic-hinge formation point.

The six ground motions were applied to the numerical model and the results obtained were compared against the test recorded values. The scenario was globally very good. Peak values were simulated with little difference relative to their experimental counterparts (like horizontal displacement and acceleration, base shear, etc) and overall time-history responses exhibited similar behavior. The main negative aspects of this modeling strategy consisted on the difficulties to reproduce adequately the strain and curvature values (probably related to the way they are recorded in the test and read in the numerical simulation), as well as mismatching the post-peak vibration period and the residual deformation from ground motion EQ5. Nonetheless, the plastic-hinge formation was quite accurately predicted.

However, perhaps the most important issue of this work was the development of a good perception of the evolution of the column non-linear response in order to enable and control the model for addressing the involved and relevant phenomena. Without a clear understanding of such phenomena, as well as the overall reinforced concrete cyclic behavior, simulation would be hardly feasible because any modeling could have many shortcomings and lead to considerable differences. Therefore, successful results within a blind prediction process reflect, not only the quality of the tools used in the work, but also the analysts ability to predict the key issues of the structural response.

Abstract. *In this paper, a method for the integration of computer aided design and analysis (I-CAD-A) is discussed. The method is based on using a finite element formulation that employs a kinematic description that is consistent with computational geometry methods. This allows for the development of an efficient interface between CAD systems and finite element (FE) and multibody system (MBS) software using simple linear coordinate transformation. The finite element absolute nodal coordinate formulation (ANCF) is used to successfully achieve this integration. ANCF structural finite elements, such as beams, plates, and shells, define shapes that are invariant under arbitrary rigid body displacements. It is shown in this paper that B-spline geometry can always be converted to ANCF geometry. The converse, however, is not true. ANCF provides the flexibility of selecting the basis functions, allowing for the development of finite elements with less number of degrees of freedom as compared to the B-spline counterparts. It is also demonstrated that the B-spline representation fails to capture certain type of discontinuities. To this end, C^0 discontinuities are classified as structural and non-structural discontinuities. Structural discontinuities do not allow for rigid body displacement between the finite elements, while non-structural discontinuities allow for such a rigid body displacement. Using ANCF finite elements, new FE/MBS meshes can be developed. These new FE meshes allow for describing mechanical joints that permit relative rigid body rotations using linear connectivity conditions. Furthermore, the new FE meshes have constant mass matrix and zero Coriolis and centrifugal forces despite the large relative rotation between the finite elements of the structure. Numerical results are presented in order to demonstrate the integration of CAD and FE/MBS analysis.*

1 INTRODUCTION

The geometry description used in many of the existing finite element (FE) formulations cannot be exactly converted to the geometry developed by computational geometry methods such as B-spline and NURBS (Non-Uniform Rational B-Splines) representations. This fact has motivated researchers in the mechanics community to adopt the methods of computational geometry as analysis tools instead of using conventional FE formulations. While the methods of computational geometry, such as B-spline, have several desirable analysis features; these methods have serious limitations when used as analysis tools. The B-spline recurrence formula and the rigid definition of the knot vector make B-spline less attractive as compared to the *absolute nodal coordinate formulation* (ANCF) geometry description. While B-spline geometry can always be converted exactly to ANCF geometry [1-3], the converse is not always true. ANCF geometry does not restrict the order of the parameters or the number of basis functions used in the interpolating polynomials [4-14]. This advantage, as will be demonstrated in this paper, allows for developing finite elements with less number of degrees of freedom as compared to those developed using the B-spline geometry. Another fundamental difference between B-spline and ANCF geometric descriptions lies in modeling discontinuities. There are two types of discontinuities when chain systems are considered [15]. The first is *structural discontinuity* which does not allow rigid body displacement between two elements connected at the joint definition point. This joint allows only for deformation degrees of freedom. The second type of discontinuity is called *non-structural discontinuity* which allows for rigid body displacement at the joint definition point. Figure 1 shows a chain which has a structural discontinuity at point C and non-structural discontinuity at point O . At the junction at C , only deformation degrees of freedom are allowed, while at point O , relative rigid body rotation is permitted. Nonetheless, the degree of continuity at both points is C^0 . B-spline can be used as an analysis tool to describe the non-structural C^0 discontinuity at point O , but because of its rigid recurrence structure and the definition of its knot vector and knot multiplicity, B-spline cannot be used in the motion analysis of structural C^0 continuity at point C since B-spline C^0 description leads to a rigid body mode; that is, the elimination of one control point by reducing the knot multiplicity by one is not sufficient for eliminating the modes of rigid body rotations between two B-spline segments. ANCF geometry, on the other hand, can be used in the analysis of both structural and non-structural discontinuities [15].

Figure 1 System with structural and non-structural discontinuities

Example of *Non-structural discontinuities* that characterize the motion of MBS applications is chain of links connected by pin joints as the one shown in Fig. 2. Each link is permitted to undergo an independent rigid body rotation. If the links are considered to be flexible bodies, the relative motion between the links is a combination of rigid body and deformation displacements. Nonetheless, the dynamics of a simple planar rigid-link chain is governed by highly nonlinear equations as the result of the geometric nonlinearities due to the finite relative rotations. Existing FE algorithms and computer programs, however, do not allow for generating a FE mesh for such chains using linear connectivity conditions. One of the main goals of this investigation is to develop a new three-dimensional flexible-link chain model using fully parameterized ANCF finite elements. This chain model is based on a new FE mesh defined using linear connectivity conditions. The FE mesh allows for relative rigid body rotations between its elements and has a constant inertia matrix and zero Coriolis and centrifugal forces. In order to develop the new flexible-link chain model presented in this paper, a new pin joint model is introduced. At the joint definition point, different degrees of continuity are used with different parameters; leading to some strain components to be continuous while the others are discontinuous. The modes of deformation at the joint definition points are discussed in order to shed light on the nature of the new joint and kinematic constraints developed in this paper.

Figure 2 Eight-link chain system

The second main contribution of this paper is to demonstrate the fundamental differences between B-spline and ANCF geometries. It is shown that while B-spline geometry can always be converted to ANCF geometry, the converse is not true because of the rigid B-spline recurrence structure. It is also shown that B-spline representation can be used only in the analysis of one type of C^0 continuity; while such a B-spline representation cannot be used in the analysis of another type of C^0 continuity referred to as structural discontinuity. It is shown that ANCF finite elements which have degrees of freedom less than their B-spline counterparts can be developed since ANCF does not have specific requirements on the order of the parameterization variables or the number of basis functions used in the interpolating polynomials.

2 CONSTRAINT NONLINEARITIES

Existing FE algorithms and computer codes allow for developing meshes in which the finite elements are rigidly connected. In the case of arbitrarily large relative rigid body rotations between the finite elements of one mesh, an incremental solution procedure based on a corotational formulation is used. This FE solution procedure leads to a highly nonlinear inertia matrix and due to the nature of the incremental approach used and the set of coordinates employed, existing FE algorithms and computer programs are not suited for the analysis of complex multibody systems that are characterized by geometric nonlinearities that result from the independent rigid body rotations of the finite elements. In most formulations, including rigid

body dynamics formulations, such non-structural geometric discontinuities are governed by nonlinear algebraic constraint equations which lead to highly nonlinear inertia matrix. For such articulated systems, components which are not rigidly connected are treated as separate bodies when MBS algorithms are used. Consider, for example, the simple planar double-pendulum example shown in Fig. 3. The pendulum consists of two rigid bodies, i and j , connected by a pin (revolute) joint at point P whose local position vector is defined in the two body coordinate systems by the vectors $\bar{\mathbf{u}}_p^i$ and $\bar{\mathbf{u}}_p^j$, respectively. The global position vector of this point in terms of the coordinates of bodies i and j are denoted as \mathbf{r}_p^i and \mathbf{r}_p^j , respectively.

Figure 3 Double pendulum example

In this simple planar rigid body example, the kinematic constraint conditions of the pin joint can be written as $\mathbf{r}_p^i = \mathbf{r}_p^j$. This equation can be written more explicitly in terms of the coordinates of bodies i and j , as

$$\mathbf{R}^i + \mathbf{A}^i \bar{\mathbf{u}}_p^i = \mathbf{R}^j + \mathbf{A}^j \bar{\mathbf{u}}_p^j \quad (1)$$

where \mathbf{R}^i and \mathbf{R}^j define the global position vector of the origins of the coordinates systems of the two bodies, and \mathbf{A}^i and \mathbf{A}^j are the transformation matrices that define the orientations of the two bodies. In the planar analysis, the vectors and matrices that appear in Eq. 1 can be written as

$$\left. \begin{aligned} \bar{\mathbf{u}}_p^k &= [\bar{x}^k \quad \bar{y}^k], \quad \mathbf{R}^k = \begin{bmatrix} R_x^k & R_y^k \end{bmatrix} \\ \mathbf{A}^k &= \begin{bmatrix} \cos(\theta^k) & -\sin(\theta^k) \\ \sin(\theta^k) & \cos(\theta^k) \end{bmatrix}, \quad k = i, j \end{aligned} \right\} \quad (2)$$

The geometric nonlinearities of the connectivity condition of Eq.1 characterize all MBS formulations including the augmented and embedding techniques. Using the embedding technique, one can show that the two equations of motion of the planar rigid body double pendulum shown in Fig. 3 can be written as

$$\left. \begin{aligned} (m^i (l^i)^2 + J^i + m^j (l^i)^2) \ddot{\theta}^i + (2m^j l^i l^j \cos \theta^{ij}) \ddot{\theta}^j = \\ -2m^i g l^i \cos \theta^i - m^j g l^i \cos \theta^i - 2m^j l^i l^j (\dot{\theta}^j)^2 \sin \theta^{ij} \\ (2m^j l^i l^j \cos \theta^{ij}) \ddot{\theta}^i + (m^j (l^j)^2 + J^j) \ddot{\theta}^j = \\ -2m^j g l^j \cos \theta^j + m^j l^i l^j (\dot{\theta}^i)^2 \sin \theta^{ij} \end{aligned} \right\} \quad (3)$$

In this equation, m^k and l^k are, respectively, the mass and length of link k , $k = i, j$, $\ddot{\theta}^k$ is the angular acceleration of link k , $\theta^{ij} = \theta^i - \theta^j$ and g is the gravity constant. It is clear from Eq. 3 that the equations of motion for a simple planar rigid body double pendulum are highly nonlinear as the result of the nonlinear connectivity conditions. The resulting inertia coefficients are also highly nonlinear because of the geometric nonlinearities that result from the non-structural discontinuities. Such non-structural geometric discontinuities also lead to more geometric nonlinearities when the deformation of the links are considered using the FE/FFR formulation due to the dynamic coupling between the reference motion and the elastic deformations. In the FFR formulation, $\bar{\mathbf{u}}_p^k$ is expressed in terms of the elastic coordinates and the number of equations of motion increases by the number of these elastic coordinates.

3 B-SPLINE CURVES AND SURFACES

In B-spline representation, any curve can be represented as a combination of several polynomial segments. Generally, B-spline curves can be defined using following equation [1, 18]:

$$\mathbf{r}(u) = N_{0,p}(u)\mathbf{P}_0 + N_{1,p}(u)\mathbf{P}_1 + \dots + N_{n,p}(u)\mathbf{P}_n = \sum_{i=0}^n N_{i,p}(u)\mathbf{P}_i \quad (4)$$

where $N_{i,p}(u)$ are the B-spline basis functions of degree p , u is the parameter, and \mathbf{P}_i are the control points that define the control polygon. The basis functions can be defined as

$$\left. \begin{aligned} N_{i,0}(u) &= \begin{cases} 1 & \text{if } u_i \leq u < u_{i+1} \\ 0 & \text{otherwise} \end{cases} \\ N_{i,j}(u) &= \frac{u - u_i}{u_{i+j} - u_i} N_{i,j-1}(u) + \frac{u_{i+j+1} - u}{u_{i+j+1} - u_{i+1}} N_{i+1,j-1}(u) \end{aligned} \right\} \quad (5)$$

where $u_i \leq u_{i+1}$, and $U = \{u_0, u_1, \dots, u_{n+p+1}\}$ is called the knot vector. The elements of the knot vector need not be distinct. Each nonzero span corresponds to a B-spline segment defined by two knot points called in this case breakpoints that represent distinct knot values. The number of equal knots at a point is referred to as the knot multiplicity.

B-spline surfaces can also be defined using the product of B-spline base functions, two parameters, and two knot vectors. B-spline surfaces can be defined in the following parametric form [1, 18]:

$$\mathbf{r}(u, v) = \sum_{i=0}^n \sum_{j=0}^m N_{i,p}(u) N_{j,q}(v) \mathbf{P}_{i,j} \quad (6)$$

where u and v are the parameters; $N_{i,p}(u)$ and $N_{j,q}(v)$ are B-spline basis functions of degree p and q , respectively; and $\mathbf{P}_{i,j}$ are a set of bidirectional net of control points. $N_{j,q}(v)$ can be defined similar to the definition introduced for $N_{i,p}(u)$ with another knot vector $\mathbf{V} = \{v_0 \ v_1 \ \cdots \ v_{m+q+1}\}$. Note that the orders of the polynomials in the u and v directions can be different; for example, a cubic interpolation can be used along u while a linear interpolation can be used along v . As in the case of B-spline curves, the knots of B-spline surfaces do not have to be distinct; distinct knots are called breakpoints and define surface segments with non-zero dimensions. The number of the non-distinct knots in \mathbf{U} and \mathbf{V} at a point is referred to as the knot multiplicity associated, respectively, with the parameters u and v at this point. At a given breakpoint, the multiplicity associated with u can be different from the multiplicity associated with v ; allowing for different degrees of continuity for the derivatives with respect to u and v . For cubic $N_{i,p}$ ($p=3$), C^0 , C^1 , or C^2 conditions correspond, respectively, to knot multiplicity of three, two, and one; while in the case of linear interpolation of $N_{j,q}$, the highest continuity degree that can be demanded is continuity of the gradients.

In B-spline surface representation, there is a relationship between the polynomial degree, the number of knots, and the number of control points. This relationship must be fully understood if B-spline geometry will be used as an analysis tool. If $r+1$ is the number of knots in \mathbf{U} and $s+1$ is the number of knots in \mathbf{V} , then in B-spline geometry, one must have

$$r = n + p + 1, \quad s = m + q + 1 \quad (7)$$

These formulas imply that, for a given polynomial order, if the number of knots decreases, the number of control points (degrees of freedom used in the analysis) must also decrease. A decrease in the knot multiplicity by one is equivalent to eliminating one control point. This can also be equivalent to increasing the degree of continuity since eliminating a control point can be the result of imposing algebraic equations that relates the derivatives at a certain breakpoint. From the bidirectional structure used in Eq. 6, a surface segment which has cubic interpolation along u ($p=3, n=3, r+1=8$) and a linear interpolation along v ($q=1, m=1, s+1=4$), should have $(n+1) \times (m+1) = 8$ control points; this is regardless of whether the surface is two- or three-dimensional. Manipulation of the B-spline surface of Eq.6 shows that these eight control points are the result of using the alternate basis set $1, u, v, uv, u^2, u^2v, u^3, u^3v$. That is, B-spline representation and the formulas of Eq. 7 do not allow for the use of the basis set $1, u, v, uv, u^2, u^3$ which can be effectively used to develop a shear deformable beam model. If a cubic interpolation is used for both u and v (thin plate), the B-spline representation will require 16 control points because the expansion must include all terms $u^k v^l$; $k, l = 0, 1, 2, 3$ regardless of whether the shape of deformation of the plate is simple or complex; one must strictly follow the B-spline rigid structure. This can be of disad-

vantage in the analysis since such a geometric representation can unnecessarily increase the dimension of the analysis model and leads to the loss of the flexibility offered by the FE method or modal analysis techniques. As the degree of the polynomial interpolation increases, the problem gets even worse.

4 ANCF FINITE ELEMENT GEOMETRY

In the absolute nodal coordinate formulation, the position vector of any arbitrary point of the finite element with respect to the fixed global reference frame can be generally written as follows

$$\mathbf{r}(x, y) = \mathbf{S}(x, y) \mathbf{e}(t) \quad (8)$$

where x and y are the element spatial coordinates, t is time, \mathbf{S} is the element shape function matrix, and \mathbf{e} is the vector of the element nodal coordinates. An example of ANCF elements can be planar two-node shear deformable beam element. The shape function matrix for this element is defined as

$$\mathbf{S} = [s_1 \mathbf{I} \quad s_2 \mathbf{I} \quad s_3 \mathbf{I} \quad s_4 \mathbf{I} \quad s_5 \mathbf{I} \quad s_6 \mathbf{I}] \quad (9)$$

In this equation, \mathbf{I} is the identity matrix, and $s_i, i = 1, 2, \dots, 6$ are shape functions defined as [16]:

$$\left. \begin{aligned} s_1 &= 1 - 3\xi^2 + 2\xi^3, & s_2 &= l(\xi - 2\xi^2 + \xi^3), & s_3 &= l\eta(1 - \xi), \\ s_4 &= 3\xi^2 - 2\xi^3, & s_5 &= l(-\xi^2 + \xi^3), & s_6 &= l\xi\eta \end{aligned} \right\} \quad (10)$$

where l is the element length, $\xi = \frac{x}{l}$ and $\eta = \frac{y}{l}$.

Each of the element nodes has six degrees of freedom; two translational coordinates defined by the two-dimensional vector $\mathbf{r} = [r_1 \ r_2]^T$, and four gradient coordinates defined by the two vectors $\mathbf{r}_x = [r_{x1} \ r_{x2}]^T$ and $\mathbf{r}_y = [r_{y1} \ r_{y2}]^T$. The vector of nodal coordinates \mathbf{e} can then be written as

$$\mathbf{e} = [\mathbf{r}^{AT} \quad \mathbf{r}_x^{AT} \quad \mathbf{r}_y^{AT} \quad \mathbf{r}^{BT} \quad \mathbf{r}_x^{BT} \quad \mathbf{r}_y^{BT}]^T \quad (11)$$

In this equation, A and B refer to the end points of the finite element. Note that the element defined by the preceding equations is based on a cubic interpolation for x and a linear interpolation for y . This element has been widely used in the analysis of large deformation problems. The standard ANCF assembly process ensures continuity of both position and gradient coordinates when two finite elements are rigidly connected.

Structural discontinuities can be systematically modeled using ANCF finite elements by using the proper gradient transformations. The gradient transformations, which are different from vector transformations, enter into the formulation of the element dynamic equations. Furthermore, constraints on higher derivatives can also be imposed at a preprocessing stage using linear algebraic equations; allowing for having a higher degree of continuity.

5 ANCF VS B-SPLINE CURVES AS ANALYSIS TOOLS

While B-spline geometry can always be converted to ANCF geometry, the converse is not true. ANCF geometry does not impose restriction on the basis functions that must be included in the interpolating polynomials. This allows for developing finite elements that have less coordinates as compared to those developed using the B-spline representation. Furthermore, ANCF geometry can be used to model both structural and non-structural discontinuities [13, 15, 17, and 18], while the rigid recurrence formula for B-spline representation cannot be used to model structural discontinuities in a straight forward manner. The basic differences between ANCF and B-spline geometries are demonstrated in this section using a planar beam example. This element is an example of ANCF elements that cannot be converted to B-spline representation. This element is based on a polynomial expansion that does not have the two basis functions x^2y and x^3y . These terms can be included in ANCF geometry by adding nodal coordinates allowing for converting B-spline representation to ANCF representation. Similar comments apply to ANCF thin plate elements that do not have to include all the basis functions $x^k y^l$; $k, l = 0, 1, 2, 3$. This flexibility offered by ANCF geometry allows for developing finite elements that have smaller number of coordinates compared to those elements developed by B-spline geometry.

One can also show that ANCF finite elements can describe structural and non-structural discontinuities. Non-structural discontinuities that allow for large rigid body rotations can be described using a C^0 model obtained by imposing constraints on the position coordinates only. For example if two elements i and j are connected by pin joint at a node, one can apply the algebraic equations $\mathbf{r}^i = \mathbf{r}^j$ at this node. These algebraic equations can be imposed at a preprocessing stage to eliminate the dependent variables and define FE mesh that has a constant mass matrix and zero Coriolis and centrifugal forces despite the finite rotations allowed between the finite elements of the mesh. Non-structural discontinuities can also be described using B-spline geometry by reducing the knot multiplicity at the joint node by one. Note that in the case of non-structural discontinuities no constraints are imposed on the gradient vectors, and therefore, the state of strain is not unique at the joint node. Each of the Lagrangian strains $\varepsilon_{xx} = (\mathbf{r}_x^T \mathbf{r}_x - 1)/2$, $\varepsilon_{yy} = (\mathbf{r}_y^T \mathbf{r}_y - 1)/2$, and $\varepsilon_{xy} = \mathbf{r}_x^T \mathbf{r}_y / 2$ have two values at the joint node; one defined on element i and the other is defined on element j . Here $\mathbf{r}_x = \partial \mathbf{r} / \partial x$, $\mathbf{r}_y = \partial \mathbf{r} / \partial y$, $\mathbf{r}_z = \partial \mathbf{r} / \partial z$.

The concept of degrees of freedom widely used in mechanics is not considered in developing the recurrence relationships on which B-spline and NURBS geometry are based. This represents another serious limitation when these computational geometry methods are used as analysis tools; as evident by the fact that B-spline geometry cannot describe structural discontinuities. This type of discontinuities, while it remains of the C^0 continuity type, requires imposing additional constraints on the gradients; these constraints cannot be captured by the B-spline recurrence formula since they require the elimination of additional vectors. In the case of B-spline, C^0 continuity is achieved by reducing the knot multiplicity by one, and this eliminates one control point leading to the definition of a pin joint (non-structural discontinuity). ANCF geometry, on the other hand, allows for imposing constraints on the gradients using the tensor transformation $(\partial \mathbf{r} / \partial \mathbf{x}_1) = (\partial \mathbf{r} / \partial \mathbf{x}_2) \mathbf{A}$, where $\mathbf{x}_1 = [x_1 \ y_1]^T$ and $\mathbf{x}_2 = [x_2 \ y_2]^T$ are two sets of coordinate lines, and \mathbf{A} is the matrix of coordinate line transformation. Using this tensor gradient transformation, the structural discontinuities can be systematically modeled using ANCF finite elements [13, 17].

6 NEW ANCF FINITE ELEMENT MESH

In this section, it is shown how fully parameterized ANCF three-dimensional finite elements can be used to develop spatial joint models that allow large relative rigid body rotation between the finite elements. ANCF finite elements connected by this joint can be assembled using linear connectivity conditions leading to FE mesh that has a constant mass matrix and zero Coriolis and centrifugal forces. The fully parameterized three-dimensional ANCF beam element is used in this investigation to demonstrate the development of such joint models. The displacement field of the element can be written as $\mathbf{r}(x, y, z) = \mathbf{S}(x, y, z)\mathbf{e}(t)$ where x , y , and z are the element spatial coordinates [12, 19]. The element has two nodes; each node has 12 nodal coordinates defined by the vector $\mathbf{e}^k = [\mathbf{r}^{kT} \quad \mathbf{r}_x^{kT} \quad \mathbf{r}_y^{kT} \quad \mathbf{r}_z^{kT}]^T$, where k is the node number. This ANCF finite element captures the cross section deformation and its coupling with extension and bending. Therefore, this element can be used to develop general models for belt drives and rubber tracked vehicles. Furthermore, this three-dimensional beam element is another example that can be used to demonstrate the generality of the ANCF geometry. This element is based on cubic interpolation in x and linear interpolation in y and z . Nonetheless, one can show that the four basis functions x^2y , x^3y , x^2z , x^3z are not used in developing the displacement field of this widely used ANCF beam element. Therefore, the geometry of this element cannot be converted to B-spline volume geometry. These missing basis functions can be systematically included in the development of another ANCF finite element that can be converted to B-spline volume geometry. However, such an element will lead to 50% increase in the number of the element nodal coordinates.

A planar pin joint between rigid or flexible bodies is an example of C^0 continuity, as previously discussed. A pin joint between two rigid bodies in the spatial analysis also allows for only one degree of freedom, which is a relative rotation about the joint axis. Since the pin joint eliminates five degrees of freedom in the rigid body analysis, its formulation requires five algebraic constraint equations that eliminate three relative translation displacements and two relative rotations between the two bodies. In the case of flexible bodies, an infinitesimal volume can have 12 modes of displacements; three rigid body translations, three rotations, and six deformation modes. In this section, a new model of pin joint between ANCF finite elements is introduced. The formulation of this pin joint between elements i and j employs the following six scalar equations defined at the joint node:

$$\mathbf{r}^i = \mathbf{r}^j, \quad \mathbf{r}_\alpha^i = \mathbf{r}_\alpha^j \quad (12)$$

Here α is the coordinate line that defines the joint axis; α can be x , y , z or any other coordinate line as discussed later in this section. The six scalar equations of Eq. 12 eliminate six degrees of freedom; three translations, two rotations, and one deformation mode. This joint model ensures C^1 continuity with respect to the coordinate line α and C^0 continuity with respect to the other two parameters. It follows that the Lagrangian strain component $\varepsilon_{\alpha\alpha} = (\mathbf{r}_\alpha^T \mathbf{r}_\alpha - 1)/2$ is continuous at the joint definition point, while the other five strain components can be discontinuous.

While the algebraic constraint equations of a pin joint between two rigid bodies are highly nonlinear. The algebraic constraint equations of Eq. 12 are linear. Therefore, these equations

can be applied at a preprocessing stage to systematically eliminate the dependent variables. Using these equations, one can develop a new kinematically linear FE mesh for flexible-link chains in which the links can have arbitrarily large relative rotations. The use of this pin joint model with ANCF finite elements leads to a constant mass matrix and zero Coriolis and centrifugal forces.

As previously mentioned in this paper, B-spline geometry can describe the type of non-structural discontinuity discussed in this section. Nonetheless, if an arbitrary axis of a pin joint is to be used in the analysis, the use of B-spline geometry can be difficult given the rigid structure of the B-spline recurrence formula. In order to be able to choose an arbitrary axis of rotation for the pin joint, one must be able to define the gradient vector in the direction of a coordinate line along this axis of rotation. Such a definition can be easily made using ANCF geometry using the gradient tensor transformation. Let u, v , and w be another set of parameters; one of them can be used to define the joint axis. It follows that $[\mathbf{r}_u \ \mathbf{r}_v \ \mathbf{r}_w] = [\mathbf{r}_x \ \mathbf{r}_y \ \mathbf{r}_z] \mathbf{A}$, where \mathbf{A} is the constant matrix of coordinate transformation defined as

$$\mathbf{A} = \begin{bmatrix} \frac{\partial x}{\partial u} & \frac{\partial x}{\partial v} & \frac{\partial x}{\partial w} \\ \frac{\partial y}{\partial u} & \frac{\partial y}{\partial v} & \frac{\partial y}{\partial w} \\ \frac{\partial z}{\partial u} & \frac{\partial z}{\partial v} & \frac{\partial z}{\partial w} \end{bmatrix} \quad (13)$$

The fact that this matrix is constant allows having linear pin joint connectivity conditions when ANCF finite elements are used [13, 17].

7 NUMERICAL RESULTS

It will be demonstrated in this section that ANCF meshes that allow relative motion between the finite elements can be developed. In these ANCF meshes, the finite elements are connected using linear algebraic equations and the mesh mass matrix remains constant. Chain example characterized by non-structural discontinuities is considered in this section. The links of the chain used in this section are assumed to be flexible with mass density of 7200 kg/m^3 , and a Poisson ratio of 0.3. Two different values of the modulus of elasticity, 2×10^8 and $2 \times 10^{11} \text{ N/m}^2$, are used in the simulations. The elastic forces of the ANCF elements are formulated using a general continuum mechanics approach that employs a Hookean constitutive model. The system is represented by one FE mesh (one flexible body).

The chain used is a multi-link chain that has an overall length of 1 m (Fig. 2). It consists of 8 links that are connected by pin joints. These pin joints ensure C^0 continuity and allow for independent relative rotations and deformation modes at the joint nodes. In computational geometry, this case of non-structural discontinuities at the joint nodes corresponds to knot multiplicity of 3 when cubic polynomials are used for the finite elements. Each link in this chain is represented by one planar shear deformable beam element. Therefore, the chain has 80 degrees of freedom; 8 degrees of freedom represent rigid body relative rotations, and the remaining 72 degrees of freedom represent deformation modes; with 9 deformation modes for each link. The chain is subjected to a base excitation defined by the func-

tion $X = -0.01\sin(0.1\pi t)$. All the links of the chain are assumed to be initially horizontal. The effect of the link gravity is considered.

In order to verify the obtained results, a simulation of a very stiff pendulum is carried out first, and the results are compared with the results of a rigid link chain model. For the very stiff chain, a modulus of elasticity of $2 \times 10^{11} \text{ N/m}^2$ is used for the finite elements. Figure 4 shows the vertical position of the center of the last link as function of time for both cases of the rigid and stiff chains.

Figure 4 Vertical displacement of the center of link 8

(— Flexible link chain, --- Rigid link chain)

Figure 5 shows the absolute rotation of the last link of the chain about an axis parallel to the pin joint axes. The results presented in Figs. 4 and 5 show a good agreement between the results obtained using the rigid and very stiff link chain models. For the rigid link chain model, nonlinear algebraic equations are used to define the pin joints and the resulting generalized mass matrix associated with the system degrees of freedom is highly nonlinear. For the flexible ANCF chain model, the chain is represented by one FE mesh (one flexible body), the pin joint constraints are linear, and the mass matrix is constant. Figure 6 shows the vertical displacement of the tip point of link 8 of the chain when the modulus of elasticity is reduced to $2 \times 10^8 \text{ N/m}^2$. Figure 7 shows the relative rotation between links 7 and 8 of the flexible chain as function of time.

Figure 5 Rotation of link 8 (— Flexible link chain, ---- Rigid link chain)

Figure 6 Vertical displacement of the tip point of link 8 of the flexible chain

Figure 7 Relative rotation between last two chain links

Figures 8 and 9 show the distribution of the normal strain components ε_{xx} and ε_{yy} . It is clear from the results presented in these figures that the strains are discontinuous as the result of the non-structural discontinuities at the joints; the strains are continuous within the elements, and ε_{xx} decreases since the links at the beginning of the chain are subjected to higher gravity forces as compared to the links at the end of the chain. It is important, however, to point out that for fully parameterized ANCF finite elements one can always define at an arbitrary point inside the element, coordinate lines in which there are continuous strain components regardless of the shape of the structure.

8 CONCLUSIONS

This paper addresses the important issue of using computational geometry methods such as B-spline and NURBS as analysis tools. B-spline and NURBS employ recurrence formulas that allow changing the degree of continuity at a breakpoint by adjusting the knot multiplicity at this point. As demonstrated in this paper, the recurrence formula has several drawbacks when B-spline representation is used as an analysis tool. Because the recurrence formula does not provide flexibility for choosing the basis functions, B-spline representation can lead to significantly larger number of coordinates and a higher dimensional model. This fact was used to demonstrate the generality of the ANCF geometry. While B-spline geometry can always be converted to ANCF geometry, the converse is not true. It is also shown that the B-spline recurrence formula cannot be used to model structural discontinuity in a straight forward manner. While structural discontinuities are of the C^0 type, they cannot be captured in the B-spline representation by reducing the knot multiplicity by one. This reduction of the knot multiplicity is equivalent to elimination of the relative translation only; and such a reduction in the knot multiplicity leads to a rigid body mode that defines the conditions of a pin joint. In the case of structural discontinuities, on the other hand, the C^0 B-spline representation does not eliminate the rigid body mode since additional algebraic constraint equations are required in order to eliminate the relative rotations between two segments. The paper also presents a new three-dimensional pin joint model that leads to linear connectivity conditions and constant mass matrix when used with ANCF finite elements. The limitations identified in this paper when B-spline geometry is used as analysis tool suggest the use of the I-CAD-A approach in which a constant transformation can be developed to convert CAD geometry to FE mesh.

Abstract: *The coupling between parametric and external resonances in inclined cables subjected to a motion of an anchorage with components both along and perpendicular to their axis is investigated. Besides posing theoretical challenges, this problem is of practical interest for inclined cables of cable-stayed bridges and guyed towers. First, the state of the art on the subject of multi-modal interactions of cables with moving anchorages is summarized. Then, the proposed analytical model is presented, which is selected to be as simple as possible, but still suitable for capturing the coupling between the first and second eigenmodes, hence between parametric and external resonances. Next, two specific cases of the general model, in which no coupling appears, are studied in order to identify the intrinsic characteristics of external and parametric resonance, respectively. Finally, the coupling between the two instabilities is investigated, aiming at a better understanding of the interaction phenomenon and at formulating practical engineering guidelines.*

1 STATE-OF-ART ON MULTI-MODAL VIBRATIONS OF CABLES

In cable stayed bridges or guyed towers, indirect excitation through the vibrations of the neighboring structural elements, the bridge deck and the tower respectively, can lead to oscillations with high amplitudes in case resonance takes place. This resonance may be external, parametric or a combination of both. External resonance is induced by a motion of the anchorage perpendicular to the cable axis and occurs when the exciting frequency is equal to any eigenfrequency of the cable. Parametric resonance describes the dynamic instability which is induced by a motion of the anchorage along the axis of the cable and is observed when the ratio between the exciting frequency and some eigenfrequency takes specific values like 2:1, 3:1, 1:2 or 1:3.

The phenomenon of external resonance is well known among bridge designers and many design guidelines of cable stayed bridges provide a description of it and propose measures to prevent its effects [1, 2]. Most current models are linear [1, 2], but models including cubic non-linearities exist, like Irvine's solution for undamped motion (chapter 3.4 of [3]) or that of Caetano including damping [4]. The phenomenon of parametric resonance has entered the structural engineers' culture more recently with the development of the new generation of cable stayed bridges [5], it is hence detailed in [2] but only mentioned in [1]. It has been described first by Kovacs [6]. Then, Uhrig [7] proposed the first expressions of the main instability zones for the excitation frequencies in which the response diverges. Lilien and Pinto da Costa [8], in parallel with Cai and Chen [9], established the first values of the amplitude of the non-linear response in the main instability zone, the so-called two to one (2:1) resonance. These results were confirmed by Clément and Crémona using the harmonic balance method [10] and by Berlioz and Lamarque using the multiple scales method [11]. Takahashi [12] has shown that there were many instability zones around the multiples of the cable eigenfrequencies but also in the neighborhood of combinations of those, the so-called combination resonances.

The interaction between external and parametric resonance has been studied using different approximations depending on the sag of the cable, as outlined in Rega's bibliographical report [13]. A detailed literature review for coupled external-parametric resonances for taut strings can be found in Nayfeh and Mook [14]. The first studies of modal interaction in sagged cables concern internal resonances [15] or the coupled response to distributed load [16, 17, 18]. Luongo *et al.* have shown that, when the sag is significant, quadratic non-linearities govern the response while cubic non-linearities dominate when the sag is small [15, 19]. For instance, the publications on uncoupled parametric resonance cited above [6, 12, 7, 8, 9, 10, 11] concern only small sagged cables and include only cubic non-linearities.

A two degrees of freedom model for in-plane external resonance / out-of-plane parametric resonance interaction of large sagged cables was proposed by Perkins [20]. He observed that, like for taut strings, for small exciting amplitudes the system is uncoupled but, when the amplitude exceeds a certain value, parametric resonance occurs and the system becomes coupled. Gonzalez-Buelga *et al.* extended this model by taking into account the second out-of-plane mode in the response, but they limited themselves to small sagged cables [21]. Two mode planar interaction was also studied by Chatjigeorgiou and Mavrakos in a marine context [22], including small bending stiffness and quadratic damping due to fluid drag forces. A four degrees of freedom model for a large sagged cable was studied by Benedettini and Rega [23]. Zhang and Tang investigated also multi-modal interaction, focusing on the bifurcation type and on the response to chaotic excitation [24]. Multi-modal interaction was also studied by Srinil and Rega who compared finite differences numerical results with multiple scales analytical results (with up to 15 modes), in order to check if simulations can capture the richness of the cable's behavior near the first cross-over region undergoing 1:1 or 2:1

resonance [25]. Srinil and Rega also investigated the accuracy of reduced order models for the modeling of 2:1 resonance in horizontal and inclined cables. They showed that “the minimal (two-degrees-of-freedom) model” involving only the resonant modes seems capable of providing reliable results only for very low-sagged cables [26].

Advanced multi-modal models are thus nowadays available for researchers studying the dynamic interaction of sagged cables excited parametrically. These models try to take into account the whole complexity of the problem (generally in a relatively theoretical manner), the problem of coupled external/parametric resonance of small sagged cables being treated as a simple specific case. There is, however, need for a coupled model of small sagged cables for structural design of stay cables in engineering practice, in order to identify clearly the instability regions and the amplitude of responses. Gonzalez-Buelga *et al.* made a first step in this direction using the multiple scales method for out-of-plane parametric resonance [21]. For small sag however, the frequencies of in-plane and out-of-plane symmetric modes are very close, so that there might be internal resonance. It is thus proposed here to study the relative influence of in-plane and out-of-plane parametric resonance and its coupling with in-plane external resonance. In section 2 an analytical model is developed based on the harmonic balance method and compared with finite element numerical results. Uncoupled external and parametric resonances are studied in the third and fourth section, respectively, in order to identify their characteristics. The fifth section is dedicated to the study of the coupled problem.

2 DEVELOPMENT OF THE ANALYTICAL MODEL

2.1 Presentation of the problem

The analytical model presented here is dedicated to the study of multi-modal non-linear vibrations of inclined cables subjected to coupled external/parametric resonance. One end of the cable is fixed while the other end is subjected to an imposed motion (figure 1). This situation could correspond to a cable of a cable stayed bridge with the upper end fixed on a stiff pylon and the lower end supporting a flexible deck. The imposed motion of the lower end could be due to wind or traffic induced vibration of the deck. The cable is assumed to have small sag, which is a realistic assumption for bridge cables.

Figure 1: Inclined cable submitted to harmonic excitation at one end.

The plane of the cable is described by coordinates X , along the line joining the two ends of the cable and Y , perpendicular to this line, with the origin located at the fixed end. The out-of-plane coordinates are represented by Z . The inclination of the cable axis with respect to the virtual line of the deck (which is here supposed to be horizontal) is denoted by the angle θ . Without loss of generality, the imposed motion is supposed to be vertical and harmonic with

amplitude Δ and frequency Ω , called respectively exciting amplitude and exciting frequency. All other forces except gravity are neglected. As noted above, it is further assumed that the sag of the cable is small, so that the difference between the abscissa along the cable and the abscissa along the chord can be neglected. Another consequence of the small sag is that the static equilibrium shape of the cable, which is in reality a catenary, can be assumed as parabolic [5].

2.2 Derivation of equations of motion

For common stay cables, axial displacements are much smaller than transverse displacements, so that here only displacements in the Y and Z directions will be considered and denoted as $V(X,t)$ and $W(X,t)$, respectively. The equations of motion being non-linear, their solutions are generally derived using Galerkin's method [20, 23, 10, 24, 11, 21]. Considering previous investigations by Gonzalez Buena *et al.* [21] and the targeted field of application (small sagged stay cables), the present study is limited to the first out-of-plane mode, the first in-plane mode and the second in-plane mode. The approximate displacements are thus expressed as:

$$v(x, t) = p_1(t) \sin(\pi x) + p_2(t) \sin(2\pi x) + \delta \cos(\Omega t) x \cos \theta \quad (1a)$$

$$w(x, t) = q_1(t) \sin(\pi x) \quad (1b)$$

where p_1 and p_2 are time functions corresponding to the first and second in-plane mode, and q_1 that of the first out-of-plane mode. Note that in the previous expressions, the various parameters have been expressed in a dimensionless form with respect to the length of the cable:

$$x = \frac{X}{L}, \quad \delta = \frac{\Delta}{L}, \quad v = \frac{V(X, t)}{L} \quad \text{and} \quad w = \frac{W(X, t)}{L} \quad (2)$$

Considering the small sag of the cable, the eigenfrequencies are obtained following the approximation proposed by Gonzalez Buena *et al.* [21] and are given by:

$$\omega_i^{\text{in}} = \frac{\pi i}{L} \sqrt{\frac{T}{\rho}} \sqrt{1 + \frac{2\lambda^2}{i^4 \pi^4} [1 + (-1)^{i+1}]^2}, \quad \omega_j^{\text{out}} = \frac{\pi j}{L} \sqrt{\frac{T}{\rho}} \quad (3)$$

where T is the tension in the cable (which is assumed constant along the length), ρ its mass per unit length and λ the so-called Irvine's parameter, which is generally smaller than 1, except for very large cable stayed bridges; it is given in terms of the elastic modulus E of the cable, its cross-sectional area S and the gravity acceleration g :

$$\lambda^2 = \frac{ES}{T} \left(\frac{\rho L g \cos \theta}{T} \right)^2 \quad (4)$$

Following then the procedure proposed by Luongo *et al.* [15], the quadratic terms in the equations of motion are neglected. Looking at the remaining equations, one observes that the roles played by the first in-plane mode p_1 and by the first out-of-plane mode q_1 are identical. Moreover, previous experiments on taut cables have shown that only one of the two modes has a nonzero amplitude [11, 20, 21] (in general only the out-of-plane mode occurs). So, for simplicity reasons, only one of the two modes will be considered. The equations of motion reduce hence to:

$$\ddot{p}_1 + 2\zeta \omega_1 \dot{p}_1 + \omega_1^2 (1 + 2a \cos \Omega t) p_1 + c_3 p_1 (p_1^2 + 4p_2^2) = 0 \quad (5a)$$

$$\ddot{p}_2 + \zeta \omega_2 \dot{p}_2 + \omega_2^2 (1 + 2a \cos \Omega t) p_2 + 4c_3 p_2 (p_1^2 + 4p_2^2) = F_2(t) \quad (5b)$$

where ω_1 denotes, indifferently, the frequency of the first out-of-plane mode ω_1^{out} or that of the first in-plane mode ω_1^{in} . ξ is the modal damping ratio of the first out-of-plane mode which is assumed identical to that of the first in-plane mode and equal to twice that of the second mode. The dimensionless amplitude a of parametric excitation, the coefficient of the cubic terms c_3 and that of external excitation in-plane F_2 are given respectively by:

$$a = \frac{ES}{2T} \delta \sin \theta, c_3 = \frac{\pi^2}{4} \frac{ES}{T} \omega_1^2 \text{ and } F_2(t) = -\frac{\delta \cos \theta \Omega^2}{\pi} \cos(\Omega t) \quad (6)$$

2.3 Method of harmonic balance

In equations (5a) and (5b), the coupling is limited to the non-linear terms. For this reason, the coupling will have an influence only near resonance conditions. Previous research [20, 23, 27] has indeed shown that the instability regions were only marginally affected by the coupling. Thus, the exciting frequencies, which might cause instability of the cable, are:

- $\Omega \approx 2 \omega_1$ for the first in-plane or out-of-plane mode (parametric resonance);
- $\Omega \approx \omega_2$ for the second in-plane mode (external resonance).

As, for small sagged cables, these three frequencies are close to each other, interactions between parametric resonance in-plane or out-of-plane and external resonance in-plane might appear. The present study will thus be limited to a frequency region in the vicinity of the frequency of the second in-plane mode. In this region, it can be assumed that the time functions p_1 and p_2 are of the following form [10]:

$$p_1(t) = p_{11} \sin(\Omega t/2) + p_{12} \cos(\Omega t/2) \quad (7a)$$

$$p_2(t) = p_{21} \sin(\Omega t) + p_{22} \cos(\Omega t) \quad (7b)$$

where p_{11} , p_{12} , p_{21} , and p_{22} are real numbers, which will be determined later.

Introducing these terms into (5a) and (5b) and using the method of harmonic balance (which allows us to neglect the terms of high frequencies), leads finally to a system of four equations with four unknowns (p_{11} , p_{12} , p_{21} and p_{22}). This system can be separated into two matrix equations, which are characteristic of the coupled problem of inclined cables submitted to a harmonic motion at one end:

$$\begin{bmatrix} \frac{3}{4} c_3 A^2 + 2c_3 B^2 + \omega_1^2 a + \omega_1^2 - \frac{\Omega^2}{4} & -\xi \omega_1 \Omega \\ \xi \omega_1 \Omega & \frac{3}{4} c_3 A^2 + 2c_3 B^2 - \omega_1^2 a + \omega_1^2 - \frac{\Omega^2}{4} \end{bmatrix} \begin{bmatrix} p_{11} \\ p_{12} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (8a)$$

$$\begin{bmatrix} 2c_3 A^2 + 12c_3 B^2 + \omega_2^2 - \Omega^2 & -\xi \omega_2 \Omega \\ \xi \omega_2 \Omega & 2c_3 A^2 + 12c_3 B^2 + \omega_2^2 - \Omega^2 \end{bmatrix} \begin{bmatrix} p_{21} \\ p_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ -\delta \cos \theta \Omega^2 / \pi \end{bmatrix} \quad (8b)$$

where $A^2 = p_{11}^2 + p_{12}^2$ and $B^2 = p_{21}^2 + p_{22}^2$.

3 UNCOUPLED EXTERNAL RESONANCE

3.1 Characteristic equation of uncoupled external resonance

Before studying the coupled system, the problems of external resonance and parametric resonance are treated separately, in order to understand better their characteristics. The study of external resonance is generally concerned with the response to an excitation according to the first mode of vibration, while here focus will be on the second in-plane mode of vibration,

which is susceptible to interact with parametric resonance terms when coupling is considered. Thus, considering a horizontal cable subjected to a vertical excitation at one end, the amplitude of the first mode vanishes in expression (8b) ($A = 0$) and one obtains the following system of equations, which is characteristic of the uncoupled external resonance:

$$\begin{bmatrix} 12c_3B^2 + \omega_2^2 - \Omega^2 & -\xi\omega_2\Omega \\ \xi\omega_2\Omega & 12c_3B^2 + \omega_2^2 - \Omega^2 \end{bmatrix} \begin{bmatrix} p_{21} \\ p_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ -\delta \cos \theta \Omega^2 / \pi \end{bmatrix} \quad (9)$$

To solve the above equation, it is necessary to check under what conditions the determinant of the matrix is different from zero:

$$144c_3^2B^4 + 24c_3(\omega_2^2 - \Omega^2)B^2 + (\omega_2^2 - \Omega^2)^2 + \xi^2\omega_2^2\Omega^2 = 0 \quad (10)$$

This is a bi-quadratic equation which has real solutions if and only if its discriminant is positive. As it is always negative, the matrix in (9) can be inverted and a third degree polynomial equation linking the square amplitude of the response B^2 with the amplitude of the excitation δ is obtained:

$$144c_3^2B^6 + 24c_3(\omega_2^2 - \Omega^2)B^4 + [(\omega_2^2 - \Omega^2)^2 + \xi^2\omega_2^2\Omega^2]B^2 - \delta^2 \cos^2 \theta \frac{\Omega^4}{\pi^2} = 0 \quad (11)$$

The real roots of (11) can be calculated with the method of Cardan. Depending on the value of the parameters, equation (11) might have one or three real roots, out of which only two are stable amplitudes of response.

3.2 Characteristics of the hysteresis region

The interval of exciting amplitudes for which two stable amplitudes exist is called hysteresis region, because of the role played by the state of the cable at the preceding time in the determination of the actual amplitude. The limits of the hysteresis region can be determined from the characteristic equation of external resonance (11), which can be rewritten in a more concise manner:

$$k_1Y^3 + k_2Y^2 + k_3Y + k_4 = 0 \quad (12)$$

where:

$$k_1 = 144c_3^2, k_2 = 24c_3(\omega_2^2 - \Omega^2), k_3 = (\omega_2^2 - \Omega^2)^2 + \xi^2\omega_2^2\Omega^2 \text{ and } k_4 = -\delta^2 \cos^2 \theta \Omega^4 / \pi^2 \quad (13)$$

Equation (12) has three real solutions if and only if its discriminant is positive. The borders of the hysteresis region are thus given by the parameters which nullify this discriminant. After some standard algebraic manipulations, one finally finds the expressions of the two critical exciting amplitudes, which limit the hysteresis region:

$$\delta_1 = \frac{\pi}{\cos \theta \Omega^2} \sqrt{\frac{1}{27}k_2 \left[2 \left(\frac{k_2}{k_1} \right)^2 - 9 \frac{k_3}{k_1} \right] - \frac{k_1}{\sqrt{2}} \left[\frac{2}{9} \left(\frac{k_2}{k_1} \right)^2 - \frac{2k_3}{3k_1} \right]^{\frac{3}{2}}} \quad (14a)$$

$$\delta_2 = \frac{\pi}{\cos \theta \Omega^2} \sqrt{\frac{1}{27}k_2 \left[2 \left(\frac{k_2}{k_1} \right)^2 - 9 \frac{k_3}{k_1} \right] + \frac{k_1}{\sqrt{2}} \left[\frac{2}{9} \left(\frac{k_2}{k_1} \right)^2 - \frac{2k_3}{3k_1} \right]^{\frac{3}{2}}} \quad (14b)$$

The critical frequency Ω_{cr} for which more than one solutions exist, is given by the intersection of the two curves resulting from (14a) and (14b). This frequency, which is higher than the frequency of the second eigenmode ($\Omega_{cr} > \omega_2$), can be evaluated using (13), (14a) and (14b):

$$\Omega_{cr} = \omega_2 \sqrt{1 + \frac{3}{2}\xi^2 + \frac{\xi}{2}\sqrt{12 + 9\xi^2}} \quad (15)$$

Expressions (14a), (14b) and (15) allow us to define four regions, each corresponding to a different nature of the response to external resonance. These regions are represented in figure 2 for excitation parameters in dimensionless forms:

- $\Omega < \Omega_{cr}$: The response is undifferentiated, the highest the frequency and the amplitude of excitation, the higher the amplitude of the response;
- $\Omega > \Omega_{cr}$ and $\delta < \delta_1$: Low external resonance occurs, small amplitude response;
- $\Omega > \Omega_{cr}$ and $\delta > \delta_2$: High external resonance occurs, large amplitude response;
- $\Omega > \Omega_{cr}$ and $\delta_1 < \delta < \delta_2$: Hysteresis region, high external resonance might occur, depending on the time history of the excitation; two amplitudes, one small and one large, are thus possible.

Figure 2: Nature of the response to external resonance.

3.3 Practical example: a cable of the Ben-Ahin Bridge

To illustrate the expressions found in the previous sub-section, some results are shown based on the geometric and mechanical properties of a cable of the Ben-Ahin Bridge in Belgium, which was abundantly studied by Da Caetano [5]. Its main characteristics are all supposed constant along its length and are the following:

- Length: $L = 110.505$ m (distance between the anchorages);
- Mass per unit length: $\rho = 64.841$ kg/m;
- Cross-sectional area: $S = 82.6$ cm²;
- Young Modulus: $E = 210$ GPa ;
- Prestress: $T = 4902.7$ kN (actually the prestress is not exactly constant in the numerical model due to gravity; the value given here is that at the lower anchorage).

From those values, the parameters characterizing the vibrations of the horizontal cable can be evaluated: Irvine's parameter $\lambda^2 = 0.0727$, the frequency of the 1st out-of-plane mode $\omega_l^{\text{out}} = 7.82$ rad/s, the frequency of the first in-plane mode $\omega_l^{\text{in}} = 7.84$ rad/s. One remarks that the value of Irvine's parameter of this cable is very low, therefore, the cable is small sagged.

The finite element software used to validate the analytical model and its hypotheses is ADINA, a software which has already been successfully used for the calculation of cable structures [27, 28]. A convergence study in time and space was first conducted for a horizontal cable subjected to gravity and to an excitation perpendicular to its axis with a

frequency equal to that of the second in-plane eigenmode and an amplitude of 10 mm. Rayleigh damping proportional to the mass is chosen, because this is what is generally used for the modeling of cables and because it is the numerical damping which is the closest to the analytical model (in the present example $\xi = 0.5\%$). Geometrical non-linearities are taken into account and the default implicit dynamic algorithm based on Newmark integration method is used with a consistent mass matrix. The time step is varied from 1 ms to 10 ms and the number of elements from 30 to 100. The calculations are separated into two parts: the transient period, from 0 s to 300 s, and the steady state, from 300 s and 340 s. From the variations of the amplitude of the steady state response, 40 truss elements and $\Delta t = 5$ ms was chosen as the best compromise between computation time and accuracy.

Then the results of the numerical model were compared with those of the analytical model for an excitation of $\Delta = 20$ mm. They globally showed very good agreement and the differences in the steady state amplitude varied from 1.5 % for $\Omega = \omega_2$ to 5 % for $\Omega = 1.05 \omega_2$.

4. UNCOUPLED PARAMETRIC RESONANCE

The phenomenon of parametric resonance is relatively well known from the literature but it is often not distinguished between in-plane and out-of-plane resonance. As, for small sagged cables, the frequency of the first out-of-plane mode is very close to that of the first in-plane mode (a few percentage points in cables of cable stayed bridges), they might often be confused. Therefore, it is meaningful to study the phenomenon and to look for a possible internal resonance between the first in-plane and out-of-plane modes.

4.1 Analytical expression of the amplitude and the threshold

The equations of uncoupled parametric resonance are often found by taking into account only the first in-plane mode in the general equations of motion [8], [10]. Here, the first in-plane and first out-of-plane modes will be considered alternatively (ω_l representing either the frequency of the first in-plane or first out-of-plane mode) and the characteristic equation of parametric resonance is deduced from (8a) by considering that the cable is horizontal and submitted to a horizontal motion ($B = 0$):

$$\begin{bmatrix} \frac{3}{4}c_3A^2 - \omega_1^2a + \omega_1^2 - \frac{\Omega^2}{4} & -\xi\omega_1\Omega \\ \xi\omega_1\Omega & \frac{3}{4}c_3A^2 + \omega_1^2a + \omega_1^2 - \frac{\Omega^2}{4} \end{bmatrix} \begin{bmatrix} p_{11} \\ p_{12} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (16)$$

This problem has a nonzero solution, if the determinant of the matrix is equal to zero:

$$\frac{9}{16}c_3^2A^4 + \frac{3}{2}c_3(\omega_1^2 - \frac{\Omega^2}{4})A^2 + \xi^2\omega_1^2\Omega^2 - \omega_1^4a^2 + \left(\omega_1^2 - \frac{\Omega^2}{4}\right)^2 = 0 \quad (17)$$

One recognizes in (17) a bi-quadratic equation in A . It has real solutions if and only if its discriminant is larger than or equal to zero, which is equivalent to the following condition:

$$a^2\omega_1^2 - \xi^2\Omega^2 \geq 0 \quad (18)$$

Equation (18) determines a first condition on the instability zone: for a given exciting frequency Ω , as long as the dimensionless amplitude of the excitation is below a certain threshold $a^2 < \xi^2\Omega^2/\omega_1^2$, there is no instability and the only solution of the problem of parametric excitation is zero ($p_{11} = p_{12} = 0$); on the contrary, when the exciting amplitude reaches the limit amplitude $a^2 \geq \xi^2\Omega^2/\omega_1^2$, equation (17) has two solutions and the characteristic amplitudes of uncoupled parametric resonance A_U are given by:

$$A_U = \sqrt{\frac{4}{3} \frac{\omega_1^2}{c_3}} \cdot \sqrt{\left(\frac{\Omega}{2\omega_1}\right)^2 - 1 \pm \sqrt{a^2 - 4\xi^2 \left(\frac{\Omega}{2\omega_1}\right)^2}} \quad (19)$$

One remarks that the limit case $a^2 = \xi^2 \Omega^2 / \omega_1^2$ corresponds to the pair “exciting amplitude/ exciting frequency” for which the two characteristic amplitudes of uncoupled parametric resonance (19) are equal. For a given exciting amplitude, this frequency is the highest frequency for which parametric resonance may occur. It is also the frequency for which the amplitude of parametric resonance is the highest. It is noted also that condition (18) is not sufficient for appearance of parametric resonance: the expression under the square root in (19) has to be positive. It is, thus, necessary for the dimensionless amplitude of parametric excitation to be higher than a certain critical value a_U which is often called the threshold of parametric excitation:

$$a_U = \sqrt{\left[\left(\frac{\Omega}{2\omega_1}\right)^2 - 1\right]^2 + 4\xi^2 \left(\frac{\Omega}{2\omega_1}\right)^2} \quad (20)$$

Another way to look at this condition, on the dimensionless amplitude of excitation, is to rewrite (20) as a condition on the exciting frequency:

$$\Omega \in \left[2\omega_1 \sqrt{1 - 2\xi^2 - \sqrt{a^2 - 4\xi^2(1 - \xi^2)}} , 2\omega_1 \sqrt{1 - 2\xi^2 + \sqrt{a^2 - 4\xi^2(1 - \xi^2)}} \right] \quad (21)$$

4.2 Numerical study of amplitudes and thresholds

As the influences of damping ratio, frequency and exciting amplitude have been studied abundantly in the past (for example in [10]), it is here focused on the interaction between in-plane and out-of-plane parametric resonance. A first model, in which a horizontal cable identical to the one in section 3.3 has an anchorage moving horizontally, is hence considered. It is then modified for the out-of-plane instability by introducing at time zero an out-of-plane perturbation in the form of a small vanishing wind gust, uniformly distributed along the cable. The variations of the amplitude of both responses with the frequency of the excitation are shown in figure 3a for $\Delta = 20$ mm and $\xi = 0.08$ %. The amplitudes of the response plotted in this figure are steady state amplitudes obtained after a transient period of 1000 cycles. It is observed that there is very good agreement between numerical and analytical results for both in-plane and out-of-plane response for the stable branches (corresponding to growing frequencies). There is also good agreement of the frequency of the jump phenomenon (obtained with a decreasing frequency) for the in-plane numerical simulations; but, numerically, the frequency of the out-of-plane jump coincides with the frequency of the in-plane jump.

From this last observation, one may suppose that the in-plane vibration is not stable and turns into out-of-plane vibration when it is disturbed. Indeed, every time that a small out-of-plane perturbation is introduced in a plane model where in-plane parametric resonance is installed, out-of-plane resonance appears and then gradually dominates the whole response and the in-plane vibration vanishes.

These results are confirmed when investigating more specifically the threshold amplitudes of the out-of-plane mode (figure 3b). Two damping factors are tested ($\xi = 0.1$ % and $\xi = 0.5$ %) and both sets of simulations lead to similar results. Figure 3b represents the threshold amplitudes for $\xi = 0.5$ %. For low frequencies, there is very good agreement between analytical and numerical results for both the in-plane and the out-of-plane threshold. For high frequencies, numerical results for the in-plane and out-of-plane threshold coincide and are in very good agreement with the analytical values of the in-plane mode. The in-plane

mode of vibration is unstable and turns into out-of-plane vibration. These results should be confirmed for other values of Irvine's parameter, thus, with other ratios between in-plane and out-of-plane frequencies. Yet, it seems that the amplitude of the response which should be taken into account is that of the out-of-plane mode and that the following bandwidth of parametric resonance has to be considered:

$$\Omega \in I^{\text{in}} \cup I^{\text{out}} \text{ where } \begin{aligned} I^{\text{in}} &= \left[2\omega_1^{\text{in}} \sqrt{1-2\xi^2 - \sqrt{a^2-4\xi^2}}, 2\omega_1^{\text{in}} \sqrt{1-2\xi^2 + \sqrt{a^2-4\xi^2}} \right] \\ I^{\text{out}} &= \left[2\omega_1^{\text{out}} \sqrt{1-2\xi^2 - \sqrt{a^2-4\xi^2}}, 2\omega_1^{\text{out}} \sqrt{1-2\xi^2 + \sqrt{a^2-4\xi^2}} \right] \end{aligned} \quad (22)$$

Figure 3: Influence of the excitation frequency
a) on the amplitude of in-plane and out-of-plane parametric resonance, b) on the corresponding thresholds.

5. COUPLED EXTERNAL/PARAMETRIC RESONANCE

5.1 Coupled threshold of parametric resonance

5.1.1 Analytical expression

Considering now the coupled system of equations (8a) and (8b), equation (8a) will be studied first. This system of equations is homogeneous, so that it has nonzero solutions if and only if the determinant of the matrix is equal to zero, which is equivalent to requiring that solutions of the following equation can be found:

$$\frac{9}{16}c_3^2A^4 + 3\frac{c_3}{2}\left[2c_3B^2 + \left(\omega_1^2 - \frac{\Omega^2}{4}\right)\right]A^2 + \left[\omega_1^2 - \frac{\Omega^2}{4} + 2c_3B^2\right]^2 - \omega_1^4a^2 + \xi^2\omega_1^2\Omega^2 = 0 \quad (23)$$

A bi-quadratic equation in A can be recognized in (23) and thus, the first condition for the existence of real roots to this equation is that its discriminant is equal to zero:

$$a^2\omega_1^2 - \xi^2\Omega^2 > 0 \quad (24)$$

It is noteworthy that this condition is identical to the one obtained for the uncoupled problem (18): the highest frequency for which parametric resonance may appear is thus identical for the coupled and the uncoupled problem. As previously, if the non-dimensional amplitude of parametric excitation is higher than a certain threshold ($a > \xi\Omega/\omega_1$), then the solution of (23) can be written:

$$A = \sqrt{-\frac{8}{3}B^2 + \frac{4}{3}\frac{\omega_1^2}{c_3}\left[\left(\frac{\Omega}{2\omega_1}\right)^2 - 1 \pm \sqrt{a^2 - 4\xi^2\left(\frac{\Omega}{2\omega_1}\right)^2}\right]} \quad \left(= \sqrt{A_U^2 - \frac{8}{3}B^2} \right) \quad (25)$$

Considering (25), one remarks that like for uncoupled parametric resonance, the problem

of coupled parametric resonance has two solutions: one stable (with the positive sign under the square root) and one unstable. Like for uncoupled parametric resonance, the non-dimensional amplitude of parametric excitation has to be higher than a certain value, called threshold of coupled parametric resonance a_c . Below the threshold, no parametric resonance appears: the system is uncoupled and external resonance only may occur. Above this threshold, coupled external-parametric resonance may occur and the amplitude of the coupled parametric resonance is always smaller than that of uncoupled parametric resonance (the amplitude of the second mode reduces the amplitude of the first mode).

The value of the threshold amplitude depends thus on the history of the vibration of the cable. If the vibration starts from a non-coupled state where only external resonance exists, then when the threshold of coupled parametric resonance is just reached, the amplitude of external resonance is still the uncoupled one ($B_c = B_u$ given by (11)). On the contrary, if the vibration starts from a coupled state where both resonances exist, then, when the threshold is reached, the amplitude of external resonance is still the coupled one.

In the first case, the coupled threshold amplitude δ_{cu} can be found without solving the coupled system of equations. Its value is obtained by solving the following non-linear equation resulting from (26) with $A = 0$ and $B = B_u$ which is a stable solution of (11):

$$\delta_{cu} = \frac{2T}{ES \sin \theta} \sqrt{\left[\left(\left(\frac{\Omega}{2\omega_1} \right)^2 - 1 \right) - \frac{2c_3}{\omega_1^2} B_u^2 (\delta_{cu}) \right]^2 + 4\zeta^2 \left(\frac{\Omega}{2\omega_1} \right)^2} \quad (26a)$$

In the second case, it is necessary to solve the coupled system of equations and to obtain the value of the coupled amplitude B_c in order to introduce it in the expression of the threshold amplitude which is then given by:

$$\delta_{cc} = \frac{2T}{ES \sin \theta} \sqrt{\left[\left(\left(\frac{\Omega}{2\omega_1} \right)^2 - 1 \right) - \frac{2c_3}{\omega_1^2} B_c^2 (\delta_{cc}) \right]^2 + 4\zeta^2 \left(\frac{\Omega}{2\omega_1} \right)^2} \quad (26b)$$

5.1.2 Nature of the coupled response

The exciting frequencies and exciting amplitudes, for which external resonance occurs, are known from section 3, so that the nature of the coupled response can be deduced by adding the curve corresponding to the threshold of coupled parametric resonance (26a) and (26b) into the diagram of external resonance (figure 2). Such a diagram is shown in figure 4 for the cable of the Ben Ahin Bridge studied previously (section 3.3), with an inclination of 30° and a damping ratio of 0.5 %. For this angle, Irvine's parameter becomes $\lambda^2 = 0.0544$ and the frequency of the first in-plane mode becomes $\omega_1^{\text{in}} = 7.84$ rad/s. The curve δ_{cu} represents the amplitude of the coupled threshold when coming from an uncoupled situation (26a), while the curve δ_{cc} represents the amplitude of the coupled threshold when coming from a coupled situation (26b). The curve δ_1 is the amplitude below which no external resonance occurs (14a) and below which the amplitude of the response is that of the lower branch of external resonance. The curve δ_2 indicates the amplitude above which external resonance occurs with certainty (14b) and above which the amplitude of the response is that of the upper branch of external resonance.

In figure 4, seven different regions can be distinguished:

- $\Omega < \Omega_{cr}$ and $\delta < \delta_{cu}$: The response is undifferentiated, the higher the frequency and the amplitude of excitation, the higher the amplitude of the response (region 1).
- $\Omega > \Omega_{cr}$ and $\delta < \delta_1$: No external resonance occurs, the response has a small amplitude (region 2).
- $\Omega > \Omega_{cr}$ and $\delta_2 < \delta < \delta_{cu}$: Only external resonance occurs with large amplitude

(region 3).

- $\Omega > \Omega_{cr}$ and $\delta_2 < \delta < \min(\delta_{CC}, \delta_2)$: Uncoupled hysteresis region. External resonance might occur alone, depending on the time history of the excitation; two amplitudes, one small and one large are possible for the response (region 4).
- $\Omega > \Omega_{cr}$ and $\delta_{CU} < \delta < \delta_2$: Coupled hysteresis region I. Coupled resonance might occur depending on the time history of the excitation. Two sets of amplitudes are possible: one uncoupled external resonance with low amplitude, coupled external and parametric resonances, both with high amplitudes (region 5).
- $\Omega > \Omega_{cr}$ and $\delta_{CC} < \delta < \delta_{CU}$: Coupled hysteresis region II. Coupled resonance might occur depending on the time history of the excitation (oscillation must come from an initial coupled situation). Two sets of amplitudes are possible and identical to those of the coupled hysteresis region I (region 6).
- $\Omega > \Omega_{cr}$ and $\max(\delta_{CU}, \delta_2) < \delta$: Coupled external/parametric resonance occurs with high amplitudes of the response of the first and second modes (region 7).

Figure 4: Nature of the response to coupled external/parametric resonance ($\xi = 0.5\%$).

Comparing then the amplitude of the uncoupled threshold δ_U (20) (dotted curve on figure 4) with the characteristic curves of the coupled thresholds δ_{CU} (26a) and δ_{CC} (26b) and those of the uncoupled hysteresis region δ_I (14a) and δ_2 (14b), it is observed that the coupling causes a shift toward the high frequencies of the instability region, as well as a widening of this instability region. This widening is reduced by the hysteresis region but still, the coupled instability region remains wider than the uncoupled one. Taking the coupling into account seems, thus, necessary.

5.1.3 In-plane/out-of-plane interaction and numerical validation

To investigate the different thresholds, three different schemes are used for the time history of the excitation because of the hysteresis region:

- the “increasing low” scheme used to get the lower branch of external resonance: the amplitude grows slowly until it reaches the desired value, and then it remains constant until steady state.
- the “increasing high” scheme used to get the higher branch of external resonance before coupling appears: calculations start from a first run in which the frequency is out-of the hysteresis region and for which the exciting amplitude is below that of the threshold of coupled parametric resonance, the exciting frequency is increased until the desired one and then the amplitude until parametric resonance appears.
- the “decreasing coupled” scheme used to get the upper branch of external resonance with coupled external/parametric resonance: the amplitude starts from a high value

which is out-of the hysteresis range of coupled external/parametric resonance and remains constant until steady state takes place, then it is decreased slowly until it reaches the desired amplitude of excitation and remains constant until steady state.

Figure 5: Thresholds of coupled external-parametric resonance out-of-plane.

Using these three time histories numerical values for the threshold have been determined and compared to analytical values obtained by expressions (26a), (26b) and (20). For the plane model, very good agreement of the various thresholds was found. The results for out-of-plane model are presented in figure 5 for the out-of-plane model. One observed that there is good agreement of the two thresholds and a slight underestimation of the amplitude of the high limit of the hysteresis region. It is however remarkable that, like for the horizontal cable, when the analytical value of the threshold of coupled in-plane parametric resonance is below that of coupled out-of-plane resonance, the numerical value of the out-of-plane threshold follows that of the in-plane threshold. In other terms, like for the horizontal cable, the first in-plane mode is unstable and almost vanishes when an out-of-plane perturbation is introduced. This time however, when the out-of-plane perturbation is introduced, the first out-of-plane mode settles slowly and finally dominates the response, but the first in-plane mode does not vanish completely. The second out-of-plane mode also accompanies the first out-of-plane mode, and indeed, develops more quickly (the interaction of these four modes is further discussed in section 5.3.2).

5.2 Coupled amplitudes and phases

5.2.1 Influence of the exciting amplitude

It is supposed now that the dimensionless amplitude of parametric excitation is above that of the threshold (26a) or (26b), which means that parametric resonance appears and that there is actually coupling between the first and second mode of vibration. The purpose of this subsection is to determine the amplitudes of coupled external and parametric resonance by solving simultaneously (8a) and (8b). The expression of parametric resonance (30) resulting from (8a) is introduced into (8b):

$$\begin{bmatrix} \frac{20}{3}c_3B^2+\omega_2^2-\Omega^2+2c_3A_U^2 & -\xi\omega_2\Omega \\ \xi\omega_2\Omega & \frac{20}{3}c_3B^2+\omega_2^2-\Omega^2+2c_3A_U^2 \end{bmatrix} \begin{bmatrix} p_{21} \\ p_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ -\frac{\delta\cos\theta\Omega^2}{\pi} \end{bmatrix} \quad (27)$$

The above matrix can always be inverted. The coupled equations (27) are thus solved and combined, writing that $B^2=p_{21}^2+p_{22}^2$, in order to find the value of the amplitude of the vibration of the second mode:

$$\frac{400}{9} c_3^2 B^6 + \frac{40}{3} c_3 (\omega_2^2 - \Omega^2 + 2 c_3 A_U^2) B^4 + \left[(\omega_2^2 - \Omega^2 + 2 c_3 A_U^2)^2 + \xi^2 \omega_2^2 \Omega^2 \right] B^2 = \frac{\delta^2 \cos^2 \theta \Omega^4}{\pi^2} \quad (28)$$

This equation differs a lot from that of the uncoupled problem (equation (11)). Again, it can be solved analytically by using Cardan's method, but developing it here is not meaningful, and it is used only for numerical analysis. Figure 6a, for example, shows the variations of the amplitude of the response with the amplitude of the excitation for an exciting frequency of $\Omega = \omega_2$. The damping ratio is 0.5 %. One notes that the exciting frequency is smaller than the critical frequency of external resonance, reducing the hysteresis region ($\Omega = \omega_2 < \Omega_{cr}$). Thus, it is verified that, below the threshold amplitude of coupled parametric resonance δ_{CU} (26a), the response is uncoupled and only the second mode is excited. Above this threshold, parametric resonance appears and the response is coupled. The amplitude of the second mode is lower than in the uncoupled situation (dotted line), which is reasonable because the second mode competes with the first mode.

Figure 6: Influence of the exciting amplitude on the amplitude of coupled response, a) $\Omega = \omega_2$, b) $\Omega = 1.026 \omega_2$.

When the frequency is higher than the critical frequency of external resonance, hysteresis phenomena appear and, for a given amplitude of excitation, many states of vibration can exist, depending on the time history of the vibration, as illustrated in figure 6b for $\Omega = 1.026 \omega_2 > \Omega_{cr}$. It is noted that:

- $0 < \delta < \delta_2$: only low amplitude external resonance occurs (heavy dotted black curve).
- $\delta_2 < \delta < \delta_{CC}$: only external resonance occurs but it might have high (heavy full black curve) or low (heavy dotted black curve) amplitude.
- $\delta_{CC} < \delta < \delta_{CU}$: the response might be coupled external-parametric resonance (blue and red curves) if it is coming from a coupled situation or, otherwise, uncoupled with external resonance only, either high or low amplitude (heavy full and dotted black curve respectively).
- $\delta_{CU} < \delta < \delta_I$: the response might be coupled (blue and red curves) if coming from a coupled situation or from a situation with high amplitude of the second mode or, otherwise, it might be uncoupled with low amplitude external resonance only (heavy dotted black curve).
- $\delta_I < \delta$: only coupled external-parametric response occurs.

5.3. Numerical validation with ADINA

5.3.1 Influence of the amplitude of excitation

To validate the analytical results presented above, purely plane simulations are conducted, as well as three dimensional simulations by introducing a small out-of-plane perturbation into the plane model. Figures 7a and 7b show the amplitude of external resonance and the

amplitude of parametric resonance, respectively. The exciting frequency is here $\Omega = 1.004 \omega_2$. Before parametric resonance occurs, the system is uncoupled and there is excellent agreement between the numerical simulations and the analytical model (figure 7a). In figure 7b, it is observed that the threshold amplitudes of parametric resonances almost coincide for the in-plane model as well as for the out-of-plane model. The numerical threshold out-of-plane is between 14 mm and 15 mm while the analytical model gives $\Delta^{thr} = 14.0$ mm, and the threshold in-plane is between 20 mm and 21 mm while analytically $\Delta^{thr} = 19.7$ mm.

Figure 7: Comparison of analytical and numerical amplitudes of a) external resonance, b) parametric resonance.

Looking now at the amplitudes of response, once parametric resonance has appeared, the numerical in-plane parametric resonance response values are slightly below the analytical ones, contrary to the numerical out-of-plane amplitudes, which are slightly higher than the analytical ones. This is in accordance with the facts that the numerical threshold in-plane is higher than the analytical threshold, and that the numerical threshold out-of-plane is smaller than the analytical one. Moreover, in figure 7a, it is observed that the analytical model slightly underestimates the amplitude of coupled external resonance (about 2 % for $\Delta = 20$ mm and 5 % for $\Delta = 100$ mm). In these two figures the agreement of the analytical and numerical results can be described as very good for small exciting amplitudes and as satisfactory for higher amplitudes.

5.3.2 Influence of the frequency of the excitation

Another set of numerical experiments is conducted to study the influence of the exciting frequency for a fixed exciting amplitude, here $\Delta = 20$ mm. The exciting frequency was increased from $0.98 \omega_2$ to $1.04 \omega_2$ and decreased from $1.04 \omega_2$ to $1.01 \omega_2$ with a step of $0.005 \omega_2$, each frequency being kept constant during 1000 cycles for the steady state to install. The results are presented in figure 8a. The curves (analytical model) and dots (numerical simulations) fit remarkably well for growing and decreasing exciting frequency.

A similar set of experiments with $\Delta = 20$ mm and $\zeta = 0.5$ % is then conducted numerically for the out-of-plane response for both increasing and decreasing frequencies from $0.98 \omega_2$ to $1.04 \omega_2$ introducing again a small out-of-plane perturbation at time zero (see figure 8b and figure 9). One remarks first that, like for the horizontal cable (section 4.2.2), the out-of-plane perturbation causes an instability of the in-plane mode, so that the first in-plane mode vanishes and the first out-of-plane mode dominates the steady state response. However, for high frequencies, the coupled out-of-plane response becomes more complex and may have nonzero components for up to four eigenmodes (see figure 9). Depending on the frequency and on the history of excitation different states might exist:

- The first one corresponds to low frequencies below that of resonance ($\Omega < \omega_2$), where response of the cable is purely external in-plane resonance.
- The second one is a bi-modal vibration state where out-of-plane parametric resonance is coupled with in-plane external resonance. It occurs for a relatively reduced

bandwidth ($\omega_2 < \Omega < 1.01 \omega_2$).

- The third one involves the first four eigenmodes and occurs also for a reduced bandwidth ($1.01 \omega_2 < \Omega < 1.02 \omega_2$).
- The fourth one corresponds to the hysteresis region ($\Omega > 1.02 \omega_2$) where the response might be either that of purely uncoupled in-plane resonance (dotted lines in figure 9), or a four modes coupled response, in which the coupling between the four modes is very strong.

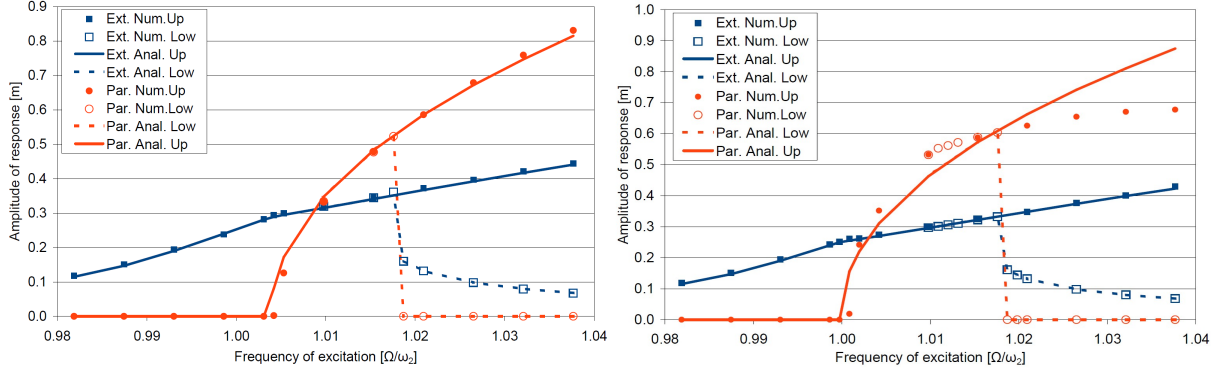

Figure 8: Influence of the excitation frequency on a) the in-plane coupled response, b) the out-of-plane response.

Figure 9: Influence of the excitation frequency on the number of modes in the out-of-plane coupled response.

It is hence clear that the two modes interaction analytical model presented here can not capture the whole response of the inclined cable because it involves up to four modes. However, it is noted in figure 8b that there is very good agreement between the amplitudes of the analytical model and the numerical simulations for the second in-plane mode. One thus deduces that in-plane external resonance is not affected by the presence of the first in-plane and second out-of plane modes, so that, practically, the two modes interaction is valid for external resonance. One observes then that the threshold of coupled out-of-plane parametric resonance is correctly predicted by the analytical model as well as the threshold of the hysteresis region. Moreover, in the regions where the response has only two non-zero components or a small contribution of the second out-of-plane mode ($\omega_2 < \Omega < 1.02 \omega_2$), the analytical model fits relatively well with numerical results.

It is therefore considered that the two modes interaction model captures the main characteristics of the response and is sufficient for practical structural design purposes. Considering the fact that for $1.01 \omega_2 < \Omega < 1.02 \omega_2$, the amplitude of the first in-plane mode is small when compared to that of the other eigenmodes, the three modes interaction model of Gonzalez-Buena *et al.* [21] is satisfactory and it can be used to determine the value of the threshold of the second out-of-plane mode. For higher frequencies, it is necessary to refer to

the general four modes interaction of Rega [23].

6. CONCLUSION

The objective of the present work was to propose the simplest possible analytical model for the proper investigation of coupled external/parametric resonance in order to bridge the gap between complex mathematical interaction models and practical design of cables in structural engineering. To this end, abundant numerical applications and simulations were conducted for realistic values, based on actual bridge cables. Two specific cases were first investigated to gain better understanding of the two resonance phenomena separately. The first one was dedicated to external resonance and dealt with a horizontal cable submitted to a vertical harmonic motion at one end. Most of the existing results on the phenomenon were re-established analytically (in particular the limits of the hysteresis region) and confirmed numerically. The second specific case was dedicated to parametric resonance and dealt with a horizontal cable submitted to a horizontal harmonic motion at one end. Again, most of the existing results on parametric resonance were re-established analytically and confirmed numerically. Moreover it was observed that, when disturbed out-of-plane, the in-plane parametric resonance was unstable and turned into out-of-plane parametric resonance, so that only out-of-plane parametric resonance is stable and its bandwidth is formed by the disjunction of the in-plane and out-of-plane bandwidth.

Then, the coupling phenomenon strictly speaking was investigated, focusing on a cable with a 30° inclination. Analytical expressions for the coupled amplitudes were developed and their comparison with numerical simulations showed very good agreement. The study has proved that the coupling shifts the bandwidth of parametric resonance toward the higher frequencies and diminishes the value of the threshold when the frequency is above that of resonance. However, very strong interaction between the hysteresis regions of the two resonances has been found. Indeed, parametric resonance requires a high amplitude of external resonance to take place, so that one could say that it is necessary that external resonance appears first to cause parametric resonance. Concerning amplitudes, when coupling appears, it diminishes both, the amplitude of external and parametric resonance.

Moreover, numerical simulations showed that the introduction of an out-of-plane perturbation led to coupled out-of-plane vibrations so that, like for the horizontal cable, the only stable parametric resonance is the out-of plane of which the instability bandwidth might be considered in a first approximation as formed by the disjunction of the in-plane and out-of-plane bandwidth. However, it has been shown that, under certain conditions, the coupling phenomenon might involve up to four eigenmodes: the first in-plane and out-plane and second in-plane and out-of-plane modes. It has been also shown that the additional vibration modes only partially affect the amplitude of the main eigenmodes in the frequency domain useful for the engineer, for frequencies out-of the hysteresis range.

AN EFFICIENT USE OF THE SYMBOLIC SPLINE-BASED DIFFERENTIAL QUADRATURE METHOD IN VIBRATION ANALYSIS OF SHELLS

Artur Krowiak

Institute of Computing Science, Cracow University of Technology
Al. Jana Pawła II 37, 31-864 Kraków
e-mail: krowiak@mech.pk.edu.pl

Keywords: differential quadrature, spline interpolation, free vibration, composite shell.

Abstract. *The paper presents the differential quadrature method (DQM) based on a modified spline interpolation and the application of the method in vibration analysis of laminated, composite shells. The goal of the modification of the spline interpolation is to improve the rate of convergence and preserve the stability of the method. The modification changes the definition of the end conditions for the spline interpolation. Two types of the end conditions are combined and appropriately applied at the stage of the determination of the weighting coefficients for the DQM. With the aid of the symbolic computation the weighting coefficients can be successfully determined for any spline degree. The efficiency of the method is examined by the example of the free vibration of composite, conical shells. The influence of the modified end conditions, number of nodes and spline degree on the convergence and accuracy is studied. The achieved results are compared with the results obtained using conventional DQM and using other numerical techniques.*

1 INTRODUCTION

More and more advanced mechanical structures as well as new construction materials require to develop computational methods that allow efficiently to estimate mechanical properties. Some of the mechanical structures can be efficiently analyzed by analytical methods but usually numerical methods give more versatility. Among the latter, the finite element method seems to be the most common and it is applied to many challenging problems. This method belongs to low order numerical techniques, what means that accurate numerical results can be achieved using large number of nodes. It requires much computational effort. In the case of eigenvalue problem, where the number of nodes corresponds to the number of obtained eigenpairs, only the lowest eigenpairs are of the much interest in mechanical problems. However, to compute these eigenpairs with acceptable accuracy using low order techniques, one has to aggregate and solve large sets of equations, unlike applying methods that use high order approximation. One of them is differential quadrature method (DQM) [1], which allows to obtain very accurate results using few discrete points. This feature as well as simple formulation cause the DQM to be applied in many fields of mathematics and mechanics [2].

However, the DQM has some drawbacks resulting from the assumed approximation of the sought solution. One of these drawbacks is computational instability. To overcome the problem, new approaches have been developed. In one of them, only some neighbouring nodes are used to approximate a derivative [3]. In others, variable order approach is applied [4] or B-Spline interpolation is used [5,6] instead of conventional polynomial. The latest advances in the DQM are presented in [7].

In [8] another idea to improve the stability of the method is proposed. In this idea, spline functions, considered as n degree polynomials, defined separately in each subinterval of the domain are used. In this manner, the solution is approximated. The developed algorithm requires to use symbolic manipulations at a initial step of computation, therefore in present paper the method is referred to Symbolic Spline-based Differential Quadrature Method (SSDQM). This algorithm allows to determine the weighting coefficients for the derivative approximation in the DQM with the use of any spline degree, unlike the technique that uses B-Spline functions [5,6]. In the latter, the formulas based on quintic and sextic B-Splines are developed so far. Obtained results indicate that the SSDQM provides a balance between low order methods and high order ones. It is characterized by less rate of convergence then the conventional DQM, but ensures computational stability, what is clearly seen in dynamic problems [9]. The SSDQM gives also reasonable results using uniform point distribution, what is usually impossible in the case of the conventional DQM. Accurate results are also obtained for problems, where the DQM fails [10].

In order to improve the rate of convergence of the SSDQM a modification is proposed in this paper. This modification changes the formulation of the end conditions for the spline interpolation. The improvement is shown by the example of the free vibration of laminated, orthotropic, conical shells.

The layout of the paper is as follows. In section 2, the short description of the DQM and the SSDQM is presented. In the latter, the way of the determination of the weighting coefficients is shown. In section 3, the approach to improve the SSDQM is proposed. In section 4, the presented idea is tested on the example of the free vibration analysis of the conical shells. On the basis of the results some concluding remarks on the convergence and accuracy are drawn.

2 SYMBOLIC SPLINE-BASED DIFFERENTIAL QUADRATURE METHOD

The basic idea of the DQM lies in the fact that the spatial derivative of a function at a given point is approximated by a linear weighted sum of the function values at all discrete points in the domain along the coordinate lines. It can be put as follows

$$\frac{d^r f(x)}{dx^r} \Big|_{x=x_i} = \sum_{j=1}^N a_j^{(r)}(x_i) f(x_j) = \sum_{j=1}^N a_{ij}^{(r)} f_j \quad i = 1, \dots, N \quad (1)$$

where N denotes the number of grid points and $a_{ij}^{(r)}$ are the weighting coefficients of the r th order derivative.

In the case of the multidimensional problem, the derivatives with respect to other spatial variables are approximated in the similar manner and the approximation of the mixed derivatives is done with the use of the weighting coefficients determined separately for derivatives with respect to appropriate variables.

Applying the governing equation with the derivatives described by Eq. (1) at each interior point of the domain and implementing boundary conditions, one obtains a set of algebraic equations. A key stage of the method is to determine the weighting coefficients. These coefficients depend on the way the sought solution is approximated. Therefore, they influence the convergence, accuracy and stability of the method.

In the conventional approach, the solution is approximated by the interpolation polynomial. The use of the Lagrange base functions and the recurrence relationships [11] allows efficiently to determine the weighting coefficients in this approach. The method provides very high rate of convergence and accuracy, when appropriate point distribution is applied. When the number of points is too large or the points are uniformly distributed then the method fails.

2.1 Spline interpolation in the DQM

The definition of the interpolation function depends on whether the spline degree n is odd or even. If the spline degree is odd then the interpolation function has the following form

$$f(x) \approx \{s_i(x), x \in [x_i, x_{i+1}], i = 1, \dots, N-1\} \quad (2)$$

where N is the number of nodes and the i th spline section $s_i(x)$ can be written as

$$s_i(x) = \sum_{j=0}^n c_{ij} (x - x_i)^j \quad (3)$$

In order to determine the interpolation function, the $(n+1) \cdot (N-1)$ coefficients c_{ij} in Eq. (3) have to be calculated. To this end, the interpolation conditions and the derivative continuity conditions at the nodes are used. They constitute the set of $(n+1) \cdot N - 2n$ equations. The detailed description of these equations is presented in [8]. To complete the set of equations, the $n-1$ end conditions have to be introduced. They can be defined in different forms. The most common form is obtained by equating some high order derivatives to zero at the end points – so-called the natural end conditions

$$s_1^{(k)}(x_1) = 0, \quad s_{N-1}^{(k)}(x_N) = 0, \quad k = \frac{n+1}{2}, \dots, n-1 \quad (4)$$

or by requiring the n th order derivative to be continuous at some nodes at the left and right end of the domain – so-called the not-a-knot end conditions

$$s_i^{(n)}(x_{i+1}) = s_{i+1}^{(n)}(x_{i+1}), \quad s_{N-1-i}^{(n)}(x_{N-i}) = s_{N-i}^{(n)}(x_{N-i}), \quad i = 1, \dots, \frac{n-1}{2} \quad (5)$$

If the spline degree is even, the auxiliary spline knots have to be introduced in order to define the sufficient number of conditions. The spline knots are introduced at the midpoints of the existing nodes as follows

$$z_1 = x_1, \quad z_{i+1} = \frac{1}{2}[x_i + x_{i+1}], \quad i = 1, \dots, N-1, \quad z_{N+1} = x_N \quad (6)$$

The interpolation function is defined between these auxiliary points by the formula

$$f(x) \approx \left\{ s_i(x), \quad x \in [z_i, z_{i+1}], \quad i = 1, \dots, N \right\} \quad (7)$$

Each spline segment $s_i(x)$ is expressed by Eq. (3). In order to calculate the $(n+1) \cdot N$ spline coefficients c_{ij} in Eq. (3) one uses the interpolation conditions at the nodes as well as at the spline knots and the derivative continuity conditions at the spline knots. It gives $(n+1) \cdot N - n$ equations. To complete the set of equations, the n end conditions are introduced in two different forms, similarly to Eqs. (4) or (5)

$$s_1^{(k)}(x_1) = 0, \quad s_N^{(k)}(x_N) = 0, \quad k = \frac{n}{2}, \dots, n-1 \quad (8)$$

$$s_i^{(n)}(z_{i+1}) = s_{i+1}^{(n)}(z_{i+1}), \quad s_{N-i}^{(n)}(z_{N+1-i}) = s_{N+1-i}^{(n)}(z_{N+1-i}), \quad i = 1, \dots, \frac{n}{2} \quad (9)$$

Equation (8) represents the natural end conditions and Eq. (9) – the not-a-knot end conditions.

2.2 Weighting coefficients in the SSDQM

Using equations discussed in section 2.1 one can express the spline coefficients c_{ij} as a function of node distribution and unknown values of the solution f_i at the nodes. It can be put in general form as

$$c_{ij} = \sum_{k=1}^N C_{ijk}(x_1, \dots, x_N) \cdot f_k, \quad i = 1, \dots, \bar{N}, \quad j = 0, \dots, n \quad (10)$$

where $\bar{N} = N-1$ when n is odd and $\bar{N} = N$ when n is even.

In order to determine the weighting coefficients for the SSDQM one should calculate an appropriate order derivative of the interpolation function (2) or (7)

$$f^{(r)}(x) \approx \left\{ s_i^{(r)}(x), \quad i = 1, \dots, \bar{N} \right\} \quad (11)$$

where

$$s_i^{(r)}(x) = \sum_{j=r}^n \left(c_{ij} \cdot (x - x_i)^{j-r} \cdot \frac{j!}{(j-r)!} \right) \quad (12)$$

and evaluate it at each node, what yields

$$\begin{aligned}
s_i^{(r)}(x_i) &= c_{ir} \cdot r!, \quad i = 1, \dots, \bar{N} \\
s_{N-1}^{(r)}(x_N) &= \sum_{j=r}^n \left(c_{N-1,j} \cdot (x_N - x_{N-1})^{j-r} \cdot \frac{j!}{(j-r)!} \right), \quad \text{when } n \text{ is odd}
\end{aligned} \tag{13}$$

Taking into account Eq. (10), the derivatives $s_i^{(r)}(x_i)$ and $s_{N-1}^{(r)}(x_N)$ in Eq. (13), after some algebraic manipulations, can be written as

$$\begin{aligned}
s_i^{(r)}(x_i) &= \sum_{k=1}^N [C_{irk} \cdot r!] f_k, \quad i = 1, \dots, \bar{N} \\
s_{N-1}^{(r)}(x_N) &= \sum_{k=1}^N \left[\sum_{j=r}^n \left(C_{N-1,jk} \cdot (x_N - x_{N-1})^{j-r} \cdot \frac{j!}{(j-r)!} \right) \right] f_k
\end{aligned} \tag{14}$$

Comparing with Eq. (1), it is easy to notice that the expressions in the square brackets in Eq. (14) are the weighting coefficients $a_{ij}^{(r)}$ for the r th order derivative in the DQM based on the spline interpolation.

The assumed spline segments are not typical base functions, what makes impossible to determine the weighting coefficients in pure numeric approach, especially deriving explicit formulas. These coefficients can be determined with the use of symbolic-numeric manipulations, where the unknown function values are noted as symbols. Equations discussed in section 2.1 allow to obtain spline coefficients (10) in symbolic-numeric form. Then, coefficients C_{ijk} in Eq. (10) can be determined by separating numbers from appropriate symbols f_k , what allows easily to compute the weighting coefficients contained in Eq. (14). This algorithm has been implemented in Computer Algebra System – Maple [12].

3 MODIFIED SSDQM – COMBINING OF THE END CONDITIONS

The research done so far indicates that the use of different forms of the end conditions (Eqs. (4) or (5) and (8) or (9)) significantly influences the quality of the solution. The use of the not-a-knot end conditions (Eqs. (5) or (9)) rapidly improves the convergence of the method but leads to the computational instability, especially when the spline degree is high. The use of the natural end conditions (Eqs. (4) or (8)) gives stable results, however the rate of convergence is significantly weaker in this case. Therefore in this paper a modification is proposed. In this approach the assumed, small number of the not-a-knot end conditions is completed by the appropriate number of the natural end conditions. These equations form the set of the combined end conditions used for computing the spline coefficients (10) and finally the weighting coefficients.

Assuming that N_{nak} denotes the assumed number of the not-a-knot end conditions, the combined end conditions take the form

$$\begin{aligned}
s_i^{(n)}(x_{i+1}) &= s_{i+1}^{(n)}(x_{i+1}), \quad s_{N-1-i}^{(n)}(x_{N-i}) = s_{N-i}^{(n)}(x_{N-i}), \quad i = 1, \dots, N_{nak} \\
s_1^{(k)}(x_1) &= 0, \quad s_{N-1}^{(k)}(x_N) = 0, \quad k = \frac{n+1}{2} + N_{nak}, \dots, n-1
\end{aligned} \tag{15}$$

for odd spline degree and

$$\begin{aligned}
s_i^{(n)}(z_{i+1}) &= s_{i+1}^{(n)}(z_{i+1}), \quad s_{N-i}^{(n)}(z_{N+1-i}) = s_{N+1-i}^{(n)}(z_{N+1-i}), \quad i = 1, \dots, N_{nak} \\
s_1^{(k)}(x_1) &= 0, \quad s_N^{(k)}(x_N) = 0, \quad k = \frac{n}{2} + N_{nak}, \dots, n-1
\end{aligned} \tag{16}$$

for even spline degree.

Equation (15) is introduced into the algorithm presented in section 2 instead of Eq. (4) or (5) and Eq. (16) – instead of Eq. (8) or (9). The presented formulation makes a balance between rapid convergence and the stability of the method.

4 FREE VIBRATION ANALYSIS OF CONICAL SHELLS

The presented modification is tested in the problem of the free vibration of thin, composite, orthotropic shells. The governing equations that follow from classical shell theory are taken under consideration.

Shell structures are commonly used in civil, mechanical and aerospace engineering. Various analytical [13-16] and numerical [17-20] methods have been used to analyze mechanical properties of these structures or to test novel computational procedures. The DQM has been also applied to these ends [21,22]. The known results enable to estimate the effectiveness of the approach presented in the paper in this type of mechanical problems.

In Fig. 1, the analyzed conical shell with the reference coordinate system (x, θ, z) and the components of the displacement field in appropriate directions (u, v, w) are shown.

Figure 1: Geometry of truncated conical shell.

The derivation of the governing equations for the thin, composite, conical shell based on classical shell theory is presented in several papers, e.g. [21].

Taking into account that the field of displacement, in the case of the free vibration of this structure, can be expressed as

$$u = U(x)\cos(m\theta)\cos(\omega t), \quad v = V(x)\sin(m\theta)\cos(\omega t), \quad w = W(x)\cos(m\theta)\cos(\omega t) \quad (17)$$

where m is the wave number in the circumferential direction and ω is the circular frequency, mathematical model of the shell can be written in a compact matrix form as follows

$$\begin{bmatrix} L_{11} & L_{12} & L_{13} \\ L_{21} & L_{22} & L_{23} \\ L_{31} & L_{32} & L_{33} \end{bmatrix} \begin{bmatrix} U \\ V \\ W \end{bmatrix} = -\rho h \omega^2 \begin{bmatrix} U \\ V \\ W \end{bmatrix} \quad (18)$$

In Equation (18), L_{ij} are differential operators, e.g.

$$L_{22} = \left(\frac{A_{66} \sin(\alpha)}{R} - \frac{B_{66} \sin(\alpha) \cos(\alpha)}{R^2} - \frac{4D_{66} \sin(\alpha) \cos^2(\alpha)}{R^3} \right) \frac{d}{dx} \\ + \left(A_{66} + \frac{3B_{66} \cos(\alpha)}{R} + \frac{2D_{66} \cos^2(\alpha)}{R^2} \right) \frac{d^2}{dx^2} - \frac{A_{22}m^2 + A_{66} \sin^2(\alpha)}{R^2} \\ - \frac{(2m^2 B_{22} - B_{66} \sin^2(\alpha)) \cos(\alpha)}{R^3} - \frac{(D_{22}m^2 - 4D_{66} \sin^2(\alpha)) \cos^2(\alpha)}{R^4},$$

These operators contain constants A_{ij} , B_{ij} and D_{ij} that denote extensional, coupling and bending stiffnesses. For a shell that is composed of different layers of orthotropic materials, these stiffnesses can be expressed as

$$A_{ij} = \sum_{k=1}^{N_l} \bar{Q}_{ij}^k (h_k - h_{k-1}), \quad B_{ij} = \frac{1}{2} \sum_{k=1}^{N_l} \bar{Q}_{ij}^k (h_k^2 - h_{k-1}^2), \quad D_{ij} = \frac{1}{3} \sum_{k=1}^{N_l} \bar{Q}_{ij}^k (h_k^3 - h_{k-1}^3) \quad (19)$$

where N_l denotes the number of layers in the shell and h_k i h_{k-1} are the distances from the shell reference surface to the outer and inner surfaces of the k th layer, respectively. \bar{Q}_{ij}^k are elements of the transformed, reduced, elasticity matrix of the k th layer.

For a given layer of orthotropic material, the $\bar{\mathbf{Q}}$ matrix is a result of the transformation of the elasticity matrix \mathbf{Q} between the principal material coordinates and the shell's coordinates according to the formula

$$\bar{\mathbf{Q}} = \mathbf{T} \mathbf{Q} \mathbf{T}^T \quad (20)$$

The transformation matrix \mathbf{T} can be expressed as

$$\mathbf{T} = \begin{bmatrix} \cos^2(\phi) & \sin^2(\phi) & -2\sin(\phi)\cos(\phi) \\ \sin^2(\phi) & \cos^2(\phi) & 2\sin(\phi)\cos(\phi) \\ \sin(\phi)\cos(\phi) & -\sin(\phi)\cos(\phi) & \cos^2(\phi) - \sin^2(\phi) \end{bmatrix} \quad (21)$$

where ϕ is the angular orientation of the fibers.

The material constants in \mathbf{Q} are defined by Young's moduli: E_1 , E_2 , the shear moduli G_{12} and the Poisson's ratios: ν_{12} , ν_{21} with the following formulas

$$Q_{11} = \frac{E_1}{1 - \nu_{12}\nu_{21}}, \quad Q_{12} = \frac{\nu_{12}E_2}{1 - \nu_{12}\nu_{21}}, \quad Q_{22} = \frac{E_2}{1 - \nu_{12}\nu_{21}}, \quad Q_{66} = G_{12} \quad (22)$$

In the paper, the shell, which is simply supported at both edges ($R = R_1, R = R_2$) is considered. At these edges, appropriate displacement functions V , W as well as force N_x and moment M_x have to be zero, what can be put as

$$V = 0, W = 0 \quad (23)$$

$$U^{(1)} + a_1 U + a_2 V + a_3 W + a_4 W^{(1)} + a_5 W^{(2)} = 0 \quad (24)$$

$$W^{(2)} + b_1 U + b_2 U^{(1)} + b_3 V + b_4 W + b_5 W^{(1)} = 0 \quad (25)$$

where constants a_i and b_i are as follows

$$\begin{aligned}
a_1 &= A_{12} \sin(\alpha) / A_{11} R, \quad a_2 = B_{12} m \cos(\alpha) / A_{11} R^2 + A_{12} m / A_{11} R, \\
a_3 &= A_{12} \cos(\alpha) / A_{11} R + B_{12} m^2 / A_{11} R^2, \quad a_4 = -B_{12} \sin(\alpha) / A_{11} R, \\
a_5 &= -B_{11} / A_{11}, \quad b_1 = -B_{12} \sin(\alpha) / D_{11} R, \quad b_2 = -B_{11} / D_{11}, \\
b_3 &= -D_{12} m \cos(\alpha) / D_{11} R^2 - B_{12} m / D_{11} R, \\
b_4 &= -B_{12} \cos(\alpha) / D_{11} R - D_{12} m^2 / D_{11} R^2, \quad b_5 = D_{12} \sin(\alpha) / D_{11} R
\end{aligned}$$

Taking advantage of the algorithm discussed in section 2, where the modification based on combining of the end conditions is introduced, the weighting coefficients $a_{ij}^{(r)}$ for the r th order derivative are computed. This approach is characterized by the number N_{nak} , that denotes the number of the not-a-knot type conditions contained in the set of the end conditions. Equation (18), which is discretized using differential quadrature rules, takes the form

$$\begin{bmatrix} \mathbf{P}_{11} & \mathbf{P}_{12} & \mathbf{P}_{13} \\ \mathbf{P}_{21} & \mathbf{P}_{22} & \mathbf{P}_{23} \\ \mathbf{P}_{31} & \mathbf{P}_{32} & \mathbf{P}_{33} \end{bmatrix} \begin{bmatrix} \mathbf{U} \\ \mathbf{V} \\ \mathbf{W} \end{bmatrix} = -\rho h \omega^2 \begin{bmatrix} \mathbf{U} \\ \mathbf{V} \\ \mathbf{W} \end{bmatrix} \quad (26)$$

where vectors \mathbf{U} , \mathbf{V} , \mathbf{W} contain nodal function values and elements of matrices \mathbf{P}_{lk} contain appropriate weighting coefficients $a_{ij}^{(r)}$, $i, j = 1, \dots, N$, for example

$$\begin{aligned}
P_{22_{ij}} &= \left(\frac{A_{66} \sin(\alpha)}{R_i} - \frac{B_{66} \sin(\alpha) \cos(\alpha)}{R_i^2} - \frac{4D_{66} \sin(\alpha) \cos^2(\alpha)}{R_i^3} \right) a_{ij}^{(1)} \\
&+ \left(A_{66} + \frac{3B_{66} \cos(\alpha)}{R_i} + \frac{2D_{66} \cos^2(\alpha)}{R_i^2} \right) a_{ij}^{(2)} - \left(\frac{A_{22} m^2 + A_{66} \sin^2(\alpha)}{R_i^2} \right. \\
&\left. + \frac{(2m^2 B_{22} - B_{66} \sin^2(\alpha)) \cos(\alpha)}{R_i^3} + \frac{(D_{22} m^2 - 4D_{66} \sin^2(\alpha)) \cos^2(\alpha)}{R_i^4} \right) \delta_{ij},
\end{aligned}$$

To implement boundary conditions, Eqs. (23)-(25) are discretized at both edges

$$V_k = 0, W_k = 0 \quad (27)$$

$$\sum_{j=1}^N a_{kj}^{(1)} U_j + a_1 U_k + a_2 V_k + a_3 W_k + a_4 \sum_{j=1}^N a_{kj}^{(1)} W_j + a_5 \sum_{j=1}^N a_{kj}^{(2)} W_j = 0 \quad (28)$$

$$\sum_{j=1}^N a_{kj}^{(2)} W_j + b_1 U_k + b_2 \sum_{j=1}^N a_{kj}^{(1)} U_j + b_3 V_k + b_4 W_k + b_5 \sum_{j=1}^N a_{kj}^{(1)} W_j = 0 \quad (29)$$

where $k = 1$ at the small edge (R_1) and $k = N$ at the large one (R_2).

Following the general approach to implement boundary conditions in the DQM [23], Eqs. (26)-(29) can be put as the final eigenvalue equation

$$\mathbf{A} \cdot \mathbf{Z} = -\rho h \omega^2 \cdot \mathbf{Z} \quad (30)$$

where vector \mathbf{Z} contains nodal function values at the inner points

$$\mathbf{Z} = [U_2, \dots, U_{N-1}, V_2, \dots, V_{N-1}, W_3, \dots, W_{N-2}].$$

The calculations are carried out for the antisymmetric cross-ply conical shell. The elementary material parameters of each layer are given as

$$E_1/E_2 = 15, \quad \nu_{12} = 0.25, \quad G_{12}/E_2 = 0.5 \quad (31)$$

As the result, the coefficients in Eq. (19) can be simplified as [15]

$$\begin{aligned} A_{11} = A_{22} &= h/2(Q_{11} + Q_{22}), & A_{12} &= Q_{12}h, & A_{66} &= Q_{66}h, \\ B_{11} = -B_{22} &= (h^2/4N_l)(Q_{11} - Q_{22}), & B_{12} &= B_{66} = 0, \\ D_{11} = D_{22} &= (h^3/24)(Q_{11} + Q_{22}), & D_{12} &= \frac{1}{12}Q_{12}h^3, & D_{66} &= \frac{1}{12}Q_{66}h^3 \end{aligned} \quad (32)$$

where N_l is the number of plies.

The calculations are carried out using uniform node distribution as well as Chebyshev-Gauss-Lobatto pattern. The results are presented in the form of dimensionless frequency parameter

$$\lambda = R_2 \sqrt{\rho h / A_{11}} \omega \quad (33)$$

The dependence on the combined end conditions (N_{nak}), spline degree (n) and the number of nodes (N) is presented in Fig. 2 (Chebyshev-Gauss-Lobatto pattern) and Fig. 3 (uniform grid). These figures show the percentage relative error $\delta = (\lambda_{SSDQM} - \lambda_{DQM}) / \lambda_{DQM} \cdot 100\%$ between the results from the SSDQM and the reference value taken as the result from the DQM ($\lambda_{DQM} = 0.1779$) obtained in present work.

Figure 2: Error of fundamental frequency parameter λ for antisymmetric cross-ply laminated conical shell ($N_l = 2$, $h/R_2 = 0.01$, $\alpha = 30^\circ$, $L \sin \alpha / R_2 = 0.25$, $m = 0$) – Chebyshev-Gauss-Lobatto grid.

Figure 3: Error of fundamental frequency parameter λ for antisymmetric cross-ply laminated conical shell ($N_l = 2$, $h/R_2 = 0.01$, $\alpha = 30^\circ$, $L \sin \alpha / R_2 = 0.25$, $m = 0$) – uniform grid distribution.

Presented results indicate that the use of the combined end conditions significantly improves the rate of convergence. When one spline segment covers more intervals at each end of the domain ($N_{nak} > 0$) then more accurate results are obtained. The results can be improved also using higher spline degree. It should be noted that the SSDQM converges, when the uniform node distribution is applied, unlike the conventional DQM.

Table 1 shows the fundamental frequency parameters (33) for different number of layers and various shell thickness. These results are obtained with the SSDQM based on the eleventh spline degree, imposing $N = 16$ nodes according to the Chebyshev-Gauss-Lobatto pattern and using the modification ($N_{nak} = 2$) discussed in section 3. As Fig. 2 reports, these computational parameters ensure fast convergence and high accuracy.

In the theoretical case, when the number of layers N_l approaches to infinity, coupling stiffnesses B_{11} , B_{22} , contained in Eq. (32), approach to zeros, unlike the case, when the number $N_l = 2$. Then the mentioned stiffnesses achieve maximum value.

h/R_2	Number of layers N_l					
	2	4	6	10	20	∞
0.01	0.1779 (0.1769)	0.1941	0.1962	0.1972	0.1976	0.1978 (0.1978)

0.10	0.3770 (0.3801)	0.4376	0.4450	0.4485	0.4500	0.4504 (0.4504)

Table 1: Fundamental frequency parameters λ for antisymmetric cross-ply laminated conical shells ($\alpha = 30^\circ$, $L \sin \alpha / R_2 = 0.25$, $m = 0$).

In Tab. 1, for two extreme cases, the results obtained in [15] (values in parenthesis) are also presented for comparison. As one can notice, very good agreement is achieved, when the coupling stiffnesses vanish ($N_l = \infty$), while some differences occur, when these stiffnesses take maximum value ($N_l = 2$). The reason may lie in the use of various shell theories. In present paper Love's shell theory is taken under consideration, while in [15] Donnell's theory is used.

5 CONCLUSION

In the paper, the method based on the differential quadrature is presented and applied to vibration analysis of shells. These type methods belong to high order approximation tech-

niques and provide high convergence and accuracy. In order to ensure the computational stability, the weighting coefficients in present method are computed using spline functions and the modification proposed in the paper improves the rate of convergence of the method under this conditions.

The effectiveness of this modification is shown by the example of the free vibration of the composite, conical shell. The results indicate that the combined end conditions, where the small number of not-a-knot end conditions are used, can significantly improve the results.

Keywords: Progressive collapse, disproportionate collapse, Lagrangian dynamics, Fracture, Strength degradation, Mixed Lagrangian Formulation (MLF).

Abstract. *Prediction of progressive collapse of buildings under extreme events is one of the challenges that the civil engineering community must face. The ability to predict progressive collapse would enable the identification of deficiencies in the common practice of structural design without having to wait for the next extreme event to occur. With such ability, new design strategies and technologies for progressive collapse prevention could be addressed.*

Progressive collapse prediction, where the capacity of structures for progressive collapse is assessed, faces a great number of challenges. In terms of feasibility, it should address the challenge of analyzing large scale buildings in all stages of collapse. The complex behavior of buildings during collapse often leads to issues of stability of the numerical scheme, hence to the collapse of the analysis prior to the actual analysis of collapse. Indeed, the area of dynamics of structures including phenomena expected during progressive collapse (e.g. contact, fracture) has been developed to a high level. Nevertheless, there is no theory and computational tool that can efficiently predict all stages of progressive collapse of large scale structures.

The Mixed Lagrangian Formulation (MLF) could potentially provide such a theory as well as an accompanied efficient, robust and stable numerical scheme. It also considers almost all stages of collapse in a unified manner, thus, almost completes the puzzle of Progressive collapse prediction. The missing part of the puzzle, considering fracture in a unified manner, is the aim of this paper. This is developed using concepts from Fracture Mechanics for brittle material by using Griffith's theory. This, in turn, will lay the foundation for considering more complex models in the future. Additional state variables required to model fracture using fracture mechanics concepts are identified. Subsequently, appropriate stored energy and dissipation functions, which lead to Griffith's theory, are formulated. Once the stored energy and dissipation functions are formulated, Hamilton's principle is discretized in time to lead to an optimization problem at each time step. The solution of the optimization problem supplies with the states at the end of the time step. This results in a sound theory as well as an efficient, robust and stable numerical scheme for progressive collapse prediction, as supported by the examples.

1 INTRODUCTION

Prediction of progressive collapse of large scale buildings due to natural or man-made extreme events is a major challenge in structural engineering. The main challenge stems from the various complex and sudden phenomena that structures experience during collapse. Those often lead to the collapse of the analysis prior to the actual analysis of collapse. With theory and tools for Progressive Collapse Prediction (PCP), deficiencies in the common practice of structural design, in the context of progressive collapse, could be identified without having to wait for the next extreme event to occur. With such theory and tools, the efficiency of existing design strategies for progressive collapse prevention (e.g. [1] and references therein) could be rigorously assessed, and the development of new strategies and technologies could be addressed. In addition, those tools could be used in forensic engineering or for the design of demolition.

The progressive collapse of the Ronan Point apartment building (England, 1968) and the terrorist attacks on the Murrah building (Oklahoma, 1995) and the WTC (New-York city, 2001) revealed the drawbacks of the traditional philosophy behind the design of structures: Buildings are designed to withstand the expected loads with a given performance level, while their capacity to withstand collapse due to extreme events remains unknown. This recognition has led to the new field of PCP in structural engineering. This field addresses the modeling and simulation of buildings up to the prediction of total collapse, where a progressive creation of "rubble" of structural mass is expected. This can be initiated by a rather local damage in a limited number of structural components. This local damage eventually causes a sequential failure of additional components, or a chain reaction, up to collapse. Several phases of behavior can be identified during the progress of collapse. These are elastic behavior, plastic behavior, stiffness and strength degradation, buckling and other geometric nonlinear phenomena, fracture, detachment of objects from the structure and impact or contact of structural elements with each other.

Pretlov et al. [2] pointed out that static analysis cannot capture important effects in progressive collapse. This statement has been verified in numerous occasions (e.g. [3, 4] and references therein). Hence, a dynamic approach should be considered. Here, the modeling for prediction of progressive collapse can be done at several levels. At the finest level, one can adopt micro-modeling, where each of the structural components (beams, columns, etc.) is modeled by a large number of solid elements. The Finite Elements Method (e.g. [5]) or the Distinct Element Method (e.g. [6]) have been adopted in that context. At the other limit, macro-modeling of large structural systems, each story or even the whole structure can be used (e.g. [7, 8]). Recently, an intermediate approach seems to gain attention in the context of PCP. This approach makes use of macro-modeling of different structural components (e.g. [3, 9, 10, 11, 12, 13, 14]). It combines advantages from the two previous approaches as it is general enough to be used for a large spectrum of types of buildings, collapse modes and extreme events, while is potentially feasible for large scale structures. Another advanced approach combines various scales of elements and is based on multibody models [15]. This efficient approach was used for the simulation of collapse considering uncertainty, where a large number of deterministic analyses is required.

A crucial issue in most approaches presented above is the time integration schemes they adopt. The theoretical basis of those methods cannot provide answers regarding the existence or uniqueness of the solutions. Those may be very important in PCP as the complex behavior may lead to bifurcations where more than a single solution may exist. In addition, those numerical schemes require very small time steps. This is due to the sudden changes in the response of structures expected when fracture or contact occur. In case where those numerical

schemes do converge to a solution, it is also not clear whether it is the true physical solution of the problem. If the problem does possess bifurcations, it is not clear what solution those schemes would follow. Additionally, no approach seems to efficiently cover all stages of progressive collapse and enable a feasible prediction for large scale structures.

A new approach for nonlinear dynamic structural analysis, namely the Mixed Lagrangian Formulation (MLF), has recently been proposed [16]. MLF was originally developed for the analysis of elastic-plastic response while considering geometric nonlinearity. This approach lays on a sound theory that may enable the investigation of existence and uniqueness of solutions. It is based on time discretization of Hamilton's principle [17]. Hence, the computation of the response quantities in each time step reduces to the solution of an optimization problem. This weak formulation in time leads to a very stable and accurate numerical scheme that allows for large time step sizes, while allowing for sharp changes in its variables. It also requires a small number of iterations within each time step. In much similarity to the generalized standard material framework [18], MLF is also based on two scalar functions: The stored energy function and the dissipation function.

MLF has been modified to enable an efficient analysis of large scale 3D buildings [19]. It was shown to scale very well with the size of the system analyzed. The theory of MLF and the numerical tool have been successfully extended to account for contact analysis by a careful formulation of an appropriate stored energy function [20]. The capabilities of this framework have been also extended to account for strength degradation and fracture [21]. This was achieved, however, by somewhat deviating from the rigorous MLF and formulating a new hybrid implicit-explicit approach. MLF can potentially present a unified approach with a strong theoretical background that accounts for all stages of collapse. A more unified approach to include fracture in MLF, which is the aim of this paper, is the missing part of this puzzle.

Development of such a strong theory that includes all stages of collapse in a unified manner would possibly enable finding the answers to some very important questions regarding existence of solutions, their uniqueness, and the sensitivity to perturbations. In addition, the numerical schemes stemming from such theory could be provided with assurance regarding their convergence and the quality of their numerical solutions. Those numerical simulation tools are expected to be efficient, robust and stable while efficiently analyzing large scale structures for all stages of collapse.

The purpose of this paper is to lay the foundations for accounting for fracture in MLF. The analysis of large scale structures in all stages of collapse requires a focus on the scale of the structural elements (beams, columns, etc.). Thus, macro-modeling is used to avoid infeasible computational effort. In this paper, a uni-dimensional brittle element is formulated. This lays the foundations to account for fracture in MLF. Formulations of more complex macro-elements and behavior could then follow, in future research. For that purpose, additional state variables are first identified and added to the formulation. In turn, appropriate Lagrangian and Dissipation functions are formulated. Those are then used with a discretized version of Hamilton's principle to result an optimization problem in each time step. The solution of the optimization problem leads to the values of the state variables at the end of the time step.

2 PROPOSED FORMULATION

In this section it will be shown that appropriate Lagrangian and Dissipation functions could be formulated such that upon their use with the Euler-Lagrange equations, the known governing equations could be attained. The proposed Lagrangian and Dissipation functions would be used in the next section to form a robust numerical scheme. In order to present the concept of

the proposed formulation the simplest case of a SDOF system with equal damage in tension and compression will be considered first. More general cases will then follow.

As discussed above, macro-modeling is used to avoid infeasible computational effort. At this stage of research, a uni-dimensional brittle element is formulated to lay the foundations to account for fracture in MLF. Being an energy based approach, MLF could strongly benefit from adopting energy based criteria for fracture. A well-known criterion for fracture of brittle materials, for example, is based on Griffith's theory (e.g. [22, 23]). This criterion states that a crack would propagate if the energy to be released by the incremental growth of the crack, or energy release rate, is larger than the surface energy of the material. This criterion is incorporated to MLF by adopting the crack area as an additional state variable in MLF. In turn, appropriate Lagrangian and Dissipation functions are carefully formulated. It should be noted that as the purpose of this paper is to lay the foundations for incorporating fracture and damage mechanics concepts in MLF, Griffith's theory is applied here to model damage in both tension and compression.

2.1 SDOF system with equal damage in tension and compression

In order to account for fracture, this section makes use of a uni-dimensional macro-element whose stiffness in both tension and compression depends on a "crack area" variable, a . Modifications will be done in the following sections to account for different behavior in tension and compression and MDOF systems.

Let us consider the SDOF system presented in Figure 1. It is comprised of a mass, m , a dashpot having a damping coefficient c and a spring whose stiffness $k(a)$ depends on a "crack area" variable, a , in an appropriate manner. Let us also assume that the evolution of the crack propagation obeys Griffith's theory. The aim of this section is to formulate appropriate Lagrangian and Dissipation function such that upon their substitution to Euler-Lagrange equations one could attain the known governing equations (the equilibrium equation and an equation to reflect Griffith's theory)

Figure 1: SDOF system with equal damage in tension and compression.

The proposed Lagrangian and Dissipation functions take the form:

$$L(u, \dot{u}, a) = \frac{1}{2} m \dot{u}^2 - \frac{1}{2} k(a) \cdot u^2 + p^T u - g(a) \quad (1)$$

$$\bar{\varphi}(\dot{u}, \dot{a}) = \frac{1}{2} c \dot{u}^2 + \varphi(\dot{a}) + 2\gamma \dot{a} \quad (2)$$

Where L is the Lagrangian function, $\bar{\varphi}$ is the Dissipation function, m is the mass of the system, c is the damping coefficient of the dashpot, $k(a)$ is the stiffness of the spring, a is the fracture area or damage parameter, $u(t)$ is the displacement of the mass, γ is the surface energy, $p(t)$ is the external force exerted on the mass, t is time, a dot represents a derivative w.r.t time and $\varphi(\cdot)$ and $g(\cdot)$ convex index functions. Figure 2a presents the function $g(\cdot)$ and Figure 2c

presents the function $\varphi(\cdot)$. In these figures a_0 is the total cross section area. Their derivatives $\partial g(a)/\partial a$ and $\partial \varphi(\dot{a})/\partial \dot{a}$ are presented in Figures 2b and 2d, respectively. Those will be used later on. As can be seen, the function $g(\cdot)$ is zero for values of $a < a_0$ and can take any positive value when $a = a_0$. This will later lead to a constraint on a such that $a \leq a_0$. The function $\varphi(\cdot)$, on the other hand, is assigned with a zero value for $\dot{a} > 0$ and can take any positive value when $\dot{a} = 0$. This will be required for controlling the propagation of fracture.

Figure 2: Index functions for the SDOF system with equal damage in tension and compression.

For the problem at hand, with both the displacement and the crack area as state variables, the Euler-Lagrange equations in terms of the Lagrangian and Dissipation functions are given as follows:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{u}} \right) - \frac{\partial L}{\partial u} + \frac{\partial \bar{\varphi}}{\partial \dot{u}} = 0 \quad (3)$$

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{a}} \right) - \frac{\partial L}{\partial a} + \frac{\partial \bar{\varphi}}{\partial \dot{a}} = 0 \quad (4)$$

Upon substitution of the proposed Lagrangian and Dissipation functions to the first of Euler-Lagrange equations (Equation 3) one could attain the first governing equation as follows:

$$m\ddot{u} + k(a) \cdot u + c\dot{u} = p \quad (5)$$

This equation is, obviously, the equation of motion of the system. Substitution of the proposed Lagrangian and Dissipation functions to the second of Euler-Lagrange equations (Equation 4) leads to:

$$\frac{1}{2} \frac{\partial k(a)}{\partial a} u^2 + \frac{\partial \varphi(\dot{a})}{\partial \dot{a}} + \frac{\partial g(a)}{\partial a} + 2\gamma = 0 \quad (6)$$

This equation could be brought to the form:

$$-\frac{\partial \Pi}{\partial a} - \frac{\partial \phi(\dot{a})}{\partial \dot{a}} - \frac{\partial g(a)}{\partial a} = 2\gamma \quad (7)$$

where $\Pi = U_E - W$, U_E is the elastic energy and W is the work performed by the applied loads. That is, $-\Pi$ is the complementary energy. This equation controls the crack propagation. It is, actually, equivalent to Griffiths theory where in order to increase the length of the crack the negative of the derivative of the potential energy, $\Pi = U_E - W$, w.r.t the crack length, should be equal to 2γ as will now be demonstrated.

Let us first consider the case where $a < a_0$. In this case, as can be seen from Figure 2b, a value of zero is assigned to $\partial g(a)/\partial a$. Hence, the value of $\partial \phi(\dot{a})/\partial \dot{a}$ (from Equation 7) depends on the value of $-\partial \Pi/\partial a$ as well as on the value of 2γ . As can be seen by Equation 7, when $-\partial \Pi/\partial a = 2\gamma$ (and $a < a_0$) a value of zero is assigned to $\partial \phi(\dot{a})/\partial \dot{a}$. Hence, from Figure 2d, \dot{a} can be equal or larger than zero and fracture can take place. If, on the contrary, $-\partial \Pi/\partial a < 2\gamma$ (and $a < a_0$) a negative value is required for $\partial \phi(\dot{a})/\partial \dot{a}$ so as to satisfy Equation 7. Hence, from Figure 2d, $\dot{a} = 0$ and fracture cannot propagate. The case where $-\partial \Pi/\partial a > 2\gamma$ (and $a < a_0$) cannot be attained since in that case fracture already would have occurred earlier.

In the case where $a = a_0$ the spring is fully fractured and fracture can no longer propagate. This is accounted for in the formulation by using the function $g(a)$ that penalizes values of a larger than a_0 . This is reflected in Equation 7 as $\partial g(a)/\partial a$ can take any non-negative value (Figure 2b) while $\partial \phi(\dot{a})/\partial \dot{a}$ can be assigned with any non-positive value. Hence, Equation 7 indicates that fracture can no longer propagate. In this case, the spring loses its stiffness. Although not necessary, the spring could be removed manually at the end of the time step where a reached a_0 . Note that fracture (or damage) evolution is enabled by considering the term $\phi(\cdot)$. Appearing in the Dissipation function, this term leads to an irreversible process. Hence, fracture (or damage) that is created by increase of area crack cannot reduce even if the force is reversed. That is, the crack area variable can only increase.

2.2 SDOF system with different damage in tension and compression

The model presented in the previous section is now extended to account for different behavior in tension and in compression. For that purpose, a tension-only element and a compression-only element are introduced. The former can take only tension forces when the relative displacement at its edges is zero while its internal force is zero when the relative displacement is negative (i.e. the element is shortens). The latter can take only compression forces when the relative displacement at its edges is zero while its internal force is zero when the relative displacement is positive (i.e. the element elongates). The assembly of the system is presented in Figure 3. It is comprised of a mass, a dashpot and two springs in parallel. The first spring is connected in series to a tension-only element while the second spring is connected in series to a compression-only element. Thus, different behavior could be modeled for tension and compression. Both springs are assumed to depend on “crack area” or damage variables. Although Griffith’s theory was originally proposed for the propagation of cracks due to tension, both “crack area” variables in tension and in compression are assumed here to evolve obeying Griffith’s theory.

Figure 3: SDOF system with different damage in tension and compression.

The proposed Lagrangian and Dissipation functions take the form:

$$L = \frac{1}{2} m \dot{u}^2 - \frac{1}{2} k_t(a_t) u_t^2 - \frac{1}{2} k_c(a_c) u_c^2 - g(a_t) - g(a_c) - \eta_t(u - u_t) - \eta_c(u - u_c) + pu \quad (8)$$

$$\varphi = \frac{1}{2} c \dot{u}^2 + \varphi(\dot{a}_t) + 2\gamma_t \dot{a}_t + \varphi(\dot{a}_c) + 2\gamma_c \dot{a}_c$$

where the subscript t represents variables related to the tension-only system, the subscript c represents variables related to the compression-only system, and the convex functions η_t and η_c are presented in Figure 4 with their partial derivatives w.r.t their arguments. Those functions would later lead to the tension-only and compression-only behavior.

Figure 4: Index functions for the SDOF system with different damage in tension and compression.

For the problem at hand, with the displacements u , u_t and u_c , as well as the “crack area” variables a_t and a_c , as state variables, the Euler-Lagrange equations are given as follows:

$$\begin{cases}
u: & m\ddot{u} + \frac{\partial \eta_t(u-u_t)}{\partial u} + \frac{\partial \eta_c(u-u_c)}{\partial u} + c\dot{u} = p \\
u_t: & k_t(a_t)u_t + \frac{\partial \eta_t(u-u_t)}{\partial u_t} = 0 \\
u_c: & k_c(a_c)u_c + \frac{\partial \eta_c(u-u_c)}{\partial u_c} = 0 \\
a_t: & \frac{1}{2} \frac{\partial k_t(a_t)}{\partial a_t} u_t^2 + \frac{\partial g(a_t)}{\partial a_t} + \frac{\partial \varphi(\dot{a}_t)}{\partial \dot{a}_t} + 2\gamma_t = 0 \rightarrow -\frac{1}{2} \frac{\partial k_t(a_t)}{\partial a_t} u_t^2 - \frac{\partial g(a_t)}{\partial a_t} - \frac{\partial \varphi(\dot{a}_t)}{\partial \dot{a}_t} = 2\gamma_t \\
a_c: & \frac{1}{2} \frac{\partial k_c(a_c)}{\partial a_c} u_c^2 + \frac{\partial g(a_c)}{\partial a_c} + \frac{\partial \varphi(\dot{a}_c)}{\partial \dot{a}_c} + 2\gamma_c = 0 \rightarrow -\frac{1}{2} \frac{\partial k_c(a_c)}{\partial a_c} u_c^2 - \frac{\partial g(a_c)}{\partial a_c} - \frac{\partial \varphi(\dot{a}_c)}{\partial \dot{a}_c} = 2\gamma_c
\end{cases} \quad (9)$$

Here the first equation is the equation of motion while the fourth and fifth equations dictate the evolution of the “crack area” variables for the tension and compression springs, respectively. The second and third equations enforce tension-only and compression-only behavior on the springs connected to the tension-only and compression-only elements, respectively, as will now be demonstrated.

Let us first note that $\partial \eta_t(u-u_t)/\partial u = -\partial \eta_t(u-u_t)/\partial u_t$. Hence, from the second of Equation 9 one could write $\partial \eta_t(u-u_t)/\partial u = k_t(a_t)u_t$. That is, in the first of Equation 9 one could replace $\partial \eta_t(u-u_t)/\partial u$ with $k_t(a_t)u_t$. Let us now focus on the second of Equation 9 with Figure 4c. As can be seen from Figure 4c, when $u < u_t$ a zero value is assigned to $\partial \eta_t(u-u_t)/\partial u_t$. Hence, from the second of Equation 9, $k_t(a_t)u_t = 0$ and the spring force is zero. It could also be seen that in that case $u_t = 0$ thus $u < 0$. If, on the other hand, $u = u_t$, a non-positive value is assigned to $\partial \eta_t(u-u_t)/\partial u_t$. Hence, from the second of Equation 9, $k_t(a_t)u_t \geq 0$ and the spring force is non-negative. It could also be seen that in that case $u_t \geq 0$. A similar argument holds for the compression only system.

2.3 MDOF system with contact

The formulation of the previous section is now generalized to MDOF systems. Here, the Lagrangian and Dissipation functions are formulated in terms of vectors representing the displacements of the various degrees-of-freedom (DOFs), \mathbf{u} , the displacements of the tension-only and compression-only elements, \mathbf{u}_t and \mathbf{u}_c , and the “crack area” variables for the tension-only and compression-only systems, \mathbf{a}_t and \mathbf{a}_c , respectively. The proposed Lagrangian and Dissipation functions take the form:

$$\begin{aligned}
L(\mathbf{u}, \dot{\mathbf{u}}, \mathbf{a}) = & \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{M} \dot{\mathbf{u}} - \frac{1}{2} \mathbf{u}_t^T \mathbf{K}_t(\mathbf{a}_t) \mathbf{u}_t - \frac{1}{2} \mathbf{u}_c^T \mathbf{K}_c(\mathbf{a}_c) \mathbf{u}_c \\
& - g(\mathbf{a}_t) - g(\mathbf{a}_c) - \eta(\mathbf{B}^T \mathbf{u} - \mathbf{u}_t) - \eta(\mathbf{B}^T \mathbf{u} - \mathbf{u}_c) + \mathbf{p}^T \mathbf{u}
\end{aligned} \quad (10)$$

$$\varphi(\dot{\mathbf{u}}, \dot{\mathbf{a}}) = \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{C} \dot{\mathbf{u}} + \varphi(\dot{\mathbf{a}}_t) + 2\gamma_t^T \dot{\mathbf{a}} + \varphi(\dot{\mathbf{a}}_c) + 2\gamma_c^T \dot{\mathbf{a}} \quad (11)$$

where \mathbf{M} is the mass matrix, \mathbf{K}_t and \mathbf{K}_c are the stiffness matrices of the tension and the compression springs in their local coordinate systems, respectively, \mathbf{B}^T is the compatibility ma-

trix, \mathbf{C} is the damping matrix, \mathbf{p} is the external force vector on the DOFs, γ_t and γ_c are the surface energy vectors (energy threshold values for damage propagation) for the tension and the compression respectively. The scalar functions g , η and φ were defined in previous sections for scalar arguments. In the case of vector arguments the sum of the values attained for each entry of the vector as the argument is taken (e.g. $g(\mathbf{a}_t) = g(a_{t,1}) + g(a_{t,2}) + \dots + g(a_{t,n})$).

It should be noted that the displacements of the DOFs are sufficient to define the state of all masses. The mass matrix, the damping matrix and the external force vector are defined in this coordinate system. Displacements of additional DOFs, however, are required to define the state of the system. Those are the displacements of the tension-only and compression-only elements. The stiffness matrices are defined in this coordinate system. The functions η , required to account for tension-only and compression-only elements, compare displacements from the two different coordinate systems. Hence, the compatibility matrix, \mathbf{B}^T , transforms displacements from one coordinate system to the other, is required (can be seen in example 4.2).

As the displacements \mathbf{u} , \mathbf{u}_t and \mathbf{u}_c , and the “crack area” variables \mathbf{a}_t and \mathbf{a}_c , are adopted here as state variables, the Euler-Lagrange equations take the following form:

$$\left\{ \begin{array}{l} \mathbf{u}: \quad \mathbf{M}\ddot{\mathbf{u}} + \frac{\partial \eta_t(\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}} + \frac{\partial \eta_c(\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} = \mathbf{p} \\ \mathbf{u}_t: \quad \mathbf{K}_t(\mathbf{a}_t)\mathbf{u}_t + \frac{\partial \eta_t(\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}_t} = 0 \\ \mathbf{u}_c: \quad \mathbf{K}_c(\mathbf{a}_c)\mathbf{u}_c + \frac{\partial \eta_c(\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}_c} = 0 \\ \mathbf{a}_t: \quad \frac{1}{2} \mathbf{u}_t^T \frac{\partial \mathbf{K}_t(\mathbf{a}_t)}{\partial \mathbf{a}_t} \mathbf{u}_t + \frac{\partial g(\mathbf{a}_t)}{\partial \mathbf{a}_t} + \frac{\partial \varphi(\dot{\mathbf{a}}_t)}{\partial \dot{\mathbf{a}}_t} + 2\gamma_t = 0 \\ \mathbf{a}_c: \quad \frac{1}{2} \mathbf{u}_c^T \frac{\partial \mathbf{K}_c(\mathbf{a}_c)}{\partial \mathbf{a}_c} \mathbf{u}_c + \frac{\partial g(\mathbf{a}_c)}{\partial \mathbf{a}_c} + \frac{\partial \varphi(\dot{\mathbf{a}}_c)}{\partial \dot{\mathbf{a}}_c} + 2\gamma_c = 0 \end{array} \right. \quad (12)$$

As in the previous section, here the first equation is the equation of motion. The second and third equations enforce tension-only and compression-only behavior on the springs connected to the tension-only and compression-only elements, respectively. And the fourth and fifth equations dictate the evolution of the “crack area” variables for the tension and compression springs, respectively.

3 PROPOSED NUMERICAL SCHEME

In the previous section, appropriate Lagrangian and Dissipation functions have been formulated. It was shown that use of those functions with the Euler-Lagrange equations leads to the expected governing equations. Those include the equations of motion as well as the equations for the evolution of the crack area. The traditional approach would make use of advanced time discretization schemes to integrate those equations in time at their strong form. With those Lagrangian and Dissipation functions at hand, however, another approach could be taken using the weak form (in time). That is, those functions could be used with Hamilton’s principal. By discretizing the action integral in time, the value of the state variables at the end of the time step may be attained by finding a stationary point of a discrete functional.

In some cases, the stationary point is actually a minimum, hence, an optimization problem could be attained. This leads to a very robust numerical scheme that allows for sharp gradients of the state variables in time. The derivations to follow do not directly apply Hamilton's principal. For the case of an elastic-plastic behavior, however, it was shown [16] that those are equivalent to directly applying Hamilton's principal.

Let us first write Equations 12 at time $i+1/2$ using the central difference approximation:

$$\begin{aligned}
 & \mathbf{M} \left(\frac{\mathbf{v}_{i+1} - \mathbf{v}_i}{h} \right) + \mathbf{C} \left(\frac{\mathbf{v}_{i+1} + \mathbf{v}_i}{2} \right) + \frac{1}{2} \left[\frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}} \Big|_{i+1} + \frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}} \Big|_i \right] \\
 & + \frac{1}{2} \left[\frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}} \Big|_{i+1} + \frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}} \Big|_i \right] - \frac{\mathbf{p}_{i+1} + \mathbf{p}_i}{2} = 0 \\
 & \frac{1}{2} [\mathbf{K}_t(\mathbf{a}_{t,i+1})\mathbf{u}_{t,i+1} + \mathbf{K}_t(\mathbf{a}_{t,i})\mathbf{u}_{t,i}] + \frac{1}{2} \left[\frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}_t} \Big|_{i+1} + \frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}_t} \Big|_i \right] = 0 \\
 & \frac{1}{2} [\mathbf{K}_c(\mathbf{a}_{c,i+1})\mathbf{u}_{c,i+1} + \mathbf{K}_c(\mathbf{a}_{c,i})\mathbf{u}_{c,i}] + \frac{1}{2} \left[\frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}_c} \Big|_{i+1} + \frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}_c} \Big|_i \right] = 0 \\
 & \frac{1}{2} \left[\frac{1}{2} \mathbf{u}_{t,i+1}^T \frac{\partial \mathbf{K}_t(\mathbf{a}_{t,i+1})}{\partial \mathbf{a}_{t,i+1}} \mathbf{u}_{t,i+1} + \frac{1}{2} \mathbf{u}_{t,i}^T \frac{\partial \mathbf{K}_t(\mathbf{a}_{t,i})}{\partial \mathbf{a}_{t,i}} \mathbf{u}_{t,i} \right] + \frac{1}{2} \left[\frac{\partial g(\mathbf{a}_t)}{\partial \mathbf{a}_t} \Big|_{i+1} + \frac{\partial g(\mathbf{a}_t)}{\partial \mathbf{a}_t} \Big|_i \right] + \frac{1}{2} \left[\frac{\partial \varphi(\dot{\mathbf{a}}_t)}{\partial \dot{\mathbf{a}}_t} \Big|_{i+1} + \frac{\partial \varphi(\dot{\mathbf{a}}_t)}{\partial \dot{\mathbf{a}}_t} \Big|_i \right] + 2\gamma_t = 0 \\
 & \frac{1}{2} \left[\frac{1}{2} \mathbf{u}_{c,i+1}^T \frac{\partial \mathbf{K}_c(\mathbf{a}_{c,i+1})}{\partial \mathbf{a}_{c,i+1}} \mathbf{u}_{c,i+1} + \frac{1}{2} \mathbf{u}_{c,i}^T \frac{\partial \mathbf{K}_c(\mathbf{a}_{c,i})}{\partial \mathbf{a}_{c,i}} \mathbf{u}_{c,i} \right] + \frac{1}{2} \left[\frac{\partial g(\mathbf{a}_c)}{\partial \mathbf{a}_c} \Big|_{i+1} + \frac{\partial g(\mathbf{a}_c)}{\partial \mathbf{a}_c} \Big|_i \right] + \frac{1}{2} \left[\frac{\partial \varphi(\dot{\mathbf{a}}_c)}{\partial \dot{\mathbf{a}}_c} \Big|_{i+1} + \frac{\partial \varphi(\dot{\mathbf{a}}_c)}{\partial \dot{\mathbf{a}}_c} \Big|_i \right] + 2\gamma_c = 0
 \end{aligned} \tag{13}$$

Using the approximation $\mathbf{u}_{j,i+1} = \mathbf{u}_{j,i} + \frac{h}{2}(\mathbf{v}_{j,i+1} + \mathbf{v}_{j,i})$ one could obtain:

$$\begin{aligned}
 & \frac{1}{h} \mathbf{M} \mathbf{v}_{i+1} - \frac{1}{h} \mathbf{M} \mathbf{v}_i + \frac{1}{2} \mathbf{C} \mathbf{v}_{i+1} + \frac{1}{2} \mathbf{C} \mathbf{v}_i + \frac{1}{2} \left[\frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}} \Big|_{i+1} + \frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}} \Big|_i \right] \\
 & + \frac{1}{2} \left[\frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}} \Big|_{i+1} + \frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}} \Big|_i \right] - \frac{\mathbf{p}_{i+1} + \mathbf{p}_i}{2} = 0 \\
 & \frac{1}{2} \mathbf{K}_t(\mathbf{a}_{t,i+1})\mathbf{u}_{t,i+1} + \frac{h}{4} \mathbf{K}_t(\mathbf{a}_{t,i+1})\mathbf{v}_{t,i+1} + \frac{h}{4} \mathbf{K}_t(\mathbf{a}_{t,i+1})\mathbf{v}_{t,i} + \frac{1}{2} \mathbf{K}_t(\mathbf{a}_{t,i})\mathbf{u}_{t,i} + \frac{1}{2} \left[\frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}_t} \Big|_{i+1} + \frac{\partial \eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t)}{\partial \mathbf{u}_t} \Big|_i \right] = 0 \\
 & \frac{1}{2} \mathbf{K}_c(\mathbf{a}_{c,i+1})\mathbf{u}_{c,i+1} + \frac{h}{4} \mathbf{K}_c(\mathbf{a}_{c,i+1})\mathbf{v}_{c,i+1} + \frac{h}{4} \mathbf{K}_c(\mathbf{a}_{c,i+1})\mathbf{v}_{c,i} + \frac{1}{2} \mathbf{K}_c(\mathbf{a}_{c,i})\mathbf{u}_{c,i} + \frac{1}{2} \left[\frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}_c} \Big|_{i+1} + \frac{\partial \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)}{\partial \mathbf{u}_c} \Big|_i \right] = 0 \\
 & \frac{1}{2} \left[\frac{1}{2} \left(\mathbf{u}_{t,i} + \frac{h}{2}(\mathbf{v}_{t,i+1} + \mathbf{v}_{t,i}) \right)^T \frac{\partial \mathbf{K}_t(\mathbf{a}_{t,i+1})}{\partial \mathbf{a}_{t,i+1}} \left(\mathbf{u}_{t,i} + \frac{h}{2}(\mathbf{v}_{t,i+1} + \mathbf{v}_{t,i}) \right) + \frac{1}{2} \mathbf{u}_{t,i}^T \frac{\partial \mathbf{K}_t(\mathbf{a}_{t,i})}{\partial \mathbf{a}_{t,i}} \mathbf{u}_{t,i} \right] \\
 & + \frac{1}{2} \left[\frac{\partial g(\mathbf{a}_t)}{\partial \mathbf{a}_t} \Big|_{i+1} + \frac{\partial g(\mathbf{a}_t)}{\partial \mathbf{a}_t} \Big|_i \right] + \frac{1}{2} \left[\frac{\partial \varphi(\dot{\mathbf{a}}_t)}{\partial \dot{\mathbf{a}}_t} \Big|_{i+1} + \frac{\partial \varphi(\dot{\mathbf{a}}_t)}{\partial \dot{\mathbf{a}}_t} \Big|_i \right] + 2\gamma_t = 0 \\
 & \frac{1}{2} \left[\frac{1}{2} \left(\mathbf{u}_{c,i} + \frac{h}{2}(\mathbf{v}_{c,i+1} + \mathbf{v}_{c,i}) \right)^T \frac{\partial \mathbf{K}_c(\mathbf{a}_{c,i+1})}{\partial \mathbf{a}_{c,i+1}} \left(\mathbf{u}_{c,i} + \frac{h}{2}(\mathbf{v}_{c,i+1} + \mathbf{v}_{c,i}) \right) + \frac{1}{2} \mathbf{u}_{c,i}^T \frac{\partial \mathbf{K}_c(\mathbf{a}_{c,i})}{\partial \mathbf{a}_{c,i}} \mathbf{u}_{c,i} \right] \\
 & + \frac{1}{2} \left[\frac{\partial g(\mathbf{a}_c)}{\partial \mathbf{a}_c} \Big|_{i+1} + \frac{\partial g(\mathbf{a}_c)}{\partial \mathbf{a}_c} \Big|_i \right] + \frac{1}{2} \left[\frac{\partial \varphi(\dot{\mathbf{a}}_c)}{\partial \dot{\mathbf{a}}_c} \Big|_{i+1} + \frac{\partial \varphi(\dot{\mathbf{a}}_c)}{\partial \dot{\mathbf{a}}_c} \Big|_i \right] + 2\gamma_c = 0
 \end{aligned} \tag{14}$$

It could be shown that the set of equations 14 is equivalent to the stationarity conditions on the following potential function:

$$\begin{aligned}
& \frac{1}{2h} \mathbf{v}_{i+1}^T \mathbf{M} \mathbf{v}_{i+1} + \frac{1}{4} \mathbf{v}_{i+1}^T \mathbf{C} \mathbf{v}_{i+1} - \frac{1}{h} \mathbf{v}_{i+1}^T \mathbf{M} \mathbf{v}_i - \frac{1}{2} \mathbf{v}_{i+1}^T \mathbf{M} \ddot{\mathbf{u}}_i - \frac{1}{2} \mathbf{v}_{i+1}^T \mathbf{p}_{i+1} + \frac{1}{2h} \mathbf{u}_{t,i}^T \mathbf{K}_t(\mathbf{a}_{t,i+1}) \mathbf{u}_{t,i} + \frac{1}{2} \mathbf{v}_{t,i+1}^T \mathbf{K}_t(\mathbf{a}_{t,i+1}) \left(\mathbf{u}_{t,i} + \frac{h}{4} \mathbf{v}_{t,i+1} + \frac{h}{2} \mathbf{v}_{t,i} \right) + \\
& \frac{1}{2} \mathbf{v}_{c,i}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \left(\mathbf{u}_{c,i} + \frac{h}{4} \mathbf{v}_{c,i} \right) + \frac{1}{2h} \mathbf{u}_{c,i}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \mathbf{u}_{c,i} + \frac{1}{2} \mathbf{v}_{c,i+1}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \left(\mathbf{u}_{c,i} + \frac{h}{4} \mathbf{v}_{c,i+1} + \frac{h}{2} \mathbf{v}_{c,i} \right) + \\
& \frac{1}{2} \mathbf{v}_{c,i}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \left(\mathbf{u}_{c,i} + \frac{h}{4} \mathbf{v}_{c,i} \right) + \dot{\mathbf{a}}_{t,i+1}^T \boldsymbol{\gamma}_t + \dot{\mathbf{a}}_{c,i+1}^T \boldsymbol{\gamma}_c + \frac{1}{h} \left(\eta_t (\mathbf{B}^T \mathbf{u} - \mathbf{u}_t) \right)_{i+1} + \eta_c (\mathbf{B}^T \mathbf{u} - \mathbf{u}_c)_{i+1} + g(\mathbf{a}_t)_{i+1} + g(\mathbf{a}_c)_{i+1} + \frac{1}{2} \left(\varphi(\dot{\mathbf{a}}_t)_{i+1} + \varphi(\dot{\mathbf{a}}_c)_{i+1} \right)
\end{aligned} \tag{15}$$

Or, equivalently, to the following constrained optimization problem:

$$\begin{aligned}
\min \quad & \frac{1}{2h} \mathbf{v}_{i+1}^T \mathbf{M} \mathbf{v}_{i+1} + \frac{1}{4} \mathbf{v}_{i+1}^T \mathbf{C} \mathbf{v}_{i+1} - \frac{1}{h} \mathbf{v}_{i+1}^T \mathbf{M} \mathbf{v}_i - \frac{1}{2} \mathbf{v}_{i+1}^T \mathbf{M} \ddot{\mathbf{u}}_i - \frac{1}{2} \mathbf{v}_{i+1}^T \mathbf{p}_{i+1} + \\
& \frac{1}{2} \mathbf{v}_{c,i}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \left(\mathbf{u}_{c,i} + \frac{h}{4} \mathbf{v}_{c,i} \right) + \frac{1}{2h} \mathbf{u}_{c,i}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \mathbf{u}_{c,i} + \frac{1}{2} \mathbf{v}_{c,i+1}^T \mathbf{K}_c(\mathbf{a}_{c,i+1}) \left(\mathbf{u}_{c,i} + \frac{h}{4} \mathbf{v}_{c,i+1} + \frac{h}{2} \mathbf{v}_{c,i} \right) + \dot{\mathbf{a}}_{c,i+1}^T \boldsymbol{\gamma}_c + \\
& \frac{1}{2} \mathbf{v}_{t,i}^T \mathbf{K}_t(\mathbf{a}_{t,i+1}) \left(\mathbf{u}_{t,i} + \frac{h}{4} \mathbf{v}_{t,i} \right) + \frac{1}{2h} \mathbf{u}_{t,i}^T \mathbf{K}_t(\mathbf{a}_{t,i+1}) \mathbf{u}_{t,i} + \frac{1}{2} \mathbf{v}_{t,i+1}^T \mathbf{K}_t(\mathbf{a}_{t,i+1}) \left(\mathbf{u}_{t,i} + \frac{h}{4} \mathbf{v}_{t,i+1} + \frac{h}{2} \mathbf{v}_{t,i} \right) + \dot{\mathbf{a}}_{t,i+1}^T \boldsymbol{\gamma}_t \\
s.t. \quad & -\dot{\mathbf{a}}_{t,i+1} \leq 0 \\
& \dot{\mathbf{a}}_{t,i+1} \leq \max \left(\frac{2}{h} (\mathbf{a}_0 - \mathbf{a}_{t,i}) - \dot{\mathbf{a}}_{t,i}, 0 \right) \\
& -\dot{\mathbf{a}}_{c,i+1} \leq 0 \\
& \dot{\mathbf{a}}_{c,i+1} \leq \max \left(\frac{2}{h} (\mathbf{a}_0 - \mathbf{a}_{c,i}) - \dot{\mathbf{a}}_{c,i}, 0 \right) \\
& \mathbf{B}^T (\mathbf{u}_{i+1}) - \mathbf{u}_{c,i+1} \geq 0 \rightarrow (\mathbf{v}_{c,i+1} - \mathbf{B}^T \mathbf{v}_{i+1}) \leq \left[\frac{2}{h} (\mathbf{B}^T \mathbf{u}_i - \mathbf{u}_{c,i}) + (\mathbf{B}^T \mathbf{v}_i - \mathbf{v}_{c,i}) \right] \\
& \mathbf{B}^T (\mathbf{u}_{i+1}) - \mathbf{u}_{t,i+1} \leq 0 \rightarrow (\mathbf{B}^T \mathbf{v}_{i+1} - \mathbf{v}_{t,i+1}) \leq \left[\frac{2}{h} (\mathbf{u}_{t,i} - \mathbf{B}^T \mathbf{u}_i) + (\mathbf{v}_{t,i} - \mathbf{B}^T \mathbf{v}_i) \right]
\end{aligned} \tag{16}$$

The solution of the optimization problem 16 in each time step results the values of the state variables at the end of the time step.

It should be noted that the attained optimization problem may not be convex thus a single local minimum is not guaranteed. Hence, in case of bifurcations the question "which minimum is the one reflecting the behavior of the physical system?" may arise. Here, the insight from the physics of the problem is accounted for. Griffith's theory is based on the partial derivatives of energy quantities w.r.t the crack area. That is, Griffith's theory sets a criterion that is based on first order conditions at the current state. Hence, the correct solution is the local minimum near the current state. For the purpose of finding the solution, a gradient based approach is to be adopted. In addition, the state at the beginning of each time step should be adopted as the initial guess for the solution of the optimization problem at that time step. Moreover, a relatively small limit should be adopted to the change in the state vector in each iteration of the optimization problem.

4 EXAMPLES

4.1 SDOF system

This example considers the SDOF system presented in Figure 3. The tension spring stiffness is taken here as $k_t(a_t) = k_{0t}(a_0 - a_t)^n$ while the compression spring stiffness is taken here as $k_c(a_c) = k_{0c}(a_0 - a_c)^n$. The following values are assigned to the various parameters: $m=1$, $k_{0t}=k_{0c}=2000$, $a_0=1.2$, $2\gamma=2\gamma_c=80$, $c=0$. No external load was considered, however an initial velocity of 15 was accounted for. The example was executed for various values of n , namely $n=1, 2, 3, 4, 5, 10$ and 20 , to explore the behavior and the stability of the algorithm. The problem is solved for a time increment of 10^{-3} and the results are summarized in Figures 5-7. Figure 5a presents the displacements of the system with various values of the exponent versus time

while Figure 5b presents the velocities. The crack area and tension stiffness versus time are presented in Figures 6a and 6b, respectively. Finally, Figure 7a presents the force-displacement relation for various values of the exponent while Figure 7b zooms on the first 1.5 time units.

Figure 5: (a) Displacement and (b) Velocity of the mass versus time.

Figure 6: (a) Crack Area in tension a_t and (b) "zoom in" of Tension Stiffness k_t versus time.

Figure 7: (a) Force-Displacement and (b) "zoom in".

It should be noted that, as expected, the area under each of the force-displacement graphs (Figure 7), that represents the spring energy, approaches $2\gamma_l \cdot a_0 = 80 \cdot 1.2 = 96$ as the crack area approaches a_0 .

4.2 MDOF system

This example considers the 2 DOF system presented in Figure 8. This system is comprised of a rigid beam of mass $m=1$ and moment of inertia $I=1$ mounted on 7 systems of springs. The characteristics of all spring systems are identical. Those include a tension spring of stiffness

$k_t(a_t)=k_{0t}(a_0 - a_t)$ and surface energy $2\gamma_t$, a compression spring of stiffness $k_c(a_c)=k_{0c}(a_0 - a_c)$ and surface energy $2\gamma_c$, and a linear dashpot with a damping coefficient c . Here, $k_{0t}=k_{0c}=2000$, $a_0=1.2$, $2\gamma_t=2\gamma_c=80$, $c=0$ and $l=0.2$. No external load was considered, however an initial angular velocity of 30 was accounted for.

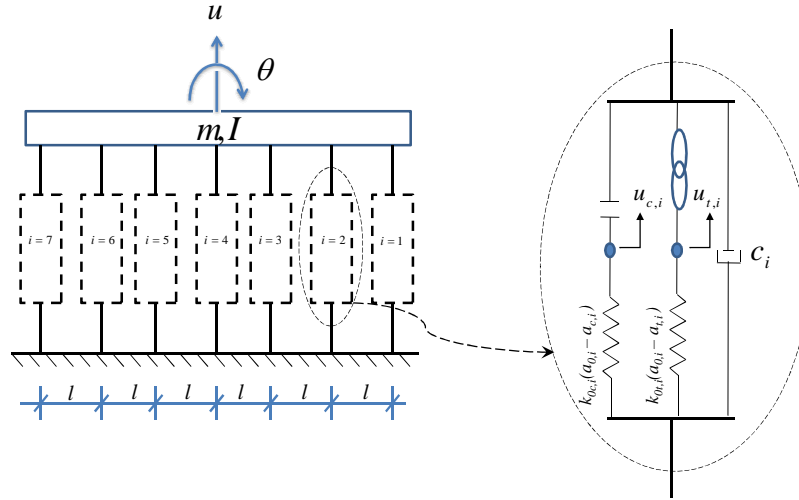

Figure 8: Two DOF system for Example 2.

The stiffness matrices for the tension-only and compression-only systems are given by:

$$\mathbf{K}_t = \begin{bmatrix} 2000(1.2 - a_{t,1}) & & 0 \\ & \ddots & \\ 0 & & 2000(1.2 - a_{t,7}) \end{bmatrix}$$

$$\mathbf{K}_c = \begin{bmatrix} 2000(1.2 - a_{c,1}) & & 0 \\ & \ddots & \\ 0 & & 2000(1.2 - a_{c,7}) \end{bmatrix}$$

Note that while those matrices look similar, they differ in the crack area variables considered. The mass and damping matrices, as well as the compatibility matrix, \mathbf{B}^T , are given by:

$$\mathbf{M} = \mathbf{I}_{2 \times 2}$$

$$\mathbf{C} = \mathbf{0}_{2 \times 2}$$

$$\mathbf{B}^T = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ -0.6 & -0.4 & -0.2 & 0 & 0.2 & 0.4 & 0.6 \end{bmatrix}^T$$

The problem is first solved for a time increment of 10^{-3} and the results are summarized in Figures 9-12. Figure 9a presents the displacements of the DOFs while Figure 9b presents their velocities. Also presented (Figures 10a and 10b, respectively) are the displacements and velocities of the connections of the springs to the beam. In addition, the tension and compression stiffnesses of the various systems are presented versus time in Figures 11a and 11b, respectively. As can be seen, during the first quarter of cycle, two pairs of springs are fractured, two in tension and two in compression. As some energy was required to result fracture, it was dissipated from the system. Hence, the total energy of the system reduced to a level such that when the direction of the angle was reversed, the potential energy was not sufficient

to result fracture. Thus, the resulted system behaves asymmetrically with reduced stiffness for rotation in one direction and full stiffness in the other. This is also reflected from Figure 10a where the time required to complete a half cycle is different in each direction.

Figure 9: (a) Displacement and (b) Velocity at DOFs versus time.

Figure 10: (a) Displacement and (b) Velocity at system points (see Fig. 8) versus time.

Figure 11: Stiffness at (a) tension and (b) compression springs versus time.

Figures 12a and 2b present the force-displacement behavior of system 1 and 2, respectively. As can be seen, both spring present a linear relation in compression up to fracture that occurs in an instant as expected. Spring 1 fractures at time 0.019 while spring 2 fractures at time 0.039. The behavior in tension remains linear as those spring systems did not fracture in tension.

Figure 12: Force-Displacement at (a) system 1 and (b) system 2

Finally, a convergence test was conducted. The problem was solved for various time increment values and the displacements and velocities of the DOFs versus time are presented in Figures 13a and 10b, respectively. Additionally, the force displacements behavior of system 1 and 2 in compression are presented in Figures 14a and 14b, respectively. As can be seen, the time increment of 10^{-3} is sufficient for convergence. This is very encouraging as the state variables of this problem show very sharp gradients in time. Those usually lead to large sensitivities. It should also be noted that while the use of a time increment of 10^{-2} leads to inaccuracy, the important phenomena are captured by the algorithm. Note also that the theoretical force and displacements of each spring at fracture are 678.82 and 0.28284, respectively. Those are traced by the algorithm with good accuracy using a time increment of 10^{-3} or smaller.

Figure 13: (a) Displacements and (b) Velocities at DOFs versus time for various time increments.

Figure 14: Force-Displacement at (a) system 1 and (b) system 2 for various time increments.

5 CONCLUSIONS

- This paper presented a first step towards accounting for fracture in MLF in a unified manner through energy based fracture mechanics criteria. This important step shows feasibility of accounting for damage and fracture mechanics concepts in MLF.
- It was shown that although problems related to damage and fracture may reach bifurcation points, gained insight from the physics of the problem may assist in choosing the right path for the evolution of the state variables in time. In the problem at hand, for example, the optimization problem attained in each time step may not be convex. Nevertheless, insight from the nature of Griffith's criteria assisted in identifying the correct local minimum that, in turn, leads to the right path of the evolution in time.
- Finally, the example problems revealed that relatively large time increments were sufficient for convergence even when sudden fracture ($n=1$) was considered. This is very encouraging and is attributed to the weak formulation in time.

Keywords: dynamics, shock, stability.

Abstract. *In Pressurized Water Reactors of nuclear power plants, steam generators act as heat exchangers between primary and secondary coolant fluids. They consist of a bundle of U-tubes in which flows the primary coolant fluid. Several support plates guide these tubes vertically. Secondary coolant fluid flows along the U-tubes and passes through the space between tubes and plates. This space, initially of a foliate shape, is filled with sludge deposits. Consequently, fluid flow is accelerated and the tubes are more excited. Moreover, the mechanical bonding between tube and plate is changed. The combination of these two phenomena can lead to dynamic instabilities and tube cracks. This paper focuses on the effects of shocks on tube instability. As we concentrate on a mechanical point of view, the study of the nonlinear dynamics is made in the following specific conditions: the tube is in air with no flowing fluid; an instability is generated by injecting a force proportional to the velocity of a point of the leg of the tube. The tube is modeled as an Euler-Bernoulli beam. The contact between tube and plate is computed assuming circular obstacles and a contact force that is linear with a gap. A reduced model is generated to represent the bandwidth of interest and the effect of contact forces. Time evolution is then computed using a nonlinear Newmark scheme. Numerical simulations show the effect of shock nonlinearities on the dynamics. Cases of unstable unconstrained tubes leading to bounded stable dynamics when shocks occur are analyzed. The instability in the unconstrained condition does not imply that the bilateral contact condition is unstable. Areas of the contact stiffness/feedback gain plane are shown to lead to stable modes of the bilateral model. The work then presents results on an experimental bench that includes the curved part of a tube and one Support Plate. The instability is generated by feeding back to a shaker the amplified signal of a velocity measurement performed with an integrated accelerometer. For great enough feedback gains, the vibration amplitudes grow until shocks occur. The permanent regime eventually found is analyzed. A good similarity between test and analysis is found.*

1 INTRODUCTION

In Pressurized Water Reactor (PWR) of nuclear power plants, steam generators exchange heat between primary coolant fluid and secondary coolant fluid (Figure 1). They consist of a bundle of inversed U-tubes in which flows the primary coolant fluid. These tubes are clamped at the bottom of their legs. Several support plates maintain them vertically. Secondary coolant fluid flows along the tubes and through the holes made on the support plates.

Figure 1 a) Scheme of a PWR nuclear plant. Three fluid circuits are described: primary circuit (red), secondary circuit (blue) and a cooling circuit (green). b) Scheme of a steam generator. The bundle of U-tubes and support plates are shown.

The space between the tubes and the support plates, initially of a foliate shape, is filled with sludge deposits. Consequently, fluid flow is accelerated and the tubes are more excited. Moreover, the mechanical bonding between tube and plate is changed, from free gap to clamping. The combination of these two phenomena can lead to dynamic instabilities and tube cracks.

Different methods are available to predict tube instability in regard with external fluid flow. The method developed by EDF uses linear boundary conditions to model the interaction between the tube and the support plates, typically clamping or supporting. Investigations have been made to get better understanding of the role played by shock non-linearity in respect with tube instability.

Piteau et al. [1] have made experiments and computations of a vibro-impacting straight tube subjected to fluid-elastic forces and planar displacements. Shocks modify the instantaneous response frequency and thus modify the fluid-elastic forces, explaining how shocks can stabilize this unstable dynamics. Here, we investigate the stabilization effect of shock non-linearity by itself. The study of the nonlinear dynamics is made in the following conditions: the U-tube is in air with no flowing fluid; instability is generated by injecting a force proportional to the velocity of a point of the leg of the tube.

Section 2 presents the experimental setup. Contact model and reduced basis used for numerical simulations are presented in section 3. The stability of a tube with linear contact stiffness is studied in section 4. Finally, numerical and experimental non-linear simulations are presented in section 5.

2 EXPERIMENTAL BENCH

The experimental bench consists of a portion of a U-tube (Figure 2), constrained at its basis to be as near as possible to a clamped condition. The two legs of the tube are inserted in fo-

liated obstacles, whose geometry reproduces real support plates. These obstacles have been machined with different radius, the gap between the plate and the tube approximating the quantity of sludge deposits. The maximum gap available is around one percent of the external diameter of the tube. The thickness of a support plate is about 1.5 times the external diameter of the tube.

Figure 2 a) Global view of the experimental bench. We distinguish the two foliated obstacles right under the curved part and the shaker on the right leg. b) Detailed view of a foliated obstacle.

A shaker excites the leg in the out-of-plane x direction (z is the vertical and y is an in-plane direction). The shaker is fixed on a lift table, so as to adjust the height of the destabilizing force. Twenty-two B&K 4375 sensors measure accelerations at different points of the structure. A B&K 2635 charge amplifier integrates the acceleration and feeds an electrical voltage proportional to the velocity of the excitation point. Measurements are sampled using LMS Scadas III Front-end, driven by LMS Test.Lab software.

3 NUMERICAL MODEL

A reduced model has been built to perform non-linear numerical simulations. An updated numerical model of the experimental bench is created in section 3.1. The contact model between tube and plate is presented in section 3.2. Reduced basis is built in section 3.3. Numerical simulations are compared with test results in section 3.4.

3.1 Beam model

The tube is modeled as a curved beam. The length of the elements is compatible with a maximum frequency of interest linked to the spectrum of the contact loads. A preliminary study of the kinematic in the contact area has led us to consider an Euler-Bernoulli formulation rather than a Timoshenko formulation.

The mechanical connection between the tube and the frame is quite stiff but is far from clamped conditions. We represent this bind with six discrete springs, three affecting the trans-

lation degrees of freedom and three affecting the rotation degrees of freedom. A modal analysis gave us twelve modes under 200Hz. The tube material parameters and the stiffness of the discrete springs were updated taking into account the frequency of the modes 4, 7, 9 and 11, out-of-plane bending or torsion modes.

The frequencies smaller than 100Hz are quite well correlated (Table 1). The MAC (Modal Assurance Criterion), normalized scalar product between two vectors, is very close to 1, indicating a linear relation between experimental mode shapes and updated numerical mode shapes. Mode shapes are quite close to the ones of a base-clamped tube (Figure 3). A double mode around 85Hz has been badly identified experimentally and the updated numerical frequencies and deformed shapes are not consistent.

Mode number	Measured frequency (Hz)	Measured damping ratio (%)	Updated frequency (Hz)	MAC
1	4.9	1.5	4.9	0.97
2	8.5	1.5	8.4	0.97
3	16.5	0.4	16.7	0.99
4	31.8	0.2	31.7	0.98
5	32.2	0.2	32.1	0.97
6	47.8	0.2	47.5	0.99
7	49.9	0.2	49.6	0.98
8	88.5	0.2	87.7	0.80
9	88.9	0.2	88.4	0.66

Table 1 Comparison between measured and updated frequencies. Damping ratio and MAC.

As the mode frequencies are well separated and providing that the damping is small, we make the modal damping assumption. The few well identified damping values will be used, typically 1.5% for the two first modes and 0.4% for the third mode. The other modes will be affected with 0.2%, common value for the metallic structures cast in one piece. The high frequency modes above 7500Hz (this limit is derived from measured contact forces) will be arbitrarily affected of a 2% damping ratio.

Figure 3 First four modal shapes of the updated numerical model: out-of-plane bending (a), in-plane bending (b), torsion (c), out-of-plane bending (d).

3.2 Contact model

The contact between tube and plates is solved using a functional representation of contact forces: if the displacement is smaller than a defined gap, then the contact force is null; else, the contact force applied to the node is proportional to the penetration and normal to the sur-

face of the obstacle. The global stiffness of the contact between tube and plate has been experimentally measured at 4.10^6 N/m , which is of the same order than the ovalization stiffness of a pipe presented in [2] or than the stiffness used in [1].

The geometry of the obstacle has been simplified, assuming that circles would be a good approximation of the foliated holes. The stiffness has to be distributed over the height of the support plate only using a few planar obstacles (Figure 4). This is done degrading the initial contact where both the plate and the tube are modeled as solids. The contact between a beam and the plate would be modeled as the interaction between a neutral fiber and a contact stiffness density. Here, contact conditions are assigned to nodes interacting with discrete springs whose value is the global stiffness divided by the number of planar obstacles.

Figure 4 Different contact models: a) solid-solid, b) neutral fiber-stiffness density, c) beam nodes-discrete springs.

When the gap between tube and plate reduces to zero, the translations along x and y are blocked. Due to the support plate thickness, the corresponding rotations are also blocked. To block the rotations, at least two levels of obstacles must be considered. When the gap is zero, the tube is connected to the discrete springs. The evolution of the eigen modes with respect to the contact stiffness is compared for different number of discrete obstacles. There are twenty-one nodes along the plate thickness so at most twenty-one obstacles can be considered. Five levels of obstacles imply very limited errors on frequencies compared to those found with twenty-one obstacles.

Figure 5 Evolution of the first eigen frequency with respect to the global contact stiffness. The modes go from unconstrained boundary conditions to supported and then clamped ones.

No shock damping was used as no physical value has been identified. Friction was not taken into account. We consider that the dissipation induced by the modal damping stands for all the physical dissipation.

3.3 Reduced basis

The tube non-linear dynamics are computed solving the discretized equation:

$$M\ddot{X} + C\dot{X} + KX = F_{\text{shaker}}(t) + F_{\text{shock}}^{NL}(X) \quad (1)$$

where M , C and K are the mass, damping and stiffness matrices of the unconstrained tube. The external excitation field has been separated between the excitation term that stems from the shaker and the contact/impact forces located at five nodes per support plate. To reduce the size of this system, we project (1) on a reduced basis T . The degrees of freedom q are solution of (2), with $X = Tq$:

$$M_r \ddot{q} + C_r \dot{q} + K_r q = T^T F_{\text{shaker}} + T^T F_{\text{shock}}^{NL}(cTq) = f_{\text{shaker}}(t) + f_{\text{shock}}^{NL}(q) \quad (2)$$

and $[c]$ is an observation matrix used to express the penetration as a linear combination of the degrees of freedom.

We now detail the reduction basis building procedure. The basis must be rich enough to solve precisely the non-linear dynamics but should be as reduced as possible to allow quick computations. The basis must describe tube displacements when the gap is large, i.e. the tube is unconstrained, and when the gap is close to zero, i.e. when the tube is constrained. Moreover, shock forces applied at a few nodes must be well projected. Finally, the induced spectral bandwidth must include the high frequencies excited by contact/impact forces (around 7500Hz).

The quality of the reduced basis is first based on the computation of the eigen modes of the tube with bilateral contact conditions. We compare frequencies and deformed shapes found solving the reduced problem or solving the un-projected problem. The error is not significant for a wide range of bilateral contact stiffness if the reduced basis is built concatenating deformed shapes of:

- the unconstrained tube,
- the tube with x and y translation degrees of freedom blocked over the thickness of the support plate,
- the tube with x and y translation degrees of freedom blocked at middle node of the support plate,
- static corrections which correspond to unitary force imposed on each degree of freedom of the obstacles ($KX=b_i$).

Family of vectors T is no more orthogonal with respect to M and K . That is, some vectors are nearly collinear. For example, the static corrections are nearly collinear one to each other and nearly collinear to the first in-plane and out-of-plane bending modes. Collinear vectors are eliminated and the remaining family is orthonormalized with respect to M and K , as presented for example in [3]. The first deformed shapes, corresponding to the unconstrained tube, are not changed. In fact, only the information (frequency and deformed shapes) about high frequencies has been modified. As C_r is assumed diagonal by hypothesis (modal damping), all the matrices appearing in (2) are diagonal. Thus, the numerical computations are accelerated.

The choice of the reduced basis, presented in Table 2, has been validated with non-linear numerical simulations. “Blocked modes” and static corrections are really useful: the same quality of results is obtained but using fewer modes.

Type of basis	Number of modes	Minimal frequency (Hz)	Maximal frequency (Hz)
Unconstrained modes	130	4.9	7430
Clamped modes	126	59.7	7490
Supported modes	126	30.0	7430
Static corrections	20	-	-
Concatenated	402	-	-
Orthonormalized	199	4.9	$1.8 \cdot 10^5$

Table 2 Comparison of different projection basis. Orthonormalisation has eliminated half of the vectors and affected high frequencies to static corrections and blocked modes.

3.4 Comparison of numerical simulations with test results

Numerical simulations have been computed for different gaps and different imposed excitations, without velocity feedback. A non-linear Newmark average acceleration scheme [4] is used, with a time-step of $2 \cdot 10^{-5}$ s, small enough to avoid energy errors during non-linear time integration. No numerical dissipation is introduced. Measurements are performed at a sampling frequency of 2048 Hz. Power Spectral Densities (PSD) (see [5] for example), are computed. The PSD estimator is normalized to compare signals with different time-steps:

$$S_{xx}(f_k) = \frac{2dt^2}{M} \sum_{m=1}^M |X_{m,k}|^2 \quad (3)$$

M windowed signals are extracted using overlap and a Hann window leading to M Discrete Fourier Transform (DFT) $X_{m,k}$. At each frequency, to take into account the variability of each windowed signal, we store the maximal and minimal value over these M DFT and compute the mean value.

Figure 6 PSD of the out-of-plane apex acceleration measured (green) or simulated (blue), for increasing RMS value of the excitation (a to d). Vertical lines indicate unconstrained modes of the tube.

A random voltage filtered between 10 and 40Hz is fed to the shaker; the injected force is modulated by the interaction between the tube and the shaker. This force is measured and used as excitation in the numerical simulations. Accelerations are computed or measured at the tube apex, in the out-of-plane direction (Figure 6). Test-analysis correlation is correct over the frequency band [10Hz, 200Hz]. For most peaks and most levels of excitation, amplitudes and frequencies match. The spread of the peaks around 90Hz and 170 Hz is well represented. The anti-resonance around 120Hz is both measured and computed. But the emerging peaks around 28-30Hz and 70Hz are not well reproduced numerically, with the response over-estimated and frequencies that not really match.

The satisfactory correlation between test results and numerical simulations validate the construction of the numerical model. A beam model, a contact model, a reduced basis and an integration scheme have been chosen to accurately and quickly compute the non-linear dynamics of a U-tube impacting support plates.

4 EFFECT OF BILATERAL CONTACT ON COMPLEX POLES

An apparent contact stiffness can be derived from the retained shock model by dividing the contact force with the node displacement. This apparent contact stiffness is null when the contact force is null and tends to the contact stiffness when the force goes to infinity. At every time instant, depending on contact conditions, an underlying linear system exists. In this part, we consider a very simple underlying linear system: each contact node is affected bilateral contact conditions with equal contact stiffness, varying from 0 to 10^8 N/m, as if the gap was null.

Assuming that a feedback loop makes the shaker inject a collocated force proportional to the out-of-plane velocity of a tube leg point and replacing contact/impact forces with bilateral contact conditions, the dynamics (2) is now solution of:

$$M_r \ddot{q} + C_r \dot{q} + K_r q = g T^T [c]^T [c] T \dot{q} - k K_{bil} q = g C_{loop} \dot{q} - k K_{bil} q \quad (4)$$

with $[c]$ the observation matrix of the degree of freedom whose velocity is measured and g the gain of the feedback loop; K_{bil} is the unitary bilateral contact stiffness matrix and k is the apparent contact stiffness. It is worth noting that C_{loop} and K_{bil} are not diagonal matrices. We study the stability of this linear system with respect to the position $[c]$, gain g and stiffness k . To do this, we compute the complex eigenmodes of the following system:

$$\left[\lambda_i^2 M_r + \lambda_i (C_r - g C_{loop}) + (K_r + k K_{bil}) \right] \{\psi_i\} = \{0\} \quad (5)$$

The complex poles are expressed in terms of frequency ω_i and damping ratio ζ_i (6). They are arbitrary sorted by increasing frequency, which is a convenient but delusive choice.

$$\lambda_i = -\zeta_i \omega_i + j \omega_i \sqrt{1 - \zeta_i^2} \quad (6)$$

We are interested in destabilizing low frequency modes. This is done choosing the point where to inject the feedback force, about 20cm below the support plate. The modes which can be easily observed, i.e. with high $[cT_i]$, are the ones whose damping ratio is changed. Every mode with large out-of-plane components becomes unstable except for the second torsion mode and the third out-of-plane bending mode (Figure 7): a vibration node is located near the shaker. We remark that frequencies are not modified when g increases. Damping ratio is a linear function of g . Even if the damping ratio is quite high (-10% for the first mode and $g=20$), mode shapes are very correlated to the mode shapes of the unconstrained model.

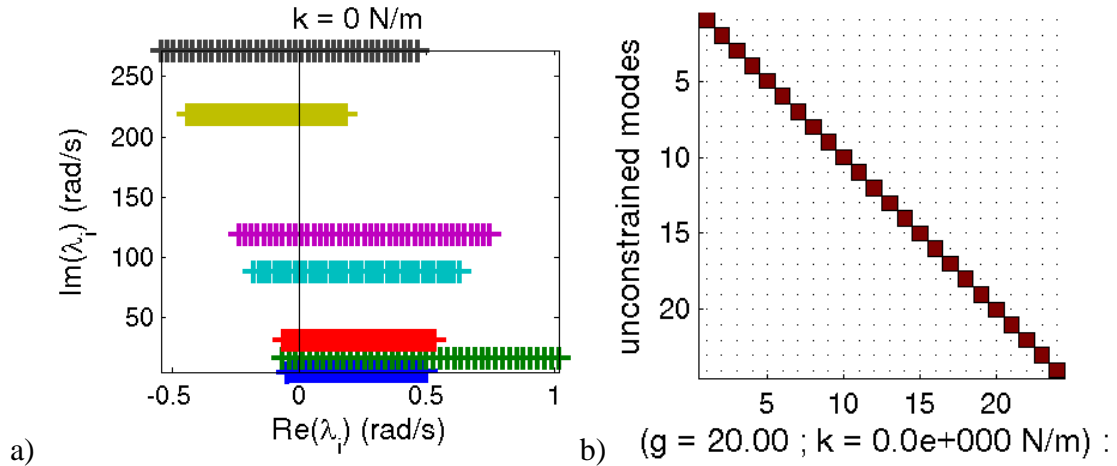

Figure 7 a) Evolution of the complex poles with respect to the feedback parameter. If the real part is positive, the mode is unstable. b) MAC-M between the unconstrained modes and the complex modes obtained for $g=20$.

Pole evolution in the complex plane with respect to the apparent contact stiffness is much more complex, with many crossings. In the meantime, deformed shapes are continuously transformed. For large enough apparent contact stiffness, the deformed shapes are no longer correlated to those of the unconstrained model. The MAC matrix between these two sets of deformed shapes is not diagonal (Figure 8). We focus on the evolution of frequencies and damping ratios (Figure 8), for a given feedback parameter (here, $g=5$). Frequencies increase with respect to the apparent contact stiffness. Damping ratio evolution is more complex. For some modes, damping ratio is not affected by the apparent contact stiffness. These modes were stable and stay stable. The first in-plane flexion mode has an initial damping ratio of 1% which decreases to 0.2%. Initially unstable modes become stable, their damping ratio increasing with respect to the apparent contact stiffness. The mechanical system is stabilized for apparent contact stiffness greater than 10^6 N/m: every damping ratio is positive.

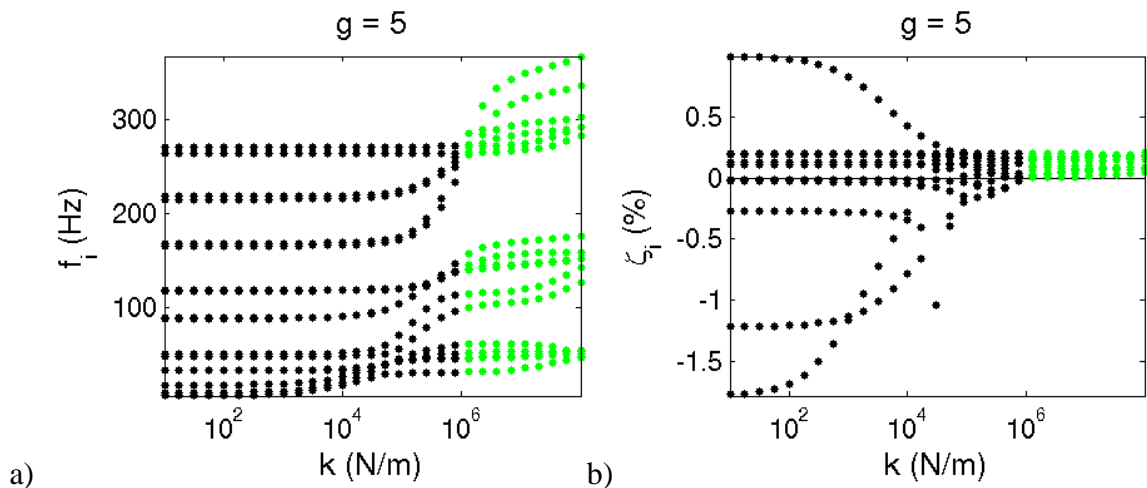

Figure 8 Evolution of the frequency (a) and the damping ratio (b) with respect to the apparent contact stiffness. Green points denote stable systems, with no negative damping ratio.

For a given feedback parameter, adding bilateral contact conditions leads to pole modifications and unstable modes are transformed to stable ones. The stability of the mechanical system has been studied for a wide range of feedback parameter and apparent contact stiffness (Figure 9). If g is small enough, the system is stable. If g is large enough, the system is unsta-

ble. If not, the system is unstable unless k is greater than a given value, which increases as g increases.

Figure 9 Stable configurations with respect to the feedback parameter and the apparent contact stiffness.

5 NON-LINEAR SIMULATIONS

Adding bilateral contact conditions to the destabilized tube can lead to stable mechanical system. In this part, we investigate the effect of shocks on the stability of the tube, subjected to a positive feedback loop on the velocity. Numerical and experimental results are presented. Computed out-of-plane displacements and measured accelerations are observed (Figure 10). Support plates are between P3 and P4 and between P8 and P9, i.e. close to the top of the legs. The shaker is right under P3.

Figure 10 a) Sensor location. b) Corresponding out-of-plane translation degrees of freedom. For example, P4X corresponds to 471.01. The shaker is indicated with a red point.

5.1 Numerical results

Initial conditions are null. Tube is excited at its apex by an impact or by a low-pass filtered noise. Non-linear simulations are made over 30s, with a time-step of $2 \cdot 10^{-5}$ s.

For low values of g , displacements are bounded (Figure 11). For $g=0$, free vibrations of a damped mechanical system are observed. $g=6$ should imply an unstable dynamics, as the apparent contact stiffness stabilizing it is greater than the contact stiffness used in the contact model. Feedback loop brings energy to the tube, which is dissipated during contact phases and in high-frequency modes. The vibration regime is stationary.

Figure 11 Computed displacements (blue: 236.01; green: 261.01; red: 471.01; cyan: 426.01) for different values of g . a) Damped vibrations. b) Stationary vibrations: displacements are bounded.

When displacements grow, penetrations and contact forces grow. This can define a criterion describing the stability of a computed non-linear dynamics: if contact forces exceed 1000N, which corresponds to a penetration equal to the tube thickness, the simulation is described as unstable. Non-linear contact forces computed in section (3.4) were less than 50N. For greater values of g , displacement amplitude increases (Figure 12). Even if crest-to-crest out-of-plane apex displacement reaches 8mm, which is quite high, simulated dynamics with $g=12$, seems stable. When displacements are big enough, contact forces grow and energy is dissipated. Unstable dynamics is exhibited for $g=12.1$. Contact forces do not stabilize the system, damping stays negative and amplitude of displacements grows until maximum contact force criterion is met.

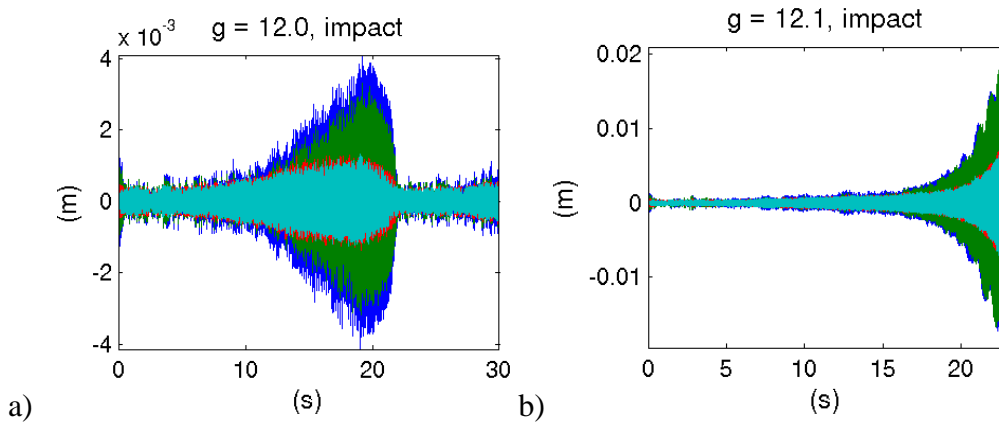

Figure 12 Computed displacements (blue: 236.01; green: 261.01; red: 471.01; cyan: 426.01) for different values of g . Tube is initially excited by an impact. a) displacements grow but remain bounded and eventually decrease; b) unstable regime: contact forces do not stabilize growing displacements

The same behavior has been observed when the impact excitation was replaced by a low-pass filtered noise. Feedback parameters lower than $g=12.6$ lead to stable dynamics. Contact forces can numerically stabilize unstable dynamics, and for a wider range of feedback parameter g than a bilateral contact model.

The apparent contact stiffness distribution drives the maximal stable value of g . For nominal value of gap between tube and support plates, bilateral contact model with equal stiffness affected at each discrete obstacle is a bad approximation of the real distribution of apparent contact stiffness (Figure 13). Apparent contact stiffness is not uniformly distributed over the different obstacles. Superior obstacles apparent stiffness is globally higher than this of inferior obstacles. The apparent stiffness of the left leg obstacles is totally linearly uncorrelated to apparent stiffness of the right leg obstacles. The apparent stiffness of neighbour contact points is highly correlated and decreases with the distance.

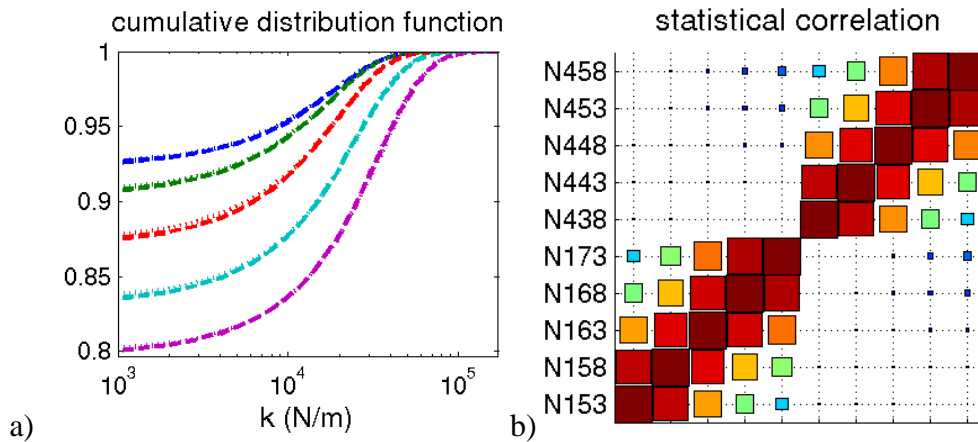

Figure 13 a) Cumulative distribution function of apparent contact stiffness. Contact nodes from bottom to top of the support plate: N153 and N438 (blue), N158 and N443 (green), N163 and N448 (red), N168 and N453 (cyan), N173 and N458 (magenta). b) Statistical correlation of apparent contact stiffness.

5.2 Experimental results

The destabilization is achieved by feeding to the shaker a velocity signal obtained by integrating measured acceleration. The feedback parameter g is fixed using a voltage amplifier. Due to the coupling between tube and shaker, the injected force is not simply proportional to the velocity: peak amplifications and differences of phase are observed. To impose null initial conditions, shaker rod and tube are manually stopped and then let free. Measurement noise is thus amplified by the feedback loop and excites the tube. If g is large enough, vibration amplitude grows. Shocks occur and vibration amplitude remains bounded.

Different regimes can be distinguished in Figure 14. The initial amplitude growth clearly appears on all measurement channels. A stabilized shock regime lasted for about one minute. Then, three different regimes were observed. They differ by their spectral repartition of energy, peak frequencies not being modified.

Operating Deflection Shapes (ODS) can be exhibited. They have vibration nodes located at nodes close to the support plates. They differ from mode shapes of the unconstrained model. They look like mode shapes of the bilateral contact model: ODS are combinations of different shapes, with phase difference, for example a torsion mode combined with an in-plane bending mode. In-plane movements are of the same amplitude as the out-of-plane movements: the specific shape of the foliate hole couples these directions.

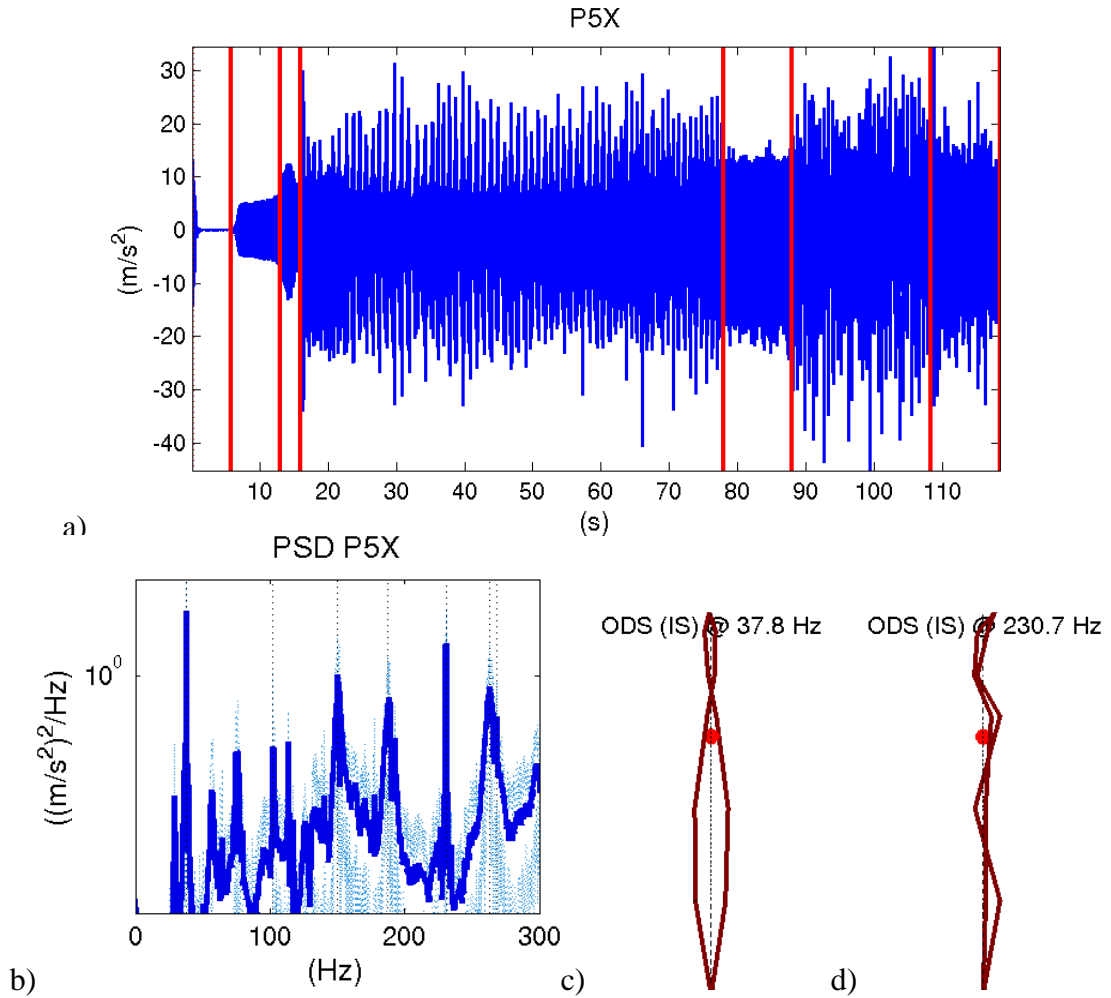

Figure 14 a) Measured acceleration signals. Red lines separate the different observed regimes. b) PSD of the stabilized regime (16s to 78s). c) ODS at 37.8 Hz for the stabilized regime: torsion mode. d) ODS at 230.7 Hz for the stabilized regime: out-of-plane bending.

Despite drawbacks on velocity measurement and on injection of a proportional force, the tube has been destabilized, and it has been shown that contact forces kept vibration amplitude bounded.

6 CONCLUSIONS

This paper presents the stabilization effect of shocks on an unstable mechanical system. An experimental bench consists of a portion of steam generator U-tube. A feedback loop injects a force proportional to a measured velocity. The tube is destabilized by this “negative damping”. Foliate obstacles stop the growth of vibration amplitudes, which remain bounded. A numerical model has been built. The choice of a beam model, a simplified contact model and a reduced basis has been presented. Numerical simulations are quick and correlated to measurements, in the absence of feedback loop. Feedback loop is idealized for numerical simulations: injected force is proportional to the velocity. Unstable free systems are kept bounded by shocks. A possible explanation of the stabilization effect is given studying a linear bilateral contact system: contact stiffness modifies the complex poles.

Some work has still to be done to make the three approaches converge and predict the same feedback parameter leading to global instability and dynamical divergence. The contact model should be more complex, the specific foliate shape coupling in in-plane and out-of-

plane motions. The feedback loop from measured velocity to injected force should be modeled and affected to numerical simulations. Finally, bilateral contact is a too rough linear model: apparent contact stiffness is not uniformly distributed over the obstacles.

ACKNOWLEDGEMENTS

The authors want to thank I. Negreanu (EDF R&D) for his valuable contribution on experimental setup and tests.

Abstract. *The threat of impact or explosive loads is regrettably a scenario to be taken into account in the design of lifeline or critical civilian buildings. These are often made of concrete and not specifically designed for military threats. Numerical simulation of such cases may be undertaken with the aid of state of the art explicit dynamic codes, however several difficult challenges are inherent to such models: the material modeling for the concrete anisotropic failure, consideration of reinforcement bars and important structural details, adequate modeling of pressure waves from explosions in complex geometries, and efficient solution to models of complete buildings which can realistically assess failure modes.*

In this work we employ LS-Dyna for calculation, with Lagrangian finite elements and explicit time integration. Reinforced concrete may be represented in a fairly accurate fashion with recent models such as CSCM model [1] and segregated rebars constrained within the continuum mesh. However, such models cannot be realistically employed for complete models of large buildings, due to limitations of time and computer resources. The use of structural beam and shell elements for this purpose would be the obvious solution, with much lower computational cost. However, this modeling requires careful calibration in order to reproduce adequately the highly nonlinear response of structural concrete members, including bending with and without compression, cracking or plastic crushing, plastic deformation of reinforcement, erosion of vanished elements etc.

The main objective of this work is to provide a strategy for modeling such scenarios based on structural elements, using available material models for structural elements [2] and techniques to include the reinforcement in a realistic way. These models are calibrated against fully three-dimensional models and shown to be accurate enough. At the same time they provide the basis for realistic simulation of impact and explosion on full-scale buildings.

1 INTRODUCTION AND MOTIVATION

The threat of impact or explosive loads is regrettably a scenario to be taken into account in the design of lifeline of critical civilian buildings. These are often made of concrete and not specifically designed for military threats. In the last years there were several cases in which civil buildings were the target of terrorism attacks.

Oklahoma City bombing [?] on April 19, 1995 in USA can show the destruction that can be caused by bombing attack. In this case 2300 kilograms of ANFO were used; The blast claimed 168 lives and injured more than 680 people; the blast destroyed or damaged 324 buildings within a sixteen-block radius. The Alfred P. Murrah Federal Building was the target; the building suffered several/enormous damages although it didn't collapse.

The Asociación Mutual Israelita Argentina (AMIA; Argentine Israelite Mutual Association) building in Buenos Aires was attack on July 18, 1994. In this attack 85 people were killed and hundreds were injured. 275 kilograms of ammonium nitrate fertilizer and fuel oil explosive mixture were used in this attack. The blast totally destroyed the exposed load-bearing walls, led to progressive failure of the floor slabs and collapse of the building.

The parking of the Terminal 4 of the Madrid-Barajas Airport in Spain was attacked on December 30, when a van bomb exploded in, killing two and injuring 52 people; 500 to 800 kilograms of an unknown kind of explosive, probably a mix of ammonium nitrate and hexogen cause the explosion that demolished almost all of the five floors of the car park and produced around 40 tones of debris [4].

The 2009 Burgos bombing occurred on July 29, 2009, when at least 65 people were injured after a van bomb carrying more than 300 kg of explosive went off outside a Civil Guard barracks in the northern city of Burgos, Spain.

This four examples shows the importance of the blast loads in order to design critical civilian buildings. In general, the measures taken to avoid those threats focus on prevent that a significative quantity of explosives could be close of those buildings. Recently several research was made in order to modeling the past terrorism attacks [3], simulate blast on concrete structures [5] and to explain the progressive collapse of civil structures [6].

With this orientation this work present a strategy for modeling frame-buildings subject to blast loads, in order to provide sufficient accuracy results for choose between structural designs and to estimate the amount of explosive that one building can resist without collapse.

1.1 Numerical models for simulation and allow evaluation of structural alternatives

Numerical simulation of such cases may be undertaken with the aid of state of the art explicit dynamic codes. This codes, like LS-Dyna [2] used in this work, are available methods to study blast loads through very short times in witch they apply. LS-Dyna use a lagrangian finite element method with explicit time integration, that can be used to model, in this case, complete concrete structures.

The computational cost of this method depends essentially on the minimum size of the model elements, number of elements and on time simulation. It is possible, in computational costs, analyze a small part of one building with very accuracy lagrangian finite element method using non-linear continuum elements for concrete modeling and non-linear beam elements for steel reinforcement modeling, constrained in concrete continuum elements, in a model with geometries of each part (columns, beams and slabs) very close to real. But the computational cost is excessive in the case of full building analysis. In the way of full building analysis it's necessary other approximation. This work propose use structural elements (shells and beams) for concrete

and reinforcement in segregate way for a low computation cost model that have approximately the same structural behaviour.

1.2 Requirements for modeling

However several difficult challenges are inherent to such models: the material modeling for the concrete anisotropic failure, consideration of reinforcement bars and important structural details, adequate modeling of pressure waves from explosions in complex geometries, and efficient solution to models of complete buildings which can realistically assess failure modes.

The model must be able to represent accurately the global structure behaviour. This includes the wave transmission through columns and slabs, the stress redistribution when any element reaches the elastic limit and plastifies, the stress redistribution and the appearance of new action due to the erosion of structural elements or parts of them, and the process of progressive collapse of the complete building.

The model must be able to evaluate the action of different quantities of explosive that must be applied in different positions in the building. The blast is a short action (the application time range is in 0.01 to 0.1 milliseconds) and, depending on quantity and distance, high values of applied pressure can be reached.

Reinforced concrete has a heterogeneous behaviour, caused by two different materials working together. So the model must represent properly this behaviour. Using an homogeneous model is more limited than using segregated elements. In the other hand, modeling concrete and steel in segregated elements needs an interface in order to work together.

Concrete has complex behaviour, it is a non-linear material with different behaviour in tension and compression, plastic deformation with softening in compression and damage due to cracking in tension. Additionally there is an increment of elastic limit due to strain rate, and the failure of concrete can be controlled in model by element erosion. Concrete has other properties like fatigue and retraction but those are not important for our application.

And steel is a non-linear material too, with same behaviour in tension and compression and with increment of elastic limit due to strain rate. It plastifies when the elastic limit is reached and when the strain is enough it fails.

The material models must represent accurately the behaviour described above and there must be an model interface to make both materials work together.

2 MATERIAL BEHAVIOR AND ELEMENT FORMULATION

This chapter is dedicated to describe the models and formulation we use to obtain a sufficient approximate behaviour in reinforced concrete on blast actions.

2.1 Concrete

For concrete we use two different materials models. The first one is used for continuum elements and the second one is used for structural elements (shells and beams).

Continuum element model: The model used for continuum elements is the CSCM LS-Dyna model [1]. This material is able to represent the complex behaviour described above (figure 1). It can be used only in continuum elements.

- Isotropic behaviour.
- Different behaviour in tension and compression.

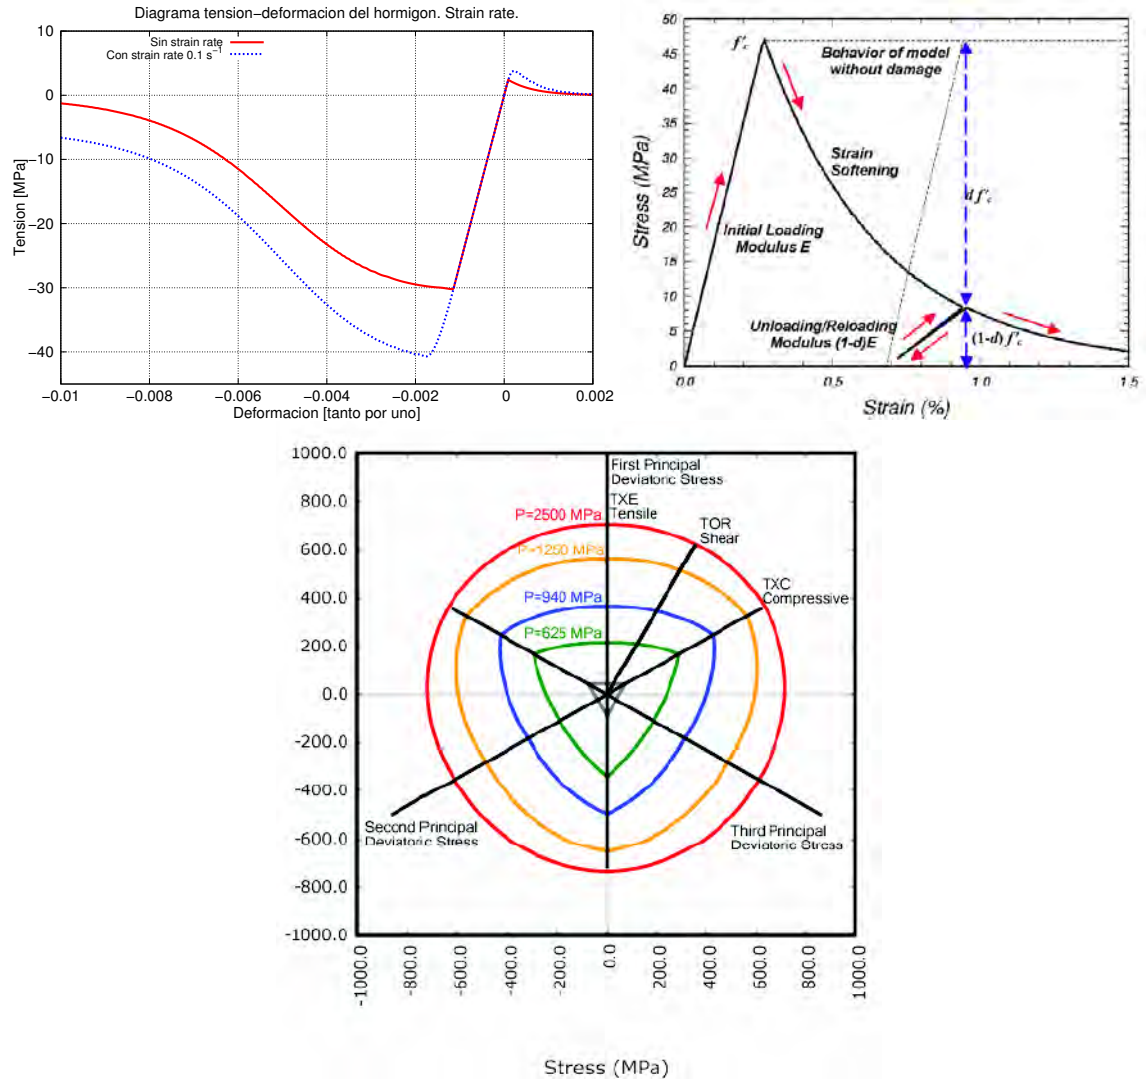

Figure 1: Properties of CSCM concrete model [7]

- Plasticity surfaces (TXE Tensile, TOR Shear, TXC Compressive).
- Softening in compression.
- Damage in tension.
- strain rate effects.
- Erosion

Structural element model. Shell and beam model: The model used for structural elements is the EC2 LS-Dyna model [7]. It can be used in shell and beam type elements. Figure 2 show the tension-deformation diagram.

- Softening in compression.
- Damage in tension.

- Erosion with mat add erosion formulation (not by itself).
- No strain rate effects.
- Plastify surfaces.
- Quantities of steel reinforcement can be included in material homogeneously.

Figure 2: Properties of EC2 concrete model

2.2 Steel reinforcement:

We use the piecewise linear plasticity LS-Dyna model [7] to represent rebar in concrete. This model represents perfectly the behaviour we need for steel reinforcement, with plastic deformation, strain rate effects and fail. We use it in beam elements.

2.3 Concrete/steel interface:

We use two options to model the interface. The first one is merge common nodes between steel and concrete elements, and the second one is use the constrain lagrange in solid [7] formulation implemented in LS-Dyna.

The constrain lagrange in solid option has one advantage: no coincident nodes of concrete and steel are needed. This implies that the size of concrete continuum elements are not limited by the rebar geometry and position, that cause low computation cost. In the other hand this option can not be applied for concrete structural elements.

The figure 3 shows the mesh of validation example for the evaluation of proper behaviour of constrain lagrange in solid formulation. Rebar is model with beam elements and concrete is model with continuum elements. We check the global behaviour is correct.

In this way we use the constrain lagrange in solid formulation for continuum models and the merge option for structural models.

There are a limitation in both methods: the adherence is not modeled but we assume this limitation.

Figure 3: Constrain lagrange in solid

2.4 Offset formulation

In structural models the reinforcement steel beam elements are linked with the concrete shells elements by nodes. It is a problem because all elements are in the same plane, and the influence of reinforcement eccentricity can not be included. To avoid this problem we use a Ls-Dyna beam offset formulation [7] to take account this influence. With beam offset is possible to define a offset distance from the plane in order to correct the position of rebar in model to simulate the real position. The table 1 shows the check of this formulation in a simple beam test model.

Eccentric Reinforcement		
Case	Reaction	Description
Theory B	25.9 kN	Bernoulli beam
Theory T	22.1 kN	Timoshenko beam
Beams	26.9 kN	Beams elements
Shells	25.5 kN	Shell and beam elements

Table 1: Validation offset beam formulation.

2.5 Blast formulation

The blast load is defined with a pressure law that depend on time and position for each quantity of explosive.

In this work we use the blast LS-Dyna formulation [8] that it is the implementation of CONWEP formulation of TM-855-1 manual from U.S. Department of the Army [9].

3 APPLICATION: EXPLOSIVE LOADS ON STRUCTURAL ELEMENTS

Material and element formulation make possible to analyze structural elements of a real frame-type building. The objective of this section is to analyze structural elements of frame-type buildings and check the viability of use structural finite elements with the same structural response.

There are three main structural elements forming part of a frame-type building: columns, beams and slabs.

In order to analyze this structural elements two models were develop. In first place, continuum elements model was develop, which represents the better characterization of the real quasi-static and dynamic behaviour, and in second place a structural finite elements model was develop, which have the similar structural behaviour and low computational cost. Similar structural behaviour for second model is achieved with properly geometry and materials models parameter adjustment.

3.1 Column

In order to analyze columns on frame-type buildings we choose a representative one which is testing in two ways: quasi-static an dynamic. Bending perform the quasi-static analysis and three different cases with two quantities of explosive perform the dynamic analysis.

We use a simply supported 40 MPa concrete column with twelve longitudinal reinforcement bars of 20 mm diameter and transversal reinforcement of 8 mm, and steel is type B500S. The column is 3.15 meters length and 45×45 centimeters section Column mesh and reinforcement for continuum elements model are showed in figure 4.

We develop two models of continuum model using CSCM concrete material for continuum elements and piecewise linear plasticity for reinforcement beam elements: the first one with the constrain lagrange in solid formulation to model the interface, with bigger elements in the mesh, and the second one with merge nodes of common elements, with the necessary smaller elements. We check both models to be ensure the constrain lagrange in solid formulation model has the same structural response than the merge nodes model. In the successive we use the constrain lagrange in solid model due to its low computational cost.

Figure 4: Column mesh and reinforcement for continuum elements model

For the structural model we develop a concrete shell model with offset beams witch nodes are merged in the cross node shells (figure 5a). The geometry properties of the shell elements are adjustment to have the same mass and inertia than the continuum model, and the longitudinal reinforcement is model in the real position with the aid of offset beam formulation. The transversal reinforcement are not model, but it is possible to include it in the EC2 concrete material model like a fraction of steel reinforcement. It is possible too develop a model with concrete beam elements, but this model, only with beam elements are unable to recibe the blast action. This is the reason to use shell elements for the structural model.

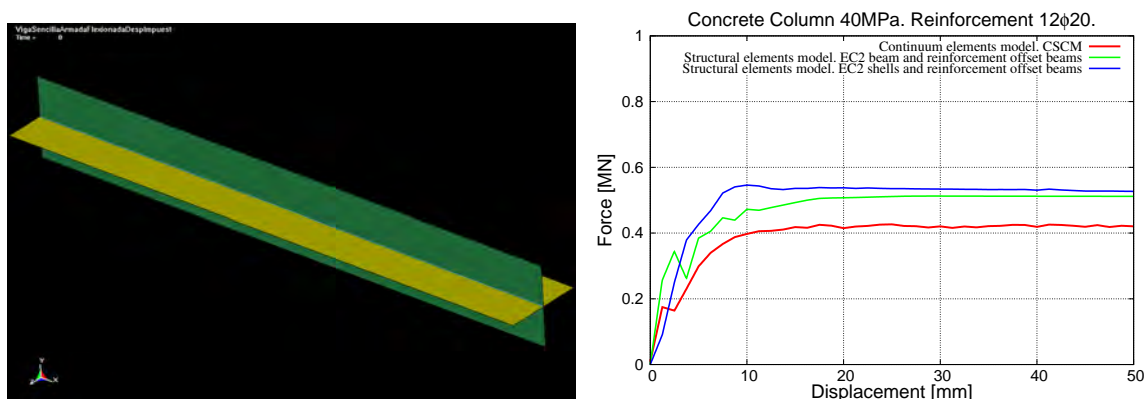

Figure 5: Column mesh for structural elements model and bending comparison column models

Quasi-static bending comparison: The figure 5b shows the response of continuum element model (red line) and structural shell element model (blue line) for a prescribed motion that produce the bending in the column. In this graphic we see that there is a good correlation between models. The structural model is more rigid than the continuum model despite it have not the transversal reinforcement. It is due to in the progressive plastify of continuum elements through the column section in continuum model, whereas the structural model with less elements in section become more rigid until the elements plastify.

Blast action. Dynamic response comparison: We must check the dynamic response to blast action in both models like the quasi-static response. In this case, we compare the response to different quantities of explosive and distances. The structural response is quite different depends on explosive quantity and distance: For incremental quantities of explosive the column have more and more damage, in first place the concrete in the rear of blast impact face plastify, then some elements of this concrete are erosioned, then the rear reinforcement plastify and the concrete plastify is extended to all the column section and finally the column collapse due to full section erosion of concrete and plastify and erosion of rebar.

The figure 6 show the response comparison of continuum and structural models for a quantity of 400 kg of TNT at four meters distance. In this case the rear concrete plastify but it is not erosioned. The center column displacement are measure in time and compare in both models. The displacement of structural model is minor than continuum model due to more transversal flexibility but is a good correlation.

The figure 7 show the response comparison of continuum and structural models for a cuantity of 400 kg of TNT at four meters distance. In this case the concrete plastify but it is not erosioned. The center column displacement are measure in time and compare in both models. The displacement of structural model is minor than continuum model due to the full erosion of the shells elements whereas in the continuum model remains some concrete elements. We take account of this behaviour and assume less displacement but more damage in structural column model.

3.2 Beam

In the same way column is analyzed we analyze a beam, to ensure there is not differences when the reinforcement is asymmetric. In this case we use a simply supported 40 MPa concrete

Figure 6: Column deformed mesh and displacement (x5 scaled) in center of column. Continuum and structural models.

column with five longitudinal reinforcement bars of 16 mm diameter in the rear face and five longitudinal reinforcement bars of 12 mm diameter in the front face.

Figure 8 show the comparison of this case for quasi-static bending. It is similar than the column one. The blast results on similar behaviour, with more damage and less displacement.

3.3 Slab

There are some types of slabs that can be used in frame-type buildings, we study the waffle slab case. This type of slab uses prefabricated hollow sheet metal or plastic domes to create a grid pattern of voids in a solid floor slab. It has several reinforcement bars, with various sections, in different positions, both sides. This case is complex due to complex reinforcement layout and the concrete geometry.

The case we study uses 30 MPa concrete and B500S steel reinforcement in a 8×8 meters waffle slab with 80×80 centimeters hollow sheet domes and 38 centimeters thickness. It has complex reinforcement layout, superior grid, superior and inferior reinforcement in joists.

We develop two models for waffle slab, like in the column case, the continuum model using CSCM concrete material model in continuum elements and piecewise linear plasticity material model in beams elements using constrain lagrange in solid to get work together, and the structural model using EC2 concrete material model in shell elements and piecewise linear plasticity material model in offset beams elements using merge nodes option to get work together.

The continuum model shown in figure 9 has detailed mesh. All reinforcement bars of real waffle slab are model with beam elements and the hollows geometry of concrete are model with continuum elements. The continuum model uses constrain lagrange in solid formulation. In this model it is not possible to use the node merge option for model the interface between steel and concrete. The complex geometry of the model and the amount of reinforcement bars and their positions led to very small size and elevated number of continuum concrete elements, producing excessive computational cost.

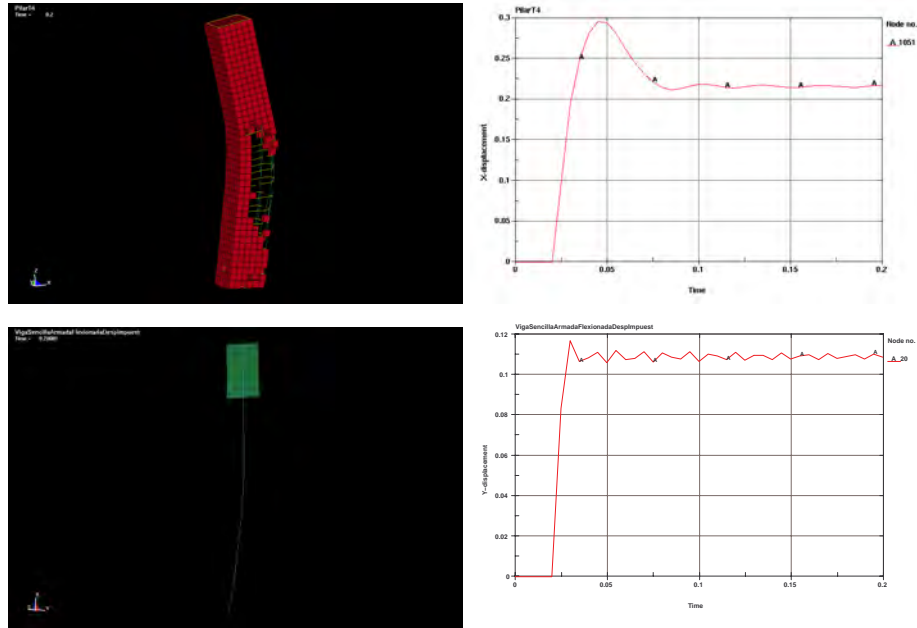

Figure 7: Column deformed mesh and displacement in center of column. Continuum and structural models.

Figure 8: Bending comparison beams models with asymmetric reinforcement

The structural model show in figure 9 has very few elements than continuum model. The concrete is model with shells elements without joists. The thickness of shell elements is calculated to obtain the same mass in continuum and structural models. The reinforcement are model for each dome with a fictional rebar section that represent the total quantities of reinforcement in each direction and differentiate between superior and inferior reinforcement. This fictional rebar are model with offset beams to represent properly the eccentricity of the rebar.

Quasi-static bending comparison: The figure 10 shows the response of continuum element model (red line) and structural shell element model (blue line) for a prescribed motion in the slab center that produce bending. In this graphic we see that there is a rough correlation between models. Both models have peaks in the graphic line of resultant force due to the successive plastify of slab parts. It is difficult obtain the same results in structural model and continuum model. But this rough approximation can provide a range to study the slab behaviour with one

Figure 9: Top left: Mesh of continuum elements waffle slab (top view); Top right: Reinforcement of continuum elements waffle slab; Bottom left: Mesh of continuum elements waffle slab (bottom view). Mesh of structural elements waffle slab (top view)

structural model.

Figure 10: Bending comparison waffle slabs models

Blast action. Dynamic response comparison: We must check the dynamic response to blast action in both models like the quasi-static response. We compare the response to different quantities of explosive and distances. We compare the damage and erosion that is produced in both models.

The figure 11 show the comparison of continuum and structural models for a quantity of 200 kg of TNT at 2 meters distance from the center of the slab in the inferior side. There is

Figure 11: Comparison: deformed mesh in continuum elements model and structural elements model. 200 kg TNT

a good correlation between both models, and we can use the structural model to evaluate the damage produced in a waffle slab from a frame-type building.

4 APPLICATION: FRAME-TYPE BUILDINGS

The final application of this work is evaluate the response of a frame-type building subject to blast action.

Column and slab models are being developed, and it can be use together in the develop of a frame-type complete building. The figure 12 show the model developed for a 3 floors building, with 4×4 waffle slabs in each floor. This model provide us a tool to evaluate the damage caused in a building by blast. In this case a 400 kg of TNT in the first floor center in one slab at 1 meter from the first floor cause the damage show in the figure.

This case can be resolved with moderate computational cost. For this application model calculation time are in the range of 0.1 to 0.5 seconds, sufficient time to evaluate the action of blast in the structure.

There are limitations on the application of this strategy. One of them is that is not possible to evaluate pressure of the blast in a second floor when a previous floor is damaged and the blast wave pass trough it. The blast energy loss in the process of breaking the previous slab is difficult to be evaluated. To avoid this problem it is necessary to use an ALE mesh [11] to evaluate the propagation of the wave trough an air mesh. Other of this problems is that there are some parts of concrete slabs that become projectiles and impact on the structure. The erosion in the shells elements needed to simulate the damage in the structure make few projectiles than be in reality.

This model can be used too to evaluate the possible progressive collapse of the structure, with the inconvenient of more model calculation time, in the range of 3 to 10 seconds for a tree floors building. This causes the CPU calculation time increases, but it can be calculated. Progressive collapse and multiple floor blast analysis are current in develop in the research project we are involved.

5 CONCLUDING REMARKS

We present a strategy for modeling such scenarios based on structural elements, using available material models for structural elements and techniques to include the reinforcement in a realistic way. These models are calibrated against fully three-dimensional models and shown to be accurate enough. At the same time they provide the basis for realistic simulation of impact

Figure 12: Blast into a frame-type building. 400 kg TNT

and explosion on full-scale buildings.

- Structural elements are needed for full frame-type building analysis due to computational cost.
- Structural elements models must be calibrated against fully three-dimensional models to obtain accurate enough.
- The strategy provide an approximate problem solution, for detailed analysis of structure parts three-dimensional model must be used.
- This strategy has limitations like action evaluation in successive floors and projectile considerations that need further develop. Structure collapse require additional adjustment of models.
- This strategy can be used to evaluate damage in building for blast loading and to test design improves on future buildings.

The studies which are presented herein have been carried out as part of a research project involving the Polytechnic University of Madrid and FHECOR Consulting Engineers, with the financial support of the Spanish Airport Authority (AENA) with the aim of modeling explosion hazards and improving robustness in the design of new structures. The work presented in this paper is but a small part of the research project whose scheduled time duration is 3 years.

Keywords: Fluid-structure interaction, modal analysis, thrust, finite element method.

Abstract. *This study aims to analyze the propulsive efficiency of a swimming multi-layers fin. For this purpose, we develop a finite element model accounting for the fluid-structure interaction and the structural anisotropy of each layer. Two types of fins have been tested by comparing their eigenfrequencies. A dynamical situation has been simulated by imposing a translation (heaving) and a rotation (pitching) motions at the end of the fin, using in some sense a relative frame attached to the ankle joint. Thrust, lift and pitching moment are evaluated and compared for the two types of fins.*

1 INTRODUCTION

The aquatic locomotion of animal constitutes a fascinating research domain in biomechanics. The search for performance of aquatic propulsion generated by a foil undergoing harmonic flapping, including translation (heaving) and rotation (pitching) motions, has stimulated numerous works during these last years e.g. [4], [10], [13], [17]. In the case of swimming with fins, the propulsive efficiency depends on several factors. Most previous models evaluate the dynamic performances, including drag and lift which are the two parameters usually considered as relevant to quantify the propulsive efficiency of a fin e.g. [12]. Some models are essentially of discrete type [11], [8], while others, inspired from propulsion of marine cetaceans, use continuous models [1], [18]. Most of these authors do not always demonstrate the highly coupled nature of the problem. In fact, for range of stresses observed in actual swimming, the coupling between the fluid and the fin cannot be neglected. Another aspect is the accounting of the ankle muscle for the propulsion. The frequency determination is deemed necessary since the muscle activity during fin swimming has important correlation with the oscillating flapping frequency e.g. [9]. The activation of muscles increases up to 25 % when the swimming frequency increases from $0.8 [Hz]$ to $1 [Hz]$. In order to improve the adequation of fin with muscle activities, previous studies highlight the role of structural composites and their arrangement for optimizing the propulsion of fin. The static deformation together with the eigenfrequencies of the fin are considered as basic parameters for optimization e.g. [7]. Unfortunately most of them do not account for the water interaction with the fin.

This work is mainly numerical and develops a continuous model in the framework of the fluid-structure interaction approach and constitutes a continuation of a previous study in [2]. The goal is to undertake a parametric analysis of two different designs of multi-layers fin by comparing their eigenfrequencies by accounting for the water interaction. We simulate the evolution of thrust and lift forces, together with the moment (torque about the pitch axis) during a steady propulsion. This approach enables a parametric study, where we can vary some data related to the geometrical, physical and kinematic model. The study consists of three parts. The first part sets out the different assumptions underlying, the development of the theoretical basic model. In the second part, we focus on the modal analysis. To this end, we analyze the changes of eigenfrequencies when varying the physical characteristics of the fin. We are interested on the influence of the layers arrangement and on the influence of the interacting water on the fin eigenmodes. The third part deals with the dynamics. For this purpose, we consider a frame attached to the fin, or more precisely at the foot of the swimmer, and impose a translational (heaving) and rotational (pitching) motions. Two types of multi-layers fins are also studied.

2 Theoretical model of the multi-layers fin

We assume an amateur swimmer, where the range of velocity U_0 is assumed to be small compared to the compression wave celerity c_L within the material of the fin. The ratio $\varepsilon = U_0/c_L \ll 1$, called displacement parameter, allows to characterize the nature of the coupling considered in this work. It has been shown in [3] that the adapted model is the inertial coupling.

The model is bidimensional (since we are mainly interested in the first bending modes in this preliminary analysis) and the (thin) fin is immersed in a large swimming pool. The fin is modeled by a multilayer linear elastic transverse anisotropic material. The fluid domain is denoted Ω_f , while each layer constituting the fin is denoted by Ω_i and has the density ρ_i .

Figure 1: Geometry of 3D fin (dimensions are given below) and scheme of the computational domain (Dimensions of the swimming pool : length 5 [m], depth 2 [m]).

2.1 Basic equations

We denote \mathbf{u}_i the displacement field in the fin and p the pressure field in the water, which is considered as non viscous compressible fluid. The quantities c_0 and ρ_0 denote the sound velocity and density of the water respectively. We accordingly remain in the framework of vibro-acoustic problems. The longitudinal axis of the fin is denoted \mathbf{x} . Use of the ALE method is not necessary in this study because the material is assumed linear and the deformation is assumed small. In the frame attached to the fin, the problem is to find (\mathbf{u}_i, p) solutions

$$\left\{ \begin{array}{ll} \rho_i \frac{\partial^2 \mathbf{u}_i}{\partial t^2} &= \nabla \cdot \sigma(\mathbf{u}_i) + \rho_i \mathbf{F} \quad (\Omega_i) \\ \frac{1}{\rho_0 c_0^2} \frac{\partial^2 p}{\partial t^2} &= \nabla \cdot \left[\frac{1}{\rho_0} (\nabla p - \rho_0 \mathbf{F}) \right] \quad (\Omega_f) \\ \mathbf{u} &= \mathbf{0} \quad (\Gamma_0) \\ \sigma(\mathbf{u}) \mathbf{n} &= -p \mathbf{n} \quad (\Gamma) \\ [\nabla p - \mathbf{q}] \cdot \mathbf{n} &= -\rho_0 \frac{\partial^2 \mathbf{u}}{\partial t^2} \cdot \mathbf{n} \quad (\Gamma) \\ [\nabla p - \mathbf{q}] \cdot \mathbf{n} &= 0 \quad (\Gamma_1) \\ p &= 0 \quad (\Gamma_L) \\ \sigma(\mathbf{u}_i) &= \mathbb{K}(\theta_i) \varepsilon(\mathbf{u}_i) \quad (\Omega_i) \end{array} \right. \quad (1)$$

where \mathbf{F} is the relative and Coriolis force induced by the heaving and pitching motions (relative frame concept) of the fin. The angle θ_i denotes the orientation of fibers relative to the longitudinal axis \mathbf{x} on the fin. In our case, each layer is made of matrix and carbon fibers. The orientation of fibers is usually 0° or 90° relative to the axis of the fin. The physical properties of each layer defined by the tangent stiffness $\mathbb{K}(\theta_i)$ are well defined for anisotropic component e.g. [14]. However, some characteristic values are not displayed for industrial confidentiality reason. In this study, each layer has the same properties, only the fiber orientation is different for each layer as indicated below.

2.2 Modal analysis of coupled problem

For the modal analysis, we search for the eigenfrequencies and modal shapes of the fin in vacuum and in water. Indeed, to test the quality of a fin, it is usual to determine its quasi-static deformed shape and dynamic response in air (approximately as in vacuum). The objective here is to test if the presence of the surrounding fluid can or cannot be quantitatively neglected. The frequencies provide key information for the dynamic behavior of the fin e.g. [8]. The modal problem associated with the system (1) is to find the displacement, the pressure and the

eigenfrequencies $(\mathbf{u}_i, p, \omega)$ solutions

$$\left\{ \begin{array}{lll} -\rho_i \omega^2 \mathbf{u}_i & = & \nabla \cdot \sigma(\mathbf{u}_i) \quad (\Omega_i) \\ -\frac{p}{\rho_0 c_0^2} \omega^2 & = & \nabla \cdot \left[\frac{1}{\rho_0} \nabla p \right] \quad (\Omega_f) \\ \mathbf{u} & = & \mathbf{0} \quad (\Gamma_0) \\ \sigma(\mathbf{u}) \mathbf{n} & = & -p \mathbf{n} \quad (\Gamma) \\ \nabla p \cdot \mathbf{n} & = & \rho_0 \omega^2 \mathbf{u} \cdot \mathbf{n} \quad (\Gamma) \\ \nabla p \cdot \mathbf{n} & = & 0 \quad (\Gamma_1) \\ p & = & 0 \quad (\Gamma_L) \\ \sigma(\mathbf{u}_i) & = & \mathbb{K}(\theta_i) \varepsilon(\mathbf{u}_i) \quad (\Omega_i) \end{array} \right. \quad (2)$$

By introducing the spaces of test functions $\mathbf{V} = \{\mathbf{v} \in \mathbf{H}^1(\Omega_1), \mathbf{v} = \mathbf{0} \text{ } (\Gamma_0)\}$ for displacement and $Q = H^1(\Omega)$ for pressure, the variational formulation of boundary value problem (2) holds

$$\left\{ \begin{array}{l} \frac{d^2}{dt^2} \int_{\Omega_s} \rho \mathbf{u} \cdot \mathbf{v} dx + \int_{\Omega_s} \sigma(\mathbf{u}) : \varepsilon(\mathbf{v}) dx + \int_{\Gamma_1} p \mathbf{v} \cdot \mathbf{n} d\Gamma = 0 \\ \frac{d^2}{dt^2} \left(\int_{\Omega_f} \frac{p \phi}{\rho_0 c_0^2} dx + \int_{\Gamma_1} \mathbf{u} \cdot \mathbf{n} \phi d\Gamma \right) + \int_{\Omega_f} \frac{1}{\rho_0} \nabla p \cdot \nabla \phi dx = 0 \end{array} \right. \quad \forall (\mathbf{v}, \phi) \in \mathbf{V} \times Q \quad (3)$$

with $\int_{\Omega_s} \rho \mathbf{u} \cdot \mathbf{v} dx = \sum_{i=1}^{N_L} \int_{\Omega_i} \rho_i \mathbf{u}_i \cdot \mathbf{v}_i dx$ and $\int_{\Omega_s} \sigma(\mathbf{u}) : \varepsilon(\mathbf{v}) dx = \sum_{i=1}^{N_L} \int_{\Omega_i} \sigma(\mathbf{u}_i) : \varepsilon(\mathbf{v}_i) dx$, where N_L is a number of layers. Using Lagrange finite elements, where $\mathbf{u}_h \in \mathbb{P}_2 \times \mathbb{P}_2$ and $p_h \in \mathbb{P}_1$, discretization of the variational problem (3) leads to the system

$$\left\{ \begin{bmatrix} \mathbb{K}_1 & \mathbb{B}_1 \\ \mathbb{O} & \mathbb{K}_p \end{bmatrix} - \omega^2 \begin{bmatrix} \mathbb{M}_1 & \mathbb{O} \\ \mathbb{M}_{1a} & \mathbb{M}_p \end{bmatrix} \right\} \mathbf{X} = \mathbf{0} \quad (4)$$

This non symetric system is solved using the commercial software Comsol Multiphysics. Two types of calculations were carried out. The first is when the fin is plunged into a vacuum and the second interacting with water. We give below the results for a model up to five layers ($N_L = 5$) and the eigenfrequencies in vacuum (V) and in the water (W).

3 Numerical results

Two designs of multi-layers fins are compared in this section. Both of them are analyzed first in a vacuum and second in the swimming pool, and then interacting with water. Each layer is a biphasic composite and the matrix (m) and fiber (f) have the following properties respectively: Volume fraction $V_m = 0.4$ and $V_f = 0.6$, Young's modulus : $E_m = 3.45E9[Pa]$, and $38E9[Pa]$; Density $\rho_m = 1200[kg/m^3]$, and $\rho_f = 1950[kg/m^3]$; Poisson's ratio : $\nu_m = 0.3$, and $\nu_f = 0.22$.

3.1 Fin with Oriented fibers : $0^\circ/90^\circ/0^\circ/90^\circ/0^\circ$

The fibers of each layer are arranged alternately along the two directions orthogonal axis \mathbf{x} and \mathbf{y} of the mean plane of the fin.

For this first fin, the first layer is oriented along \mathbf{x} . The length of each layer is not the same. Lengths of layers are respectively $\ell := \ell_1 = 0.8[m]$, $\ell_2 = 0.6[m]$, $\ell_3 = 0.5[m]$, $\ell_4 = 0.4[m]$, and $\ell_5 = 0.3[m]$. Layer's length corresponds to the ply drop in [7]. The total thickness of the fin is maintained constant $e = 5.8[mm]$, and it is not depending on the number of layers. The fin is clamped at the end $x = 0$ and free of stress at end $x = \ell$.

1. Eigenfrequencies of fin in the vacuum

The three-layers fin presents the highest eigenfrequencies in either a vacuum or in the water (see table 1), at least for the first frequencies.

	f_1	f_2	f_3	f_4	f_5	f_6	f_7	f_8
2L(V)	12.62	76.02	205.33	389.27	628.95	929.39	1293.32	1717.79
3L(V)	29.38	122.99	265.07	555.85	825.17	1326.14	1764.36	2321.13
4L(V)	22.68	90.16	192.04	404.72	600.38	958.85	1303.21	1692.38
5L(V)	28.82	79.74	185.16	373.97	560.99	904.69	1185.87	1632.83

Table 1: Eigenfrequencies f_n [Hz] of the multi-layers fin in vacuum. Row 2L up to 5L indicates the number of layers of the fin.

2. Eigenfrequencies of fin interacting with water

	f_1	f_2	f_3	f_4	f_5	f_6	f_7	f_8
2L(W)	1.71	46.06	103.15	180.88	186.73	232.08	297.77	342.08
3L(W)	3.52	21.72	55.17	136.63	181.29	222.63	232.10	341.95
4L(W)	2.42	14.56	37.35	92.22	150.82	181.27	232.08	263.14
5L(W)	2.77	11.85	33.49	78.53	128.93	181.22	227.74	232.11

Table 2: Eigenfrequencies f_n [Hz] of the multi-layers fin interacting with water. Row 2L up to 5L indicates the number of layers of the fin.

The fundamental eigenfrequency f_1 (and the others) depends on the arrangement of the layers. The two-layers fin has mostly the lowest fundamental frequency either in the vacuum or in the water (see table 2). There is systematically a peak of frequencies for the three-layers fin, not depending on the environment (vacuum or water). This means that this arrangement induces the stiffest fin, at least for a dynamics point of view. The fundamental eigenfrequency of the coupled fin-water is far lower than of the fin in vacuum. This observation does not depend on the number of layers. To give an idea of the eigenmodes, we display on figure 2 the first six modal shapes of the fin interacting with the water for a five-layers case (5L(W)).

Figure 2: The first six mode shapes of the five-layers fin (5L(W)).

These are mainly bending modes for this 2D model. Due to the clamping at $x = 0$, and due to the progressive ply drop, the largest deformation is mainly located at the free end of the fin. For the terminology, if the first and second modes are involved for the propulsion, the fin swimming could be considered as undulatory type (anguilliform), whereas if the higher mode ranks are involved (oscillation of posterior part of the fin) then the fin swimming could be considered as carangiform e.g. [17].

3.2 Fin with Oriented fibers : $90^\circ/0^\circ/90^\circ/0^\circ/90^\circ$

As for previous fin, fibers of each layer are arranged alternately along the two directions orthogonal axis \mathbf{x} and \mathbf{y} of the mean plane of the fin. However for this second fin, the first layer is oriented along \mathbf{y} . The length of each layer is not the same. Lengths of layers are respectively $\ell := \ell_1 = 0.8[m]$, $\ell_2 = 0.6[m]$, $\ell_3 = 0.5[m]$, $\ell_4 = 0.4[m]$, and $\ell_5 = 0.3[m]$. The total thickness of the fin is also maintained constant $e = 5.8[mm]$, and it is not depending on the number of layers. The fin is also clamped at the end $x = 0$ and free of stress at $x = \ell$.

1. Eigenfrecncies of fin in a vacuum

	f_1	f_2	f_3	f_4	f_5	f_6	f_7	f_8
2L(V)	12.61	73.51	158.46	273.94	488.33	757.90	997.37	1284.11
3L(V)	9.52	51.39	105.50	186.01	327.05	507.18	670.71	861.59
4L(V)	21.21	56.23	115.59	237.62	395.78	560.89	773.54	1093.47

Table 3: Eigenfrequencies f_n [Hz] of the multi-layers fin in the vacuum. Row 2L up to 5L indicates the number of layers of the fin.

2. Eigenfrequencies of fin interacting with water

	f_1	f_2	f_3	f_4	f_5	f_6	f_7	f_8
2L(W)	1.71	13.30	39.45	72.24	136.51	181.24	232.04	235.54
3L(W)	1.14	8.74	23.87	45.06	86.89	147.57	181.24	215.08
4L(W)	2.28	9.53	23.83	50.30	97.46	156.71	181.22	219.41
5L(W)	1.68	6.89	17.23	36.93	70.87	113.85	161.15	181.31

Table 4: Eigenfrequencies f_n [Hz] of the multi-layers fin interacting with water. Row 2L up to 5L indicates the number of layers of the fin.

Contrarily to the first type, the three-layers fin presents the lowest eigenfrequencies, and it is depending neither on the environnement vacuum or water, nor on the mode rank. Highest eigenfrequencies mostly correspond to the two-layers fin. Again, the influence of the fin-water interaction is pointed out, the presence of water, which is more realistic, in the model drastically decreases the eigenfrequencies of the fin.

Comparing the two types of multi-layers fins, we may observe that : the eigenfrequencies value depends strongly on the arrangement of layers, and such is the case either in a vacuum or in water. Fibers of the first layer along \mathbf{x} seems to give highest fundamental eigenfrequency when there are several layers in the fin. The frequencies of the coupled model are always lower. It is quite understandable due to the effect of added mass from water interaction. Anticipating a study in progress in our team, it should also be observed that accounting the 3D effects decreased the fundamental frequency, which also corresponds to a bending modes, for instance the four-layers fin gives in vacuum $f_1 \simeq 7.74$ [Hz], and in water $f_1 \simeq 1.13$ [Hz] as fundamental eigenfrequency.

4 The dynamic problem

The dynamic problem was conducted using data in [15]. For this purpose, the fin is immersed in water, and is subjected to a combined heaving and pitching motions, mimicking the ankle joint motion. This motion is imposed at the end $x = 0$, the other end $x = \ell$ remains free. In this case, the force \mathbf{F} induced by the relative frame motion introduced in the equation (1) has the expression :

$$\mathbf{F}(t) = - \begin{bmatrix} \ddot{h}(t) \sin[\omega(t)] - y\ddot{\omega}(t) - x\dot{\omega}^2(t) \\ \ddot{h}(t) \cos[\omega(t)] + x\ddot{\omega}(t) - y\dot{\omega}^2(t) \end{bmatrix} \quad (5)$$

in which we have defined the imposed translation and rotation e.g. [15] :

$$\begin{cases} \omega(t) = \theta_0 \sin(2\pi ft) ; h(t) = h_0 \sin(2\pi ft - \psi) \\ \theta_0 = 40^\circ ; \psi = \frac{\pi}{2} ; h_0 = 1c ; f = 0.225Hz \end{cases} \quad (6)$$

where $c = 0.7$ is the chord of the profile, that is to say, the length of the fin. The phase ψ is introduced to model the muscle dissymmetry. To avoid a resonance phenomenon, the excitation frequency is imposed small enough compared to the first natural frequency of the coupled system. The most relevant hydrodynamic parameters are the total force \mathbf{R} and moment \mathbf{M} exerted on the fin during the movement. Notice that these forces and moment are solely due to the water reaction. These quantities are defined by

$$\mathbf{R} = \int_{\Gamma} \sigma(\mathbf{u}) \mathbf{n} d\Gamma ; \mathbf{M} = \int_{\Gamma} \mathbf{OM} \wedge \sigma(\mathbf{u}) \mathbf{n} d\Gamma \quad (7)$$

The two components of D and L onto the axes \mathbf{x} and \mathbf{y} , are respectively the drag and lift of the fin. The quantity $T(t) = -X(t)$ is called thrust. Different types of layers exist in the manufacture of fins, where the thickness is mostly fixed in advance. We test the same fins as in the modal analysis. Using the same notation as before, the variational formulation of boundary value problem (1) is then written

$$\begin{cases} \frac{d^2}{dt^2} \int_{\Omega_s} \rho \mathbf{u} \cdot \mathbf{v} dx + \int_{\Omega_s} \sigma(\mathbf{u}) : \varepsilon(\mathbf{v}) dx + \int_{\Gamma_1} p \mathbf{v} \cdot \mathbf{n} d\Gamma = - \int_{\Omega_s} \rho \mathbf{F} \cdot \mathbf{v} dx \\ \frac{d^2}{dt^2} \left(\int_{\Omega_f} \frac{p\phi}{\rho_0 c_0^2} dx + \int_{\Gamma_1} \mathbf{u} \cdot \mathbf{n} \phi d\Gamma \right) + \int_{\Omega_f} \frac{1}{\rho_0} \nabla p \cdot \nabla \phi dx = \int_{\Omega_f} \frac{1}{\rho_0} \mathbf{q} \cdot \nabla \phi dx \end{cases} \quad (8)$$

for all $(\mathbf{v}, \phi) \in \mathbf{V} \times Q$, with $\mathbf{V} = \{\mathbf{v} \in \mathbf{H}^1(\Omega_1), \mathbf{v} = \mathbf{0}(\Gamma_0)\}$ and $Q = H^1(\Omega)$.

Using Lagrange finite elements, where $\mathbf{u}_h \in \mathbb{P}_2 \times \mathbb{P}_2$ et $p_h \in \mathbb{P}_1$, discretization of the variational problem (8) leads to the semi-discretized system

$$\begin{bmatrix} \mathbb{M}_1 & \mathbb{O} \\ \mathbb{M}_{1a} & \mathbb{M}_p \end{bmatrix} \frac{d^2 \mathbf{X}}{dt^2} + \begin{bmatrix} \mathbb{K}_1 & \mathbb{B}_1 \\ \mathbb{O} & \mathbb{K}_p \end{bmatrix} \mathbf{X} = \mathbf{F} \quad (9)$$

with $\mathbf{X} = [\mathbf{U}, \mathbf{P}]^T$ and $\mathbf{F} = [\mathbf{F}_1, \mathbf{F}_2]^T$. In this section, we use a particular kinematics proposed in [15]-[16], even if our models are not exactly similar. Indeed, the kinematics will allow us in future to develop a new experimental protocol for measuring various hydrodynamic parameters of a fin.

4.1 Dynamic response to the fin

To better define a reasonable performance of the fin, we take the total expression of the excitation force $\mathbf{F}(t)$ resulting from (6). We then obtain the different response curves where the end $x = 0$ is constrained to a combined translational and rotation motions.

4.1.1 Oriented fibers : $0^\circ/90^\circ/0^\circ/90^\circ/0^\circ$

As a recall, fibers of each layer are arranged alternately along the two directions orthogonal axis \mathbf{x} and \mathbf{y} of the mean plane of the fin. For this first fin, the first layer is oriented along \mathbf{x} . The length of each layer is not the same. Lengths of layers are respectively $\ell := \ell_1 = 0.8[m]$, $\ell_2 = 0.6[m]$, $\ell_3 = 0.5[m]$, $\ell_4 = 0.4[m]$, and $\ell_5 = 0.3[m]$. The total thickness of the fin is maintained constant $e = 5.8[mm]$, and it is not depending on the number of layers.

Figure 3: Thrust force $[N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

The magnitude of thrust force induced by the two-layers fin is greater than the other fins, although its value is mostly negative. Remind that the eigenfrequency of this fin is the lowest. This nevertheless seems abnormal and requires further close analysis. The behaviours of the other three fins are quite similar.

Figure 4: Lift force $[N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

We remark that the lift force for the two-layers and the five-layers fins behaves similarly (they are mostly positive), whereas the three and four-layers are quite comparable (they are mostly negative). Magnitude of lift force is greater for the two-layers and the five-layers fins. By the way, they are mostly positive.

The moment magnitude is lowest for the two-layers models, compared to the other fins. Again the two- and five-layers fins have similar behaviour (positive moment), although with

Figure 5: Moment $[m N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

different magnitude; whereas the three- and four-layers fins have negative moment.

4.1.2 Oriented fibers : $90^\circ/0^\circ/90^\circ/0^\circ/90^\circ$

Recall also that fibers of each layer are arranged alternately along the two directions orthogonal axis \mathbf{x} and \mathbf{y} of the mean plane of the fin. However for this second fin, the first layer is oriented along \mathbf{y} . The length of each layer is not the same. Lengths of layers are respectively $\ell := \ell_1 = 0.8[m]$, $\ell_2 = 0.6[m]$, $\ell_3 = 0.5[m]$, $\ell_4 = 0.4[m]$, and $\ell_5 = 0.3[m]$. The total thickness of the fin is maintained constant $e = 5.8[mm]$, and it is not depending on the number of layers.

Figure 6: Thrust force $[N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

Again, the magnitude of thrust force induced by the two-layers fin is greater than the other fins, although its value is mostly now positive. Remind also that the eigenfrequency of this fin is the lowest. The behaviours of the other three fins are quite similar, with a positive thrust force for all of them (Figure 6).

The four-layers fin present the lowest magnitude for the lift force (mostly negative values), whereas the three-layers fin has the greatest amplitude. The other three models have positive lift force (Figure 7).

The five-layers fin induces very low moment magnitude compared to the other fins. Again

Figure 7: Lift force $[N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

Figure 8: Moment $[m N]$ during the course of time $[s]$ for the $2L$, $3L$, $4L$, and $5L$ models.

the four-layers fin has mostly negative moment (Figure 8). Such is not the case for the other models.

Again comparing the two types of multi-layers fins, we may draw some remarks. The two-layers model always gives a greater thrust than the other models. It should be however pointed out that the fibers arrangement may induce negative or positive thrust for this fin. If we eliminate this case, we may see that the five-layers fin gives the best performance.

In a general manner, the three-layers fin seems to give a better compromise. Indeed, its thrust remains positive all the time, while its lift has negative value and nevertheless less of lower importance than other fins. The moment magnitude associated to the three-layers model is also the lowest. In sum, it is then shown that by varying some physical parameters, we can significantly reduce or increase hydrodynamic quantities, such as the thrust, the moment, and the lift.

4.1.3 Water pressure for fin with Oriented fibers : $0^\circ/90^\circ/0^\circ/90^\circ/0^\circ$

To see how the overall response of the coupled system evolves, we display in the figures below (Figure 9) and at different times $t = 2, 4, 6, 8 [s]$ the pressure field within water, and the iso-acceleration lines. We also display the deformed shapes of the fin (first layer parallel

to \mathbf{x}) at the associated times. The present model uses an acoustic model of the water, and

Figure 9: Pressure contour plot $p(\mathbf{x}, t)$, iso-acceleration lines, and associated deformed shapes of the five-layers fin, at different times $t = 2, 4, 6, 8$ [s]. Remind that the fundamental frequency of this fin is $f_1 = 2.77$ [Hz], and the excitation frequency $f_{exc} = 0.225$ [Hz]. The fin is displayed in the middle region of the pool.

neglects the viscosity, although the thrust production is thought to be strongly correlated with the formation and shedding of leading edge vortices. In a viscous situation, the wake formed behind the fin is affected by the interaction of the leading edge vortex with the fin and with the training vortex. This could be captured in our model. In the present study, the evolution of the field pressure $p(\mathbf{x}, t)$ in the course of time shows the influence of the swimming pool dimensions on the result. Accuracy of results may be improved by considering much larger dimensions of the pool.

5 CONCLUDING REMARKS

A parametric analysis of eigenfrequencies of multilayers composite fin has been done by considering the influence of the surrounding water. The fluid flow, and more precisely the evolution of water pressure around a 2D deformable fin, and the deformation of the fin itself in a steady motion due to a harmonic heaving and pitching motions, have been simulated by accounting the mutual interaction of the water and the fin. From the present results, we may draw some concluding remarks.

- The presence of layers provides some flexibility for the fin design as indicated by the results of modal analysis. The first mode is bending type, which justifies the use of models proposed in [11].
- Fins with anisotropic material structures allow to develop a method of layers parametrization to improve performance. It is quite possible now to bring special attention to the structure of the layers, and types of constituent materials thereof.
- The present study points out the sensitivity of the dynamic behavior of the fin with respect to the constituent materials, and also the influence of the boundary conditions for the fluid

domain. Indeed, the presence of rigid walls alters significantly the eigenmodes and frequencies of the coupled system. Accordingly, the dynamic behavior of a swimmer may depend on this location at each time in the pool.

- Finally, to obtain a better thrust, the fin has to be elastic at least in rotation. The amplitude of the vertical translation must be controlled to avoid a too great lift, which may lead to an expenditure of extra energy of the swimmer to remain at a constant depth. The use of multilayer fins allows to control the non desirable excessive variation of lift.

Extension of the present study to 3D fins together with viscous fluid is ongoing.

Keywords: Plasticity, Damage, Cyclic Loading, FEM.

Abstract. *Micromechanics is employed in order to define the whole nonlinear inelastic behavior of a structure at meso/macro scale level where the presence of the inelastic phenomena (plasticity and/or damage) affects the material constitutive response depending on the loading conditions. This concept is important in the design of civil and mechanical engineering applications. This study illustrates a comprehensive theoretical formulation for a coupled damage-plasticity model and its numerical implementation under an extreme loading type such as an earthquake, which causes cyclic response and can lead to failure. Irreversible plastic deformation by plasticity, elastic response modification by the damage and the cyclic accumulation of deformation are modeled. A couple of numerical examples are presented in order to show the capability and efficiency of the proposed model for 2D membrane element, by using the operator split methodology.*

1 INTRODUCTION

Materials, which are used in the different domains of civil and mechanical engineering, can most probably be heterogeneous at a micro-scale. It may be difficult to predict the response of the whole structure to different kinds of loading due to the material characteristics.

Simo et al. [1] employed the stress-based formulation, which is the core of the numerical part of this current study for the elasto-plastic material behavior by using the classical finite element method [2]. Here, this type of formulation is constructed in order to couple both plasticity and damage [3]. The dependent Gauss point equations, which represent the evolution equations of the internal variables for both inelastic behaviors just mentioned, are solved simultaneously, so as to provide a single return mapping algorithm per element to control the equilibrium equations at macro scale. We use the operator split method to simplify the details of the numerical implementation, concerning the calculation of internal variables and equilibrium equations resulting with finite element approach at the structural state.

Study realized by Drucker and Palgen [4] stated that the material behavior under cyclic loading are much more complex than monotonic loading and cannot be modeled by isotropy alone. Therefore, the purpose of the present research is to present a plasticity model, in which both isotropic and kinematic hardening is taken into account. This will also be coupled with the damage model, which is defined in an analogous way as the plasticity model.

There are some important notifications based on researches [5, 6] for cyclic inelastic models; (i) symmetric stress and strain cycles occur with a well defined kinematic hardening, (ii) unsymmetrical stress cycles cause the ratcheting effect and (iii) unsymmetrical strain cycles cause the progressive relaxation.

This paper is organized as follows. In section 2, we describe basic concepts of inelastic behavior of the model. In section 3, the computational algorithm is presented. Section 4 is devoted to numerical examples for illustrating the proposed model. Finally, a brief conclusion is presented in section 5.

2 MODEL FORMULATION

2.1 Basic concepts of internal variables

State variables defining the inelastic behavior of the material, which are composed of the plastic strain ($\boldsymbol{\varepsilon}^p$), damage compliance (\mathbf{D}), the internal variables ($\xi^p, \boldsymbol{\kappa}^p$), which control isotropic and kinematic hardening of the plasticity, and the internal variable (ξ^d) of damage, are obtained by using the standard thermodynamic consideration

$$0 \leq \dot{\mathcal{D}} = \boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} - \dot{\psi} \quad (1)$$

and the principle of maximum plastic and damage dissipations, which are decomposed from total inelastic dissipation \mathcal{D} , with these three fundamental equations firstly defining;

- the decomposition of the total strain

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^p + \boldsymbol{\varepsilon}^d \quad (2)$$

- the total strain energy

$$\psi(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}^d, \mathbf{D}, \xi^d, \boldsymbol{\varepsilon}^p, \xi^p, \boldsymbol{\kappa}^p) = \psi^e(\boldsymbol{\varepsilon}^e) + \psi^d(\boldsymbol{\varepsilon}^e, \mathbf{D}) + \Xi^p(\xi^p) + \Xi^d(\xi^d) + \Lambda^p(\boldsymbol{\kappa}^p) \quad (3)$$

- the yield criteria of plasticity and damage

$$\begin{aligned}\phi^p(\boldsymbol{\sigma}, q^p, \boldsymbol{\alpha}) &= \|\mathbf{Dev}\boldsymbol{\sigma} + \boldsymbol{\alpha}\| - \sqrt{\frac{2}{3}}(\sigma_y - q^p) \leq 0 \\ \phi^d(\boldsymbol{\sigma}, q^d) &= \frac{1}{3}\mathbf{Tr}(\boldsymbol{\sigma}) - (\sigma_f - q^d) \leq 0\end{aligned}\quad (4)$$

where q^p, q^d are the stress-like variables describing the hardening phenomena, $\boldsymbol{\alpha}$ is the deviatoric back stress representing the kinematic hardening behavior and σ_y, σ_f are the yield and fracture stresses, respectively.

The principle of maximum inelastic (plastic and damage) dissipation states that among all the admissible values of dual variables $(\boldsymbol{\sigma}, q^p, \boldsymbol{\alpha}, q^d)$, those, which maximize the plastic and damage dissipation, must be selected. This maximization problem is presented as a minimization problem by introducing Lagrange multiplier. We obtain the evolution equations of internal variables for plasticity and damage phenomenon separately by using the Kuhn-Tucker optimality conditions. Once the suitable values of internal variables are obtained, we can go through the finite element calculation.

2.2 Variational formulation

We use the mixed variational formulation of the Hellinger-Reissner type in order to couple both plastic and damage behaviors for fixed given values of internal variables.

$$\Pi(\boldsymbol{\sigma}, \mathbf{u}) = \int_V (\psi^e(\boldsymbol{\varepsilon}^e) + \psi^d(\boldsymbol{\varepsilon}^d, \mathbf{D})) dV - \int_{\partial V} \bar{\mathbf{t}} \cdot \mathbf{u} dS \quad (5)$$

where we can rewrite the same functional by using the complementary energies instead of the strain energies.

$$\Pi(\boldsymbol{\sigma}, \mathbf{u}) = \int_V (\boldsymbol{\sigma} : \boldsymbol{\varepsilon}^e - \chi^e(\boldsymbol{\sigma}) + \boldsymbol{\sigma} : \boldsymbol{\varepsilon}^d - \chi^d(\boldsymbol{\sigma}, \mathbf{D})) dV - \int_{\partial V} \bar{\mathbf{t}} \cdot \mathbf{u} dS \quad (6)$$

The stationary conditions of the functional for each independent displacement and stress fields are taken into account as follows.

$$\begin{aligned}G_u(\mathbf{u}, \boldsymbol{\sigma}, \delta \mathbf{u}) &= \int_{\Omega} \nabla^s \delta \mathbf{u} \boldsymbol{\sigma} dV - \int_{\Gamma_\sigma} \delta \mathbf{u} \bar{\mathbf{t}} dS \\ G_\sigma(\mathbf{u}, \boldsymbol{\sigma}, \delta \boldsymbol{\sigma}) &= \int_{\Omega} \delta \boldsymbol{\sigma} (\nabla^s \mathbf{u} - \boldsymbol{\varepsilon}^p - \frac{\partial \chi^e}{\partial \boldsymbol{\sigma}} - \frac{\partial \chi^d}{\partial \boldsymbol{\sigma}}) dV\end{aligned}\quad (7)$$

The first equation is the weak form the local equilibrium equation based on Euler-Lagrange equation and the second one is the weak form of the additive decomposition field.

The discretized model is constructed from the weak formulations (7) by using the interpolation functions for the stress (\mathbf{S}) and the displacement (\mathbf{N}) fields.

$$\begin{aligned}\mathbf{u} &= \mathbf{N}\mathbf{U} \\ \boldsymbol{\sigma} &= \mathbf{S}\boldsymbol{\beta}\end{aligned}\quad (8)$$

Next, we implement into the equation (7) the internal variables considering with the time integration and then define the residuals, which is commonly used for the finite element method.

3 COMPUTATIONAL ALGORITHM

We define three levels of computations; (i) local level computation at each Gauss quadrature point for plastic and damage internal variables, for which the implicit backward Euler time integration is used, (ii) element level computation, which is characterized by the stress field, (iii) global level computation of the set of equilibrium equations from which we obtain the displacement values. We verify the convergence of the result at a given level in the spirit of operator-split approach before going through the subsequent level. Newton method is used in order to solve the nonlinear equations, for which 3 to 10 iterations are sufficient at each level. This computational model is implemented into FEAP [7] for numerical examples.

4 NUMERICAL EXAMPLES

In this part, three numerical simulations are presented for a quadrilateral element, which is fixed at one side with displacements or forces imposed at the other side. It is shown that different kinds of cyclic response can be obtained due to the loading types. A comparison is made between the plasticity versus coupled plasticity-damage phenomenon for the same material. The characteristic of the material, which is stainless steel 304, is given in Table 1.

Elasticity Modulus E (MPa)	Poisson ratio ν	Yield stress σ_y (MPa)	Saturation stress σ_∞ (MPa)	Fracture stress σ_f (MPa)
$1,93 \cdot 10^5$	0,29	241	579	300

Table 1: Characteristics of the stainless steel 304

4.1 Cyclic response for symmetric imposed displacement

In this example displacement is imposed at the right side of the membrane, which value is between 0.05 and -0.05 in the direction of x-axis for a time interval 0 to 25 seconds, defining as “loading condition 1” in Fig.1.

Figure 1: Comparison of the plasticity and coupled plasticity-damage behavior

The diagram obtained from this type of loading shows the coupled plasticity-damage effect over the plasticity phenomenon. It can be seen that the stress values decrease in the same imposed displacement by taking into account damage and plasticity together. Besides, the slope, which gives an idea about the tangent modulus of the material, is reduced for the coupled phenomenon.

Figure 2: Comparison of the plasticity and coupled plasticity-damage behavior

4.2 Progressive relaxation effect

This response of the material is caused by the strain cycling between any two fixed values. We should define the cyclic loading condition in two parts. At the beginning, it takes the values between $[-0.02, 0.02]$ in the time interval $T [0, 7.5s]$ and then jumps to the value of 0.07. This type of imposed displacement is presented with the name “loading condition 2” in Fig.1. We can see from Fig.3 that stress attained by the element increase with these increasing levels of such imposed displacement.

Figure 3: Strain-stress response showing the progressive relaxation phenomenon

4.3 Ratcheting effect

A cyclic loading program in tension and compression between fixed values of stress as seen in Fig.4 has been performed in order to simulate the ratcheting effect of the constitutive material behavior.

Figure 4: Stress-strain response to cyclic loading resulting in ratcheting of strain

Ratcheting, which is one of the characteristic of the material, is presented here for the asymmetrical stress cycling. The ratcheting deformation accumulates continuously with the applied number of cycles. It can be inferred that the strain limits of the cycles are displaced progressively along the strain axis from one cycle to the next one.

Figure 5: Stress-strain response to cyclic loading resulting in ratcheting of strain.

5 CONCLUSION

In this study, we have presented the phenomenological model of classical plasticity, which is capable of accounting for both isotropic and kinematic hardening effects, and damage

model, which is described in an analogous way to the classical plasticity model. The coupled plasticity-damage model points out the irreversible deformation and change of elastic response. The defined elasto-plastic damage model is adapted to the stress based formulation. The mechanism of damage and elasto-plasticity behavior depends on the stress field. For that purpose, the mixed variational type of Hellinger-Reissner is used to develop the finite element approach.

Numerical computations and results are shown in order to illustrate the effectiveness of the algorithmic procedure. The performed analysis allows to have better understanding on the in-elastic behavior, which depend on the cyclic loading conditions.

Keywords: Drop-test, Shock, Corrugated cardboard, Finite element, Homogenization model, Crushable foam model.

Abstract. *This paper presents experimental and numerical studies of drop tests of corrugated cardboard packaging containing different foam inserts. An efficient homogenization model for the corrugated cardboard has been developed. In our H-model, the corrugated cardboard is represented by a 2D plate. Instead of using a local constitutive law (relating the strains to the stresses) at each material point, the homogenization process leads to a generalized constitutive law (relating the generalized strains to the resultant forces) for the equivalent homogeneous plate. Our H-model was implemented into the finite element software ABAQUS. The foam behaviour was experimentally determined and modeled with a crushable foam model of ABAQUS. The drop tests were performed as a free fall from a given height onto a rigid floor. The acceleration of the packed product was recorded using a triaxial accelerometer. The numerical results obtained using the FE simulation with our H-model agree very well with the experimental results. We have also shown that the contribution of the corrugated cardboard box to the shock response is very important.*

1 INTRODUCTION

During storage and transportation, products can accidentally fall onto the floor causing some damages on the products. The corrugated cardboard packages and the foam inserts are designed to protect the product from the shock it can undergo. As the product design always tends towards light, a high impact performance becomes extremely critical for product design issues [1-2]. Conventionally, a product reliability test to prevent impact-induced damage is carried out by a procedure of “design – prototype – test – redesign” which is highly cost and time consuming. A numerical modelling of the product and its packaging provides an efficient methodology to predict the structural strength during impact [3]. Moreover, the finite element simulation allows to avoid numerous experimental drop tests and to predict possible failures during the design stage. This study deals with the drop impact problem of product-packaging systems using both numerical and experimental methods. Different packaging systems, using corrugated cardboard box and different foam inserts, are studied to analyse the influence of corrugated cardboard and the foam inserts configurations.

Firstly, we present the experimental setups and results. Then, we describe the homogenization model for the corrugated cardboard and its implementation in the finite element code ABAQUS. Finally, the accelerations measured during the shock using the data acquisition system of drop test platform are compared with the results obtained from ABAQUS simulations.

2 EXPERIMENTAL TESTS

2.1 Materials and products

The corrugated cardboard boxes with interior dimensions of $150 \times 150 \times 90 \text{ mm}^3$ are used for the experimental drop tests (figure 1). The product in the box is a thick steel plate of $87 \times 87 \times 30 \text{ mm}^3$, with a total mass of 1.686 kg. The boxes are made with a corrugated C flute cardboard. The insert between the boxes and the product is the Ethafoam 400 extruded polyethylene (PE) foam produced by DOW, with a density of 58 kg/m^3 . In this study, we have used two configurations shown in figure 2: the foam surrounds the product (figure 2.a), or it is only placed in the corners of the product (figure 2.b).

Figure 1: Corrugated cardboard box.

Figure 2: Two types of foam configurations.

2.2 Characterization of corrugated cardboard constituents

The procedure to determine the elastic parameters of the corrugated cardboard constituents is described below. The corrugated cardboard consists of two flat layers and a flute (figure 3). These constituents are separated according to the French norm NFQ03-043 in order to determine the material parameters of each layer. The tensile test samples are cut using the ELCEDE MFT20 cutting table. The tensile tests are performed on the 3 layers in the Machine Direction (MD), Cross Direction (CD) and 45° Direction. We observe that the paperboards have a higher strength in the MD direction (figure 4).

Figure 3: Corrugated cardboard constituents.

The orthotropic constitutive relation between the stresses and strains is defined as follows:

$$\{\sigma\} = \begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_{12} \end{Bmatrix} = [D]\{\varepsilon\} = \begin{bmatrix} \frac{E_1}{1-\nu_{12}\nu_{21}} & \frac{\nu_{12}E_2}{1-\nu_{12}\nu_{21}} & 0 \\ \frac{\nu_{21}E_1}{1-\nu_{12}\nu_{21}} & \frac{E_2}{1-\nu_{12}\nu_{21}} & 0 \\ 0 & 0 & G_{12} \end{bmatrix} \begin{Bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{Bmatrix} \quad (1)$$

where the subscripts 1 and 2 refer to the MD and CD directions respectively.

The Young's moduli are obtained by calculating the slopes of the tensile curves in the elastic zones. The empirical relations established by Baum *et al.* [4] are used to determine the Poisson ratios and the in-plane shear modulus:

$$\begin{cases} \sqrt{\nu_{12}\nu_{21}} \approx 0.293 \\ G_{12} \approx 0.387\sqrt{E_1E_2} \end{cases} \text{ with: } \frac{\nu_{12}}{E_1} = \frac{\nu_{21}}{E_2} \quad (2)$$

The above characterization procedure allows obtaining the elastic properties of the three cardboard layers (Table 1).

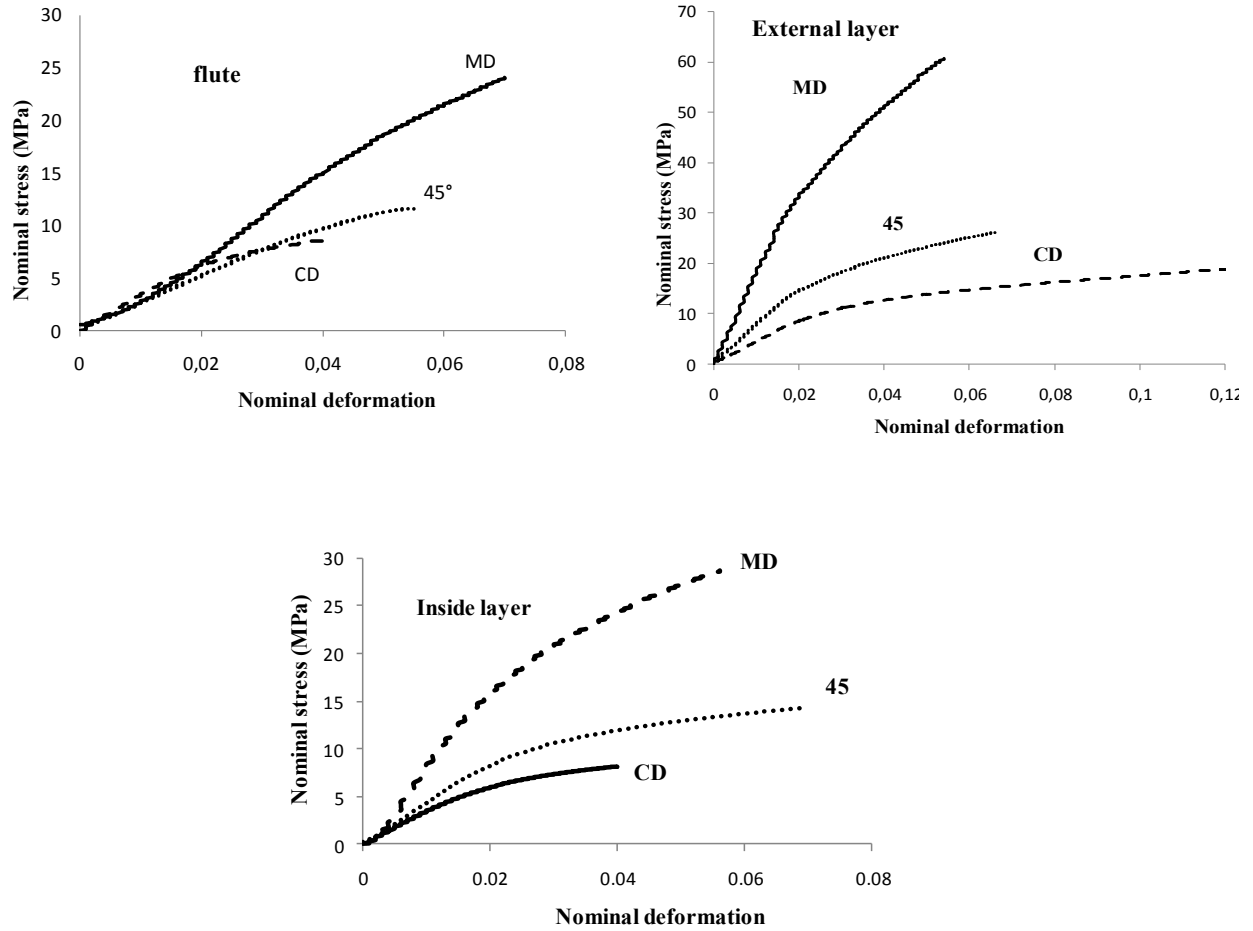

Figure 4: Tensile test on the corrugated cardboard constituents.

Layers	E_1 (MPa)	E_2 (MPa)	ν_{12}	G_{12} (MPa)	Thickness (μm)
Outside layer	1913.7	526.2	0.56	322.0	216.5
Flute	464.3	355.9	0.33	93.0	191.0
Inside layer	1006.8	279.8	0.56	214.0	282.4

Table 1: Material characteristics of the corrugated cardboard constituents.

2.3 Characterization of the foam

Uniaxial and hydrostatic compression tests are performed to characterize the foam. The nominal stresses versus nominal strains are plotted in figure 5. These curves are used to determine the elastic modulus ($E_{foam} = 1.5 \text{ MPa}$) and the hardening curve needed for the crushable foam model of ABAQUS.

Figure 5. Uniaxial and hydrostatic compression curves of Ethafoam 400.

2.4 Drop tests

The drop test is a simple test method and corresponds well to the reality. The impact velocity of the package is a crucial parameter since great forces affect the package during a short time. This velocity depends on the drop height. The package is placed on a fork at a given height. The fork is withdrawn very fast and the package falls to the ground.

The drop test equipment used here is an AccruDrop Tester from L.A.B. Equipment Inc. (figure 6). The drop height is fixed to $H_{drop} = 1.05\text{ m}$. To record the acceleration of the product, a triaxial accelerometer (Andevco Isotron 2258A-10) is glued to its horizontal top face as shown in figure 2. The analysis and the visualisation of the measurements are done with Lansmont Test Partner 3 software.

Figure 6: Drop test equipment.

Two types of tests are carried out to study the influence of the packaging for the product protection. In the first one, the product is protected only by the foam. In the second one, the

product is protected by the foam and the corrugated cardboard box. Figure 7 shows typical curves of acceleration versus time corresponding to the shock of the box on the floor. We observe that the protection by the foam insert alone gives the maximum acceleration, which is about 20% higher than the acceleration recorded when using both the foam insert and the corrugated cardboard. Two configurations are studied, one with the foam inserts surrounding the product and the other with the foam inserts on the corners of product.

Figure 7: Drop tests with/without corrugated cardboard box using the foam surrounding product (left) or only on the corner of the product (right).

3 MATERIAL MODELS

The material models in the FE simulation are presented in this section. The 3D corrugated cardboard structure is homogenised and replaced by an orthotropic elastic shell. The H-model is then implemented into ABAQUS using UGENS subroutine [5]. The crushable foam model of ABAQUS is used for the foam which is considered as an isotropic material, whose hardening behaviour is a function of the volume change [6].

3.1 Homogenization model of the corrugated cardboard

A 3D geometrical modelling of the three layers of the corrugated cardboard is very tedious and time consuming. In our homogenization model, the corrugated cardboard is represented by a 2D plate. Instead of using a local constitutive law (relating the strains to the stresses) at each material point, the homogenisation leads to a generalised constitutive law (relating the generalised strains to the resultant forces) for the equivalent homogeneous plate. The integrations through the thickness and the machine directions MD are required.

After the integrations or other calculations based on the beam theories [7-8], we obtain the generalised constitutive law in a matrix form:

$$\begin{Bmatrix} \{N\} \\ \{M\} \\ \{Q\} \end{Bmatrix} = \begin{bmatrix} [A] & [B] & 0 \\ [B] & [D] & 0 \\ 0 & 0 & [F] \end{bmatrix} \begin{Bmatrix} \{\epsilon_m\} \\ \{\kappa\} \\ \{\gamma\} \end{Bmatrix} \quad (3)$$

where $\{N\}$, $\{T\}$ and $\{M\}$ are the internal forces and moments obtained by integrating the local constitutive laws through the thickness of the corrugated cardboard, $[A]$ is the membrane rigidity matrix, $[D]$ is the bending-torsion rigidity matrix, $[F]$ is the transverse shear rigidity matrix and $[B]$ is the membrane-bending coupling matrix.

The corrugated cardboard is more complex than a laminated plate because of the fluting core and the cavities between the two flat layers. In the above matrix, some global effective rigidities obtained by the theory of laminated plates should be modified, such as the rigidities related to the membrane forces and bending moments on the MD section, the transverse shear forces and the torsion moments.

In this paper, the corrugated cardboard is modelled by shell elements, the strains and stresses at every integration point of an element are calculated incrementally. Let $\{dN\}$ the external forces and moments per unit length, they have the following relationship with the increments of the membrane strains and bending curvatures:

$$\{dN\} = [Q]\{d\varepsilon\} \quad (4)$$

The resultant forces and generalized strains at a given point are updated as follows:

$$\{N\} = \{N\} + \{dN\}; \{\varepsilon\} = \{\varepsilon\} + \{d\varepsilon\} \quad (5)$$

The above homogenization model is implemented into ABAQUS using a user subroutine UGENS. The main purpose of this subroutine is to compute the element material stiffness matrix $[Q]$ defined in equation (4), which is used to define the elemental stiffness matrix.

3.2 Model of the foam plastic behaviour

The foam materials have a cellular structure and hence behave in a complex manner, especially under crush conditions [9]. A usual stress-strain curve of polymeric foam has distinct major regions, which are caused by different mechanisms. A linear elastic region, followed by an almost horizontal plateau; this plateau is caused by the cells' collapsing; they buckle elastically and recover completely when the foam is unloaded. When the cells collapse completely, the stress rises steeply (densification) [9-11]. In this section a phenomenological plasticity model, based on the models presented, is proposed for isotropic crushable foam materials. It consists of a modified plasticity model that accounts for a different response in compression or tension, which incorporates uniaxial and hydrostatic compressive hardening laws.

This model with volumetric hardening uses a yield surface with an elliptical dependence of the deviatoric stress $[s]$ on the pressure p in the meridional plane. The elastic behaviour of the foam can be considered as isotropic and linear. The yield surface and the flow potential for the crushable foam model is defined in terms of the pressure $p - \frac{1}{3}\text{trace}[\sigma]$ and the von Mises

stress $q = \sqrt{\frac{3}{2}[s]:[s]}$. The yield surface is defined as follows:

$$F = \sqrt{q^2 + \alpha^2(p - p_0)^2} - B = 0 \quad (6)$$

where the parameter α represents the shape of the yield ellipse in the p - q stress plane; α can be calculated from the initial yield strength in an uniaxial compression (σ_c^0 taken as a positive value), the initial yield strength in hydrostatic compression (p_c^0) and the yield strength in hydrostatic tension (p_t):

$$\alpha = \frac{3k}{\sqrt{(3k_t + k)(3 - k)}} \quad \text{with } k = \frac{\sigma_c^0}{p_c^0} \quad \text{and} \quad \sigma_t = \frac{p_t}{p_c^0} \quad (7)$$

The plastic flow potential G is given by:

$$G = \sqrt{q^2 + \beta^2 p^2} \quad (8)$$

where β is related to the plastic Poisson's ratio ν_p as:

$$\beta = \frac{3}{\sqrt{2}} \sqrt{\frac{1-2\nu_p}{1+\nu_p}} \quad (9)$$

The plastic Poisson's ratio, which is the ratio between the transverse and the longitudinal plastic strains under uniaxial compression, must be in the range of -1 and 0.5.

4 RESULTS AND DISCUSSION

The product is considered as a rigid body. The corrugated cardboard box is modelled with a 1024 S4R linear quadrilateral shell elements. The foam is modelled with a 4892 C3D4 tetrahedral elements. The ground is considered as a flat rigid body and fixed in the space. A frictionless contact is assumed between the ground-box, box-foam and foam-product.

The box is positioned 2 mm from the ground and has an initial velocity $V = \sqrt{2gH_{drop}}$, with $H_{drop} = 1.05m$.

The comparisons of experimental and simulated curves of acceleration versus time for three configuration tests are shown in figures 8, 9 and 10. We can see that the finite element simulation results agree well with the experimental results. In table 2, we present the maximum acceleration and the duration of the shock for different configurations. Between the experimental and the numerical results, we have an error of 2.8% for the case with the foam around the product, 9.7% for the case with the foam on the corners of the product and 7.7% for the same case but for the shock in the lateral direction.

It can be noted that the corrugated cardboard box contribute about 20% to the shock absorption. We observe that the corrugated cardboard box undergoes higher von Mises stresses than the foam as shown in figure 11. The comparison between figures 8 and 9 shows also that the surrounding foam gives a more rigid support to the product, leading to a shorter shock so a much stronger impact to the product with respect to the corner foams.

Figure 8: Experimental and numerical curves of acceleration vs. time in the case of surrounding foam.

Figure 9: Experimental and numerical curves of acceleration vs. time in the case of corner foams.

Figure 10: Experimental and numerical curves of acceleration vs. time in the case of corner foams with the shock in lateral direction.

	Foam around product		Foam on the corners		Foam on the corners under lateral shock	
	Simulation	Test	Simulation	Test	Simulation	test
Maximum acceleration (#g)	139	143.12	80	70.2	73.2	65.5
Duration of shock (ms)	6.5	9.3	16.2	19.5	17.3	19.1

5 CONCLUSION

In the design stage of packaging systems, we need to simulate the contributions of both the corrugated cardboard box and the foam. According to the drop tests, it is evident that one cannot neglect the corrugated cardboard contribution in the protection of the product. An efficient homogenization model for the corrugated cardboard is developed and implemented into the FE software ABAQUS through the user subroutine UGENS. This model has been used to simulate the drop test of corrugated cardboard box containing different foam inserts and a rigid product. The drop test is instrumented, giving the curves of acceleration vs. time. The FE simulation results agree well with the experimental results. We have also shown that the corrugated cardboard box with supple foams gives a more damping effect to the shock response of the product.

Keywords: Arlequin method, Structural dynamics, Multiscale, Multimodel, Heterogeneous time integrators.

Abstract. *Arlequin method is a modeling framework based on the combination of concurrent multiscale and multi mechanical models. It is a general application of overlapping domain decomposition. The choice of the coupling operators written in common areas between different models provide the main key to ensure the continuity of displacement, velocity, and equilibrium of forces. Using overlap coupling methods in the context of structural dynamics is advantageous when treating dissimilar domains, mainly when wave propagation between the different models is taken into consideration. In this paper we propose to couple and analyze different numerical time schemes using the Arlequin method. Numerical studies, based on multiscale and multimodel space coupling are used to exemplify the efficiency of our approach.*

1 INTRODUCTION

Performing numerical simulations of the dynamic response in rotating machinery is mostly based on beam structures representing the coarse model.

Taking into consideration local physical phenomena occurring at microscopic levels such as crack propagation or contact requires a fine three dimensional modeling of the structure. On the other side, carrying out calculations on very finely meshed models can be very expensive in computational terms.

Many adaptive methods [1] proposing solutions for this kind of multiscale studies have been developed in order to enhance the accuracy of the numerical approximations and also reduce CPU (Central Processing Unit) and memory problems. But in spite of their main advantage, these multi-meshes methods are considered very expensive to implement in practical computations.

An other approach is offered by multiscale methods. The main idea is to have one global domain with a coarse mesh, including a zone of interest where a very fine mesh is super-imposed. These methods are to divide into two major classes: the first one is based on coupling domains at discrete interface [2], and the second consists on using an overlapping zone [3] where the two interfaces are superposed.

Arlequin method [4] is developed in the context of multiscale overlapping methods. Using a partition of models, this approach provides a progressive passage between different models with enhanced flexibility by means of multiple parameters [5]. In static and dynamic cases, Arlequin method gives the possibility of coupling dissimilar models with concurrent scales such as 2D-1D and 3D-1D models. In dynamic studies, it presents an important ability to treat problems where aspects like wave propagation are taken into consideration. It has been shown in [6], that if the coupling parameters of this method are correctly used, wave transition is guaranteed and problems of spurious reflections are avoided while transiting between models.

Moreove, being capable of coupling different models where each one has its own time integration scheme is a very important aspect. It can be considered as a first step for introducing different time discretizations, as well as a main key for coupling multiple finite element codes. Extending the Arlequin method to such application can be very advantageous.

In this study, we will visit energy conservation aspects for continuous and discrete Arlequin formulations. Then we will analyze the energy balance of the Newmark [10] algorithm while coupling different Newmark schemes, and propose a formalism for coupling different time integration schemes in the Arlequin framework.

Based on this formalism, two numerical applications are presented. The first one considers a multiscale coupling of two bar models. The second concerns a multimodel coupling of continuous 2D and beam structures. Future industrial applications of this work will mainly be used in the domain of rotor dynamics where multimodel coupling authorizing multiscale time integration is believed to be useful for such studies.

Figure 2: 2D-1D mesh coupling.

2 ARLEQUIN CONTINUOUS FORMULATION IN DYNAMIC REGIMES

An Arlequin-based mechanical study consists in dividing a global model Ω into two or more sub-domains Ω_i . These sub-domains have a common overlap area S .

Considering two domains Ω_1 and Ω_2 , the overlap is equivalent to their intersection $S = S_1 \cap S_2$.

In general terms, the Arlequin formulations are obtained by three main steps:

- super-imposing a local model Ω_2 to a global one Ω_1 in a zone of interest S .
- distributing the mechanical energies between the overlapping sub-systems by means of partition of unity functions.
- gluing the models in a part S_g of S .

We note that for the numerical applications presented in this paper, the gluing area S_g is equal to the overlapping zone S (external junction).

We consider a time dependent problem, where Ω_1 and Ω_2 are subjected to a field of volume density of forces f_i ($i = 1, 2$) and clamped in a non zero measured part Γ_1 of its boundary $d\Omega_1$. We denote W_1 and W_2 as the spaces of kinematical admissible fields related to Ω_1 and Ω_2 , and M the Lagrange multiplier space called the mediator space (for more details on these definitions we refer to [7]):

$$W_1 = \{v_1 \in H^1(\Omega_1); v_1 = 0 \text{ on } \Gamma_1\} \quad (1)$$

$$W_2 = H^1(\Omega_2) \quad (2)$$

Based on the Virtual Work Principle (VWP), the classical continuous Arlequin formulation consists in finding the admissible displacement fields u_1 and u_2 , as well as the Lagrange multiplier fields λ .

It can be written as follows:

$$Find (u_1, u_2, \lambda) \in W_1 \times W_2 \times M; \quad (3)$$

$$\forall (w_1, w_2, \mu) \in W_1 \times W_2 \times M, \quad (4)$$

$$G_{dyn}(u_1, w_1, u_2, w_2, \alpha) + G_{int}(u_1, w_1, u_2, w_2, \beta) + G_{arl}(\lambda, w_1, w_2) = G_{ext}(w_1, w_2, \varphi) \quad (5)$$

$$G_{arl}(\mu, u_1, u_2) = 0 \quad (6)$$

Weight parameters α, β , and $\varphi \in [0, 1]$ used to distribute energy between different models are defined by two main properties:

- $\alpha = \beta = \varphi = 1$ in $\Omega|S_g$
- $0 < \alpha, \beta, \varphi < 1$ in S_g

We note:

- $\alpha_2 = 1 - \alpha_1$
- $\beta_2 = 1 - \beta_1$
- $\varphi_2 = 1 - \varphi_1$

$G_{dyn}, G_{int}, G_{arl}, G_{ext}$ represent respectively the work of inertial forces, the work of the internal forces, the work of the Arlequin forces, and finally the work of the external forces applied on the different models. They are defined by:

$$G_{dyn}(u_1, w_1, u_2, w_2, \alpha) = \int_{\Omega_1} \alpha_1 \rho_1 \ddot{u}_1 w_1 d\Omega_1 + \int_{\Omega_2} \alpha_2 \rho_2 \ddot{u}_2 w_2 d\Omega_2 \quad (7)$$

$$G_{int}(u_1, w_1, u_2, w_2, \beta) = \int_{\Omega_1} \beta_1 \sigma(u_1) : \varepsilon(w_1) d\Omega_1 + \int_{\Omega_2} \beta_2 \sigma(u_2) : \varepsilon(w_2) d\Omega_2 \quad (8)$$

$$G_{ext}(\varphi, w_1, w_2) = f_1(w_1) + f_2(w_2) = \int_{\Omega_1} \varphi_1 f \cdot w_1 d\Omega_1 + \int_{\Omega_2} \varphi_2 f \cdot w_2 d\Omega_2 \quad (9)$$

$$G_{arl}(\lambda, w_1, w_2) = \langle \lambda, w_1 - w_2 \rangle \text{ where } \langle, \rangle \text{ represent a coupling operator} \quad (10)$$

Where $\sigma(u)$ and $\varepsilon(u)$ respectively denote the strain and stress tensors associated to the displacement field u .

2.1 COUPLING OPERATORS

Constructing the coupling matrix is a main step in the application of the Arlequin method especially when a multimodel coupling is taken into consideration (2D or 3D models coupled with 1D models). The gluing volume of displacement field is treated in a natural way by introducing the Lagrange multiplier field.

Several operators are proposed for coupling models in the context of the Arlequin framework [4], [5], [7], [8]. We define u as the general displacement vector formed of u_1 and u_2 . The three main operators are presented as follows:

$$L^2 \text{ coupling } G_{arl} = \int_{S_g} \lambda \cdot u dS_g \quad (11)$$

$$H^1 \text{ coupling } G_{arl} = \int_{S_g} [\lambda \cdot u + l^2 \varepsilon(\lambda) : \varepsilon(u)] dS_g \quad (12)$$

where l is a strictly positive parameter homogeneous to a length.

$$\text{Energy coupling } G_{arl} = \int_{S_g} \sigma(\lambda) : \varepsilon(u) dS_g \quad (13)$$

Depending on the application, L^2 coupling may introduce ill conditioning of the global stiffness matrix. This can be treated in an artificial manner by introducing an homogenous parameter (H^1 coupling), or in a more natural way by using the energy coupling.

The three operators listed above are tested in the context of our applications (2D-1D and 1D-1D coupling). In general terms, they all present similar results.

3 ENERGY CONSERVATION: CONTINUOUS ARLEQUIN FORMULATION

In this section we will write the energy conservation in a transient dynamic regime while using the Arlequin continuous framework.

Considering the same problem presented in the section 2 but with no external loads, the expression of total mechanical energy (E_{tot}) of the system is given by:

$$E_{tot} = E_{kinetic} + E_{potential} \quad (14)$$

where kinetic and potential energies are respectively defined as:

$$E_{kinetic} = \int_{\Omega_1} \frac{1}{2} \alpha_1 \rho_1 (\dot{u}_1)^2 d\Omega_1 + \int_{\Omega_2} \frac{1}{2} \alpha_2 \rho_2 (\dot{u}_2)^2 d\Omega_2 \quad (15)$$

$$E_{potential} = \int_{\Omega_1} \frac{1}{2} \rho_1 \sigma(u_1) : \varepsilon(u_1) d\Omega_1 + \int_{\Omega_2} \frac{1}{2} \rho_2 \sigma(u_2) : \varepsilon(u_2) d\Omega_2 \quad (16)$$

We assume that the constitutive material follows a hooke's law:

$$\sigma_i = \mathbf{D} \varepsilon(u_i) \quad (17)$$

with \mathbf{D} the elastic constant matrix.

The derivative of the total energy formula with respect to time gives:

$$\frac{dE_{tot}}{dt} = \int_{\Omega_1} \alpha_1 \rho_1 \dot{u}_1 \ddot{u}_1 d\Omega_1 + \int_{\Omega_2} \alpha_2 \rho_2 \dot{u}_2 \ddot{u}_2 d\Omega_2 + \int_{\Omega_1} \rho_1 \sigma(u_1) : \varepsilon(\dot{u}_1) d\Omega_1 + \int_{\Omega_2} \rho_2 \sigma(u_2) : \varepsilon(\dot{u}_2) d\Omega_2 \quad (18)$$

We assume that virtual fields are equivalent to velocity fields $w_1 = \dot{u}_1$ and $w_2 = \dot{u}_2$.

Comparing (18) and (5) enables us to write:

$$\frac{dE_{tot}}{dt} = - \langle \lambda, \dot{u}_1 - \dot{u}_2 \rangle \quad (19)$$

For $\lambda = \mu$, the derivative of (6) gives:

$$\frac{dG_{arl}}{dt} = \langle \lambda, \dot{u}_1 - \dot{u}_2 \rangle + \langle \frac{d\lambda}{dt}, u_1 - u_2 \rangle \quad (20)$$

Assuming λ as a time independent field, the second term of 20 is reduced to zero, and we are capable to write the energy conservation as:

$$\frac{dE_{tot}}{dt} = \langle \lambda, \dot{u}_1 - \dot{u}_2 \rangle = 0 \quad (21)$$

Based on (21), we proved that in a general case, when the Lagrange multiplier field is time independent, the Arlequin framework provides an energy conservation of the global problem.

4 DISCRETIZED PROBLEM

In the following sections, we consider the energy coupling (13). This choice is based on several study results realized in the context of our 2D-1D and 1D-1D applications, and on the homogeneity between the ingredients of this operator and the quantities evaluated in (8). We now introduce the spatio-temporal discretizations corresponding to (5) and (6). We take into consideration the effect of the damping matrix:

$$M_1 \ddot{u}_{n+1}^1 + C_1 \dot{u}_{n+1}^1 + K_1 u_{n+1}^1 + L_1^t \lambda_{n+1} = f_{n+1/ext}^1 \quad (22)$$

$$M_2 \ddot{u}_{n+1}^2 + C_2 \dot{u}_{n+1}^2 + K_2 u_{n+1}^2 + L_2^t \lambda_{n+1} = f_{n+1/ext}^2 \quad (23)$$

$$L_1 u_{n+1}^1 + L_2 u_{n+1}^2 = 0 \quad (24)$$

In this discretized equation system, M_i , C_i , and K_i are the mass, damping, and stiffness matrices of the system, and $f_{n+1/ext}^i$ is the external load vector. L_i matrices are the Arlequin coupling matrices (24) acting on the displacement fields in this case.

We note that the different matrices figuring in (22) and (23), with the exception of the L_i matrices, are weighted by the mean of the weight parameters defined in section 2. C_i matrix has a special importance in the rotor dynamics domain since it can contain the gyroscopic terms essential for such studies.

5 NUMERICAL INTEGRATION

For our two applications we apply the Gravouil-Combescure [14] method for coupling two sub-domains with different Newmark integration schemes and the same time scale.

5.1 Problem statement

Tests realized on the 2D-1D and 1D-1D couplings show coherent results and balanced energy Newmark algorithm when the average acceleration method is applied or when the same scheme is used for both models. However, when different Newmark schemes are involved, the energy balance is no more respected and differences caused by the work of the gluing forces appear.

5.2 Energy balance of the Newmark algorithm

Ideally, a single-step time integration algorithm should lead to a similar energy balance equation for finite increments. Using ([11]), we will establish the energy balance for multi-Newmark scheme coupling. Our main goal is to focus the contribution of the Arlequin forces in this equilibrium equation.

The work of these forces at the interface between the overlapping domains leads to undesirable energy dissipation effects. The discrete form of the energy balance equation involves the increment of the mechanical energy over the time interval from t_n to t_{n+1} . This increment can be expressed in terms of mean values and increments of the displacement and velocity as follows:

$$\sum_{i=1,2} [E_c^i + E_p^i]_n^{n+1} = \sum_{i=1,2} \left[\frac{1}{2} (\dot{u}^i)^t M_i (\dot{u}_n^i) + \frac{1}{2} (u^i)^t K_i (u^i) \right]_n^{n+1} \quad (25)$$

$$= \sum_{i=1,2} \left[\left(\frac{1}{2} (\dot{u}_{n+1}^i + \dot{u}_n^i)^t M_i (\dot{u}_n^i - \dot{u}_{n+1}^i) + \frac{1}{2} (u_{n+1}^i + u_n^i)^t K_i (u_n^i - u_{n+1}^i) \right) \right] \quad (26)$$

Using different ingredient of the Newmark scheme, the energy balance equation taking into consideration the contribution of the gluing forces at the interface can be written as following:

$$\sum_{i=1,2} \left[\frac{1}{2} (\dot{u}^i)^t M_i (\dot{u}_n^i) + \frac{1}{2} (u^i)^t K_i (u^i) + (\beta^i - \frac{1}{2} \gamma^i) \frac{1}{2} (\Delta t)^2 (\ddot{u}^i)^t M_i (\ddot{u}^i) \right]_n^{n+1} \quad (27)$$

$$= \sum_{i=1,2} (\Delta u^i)^t \left[\left(\bar{f}^i + (\gamma^i - \frac{1}{2}) \Delta f^i \right) \right] \quad (28)$$

$$- \sum_{i=1,2} (\Delta u^i)^t \left(L_i^t \bar{\lambda} + (\gamma^i - \frac{1}{2}) L_i^t \Delta(\lambda) \right) \quad (29)$$

$$- \sum_{i=1,2} (\gamma^i - \frac{1}{2}) \left\{ (\Delta u^i)^t K_i \Delta u^i + (\beta^i - \frac{1}{2} \gamma^i) (\Delta t)^2 (\Delta \ddot{u}^i)^t M_i (\Delta \ddot{u}^i) \right\} \quad (30)$$

$$- \sum_{i=1,2} (\Delta u^i)^t C_i \left\{ \frac{1}{2} (\dot{u}_{n+1}^i + \dot{u}_n^i) + (\gamma^i - \frac{1}{2}) \Delta \dot{u}^i \right\} \quad (31)$$

where

$$\Delta f^i = f_{n+1}^i - f_n^i$$

$$\Delta \lambda = \lambda_{n+1} - \lambda_n$$

$$\Delta u = u_{n+1} - u_n$$

$$\bar{f}^i = \frac{1}{2} (f_{n+1}^i + f_n^i)$$

$$\bar{\lambda} = \frac{1}{2} (\lambda_{n+1} + \lambda_n)$$

Terms in (27) are the total mechanical energy plus a conservative Newmark term. In (28) and (29), we respectively have the work of the external forces and the work of gluing forces. In (30) we have a Newmark dissipative term, and in (31) the contribution of the damping matrix. We are mainly interested in (29). It represents the Arlequin contribution and it will be studied in details in the next section.

In order to show conservative terms on the left side of Newmark's energy balance, and dissipative terms on the right side, we can express (30) with quadratic terms.

If the mass matrix M_i is replaced with an equivalent mass matrix M_i^* defined by:

$$M_i^* = M_i + (\gamma - \frac{1}{2}) h C \quad (32)$$

Equations (27) to (31) can be written as:

$$\sum_{i=1,2} \left[\frac{1}{2} (\dot{u}^i)^t M_i^* (\dot{u}_n^i) + \frac{1}{2} (u^i)^t K_i (u^i) + (\beta^i - \frac{1}{2} \gamma^i) \frac{1}{2} (\Delta t)^2 (\ddot{u}^i)^t M_i^* (\ddot{u}^i) \right]_n^{n+1} \quad (33)$$

$$= \sum_{i=1,2} (\Delta u^i)^t \left[\left(\bar{f}^i + \left(\gamma^i - \frac{1}{2} \right) \Delta f^i \right) \right] \quad (34)$$

$$- \sum_{i=1,2} (\Delta u^i)^t \left(L_i^t \bar{\lambda} + \left(\gamma^i - \frac{1}{2} \right) L_i^t \Delta(\lambda) \right) \quad (35)$$

$$- \sum_{i=1,2} \left(\gamma^i - \frac{1}{2} \right) \left\{ (\Delta u^i)^t K_i \Delta u^i + \left(\beta^i - \frac{1}{2} \gamma^i \right) (\Delta t)^2 (\Delta \ddot{u}^i)^t M_i^* (\Delta \ddot{u}^i) \right\} \quad (36)$$

$$\frac{1}{2} \Delta t \left\{ \Delta t^{-2} \Delta u^t C \Delta u + \frac{1}{4} (\dot{u}_{n+1} + \dot{u}_n)^t C (\dot{u}_{n+1} + \dot{u}_n) \right\} \quad (37)$$

$$- \frac{1}{2} \left(\beta^i - \frac{1}{2} \gamma^i \right) \left\{ \left(\gamma^i - \frac{1}{2} \right)^2 - \frac{1}{2} \left(\beta^i - \frac{1}{2} \gamma^i \right) \right\} \Delta t^3 \Delta \ddot{u}^t C \Delta \ddot{u} \quad (38)$$

Now we have a Newmark energy balance system with conservative and dissipative terms respectively on the left and right side of the equation.

6 ARLEQUIN INTERFACE WORK

The contribution of the Arlequin gluing forces at the interface appear in the Newmark energy balance equation and it is given by:

$$W_{inter}^{arl} = \sum_{i=1,2} (\Delta u^i)^t \left(L_i^t \bar{\lambda} + \left(\gamma^i - \frac{1}{2} \right) L_i^t \Delta(\lambda) \right) \quad (39)$$

We can re-write this term as an interpolation of λ between n and $n + 1$ as follows:

$$\begin{aligned} W_{inter}^{arl} &= \sum_{i=1,2} (\Delta u^i)^t \left(L_i^t \bar{\lambda} + \left(\gamma^i - \frac{1}{2} \right) L_i^t \Delta(\lambda) \right) = \sum_{i=1,2} (\Delta u^i)^t L_i^t \left(\gamma^i \lambda_{n+1} + (1 - \gamma^i) \lambda_n \right) \\ &= (\Delta u^1)^t L_1^t \left(\gamma^1 \lambda_{n+1} + (1 - \gamma^1) \lambda_n \right) + (\Delta u^2)^t L_2^t \left(\gamma^2 \lambda_{n+1} + (1 - \gamma^2) \lambda_n \right) \end{aligned} \quad (40)$$

$$= \left((\Delta u^1)^t L_1^t \gamma^1 + (\Delta u^2)^t L_2^t \gamma^2 \right) \lambda_{n+1} + \left((\Delta u^1)^t L_1^t (1 - \gamma^1) + (\Delta u^2)^t L_2^t (1 - \gamma^2) \right) \lambda_n \quad (41)$$

In order to find a solution to the problem statement (5.1) we have to be able to use the Arlequin condition (24).

In (41) we can notice that the presence of γ^1 and γ^2 makes the factorization unrealizable and the use of the Arlequin condition impossible.

Based on [13], we propose to introduce **a time independent Lagrange multiplier field** $\lambda_{n+\gamma}$.

In other terms, between two successful time steps, $\lambda_{n+\gamma}$ is a constant field.

Equation (39) can now be written as:

$$W_{inter}^{arl} = \sum_{i=1,2} (\Delta u^i)^t L_i^t \lambda_{n+\gamma} \quad (42)$$

If the numerical integration conditions are well respected, between two successive time steps, Arlequin condition (24) gives:

$$\sum_{i=1,2} (L_i u_{n+1}) = 0 \text{ and } \sum_{i=1,2} (L_i u_n) = 0 \quad (43)$$

Now we have (42) equivalent to zero.

In this section we have demonstrated that by the mean of a time independent Lagrange multiplier field, the work of the Arlequin gluing forces is reduced to zero while using two different Newmark schemes and a space recovering method.

6.1 A PRACTICAL WAY TO ENFORCE THE INTERPOLATION OF $\lambda_{n+\gamma}$

The idea proposed in the last section, is a theoretical framework permitting the suppression of undesirable interface effects. But no indications concerning constant value of the time independent field $\lambda_{n+\gamma}$ are presented.

We will now suggest a method which aims to determine a general form of $\lambda_{n+\gamma}$. This form should be applicable on both models and on the gluing zone.

Based on (41),

$$\lambda_{n+\gamma} = (\gamma^i \lambda_{n+1} + (1 - \gamma^i) \lambda_n) \quad (44)$$

we define $\lambda_{n+\gamma}$ as follows:

$$\lambda_{n+\gamma} = (\gamma^* \lambda_{n+1} + (1 - \gamma^*) \lambda_n) \quad (45)$$

One can notice that with this definition, according a value to $\lambda_{n+\gamma}$ is equivalent to according a value to γ^* .

In order to stay coherent with the partition of unity used for spatial gluing part, we propose to weight the Newmark parameters γ^1 and γ^2 with a weight parameter ξ .

By means of this approach we will have:

- $\gamma^* = \gamma^1$ in $\Omega_1 | S_c$;
- $\gamma^* = \gamma^2$ in $\Omega_2 | S_c$;
- $\gamma^* = \xi \gamma^1 + (1 - \xi) \gamma^2$ in S_c ;

Figure 3: Wave propagation.

We are now able to write (42) as:

$$W_{inter}^{arl} = \left(L_1(\Delta u^1) + L_2(\Delta u^2) \right) \gamma^* \lambda_{n+1} + \left(L_1(\Delta u^1) + L_2(\Delta u^2) \right) (1 - \gamma^*) \lambda_n \quad (46)$$

We can notice that (46) is very similar to (41). The main difference is that in 46 the Arlequin conditions can take effect and suppress the undesirable energy dissipation introduced at the interface.

7 NUMERICAL APPLICATION

The proposed methodology here below, is applied for both 2D-1D and 1D-1D couplings. We used two different dissipative Newmark schemes, and a unique time scale. Results were validated by comparison with an analytic solution [9] of a free climbed bar model, undergoing a constant concentrated effort at its free edge. The same work was realized with sinusoidal loading.

Figure 4: Wave propagation.

In figure 5, the left graph shows the work of the gluing forces at the interface while using two different Newmark schemes on the 1D-1D bar coupling. The right one represents the same work but here we use the $\lambda_{n+\gamma}$ introduced in section 5.1. We can clearly see that the numerical dissipation disappear, and the contribution of the gluing forces at the interface is reduced to zero. We can find the corresponding energy balance of the Newmark algorithm (figure7).

Figure 5: Arlequin interface work ; $\lambda_{n+\gamma}$ Effect.

Graphs in figure 5 are generated for compatible bar meshes. Next results (figure 6) are obtained when bar models presenting incompatible mesh are coupled. For both cases the contribution of the Arlequin forces at the interface is negligible. But we can notice a degradation of the results when incompatible mesh are used. Properly treating the numerical integration issue is the main clue to address this kind of difficulties.

Figure 6: Arlequin interface work - Mesh compatibility effect.

Energy balance equation (27) to (31) is represented in the figure 7. Both cases described in figure 5 are reviewed in the global energy balance system. (Left term holds for (27) and right term holds for (28) to (30)). The contribution of the gluing forces disappear on the right side graph. On the other side, one can notice coherent kinetic and potential energy profiles. The proposed method present satisfying results.

Figure 7: Newmark energy balance - 1D-1D coupling.

Other interesting aspects are currently being investigated. For instance, we are evaluating the model's response to high frequency solicitations and studying how do high frequency waves transit between the different mesh scales.

The study was reviewed in the context of a multimodel 2D-1D coupling (Figure 8), and we obtained similar results.

Figure 8: Newmark energy balance - 2D-1D coupling.

8 CONCLUSION

In this article we propose a general formalism to couple different time schemes without introducing undesirable numerical dissipation due to the gluing forces work effects at the interface. This formalism authorizes multiscale/multimodel coupling since it is based on the Arlequin method. Two applications (1D-1D and 2D-1D) were presented in order to exemplify the relevance of the method. An extension to a 3D-1D coupling is planned to be developed. Our main goal is to formulate a generale formalism leading to a space-time multimodel-multiscale/multischeme coupling which guaranties a global energy balance of the system during the resolution, in the context of the Arlequin method.

More elaborated applications are under progress and will be presented during the conference.

Keywords: Ground vibrations, rock concert vibrations, building vibrations, crowd induced rhythmic vibrations.

Abstract. *Rock concerts events in the River Plate Stadium in Buenos Aires (and other stadiums) has raised neighborhood complains due to molest vibrations felt by the inhabitants of some buildings at distances up to 3 km. In this paper are described the results of the studies conducted to determine the origin and the effects on buildings of vibrations generated during rock concerts in stadiums. First, are presented the equations for modeling: a) the coordinate jump of the public on the field and the generated load; b) the acceleration wave propagation over the surface of an elastic solid and c) the response of buildings at different distances from the stadium. The resulting equations are used to estimate the accelerations at top of buildings at distances inside a 3 km radio from the stadium. Then, the planned and obtained measurements during the concerts are shown and evaluated. Finally the conclusions and recommendations in relation with the effects of the coordinate jump of the public on the field, the properties of the affected buildings, their distance to the stadium and the effects on the structures, contents and inhabitants are presented. It is shown that for buildings in resonance with the spectator jumps (2 Hz of natural frequency, i.e. buildings around 10 to 12 stories at Buenos Aires), the acceleration level at the upper stories is severe to persons (even is not high enough to produce structural and non structural damage) to distances of more than 3 km from the stadium.*

1. INTRODUCTION

This paper summarize the studies carried out at University of Buenos Aires (UBA) to establish the causes and effects of building vibrations generated by rock concerts at River Plate stadium at Buenos Aires city.

The research activities were developed in the framework of a Cooperation Agreement between the UBA College of Engineering and the Enviromental Protection Agency (APRA) of Buenos Aires City due to vibration claims from owners of multistory buildings during rock concert events in the River Plate Stadium. The buildings (in general, 10 and 11 levels) were 600 to 2000m away from the Stadium (Fig. 1).

Fig. 1. Vibrations claims during rock concert events at River Plate Stadium in Buenos Aires

Due to the lack of an analytical model generally accepted and a systematic and planned set of acceleration records, there is a broad controversy regarding the causes, the intensity and the effects of stadium field crowd-induced vibrations during rock concerts on neighborhood buildings.

In order to have a correct diagnosis about the level of annoyance and the possible solutions to the problem is needed a physical model capable of predict the building vibrations due to the actions generated by the spectacle. To satisfy this objective it was necessary to develop: a) an analytical model capable of representing the building responses, b) a planned set of acceleration records at soil and building floors at different distances of stadium during the rock concerts and c) the adjustment of the model according to the experimental results.

In this paper, are first summarized the limits of the vibrations human sensitivity. Then, the dynamic loads generated by the public during a rock concert, and in particular, the action on the environmental generated by the coordinated crowd jumping at the rhythm of the music at the field of the stadium are presented.

After that, it is developed an acceleration wave propagation model with origin at the periodic type of loading generated by the coordinated crowd jumping. The soil is represented by a

semi-infinite isotropic elastic solid where the energy is propagated through volumetric waves (compression waves P and shear waves S) and surface Rayleigh waves R as shown in Fig. 2.

On turn, the acceleration waves reach the building foundations so that the accelerations at the different levels of the buildings can increase or decrease according to the dynamical structural properties. In particular, if the natural frequency of the building coincides with the excitation frequency, the resonance effect produces a large amplification of accelerations at upper floors.

Finally, from the equations describing the above behavior and the results obtained in the planned measurements, conclusions regarding the effects on the structural, non-structural components and inhabitants of buildings are presented.

Fig. 2. Wave propagations in a semi-infinite isotropic elastic solid

2. HUMAN SENSIVITY TO VIBRATIONS

In Argentina, the human exposure to vibrations in buildings (frequency between 1 Hz to 80 Hz) is regulated by the norm IRAM 4078 Parte II (December 1990) based on the ISO Standard 2631/1985 "Evaluation of Human Exposure to whole-body Vibration".

According to that norm, the experience in several countries has shown that it is usual that the vibration claims in dwelling buildings start as soon as the vibrations reach the perception threshold. Therefore the allowable levels of vibrations are established in the norm mainly to minimize inhabitant complains than to other factors like health risk or work difficulties.

The norm defines basic curves representing constant levels of human response to vibrations considering the human perceptions or complaints. These curves are acceleration levels as a function of the excitation frequency. The allowable acceleration levels for different building uses and event hours are established as a multiple of these basic curves. For acceleration of velocity levels below these basic curves it is expected no comments or complain due to vibrations.

The primary magnitude used in the norm to describe the vibration intensity is the root mean square (RMS) of the accelerations. Given an acceleration history $a(t)$, the acceleration RMS (σ_a) for a period of time T is computed as

$$\sigma_a = \sqrt{\frac{1}{T} \cdot \left(\int_0^T a(t)^2 dt \right)} \quad (1)$$

Thus, in the particular case of an harmonic excitation, $a(t) = A \sin\left(\frac{2\pi t}{T}\right)$, the amplitude A , satisfy the following equation

$$\sigma_a = \frac{A}{\sqrt{2}} \quad (2)$$

Fig. 3 shows the basic curves defined by the norm for accelerations $a_x(f)$ and $a_z(f)$ (m/s^2) as a function of frequency f in the directions of the axis x (horizontal accelerations) and z (vertical accelerations).

Fig. 3. Curvas básicas de respuesta humana constante a las vibraciones en las direcciones X y Z

For dwellings, the norm establishes the following multiplication factors for the allowable levels of vibration: a) During day hours: (2.0 to 4.0) and b) at night: (1.40). Since most of the musical events are at night, the last factor is used in this paper as a multiplication factor of the basic curves of Fig. 3 to obtain the acceleration limits.

If it is considered an excitation frequency of 130 beats/minute, $f_b = 130 \cdot \frac{1}{\text{min}} = 2.167 \frac{1}{s}$ (corresponding to the music rhythm in a rock concert), the allowable continuous acceleration RMS in the vertical and horizontal directions are respectively $A_z(f_b) = 0.097 \% \cdot g$ and

$A_x(f_b) = 0.056\% \cdot g$, where g is the gravity acceleration. Note that for the frequency of the music beat in a rock concert, the human body is more sensitive to the horizontal than to the vertical vibrations.

It is important to take into account that in residential areas the tolerable vibrations can vary in a wide range. The specific values depend on cultural and social factors as well as psychological predisposition of building occupants.

Considering the international recommendations and the observations obtained in this study, it is assumed in this paper that the level of the acceleration RMS above what intermittent vibrations are clearly noticed for most of the people at buildings away of the stadium - where the vibrations are generated by the coordinate crowd jumping on the field following the rhythm of the music of a rock concert - is $A_1 = 0.1\% g$ ($0.01 m/s^2$).

On the other hand, for ten times larger values, about $1\% g$ ($0.10 m/s^2$), the accelerations are molest for persons, the hanging objects (lamps, flower-pots) can oscillate few millimeters and persons can feel alarmed by the movement.

3. DYNAMIC LOADS GENERATED BY THE CROWD DURING A ROCK CONCERT

3.1. Experimental studies and analytical representation of loads

During a rock concert, the music has the effect of synchronizing the movement of the spectators. Thousands of people, particularly, on the field jump exactly at the same time due to auditive and, specially, visual impact. For people on the stadium tribunes' exact synchronization for so many people is much more difficult.

In this paper the action of the crowd is modeled following the experimental studies carried out in the University of Surrey, UK [1]. In these studies it was examined thoroughly the statistical nature of crowd loading by measuring the individual performance of 100 people jumping and bobbing (oscillating vertically with feet in permanent contact with the ground) to four different tempos (frequencies of 1.5, 2.0, 2.67 y 3.5 Hz) in such a way as to allow the loading from very large crowds to be estimated by summing the individual force histories of the participants. They were encouraged to move as if they were enjoying a lively rock concert (Fig. 4).

From the studies of the University of Surrey it was recommended a synchronized load representing the crowd action given by eq.(3), where W is the weight of the crowd, f is the frequency of the beat, DLF_n is the dynamic load factor for each harmonic n y φ_n is the phase lag of each harmonic.

$$P(t) = W \cdot \left[1 + \sum_{n=1}^{\infty} (DLF_n \cdot \cos(2 \cdot \pi \cdot n \cdot f \cdot t - \varphi_n)) \right] \quad (3)$$

Fig. 4. Studies of Crowd-induced rhythmic loading at University of Surrey [1]

In **Fig. 5** it is shown the normalized force of people jumping following a beat of 2 Hz [1].

Fig. 5. Segment superposition of 29 s of force history and their mean [1]

In Fig. 6 it is shown the variation of dynamic load factors with crowd size for the first three harmonics.

The loads in the study of the University of Surrey have been measured on a rigid base. Considering that the crowd jumping on grass maintains the feet in permanent contact with the ground, the bobbing values have been used in this paper.

Therefore, from the values recommended in the study of the University of Surrey and considering a frequency of 120 beats/minute (2 Hz) coincident with the experimental values obtained around the River Plate Stadium, the following dynamic loads factors were used in this

paper for the first three harmonics $DLF = \begin{pmatrix} 0.321 \\ 0.080 \\ 0.010 \end{pmatrix}$, with a beat frequency, $f_b = 120 \cdot \frac{1}{\text{min}} = 2 \cdot \frac{1}{s}$

Fig. 6. Variation of dynamic load factors with crowd size [1]

3.2. Crowd-induced rhythmic loading on the stadium field

Assuming the synchronized jumping of 35,000 people on the field and an average weight of 62.4 kgf for the assistants to a rock concert a total weight of $W_t = W_0 \cdot N_{esp} = 2.204 \cdot 10^4 \cdot kN$ is obtained. Considering eq. (3), it is possible to compute the power spectral density for the first three harmonics of the crowd-induced rhythmic loading as

$$S_{esp_i} = \frac{1}{2} \cdot [(DLF_i \cdot W_t)^2] = \begin{pmatrix} 2.502 \cdot 10^7 \\ 1.554 \cdot 10^6 \\ 2.428 \cdot 10^4 \end{pmatrix} \cdot kN^2 \quad (4)$$

with the following frequencies for each harmonic:

$$F_{b_i} = f_b \cdot i = \begin{pmatrix} 2 \\ 4 \\ 6 \end{pmatrix} \cdot Hz \quad (5)$$

$$\omega_b = 2 \cdot \pi \cdot F_b = \begin{pmatrix} 12.566 \\ 25.133 \\ 37.699 \end{pmatrix} \frac{1}{s} \quad (6)$$

4. WAVE PROPAGATION FROM THE STADIUM TO THE NEIGHBORHOOD

4.1. Dynamic soil properties at the stadium neighborhood

Considering the average soil properties in a depth according to the length of the Rayleigh waves corresponding to the 2 Hz frequency of the crowd jumping, the following values are obtained from soils studies around the stadium:: shear modulus $G = 60.3 MPa$, soil density, $\rho = 1900 \cdot \frac{kg}{m^3}$, Poisson modulus $\nu = 0.35$, soil damping factor $\zeta = 0.005$, elasticity modulus,

$E = 2 \cdot (1 + \nu) \cdot G = 162.795 \text{ MPa}$, Lamé constant $\lambda = \frac{\nu \cdot E}{(1 + \nu) \cdot (1 - 2 \cdot \nu)} = 140.687 \text{ MPa}$, P wave propagation velocity $C_p = \sqrt{\frac{\lambda + 2 \cdot G}{\rho}} = 370.828 \frac{m}{s}$, S wave propagation velocity $C_s = \sqrt{\frac{G}{\rho}} = 178.14 \frac{m}{s}$, R wave propagation velocity for $\nu = 0.35$, $C_R = \sqrt{c_{R1}} \cdot C_s = 166.563 \frac{m}{s}$, with a wave propagation velocity ratio, $\frac{C_R}{C_s} = 0.935$.

4.2. Wave propagation on the surface of a semi-infinite isotropic elastic solid

In 1904, assuming that most of the vibration energy is transported by the Rayleigh waves, Lamb [2] obtained analytically the displacements $u(t)$ at any point of a semi-infinite isotropic elastic solid located at a distance r from an harmonic load $P e^{i\omega t}$ of frequency ω . The Lamb solution can be written as [3]:

$$u(t) = U(\omega, \zeta, r) e^{i\omega t} = -\frac{\omega H}{2\rho C_R^3} e^{-\frac{\zeta \omega r}{2C_R}} H_1^{(2)}\left(\frac{\omega r}{C_R}\right) P e^{i\omega t} = H_u(\omega, \zeta, r) P e^{i\omega t} \quad (7)$$

where $H_1^{(2)}(\cdot)$ is the Hankel function of second kind and first order. H is a constant that depends on the Poisson modulus only ($H = 0.095$ for $\nu = 0.35$). Therefore, $H_u(\omega, \zeta, r)$ is the transfer function representing the displacement soil response.

By double differentiation of eq. (7) respect of time, the acceleration response $\ddot{u}(t)$ in any point of the semi-infinite space can be computed as

$$\ddot{u}(t) = \ddot{U}(\omega, \zeta, r) e^{i\omega t} = -\omega^2 H_u(\omega, \zeta, r) P e^{i\omega t} = H_{\ddot{u}}(\omega, \zeta, r) P e^{i\omega t} \quad (8)$$

4.3. Soil accelerations away the stadium due to crowd-induced rhythmic loading on the field

Using the random vibrations theory [4], the transfer function of eq.(8) $H_{\ddot{u}}(\omega, \zeta, r)$ and the power spectral density of the crowd-induced rhythmic loading S_{exp_i} [eq.(4)] it is possible to obtain the power spectral density of the horizontal acceleration at different distances from the stadium r for each harmonic i as

$$S_{\ddot{u}}(i, \zeta, r) = S_{\text{exp}_i} \cdot \left(|H_{\ddot{u}}(2\pi f_b i, \zeta, r)| \right)^2 \quad (9)$$

Thus, the RMS horizontal accelerations can be computed as

$$\sigma_{\ddot{u}}(\zeta, r) = \left(\sum_{i=1}^3 S_{\ddot{u}}(i, \zeta, r) \right)^{\frac{1}{2}} \quad (10)$$

In Fig. 7 are shown the RMS horizontal accelerations obtained on soil at 500, 1000 and 1500 m distance from the River Plate stadium (0.081 %g, 0.042 %g and 0.026 %g respectively) using eq. (10).

These small values explain why the vibrations are practically no felt at the one or two story dwellings, even at those located closest to the River Plate stadium. In Section 2, it was

shown that the limit above what intermittent vibrations are clearly noticed for most of the people is around 0.1 %g.

Fig. 7. RMS horizontal acceleration on soil at 500, 1000 y 1500 m from River Plate stadium

4.4. Building accelerations away the stadium due to crowd-induced rhythmic loading on the field

As shown in Fig. 7, the accelerations on soil and at rigid dwellings (no amplification) are just perceptible, even for those in the closest zone near the River Plate stadium.

However, when the low frequency horizontal accelerations reach the foundations of multi-story buildings the accelerations can be amplified or reduced at the different floors depending on the dynamic building properties. In particular, when the excitation frequency coincides with the building natural frequency, a large amplification is obtained at the upper stories due to the resonance condition.

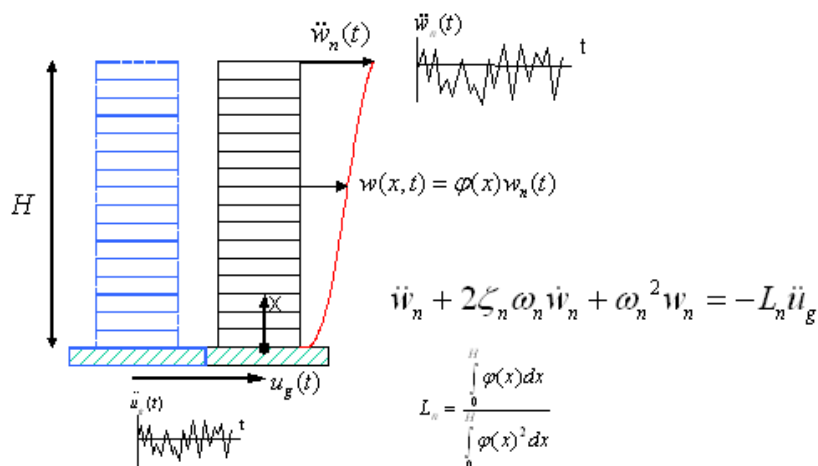

Fig. 8. Building vibrations due to base accelerations. Generalized single degree of freedom system model.

Fig. 8 shows the response to base accelerations of a multi-story building using a generalized single degree of freedom system [5]. The equation of motion is

$$\ddot{w}_n(t) + 2\xi_n \omega_n \dot{w}_n(t) + \omega_n^2 w_n(t) = -L_n \ddot{u}(t) \quad (11)$$

where w_n is the displacement of the top of the building, ξ_n is the building damping factor, ω_n

is the building natural vibration frequency, $L_n = \frac{\int_0^H m(x)\varphi(x)dx}{\int_0^H m(x)\varphi(x)^2 dx} = 1.50$ for $\varphi(x) = \frac{x}{H}$ is the

generalized participation factor, $m(x)$ is the mass along the building height assumed constant in this paper, H is the building height, $\varphi(x)$ is the shape function that define the form of deflections (assumed linear in this paper) and $\ddot{u}(t)$ is the soil acceleration as described in the previous section.

By applying the Fourier transform to eq.(11), the response in the frequency domain is obtained as

$$W_n(\omega, \omega_n, \xi) = -\frac{L_n}{\omega_n^2 - \omega^2 + 2\xi_n \omega_n \omega i} \ddot{U}(\omega) = H_n(\omega, \omega_n, \xi_n) \ddot{U}(\omega) \quad (12)$$

where $H_n(\omega, \omega_n, \xi_n)$ is the transfer function representing the building top displacement response for a building of frequency ω_n and damping factor ξ_n , $\ddot{U}(\omega)$ is the Fourier transform of $\ddot{u}(t)$ and $W_n(\omega, \omega_n, \xi)$ is the Fourier transform of the top building displacement $w(t)$.

Using eq. (12), the Fourier transform of the top building acceleration $\ddot{w}(t)$ can be computed as

$$\ddot{W}_n(\omega, \omega_n, \xi) = \frac{\omega^2 L_n}{\omega_n^2 - \omega^2 + 2\xi_n \omega_n \omega i} \ddot{U}(\omega) = \omega^2 H_n(\omega, \omega_n, \xi_n) \ddot{U}(\omega) = H_{\ddot{w}}(\omega, \omega_n, \xi_n) \ddot{U}(\omega) \quad (13)$$

Therefore, the power spectral density of top building accelerations for each excitation frequency ω_i can be computed as

$$S_{\ddot{w}_n}(\omega_n, \xi_n, \omega_i, \zeta, r) = \left(|H_{\ddot{w}}(\omega_i, \omega_n, \xi_n)| \right)^2 S_{\ddot{u}}(\omega_i, \zeta, r) \quad (14)$$

Thus, the RMS top building acceleration can be computed for the first three harmonics as

$$\sigma_{\ddot{w}_n}(\omega_n, \xi_n, \zeta, r) = \left(\sum_{i=1}^3 S_{\ddot{w}_n}(\omega_n, \xi_n, \omega_i, \zeta, r) \right)^{\frac{1}{2}} \quad (15)$$

Fig. 9 shows the RMS top building accelerations (building damping factor $\xi_n = 0.02$) as a function of the period of the first vibration mode $T_n = \frac{2\pi}{\omega_n}$ obtained using eq.(15) at distances of 1000, 1500 and 2000 m away of River Plate stadium.

Fig. 9 RMS building top accelerations [%g] for natural periods between 0 to 1 sec

Fig. 9 clearly shows the resonance with the first and second harmonic of the crowd-induced rhythmic loading [eq. (5)] at frequency of 2 and 4 Hz (Periods of 0.5 and 0.25 s respectively).

Although in most of the cases, the building top accelerations are below the perception threshold of 0.1%g, they reach values near 1% g, even for distances larger than 1500m from the stadium, for buildings whose natural frequencies coincide with the crowd jumping frequencies.

In Fig. 10 are shown the RMS building top accelerations for buildings with 2 Hz of natural frequency obtained at 500, 1000, 1500 and 2000 m distance from the River Plate stadium (1.93 %g, 1.13 %g, 0.76 %g and 0.55 %g respectively) using eq.(15).

The period of the building first mode of vibration is strongly correlated to the building height. From experimental data on reinforced concrete shear wall buildings (the usual structural construction for multi-story buildings in Buenos Aires), Satake et al [6] proposed in 2003 the following relationship,

$$T_n = 0.015 \frac{H}{m} \quad (16)$$

Considering an average inter-story height of 3 m and using eq.(16), the resonance frequencies of 2 and 4 Hz would correspond to buildings between 11 and 12 stories and 6 stories respectively, depending on the specific values of the dynamic building parameters (stiffness, mass and damping).

The analytical results clearly explain why the vibrations are mostly felt at buildings of that number of stories, even to long distances away the stadium (3000 m), meanwhile the inhabitants of lower and taller buildings do not feel vibrations even if they are located closer the River Plate stadium.

Fig. 10. RMS building top accelerations for buildings with 2 Hz of natural frequency computed at 500, 1000, 1500 and 2000 m distance from the River Plate stadium

5. STRUCTURAL AND NON-STRUCTURAL DAMAGE RISK

For accelerations smaller than 2% g at the building top, the influence of the acceleration on damage is neglectful. The structural and non-structural building damage is more related with the level of displacements, particularly the inter-story relative displacements as considered for wind and earthquake building codes.

Considering that the maximum building horizontal acceleration, A , happens at resonance with the first harmonic of the spectators jumping ($f_b = 2Hz$), it is possible to compute the maximum displacement at the building top, X , as

$$X(A) = \frac{A}{(2\pi f_b)^2} \quad (17)$$

The buildings closest to the River Plate stadium with a height susceptible of reaching the resonance condition are located about 800 m away from the stadium. Using the RMS building top acceleration $\sigma_{\ddot{w}_n}$ [eq. (15)] and eq. (2), the acceleration amplitude can be computed as

$$A = \sqrt{2} \cdot \sigma_{\ddot{w}_n} (2\pi f_b, \zeta_n, 0.005, 800m) = 1.927 \% g \quad (18)$$

Although this acceleration level is very molest for building inhabitants, the corresponding maximum displacement is only

$$X(A) = 1.2 \text{ mm} \quad (19)$$

Considering that the approximate height of a building in resonance with the crowd jumping is [eq.(16)], $H = \frac{T_b}{0.015} m = \frac{0.5}{0.015} m = 33.33 m$, the ratio displacement/height can be computed as

$$\frac{X(A)}{H} = \frac{1.2 \cdot 10^{-3} m}{33.33 m} = \frac{1}{1000} \frac{1}{28} \quad (20)$$

That means that the maximum displacement of the closest buildings near the River Plate stadium due to the crowd-induced rhythmic loading on the stadium field is about 30 times smaller than the serviceability allowable displacement for wind action established by most of the structural codes ($H/1000$).

Therefore, this level of relative displacement is much smaller than the required to produce damage to structural and non-structural elements.

6. ACCELERATION RECORDS OBTAINED DURING THE CONCERTS

In order to validate the analytical model a measurement plan was developed. The ground accelerations and the building responses were measured during the concerts of ACDC (4th and 6th of December, 2009), Metallica (21st and 22nd of January, 2010) and Cold Play (26th of February, 2010) at the River Plate Stadium. Measures were also taken during the Gustavo Cerati concert (20th of December, 2009) at Club Ciudad. In Fig. 11 it is shown where the measures were obtained during the concerts. The coordinate jump of the spectators was caught on video during the Metallica and Cold Play concerts.

Fig. 11. Locations where the ground accelerations and the building response were obtained

The ground accelerations obtained at 450 m away from the stadium show that the frequency content matches the spectator's movement during rock concerts (Fig. 12). The acceleration levels measured at the ground were below the human perception threshold (0.06% g).

Fig. 12. Acceleration record obtained on ground 450m away from the stadium during the coordinate crowd jumping at stadium field – Metallica concert (sample duration 7sec)

On the other hand, during the concerts, the recorded accelerations at buildings inside a 1000m radius were well above the comfort limits. The buildings having natural frequencies around 2-2.5 Hz were the most affected by the Rayleigh wave's transmitted through the foundations. The maximum measured accelerations reached up to 1.5% g (RMS 1.1% g) at the top of an 11-story building located 850m away from the stadium (Fig. 13).

Fig. 13. Accelerations recorded at the top of an 11-story building located 850m away from the stadium during the ACDC concert (sample duration 20 minutes)

7. CONCLUSIONS

7.1. Conclusions from the obtained measures

As a result of the obtained measures the following conclusions were reached:

- From the acceleration records and the simultaneous crowd jumps caught on video, it was established that the Rayleigh waves were the result of the coordinate jump of the spectators during some segments of the rock concerts. The obtained accelerations and the radius where the vibrations are felt by the building inhabitants are related to the number of spectators coordinately jumping following the rhythm of the music.
- The recorded ground and building accelerations matched reasonably with the results of the analytical model of wave propagation and building response.
- The recorded accelerations and displacements are below the levels required to produce structural and/or non-structural damage on buildings. However the accelera-

tions on 10 to 12 story buildings located about 1000m away the stadium produced alarm in the inhabitants of the upper floors.

7.2. Conclusions from the analytical model

This paper studies the vibration transmitted from the ground to the buildings (and the people living in them) due to the coordinated jump of 35,000 spectators during rock concerts developed at River Plate Stadium, in Buenos Aires. The main conclusions are:

- The coordinated movement of the spectators jumping to rhythm of the music generates acceleration waves with a frequency of 2 and 4 Hz. These waves (mainly Rayleigh waves) are propagated over the ground reaching the buildings foundations in the surrounding area of the stadium.
- At the ground level of dwellings some occupant could perceive the vibrations inside approximately 380m radius from the stadium (Fig. 14).

Fig. 14. Area where some people could feel vibrations on ground level

- The horizontal vibrations are magnified by buildings whose natural frequency matches the frequency of the spectator's movement.
- The RMS accelerations could reach values between 0.6% g and 1.1% g at the top level of buildings about 10-12 stories (at resonance with the first harmonic of the spectators movement) and at the top level of buildings about 6 stories (at resonance with the second harmonic of the spectators movement) inside a 3000m radius away from the stadium (Fig. 15). The number of stories to get resonance can slightly change as a function of the characteristics of the structural system, the foundation type, the quantity of the non-structural walls and the spectator's movement.

- For RMS values larger than 0.6% g, the accelerations are very molesting for persons. The hanging objects (lamps, flower-pots) can oscillate few millimeters, the water in fishbowls can move clearly and inhabitants can alarm by the movement.
- The calculated drifts and accelerations on buildings in the surrounding areas of the stadium are not high enough to produce structural and/or non-structural damage.
- This study was conducted assuming the simultaneous jump of 35,000 spectators at the stadium field. The ground and building accelerations are directly proportional to the number of spectators jumping in a coordinated manner with the music.
- As a result of the low frequency of the vibration it is not possible to use the traditional vibration control methods such as digging a shallow trench around the source (because of the depth of the Raleigh waves).

Fig. 15. Area where people at the upper floors could feel vibrations on buildings at resonance with the spectators movement

Keywords: reinforced concrete panel, membrane model, nonlinear analysis, damage model

Abstract. *The paper presents an efficient numerical model for the inelastic response analysis of R/C panels under cyclic excitations. A plane stress 2d membrane model has been developed that accounts for the concrete and reinforcing steel interaction. The reinforcing bars are modeled as multiple smeared steel layers with an uniaxial stress-strain relation in the bar direction following the Menegotto-Pinto constitutive model with isotropic hardening. The concrete material model is based on damage mechanics with an efficient two parameter damage law. At this stage of the research the bond-slip between concrete and rebars is not taken into account.*

The new model is validated by comparison with several experimental results on reinforced concrete panels from the literature. The tests are carried out under quasi-static conditions. The accuracy of the model in reproducing the cyclic behavior of reinforced concrete panels with different reinforcement ratio and bar inclination is excellent.

1 INTRODUCTION

Reinforced concrete (R/C) panels are commonly used in the lateral force resisting system of structures in seismic risk zones for serviceability, ultimate strength and ductility considerations. They are either used alone or are coupled with moment resisting frames to resist the lateral forces.

The assessment of the behavior of R/C panels have been the focus of important analytical and experimental investigations aiming to evaluate the strength and particularly the shear transfer across the cracks [1–4].

The necessity of assessing advanced performance levels in high seismic zones has encouraged the research towards a deeper understanding on the nonlinear cyclic behavior of the R/C panels [5–9].

All the while many investigations on nonlinear analysis of R/C panels by finite element methods have been carried out. The available studies are not reviewed here in details, nonetheless, in the opinion of the authors, they can be subdivided into two categories: some researchers developed very sophisticated models while others searched for simplified ones as it is clarified below.

The works of the first category focus their attention on addressing the general two-dimensional problem, by means of R/C nonlinear constitutive models belonging to the different frameworks; i.e. elasto/viscoplasticity [10–12], fracture theory [13, 14], continuum damage mechanics [15–17], smeared crack models [18], modified compression field theory [19–21], softened membrane models [22].

Some of the cited works found their way into modern computer codes, but they often turn out to be rather complex or excessively expensive from the computational point of view, especially if applied to large scale structures.

The models in the second category are less general and they are addressing specific problems as beam-column joint panel [23], macroscopic fiber based model for shear walls [24, 25] or enhanced beam model [26, 27]. These models are suitable for large scale structures but they can be applied only for moderate shear demand since they do not address all the physical issues in the case of significant biaxial membrane stresses. Because of these limitations, the use of such nonlinear methods for the R/C panel design and assessment do not seem to meet the challenges of the earthquake engineering practice.

The purpose of the present study is the development of a membrane model for R/C panels addressing the evaluation of strength and ductility under cyclic loading. The proposed model belongs to the first model category while being suitable for the analysis of large scale structures. The membrane under plane stress state conditions is defined by superposition of distinct concrete and reinforcing steel material models. The model takes into account only the axial response of the reinforcing bars [28]. The bond slip effects are not taken into account at the present stage as well as the stiffness and strength of the bars perpendicularly to their alignment. The selection of the damage mechanics as framework for the concrete constitutive law comes from its ability in describing concrete behaviors avoiding excessive complications in the numerical procedure for the material state determination. In order to study the cyclic behavior of concrete panels subjected to shear loading, it is necessary to introduce two damage parameters, that account for the two different concrete failure modes in tension and in compression [16, 28]. The model of Faria et al. [29], although notably efficient, was developed for massive concrete structure such as dams in which the influence of the plastic strain in tension is supposed to be very low. Thus the simplified plastic evolution law, that disregards the plastic strains for tensile stresses, cannot capture the progressive crack opening typical of a cyclic loading of R/C panels. A more general plastic evolution law, that is more accurate for plane

stress state problem, is proposed to reproduce the plastic strains for general stress configurations.

For what concerns the reinforcing steel material, the simulation of the Baushinger effect is important to estimate the dissipated energy in hysteretic cycles precisely. Thus the model of Menegotto-Pinto with isotropic hardening developed by Filippou et al. [30] is profitably used.

2 CONCRETE DAMAGE MODEL

2.1 The model fundamentals

The proposed concrete constitutive law belongs to the class of energy-based isotropic continuum damage models. The model presented in this work takes into account both tensile and compressive concrete failure modes, by means of two damage parameters, and also the micro-crack opening and closing, by considering the spectral decomposition of the stress tensor.

The damage and plastic unloading processes are assumed to be elastic. Reference is made to the paper of Ju [31] for the detailed explanation of the elastoplastic damage model framework and the adopted notations.

The split of the total strain tensor into “elastic-damage” and “plastic-damage” parts is assumed:

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^p \quad (1)$$

The locally averaged free energy potential is postulated according to the work of Faria et al. [29]:

$$\begin{aligned} \Psi(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}^p, d^+, d^-) &= (1 - d^+) \Psi_0^+(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}^p) + (1 - d^-) \Psi_0^-(\boldsymbol{\varepsilon}, \boldsymbol{\varepsilon}^p) = \\ &= (1 - d^+) \frac{1}{2} \bar{\boldsymbol{\sigma}}^+ : \boldsymbol{\varepsilon}^e + (1 - d^-) \frac{1}{2} \bar{\boldsymbol{\sigma}}^- : \boldsymbol{\varepsilon}^e \end{aligned} \quad (2)$$

where d^+ , d^- represent the positive and negative damage parameters respectively and $\bar{\boldsymbol{\sigma}}^+$, and $\bar{\boldsymbol{\sigma}}^-$ are the positive and negative part of the effective stress tensor defined by:

$$\bar{\boldsymbol{\sigma}} \equiv \mathbf{C}^0 : \boldsymbol{\varepsilon}^e \quad (3)$$

where \mathbf{C}^0 is the fourth-order elastic stiffness tensor.

During any physical process the energy dissipation shall be always non-negative in agreement with the first thermodynamic principle. This condition is expressed by the following Clausius-Duhem inequality that holds for any admissible process:

$$\dot{\boldsymbol{\varepsilon}} : \left[\boldsymbol{\sigma} - \frac{\partial \Psi}{\partial \boldsymbol{\varepsilon}} \right] - \left[\frac{\partial \Psi}{\partial d^+} : \dot{d}^+ + \frac{\partial \Psi}{\partial d^-} : \dot{d}^- \right] - \frac{\partial \Psi}{\partial \boldsymbol{\varepsilon}^p} : \dot{\boldsymbol{\varepsilon}}^p \geq 0 \quad (4)$$

With the total strain a free variable, the term within the first square brackets shall be always zero. Thus the definition of the relation between the Cauchy stress tensor and the effective stress tensor can be obtained:

$$\begin{aligned} \boldsymbol{\sigma} = \frac{\partial \Psi}{\partial \boldsymbol{\varepsilon}} = \frac{\partial \Psi}{\partial \boldsymbol{\varepsilon}^e} &= (1 - d^+) \frac{\partial \Psi_0^+}{\partial \boldsymbol{\varepsilon}^e} + (1 - d^-) \frac{\partial \Psi_0^-}{\partial \boldsymbol{\varepsilon}^e} = (1 - d^+) \bar{\boldsymbol{\sigma}}^+ + (1 - d^-) \bar{\boldsymbol{\sigma}}^- = \\ &= (\mathbf{I} - \mathbf{D}) : \bar{\boldsymbol{\sigma}} \end{aligned} \quad (5)$$

The second and the third terms of the Equation (4) provide the damage and the plastic dissipation inequalities:

$$-\frac{\partial \Psi}{\partial d^+} : \dot{d}^+ - \frac{\partial \Psi}{\partial d^-} : \dot{d}^- = -\frac{\partial \Psi}{\partial \mathbf{d}} : \dot{\mathbf{d}} \geq 0 \quad (6)$$

$$-\frac{\partial \Psi}{\partial \boldsymbol{\varepsilon}^p} : \dot{\boldsymbol{\varepsilon}}^p \geq 0 \quad (7)$$

The reader is referred to the work of Faria et al. [29] that contains the demonstration of the validity of these inequalities.

Starting from the stress-strain relation of Equation (5), the fourth-order damage tensor \mathbf{D} can be defined by the following expression [32]:

$$\mathbf{D} = d^+ \mathbf{P}^+ + d^- \mathbf{P}^- \quad (8)$$

with \mathbf{P}^+ and \mathbf{P}^- standing for the fourth-order projection tensors, positive and negative respectively, that have the following definitions:

$$\mathbf{P}^+ = \sum_i H(\bar{\sigma}_i) \mathbf{p}_i \otimes \mathbf{p}_i \quad (9)$$

$$\mathbf{P}^- = \mathbf{I} - \mathbf{P}^+ \quad (10)$$

where H is the Heaviside step function, $\bar{\sigma}_i$ is the i -th principal stress of the effective stress tensor $\bar{\boldsymbol{\sigma}}$ and \mathbf{p}_i stands for the associated principal direction.

Then developing the Equation (6), the energy dissipated by the damage process shall be defined. The thermodynamic force, also called damage energy released rate, is expressed as:

$$-Y = \frac{\partial \Psi}{\partial d} \quad (11)$$

The damage energy release rate characterizes the damage evolution taking into account the progressive degradation of the mechanical properties of the material.

For the damage criteria, the damage energy release rate functions are defined with the following formulas:

$$Y^+ = \sqrt{E^0 \bar{\boldsymbol{\sigma}}^+ : \mathbf{C}^{0-1} : \bar{\boldsymbol{\sigma}}^+} \quad (12)$$

$$Y^- = \sqrt{3}(K \bar{\sigma}_{oct}^- + \bar{\tau}_{oct}^-) \quad \text{or} \quad Y^- = \sqrt{3}(K I_1 + \sqrt{J_2}) \quad (13)$$

where $\bar{\sigma}_{oct}^-$ and $\bar{\tau}_{oct}^-$ are the octahedral normal and shear stresses respectively (while I_1 and J_2 are the first invariant of the effective stress tensor and the second invariant of the deviatoric effective stress tensor), E^0 is the concrete Young modulus and K is a material property that accounts for the increase of compressive strength due to biaxial compression [29].

The energy release rate functions have also been called equivalent effective stresses $\bar{\tau}^+$ and $\bar{\tau}^-$ since they provide two scalar measures of the effective stress tensor [29].

With respect to the work in [29], the negative equivalent stress is defined slightly different so as to be homogeneous to the positive equivalent stress. As a result both the equivalent stresses have the same dimension of a stress component.

The damage threshold in uniaxial tension and uniaxial compression is described by variable r^+ and r^- , respectively, and they monitor the size of the expanding damage surface.

The numerical applications, carried out by the same authors, showed that the original damage criteria proposed by Faria et al. [29] agrees quite well with the experimental results for uniaxial, biaxial tension and biaxial compression stress states, whereas it has been demonstrated that improvements were necessary to better fit the experimental information for biaxial tension-compression states (see Figure 1).

A substantial improvement can be obtained by defining a unique damage criterion instead of two distinct ones in the earlier studies [29, 32].

Taking advantage from the homogeneity of the equivalent stresses, the following unique expression can adequately account for the interaction between tensile and compressive damage evolutions [36]:

$$g(Y^+, Y^-, r^+, r^-) = \left(\frac{Y^+}{r^+}\right)^2 + \left(\frac{Y^-}{r^-}\right)^2 - 1 \leq 0 \quad (14)$$

Figure 1: Initial elastic domain for plane stress states

The new damage criterion, that constitutes the damage surface, is superimposed to Faria's proposal in Figure 1.

It can be easily verified that, in the compression field ($Y^+ = 0$), the damage criterion becomes the modified Drucker-Pruger criterion and its suitability in representing biaxial stresses has been demonstrated by several studies [17, 29, 32].

In addition to the damage criterion the evolution of the damage threshold is determined by the following flow rule:

$$\dot{\mathbf{r}} = \dot{\gamma} \frac{\partial g(\mathbf{Y}, \mathbf{r})}{\partial \mathbf{Y}} \quad (15)$$

where γ is the damage consistency parameter. The relative Khun-Tucker conditions give:

$$g(\mathbf{Y}, \mathbf{r}) \leq 0 \quad \dot{\gamma} \geq 0 \quad \dot{\gamma} g(\mathbf{Y}, \mathbf{r}) = 0 \quad (16)$$

while the consistency condition is

$$\dot{\gamma} \dot{g}(\mathbf{Y}, \mathbf{r}) = 0 \quad (17)$$

The new damage threshold variables \mathbf{r} can be computed with the Newton-Raphson method assuring the quadratic convergence of the material state determination.

It can be underlined that the elliptical shape of the damage criteria assures independent evolution of the positive and negative damage threshold for uniaxial tensile and compressive tests respectively.

In fact the tangent of the damage criteria is orthogonal to the normal vector when one of the thermodynamic forces is null.

Four parameters are needed to determine the initial damage surface: r_0^+ and r_0^- are the initial elastic damage thresholds for uniaxial tension and compression loadings respectively, K takes into account the additional strength under condition of biaxial compression and ν is the Poisson modulus.

Three common lab tests are necessary to compute the value of those parameters [29]: an uniaxial tension experiment, an uniaxial and a biaxial compression ones.

Using the Equation (12), the positive damage initial threshold is exactly equal to the concrete tensile strength, that is assumed to characterized the end of the elastic domain in the constitutive stress-strain relationship:

$$r_0^+ = f_0^+ = f_{ct} \quad (18)$$

Since the compressive constitutive law ends the linearity before reaching the peak strength, the uniaxial initial elastic limit f_0^- shall be evaluated from the uniaxial compression test leading to the corresponding negative damage threshold from the Equation (13):

$$r_0^- = \frac{\sqrt{3}}{3}(K - \sqrt{2})f_0^- \quad (19)$$

From the results of a biaxial compression test, the biaxial compression elastic limit $f_{0,2D}^-$ can be obtained. Thus the parameter K , accounting for the increase of compressive strength due to biaxial compression, can be computed as

$$K = \sqrt{2} \frac{(f_{0,2D}^- - f_0^-)}{2f_{0,2D}^- - f_0^-} \quad (20)$$

The present constitutive model considers that damage criteria describes also the plastic surface so that the development of material damaging is simultaneous to the accumulation of irreversible strains for all the stress states.

Recalling the considerations of the work by Faria et al. [29] the following plastic evolution law is defined:

$$\dot{\epsilon}^p = \beta E^0 \frac{\langle \bar{\sigma} : \dot{\epsilon} \rangle}{\bar{\sigma} : \bar{\sigma}} \mathbf{C}^{0-1} : \bar{\sigma} \quad (21)$$

having introduced β for the plastic strain coefficient.

It is clear that the plastic strain evolution proposes several simplifications with respect to the “effective stress space plasticity” [31] used to couple the damage evolution and the plastic flows in the spirit of obtaining a powerful tool for large time consuming seismic analyses.

In fact the adopted law determines the efficiency of the procedure. The presented choice leads to have the direction of the plastic strain rate parallel to those of the total strain rate. The effect is to introduce a simplification in the coupling between damage and plasticity and thus eliminating the additional iterative cycles inside the material state determination procedure. A consequent accepted limitation is a low efficacy in predicting the dilatancy of the concrete. In the cases in which the dilatancy plays an important role, the proposed model can be suitably applied taking care of choosing a different plastic potential.

The damage parameter evolution laws can be defined and they shape the concrete constitutive behavior. The analyses presented in this paper have been carried out using the laws proposed by Wu et al. [32].

The elastoplastic damage tangent modulus in the effective stress space can be derived from the previous expressions

$$\bar{\mathbf{C}}^{\text{ep}} = \mathbf{C}^0 - \frac{(\mathbf{C}^0 : \mathbf{l}(\bar{\boldsymbol{\sigma}})) \otimes (\mathbf{C}^0 : \frac{\partial g}{\partial \bar{\boldsymbol{\sigma}}})}{\frac{\partial g}{\partial \bar{\boldsymbol{\sigma}}} : \mathbf{C}^0 : \mathbf{l}(\bar{\boldsymbol{\sigma}}) - \frac{\partial g}{\partial \mathbf{r}} \cdot \frac{\partial \mathbf{r}}{\partial \bar{\mathbf{Y}}}} \quad (22)$$

in which the following symbol

$$\mathbf{l}(\bar{\boldsymbol{\sigma}}) = \frac{\bar{\boldsymbol{\sigma}}}{\sqrt{\bar{\boldsymbol{\sigma}} : \bar{\boldsymbol{\sigma}}}} \quad (23)$$

has the physical meaning of the unit tensor parallel to the effective stress tensor.

2.2 Notes on integration algorithm

The concrete material state determination presents similarities to the classical plasticity return-mapping algorithm and it is quite straightforward.

The total strain is updated by the given incremental displacement field:

$$\boldsymbol{\varepsilon}_{n+1} = \boldsymbol{\varepsilon}_n + \nabla^s(\Delta \mathbf{u}) \quad (24)$$

And the trial elastic state is computed as

$$\bar{\boldsymbol{\sigma}}_{n+1}^{\text{trial}} = \mathbf{C}^0 : (\boldsymbol{\varepsilon}_{n+1} - \boldsymbol{\varepsilon}_n^p) \quad (25)$$

If the plastic-damage criteria is respected there is evolution neither of the plastic strain, nor of the damage thresholds, nor of the damage parameters:

$$\boldsymbol{\varepsilon}_{n+1}^p = \boldsymbol{\varepsilon}_n^p \quad (26)$$

$$\mathbf{r}_{n+1} = \mathbf{r}_n \quad (27)$$

$$\mathbf{d}_{n+1} = \mathbf{d}_n \quad (28)$$

and therefore the trial effective stress can be confirmed

$$\bar{\boldsymbol{\sigma}}_{n+1} = \bar{\boldsymbol{\sigma}}_{n+1}^{\text{trial}} \quad (29)$$

If the plastic-damage criteria is not respected it is necessary to use a return-mapping algorithm to update effective stress, plastic strain and plastic-damage thresholds such that the following equalities hold:

$$\bar{\boldsymbol{\sigma}}_{n+1} = \mathbf{C}^0 : (\boldsymbol{\varepsilon}_{n+1} - \boldsymbol{\varepsilon}_{n+1}^p) \quad (30)$$

$$\boldsymbol{\varepsilon}_{n+1}^p = \boldsymbol{\varepsilon}_n^p + \beta E \frac{\langle \bar{\boldsymbol{\sigma}}_{n+1} : \Delta \boldsymbol{\varepsilon} \rangle}{\bar{\boldsymbol{\sigma}}_{n+1} : \bar{\boldsymbol{\sigma}}_{n+1}} \mathbf{C}^{0-1} : \bar{\boldsymbol{\sigma}}_{n+1} \quad (31)$$

$$g(Y_{n+1}^+, Y_{n+1}^-, r_{n+1}^+, r_{n+1}^-) = \left(\frac{Y_{n+1}^+}{r_{n+1}^+} \right)^2 + \left(\frac{Y_{n+1}^-}{r_{n+1}^-} \right)^2 - 1 = 0 \quad (32)$$

The solution of the previous nonlinear equations requires an iterative scheme that can be solved by the Newton method using the elastoplastic damage tangent modulus of the Equation (22).

As a consequence the damage parameters can be calculated directly

$$\mathbf{d}_{n+1} = \mathbf{d}_{n+1}(\mathbf{r}_{n+1}, \mathbf{r}_0) \quad (33)$$

When the two alternative branches of the integration have been completed, the Cauchy stress is obtained from the following equation

$$\boldsymbol{\sigma}_{n+1} = (1 - \mathbf{d}_{n+1}) : \bar{\boldsymbol{\sigma}}_{n+1} \quad (34)$$

3 VALIDATION EXAMPLE FOR CONCRETE MATERIAL

Two simple numerical examples are reported in order to show the ability of the concrete damage model in reproducing the typical concrete behavior for 1D cyclic tests under tensile and compressive solicitations.

3.1 Cyclic uniaxial compressive loading test

In Figure 2 the experimental results, taken from Sinha et al. [33], are plotted against the numerical results. This experiment was already selected by Faria et al. [29], among others, to validate their model. The concrete material properties assumed for the model are derived from those reported by the authors of the experimental study: the compressive peak strength $f_c^- = 32$ MPa, the Young modulus $E = 26$ GPa, the compressive uniaxial initial elastic threshold $f_0^- = 15$ MPa, the plastic strain coefficient $\beta = 0.590$. The numerical model is very capable in reproducing the concrete nonlinear behavior. When the initial elastic limit is passed, the plastic strain and the damage parameter increase. The hysteresis of the reloading loop cannot be simulated by the model because of the rate-independent elastic loading/unloading assumption but the progressive degradation of the secant modulus fits the loading/unloading test curves on average very well.

Figure 2: Cyclic uniaxial compressive loading test

The values reached by the negative damage parameter at the maximum strain of each cycle are depicted in Figure 3. It can be noted that its value is about 0.2 when the compressive peak strength is achieved. After a strength decay of about 25%, the damage parameter approaches 0.6. A damage value equal to 1.0 means that the strength and stiffness of the material are completely lost. It should be underlined that the damage parameters are positive scalar values

that cannot decrease since they depend on the maximum recorded damage threshold. This implies that a damage parameter remains constant during an unloading/reloading cycle until the maximum effective stress is exceeded again.

Figure 3: Negative damage index evolution

3.2 Cyclic uniaxial tensile loading test

The comparison between the experimental data (Gopalaratnam and Shah [34]) and the numerical results by means of a simple element patch, 82.6 x 82.6 mm, is illustrated in Figure 4. Also Lee and Fenves [17] chose this test to showcase their plastic-damage model. The degradation of stiffness is simulated at each unloading/reloading cycle as well as the softening behavior.

Figure 4: Cyclic uniaxial tensile loading test

Attention should be focused on the residual strain after complete unloading. In fact the residual strain consistently increases even for relatively high strain and very low residual tensile concrete strength. The numerical model can capture very effectively this effect though the plasticity extended in the present work also for tensile concrete stresses. The residual strains in tension are quite important because they affect crack closure state at loading reversals and they become particularly evident for cyclic shear tests of reinforced concrete membranes.

On the contrary, the gap between the experimental curve and the numerical one immediately after the peak strength does not condition the effectiveness of the model for the purposes of the present work because of two reasons: the difference of the two curves is relatively insigni-

ficant in terms of dissipated energy having the concrete material a very low tensile peak strength compared to the compressive one; the post crack behavior for reinforced concrete elements subjected to tension is characterized by the steel response and by the narrow tension stiffening effect.

The evolution of the positive damage parameter is shown in Figure 5. The damage parameter increases drastically at the beginning of the softening branch and then it approaches the unit asymptotically since the depletion of the fracture energy take place at strains much larger than the elastic limit.

Figure 5: Positive damage index evolution

4 R/C MEMBRANE MODEL

The general three-dimensional concrete model has been developed in a plane stress state to represent the behavior of concrete panels.

Several choices are possible in order to reproduce the reinforcements. The simplest model considers the use of different finite elements for the reinforcing bars joining the concrete panels at the nodes (discrete approach). The main drawbacks of this choice are the need of introducing a steel element for each reinforcement position and the difficulty of introducing bars inclined differently respect to the panel mesh.

The proposed model considers the superposition of different material models to create the membrane model (embedded approach). Thus the reinforcements shall be represented as smeared since the overall behavior of the membrane shall comply with the panel kinematic. As a result the equivalence of the total strains of the different material is imposed. From the physical point of view this is equal to assume a perfect bond between concrete and reinforcing steel. Each steel layer can reproduce the behavior of a set of bars aligned to a generic direction respect to the element principal axis. As a simple generalization a steel layer can simulate the response of a reinforcement net with bars disposed in two orthogonal directions.

An important benefit of the membrane model is the possibility to reproduce all possible reinforcement configurations by simply adding the appropriate number of layers.

The model could be further extended to take into account the bond slip between the two materials at the cost of additional computational effort.

If a steel layer represents one set of parallel rebars, it has an uniaxial stress response in the direction of the bars. On the contrary, a net with bars in two orthogonal directions is simulated by a biaxial orthotropic stress response.

In the first case, the reinforcing layer state determination starts with the projection of the generic total strain tensor in the direction of the bars. Without losing in generality that direction is denoted by its cosine directors \mathbf{u} .

The total strain along the steel bar is easily obtained as:

$$\varepsilon_\varphi = \boldsymbol{\varepsilon} \mathbf{u} \cdot \mathbf{u} \quad (35)$$

that is used to compute the uniaxial steel material state determination by using the reinforcement constitutive law. In the present work the Menegotto-Pinto law with the isotropic hardening introduced by Filippou et al. [30] has been profitably selected for its ability to evaluate precisely the hysteretic behavior of the reinforcing steel.

The material state in terms of steel stress and tangent modulus are therefore re-projected in the original element reference frame:

$$\boldsymbol{\sigma}_s = \sigma_\varphi (\mathbf{u} \otimes \mathbf{u}) \quad (36)$$

$$\mathbf{C}_s = C_{s,\varphi} (\mathbf{u} \otimes \mathbf{u} \otimes \mathbf{u} \otimes \mathbf{u}) \quad (37)$$

These layer responses are added to those coming from the other concrete and steel layers. It can be underlined that the membrane model can be applied to any two-dimensional finite element. The authors have carried out several analyses running different elements i.e. four-node and nine-node quadrilateral and six-node triangular.

5 QUASI-STATIC EXAMPLES FOR THE R/C MEMBRANE MODEL

5.1 Examples of deep beams

The well known reinforced concrete beams tested by Leonhardt and Walther [35] are selected to validate the proposed model. Table 1 summarizes their geometry and the reinforcing steel. They are simply supported beams with two concentrated vertical loads symmetric respect to the beam midspan. The beams are characterized by the absence of shear reinforcement and a constant longitudinal reinforcement ratio of $\rho = 2.0\%$.

Beam ID	L (mm)	a (mm)	h (mm)	b (mm)	a/d	ρ (%)
T4	1700	670	320	190	2.5	2.0
T5	1950	810	320	190	3.0	2.0
T6	2350	1080	320	190	4.0	2.0
T7	3100	1350	320	190	5.0	2.0
T8	3600	1620	320	190	6.0	2.0
T9	5800	1890	320	190	7.0	2.0
T10	4700	2160	320	190	8.0	2.0

Table 1: geometry and reinforcement of the beams

The shear span-to-depth ratio a/d conditioned the experimental failure mode: flexural failure took place for high ratios while shear failure occurred for low ratios. In particular the transition from flexural to shear failure can be distinguished for $a/d = 6$.

The experimental setup has been numerically simulated. The constitutive laws of the concrete and steel have been calibrated using the parameters of Table 2, starting from the material mechanical properties of the specimens [35].

In Figure 6 the experimental failure loads are compared with the one related to the theoretical flexural strength and with those obtained by the numerical membrane model. The good

agreement between the experimental and the numerical values confirms the accuracy of the non linear model.

Figure 6: Comparison between experimental and numerical results for the failure load vs. span to depth ratio

Concrete		Reinforcing steel	
Young modulus	36 GPa	Young modulus	190 GPa
Poisson coefficient	0.15	Yielding strength	360 MPa
1D compr. strength	28.0 MPa	Hardening modulus	3 GPa
2D compr. strength	33.6 MPa		
1D compr. elastic threshold	18.2 MPa		
1D tensile strength	2.0 MPa		

Table 2: material model parameters used for the numerical analysis

Figure 7: Numerical load vs. displacement curves of the beams

Figure 7 shows the load vs. displacement curves obtained by the numerical models. The corresponding experimental curves were not reported by the test authors.

The curves for the beam T9 and T10 show high plastic deformations, after the longitudinal bar yielding characteristic of a flexural failure mode, whereas the remaining beams with lower span-to-depth ratios suffered shear failure as the abrupt termination of their curves demonstrates.

The specimen T4, with the lowest $a/d = 2.5$, showed a so-called “shear compression failure” that is the crushing of upper compressed concrete area due to the progressive development of the diagonal cracks induced by shear stresses under the point of load application. The experimental failure occurred at the load of 87.5 kN, while the numerical simulation provides a corresponding value of 83 kN. This beam characterizes the deepest point for the “shear valley” of the specimen set having a reduction of the failure moment equal to the 53% of the theoretical flexural value.

5.2 Example of R/C panels

The new model has been validated by comparison with several experimental results on reinforced concrete panels from the literature.

In particular all the specimens presented by Mansour and Hsu [8] have been considered. The comparison has been even more significant thanks to the kind availability of Professor Hsu to produce the experimental measured data upon request.

These R/C panels were submitted to increasing amplitude cyclic load reversals of pure shear solicitations in their mid-plane by means of the “Universal Panel Tester” at the University of Huston (Texas, USA). The loads had been applied uniformly on the panels edges.

The reinforcement had been placed in different directions respect to the solicitation principal axes and with variable ratios for each panels.

Table 3 recalls the main panel properties while the exhaustive specimen description can be found in the work of the test authors [8]. The symbols assume the following meanings:

- f'_c compressive strength of cylindrical concrete specimen;
- α_2 angle between the vertical specimen direction and the \mathbf{l} reinforcing bar one;
- ρ_l reinforcement ratio in \mathbf{l} direction;
- f_{ly} tensile yielding strength of reinforcing bar in \mathbf{l} direction;
- ρ_t reinforcement ratio in \mathbf{t} direction (at 90° respect to \mathbf{l} direction);
- f_{ty} tensile yielding strength of reinforcing bar in \mathbf{t} direction.

The specimens had been loaded through cyclic load reversals under load control before the yielding strength and under displacement control for further cycles. During this last part the shear deformation has been used as controlling parameter and the shear strain values are multiple of the yield shear strain.

Panel ID	f'_c	α_2	ρ_l	f_{ly}	ρ_t	f_{ty}
CA2	45.0	45.0°	0.0077	424.1	0.0077	424.1
CB3	48.0	45.0°	0.0170	425.4	0.0077	424.1
CD3	47.0	68.2°	0.0130	425.3	0.0130	425.4
CF2	44.0	79.8°	0.0056	424.1	0.0056	424.1
CE3	50.0	90.0°	0.0120	425.4	0.0120	425.4

Table 3: Mechanical properties of the panel materials

The pure shear solicitation had been applied by imposing normal stresses equal in absolute value but opposite in sign along the vertical and the horizontal directions of the specimens.

The applied loads and the panel averaged strains had been measured by load cells placed on each jack and by displacement transducers over a length traversing several cracks.

In order to verify the accuracy of the numerical model and thanks to the availability of the experimental data, the numerical results are compared to the specimen ones.

In sake of brevity the results of one panel for each series of bar inclination are presented in terms of shear stress vs. shear strain response (see from Figure 8 to Figure 12).

The specimens identified by CA2, CB3, CD3, CF2, CE3 are considered in decreasing order of angle amplitude between the rebar directions and the principal stress ones.

The letter A stands for an angle between the steel bar orientation and the vertical principal stresses equal to 45° . The specimen CA2 has equal reinforcement ratios of 0.0077 in both the net directions. The experiment authors have reported that an “out of stroke” happened at the end of the test. That inconvenience had inevitably conditioned the data recorded in the last load cycles both for positive and negative shear stresses (see Figure 8). Thus the strength decay, in the last cycles, was not caused by the panel failure but rather by the insufficient push of the jacks. It is confirmed by the same authors when they admit that the ductility of the panel CA2 shall be considered higher than that recorded because the collapse of the panel was not reached due to “equipment limitations”.

Figure 8: Comparison between experimental and numerical results of the specimen CA2 for shear stress vs. shear strain response

The behavior of the specimen has been rather correctly simulated in terms of fracture load, shear strength, ductility of the panel, pinching effect of the hysteretic curve.

Since the bar net is inclined of 45° respect to the principal stress directions, all the reinforcements bear the tensile loads in both the principal directions with equal stresses. This leads to a progressive delay in recovering the stiffness and the strength at load reversals as far as the plastic strain increases. Even if the numerical model cannot account for the crack interlocking and the progressive stiffness recovering of the specimen, nonetheless it can fairly simulate the stiffness recovering in the average.

The tension stiffening effect does not seem to be captured by the numerical model, but also the experimental data appear to be definitely unstable.

The unloading stiffness of the model is lower than the specimen one after the yielding conditions. This evidence is likely due to the inability of the model to account for bar bond slip and bar dowel action effects.

The specimen CB3 has reinforcement ratios equal to 0.0077 and 0.0170 in the two rebar directions aligned again at 45° respect to the principal stress ones. The experiment authors did not have reported any inconvenience occurred during the test. The numerical model shows good results referring in particular to the cyclic response envelope that includes (see Figure 9): the initial stiffness, the yielding load, the peak strength and the compressive concrete failure. The unloading stiffness seems underestimated especially after the concrete crushing as for the previous example.

Figure 9: Comparison between experimental and numerical results of the specimen CB3 for shear stress vs. shear strain response

Figure 10: Comparison between experimental and numerical results of the specimen CD3 for shear stress vs. shear strain response

The specimen CD3 has the bar inclination angle equal to 68.2° and a reinforcement ratio of 0.0130 in both the net directions. The strength reduction of the specimen in the cycles can be attributed to the panel failure and the panel ductility had been accurately described. No comment was pointed out by the experimenters on the equipment functioning even though the strain transducers show a certain instability both in the loading and unloading cycle branches. The measured strength turned out to be markedly non symmetric for the positive and negative shear values. Such evidence is not justified by any specimen theoretical asymmetry and it can be caused by an unknown realization fault in the test geometrical configuration. The response of the numerical model is necessarily symmetric and it fits very well the envelope for the negative shear stresses being able to simulate the concrete cracking, the post-cracking loading stiffness, the yielding strength, the maximum ductility determined by the compressive concrete crushing and the pinching effects of the hysteretic curve. The panel progressive cracking phase does not seem to be fully captured even if the experimental data look quite asymmetric and partially unstable.

Figure 11: Comparison between experimental and numerical results of the specimen CF2 for shear stress vs. shear strain response

Figure 12: Comparison between experimental and numerical results of the specimen CE3 for shear stress vs. shear strain response

The CF2 panel is the only panel with an angle of 79.8° between the steel net and the principal stress axes and the reinforcement ratio is 0.0056 in both the directions. The numerical model describes accurately the specimen behavior being able to catch the cracking load, the yielding strength, the ductility and the dissipation capacity (see Figure 11). As it is shown by the present example, but it can be noted in general, the proposed model provide an estimation of the dissipated energy that is lightly less than the real one. This fact might be caused by the hypothesis of disregarding the bond slip phenomenon and by considering only the axial response of the reinforcing bars. In compensation the numerical procedure is quite efficient and it is suitable for application to large scale structures. Furthermore a light underestimation of the dissipated energy is pro-safety in executing nonlinear seismic analyses.

The example of the last series is the panel CE3 which has the reinforcing bars parallel to the applied principal stresses and a symmetric reinforcement ratio equal to 0.0120. The test authors reported that the ductility of the specimen could not have completely exploited since the maximum lengthening of the jacks was reached. The experimental data show an unexplained minor asymmetry concerning the last two reloading negative branches of the global response as it can be seen from Figure 12. Nonetheless the example show clearly how the numerical model can reproduce precisely the recorded panel behavior in all its features such

as, for instance, the yielding strength and the following hardening behavior, the unloading stiffness and the residual deformation at load reversals and energy dissipation capacity.

In order to further investigate in the response of the numerical model for the last example, other two responses are herein presented: the vertical strain vs. horizontal strain curve and the vertical normal stress vs. the corresponding vertical strain one (see. Figure 13 and Figure 14).

Figure 13: Comparison between experimental and numerical results of the specimen CE3 for vertical strain vs. horizontal strain response

Figure 14: Comparison between experimental and numerical results of the specimen CE3 for vertical normal stress vs. vertical strain response

It can be noted that the axial strains are evaluated with high accuracy. This shall not be considered an automatic consequence of imposing the shear strain in the cycles after the panel yielding. In fact the shear strain compels only the difference between the positive and the negative axial strains but not their values separately.

The progressive expansion of the panel due to the accumulation of plastic strain is correctly captured by the proposed model. The gap between the two curves visible in the central part between following tips is explained by the sudden closure of the cracks in the numerical model, whereas the experiment exhibits a progressive stiffness recovery due to local effects occurring when the opposite irregular surfaces of a crack move close again. This fact is evident also comparing the vertical stress-strain response depicted in Fig. 14.

It is important to notice that the strain data are computed from dilatation measures over several crack distances leading to averaged values while the numerical response is punctual and would properly represent the behavior of a cracked section.

6 CONCLUSIONS

- An efficient two parameter concrete plastic damage model has been developed that is suitable for the simulation of large scale structural models with RC panels.
- The validation examples have confirmed the ability of the concrete material to simulate the nonlinear cyclic behavior of concrete under tensile and compressive strains.
- A straightforward formulation of a R/C membrane model has been proposed by superimposing different materials, concrete and reinforcing steel, to create a single membrane model with smeared reinforcement of general orientation.
- The well-known Leonhardt beams are simulated to point out the efficiency of the model in reproducing the transition from flexural to shear failure mode for deep beams. The membrane model has been able to correctly predict the “shear valley”.
- A second set of simulation of R/C panel is carried out. The examples show clearly the ability of the proposed model to reproduce the main features of the experimental panel behavior such as: the yield strength, the subsequent hardening/softening behavior, the residual deformation at load reversals and energy dissipation capacity.

ACKNOWLEDGEMENT

The authors warmly thank Professor T.T.C. Hsu for making available the experimental data obtained in the Structural Research Laboratory at the University of Houston (Texas, USA).

Key words: Seismic shear forces, Shear magnification factor, Multi-storey precast structures, Multi-storey cantilever columns, Eurocode 8.

Abstract. *Seismic shear force magnification in the columns of multi-storey precast structures entering far into inelastic domain is addressed in the paper. Such structures consist of an assemblage of cantilever columns connected with ties. Considering analogy with cantilever walls, it has been expected that during inelastic response the actual shear forces in multi-storey cantilever columns could be considerably higher than the forces foreseen by traditional equivalent elastic analytical procedures (equivalent lateral force or modal spectrum).*

A parametric study of a set of realistic three-storey structures/columns was performed. These structures were designed according to Eurocodes and shear forces were determined by the equivalent elastic (modal spectrum) analysis. Average values of the shear forces obtained by the inelastic response analysis were compared to those of the traditional (modal spectrum) procedure. They were also compared to magnified shear forces predicted using the shear magnification factor ε suggested in Eurocode 8 for RC ductile walls. In parallel, modelling issues related to the inelastic response analysis of multi-storey cantilever columns were also discussed.

Very large seismic shear force magnifications (up to 3 times and more) were observed. Therefore it is essential to account for this phenomenon in the seismic (capacity) design of cantilever columns in multi-storey precast buildings. It was demonstrated that for this purpose the expression given in Eurocode 8 to account for seismic shear force magnification in ductile cantilever walls could be used with some minor modifications.

1 INTRODUCTION

Precast buildings house a predominant share of industrial facilities in many European countries. The most common precast system in Europe has been using dowel joints providing hinged connection between the beams and columns. Therefore such structures behave essentially as an assemblage of cantilever columns with ties. Up to now many precast industrial buildings have been one-storey structures. In such structures the capacity design for shear in the columns and joints is straightforward. However, recently the multi-storey structures are emerging as competitive market potential in the reinforced concrete construction sector. Question arises how to perform seismic (shear) design of multi-storey cantilever columns entering far into inelastic domain. Indeed, considering analogy with cantilever walls [1 – 6] and the results of the PRECAST [7] and SAFECAST 7th EU Framework research projects, a considerable dynamic magnification of shear forces during inelastic response has been expected. The main reasons for the shear magnification are the following:

- **Overstrength:** a consideration of simple equilibrium shows that the design seismic shear forces increase proportionally to the flexural overstrength.
- **Period shift:** Due to the softening of the structure in the inelastic range, the first mode spectral acceleration value typically diminishes, whereas the spectrum values for the higher modes (having the natural period at least 6 times lower than that of the first mode) usually remain in the plateau of the spectrum. The relative influence of the higher modes therefore increases in the inelastic range.
- **Amplified influence of higher modes:** The first mode seismic forces contribute most of the overall seismic moment at the base of the cantilever, which is limited by its flexural resistance. Energy dissipation is therefore predominantly limited to the flexural response in the first mode. Consequently, the first mode shear forces are reduced due to the energy dissipating mechanism, whereas the shear forces due to the higher modes are not. This significantly increases the relative contribution of the higher modes to the shear force which occurs during the inelastic response.

The increased relative importance of higher modes lowers the position of the resultant of the seismic forces closer to the base of the wall (Figure 1). With the given bending moment at the base, which is equal to the flexural capacity of the column, it is obvious that the resultant seismic force (shear force) should increase.

Figure 1 - Higher modes effects on the distribution of lateral forces and base shear

Since in the present design practice this increase in shear forces is frequently not considered properly, there is a danger of brittle shear failure, both in the column and in the connections at each storey.

The capacity design for shear in single storey cantilever columns is straightforward. Since there is no influence of the higher modes, only overstrength has to be considered. The maximum expected shear force is therefore simply obtained by dividing flexural moment capacity at the base by the height of the column. However, in the case of multi-storey cantilevers, the distribution of the moment over the height of the column is not known and it also changes during the response (see Figure 2(a) and 2(b)).

Figure 2 – Typical moment diagram shape in frame and cantilever multi-storey column

So designers are facing serious problem how to perform the capacity design of columns and connections required by Eurocode 8 [8] in order to preclude the brittle failure of these key components of the structural system. Contrary to the case of RC structural walls, the problem of the shear magnification in the multi-storey cantilever columns in RC precast structures has not been explicitly addressed in the current version of the Eurocode 8. It has been believed by the authors that appropriately modified shear magnification factors defined in Eurocode for structural walls could be also used for multi-storey cantilever columns in precast buildings.

To address the problems mentioned in the previous paragraph, a parametric study of the inelastic response of realistic three-storey cantilevered multi-storey precast buildings, designed according to Eurocode 8, was made [9]. The configuration of the building was defined by the three-storey building prototype which is being pseudo-dynamically tested in the European Laboratory for Structural Assessment in Ispra within the frame of the SAFECAST research project (coordinated by the Association of the precast producers in Italy ASSOBETON). Shear forces obtained during the inelastic response were compared to those predicted by traditional equivalent elastic design procedures to evaluate the expected shear magnification. Finally the shear magnification factor (ε) used in Eurocode for shear walls was tested in the case of multi-storey cantilever columns in precast structures.

2 MODELLING ISSUES

As shown before (see cases “a” and “b” in Figure 2), moment diagram shape can vary considerably during the response of the analysed structural systems. Since in lumped plasticity models it is assumed that the moment distribution along the element does not change during the time, the use of only one lumped plasticity element per storey is precluded or at least questionable. Several models were studied to overcome this problem. Two relatively simple models could yield appropriate solution. One is using several lumped plasticity elements per storey (Figure 3) and the other is based on the fiber approach.

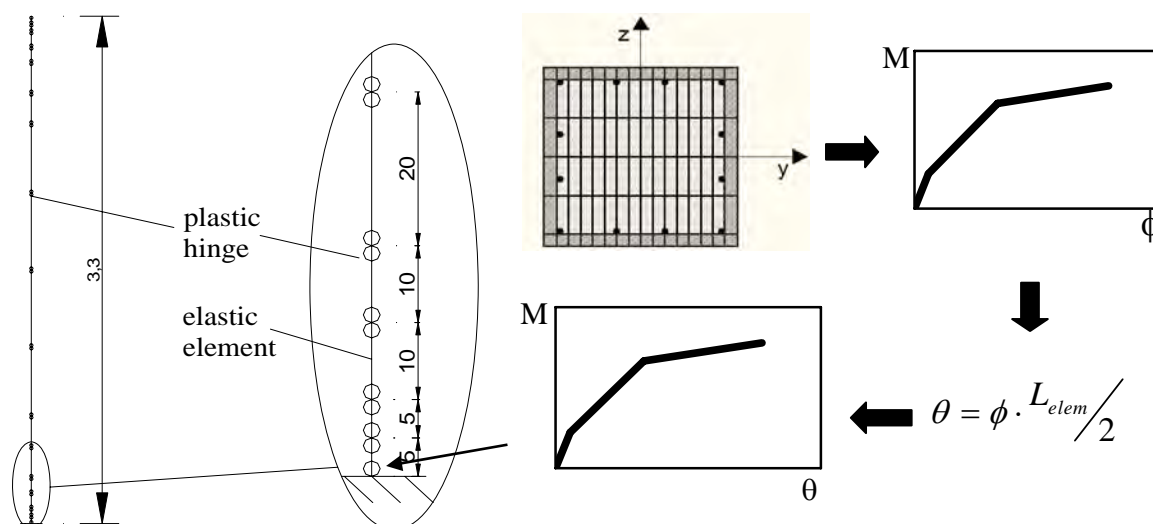

Figure 3 – Analytical model with several lumped plasticity elements per storey (bending in $x - y$ plane is considered only)

Both models were extensively tested to check their efficiency and first of all their numerical stability. Finally the model with several short lumped plasticity elements per storey was chosen. This model did not exhibit larger problems with numerical stability opposed to the fiber element which was strongly dependent on the number of the integration points and the influence of the second order theory effects. In addition to the pure flexural behaviour (described by both models) some other phenomena (like slip of the reinforcement and deformability due to the shear cracking) can be approximately (empirically) included into the hysteretic rules used in the lumped plasticity model.

3 PARAMETRIC STUDY

3.1 Description of the analyzed structures

The actual shear magnification factors were determined by inelastic response analyses on five three-storey cantilevered structures, typical for the construction practice in Europe. The height of the typical storey was $3.2m$.

Due to the hinged beam-column connections and assuming floors being rigid in their own plane, buildings were modelled as single multi-storey columns. To each of the five buildings/columns different value of the normalized axial force ν_d ($0.05 \leq \nu_d \leq 0.20$) was assigned to reflect actual spans and loads used in practice (Table 1). Only the highest value (0.20) tends to be unrealistic due to the drift limitations. However it was included in the research just to study the general trends of the results. Square section $80 \times 80cm$ was chosen for the column, while masses (assumed to be the same at each floor) and fundamental periods depended on the level of normalized axial forces.

The buildings were designed according to Eurocode 8, using standard design procedures based on the results of the equivalent elastic spectrum modal analysis ($a_{g,max} = 0.25g$ and Soil Type B) considering one half of the inertia characteristics of the uncracked sections. The same reduction as for DCH cast-in-situ frames ($q = 4.5$) was assumed [10]. Concrete C45/55 and steel B450C was used in the design.

v_d [-]	m [t]	A_{inf} [m ²]
0.05	32.6	45.7
0.075	48.9	68.6
0.10	65.2	91.4
0.125	81.6	114.3
0.20	130.5	182.9

Table 1 – Normalized axial force, floor mass and influence area (assuming distributed storey weight of $w=7\text{kN/m}^2$) of the five analyzed buildings

The response history analyses were performed using OpenSees [11] with a set of 9 accelerograms, matching the EC8 spectrum for $a_g = 0.25g$ and Soil Type B (Figure 5). These accelerograms were obtained by the modification of the actual accelerograms recorded in Europe. Again the mean spectrum of these recorded accelerograms matched the EC8 spectrum (Figure 4). Five percent mass and current stiffness proportional Rayleigh damping was considered in the first and second modes.

Figure 4 - Spectra of the recorded accelerograms (note that the mean spectrum matches the EC8 spectrum very well)

Figure 5 – Normalized spectra of the modified accelerograms matching EC8 – Soil B spectrum

3.2 Results for the shear magnification factors

Figure 6 shows the shear magnification factor (the ratio between the shear forces obtained by the inelastic analyses and those obtained by the equivalent elastic spectrum modal analysis) for the five investigated structures, which are denoted using the corresponding normalized axial force value v_d .

For each structure, three different assumptions regarding stiffness of the columns and overstrength were considered in the inelastic response analyses. In Figure 6 the circles denote results of the model based on the actual stiffness during response (model 1). Squares indicate the results obtained with the inelastic analysis using the bilinear model having the same initial stiffness as it had been used in the design – model 2 (one half of the inertia characteristics based on the uncracked section were used). Model 3 (triangles) is basically the same as Model 2, except for the overstrength, which is not considered.

Figure 6 - Shear magnification ratios evaluation for the five analyzed structures using different stiffness/overstrength models

As clearly shown in Figure 6, the actual shear forces induced during the inelastic response of multi-storey columns in typical precast industrial buildings are much higher (2 to 4 times) of those predicted with equivalent elastic procedures commonly used by the design engineers! So the shear forces provided by standard computer design programs, using the reduced seismic forces, grossly underestimate actual shear demand if they are not appropriately corrected. Fortunately in these slender columns the absolute value of the shear forces predicted by traditional methods is typically quite low. However, when multiplied with a factor up to 4 to obtain the actual level of shear forces, it becomes clear that this problem calls for serious attention. Therefore, to avoid brittle failure of the columns and/or in the beam-to-column connections it is essential to account for this phenomenon in the capacity design of cantilever columns in multi-storey precast buildings.

It can be further observed that:

- The shear force magnification is much larger if the same initial stiffness as in the case of design (one half of that obtained for the uncracked gross section – squares in Figure 6) is used also in the inelastic analysis. Considering the actual/realistic stiffness degradation due to cracking (up to 4 times in the case of elements with small to moderate compressive axial force) the shear increase is smaller (circles in Figure 6).
- If the effect of overstrength is eliminated (Model 3; triangles in the Figure 6) the magnification is still high (over 2). This demonstrates that, at least in the case of the analyzed buildings, the effect of higher modes on the shear magnification is predominant.

4 PROPOSAL OF THE DESIGN SHEAR MAGNIFICATION FACTOR

Eurocodes [8] already provide a shear magnification factor ε for RC ductile walls, while for multi-storey precast structures this problem is not properly addressed in the current codes as well as in the literature.

The ε factor for walls is used in Eurocode to multiply the values obtained by the linear-elastic lateral force or modal response spectrum analysis. For walls which enter far into the inelastic range (ductility class “high”), large shear magnifications are expected, and the factor ε should be calculated using the expression proposed by Keintzel [2], which explicitly takes into account the effects of higher modes in the inelastic range as well as flexural overstrength:

$$\varepsilon = q \cdot \sqrt{\left(\frac{\gamma_{Rd}}{q} \cdot \frac{M_{Rd}}{M_{Ed}}\right)^2 + 0.1 \cdot \left(\frac{S_e(T_C)}{S_e(T_1)}\right)^2} \begin{cases} \leq q \\ \geq 1.5 \end{cases} \quad (1)$$

where:

q is the behaviour (seismic force reduction) factor used in the design;

M_{Ed} is the design bending moment at the base of the wall;

M_{Rd} is the design flexural resistance at the base of the wall;

γ_{Rd} is the model uncertainty factor on design value of resistances accounting for various sources of overstrength;

T_1 is the fundamental period of vibration of the building in the direction of shear forces;

T_C is the upper limit period of the constant spectral acceleration region of the spectrum;

$S_e(T)$ is the ordinate of the elastic response spectrum.

Although Keintzel's expression for the shear magnification factor in RC structural walls has been based on a series of quite crude assumptions and approximations, like superposition principles in inelastic range, it was demonstrated by numerical tests that it has been working fine [6, 12]. It has been believed by the authors that a similar modified expression for the ε factor could be used also in the case of RC multi-storey columns in precast structures.

In the study, the values of the seismic design shear forces (denoted as V_{Ed}), evaluated by applying ε to the base shear resulting from the SRSS analysis, are compared with those obtained by inelastic response history analysis (denoted as V_{an}). The ratios V_{Ed}/V_{an} are illustrated in Figure 7.

If ε is applied to the base shear determined by the contribution of the first mode only (white dots in Figure 7), as originally intended by Keintzel, the magnification is very well estimated (note that $v_d = 0,20$ is not realistic in practical design). The proposed factor is slightly conservative, which makes it suitable for design purposes.

Most computer programs would, however, output the total base shear based on the contribution of all the considered modes. It is therefore most likely that designers will tend to apply ε to the total shear forces. This would be somewhat (up to 1,5 times) conservative (see black dots in Figure 7). An alternative solution is to propose a modified magnification factor, which is still under investigation.

It should be also noted that:

- The equivalent elastic shear forces were calculated based on the inertia of the cracked concrete sections equal to one half of the uncracked gross section. In this way the actual stiffness of the typical precast columns is overestimated. Therefore if the designer opts to use realistic (calculated) yielding stiffness in design, the proposed ε factor may be unconservative.
- It is suggested in Eurocode 8 that the overstrength factor $\gamma_{Rd} = 1.2$ should be used in Keintzel's formula for structural walls. In the presented study the actual overstrength factor for the analysed columns was closer to 1,3. If considered, the proposed factor will be slightly more conservative.

Figure 7 – Design base shear evaluated according to Keintzel's factor compared to actual base shear resulting from dynamic analysis

5 SELECTED IMPORTANT RESULTS OF THE RELEVANT AND/OR ONGOING RESEARCH

Some other relevant conclusions of the research, which are not discussed in detail in this paper include (see [9] for additional information):

- A short study on a hypothetical 10-storey building suggested that the same base shear magnification factor could be used also for buildings higher than 3-storeys.
- ϵ factor was originally proposed for the base shear and all the above conclusions and discussions apply for the base shear. However, it was demonstrated (though by the study, which was limited in scope) that the same factor could be used over the entire height of the column (at least in the case of 3-storey buildings).
- Local shear magnification can be very critical for the design of the dowel beam-to-column connections. In particular in the first storey the design force on the connection could be underestimated up to 10-times if proper magnification was not considered.

6 CONCLUSIONS

The actual shear forces in multi storey cantilevered structures due to seismic loads are considerably higher than the forces foreseen by the equivalent linear-elastic lateral force analysis, or by the modal response spectrum analysis specified in the codes. Simply said, this magnification occurs due to flexural overstrength and the amplified effect of the higher modes in the inelastic range.

In this study five realistic three-storey cantilevered structures, typical for the construction practice in Europe and designed according to Eurocode provisions were tested. The actual shear magnifications were determined by the inelastic response analyses as well as compared with the values obtained by the EC8 (Keintzel's) shear magnification factor, valid for RC structural walls.

Two main conclusions have been made:

- 1) It has been demonstrated that the actual shear forces induced during the inelastic response of multi-storey cantilever columns in typical precast industrial buildings are much higher (2 to 4 times) of those predicted with equivalent elastic procedures commonly used by the design engineers. So the shear forces provided by standard computer design programs using the reduced seismic forces grossly underestimate actual

shear demand if they are not appropriately corrected. Therefore to avoid brittle failure of the columns and/or in the connections, it is essential to account for this phenomenon in the capacity design of the cantilever columns in multi-storey precast buildings. However, neither Eurocodes, nor national seismic codes explicitly require appropriate seismic shear magnification for such columns. Related capacity design procedures are also not defined.

- 2) It has been demonstrated that the similar shear magnification factor as proposed in Eurocode 8 for ductile (DCH) RC structural walls can be used also in the case of multi-storey cantilever columns in precast buildings:

$$\varepsilon = q \cdot \sqrt{\left(\frac{\gamma_{Rd}}{q} \cdot \frac{M_{Rd}}{M_{Ed}}\right)^2 + 0.1 \cdot \left(\frac{S_e(T_C)}{S_e(T_1)}\right)^2} \begin{cases} \leq q \\ \geq 1.5 \end{cases} \quad (2)$$

This factor primarily depends on (a) the flexural overstrength and (b) the magnified contribution of the higher modes during inelastic response.

The above results strictly apply for the base of the analyzed 3-storey structures. However, in parallel research the conclusions were generalized also to higher buildings as well as for the shear forces along the entire height of the column.

ACKNOWLEDGEMENT

Part of the Graduation dissertation of Crescenzo Petrone, done in the frame of the research collaboration of the University of Ljubljana and the University of Napoli "Federico II" is presented in this paper. The structures analyzed in the numerical study are based on the prototype structure being tested in ELSA in Italy in the frame of the EU research project SAFECASST coordinated by ASSOBETON. The advice provided by Klemen Rejec, Ph.D. student at the University of Ljubljana is gratefully acknowledged.

Keywords: Bond Slip, Bond Strength, Reinforcement, Large-Diameter Bars, Reinforced Concrete, Pull-out Tests, Cyclic Loading

Abstract. *The performance of reinforced concrete structures depends on the bond strength and bond-slip behavior between the concrete and reinforcing steel. Although the bond behavior of deformed bars has been extensively studied, there is little data available for large-diameter reinforcing bars under cyclic load reversals. As a result, current code specifications for the development lengths of reinforcing bars are largely based on experimental data obtained for bars with diameters of 36 mm or smaller. This paper presents an analytical model to describe the bond-slip behavior of reinforcing bars in well-confined concrete under monotonic and low-cycle fatigue loads. The model has been validated and calibrated with recently obtained experimental data from pull-out tests conducted on reinforcing bars with diameters of 36, 43, and 57 mm. It is successful in predicting the bond-slip behavior including the degradation of the bond strength and stiffness under monotonic as well as different cyclic load histories. This model has been implemented in an interface element in a finite element program. Analyses have been conducted with finite element models to estimate the minimum development length required for these large-diameter bars under a well-confined situation.*

1 INTRODUCTION

The performance of reinforced concrete (RC) structures depends on the composite action of the concrete and reinforcing steel, which relies on the bond between the two materials. When RC structures are subjected to earthquake loads, they may experience severe bond demands in regions where the reinforcement is anchored, e.g., in the foundation of a bridge column. Inadequate embedment lengths in these regions can lead to bond failures like those observed in bridge columns during the San Fernando (1971) earthquake, where the longitudinal reinforcement was pulled out from the foundation, as shown in Figure 1.

Figure 1: Pull-out of longitudinal reinforcement in bridge columns from foundations during the San Fernando (1971) earthquake [1]

For very large structural components, such as large bridge columns and piles, the use of reinforcing bars with diameters larger than 25 mm is common. This can avoid too close a bar spacing and allows the ease in concrete placement. However, despite the extensive studies carried out on the bond behavior of deformed bars, there is little data available on the bond strength and bond-slip behavior of large-diameter bars under cyclic load reversals. As a result, current code specifications in the United States for the development lengths of reinforcing bars are largely based on experimental data obtained for bar sizes of 36 mm or smaller, and they do not allow lap-splicing of bars with diameters larger than 36 mm because of the lack of experimental data [2].

This paper presents an analytical model to describe the bond-slip behavior of reinforcing bars embedded in well-confined concrete under monotonic and low-cycle fatigue loads. This model has been validated and calibrated with data obtained from pull-out tests recently conducted on bars with diameters of 36, 43 and 57 mm, which correspond to sizes #11, #14 and #18, respectively, in the United States. This study is part of an experimental and analytical investigation aimed to produce basic bond data and improved specifications on the required embedment length of column reinforcement extended into drilled shaft foundations.

2 BOND OF REINFORCEMENT

With numerous studies carried out in the last 40 years [3], the bond-slip behavior and mechanisms between a reinforcing bar and concrete are well understood. The bond force between a deformed bar and the surrounding concrete can be attributed to several sources: a) chemical adhesion between the bar and the concrete; b) frictional forces at the interface; and c) bearing of the ribs against the concrete surface.

The source and magnitude of the bond resistance between the steel and concrete depends on the relative displacement (slip) between the two. There are many factors that have been

found to affect the bond strength: the bar size and deformation pattern, the compressive and tensile strengths of concrete, the aggregate size, the concrete cover, the transverse reinforcement, the casting position, the bar corrosion level, etc. [4]. A detailed explanation of bond-slip mechanisms can be found in [3] and [4]. They are briefly summarized below.

At very low level of bond stress, bond is assured mostly by chemical adhesion. After the initial slip of the bar with respect to the concrete, chemical adhesion is lost, and friction forces at the surface of the bar and bearing forces at the ribs caused by the interlocking action are mobilized. Transverse micro-cracks originate at the tips of the ribs, allowing the bar to slip as shown in Figure 2a. As slip increases, concrete in front of the ribs starts to crush, which in turns induces a wedging action that increases the normal component of the bearing forces. This normal component is resisted by hoop stresses in the concrete, which cause splitting cracks to develop at the contact with the bar and to propagate radially, as shown in Figure 2b. At this stage, the bond resistance is provided by an interlocking mechanism from the concrete struts confined by the undamaged outer concrete ring as well as the confining reinforcement if any. Depending on the level of the confinement, bond can fail by the splitting of the concrete or pull-out of the bar. For low confinement conditions, splitting cracks can propagate radially through the concrete cover and the bond fails abruptly, as shown in Figure 3. When the concrete is well confined, the splitting failure mode is precluded and higher bond strengths can be achieved, as shown in Figure 3. In this case, the bond fails due to the crushing and shearing of the concrete keys between the ribs, diminishing the interlocking action. Finally, the bar is pulled-out from the concrete, which eventually provides only a residual frictional resistance.

Bond deterioration under low-cycle fatigue (e.g., caused by earthquake loads) was studied by Eligehausen et al. [5] for bars with a diameter of 25 mm. They conducted an extensive experimental program of pull-out tests with specimens representing the confined region of a beam-column joint, and proposed a relatively simple analytical cyclic bond-slip law based on the experimental observations.

3 BOND-SLIP TESTS ON LARGE-DIAMETER BARS

As part of the study reported here, pull-out tests were conducted on large-diameter reinforcing bars embedded in well-confined concrete to obtain their local bond-slip behavior. These tests tried to reproduce the confinement conditions of a vertical bridge column rebar that is embedded in a foundation shaft, where no splitting failure is expected. Four series of tests were carried out: three to study the bond-slip behavior for each of the 35, 43 and 57-mm bar sizes; and the fourth to study the influence of the compressive strength of concrete on the bond strength. A total of 22 specimens were tested, of which 8 were subjected to monotonic loading and 14 to cyclic loading.

3.1 Specimens and test set up

A typical test specimen and the test setup are shown in Figure 4. Each specimen consisted of a reinforcing bar embedded in a 3-ft.-diameter concrete cylinder with an embedment length equal to 5 times the bar diameter (D_b). The bar was bonded only in the central portion of the cylinder, and ungrouted PVC tubes were used to create unbonded zones in the upper and lower regions of the concrete cylinder to minimize any local disturbance to the bonded zone during the loading process. The test setup was designed to allow the bar to be pulled upwards or downwards using two center-hole hydraulic jacks, one at each end. A threaded T-head was used to anchor the bar at each end. The bar was pulled out from the concrete cylinder when one of the hydraulic jacks pushed against the adjacent anchor head. This was a self-reacting system; thus, the concrete was subjected to compression while the bar was being pulled out. During the test, the pull-out force was measured with a load cell and confirmed with strain gages attached to two opposite sides of the bar near each end of the concrete cylinder; and bar slips were measured at both ends by two linear potentiometers at each end mounted on two opposite sides of the bar. The local bond stress (τ) vs. slip (s) relation was obtained as the average bond stress vs. the average of the slip at the two ends of the bonded portion, s_{top} and s_{bottom} . These slip values are calculated as the average of the slips measured at the two linear potentiometers with the bar deformation on the loaded side between the attachment point of the pair of linear potentiometers and the end of bonded zone taken out. The bar deformation was calculated from strain-gage readings.

$$\tau = \frac{F}{5\pi D_b^2} \quad (1)$$

$$s = 0.5(s_{top} + s_{bottom})$$

The tests were started once the concrete reached the targeted strength. Test Series 1 through 3 had a targeted concrete compressive strength of 35 MPa, while Series 4 had a minimum targeted strength of 55 MPa.

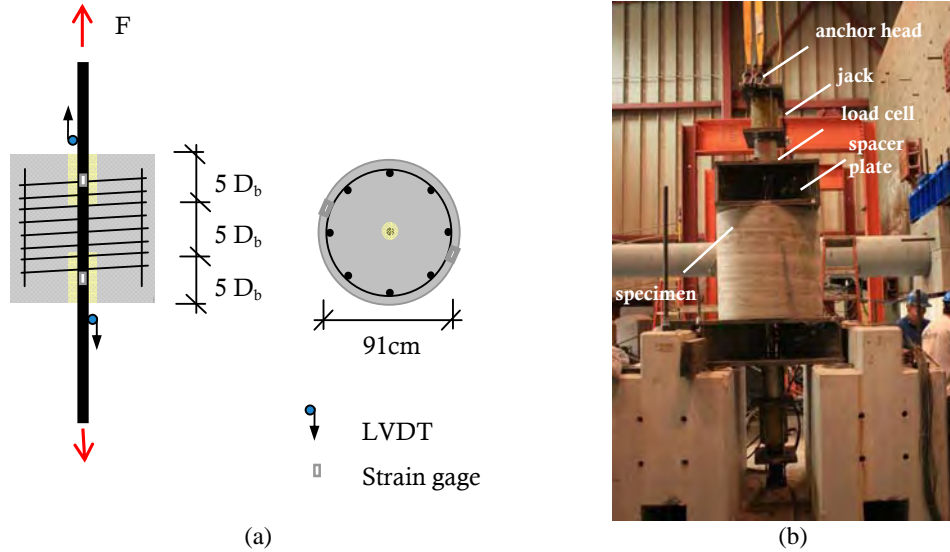

Figure 4 : (a) Test specimen; and (b) test setup

3.2 Test results

The bond strengths, τ_{max} , obtained from the experiments are summarized in Table 1. The values are the average of the bond strengths obtained from monotonic pull-out tests in which the bars were pulled up. Results from the first three series, which had a concrete compressive strength of 35 MPa, have shown that τ_{max} increased with the bar diameter from 15.2 MPa for 36-mm bars to 17.6 MPa for 57-mm bars. The tests conducted by Eligehausen et al. [5] for 25-mm bars obtained an average bond strength of 13.9 MPa; but the concrete used in their tests had a slightly lower compressive strength of 30 MPa and lower level of confinement. Results from Series 4, which had 55-MPa concrete and 43-mm bars, have shown a 45% increase of the average bond strength as compared to that obtained from Series 2, which had the same bar size but 35-MPa concrete. Based on the data from these tests, the bond strength is more or less proportional to $f_c^{0.75}$ rather than $f_c^{0.5}$, which has been often reported in the literature [4], [5]. Finally, the tests have shown that the bond strength could decrease by 10 to 20% when the bar was pulled downward instead of upward. This observation is consistent with results from previous studies [3].

The averaged bond stress vs. slip relations obtained from monotonic pull-out tests for series 1, 2 and 3 are plotted in Figure 5. The shape of the curves is similar to the one obtained for 25-mm bars by Eligehausen et al. [5]. In all cases, a practically constant residual bond resistance is attained when the slip equals the clear rib spacing of the bar. Since the clear rib spacing is usually proportional to the bar diameter, this slip level is larger for larger bars. On the contrary, the value of the slip at the peak strength does not show a clear relation with the bar size. It is around 1.5 mm for 25 mm bars [5], and remains at about 3.0 mm for 35-mm, 43-

mm, and 57-mm bars. The concrete characteristics and test set up may also have an influence in the slip level at which the peak strength is reached.

Series	Series 1	Series 2	Series 3	Series 4	Tested by [5]
D_b (mm)	36	43	57	43	25
f'_c (MPa)	35	35	35	55	30
τ_{max} (MPa)	15.2	16.2	17.6	23.7	13.9

Table 1: Average bond strength obtained from pull-out tests

Figure 5: Monotonic bond stress vs. slip relations obtained from tests (the curve for 25-mm bars was from Eligehausen et al. [5])

Several load histories were used for the cyclic tests, with variables including the increment of the slip amplitude in each loading cycle, the number of cycles per amplitude, and the type of cyclic reversals. Two types of cyclic reversals were considered: (a) full cycles with the same slip amplitudes in both directions for each cycle; and (b) half cycles with slips mainly in one direction and slightly passing the origin in the other. Figure 6 shows the bond stress vs. slip relations for four cyclic tests carried out in Series 2 and 3. The comparison of the results from different cyclic load histories has indicated that the bond strength started to deteriorate when a load cycle went beyond 70% of the peak strength. Moreover, it has been observed that full cycles induce a faster degradation than half cycles. In general, the large-diameter bars show a similar hysteretic bond-slip behavior as the 25-mm bars tested by Eligehausen et al. [5].

4 BOND-SLIP LAW FOR CONFINED BARS

A phenomenological bond-slip model for bars embedded in well-confined concrete has been developed based on the experimental data presented in the previous section. The model is similar to the ones proposed in [5] and [6] but has a more general bond-slip law. For monotonic loading, the bond stress is defined as a function of the slip by means of simple polynomial functions. This law is extended to cyclic loading by scaling down the monotonic envelope using damage parameters that depend on the slip history to account for cyclic bond degradation. The main difference with previous models is that the degradation of the envelope curve is governed by two damage parameters presenting the degradations of the bearing resistance and friction resistance, respectively. In addition, the model is more general in that it can be used for different bar sizes and concrete types with the calibration of only three parameters.

4.1 Bond-slip law for monotonic loading

The bond stress (τ) vs. slip (s) relation for monotonic loading is defined piecewise by a set of five polynomial functions, as shown in Figure 7, based on experimental observations. Up to 40% of the peak strength (τ_{\max}), the bond stress increases linearly with the slip. The nonlinear hardening behavior is represented by a fourth-order polynomial, followed by a plateau at τ_{\max} . The bond strength degradation is described by a linear descending branch. When the slip equals the clear rib spacing of the bar (s_R), a residual bond stress equal to 25% of τ_{\max} is assumed, and this value remains constant for further slip.

The expression for the monotonic envelope is provided in Equation 2 in terms of three parameters: the maximum bond strength (τ_{\max}), the slip at which τ_{\max} is attained (s_{peak}), and the clear spacing between the ribs (s_R). The details are shown in Figure 7.

Figure 7: Analytical bond stress - slip law for monotonic loading

The values of s_R , τ_{\max} , and s_{peak} determined for the bars tested here are presented in Table 2. The analytical and experimental curves for monotonic pull-out tests from Series 2 and 3 are compared in Figure 8. The same analytical law has been used to model the bond-slip behavior of smaller bars by changing the values of the three governing parameters (see Table 2). Figure 9 shows that the model matches the experimental results ([5] and [7]) for the smaller bars well.

Bar size	36 mm	43 mm	57 mm	43 mm	25 mm [5]	16 mm [7]
s_R (mm)	19.0	25.0	24.5	25.0	11.5	8
τ_{\max} (MPa)	15.2	16.2	17.6	23.7	13.9	20.9
s_{peak} (mm)	3.0	3.0	3.0	3.0	1.5	1.2

Table 2: Modeling parameters

The clear rib spacing (s_R) is a measured geometric property of the rebar, and it is usually between 40 to 60% of the bar diameter. Since the bond strength depends on many factors, no theoretical formulas are available to accurately determine τ_{\max} and s_{peak} . Therefore, they have to be determined experimentally. When no experimental data are available, the following empirical rules are suggested to estimate these values. The slip at the peak strength, s_{peak} , can be taken to be 7 % of the bar diameter, which is the average of the values presented in Table 2. The bond strength, τ_{\max} , can be assumed to be equal to 16.3 MPa, which is the average from the values shown in Table 2 for 36-mm, 43-mm, and 57-mm bars and 35-MPa concrete, and scaled by a factor of $f_c^{0.75}$, if necessary.

Figure 9: Comparison of experimental and analytical bond stress – slip relations for monotonic tests on smaller bars; (a) 25-mm bars and 30-MPa concrete [5], (b) 16-mm bars and 36-MPa concrete [7]

4.2 Bond-slip law for cyclic loading

Under cyclic loading, bond stress is defined as a function of the current slip and the slip history. Similar to that suggested in [5], the cyclic bond-slip law proposed here assumes that cyclic bond degradation can be represented by the degradation of a bond stress-slip envelope curve governed by damage parameters that depend on the slip history. The initial envelop curve corresponds to the monotonic bond stress – slip curve. However, while [5] uses a single damage parameter related to the energy dissipated, the model proposed here distinguishes between the cyclic deterioration of the bearing forces and the cyclic deterioration of the friction forces. This is based on the observation from tests that the cyclic deterioration for the peak bond strength, which is provided by bearing and friction forces, and that of the residual bond strength, which is provided by friction forces only, are different. Based on this observation, the total bond stress is decomposed into bearing and friction contributions as represented in Figure 10. The maximum frictional resistance $\tau_{f,max}$ is assumed to be equal to 25% of τ_{max} , which is the same value as the residual bond strength observed in typical monotonic bond stress – slip curves. This resistance is fully developed at s_{peak} , and remains constant for higher slip levels. The maximum bearing resistance $\tau_{b,max}$ is considered to be equal to 75% of τ_{max} . It is fully developed at s_{peak} , and decays linearly to zero at a slip equal to s_R . The aforementioned relations for the initial monotonic bond stress – slip curve are shown in Equation 3.

$$\begin{aligned}\tau &= \tau_b + \tau_f \\ \tau_{b,max} &= 0.75\tau_{max} \\ \tau_{f,max} &= 0.25\tau_{max}\end{aligned}\quad (3)$$

Figure 10: Analytical decomposition of bond stress into bearing and friction

Figure 11 shows a sketch of the analytical bond-slip law for cyclic loading including the initial monotonic bond stress – slip curve and a deteriorated envelope (labeled as curve 1). The total deteriorated resistance τ_{red} at any time is assumed to be the sum of the deteriorated bearing resistance, $\tau_{b,red}$, and the deteriorated friction resistance, $\tau_{f,red}$. The reduction of the two resistance components is controlled by two damage parameters that depend on the loading history and are updated every time the load is reversed. These relations are shown in Equation 4.

$$\begin{aligned}\tau_{red} &= \tau_{b,red} + \tau_{f,red} \\ \tau_{b,red} &= (1 - d_b)\tau_b \\ \tau_{f,red} &= (1 - d_f)\tau_f\end{aligned}\quad (4)$$

Figure 11: Analytical bond-slip law for cyclic loading

The damage factor for the bearing resistance, d_b , is assumed to be a function of the maximum slip. Since full cycles have shown to produce more damage than half cycles, the maximum slip considered here is a weighted average of the absolute maximum slip reached in any of the two directions and the average of the maximum slips in the two directions, s_{\max}^+ and s_{\max}^- . This damage parameter is defined in Equation 5.

$$d_b(\hat{s}_{\max}) = 1 - e^{-2.5 \left(\frac{\hat{s}_{\max}}{s_R} \right)^{0.8}} \quad (5)$$

$$\hat{s}_{\max} = 0.75 \max(s_{\max}^+, s_{\max}^-) + 0.125(s_{\max}^+ + s_{\max}^-)$$

The damage parameter for the friction resistance, d_f , is assumed to be a function of both the maximum slip in each direction and the total accumulated slip s_{acc} , shown in Equation 6. The frictional resistance is reduced progressively due to the smoothening of the interface.

$$d_f(s_{acc}, s_{\max}^+, s_{\max}^-) = \frac{s_{\max}^+ + s_{\max}^-}{s_R} \left(1 - e^{-0.4 \left(\frac{s_{acc}}{s_R} \right)^{0.75}} \right) \quad (6)$$

When sliding is between the levels of slip achieved previously, there is no contact between the ribs and the concrete, and the bond stress developed is entirely contributed by the friction generated at the bar barrel. This frictional resistance generated at slip reversal, τ_{rev} , is defined as a function of the reduced residual friction and the maximum slip achieved. This branch of the bond-slip law is labeled as curve 2 in Figure 11.

$$\tau_{rev} = k_{rev} \tau_{f,red}$$

$$k_{rev} = \frac{\max(s_{\max}^+, s_{\max}^-)}{s_{peak}} \leq 1 \quad (7)$$

With the above considerations, cycling between previously achieved slip levels induces additional deterioration to the friction forces but not to the bearing forces, which is consistent mechanical considerations. Bearing forces are only activated when concrete is in contact with

the ribs, and this happens for slip levels exceeding previously reached values. Deterioration of the bearing forces is caused by crushing and shearing of concrete in front of the ribs.

To fully define the cyclic law, unloading and reloading rules need to be specified. Upon slip reversal, bond stress decreases linearly until τ_{rev} is achieved. This branch of the bond-slip law is labeled as curve 3 in Figure 11. For the reloading branch, labeled as curve 4 in Figure 11, the stress increases linearly from τ_{rev} until the reduced envelope is reached. Both unloading and reloading stiffnesses are equal to the initial stiffness of the monotonic bond stress - slip curve: $k = 4 \frac{\tau_{max}}{s_{peak}}$.

The aforementioned damage law has been calibrated using the experimental data from the test series 1, 2 and 3. The experimental and analytical bond-slip laws for a cyclic test in Series 1 are compared in Figure 12a. The analytical model reproduces very well the cyclic bond deterioration, the resistance right after slip reversal, and the unloading and reloading branches. The model is compared to a test in Series 4 in Figure 12b, which also shows a good match between the experiment and the analytical results. The cyclic deterioration rules obtained for large-diameter bars are also applicable to smaller bars, as demonstrated by the good match between the experiments and analytical results shown in Figure 13.

5 FINITE ELEMENT ANALYSIS APPLICATION

The bond-slip law described above has been implemented in an interface element in ABAQUS [8], and finite element analyses have been conducted on large-diameter bars to determine the minimum development lengths required to prevent pull-out failure. The results are compared to those required by the AASHTO LRFD Specifications [2]. Figure 14 shows a 2-dimensional axi-symmetric model of a bar embedded in concrete developed for these analyses. The concrete is modeled using a damaged-plasticity law based on [9] and [10], and the steel is modeled with a von Mises plasticity law with linear hardening. Both material laws are available in ABAQUS. The steel bar is connected to the concrete elements using interface elements with the proposed bond-slip law. The compressive strength of concrete is taken as 35MPa. The nominal yield strength of the steel is 414 MPa, but in the analyses the actual yield strengths obtained from material tests have been used: 510 MPa for 35-mm bars, 490 MPa for 43-mm bars, and 450 MPa for 57-mm bars. The tensile strength of the steel is 680 MPa for 35-mm bars, 655 MPa for 43-mm bars, and 620 MPa for 57-mm bars.

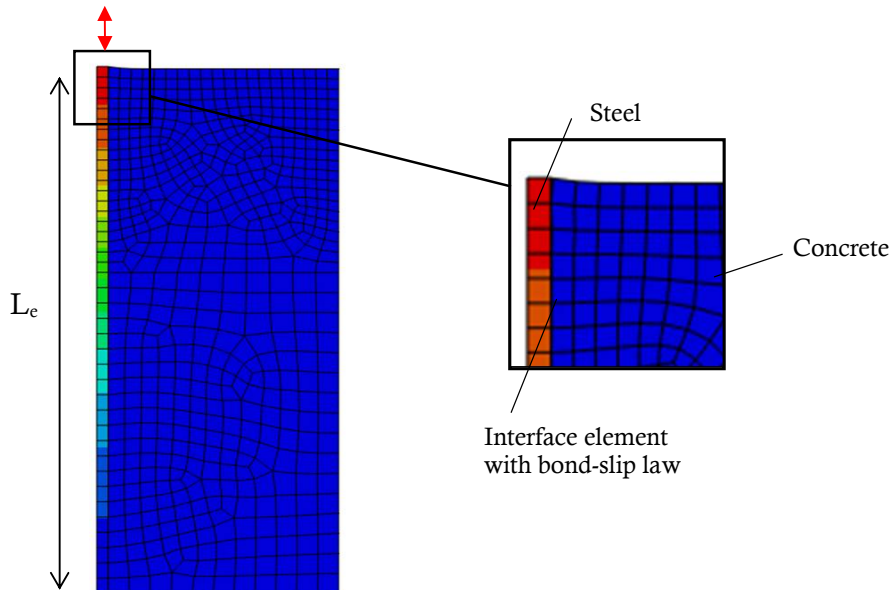

Figure 14: FE model of the pull-out simulation of a reinforcing bar

Analyses have been carried out with the embedment length of the bar, L_e , gradually reduced until pull-out failure occurs. Figure 15 presents the results of a pull-out simulation of a 43-mm rebar using four different values for L_e . It can be concluded from these results that the minimum embedment length necessary to reach the ultimate strength of the steel is equal to 12 times the bar diameter, D_b . This value is less than half of the development length required by the AASHTO Specifications [2], which in this case is equal to $26D_b$. Moreover, the responses with $L_e=12D_b$ and $L_e=26D_b$ are very similar, showing no substantial loss of stiffness by using a significantly shorter length. The results also show that for $L_e=10D_b$, yielding of the bar can occur, but it can be followed by a pull-out failure before the bar could rupture; and for $L_e=8D_b$, a pull-out failure can take place without yielding the bar.

Results have also been obtained for 36-mm and 57-mm bars. The values of the development lengths required by [2] for well confined bars, $L_{e,AASHTO}$, and the minimum required values obtained from the analyses, $L_{e,min}$, are presented in Table 3. The minimum required development lengths shown by the analyses are about half of the values required by the

AASHTO Specifications. In addition, it is interesting to note that the AASHTO requirements and the numerical results show opposite trends with respect to the relation between the required development length and the bar size. According to AASHTO, the L_e/D_b ratio is higher for larger-diameter bars, while the numerical results show that the required L_e/D_b ratio decreases with the bar size.

Figure 15: Bar stress vs. slip at pulled end for different embedment lengths ($D_b=43$ mm and $f'_c=35$ MPa)

Bar size	$L_{e,AASHTO}$	$L_{e,min}$
36 mm (US #11)	$22D_b$	$14D_b$
43 mm (US #14)	$26D_b$	$12D_b$
57 mm (US #18)	$25D_b$	$11D_b$

Table 3: Minimum embedment lengths

6 CONCLUSIONS

An analytical model to predict the cyclic bond-slip behavior of reinforcing bars embedded in well-confined concrete has been presented. The model has been calibrated with recent monotonic and cyclic pull-out tests conducted on bars with diameters of 36, 43 and 57 mm. The model successfully reproduces the bond-slip behavior of these bars as well as that of smaller bars, including the degradation of the bond strength and bond stiffness under different load histories.

The bond-slip law proposed has been implemented in an interface element in a finite element program. Finite element analyses have been carried out to obtain the minimum development length required of large-diameter bars (35, 43, and 57 mm). The results show that the development length requirements in the current AASHTO Specifications for bridge structures in the U.S. are very conservative.

Keywords: Cracked shear walls, rough interfaces, fractal geometry, fractal resolution, unilateral contact, variational formulation

Abstract. *Shear walls play an important role to the seismic strength of modern seismic resistant structures. They are designed so that they have significant bending and shear strengths and ductility. However, existing structures have lightly reinforced shear walls. In most cases, especially under cycling loading, shear cracks appear reducing the shear capacity of the wall. Here, a typical shear wall of an existing structure is examined in which it is assumed that a crack has been formed. For the modeling of the geometry of the crack a new approach is applied, using the notion of fractal geometry. The aim of the paper is the estimation of the post-cracking strength of the wall, taking into account the geometry of the cracks and the mixed friction-plastification mechanisms that develop in the vicinity of the crack. Due to the significance of the crack geometry a multi-resolution analysis is performed. The materials (steel and concrete) are assumed to have elastic-plastic behaviour. For concrete both cracking and crushing are taken into account in an accurate manner. On the interface unilateral contact and friction conditions are assumed to hold. For every structure resulting for each resolution of the interface, a classical Euclidean problem is solved. The obtained results lead to interesting conclusions concerning the post-cracking strength of lightly reinforced shear walls.*

1 INTRODUCTION

Shear walls play a significant role to the seismic strength of structures built in seismic prone areas. Shear walls in modern structures are designed to have significant bending and shear strengths and ductility. However, shear walls in old, existing buildings have been constructed using poor materials and usually have inadequate shear strength. In such elements, shear cracks appear reducing their overall capacity. The aim of this paper is to apply, a new approach in order to estimate the post-cracking strength of a shear wall which is part of an existing structure, taking into account the geometry of the formed cracks. To this end, the notion of fractal geometry is applied in order to approximate the geometry of the crack.

It is well known that the geometry and structure of the interface between two solid surfaces in contact is of fundamental importance to the study of friction, wear, lubrication and also strength evaluation. Experimental studies [1], [2], [3], [4] have shown that the fracture interfaces have irregularities of all scales, and require advanced mathematical models for their description. In general, the actual contact between two real interfaces is realized only over a small fraction in a discrete number of areas. Consequently, the real area of contact is only a fraction of the apparent area [5], [6] and the parameters of the actual contact regions are strongly influenced by the roughness of the contacting surfaces. For that, fractal contact models are suitable for the simulation of contact.

The fractal approach adopted here for the simulation of the geometry of the cracks formed in the shear wall, uses computer generated self-affine curves for the modelling of the interface roughness, which is strongly dependent on the values of the structural parameters of these curves. The computer generated interfaces, which are characterized by a precise value of the resolution δ of the fractal curve, permit the study of the interface roughness on iteratively generated rough profiles. This fact makes this approach suitable for engineering problems, since it permits the satisfactory study of the whole problem with reliable numerical calculations.

Among the aims of this paper is to study how the resolution of a fractal interface F affects the strength of a reinforced concrete shear wall element, in which it is assumed that a crack has been developed. The geometry of the crack is modelled through the application of the principles of fractal geometry. On the interface between the two cracked surfaces, unilateral contact and friction conditions are assumed to hold. The applied approach takes into account the nonlinear behaviour of the materials, including the limited strength of the concrete under tension. The shear wall is applied to shear loading. As a result of the applied approach, the contribution of the friction between the cracked surfaces is taken into account, as well as the additional strength coming from the mechanical interlock between the two faces of the crack. For every structure resulting for each resolution of the interface, a classical Euclidean problem is solved by using a variational formulation [7].

2 FRACTAL REPRESENTATION OF ROUGH INTERFACES

The fractal nature of material damage has been a matter of a very intense research during the last three decades. The fractal nature of fracture surfaces in metals was shown more than 20 years ago by Mandelbrot et. al. [1]. In this paper the authors studied the fracture of cracked surfaces in metals fractured either by tensile or impact loading, which were shown to develop fractal structure over more than three orders of magnitude. In quasi-brittle materials observations have shown that fracture surfaces display self-affine scale properties in a certain range of scales which is in most cases very large and which greatly depends on the material micro-

structure. This is true for a large variety of quasi-brittle materials such as rock, concrete, wood and ceramics [8], [9].

Fractal sets are characterized by non-integer dimensions [10]. The dimension of a fractal set in plane can vary from 0 to 2. Accordingly, by increasing the resolution of a fractal set, its length tends to 0 if its dimension is smaller than 1 (totally disconnected set), or tends to infinity if it is larger than 1. In these cases the length is a nominal, useless quantity, since it changes as the resolution increases. Conversely, the fractal dimension of a fractal set is a parameter of great importance because of its scale-independent character.

Many methods which are based on experimental or numerical calculations, such as the Richardson method [10], have been developed for the estimation of the fractal dimension of a curve. According to this method, dividers, which are set to a prescribed opening δ , are used. Moving with these dividers along the curve so that each new step starts where the previous step leaves off, one obtains the number of steps $N(\delta)$. The curve is said to be of fractal nature if by repeating this procedure for different values of δ the relation

$$N(\delta) \sim \delta^{-D} \quad (1)$$

is obtained in some interval $\delta^{(*)} < \delta < \Delta^{(*)}$. The power D denotes the fractal dimension of the profile, which is in the range $1 \leq D < 2$. The relation between the fractal dimension D of this profile and the dimension of the corresponding surface is $D_s = D + 1$ [10].

The idea of self-affinity is very popular in studying surface roughness because experimental studies have shown that usually, under repeated magnifications, the profiles of real surfaces are statistically self-affine to themselves [1], [11]. The self-affine fractals were used in a number of papers as a tool for the description of rough surfaces [12]-[17]. Typically, such a profile can be measured by taking height data y_i with respect to an arbitrary datum at N equidistant discrete points x_i and following the procedure presented in [18]. Here, fractal interpolation functions are used for the passage from this discrete set of data $\{(x_i, y_i), i = 0, 1, 2, \dots, N\}$ to a continuous model, where $F(x_i) = y_i, i = 0, 1, \dots, N$. It has been proved [18] that there is a sequence of functions $F_{n+1}(x) = (TF_n)(x)$, where $T: C^0 \rightarrow C^0$ is an operator defined by:

$$F_{n+1}(x) = (TF_n)(x) = c_i l_i^{-1}(x) + d_i F_n(l_i^{-1}(x)) + g_i \quad (2)$$

for $x \in [x_{i-1}, x_i], i = 1, 2, \dots, N$. The operator T converges to a fractal curve F , as $n \rightarrow \infty$. The transformation l_i transforms $[x_0, x_N]$ to $[x_{i-1}, x_i]$ and it is defined by the relation

$$l_i(x) = a_i x + b_i. \quad (3)$$

The factors d_i are the hidden variables of the transformations and they have to satisfy $0 \leq d_i < 1$ in order for $T: C^0 \rightarrow C^0$ to have a unique fixed point. Moreover, the remaining parameters are given by the following equations:

$$a_i = (x_i - x_{i-1}) / (x_N - x_0) \quad (4)$$

$$c_i = (y_i - y_{i-1}) / (x_N - x_0) - d_i (y_N - y_0) / (x_N - x_0) \quad (5)$$

$$b_i = (x_N x_{i-1} - x_0 x_i) / (x_N - x_0) \quad (6)$$

$$g_i = (x_N y_{i-1} - x_0 y_i) / (x_N - x_0) - d_i (x_N y_0 - x_0 y_N) / (x_N - x_0). \quad (7)$$

The fractal interpolation functions give profiles which look quite attractive from the view-point of a graphic roughness simulation. In higher approximations these profiles appear rougher as it is shown in the next section where the first to fourth approximations of a fractal interpolation function are presented. Moreover, the roughness of the profile is strongly affected by the free parameters $d_i, i = 1, \dots, N$ of the interpolation functions. As these parameters take larger values, the resulting profiles appear rougher.

It must be mentioned here that an important advantage of the fractal interpolation functions presented here is that their fractal dimension can be obtained numerically [18] and is given by the relation:

$$\delta^{-D} \approx \sum_{i=1}^N |d_i| a_i^{D-1} \delta^{-D} \Leftrightarrow \sum_{i=1}^N |d_i| a_i^{D-1} = 1. \quad (8)$$

3 DESCRIPTION OF THE CONSIDERED PROBLEM

In Figure 1 a reinforced concrete shear wall element is presented which is assumed to be part of a typical existing structure built during the 60s or 70s. The wall is reinforced by a double steel mesh consisting of horizontal and vertical rebars having a diameter of 8mm and a spacing of 200mm. The quality of the steel mesh is assumed to be S220 (typical for buildings of that age). At the two ends of the wall the amount of reinforcement is higher. Four 20mm rebars of higher quality (S400) are used, without specific provisions to increase the confinement. The thickness of the wall is 200mm and the quality of concrete is assumed to be C16, typical for this kind of constructions. The wall is fixed on the lower horizontal boundary.

The considered shear wall is divided into two parts by a crack which is assumed that has been formed as a result of the action of an earthquake. Obviously, the depicted crack has been formed due to shear failure of concrete. For the description of the geometry of the crack, the notion of fractals is used. More specifically, the crack is assumed to be a fractal interface, described by the fixed point of a fractal interpolation function interpolating the set of data $\{(-1.0, 2.95), (0.4, 2.0), (1.8, 1.0), (3.2, 0.5)\}$. The free parameters of the fractal interpolation function are taken to have the values $d_1 = d_2 = d_3 = 0.50$.

The objective here is to estimate the capacity of the shear wall under an action similar to the one that has created the crack. For this reason, a horizontal displacement of 20mm is applied on the upper side of the wall (see Fig. 1). Moreover, a vertical distributed loading q_N is applied on the upper horizontal boundary, creating a compressive axial loading. The resultant of this loading is denoted by N . For N , six different values will be considered from 0 to 2.500 kN with a step of 500 kN.

As it was mentioned in the previous section, self-affine interfaces are adopted for the interface simulation. The computer generated interfaces $F_n, n = 1, 2, \dots$ are only images “pre-fractals” characterized by a precise value of the resolution $\delta^{(n)}$ of the fractal set. The resolution $\delta^{(n)}$ is related to the (n) -th iteration of the fractal interpolation function and represents the characteristic linear size of the interface. As it is shown in Fig. 2 where four iterations of a fractal interface are given, the linear size of the interface changes rapidly when higher order approximations are taken into account. It is assumed that the opposite sides of the fracture are perfectly matching surfaces, so only one side of the fracture was generated by using the de-

scribed fractal interpolation function. By applying relation (8) the fractal dimension D of the interface studied here results to be equal to 1.369.

Figure 1: The considered shear wall.

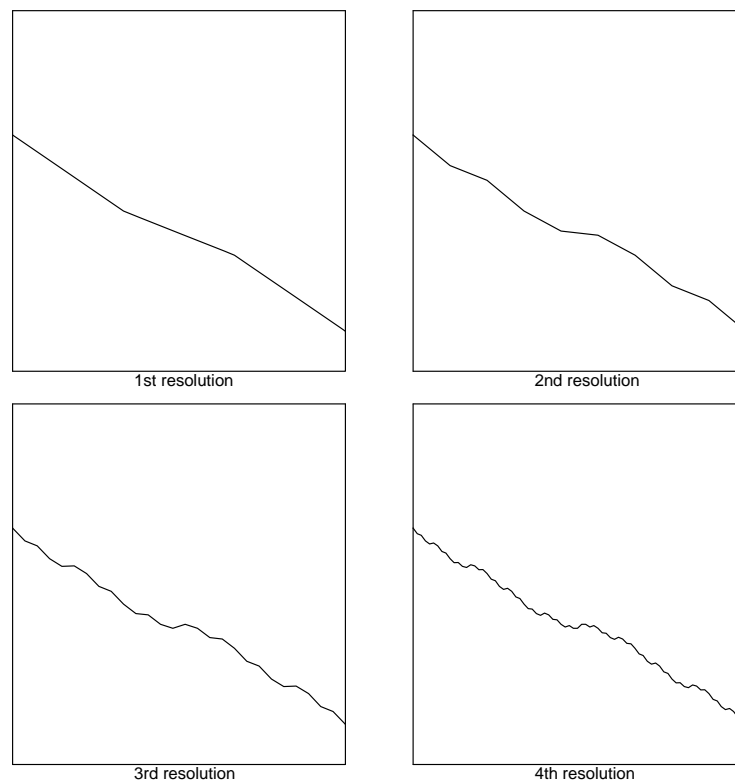

Figure 2: The first four resolutions of the fractal crack.

In Table 1 the characteristics of each resolution are presented. The resolution $\delta^{(n)}$ for each iteration (n) is given in the second column of Table 1. The last column of this table presents the total crack lengths $L^{(n)}$ in m.

Iteration (n)	Resolution $\delta^{(n)}$ (m)	Interface length $L^{(n)}$ (m)
1st	1.404	4.888
2nd	0.468	4.946
3rd	0.156	5.080
4th	0.052	5.373

Table 1: Characteristics of the considered structures

For the modelling of the above problem the finite element method is used. In order to avoid a much more complicated three-dimensional analysis, two-dimensional finite elements were employed, however, special consideration was given to the incorporation of the nonlinearities that govern the response of the wall. More specifically, the mass of the concrete was modelled through quadrilateral and triangular plain stress elements. The finite element discretization density is similar for all the considered problems [19]. This rule ensures that the discretization density will not affect the comparison between the results of the various analyses that were performed.

The modulus of elasticity for the elements representing the mass of concrete was taken equal to $E = 21 \text{ GPa}$ and the Poisson's coefficient equal to $\nu = 0.16$. The material was assumed to follow the nonlinear law depicted in Fig. 3a. Under compression, the material behaves elastoplastically, until a total strain of 0.004. After this strain value crushing develops in the concrete, leading its strength to zero. A more complicated behaviour is considered under tension. More specifically, after the exhaustion of the tension strength of concrete, a softening branch follows, having a slope $k_s = 10^7 \text{ MPa}$. Progressively the tension strength of concrete is also zeroed. The above uni-directional nonlinear law is complemented by an appropriate yield criterion (Tresca) which takes into account the two-dimensional stress fields that develop in the considered problem. For the simulation of cracking a smeared crack algorithm is used, in which the cracks are evenly distributed over the area of each finite element [20].

The steel rebars were modelled through two-dimensional beam elements, which were connected to the same grid of nodes as the plain stress elements simulating the concrete. At each position, the properties that were given to the steel rebars take into account the reinforcement that exists in the whole depth of the wall. For example, the horizontal and vertical elements that simulate the steel mesh are assigned an area of 100.5 mm^2 that corresponds to the cross-sectional area of two 8mm steel rebars. For simplicity, the edge reinforcements were simulated by a single row of beam elements that have an area of 1256 mm^2 (i.e. $4 \times 314 \text{ mm}^2$). For the steel rebars, a modulus of elasticity $E = 210 \text{ GPa}$ was assumed. Moreover, the nonlinear laws of Fig. 3b,c were considered for the S220 and S400 steel qualities respectively. These laws exhibit a hardening branch, after the yield stress of the material is attained.

Figure 4 depicts the finite element discretizations for the structures that correspond to the third and fourth iterations of the fractal interface. The grey lines in the finite element meshes correspond to the positions of the steel rebars. The distance between the two facing parts of the interface is only 0.1mm. Special attention was given in the modelling so that the steel rebars retain their initial horizontal and vertical positions, i.e. no eccentricity exists between the corresponding rows of beam finite elements due to the formation of the crack.

Figure 3: The adopted materials laws a) C16 concrete, b) S220 steel, c) S400 steel.

Figure 4: F.E. discretizations for third and fourth approximations of the fractal interface.

In this paper, only the finite element models corresponding to the 3rd and 4th approximations of the fractal crack were considered, because 1st and 2nd approximations don't have meaning from the engineering point of view.

At the interfaces, unilateral contact and friction conditions were assumed to hold. The Coulomb's friction model was followed with a coefficient equal to 0.6. At each scale, where a classical Euclidean problem is solved, a variational formulation [7] was used in order to describe the contact between the two parts of the crack.

For every value of the vertical loading N , a solution is taken in terms of shear forces and horizontal displacements at the interface, for different values of the resolution of the cracked wall and for the case of the uncracked wall. The aim of this work is to study the behaviour of the shear wall, i.e. the behaviour of the concrete and the forces in the rods, as the vertical loading and the resolution of the interface change.

Two cases are considered:

- In the first case the wall is uncracked.
- In the second case, where a fractal crack F has been developed in the wall, different resolutions are taken into account in order to examine how the resolution of a fractal interface F affects the strength of a reinforced concrete shear wall element.

The solution of the above problems is obtained through the application of the Newton-Raphson iterative method. Due to the highly nonlinear nature of the problem, a very fine load incrementation was used. The maximum value of the horizontal displacement (20mm) was applied in 2000 loading steps, while the total vertical loading was applied in the 1st load step and was assumed as constant in the subsequent steps.

4 EXPERIMENTAL AND NUMERICAL RESULTS

Figure 5 presents the applied horizontal load verse the corresponding displacement ($P-\delta$ curves) for the different values of the vertical loading N . It has to be noticed, starting from the case of the uncracked wall, that the value of the vertical loading plays a significant role. As the value of the vertical loading increases, the capacity of the wall to undertake horizontal loading increases as well. However, for the higher load values (for $N=2.000$ and 2.500 kN), strength degradations are noticed. As it will be explained later, these degradations have their nature to the exhaustion of the shear strength of concrete. However, after this strength degradation, the resistance of the wall increases again as a result of the transfer of the loading from the concrete to the horizontal steel rebars.

Coming now to the cases of the cracked walls, the beneficial effect of the normal compressive loading is once more verified. This result holds for both the 3rd and the 4th approximations of the fractal crack but for small displacement values only. For larger displacement values, the two variants of the cracked wall behave differently. The 4th approximation appears to have a stable behaviour without strength degradations. However, it is noticed that in the case of the 3rd approximation and for heavy axial loading, significant strength degradation takes place.

The above results can be more easily understood if we compare in the same diagram the curves obtained for the three different structures studied here (uncracked, 3rd iteration, 4th iteration) for specific load levels. Figure 6 gives the $P-\delta$ curves for three cases of axial loading, namely for $N=0$, $N=1500$ kN and $N=2.500$ kN. It is noticed that for low values of the compressive axial loading, there is actually no difference between the uncracked and the cracked walls. In all the cases the horizontal loading is easily transferred and no signs of strength degradation are noticed. That means that the wall works mainly in bending and the shear forces are well below the shear strength of the wall. For moderate axial loading values (i.e. for $N=1.500$ kN), it is noticed that the uncracked wall appears to have greater strength than the cracked variants examined here. It is also noticed that the 4th iteration of the fractal crack

leads to greater ultimate strength. This fact can be primarily attributed to the fact that the 4th iteration seems to lead to a greater degree of interlocking between the two parts of the crack.

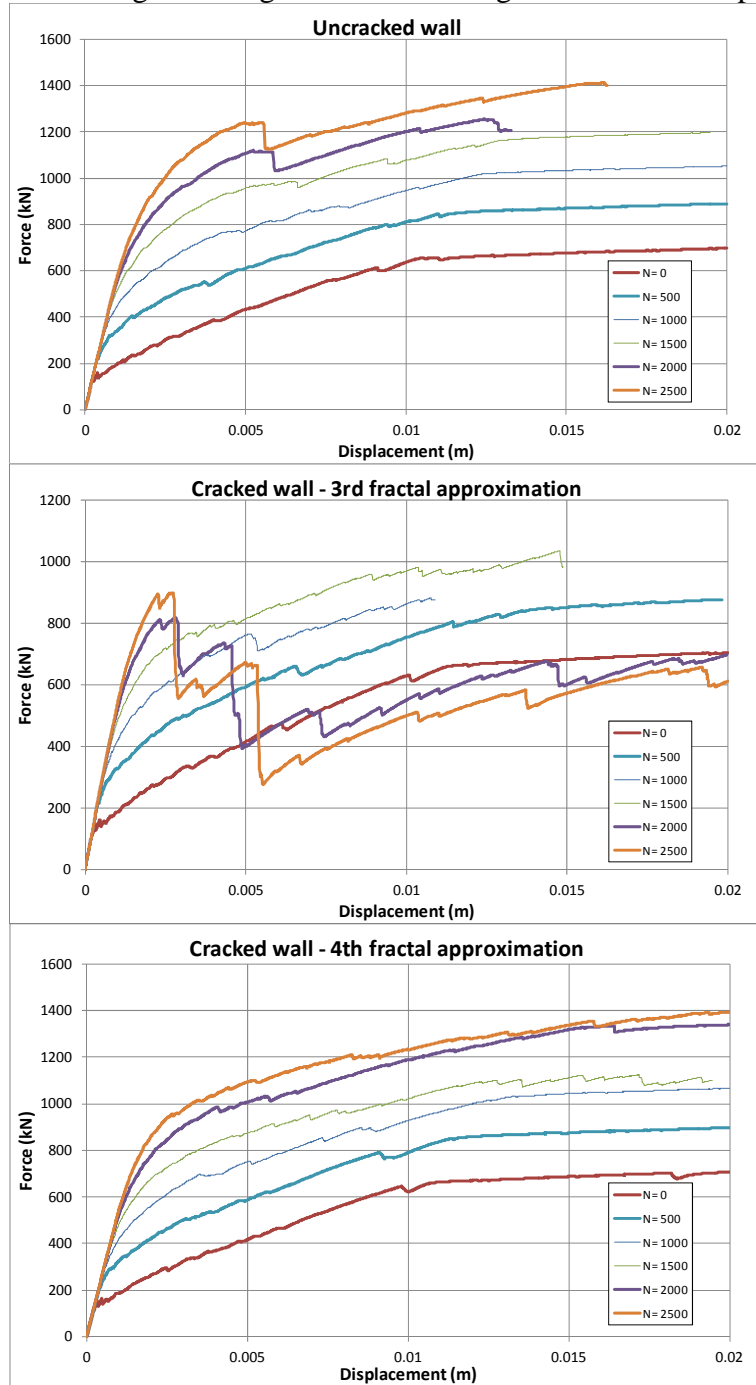

Figure 5: Load-displacement (P - δ) curves for the cases of the uncracked and cracked walls.

However, the most interesting case is that of the heave axial loading ($N=2.500$ kN). First, it can be noticed that the behavior of the 4th approximation of the fractal crack leads to results that are close enough to those of the uncracked wall. There exist some differences for horizontal displacements in the range of 2-6mm. In this range the uncracked wall exhibit greater resistance. However, for 6mm, the uncracked wall appears strength degradation and after this displacement value the results of the 4th approximation of the fractal crack are again very close to those of the initially uncracked wall.

Significantly different is the case of the 3rd approximation of the fractal crack. It is noticed that although in the first loading steps the results follow closely those of the 4th approximation, after a displacement value of 3mm significant strength degradation appears, having the form of successive vertical branches. The ultimate strength of this wall is significantly lower than the other variants.

Figure 6: Comparison of the behaviour of the three variants of the examined wall for specific values of the compressive axial loading.

It is interesting to try to explain this significantly different behaviour that appears between the walls corresponding to the 3rd and 4th approximations of the fractal crack. For this reason,

all the parameters affecting the behaviour of the wall will be comparatively studied in the sequel.

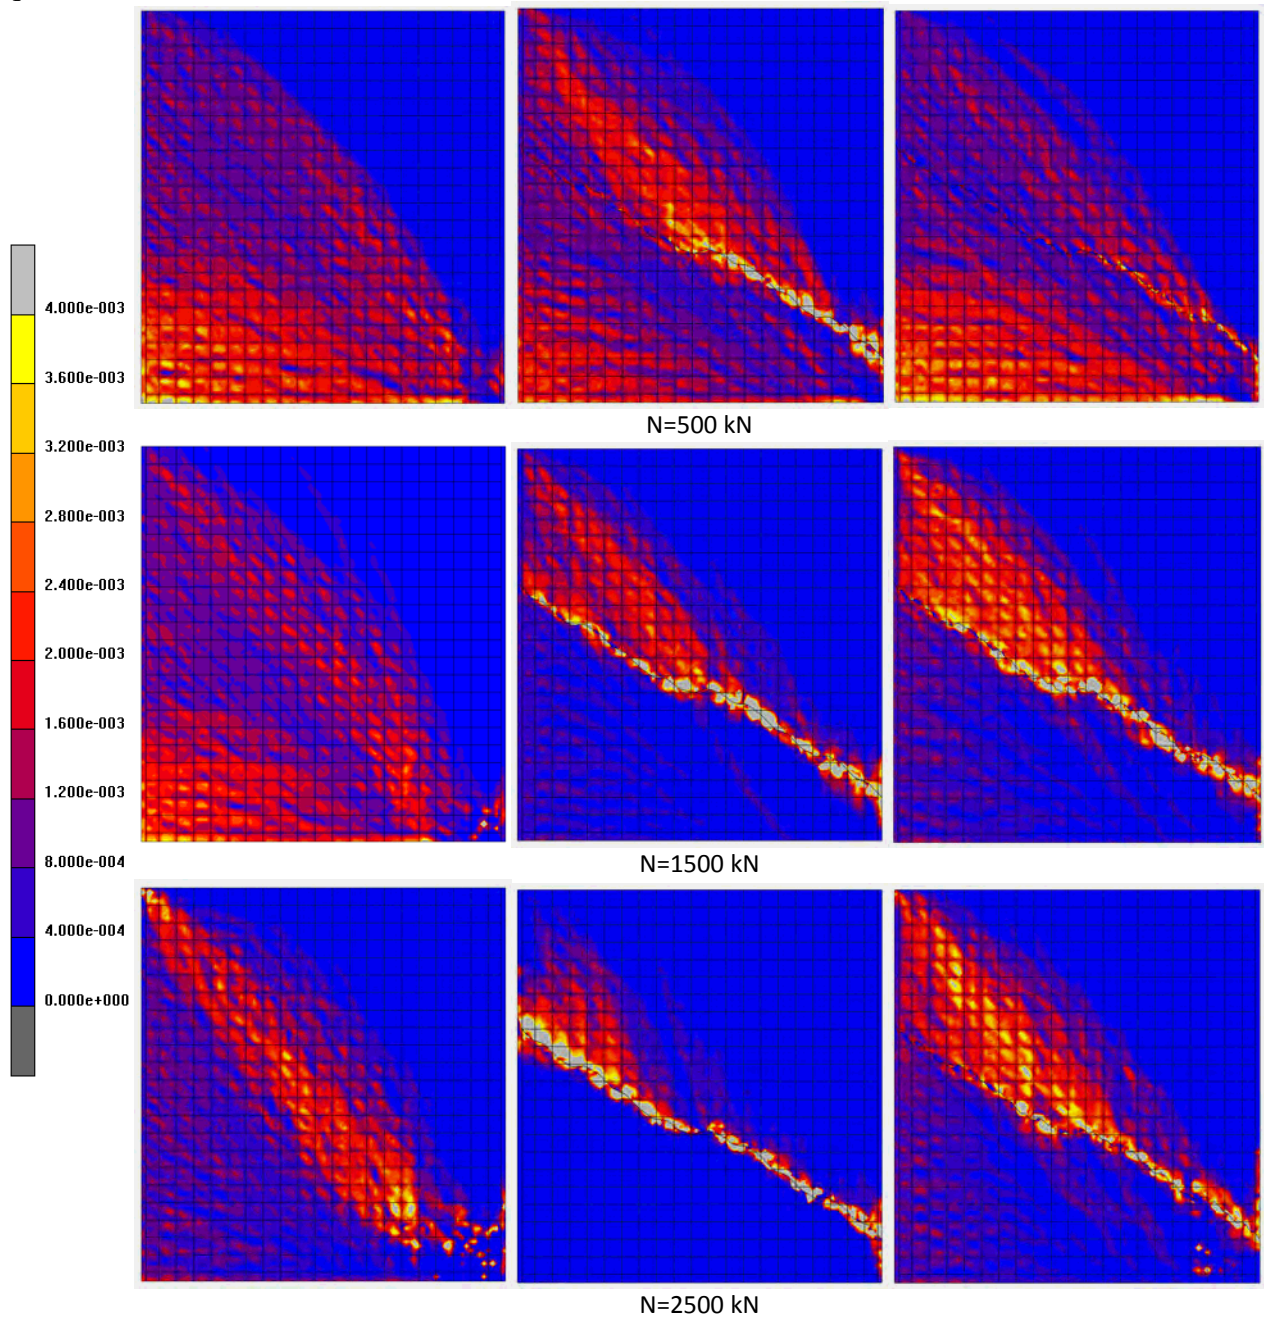

Figure 7: Cracking strains for various values of the vertical loading, for the cases of the uncracked wall (left column) and the cracked walls (3rd approximation- middle column and 4th approximation – right column).

Figure 7 depicts the cracking strains of concrete for specific values of the axial loading. All the depicted results correspond to the end of the analysis, i.e. they have been obtained for an applied horizontal displacement of 20mm. First of all, it can be noticed that for low values of the axial loading, the cracking patterns that have been developed in all the studied walls are rather similar. The larger cracking strain values (yellow and grey colours) have their nature in the bending deformation of the wall. For moderate axial loading, the cracking patterns are quite different. The uncracked wall has again a bending type cracking pattern. The cracked walls seem to behave differently. Both of them exhibit significant cracking in the vicinity of

the crack (grey colors). Apart from this, shear type cracking patterns develop at the upper parts of the walls.

The above results alone cannot explain the significantly different responses that the two cracked variants of the wall exhibit. For this reason, the plastic strains of concrete are examined in the following. Figure 8 depicts the plastic concrete strains for the three different variants of the wall and for specific values of axial loading. The upper value of the presented scale corresponds actually to the crushing limit (grey values). Therefore, it can be considered that the concrete stresses in these areas are actually zero. For the uncracked wall (left column of Fig. 8) it can be noticed that the more heavily deformed region is the lower right corner. It is clear that in this case the wall exhibits a typical bending type deformation behaviour (cracking at the lower left region, crushing at the lower right corner).

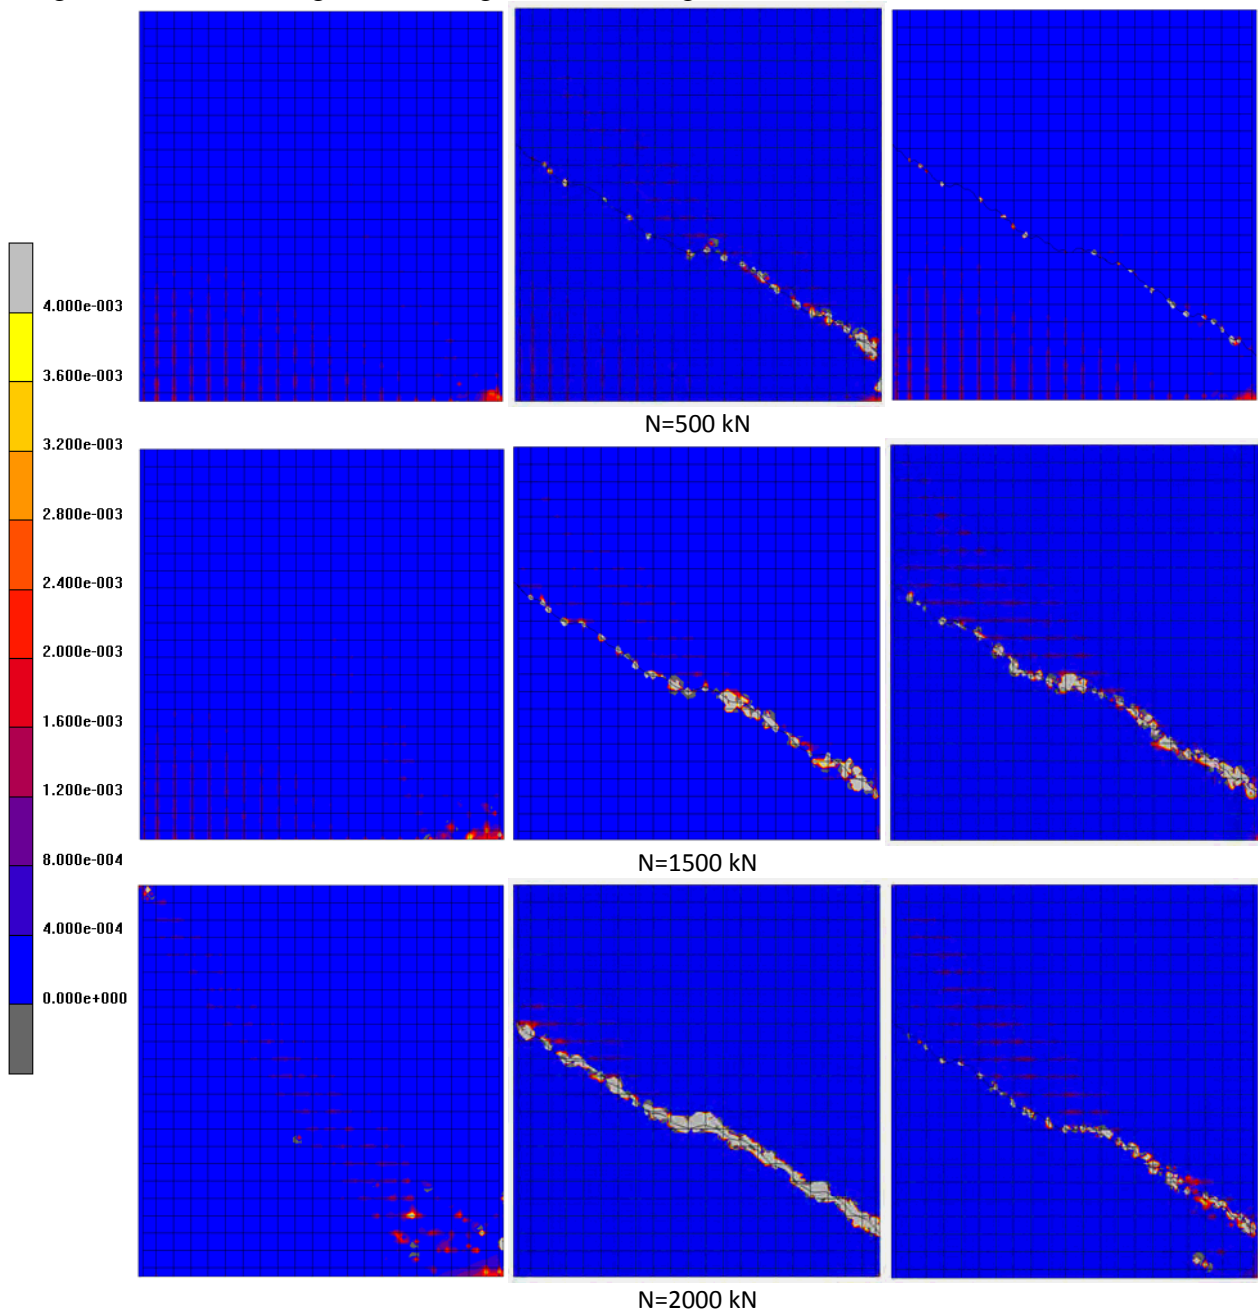

Figure 8: Plastic strains for various values of the vertical loading, for the cases of the uncracked wall (left column) and the cracked walls (3rd approximation- middle column and 4th approximation – right column)

On the other hand, the cracked walls seem to deform significantly in the vicinity of the crack. This phenomenon is more pronounced in the case of the 3rd approximation of the fractal wall. Especially in the case of heavy axial loading, it can be noticed that the vicinity of the crack is in crushed state, i.e. in this region the forces are transmitted solely by the steel mesh (the concrete has no ability to transfer any kind of forces). For the case of the 4th approximation, this phenomenon is rather limited, i.e. it can be concluded that in this case the crack retains partial its ability to transfer shear and compressive forces through the contact and friction phenomena that develop in the interface and through the mechanical interlocking that occurs between the two interface parts.

It is now interesting to examine the deformations that have occurred at the steel mesh. Figure 9 displays the steel mesh for the three variants of the considered wall and for different values of the vertical loading. The presented deformations correspond to the last load step and have been magnified by a factor of 10 so that the differences between the examined cases visible.

Figure 9: Deformation of the steel mesh for various values of the vertical loading, for the cases of the uncracked wall (left column) and the cracked walls (3rd approximation- middle column and 4th approximation – right column).

For low vertical loading values, the deformations of the steel meshes are actually very similar. However, for moderate values of the vertical loading ($N=1.000\text{kN}$) there exist some differences. The steel meshes of the cracked walls seem to be distorted in the vicinity of the right part of the formed crack. In this region the vertical rebars above and below the crack present an offset which can be attributed to the inability of the interface to transfer shear forces. For the case of heavy vertical loading, the situation is different again. The wall corresponding to the 4th resolution of the fractal crack has a deformation similar to that of the case of the moderate loading. However, the steel mesh of the wall corresponding to the 3rd resolution of the fractal crack exhibits significant deformations all along the crack. All the upper vertical rebars present a significant horizontal offset with respect to the lower ones. This horizontal offset is obvious even in the leftmost part of the wall. Moreover, the horizontal rebars of the upper part present a vertical offset with respect to the ones of the lower part. This deformation pattern verifies the findings that were noticed in Fig. 8 concerning the excessive strains in the vicinity of the crack (which had values well above the crushing strain limit). This deformation type of the steel mesh has its nature to the inability of the concrete to transfer any loading in this case.

In the sequel, the difference in the response between the 3rd and the 4th approximations of the fractal crack for the case of the heavy vertical loading will be explained. First of all, it has to be noticed that the higher vertical loading leads also to higher values of the horizontal loading, as it has been explained for the case of the uncracked wall. These increased horizontal forces have to be transferred from the upper part of the cracked wall to its lower part. In this respect, three mechanisms develop in order to facilitate the horizontal load transfer:

- Exploitation of the tensile strength of the horizontal rebars;
- Development of friction on the part of the crack where contact forces occur;
- Mechanical interlock between the two faces of the crack.

The first two mechanisms are almost similar in both cracked walls. However, it is obvious from Fig. 6 that the higher resolution approximations of the fractal crack have improved capacity to transfer forces through the mechanical interlock mechanism. To the authors' opinion, this is the most important reason for the difference in the response between the walls corresponding to the 3rd and the 4th approximation of the fractal crack. For lower vertical load values the differences are rather limited, however, as the vertical loading increases, the response is completely different because the increased vertical forces are combined with the increased horizontal forces and “destroy” completely the vicinity of the interface.

Figures 10, 11 and 12 display the forces that develop at the horizontal and vertical rebars of the steel mesh for the three variants of the wall examined here (uncracked, 3rd approximation, 4th approximation respectively) for displacements of 5 and 20mm. The left column of each figure corresponds to lower values of the axial loading ($N=500\text{kN}$), the middle column to moderate loading values ($N=1500\text{ kN}$) and the right column to heavy axial loading ($N=2.500\text{ kN}$).

For the case of the uncracked wall (Fig. 10) it is noticed that in the early horizontal loading steps ($\delta=5\text{mm}$), only the vertical rebars are significantly loaded. The rebars in the left side of the wall have tensile forces while the rebars in the right side develop compressive forces, as a result of the bending of the wall. For $\delta=20\text{mm}$, after the development of cracking in various parts of the initially uncracked wall, the horizontal rebars are also stressed, mainly in the areas

where the corresponding cracks have reduced or zeroed the ability of concrete to transfer shear forces.

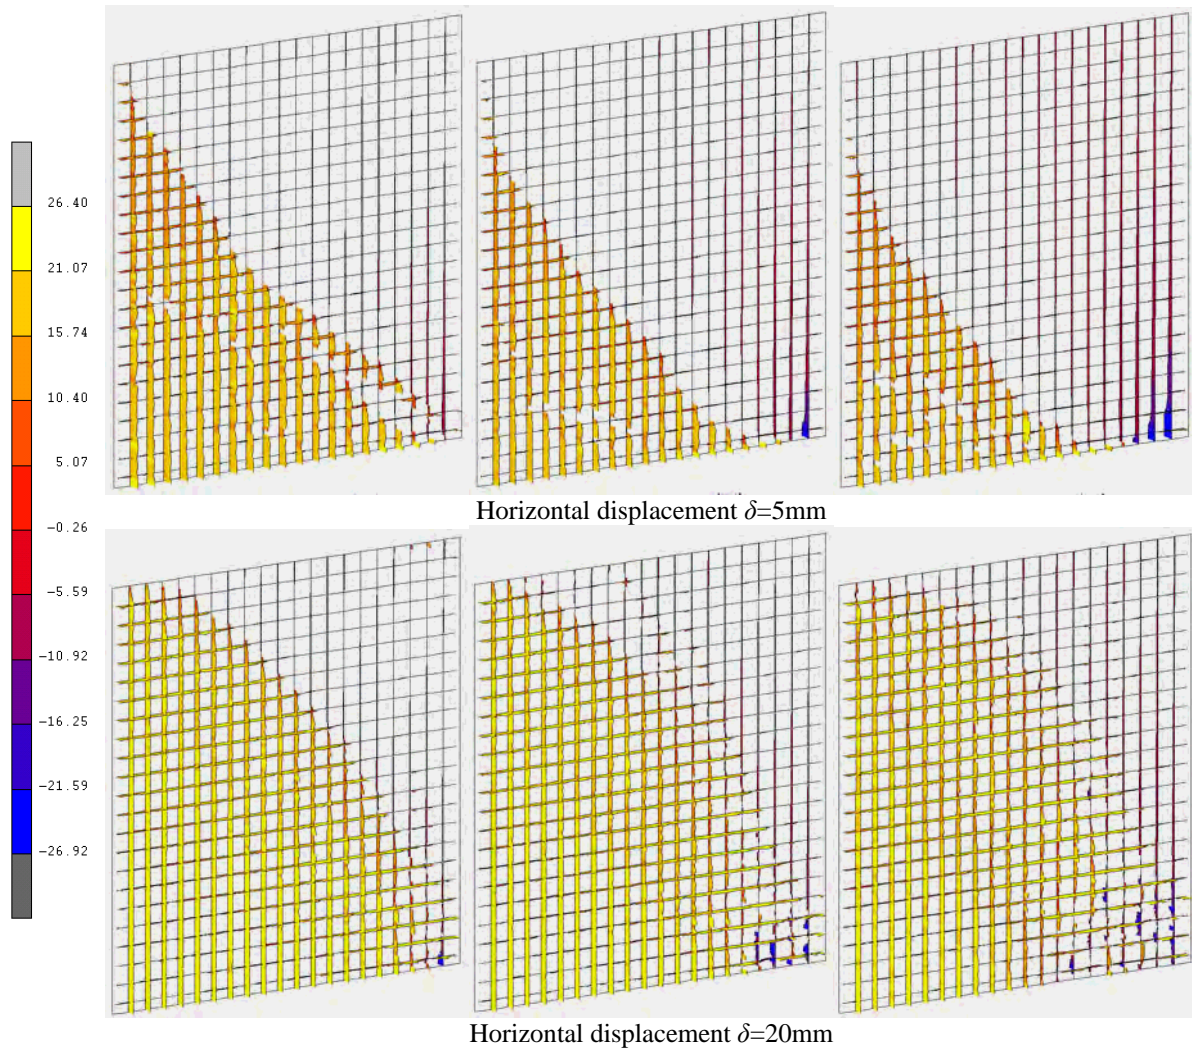

Figure 10: Forces developed in the steel mesh for various values of the vertical loading for the uncracked wall (left column: $N=500$ kN, middle column: $N=1500$ kN, right column: $N=2500$ kN).

For the case of the 3rd approximation of the crack, it is noticed that the vertical rebars are stressed only for small axial loading values. For moderate and heavy axial loading, the vertical rebars are only partial stressed. It deserves to be noticed that the rebar stresses are negative in the vicinity of the crack, a fact that verifies that the concrete is unable to transfer even compressive loading. Moreover, it is noticed that the rebars of the right side of the wall do not develop compressive stresses any more, due to the fact that the magnitude of bending that develops in this case is significantly smaller than that in the case of the uncracked wall. The horizontal rebars are stressed only in specific areas, near the crack and in the regions where cracking strains have been developed. In any case, a closer look in the forces that have been developed in the rebars verifies the significantly decreased bending capacity of the specific wall.

The situation is rather different for the case of the 4th approximation of the fractal crack. The corresponding rebar forces are depicted in Fig. 12. It can easily be verified that for small values of the axial loading, the picture of the forces of the vertical rebars is quite similar to that of the uncracked wall. The same holds also for the forces of the horizontal rebars. For moderate axial load values, the forces of the vertical rebars appear discontinuities. At the right

part of the crack it can be noticed that in some rebars the forces are compressive, indicating again the partial inability of the concrete in this region to transfer compressive loading. The horizontal rebars are mainly stressed in the upper part of the cracked wall and in the vicinity of the crack. Notice that this result is absolutely compatible with the remarks given for the cracked areas in Fig. 7.

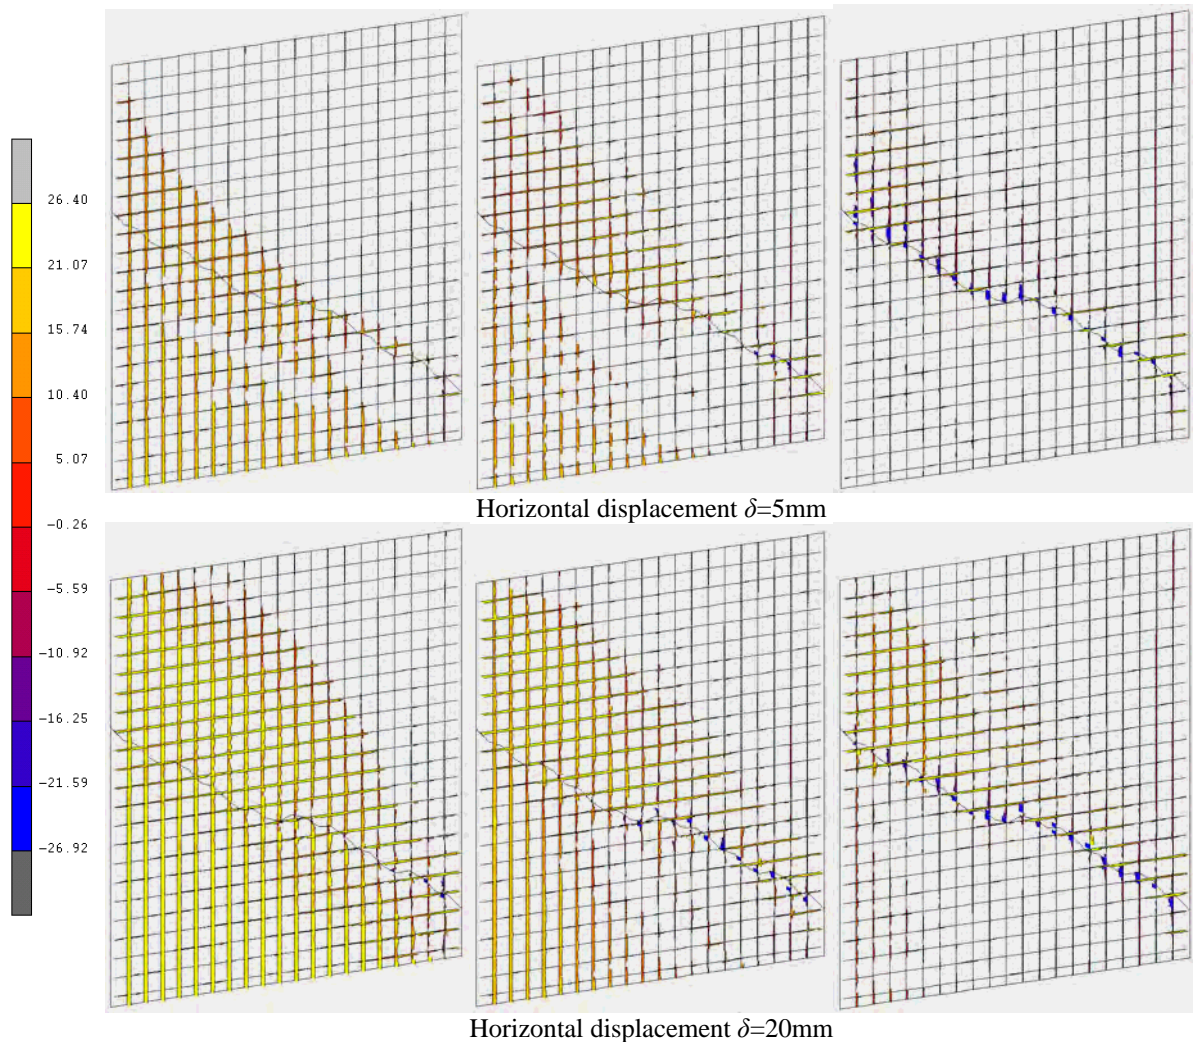

Figure 11: Forces developed in the steel mesh for various values of the vertical loading for the 3rd approximation (left column: $N=500\text{ kN}$, middle column: $N=1500\text{ kN}$, right column: $N=2500\text{ kN}$).

5 CONCLUSIONS

In the paper, the finite element analysis of a typical wall element was presented assuming that a certain crack has been developed as a result of an earthquake action. The crack was modelled following tools from the theory of fractals. Two different resolutions of the fractal curve were considered and their results were compared to those of the initially uncracked wall. The main finding of the paper is that the cracked wall still has the capacity to sustain monotonic horizontal loading. For small axial loading values, this capacity is similar to that of the initially uncracked wall. However, for larger axial loading values, the demands increase. In this case, it seems that a more accurate modelling of the fractal crack (i.e. considering higher values of the resolution) leads to better result. Using lower resolution values, the mechanical interlock between the two faces of the crack is rather limited, leading the concrete in vicinity

of the crack to overstressing and gradually to a complete loss of its capacity to sustain any kind of forces. In this case the bending capacity of the wall is significantly limited with respect to that of the uncracked concrete.

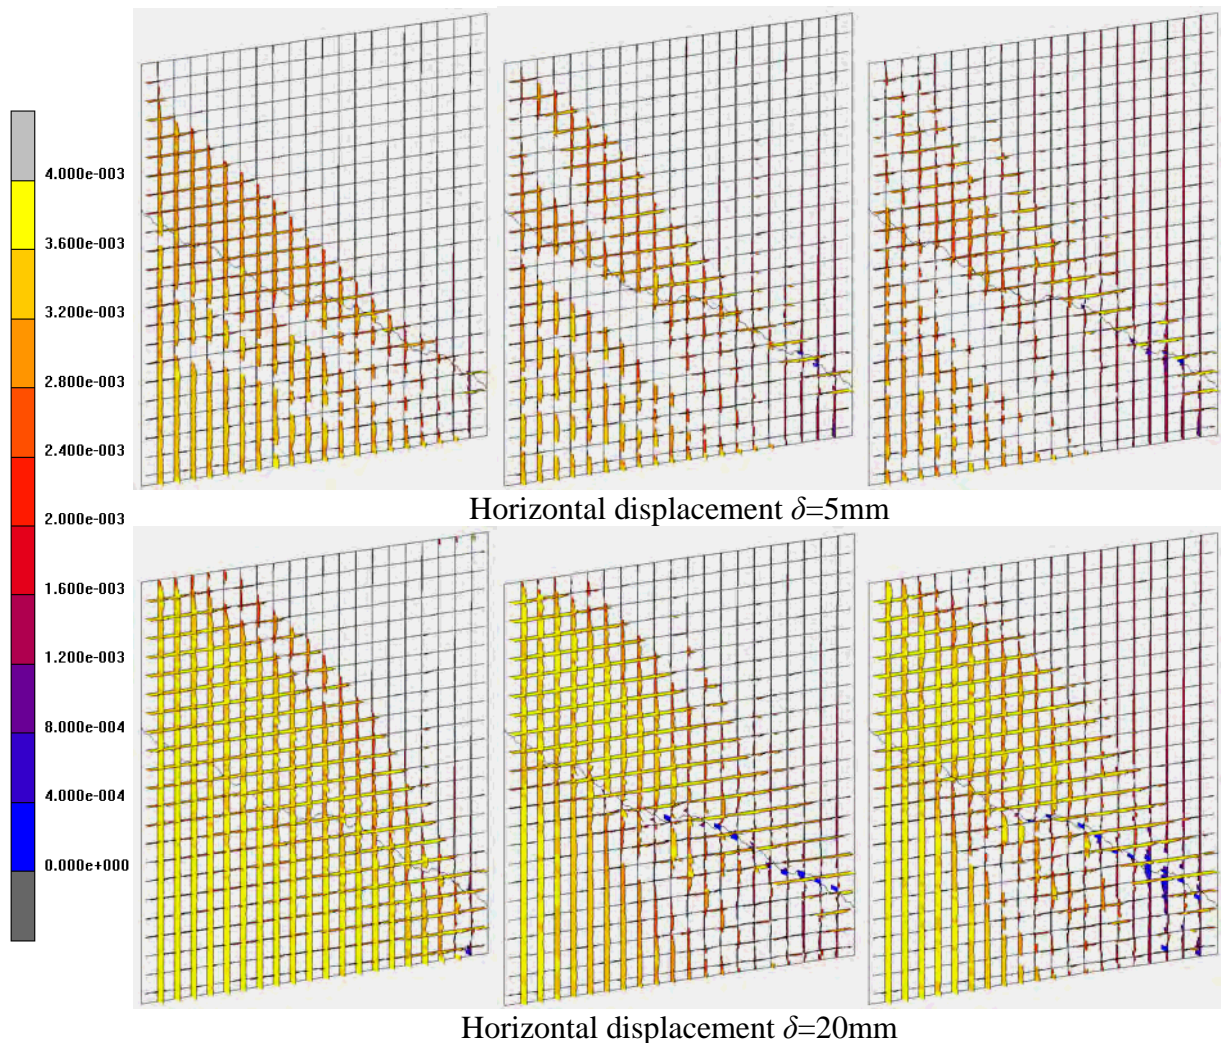

Figure 12: Forces developed in the steel mesh for various values of the vertical loading for the 4th approximation (left column: $N=500$ kN, middle column: $N=1500$ kN, right column: $N=2500$ kN).

Keywords: Concealed beam-column connection, connection, cyclic load, joints, seismic.

Abstract. Reinforced concrete (RC) wide concealed beam-narrow column connections represent the predominant structural system of building structures in Lebanon and the region. For a long time, engineers have paid little attention to the seismic design of these connections, despite their critical role in transferring internal forces when subjected to lateral earthquake load. A two-part experimental study is carried out for evaluating the seismic behaviour of these connections. The first part concentrates on the seismic performance of the connections when designed and detailed for gravity loads (as built) in accordance with local design and construction practices, while the second part focus on the seismic behaviour of the same connections when the reinforcement is detailed more properly against earthquake loads. This paper presents the results of two as built full-scale concealed beam-narrow column connections tested in the first part of the investigation. The connections experienced shear failure within the joint core at relatively small drift ratios varying between 1.5% and 2.0%, and before yielding of the beam or column reinforcement. At drift ratios of about 4.0%, corresponding to drift demands of building structures in regions of high seismic hazard, the connections experienced excessive and un-reparable damage within the joint core. The findings of this first part of the investigation guided the second part for introducing more adequate reinforcement detailing for improving the seismic performance of such type of connections.

1 INTRODUCTION

The predominant building structural system in Lebanon and neighbouring countries is composed of a monolithic flexible ribbed (joist) one-way slab supported on wide concealed (shallow) beams. The beams frame into narrow columns having section aspect ratio between two to four so as to be merged with the infill masonry block walls. The long side of the column could be either parallel or normal to the axis of the beam. Being shallow or concealed the beams have to be quite wide for resisting the shear forces and bending moments produced by the applied loads. The corresponding structural system offers several advantages over the conventional slab-drop beam system in that the concealed beams and narrow columns are preferred by architects and interior designers as they are less obstructing and provide more flexible space. Also, concealed beams (having the same depth as the slab) lead to a more economical formwork, they minimize story heights, and, being wide, they reduce reinforcing steel congestions.

Unfortunately, despite being a region of moderate to high seismic hazard, [1, 2], the majority of building structures in this part of the world, particularly those between 5 and 12 stories in height, are designed with no regards to the seismic activities in the region. Accordingly, the concealed beam–narrow column connections, which constitute an important part of the building structural system, are designed to resist gravity load only. That is, the columns in these connections are designed to resist pure axial compression, with little or no attention to the moment transfer between the floor beams and the columns, and at each floor level, the column reinforcement is spliced with the reinforcement extending from the column below and tied with minimum ties required for gravity load design only. Also, the concealed beams in these connections are designed to resist flexure induced by gravity loads, where the beam positive (bottom) reinforcement on either side of the connection is terminated within a very short length inside the joint core or beyond the beam-column interface section. Furthermore, the core of these joints is constructed with no confinement reinforcement usually required in seismic design.

Little research has been conducted on shallow or wide beam - narrow column connections, [3, 4]. Consequently, most design codes place restrictions on the use of wide beam framing systems in seismic regions because there are insufficient information about their behaviour under the effects of earthquake loadings. A limited number of studies have been carried out on wide shallow beam-column connections, [5, 6, 7, 8], but most of these studies have concentrated on connections that are already designed for earthquake loads and which to a large extent satisfy the dimensions limitations set forth in recognized codes of practice. Consequently the experimental observations and conclusions reported in these studies may not be applicable to the connections under investigation.

A two-part experimental research program is being carried out at the American University of Beirut for evaluating the seismic response of concealed wide beam-narrow column connections. The first part deals with joints that were designed and constructed for gravity load (as built) in accordance with local design and construction practices. The second part, the testing of which is still underway, focus on the seismic behaviour of the same connections when detailed more properly for lateral earthquake loads. In the first part of the investigation, two types of as built beam-column sub-assemblages, representing local construction practices, were tested under lateral earthquake loads. One type in which the long dimension of the narrow column is normal to the direction of lateral load (or beam axis), while the second type is when the long dimension of the column is oriented parallel to the direction of lateral load (or beam axis). This paper presents the experimental results of the first type.

2 EXPERIMENTAL PROGRAM

The dimensions and reinforcement details of two joint specimens, one interior (IJ-F2) and one exterior (EJ-F2), tested in this investigation, are provided in Fig. 1 and are summarized for convenience in Table 1. The connections are composed of 800 mm wide by 250 mm deep beams framing into 700 mm wide by 250 mm deep column for Specimen IJ-F2 and 650 mm wide by 200 mm deep column for Specimen EJ-F2. The connections represent the frame of actual building structures that were designed for gravity load and detailed in accordance with local construction practices.

Figure 1: Dimensions and reinforcement details of the specimens

Joint Component	Dimension and steel reinforcement	IJ-F2	EJ-F2
Column	Size ($b_c \times h_c$) mm	700x250	650x200
	Reinforcement & Reinforcement ratio (%)	12 ϕ 16 (1.37%)	10 ϕ 16 (1.53%)
	Transverse reinforcement	4 legs ϕ 8@200	4legs ϕ 8@200
Beam	Size($b_w \times h_b$) mm	800x250	800x250
	Top reinforcement & Reinforcement ratio	2x9 ϕ 14 (1.65%)	9 ϕ 14 (0.83%)
	Bottom reinforcement & Reinforcement ratio (%)	9 ϕ 16 (1.08%)	9 ϕ 16 (1.08%)
	Transverse reinforcement	4 legs ϕ 8@200	4 legs ϕ 8@200
Joint	Shear reinforcement	None	None

b = section width, h = section depth

Table 1: Dimensions and reinforcement of the joint specimens

Some of the specific reinforcement details that are pertinent to local construction practices include: (i) the lap splice length (of 650 mm) at which the column reinforcement is spliced above the floor level; (ii) the embedment length of the beam bottom reinforcement inside the joint core of 225 mm for the interior and 180 mm for the exterior joint, respectively; (iii) the distance at which the beam top reinforcement is extended on either side of the interior connection beyond the beam-column interface (of 800 mm); and (iv) the anchorage length (of 180 mm) of the beam top and bottom reinforcement inside the exterior connection core beyond the beam-column interface section.

Commercially available Grade 60 steel bars (design yield strength of 415 MPa) having 14 mm and 16 mm diameter were used as the main beam and column longitudinal reinforcement. The measured yield strengths of the steel bars were 627 MPa for the 14 mm and 545 MPa for the 16 mm bars, respectively. The transverse steel reinforcement in both the beams and the columns consisted of plain 8 mm diameter bars having yield strength of 284 MPa.

Both specimens were cast using one batch of Ready Mix concrete. The concrete mix was prepared using Portland cement type I, coarse aggregate with maximum aggregate size of 19 mm and natural sand. The mix was designed for producing a target 28-day cylindrical concrete compressive strength of 20 MPa. The actual compressive strength, measured using standard 150 x 300 mm cylinders, was 21.0 MPa.

2.1 Testing setup and measurements

A schematic view of the test setup is given in Fig. 2. Each connection sub-assembly was supported on steel fixtures to simulate a statically determinate structure with hinge points to represent points of inflection for the actual building structure when subjected to lateral loads. A 500 kN capacity hydraulic actuator with a maximum stroke of ± 127 mm in tension and compression was used to generate cyclic displacements. Axial force was applied at the top of the column using a hydraulic jack. The jack force was transmitted to the column

through four steel rods tied to steel plates at the top and bottom of the column. The magnitude of the column axial force was approximately $0.1f'_c A_g$ for Specimen IJ-F2 and $0.15f'_c A_g$ for Specimen EJ-F2 where A_g is the gross area of the column section. The loading history for all specimens was composed of a sequence of displacement-controlled cycles as shown in Fig. 3, given in *percent* of story drift or drift ratio DR . The drift ratio DR is expressed as $DR, \% = \frac{\Delta_\ell}{h_o} \times 100$ where Δ_ℓ is the lateral drift at the point where the actuator

load is applied, and h_o is the story height or height of the column (measured from the point where the lateral load is applied to the bottom pin support of the column) which is equal to 2.8 m for both specimens. The loading history is composed of two cycles at each drift ratio which varied between 0.5% and 4.5%. Notice that while a maximum drift ratio of 4.5% is considered as a satisfactory story drift in regions of high seismic hazard, the stroke limit of ± 127 mm of the hydraulic actuator used to apply the lateral load and the size of the specimens (column or story height) did not allow symmetrical drift history beyond 4.5%. Nevertheless, specimen IJ-F2 was tested beyond 4.5% using two stages of applied load: in the first stage (Stage 1), the specimen was subjected to cyclic displacements up to a maximum drift ratio of 4.5% (lateral drift of ± 127 mm) in accordance with loading history of Fig. 3. In the second stage (Stage 2), the specimen was subjected to half-cycle displacement protocol ranging between a drift ratio of 5.0% (lateral drift of 140 mm) and a drift ratio of 8.5% (lateral drift of 240 mm). This was achieved by readjusting (retracting) the position of the actuator for utilizing its full stroke capacity in one direction.

Fig. 2: Test setup

Fig. 3: Loading history

Test measurements included applied load and lateral drift, strain in the outermost column reinforcement (starter bars) at the column-beam interface, strain in the top and bottom longitudinal bars of the beams, and average curvature or rotation in the end zones of the columns and beams. The strains were measured using electric strain gauges, while curvatures were measured using Linear Variable Differential Transducers (LVDTs). The test data was recorded using a data acquisition and control system.

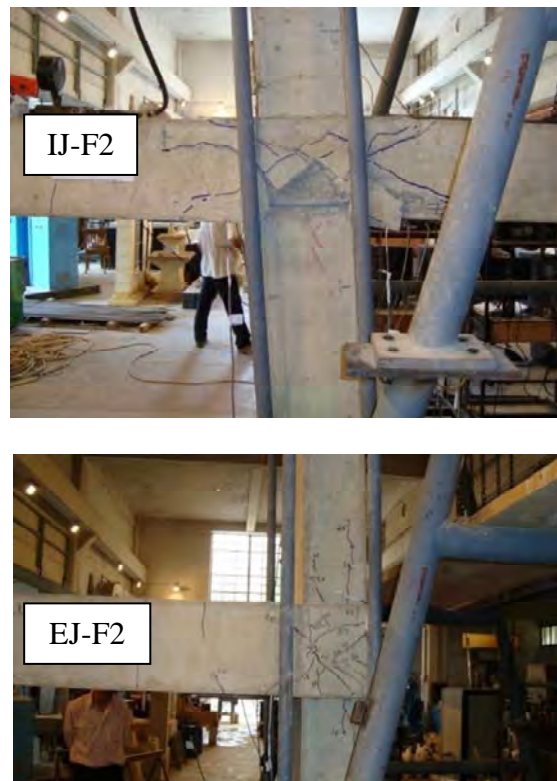

Figure 4: Failure mode of the joint specimens

3 TEST RESULTS

3.1 General behaviour and mode of failure

(i) Specimen IJ-F2

A typical photo of the specimen taken at the conclusion of the test is shown in Fig. 4. As indicated earlier, this specimen was subjected to two stages of load application (Stages 1 and 2). The first flexural crack in this specimen developed in the beam at the joint interface section at a drift ratio of 1.0%. As the lateral drift increased to somewhere between 1.5% and 2.0% diagonal shear cracks started to develop mainly in the joint core indicating the initiation of a joint shear failure. These diagonal cracks continued to spread and widen as the lateral drift increased and to propagate outside the joint core a distance equal approximately a beam depth away from the beam-column interface section (Fig. 4). However, at the end of Stage 1 of the test, corresponding to a maximum drift ratio of 4.5%, despite the development of shear cracks, the specimen did not show signs of strength degradation. In fact, during Stage 2 of the test, the specimen continued to resist lateral load steadily until a drift ratio of 7.0%, beyond which the specimen started experiencing gradual strength degradation. The width of the shear cracks at the maximum drift ratio in Stage 2 of load application reached 6 mm, causing considerable concrete damage.

During the first stage of load application, bond splitting cracks appeared along one of the outermost bottom beam bars on one side of the beam at a drift ratio of about 4.0%. During the second stage, splitting cracks developed as well along the outermost bottom bar on the other side of the beam. At the end of the test in Stage 2, these splitting cracks widened leading to concrete spalling at the bottom corners of the beam (Fig. 4).

(ii) Specimen EJ-F2

The first flexural cracks in specimen EJ-F2 appeared in the beam at the beam-column interface sections at drift ratios of about 1.0%. As the drift increased between 1.0% and 1.5%, the lateral applied load increased gradually, and at the same time, diagonal shear cracks started to develop within the joint core indicating the start of joint shear failure. These diagonal cracks continued to spread and widen as the lateral load increased until the development of a complete joint shear failure which occurred in this specimen at a drift ratio of approximately 1.75% to 2%. The width of the shear cracks at this stage reached between 2 to 3 mm. Beyond a drift ratio of 2%, the specimens experienced progressive strength degradation towards the end of the test. At maximum drift ratios of about 4.5%, the width of the shear cracks increased to about 6 mm, leading to a substantial concrete damage within the joint core (Fig. 4).

While the shear cracks concentrated mainly within the joint core, beyond a drift ratio of 2.0% the cracks tended to propagate outside the joint core similar to Specimen IJ-F2. Although few flexural cracks developed in the beam close to the beam-column interface, the number and width of these cracks stabilized as soon as the diagonal cracks in the joint core started to prevail.

During the tests, at drift levels of 3.0%, bond splitting cracks developed along the beam bottom longitudinal reinforcement outside the column core (one corner bar from each side). These cracks propagated along the full embedment length of the bars beyond the beam-column interface section, of 180 mm (Figs. 3). Eventually these cracks led to spalling of the concrete at the bottom face of the beam indicating bond splitting failure in localized regions of the specimens. This was regarded however as a secondary mode of failure as the development of these cracks did not affect the overall response of the specimens

3.2 Column shear-drift response

The hysteresis response of applied lateral load (column shear force) versus drift ratio are presented in Fig. 5 for both the interior and exterior specimens, and compared with the estimated maximum lateral load capacities H_{\max} of the connections. The estimated capacities H_{\max} were obtained using force equilibrium of the whole connection sub-assemblages calculated as the minimum lateral force required for developing the nominal positive or nominal negative flexural strength of the beam, respectively, or nominal flexural strength of the column. As indicated earlier, the specimens experienced connection shear failure at drift ratios varying between 1.75% and 2.0%.

For Specimen IJ-F2, despite the development of joint shear cracks at a drift ratio of 2.0%, the specimen continued to resist lateral loads at a small rate reaching a load of 72.0 kN at a drift ratio of 4.5% (end of the test in the first loading stage). The corresponding lateral load resistance is 59% of the estimated static lateral load capacity H_{\max} of the specimen of 122 kN. It is interesting to observe in Fig. 5 that even subjecting the specimen to 8.5% lateral drift in a half-cycle mode, it did not lead to significant strength degradation. The low strength degradation of this specimen below the load at which shear failure occurred may be attributed to the relatively low lateral load at which the specimen failed in shear (of about 56 kN) combined with relatively low shear decay associated with stabilization of the shear cracks within the joint core. The stiffness of the specimen (defined as the slope of the line that passes from the origin to the point on the envelope response) decreased to about 50% of the initial stiffness (stiffness at initial loading) at drift ratio of 4.5% (Stage 1) and 25% of the initial stiffness at drift ratio of 8.0% (Stage 2), respectively.

After the initiation of shear cracks at a drift ratio of about 1.75%, Specimen EJ-F2 displayed a stable behaviour without loss in load resistance until reaching a drift ratio of 2.5%. The peak lateral load developed in this specimen was approximately 20.0 kN which is only 35% of the estimated static lateral load resistance H_{\max} of 54 kN. Beyond a drift of 2.5%, the lateral load resistance degraded gradually, reaching at 4.0% drift about 50% of the peak load. Also, at a drift ratio of 4.0%, the stiffness of the specimen decreased to about 17.0% of the initial stiffness.

3.3 Reinforcement strains/stresses and bond performance

3.3.1 Beam reinforcement

Cyclic response of the beam reinforcement strain with lateral drift of the specimens is presented in Fig. 6. As a result of the premature connection shear failure, the strains developed in the steel reinforcement were well below yield. The maximum tension strains of the beam bottom and top bars at peak lateral load were $1536 \mu\epsilon$ and $1847 \mu\epsilon$ for Specimen IJ-F2; and $1435 \mu\epsilon$ and $1670 \mu\epsilon$ for Specimen EJ-F2, respectively.

As indicated earlier, both of Specimens IJ-F2 and EJ-F2 developed localized bond splitting cracks in the outermost beam bottom bars outside the column core. Some of the main reasons for the localized bond splitting failure are the short development length provided for the beam bottom bars beyond the beam-column interface section, and the lack of concrete or steel confinement for the bars outside the column core. Notice that the development

Figure 5: Lateral load-drift ratio response of the specimens

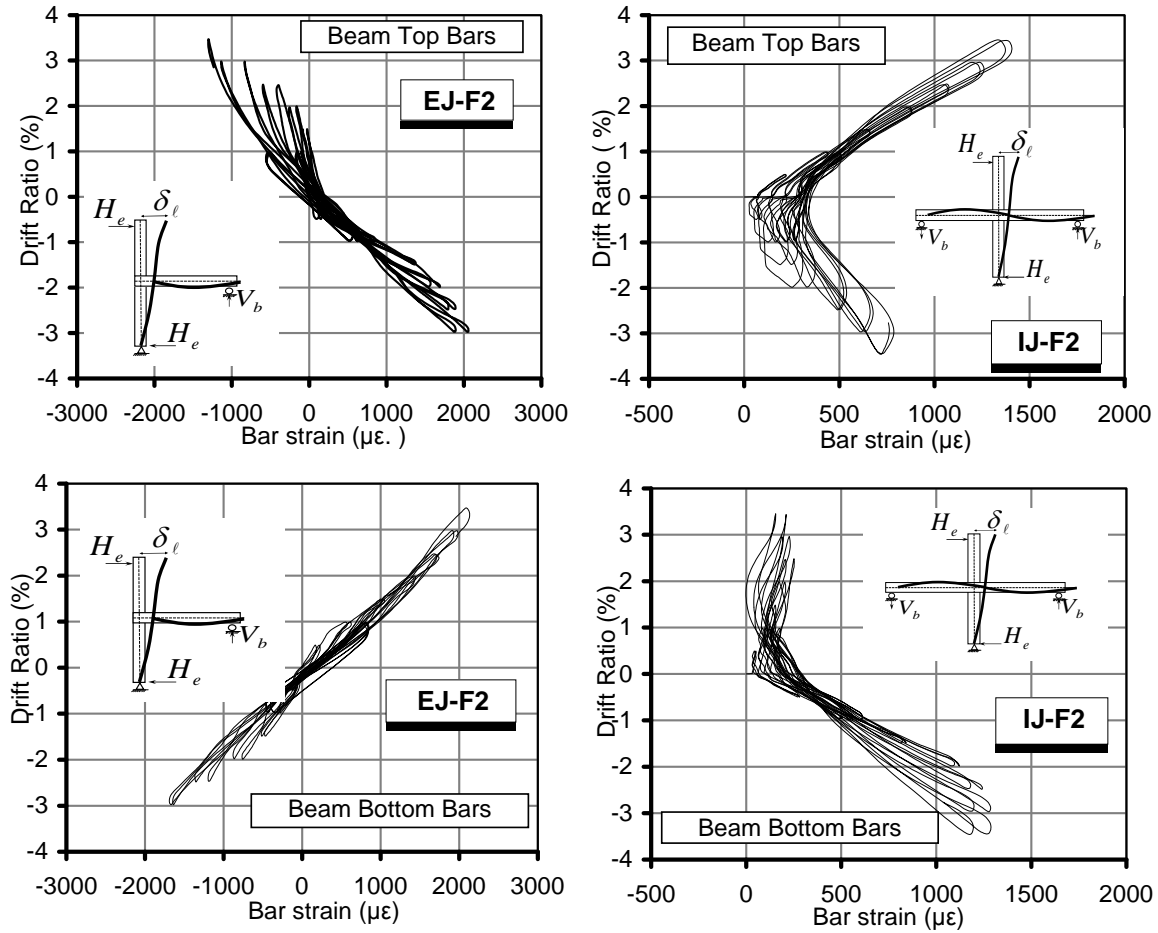

Fig. 6: Variation of beam reinforcement strain with drift ratio

lengths provided for the beam bottom bars were 225 mm or $14.0d_b$ for Specimen IJ-F2, and 180 mm or $11.3d_b$ for EJ-F2, respectively. These development lengths are less than the minimum of $27d_b$ required by ACI 318-08 for $f'_c = 21$ MPa.

3.3.2 Column reinforcement

The maximum strain developed in the column reinforcement of Specimen EJ-F2 was $2630 \mu\epsilon$, which is below yield. However, during the second stage of loading, the outermost left column bar in Specimen IJ-F2 did indeed develop yielding and attained a measured strain of $4545 \mu\epsilon$ at a drift ratio of 5.0%.

It should be mentioned that, based on test observations, all of the column reinforcement for Specimen EJ-F2 did not exhibit bond deterioration associated with bond splitting and/or excessive bond slip. However, during the second stage of loading for Specimen IJ-F2, a bond splitting crack was observed along one the corner column bars, but it was not critical as it did not result in a noticeable change of the specimen behaviour. Notice that the ACI Building code prohibits splicing of column reinforcement at the base of the column in regions of high seismic hazard so as to avoid possible bond failure at the column base where plastic hinging is likely to develop. However, because of the premature joint shear failure and the consequent development of relatively small stresses in the column reinforcement at nominal lateral load capacities of the specimens, no conclusions can be drawn regarding this requirement in

relation to the beam-column connections under investigation. A conclusion regarding this requirement is addressed during the second part of this investigation dealing with the seismic response of the same beam-column connections after being detailed more properly for avoiding joint shear failure.

4 CONCLUSIONS

The following conclusions can be drawn from this investigation:

- When subjected to drift reversals induced by even moderate earthquakes, gravity load designed concealed wide beam-narrow column connections of the type under investigation will develop sizable diagonal shear cracks and consequently joint shear failure at drift ratios varying between 1.5 and 2.0%. These connections are expected to experience large damage beyond repair and possibly structural collapse when subjected to large drift reversals induced by strong earthquakes.
- As a result of the premature joint shear failure, the strains in the beam and column reinforcement developed at maximum lateral load capacity were well below yield. The lateral load capacities reached by the specimens in percent of the estimated capacities should the beams or columns acquire their nominal flexural strength were 59% for the interior and 35% for the exterior connection, respectively.
- Bond splitting cracks did develop around the outermost beam bars outside the column core due to the short embedment length beyond the beam-column interface section and the lack of concrete or steel confinement, but these cracks were not as critical in controlling the performance of the joints when compared with the joint diagonal shear cracks.
- Even in regions of moderate seismic hazard, unless designed and detailed to prevent joint shear failure, the connections under investigation are significantly weak to be considered as part of the earthquake lateral load resisting system.

ACKNOWLEDGMENTS

The authors are most grateful for the support of the Faculty of Engineering and Architecture at the American University of Beirut (AUB) for providing the test facilities.

Key words: wave propagation, modal analysis, energy-orthogonal stiffness.

Abstract. *This paper studies the propagation of plane harmonic waves in unbounded media discretized by the standard twenty-node hexahedral finite element. The element stiffness matrix is split into basic and higher order components which are obtained from mean and deviatoric strain fields, respectively. This decomposition is applied to the elastic energy. Based on the properties of the higher order energy, two values of the wave number are selected. Depending on the desired precision one of those values can be used as optimum cutoff wave number to properly capture a wave field.*

1 INTRODUCTION

The wave propagation in solids is a so broad scientific subject that analytical solutions to the governing equation of motion exist for just the simplest cases and only approximate solutions are feasible for the others. One method for obtaining approximate solutions is to use numerical procedures, such as the finite element method, which often introduce phenomena that are not present in the physical system [1]. In references [2, 3] the wave propagation in solids is analyzed through.

The governing equation of motion for a homogeneous isotropic elastic solid may be summarized as

$$(\lambda + \mu)\nabla\nabla \cdot \mathbf{u} + \mu\nabla^2\mathbf{u} + \rho\mathbf{f} = \rho\ddot{\mathbf{u}} \quad (1)$$

where: the elastic constants for the material are λ and μ , the Lamé constants; ρ , the mass density per unit volume of the material; \mathbf{u} , the displacement vector; \mathbf{f} , the body force per unit mass of material.

The Lamé constants can be expressed as

$$\lambda = \frac{E\nu}{(1+\nu)(1-2\nu)}, \quad \mu = \frac{E}{2(1+\nu)} \quad (2)$$

where: E , Young's modulus; ν , Poisson's ratio for the material.

Let us consider the Helmholtz decomposition of the displacement vector as the gradient of a scalar and the curl of a zero divergence vector,

$$\mathbf{u} = \nabla\Phi + \nabla \times \mathbf{H}, \quad \nabla \cdot \mathbf{H} = 0 \quad (3)$$

The scalar potential Φ is associated with the dilatational part of the disturbance, and the vector potential \mathbf{H} with the rotational part.

By considering Eq. (3), the governing equation of motion Eq. (1) is decomposed as two simplified wave equations, in the absence of body forces,

$$\nabla^2\Phi = \frac{1}{c_L^2} \frac{\partial^2\Phi}{\partial t^2}, \quad \nabla^2\mathbf{H} = \frac{1}{c_T^2} \frac{\partial^2\mathbf{H}}{\partial t^2} \quad (4)$$

where:

$$c_L = \left(\frac{\lambda + 2\mu}{\rho} \right)^{1/2}, \quad c_T = \left(\frac{\mu}{\rho} \right)^{1/2} \quad (5)$$

Bulk wave propagation refers to wave propagation in unbounded media; guided waves are those that require a boundary for their existence, such as surface waves, Lamb waves, and interface waves. This paper will focus on bulk wave propagation in unbounded media. By considering Eq. (4) we deduce that the dilatational and rotational bulk waves propagate without interaction in unbounded media with the velocities c_L and c_T , respectively. These two types of waves are coupled only on the boundary of the elastic solid, an obvious consequence of satisfying the boundary conditions. The dilatational and rotational bulk waves are also called primary (P) and secondary (S) waves, respectively.

In this paper we consider the propagation of uniform plane harmonic waves,

$$\mathbf{u} = A\hat{\mathbf{a}} \exp[i(\kappa\mathbf{n} \cdot \mathbf{r} - \omega t)] \quad (6)$$

where: A , amplitude of the wave; ω , radial frequency; κ , wave number; $\hat{\mathbf{a}}$, polarization vector, unit vector indicating the direction of the particle displacement; \mathbf{n} , wave normal, unit vector indicating the direction of the wave propagation; \mathbf{r} , position vector.

The wave number and the radial frequency will be

$$\kappa = \frac{2\pi}{\lambda} = \frac{\omega}{c}, \quad \omega = \frac{2\pi}{T} = 2\pi f \quad (7)$$

where: λ , wavelength; c , phase speed of the continuum; T , period of wave; f , cyclic frequency.

The longitudinal plane waves, where the displacements are in the direction of the wave normal and only normal stresses are acting along the wave front, are dilatational waves; nevertheless, the transverse plane waves, where the displacements are perpendicular to the wave normal and only shearing stresses are acting along the wave front, are rotational waves.

For isotropic elastic material, the relationship between strains and stresses, in the absence of initial strains and stresses, can be expressed in matrix form as

$$\{\sigma_x \quad \sigma_y \quad \sigma_z \quad \tau_{xy} \quad \tau_{xz} \quad \tau_{yz}\}^t = \mathbf{E} \{\varepsilon_x \quad \varepsilon_y \quad \varepsilon_z \quad \gamma_{xy} \quad \gamma_{xz} \quad \gamma_{yz}\}^t \quad (8)$$

where \mathbf{E} is the elasticity matrix,

$$\mathbf{E} = \begin{bmatrix} \lambda + 2\mu & \lambda & \lambda & 0 & 0 & 0 \\ \lambda & \lambda + 2\mu & \lambda & 0 & 0 & 0 \\ \lambda & \lambda & \lambda + 2\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu \end{bmatrix} \quad (9)$$

By considering Eq. (5), the elasticity matrix also can be expressed in the forms

$$\mathbf{E}_L = \rho c_L^2 \begin{bmatrix} 1 & p & p & 0 & 0 & 0 \\ p & 1 & p & 0 & 0 & 0 \\ p & p & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & q & 0 & 0 \\ 0 & 0 & 0 & 0 & q & 0 \\ 0 & 0 & 0 & 0 & 0 & q \end{bmatrix}, \quad \mathbf{E}_T = \rho c_T^2 \begin{bmatrix} \varepsilon & r & r & 0 & 0 & 0 \\ r & \varepsilon & r & 0 & 0 & 0 \\ r & r & \varepsilon & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (10)$$

where: $p = 1 - 2/\varepsilon$, $q = 1/\varepsilon$, $r = \varepsilon - 2$ and $\varepsilon = c_L^2/c_T^2 = (\lambda + 2\mu)/\mu = (2 - 2\nu)/(1 - 2\nu)$. Since $0 \leq \nu \leq 1/2$ always, we deduce the inequality $c_L > c_T$.

The forms of the elasticity matrix given by the Eq. (10) will be useful to analyze the propagation of longitudinal and transverse waves, respectively.

This work essentially extends the author's previous work on the eight-node quadrilateral and the six-node triangle [4, 5]. The elastic media is discretized by the standard twenty-node hexahedral finite element [6] with consistent mass matrix [7]. By splitting the strain-nodal displacements matrix into mean and deviatoric components

$$\mathbf{e}^e = \mathbf{B}^e \mathbf{x}^e = (\bar{\mathbf{B}}^e + \mathbf{B}_d^e) \mathbf{x}^e \quad (11)$$

$$\bar{\mathbf{B}}^e V^e = \int_V \mathbf{B}^e dV, \quad \mathbf{B}_d^e = \mathbf{B}^e - \bar{\mathbf{B}}^e \quad (12)$$

the element stiffness matrix will be

$$\mathbf{K}^e = \mathbf{K}_b^e + \mathbf{K}_h^e \quad (13)$$

$$\mathbf{K}_b^e = \int_V (\bar{\mathbf{B}}^e)^t \mathbf{E} \bar{\mathbf{B}}^e dV \quad (14)$$

$$\mathbf{K}_h^e = \int_V (\mathbf{B}_d^e)^t \mathbf{E} \mathbf{B}_d^e dV \quad (15)$$

where: \mathbf{K}_b^e , basic stiffness matrix; and \mathbf{K}_h^e , higher order stiffness matrix.

In this case the element stiffness matrix is decomposed in energy-orthogonal form [8]. The basic and higher order matrices are related to the mean and deviatoric strain fields,

$$\bar{\mathbf{e}}^e = \bar{\mathbf{B}}^e \mathbf{x}^e, \quad \mathbf{e}_d^e = \mathbf{B}_d^e \mathbf{x}^e \quad (16)$$

respectively.

The concept of energy-orthogonal stiffness matrix used in this paper was explicitly introduced by Bergan and Nygård in the context of the Free Formulation [9], and by Felippa within the framework of the Parametrized Variational Principles [10].

The decomposition Eq. (13) holds for the complete model whenever \mathbf{K}_b^e and \mathbf{K}_h^e are independently assembled,

$$\mathbf{K} = \mathbf{K}_b + \mathbf{K}_h \quad (17)$$

This decomposition is also applied to the elastic energy of the finite element assemblage,

$$U = U_b + U_h \quad (18)$$

$$U_b = \frac{1}{2} \mathbf{x}^t \mathbf{F}_b, \quad \mathbf{F}_b = \mathbf{K}_b \mathbf{x} \quad (19)$$

$$U_h = \frac{1}{2} \mathbf{x}^t \mathbf{F}_h, \quad \mathbf{F}_h = \mathbf{K}_h \mathbf{x} \quad (20)$$

where: U_b , basic elastic energy; U_h , higher order elastic energy; \mathbf{F}_b and \mathbf{F}_h , basic and higher order forces vector, respectively.

In this paper the dispersion properties and the elastic energy of both longitudinal and transverse waves are computed for the unbounded media discretized by regular meshes. If the exact solution of the problem consists of a constant stress state, the higher order elastic energy vanishes over each element. Similarly, as the solution converges on account of mesh refinement, the element energy is increasingly dominated by the basic energy. This behavior has been numerically verified for the standard twenty-node hexahedral finite element in the context of modal analysis [11].

The above heuristic argument shows that the higher order elastic energy may be regarded as a local error indicator [10]. Although this assumption is based largely on numerical experiments motivates to explore the relationship between the higher order elastic energy and the numerical dispersion introduced by the finite element method.

In this paper the behavior of the higher order elastic energy is investigated and based on its properties two values of the wave number are selected as reference values. The use of one of those values as optimum cutoff wave number to properly capture a wave field is investigated. The concept is extended to define an optimum cutoff frequency to properly capture the natural modes of a solid.

The distinctive contributions of this paper over the author's previous works [4, 5] are related to the consideration of hexahedral elements both moderately and highly distorted. These ones could be useful for the 3D modelling of structural elements.

2 WAVES IN UNBOUNDED MEDIA

2.1 Characteristic equations

In a solid discretized by the finite element method the equations of equilibrium governing its linear dynamic response may be cast in matrix form

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f} \quad (21)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping, and stiffness matrices; \mathbf{f} is the external load vector; and \mathbf{x} is the displacement vector of the finite element assemblage [12].

The homogeneous and isotropic unbounded media is discretized by a regular mesh of standard twenty-node hexahedral elements, Figure 1. The nodal lattice has four nodes per unit cell which are labeled A , B , C and D , respectively. The node A is a corner one, whereas the nodes B , C and D are mid-side ones. Specifically, the elements analyzed are of brick geometry. Different meshes with the same element volume can be obtained by changing the aspect ratio parameter, γ ; where, $1 \geq \gamma > 0$. The finite element analysis will be performed by using the rectangular coordinate system Σ : XYZ .

Figure 1: Regular mesh of standard twenty-node hexahedral elements and unit cell.

The characteristic equations can be found assuming uniform plane harmonic waves with different amplitudes in each node of the unit cell,

$$\mathbf{u} = A_i \hat{\mathbf{a}} \cos[\mathbf{k}\mathbf{n} \cdot \mathbf{r} - \omega t], \quad i = 1, 2, 3, 4 \quad (22)$$

where: A_1 , A_2 , A_3 and A_4 , wave amplitudes in the nodes A , C , B and D , respectively.

The wave normal \mathbf{n} and the assumed polarization vector $\hat{\mathbf{a}}$ are related to the rectangular coordinate system Σ_p , obtained from Σ by three successive rotations defined by the Euler angles, Figure 2. For longitudinal waves, $\mathbf{n} = \hat{\mathbf{a}} = \mathbf{i}_p$; for transverse waves, $\hat{\mathbf{a}} = \mathbf{j}_p$ or $\hat{\mathbf{a}} = \mathbf{k}_p$.

The components of the displacement vector \mathbf{u} with respect to the coordinate system Σ are obtained from the ones respect to the coordinate system Σ_p by

$$\{u \quad v \quad w\}^t = \mathbf{R}^t \{u_p \quad v_p \quad w_p\}^t \quad (23)$$

The transformation matrix will be

$$\mathbf{R} = \mathbf{CBA} \quad (24)$$

where

$$\mathbf{A} = \begin{bmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & \sin \theta \\ 0 & -\sin \theta & \cos \theta \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} \cos \psi & \sin \psi & 0 \\ -\sin \psi & \cos \psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (25)$$

are the transformation matrices for the rotations $\Sigma \rightarrow \Sigma_a$, $\Sigma_a \rightarrow \Sigma_b$ and $\Sigma_b \rightarrow \Sigma_p$, respectively. The three Euler angles are called the precession ϕ , the nutation θ , and the spin ψ [13].

Figure 2: Rectangular coordinate transformation corresponding to three successive rotations defined by the Euler angles.

By considering the homogeneous part of Eq. (21) with damping neglected and substituting the assumed harmonic solutions we obtain the characteristic equation for each node of the unit cell by the equilibrium of nodal forces into the direction of the particle displacement [14].

The four characteristic equations form a system of homogeneous algebraic equations,

$$\mathbf{Z}\mathbf{A} = \begin{bmatrix} z_{11} & z_{12} & z_{13} & z_{14} \\ z_{21} & z_{22} & z_{23} & z_{24} \\ z_{31} & z_{32} & z_{33} & z_{34} \\ z_{41} & z_{42} & z_{43} & z_{44} \end{bmatrix} \begin{Bmatrix} A_1 \\ A_2 \\ A_3 \\ A_4 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \quad (26)$$

$$z_{ij} = a_{ij}(m, \phi, \theta, \psi, \nu, \gamma) + \varpi^2 b_{ij}(m, \phi, \theta, \psi, \nu, \gamma) \quad (27)$$

$$m = \frac{b\kappa}{\pi} = \frac{2b}{\lambda}, \quad \varpi = \frac{2b}{c} \omega \quad (28)$$

where: m , dimensionless wave number; b , half of the cubic element size; ϖ , dimensionless frequency of the discretized media.

The dimensionless wave number will be $m_L = b\kappa_L/\pi$ and $m_T = b\kappa_T/\pi$ for longitudinal and transverse waves, respectively. From the continuum frequencies and Eq. (7) we obtain the relationship $m_T/m_L = c_L/c_T$. From $c_L > c_T$ we deduce the inequality $m_L < m_T$.

2.2 Dispersion equations

The system of homogeneous algebraic equations given in Eq. (26) has a non-trivial solution only if the matrix \mathbf{Z} is singular; that is,

$$\det[\mathbf{Z}(m, \phi, \theta, \psi, \nu, \gamma, \varpi)] = 0 \quad (29)$$

By considering Eq. (27), from Eq. (29) we obtain the quartic equation

$$q^4 + d_3 q^3 + d_2 q^2 + d_1 q + d_0 = 0 \quad (30)$$

where: $q = \varpi^2$; $d_i(m, \phi, \theta, \psi, \nu, \gamma)$, coefficients obtained from a_{ij} and b_{ij} .

Either of Eq. (29) and (30) is called a characteristic frequency equation for plane wave propagation.

It is an important fact that the n zeroes of a polynomial of degree $n \geq 1$ with complex coefficients depend continuously upon the coefficients [15]. Thus, sufficiently small changes in the coefficients of a polynomial can lead only to small changes in any zero. However there is no simple way to define a function which takes the n coefficients (all but the leading 1) of a monic polynomial of degree n to the n zeroes of the polynomial, since there is no natural way to define an ordering among the n zeroes. In the case of the quartic polynomial Eq. (30), this problem has been solved by obtaining the zeroes in closed form. Then, the components

$$q_i = q_i(d_0, d_1, d_2, d_3), \quad i = 1, 2, 3, 4 \quad (31)$$

or, alternatively,

$$\varpi_i = \varpi_i(m, \phi, \theta, \psi, \nu, \gamma), \quad i = 1, 2, 3, 4 \quad (32)$$

will be continuous functions precisely defined. They are called dispersion equations. Obviously, we suppose that the coefficients $d_i(m, \phi, \theta, \psi, \nu, \gamma)$ are also continuous functions.

Substituting Eq. (32) into Eq. (26), the wave amplitudes for each dispersion equation are produced. In this work, each set of linear algebraic equations is numerically solved by using the singular value decomposition method SVD [16].

The range of dimensionless wave number values where each dispersion equation represents the propagation of acoustic waves in the discretized media will be called the

acoustical branch of the dispersion equation. In order to determine the acoustical branches, a preliminary constraint condition over the dimension of the null space of \mathbf{Z} must be imposed,

$$\dim[\mathbf{N}(\mathbf{Z})] = 1 \quad (33)$$

The constraint condition Eq. (33) implies that the subspace of solutions to Eq. (26) must be one-dimensional. In this case the vector of wave amplitudes \mathbf{A} is arbitrary to the extent that a scalar multiple of it is also a solution. Then the following constraint conditions are imposed,

$$A_{1,i} = 1, \quad \begin{cases} A_{2,i}(m, \phi, \theta, \psi, \nu, \gamma) > 0 \\ A_{3,i}(m, \phi, \theta, \psi, \nu, \gamma) > 0, \quad i = 1, 2, 3, 4 \\ A_{4,i}(m, \phi, \theta, \psi, \nu, \gamma) > 0 \end{cases} \quad (34)$$

$$\left(\frac{\partial \varpi_i}{\partial m} \right)_{\phi, \theta, \psi, \nu, \gamma} > 0, \quad i = 1, 2, 3, 4 \quad (35)$$

The constraint condition Eq. (34) implies that the four nodes on the unit cell vibrate along the same direction. In molecular physics, condition Eq. (34) is called the restriction of the lattice spectrum to the acoustical branch [17]. Obviously, if the constraint condition Eq. (33) is not imposed, the constraint condition Eq. (34) is meaningless.

From Eq. (28) we obtain both the phase velocity and group velocity of the discretized media,

$$c_d = \frac{c}{2\pi} \frac{\varpi}{m}, \quad c_{g,d} = \frac{\partial \omega}{\partial \kappa} = \frac{c}{2\pi} \frac{\partial \varpi}{\partial m} \quad (36)$$

Therefore, the constraint condition Eq. (35) is equivalent to

$$c_{g,d} > 0 \quad (37)$$

It can be proven that for general periodic motion in lossless or low loss media the energy propagates with the group velocity [2]; therefore, the constraint condition Eq. (37) imposes that the energy propagates into the wave direction.

From this point, for each dispersion equation only the acoustical branch will be considered. This one represents the physically admissible solution for mechanical wave propagation.

It must be recall that the group velocity of the continuum will be equal to the phase velocity because the waves propagate non-dispersively. Nevertheless, for the dispersive discretized media the group velocity will be different from the phase velocity; therefore, the velocity of energy transport will be different from the phase velocity. As a consequence, when we consider the numerical dispersion associated with the finite element spatial discretization, not only the effect over the phase velocity must be analyzed but also the effect over the group velocity or velocity of energy transport.

2.3 Indicators of dispersion

By considering Eq. (36), the indicators of the dispersion associated with spatial discretization that is introduced by the finite element model are defined as

$$e_d = \frac{c_d}{c} = \frac{\varpi}{2m\pi}, \quad e_d = e_d(m, \phi, \theta, \psi, \nu, \gamma) \quad (38)$$

$$e_{g,d} = \frac{c_{g,d}}{c} = \frac{1}{2\pi} \frac{\partial \varpi}{\partial m}, \quad e_{g,d} = e_{g,d}(m, \phi, \theta, \psi, \nu, \gamma) \quad (39)$$

These indicators consider the effect of the spatial discretization over the wave velocity and the velocity of energy transport, respectively. The indicators of spatial dispersion Eq. (38) and Eq. (39) are computed versus the dimensionless wave number both for longitudinal and transverse waves. Specifically, three test problems are analyzed in this paper, Figure 3.

For the Test A, the wave normal has direction parallel to two faces of the brick, and the polarization vector has direction either parallel to or perpendicular to those faces. Depending on the selected faces it can be distinguish three different cases:

$$\begin{aligned} \text{TEST } A - XY : \quad & \phi = 0^\circ, \quad \theta = 0^\circ; \quad 0 \leq \psi \leq 90^\circ. \\ \text{TEST } A - XZ : \quad & \phi = 0^\circ, \quad \theta = 90^\circ; \quad 0 \leq \psi \leq 90^\circ. \\ \text{TEST } A - YZ : \quad & \phi = 90^\circ, \quad \theta = 90^\circ; \quad 0 \leq \psi \leq 90^\circ. \end{aligned} \quad (40)$$

Figure 3: Test problems to evaluate the numerical dispersion.

For the Test B, the wave normal has direction parallel to a plane that diagonally intersects two opposite faces of the brick, and the polarization vector has direction either parallel to or perpendicular to that plane. Depending on the selected faces it can be distinguish three different cases:

$$\begin{aligned}
 \text{TEST } B - XY: \quad & \text{tg}\phi = \frac{1}{\gamma^2}, \quad \theta = 90^\circ; \quad 0 \leq \psi \leq 90^\circ. \\
 \text{TEST } B - XZ: \quad & \phi = 90^\circ, \quad \text{tg}\theta = \frac{1}{\gamma}; \quad 0 \leq \psi \leq 90^\circ. \\
 \text{TEST } B - YZ: \quad & \phi = 0^\circ, \quad \text{tg}\theta = \gamma; \quad 0 \leq \psi \leq 90^\circ.
 \end{aligned} \tag{41}$$

For the Test C, the wave normal has direction parallel to a plane that diagonally intersects three faces of the brick, and the polarization vector has direction either parallel to or perpendicular to that plane,

$$\text{TEST } C: \quad \text{tg}\phi = -\frac{1}{\gamma^2}, \quad \text{tg}\theta = \sqrt{\gamma^2 + \frac{1}{\gamma^2}}; \quad 0 \leq \psi < 180^\circ. \tag{42}$$

For the Test C, a particular case of Eq. (38) is plotted in Figure 4. Three values of the angle of wave propagation are considered in order to represent the anisotropy induced by the spatial discretization. The dispersion associated with spatial discretization is clearly displayed as the dimensionless wave number increases.

It must be remarked that for the Test A and $\gamma = 1$, the values of Eq. (38) and Eq. (39) obtained both for longitudinal waves $\mathbf{n} = \hat{\mathbf{a}} = \mathbf{i}_p$ and transverse waves $\hat{\mathbf{a}} = \mathbf{j}_p$ are coincident with the ones obtained for the eight-node square element [4].

Figure 4: Test C. Indicator of spatial dispersion associated to the phase velocity versus dimensionless wave number for three values of the angle of wave propagation.

2.4 Higher order elastic energy at the unit cell

By considering the decomposition Eq. (18), in this paper we explore the relationship between the higher order elastic energy at the unit cell and the discretization error introduced by the finite element method. Assuming the harmonic waves Eq. (22), we obtain the higher order energy at the unit cell as the sum of the component associated with the corner node A ,

$$U_h^A = \rho c^2 (2b) F_h^A(m, \phi, \theta, \psi, v, \gamma, \tau) \tag{43}$$

and the component associated with the mid-side nodes B , C and D ,

$$U_h^M = \rho c^2 (2b) F_h^M(m, \phi, \theta, \psi, \nu, \gamma, \tau) \quad (44)$$

where: $\tau = t/T$, dimensionless time.

The period-averaged values,

$$\bar{F}_h^A(m, \phi, \theta, \psi, \nu, \gamma) = \int_0^1 F_h^A(m, \phi, \theta, \psi, \nu, \gamma, \tau) d\tau \quad (45)$$

$$\bar{F}_h^M(m, \phi, \theta, \psi, \nu, \gamma) = \int_0^1 F_h^M(m, \phi, \theta, \psi, \nu, \gamma, \tau) d\tau \quad (46)$$

are defined as the specific higher order corner energy and the specific higher order mid-side energy, respectively. The sum of these two components is the specific higher order energy at the unit cell.

The specific higher order corner and mid-side energies are computed versus the dimensionless wave number both for longitudinal and transverse waves. For the Test C, a particular case is plotted in Figures 5 and 6.

Figure 5: Test C. Specific higher order corner energy versus the dimensionless wave number.

We focus on the specific higher order corner energy. It is observed that the computed value decreases from zero as the dimensionless wave number increases until it reaches a minimum, then increases and eventually becomes positive. The sign-reversal value depends on the three Euler angles, the Poisson's ratio and the aspect ratio parameter,

$$m_{L0}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TY0}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TZ0}(\phi, \theta, \psi, \nu, \gamma) \quad (47)$$

The first derivative of the specific higher order corner energy with respect to the dimensionless wave number is also computed. For the Tests C, a particular case is plotted in Figure 7. It is observed that the computed value decreases from zero as the dimensionless wave number increases until it reaches a minimum, then increases and eventually becomes positive. Obviously, the second derivative changes from negative to positive when the first

derivative reaches its local minimum. The sign-reversal value depends on the three Euler angles, the Poisson's ratio and the aspect ratio parameter,

$$m_{L1}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TY1}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TZ1}(\phi, \theta, \psi, \nu, \gamma) \quad (48)$$

$$m_{L2}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TY2}(\phi, \theta, \psi, \nu, \gamma), \quad m_{TZ2}(\phi, \theta, \psi, \nu, \gamma) \quad (49)$$

Figure 6: Test C. Specific higher order mid-side energy versus the dimensionless wave number.

Figure 7: Test C. First derivative of the specific higher order corner energy versus the dimensionless wave number.

By also considering the behavior of the specific higher order mid-side energy, we can conclude that the components of the specific higher order energy at the unit cell satisfy the inequalities,

$$\bar{F}_h^A < 0, \quad \bar{F}_h^M > 0 \quad \text{if} \quad 0 < m < m_0 \quad (50)$$

$$\frac{\partial}{\partial m} \bar{F}_h^A < 0, \quad \frac{\partial}{\partial m} \bar{F}_h^M > 0 \quad \text{if} \quad 0 < m < m_1 \quad (51)$$

$$\frac{\partial^2}{\partial m^2} \bar{F}_h^A < 0, \quad \frac{\partial^2}{\partial m^2} \bar{F}_h^M > 0 \quad \text{if} \quad 0 < m < m_2 \quad (52)$$

where m_0 , m_1 and m_2 are the values defined in Eq. (47)-(49).

Obviously, the specific higher order energy is always positive; nevertheless, as the discretization error decreases with the dimensionless wave number, it vanishes as a cancellation of two components, the positive mid-side energy and the negative corner energy. This behavior, which is called the cancellation property of the higher order energy at the unit cell, already has been observed by the author for the eight-node quadrilateral and the six-node triangle [4, 5]. Therefore, as the discretization error decreases, the higher order energy components tend to be equal but opposite in sign. By considering this evolution to the symmetry and the inequalities Eq. (50)-(52) we can conclude that the dimensionless wave numbers Eq. (47)-(49) determine behavioral ranges for the specific higher order energy. By considering this behavior, in this paper we propose to define Eq. (48) as the first reference wave number, and Eq. (49) as the second reference wave number. Both reference wave numbers basically depend on the three Euler angles and the aspect ratio parameter, and they exhibit a weak dependence respect to the Poisson's ratio.

For a brick with cubic geometry, and for the Test A, in Tables 1 and 2 some computed values of the first and the second reference wave number are presented.

Table 1: Test A. Dimensionless wave number for which the sign of the first derivative of the specific higher order corner energy changes from negative to positive.

For non-cubic brick, and for each of the test problems, some computed values of the first and the second reference wave number are plotted in Figures 8-10. It must be remarked that the strong numerical anisotropy induced by the non-cubic brick results in broad variations of

both reference wave numbers versus the angle of wave propagation. Clearly, the numerical anisotropy increases as the aspect ratio parameter decreases.

Table 2: Test A. Dimensionless wave number for which the sign of the second derivative of the specific higher order corner energy changes from negative to positive.

Figure 8: Test A-YZ. Reference wave numbers versus the angle of wave propagation.

Both reference wave numbers decrease as the angle of wave propagation exhibits a higher numerical dispersion, as it is observed for the Test C in Figures 4, 5 and 7. By considering this property, we investigate the use of one of the reference wave numbers as optimum cutoff wave number to properly capture the harmonic wave.

For the Test C, in Figures 11 and 12 we compute the maximum of Eq. (38) and the maximum of Eq. (39), respectively, for dimensionless wave number up to reach the first reference value. In this case, we consider that the harmonic wave is only properly captured from the wave velocity standpoint. In Figure 13 we compute the maximum of Eq. (39) for dimensionless wave number up to reach the second reference value. In this case, we consider

that the harmonic wave is properly captured also from the velocity of energy transport standpoint. Similar results have been obtained for the Test A and the Test B.

We can conclude that, depending on the desired precision, the reference wave numbers could be used as optimum cutoff wave numbers tuned to taking into account the effect of the numerical anisotropy induced by the spatial discretization. The tuning effect can be clearly observed for the Test C by considering Figures 4, 5 and 7.

Figure 9: Test B-XY. Reference wave numbers versus the angle of wave propagation.

Figure 10: Test C. Reference wave numbers versus the angle of wave propagation.

Figure 11: Test C. Maximum of the indicator of spatial dispersion associated to the phase velocity for dimensionless wave number up to reach the first reference value versus the angle of wave propagation.

Figure 12: Test C. Maximum of the indicator of spatial dispersion associated to the group velocity for dimensionless wave number up to reach the first reference value versus the angle of wave propagation.

The mean values of the first reference wave number and the ones of the second reference wave number are computed in Tables 3 and 4, respectively, for each of the test problems. By considering the minimum mean values computed for the tests A and B, which are obtained for the cases Test A-YZ and Test B-XY, and the mean values computed for the Test C, we propose to select the values,

$$\gamma = 1: \quad m_1 = 0.38, \quad m_2 = 0.2 \quad (53)$$

$$\gamma = 0.75: \quad m_1 = 0.33, \quad m_2 = 0.17 \quad (54)$$

$$\gamma = 0.5: \quad m_1 = 0.25, \quad m_2 = 0.13 \quad (55)$$

as the first and the second standard reference wave number, respectively. Both standard reference wave numbers decrease as the distortion of the regular mesh increases.

The use of one of the standard reference wave numbers as optimum cutoff wave number to properly capture an arbitrary interference field composed of both longitudinal and transverse harmonic waves is also investigated. To approach this question, the computation of natural modes when a solid is discretized by a regular mesh will be analyzed.

3 MODAL ANALYSIS

In order to properly capture a natural mode, a discretized solid must properly capture both the longitudinal and transverse waves with frequency equal to the associated natural frequency. From the inequality $m_L < m_T$ we deduce that if the solid discretized by a regular mesh properly captures the transverse waves also properly captures the longitudinal waves; obviously, the inverse is not true.

From Eq. (7) and Eq. (28), given the dimensionless wave number based on the transverse wave, we obtain the associated frequency at the continuum, for the solid discretized by a regular mesh,

$$f_T = \frac{c_T}{2b} m_T \quad (56)$$

From Eq. (56) and Eq. (53)-(55) we obtain the first and the second reference frequency. Both reference frequencies depend on the aspect ratio parameter.

Two test problems will be analyzed: the clamped block and the cantilever beam [18], which are discretized by the regular meshes represented in Figure 14. The clamped block is a relatively bulk solid which is discretized by a moderately distorted mesh. The cantilever beam is a slender structural element which is discretized by a highly distorted mesh. For the clamped block: Young's modulus, $E = 68.95 \times 10^9$ Pa; Poisson's ratio, $\nu = 0.3$; mass density per unit volume of the material, $\rho = 2560$ kg/m³; aspect ratio parameter, $\gamma = 3/4$. For the

cantilever beam: Young's modulus, $E = 2.068 \times 10^{11}$ Pa; Poisson's ratio, $\nu = 0.3$; mass density per unit volume of the material, $\rho = 8058 \text{ kg/m}^3$; aspect ratio parameter, $\gamma = 1/2$.

Figure 14: Clamped block and cantilever beam.

The reference frequencies for the clamped block and the cantilever beam are, respectively,

$$f_{T1} = 8496.98 \text{ Hz}, \quad f_{T2} = 4377.23 \text{ Hz} \quad (57)$$

and

$$f_{T1} = 5236.29 \text{ Hz} \quad f_{T2} = 2722.87 \text{ Hz} \quad (58)$$

An estimation of the error for the natural frequencies and modes obtained with the discretized solid is presented. In each case the reference model is obtained by dividing each element of the actual mesh into eight elements. The natural frequencies and the modal displacements obtained with the actual model and the ones obtained with the reference model are compared by the frequency error and the correlated coefficient for modal vector [19], respectively,

$$FE = \frac{\omega - \omega_{ref}}{\omega_{ref}} \times 100 \quad (59)$$

$$CCFMV = \frac{|\boldsymbol{\varphi}^t \cdot \boldsymbol{\varphi}_{ref}|}{(\boldsymbol{\varphi}^t \cdot \boldsymbol{\varphi})^{1/2} (\boldsymbol{\varphi}_{ref}^t \cdot \boldsymbol{\varphi}_{ref})^{1/2}} \quad (60)$$

The vectors in Eq. (60) are obtained by computing each modal displacement at the nodes of the reference mesh. A value of $CCFMV$ close to 1 suggests that the two vectors are well correlated, and a value close to 0 indicates uncorrelated vectors. A poor correlation between the results obtained with the actual model and the ones obtained with the reference model is indicated by frequency error greater than 5, and by $CCFMV$ less than 0.90 [20].

For the test problems, in Tables 5-8 we present the evolution of Eq. (59) and Eq. (60) versus the natural frequency computed by the actual model.

Table 5: Clamped block. Frequency error and correlated coefficient for modal vector versus the computed natural frequency. Modes SS and SA.

For the clamped block is observed that whenever the computed natural frequency is less than the second reference frequency the results obtained with the actual model and the ones obtained with the reference model exhibit a high correlation. The results in the range between the second reference frequency and the first one are generally well correlated; nevertheless, if the first reference frequency is gone through the results clearly exhibit a poor correlation.

For the cantilever beam is observed that whenever the computed natural frequency is less than the second reference frequency the results obtained with the actual model and the ones obtained with the reference model exhibit a high correlation or, alternatively, a good correlation; nevertheless, in the range between the second reference frequency and the first one a non-negligible number of modes exhibit a poor correlation.

4 CONCLUSIONS

This paper studies the propagation of plane harmonic waves in unbounded media discretized by the standard twenty-node hexahedral finite element. The element stiffness matrix is split into basic and higher order components which are obtained from mean and deviatoric strain fields, respectively. This decomposition is applied to the elastic energy. The research is focused on the properties of the higher order elastic energy versus the wave number. Based on the properties of the higher order energy, two values of the wave number are selected as reference values. The noteworthy conclusions of this paper are:

Table 7: Cantilever beam. Frequency error and correlated coefficient for modal vector versus the computed natural frequency. Modes SS and SA.

- The numerical research reveals that the first reference wave number could be used as an optimum cutoff wave number to properly capture an harmonic wave from the wave velocity standpoint. For dimensionless wave number less than the second reference wave number the harmonic wave would be properly captured also from the velocity of energy transport standpoint.
- The strong numerical anisotropy induced by the non-cubic meshes results in broad variations of both reference wave numbers versus the direction of wave propagation; nevertheless, by considering the mean values, the first and the second standard reference wave number can be defined. These ones depend on the aspect ratio parameter. Given the standard reference wave numbers based on the transverse wave, the first and the second reference frequency are defined.
- The numerical research reveals that a finite element natural mode exhibits a high precision or, alternatively, a good precision whenever the natural frequency is less than

the second reference frequency; nevertheless, in the range between the second reference frequency and the first one, the precision of the natural modes is clearly depending on the problem. Generally, it could be regarded that, in the range between the second reference frequency and the first one, the finite element model has an intermediate precision.

The consideration of more complex waves and media is subject of research.

DETECTION OF INTERLAMINAR CRACKS IN COMPOSITE STRUCTURES WITH THE USE OF PIEZOELECTRIC SENSORS AND THERMOGRAPHY

Piotr Kędziora

Cracow University of Technology
31-155 Kraków, ul. Warszawska 24, Poland
kedziora@mech.pk.edu.pl

Keywords: Delaminations, Thermography, Piezoelectric Sensors and Actuators, Lamb Wave, Composite Laminate.

Abstract. *Delaminations are one of the most severe defects associated with multilayered laminated composite structures. Initiation of delamination and numerical analysis of delamination growth are presented. Results of damage detection in composite laminated panels are demonstrated with use of piezoelectric patches and thermography. Thermography is utilized to detect and visualize the size of delaminations. Damage detection in fiber-reinforced composite laminated panels using Lamb waves (wave propagation) is demonstrated with the use of a sensor array. Experiments are conducted to empirically characterize the wave propagation behavior in a manufactured laminate. Piezoelectric patches are used as sensors and actuators in the experiments. Composite laminates are manufactured with an embedded defect to simulate inter-ply delamination.*

1 INTRODUCTION

Delaminations are one of the most severe defects associated with multilayered laminated composite structures. They may be caused by imperfections such as air entrapment and insufficient resin during fabrication or by impact and fatigue loads during services. Delaminations may lead to the severe degradation of the mechanical behavior of structures due to the loss of structural integrity. The detection of delaminations and the study of their effects on the mechanical behavior of delaminated composite structures become important practical issues.

Damage modeling in composite structures has been attempted by various researchers in the past. The latest effort includes a generalized laminate model featuring both weak interfacial bonding and local delamination by Shu [1]; a plasticity model coupled with the damage and identification for carbon fibre composite laminates by Boutaous et al. [2].

There have been many works on wave propagation problems related to composite shells. The first work (Lord-Rayleigh [3]) of this field dealt with wave propagation in a semi-infinite solid. In 1917 Lamb published the first work [4] of dealing with guided wave propagation in thin elastic specimens. Mirsky [5] and Nowinski [6] solved for axially symmetric waves in orthotropic shells. Chou and Achenbach [7] provided a three-dimensional solution for orthotropic shell as well. Nayfeh [8] discussed scattering of horizontally polarized elastic waves from multilayered anisotropic cylinders embedded in isotropic solids. Yuan and Hsieh [9] proposed an analytical method for the investigation of free harmonic wave propagation in laminated shells. The numerical description of the waves traveling into waveguides and slender structures has also raised many interests – information about those problems is discussed in Refs [10].

The first introduction of Lamb waves as a means of damage detection was made by Worlton [11] in 1961. He noticed that distinguish characteristics of the various modes of Lamb waves can be useful in nondestructive testing applications. Prosser et al. [12] used acoustic emission to identify cracking of thin composite specimens; also outlined the difficulties associated with acoustic emission. Wevers [13] outlined the advantages of acoustic emission techniques over other NDE methods for identifying damage in a loaded composite component. Lakshmanan and Pines [14] used and developed a wave propagation method to identify delaminations and transverse cracks in Gr/Ep composite rotorcraft. Ihn and Chang [15] used spectrograms to process guided wave signals obtained from an array of piezoelectric transducers to detect and monitor fatigue crack growth.

In this paper, we intend in order to assess the effect of delamination on the global characteristics of composite laminated cylindrical shells. Theoretical and numerical analysis of deformation initiation and growth is presented by Muc and Kędziora [16] and Muc [17]. Thermography is used to detect and visualize the size of delaminations. Results of damage detection in composite laminated panels are demonstrated with use of a piezoelectric sensor and thermography. Damage detection in fiber-reinforced composite laminated panels using Lamb waves (wave propagation) is demonstrated with the use of a sensor array. Experiments were conducted to empirically characterize the wave propagation behavior in a manufactured laminate. Piezoelectric patches were used as sensors and actuators in the experiments. Sensor arrays and associated processing were used for wave number decomposition and filtering of the Lamb wave modes. Composite laminates were manufactured with an embedded defect to simulate inter-ply delamination. Experiments were conducted to detect the presence of delamination damage in a composite laminate.

Comparisons were made between analytical predictions and experimental results, which demonstrate that the model captured essential wave propagation behavior at frequencies of interest.

2 INITIATION OF DELAMINATIONS – LINEAR FRACTURE MECHANICS

Using the continuum fracture (damage) mechanics concept it is possible to model fatigue phenomena taking into account macroscopic degradation models in the evaluation of an individual finite element (or group of them) mechanical properties – see e.g. Muc et al. [18]. However, in the distinction to the continuum fracture mechanics approach, the damage behavior of composites is represented here in the differential (incremental – not global, integral) form but in general, the method of the description is almost identical.

Employing formulations introduced in classical fracture mechanics several models for delamination growth in laminates may be proposed. Early experimental works point to strong correlation between the growth of cracks and the strain energy release rate G . The approximate size of delamination area A is governed by the following equation:

$$\frac{dA}{dN} = f(G_{\max}, \xi, \psi), \quad \xi = \frac{G_{\min}}{G_{\max}}, \quad \psi = a \tan\left(\frac{K_{II}}{K_I}\right) \quad (1)$$

where N is a number of cycles, and f denotes a function.

The parameter ξ expresses the ratio of minimum to maximum loading, and ψ denotes the relative amount of mode I (opening) and mode II (shearing). However, the mode dependence of the delamination growth is not yet fully understood and is a subject of considerable research.

For constant amplitude loading and a stable delamination growth, a power law relation has been first developed by Paris et al. [19]:

$$f(G_{\max}, \xi, \psi) = c(\Delta G)^n, \quad \Delta G = G_{\max} - G_{\min} \quad (2)$$

where c and n are material constants.

In the high stress intensity factor (SIF) range, the curve obtained from Eqs (1) and (2) is very steep indicating unstable crack propagation and hence the region does not contribute much to the propagation life of a component. Therefore, Forman et al. [20] improved the crack growth rate equation and proposed to apply the function f in the following form:

$$f(G_{\max}, \xi, \psi) = \frac{c(\Delta G)^n}{(1-R)K_c - \Delta G} \quad (3)$$

where R is the stress ratio, and K_c means the fracture toughness.

Since the delamination growth can be attributed to a mixed mode of fracture, the criterion for determining the initiation of the delamination growth was selected as [21]:

$$RB = g_1^\delta + g_2^\gamma, \quad g_1 = \frac{G_I}{G_{Ic}}, \quad g_2 = \frac{G_{II}}{G_{IIc}} \quad (4)$$

where RB is the failure index, G_{Ic} and G_{IIc} are the critical strain energy release rates corresponding to mode I and mode II fracture, respectively. δ and γ are coefficients – it was found that $\delta=\gamma=1$ provides the best fit to the experimental results (see [21]). A delamination would start to propagate when $RB \geq 1$.

3 NUMERICAL ANALYSIS OF DELAMINATION GROWTH

For instance let us consider the cross-ply laminate $[0^0, 90^0_n]_s$, loaded in a tension (equal to 1 MPa) along the x direction. The thickness of each individual ply is equal to t , so that the total thickness of the laminate is equal to $2(n+2)t$. The crack is described by its size a in the y direction and the position of its center x_a . The geometrical parameters of the laminate and of the crack are shown in Fig.1.

Figure 1: The geometrical parameters of the laminate with the crack.

The crack is always symmetric with respect to the x axis. Thus, only a half of the laminate is discretised with the use of finite elements. The plate have been modeled using 1536 2-D eight node isoparametric plane stress element. In the model crack face nodes are left free. The thickness of the laminate in the z direction is assumed to be equal to one. All geometrical quantities are given in mm.

With the aid of the presented finite element model the J-integral have been computed. In terms of stresses and strains it is defined as follows:

$$J = \int_{\Gamma} (W n_1 - t_i u_{i,1}) ds \quad (5)$$

where W is the strain energy, u is displacement vector at any point on the contour, n_1 is the normal vector component, $u_{i,1}$ is the derivative of the displacement and t_i is the traction vector at the same point at the contour Γ . Γ is the contour starting from the crack face and going round the crack tip in an anti-clock wise direction and ending on the other crack face. This J-integral is seen to be the rate of change of potential energy with respect to the crack length a . For the linear elastic material the J-integral is equal to the energy release rate G . Since the laminate is subjected to the remote tension the first mode only is analyzed herein. In the evaluation of the J-integral, contour path is taken along the finite element edge and values and quantities in Eqn (5) are computed at the element level.

In the numerical analysis each ply is assumed to be made of carbon/epoxy resin having the following material properties (treated as it will be explained later as mean values): $E_1 = 200$ [GPa], $E_2 = 12$ [GPa], $G_{12} = 8$ [GPa], $G_{23} = G_{12} = 8$ [GPa], $G_{13} = 0.6 \cdot G_{12} = 4.8$ [GPa], $\nu_{12} = 0.3$. In order to verify the effectiveness of the proposed method of the numerical computations the analytical example dealing with the fracture analysis of a square isotropic homogeneous plate with central crack subjected to tension have been solved – see Broek [22]. Due to the central symmetry one quarter of the plate have been analyzed and discretised with the use of 768 finite elements. In the evaluation of the J-integral two contour paths are taken

to compare the results. Each contour paths runs around the crack tip from lower crack face up to the top crack surface along the finite element edges – it is drawn schematically in Fig. 2.

Figure 2: Contour paths Γ definitions.

The results of computations are presented in Table 1 together with the analytical results. The agreement between them seems to be very good. In further computations two different contour paths are always taken into considerations in order to eliminate possible errors in modeling of the path.

Path I	Path II	Analytical [22]

4 EXPERIMENTAL ANALYSIS DAMAGE IDENTIFICATION

4.1 Detection of delamination via thermography

Thermography is a measurement technique which provides an image of the distribution of the temperature on the surface of the examined object. Thermography proceeds by decoding, using an adapted detector, information “temperature” resulting from the infra-red radiation emitted by any object. The principal advantage of infra-red thermography is its non-intrusive character. Indeed, it forms part of the techniques of non-destructive testing and can be carried out on installations in service. The deformation of solid materials is almost always accompanied by releases of heat. When the material becomes deformed or is damaged and fissured, a part of energy necessary to starting and the propagation of the damage is transformed in an irreversible way into heat [23].

During low frequency mechanical excitation, the average temperature in the gage section of the specimen increased with cycles. The small amplitude oscillatory temperature variation is due to the reversible thermal heating and cooling during each loading cycle. The objective in this study was to make a correlation between the increase in the temperature of specimen and the evolution of the damage [24].

The experimental analysis was conducted with the use of the thermovision camera Flir joined with the system IRNDT. The tested cylindrical panel was made of 8 layers and had the following geometrical parameters: $L=298$ [mm], $R=92$ [mm], $t=1.8$ [mm] – see Fig. 3. The thermal excitation was obtained from halogen lamps. During tests the temperature on the surface does not exceeded 40 [$^{\circ}\text{C}$] and the time of heating was equal to 20 [s].

In the tested specimen delaminations were inserted at the shell mid-surface. They have different dimensions as it may be seen in Fig. 4. The plotted results demonstrate that the sensitivity of detection depends on the distance of the camera to the cylinder and on the lens diameter. It shows that those values have to be carefully chosen for each individual experimental case.

Figure 3: Experimented setup – an overview.

a) lens 18 [mm], distance 88 [cm]

b) lens 18 [mm], distance 16 [cm]

c) lens 10 [mm], distance 30 [cm]

Figure 4: Effects of lens diameter and of distance to the specimen on the sensitivity of results.

Figure 5 represents the decrease of temperature with time for selected points at the panel. These values are particularly attributed to the location of delaminations.

Figure 5: Graph of thermal response at selected locations.

4.2 Piezoelectric sensors

Damage detection in composite laminated panels using Lamb waves is demonstrated with use of a sensor array. Experiments were conducted to characterize empirically the wave propagation behavior in a manufactured laminate. Piezoelectric patches were used as sensors and actuators in the experiments. Sensor arrays and associated processing were used for wave number decomposition and filtering of the Lamb wave modes. Composite laminates were manufactured with an embedded defect to simulate inter-ply delamination. Experiments were conducted to detect the presence of delamination damage in a composite laminate.

A cylindrical panel made of glass woven roving having the mechanical and geometrical parameters identical to those mentioned in section 4.1 – Fig.6. An excitation signal took the form of sine wave function was modulated with the Hanning window and was applied at the left piezoelectric actuator in Fig.6; its frequency is varies from $100 \div 500$ [kHz]. The piezoelectric sensor (on the right side in Fig.6) was placed close to the local square delamination having the size 10 [mm] and being in the middle of the laminate.

Figure 6: General configuration of the cylindrical panel with one sensor and one actuator – they are located parallel to the delaminated area.

The wave propagation in the panel with local delamination was analyzed experimentally. The excitation signal and the response signal were generated and collected by the analyzer and then those signals were converted to digital ones with the use of MATLAB package.

Figure 7 demonstrates the response signals obtained experimentally for the perfect and imperfect (with the single delamination) cylindrical panel. As it may be seen there is a visible difference between response signals for perfect and imperfect shells for each excitation signal frequency considered.

Figure 7: Experimental wave propagation results (blue line – without delamination, red line – with delamination); for various frequencies.

However, the reasonable detection of the size and the location of delamination require the careful analysis and optimal design of the location and number of piezoelectric sensors and actuator. In addition, in the delaminated region the interference between generated and reflected waves is observed that affects the signal collected by the sensor (see Figs 7a, b and c). In order to obtain better experimental results it is necessary to conduct further work dealing particularly with the optimal design of sensors number, locations and the frequency of the excitation signal.

The locations of piezoelectric sensor and actuator have significant effects on the displacement response. Different locations are presented in Figs 8 and 10. The response result (Figs 9 and 11) are plotted for one value of the signal excitation frequency equal to 100 [kHz]. The amplitude of response displacement is strongly affected by the distance between sensor and actuator – compare results plotted in Figs 7a and 11. The growth of the distance reduces the amplitudes. For the sensor and actuator located in the parallel direction to the delamination the amplitude for imperfect shell is lower than for perfect one, whereas for other locations the amplitude is higher – compare the results presented in Figs 7a and 9, 11.

Figure 8: Configuration of the cylindrical panel with the sensor and actuator – they are located below delaminated area 5 [cm] from the panel edge.

Figure 9: Experimental wave propagation results (blue line – without delamination, red line – with delamination); frequency is equal to 100 [kHz].

Figure 10: Configuration of the cylindrical panel with the sensor and actuator – the actuator is located above delaminated area 5 [cm] from the upper panel edge and the sensor 5 [cm] from lower panel edge.

Figure 11: Experimental wave propagation results (blue line – without delamination, red line – with delamination); frequency is equal to 100 [kHz].

5 CONCLUSIONS

- This study is intended to show the relation between the dissipation of heat and the damage of the composites.
- These techniques propose to pass from temperature information given by the infrared camera to a distribution of heat sources on surface of the composites.
- The amplitude of the response is strongly affected by the excitation signal frequency and location of sensor and actuator; therefore, the optimization of they location and number is required.

Keywords: Nonlinear Analysis, Beam-Column Element, Resultant Plasticity, Generalized Plasticity.

Abstract. *A three-dimensional nonlinear beam-column element for the simulation of the global and local response of frames under monotonic and cyclic loading conditions is presented. The element belongs to the group of concentrated plasticity models, with plastic hinges located at the ends of the element and described with yield and limit surfaces. The concept of generalized plasticity, originally developed for material plasticity, is extended to force resultants in the element formulation. The element takes into account the interaction of the axial force and the bending moments about the principal axes of the cross section and the hardening behavior. The gradual yielding of the cross section is described by the asymptotical approaching of the limit surface.*

1 INTRODUCTION

The adoption of performance-based guidelines for the earthquake resistant design of structures encourages the use of nonlinear analysis methods in professional engineering practice, since it provides more detailed information about the structural response, such as inelastic deformations, than traditional design procedures. Besides the need for a more accurate evaluation method, it is equally important to assess the efficiency and cost of the analysis, which directly, depends on the efficiency and cost of the deployed nonlinear elements. Because of the good compromise between accuracy and computational efficiency, frame elements are commonly used in earthquake engineering practice. In this context distributed inelasticity beam-column elements with integration of the inelastic material response over the cross-section, commonly called fiber beam-column elements, offer a high level of accuracy and flexibility in modeling the 3d inelastic response of structural members, but are computationally expensive, and put high demands on computer storage and memory. Consequently, more economical point hinge models are still widely used for the simulation of the hysteretic response of frames.

To date, many studies have been conducted on concentrated plasticity (or point hinge) beam-column elements [1-6]. The resultant plasticity beam-column elements use concepts of plasticity theory to describe the relation between basic element forces and deformations. The interaction of the axial force and bending moments about the principal axes of the cross section is described by a stress-resultant yield surface, which will be called yield surface in the following presentation. Yield surface equations for different types of cross sections are available [1, 7-9]. Also, different strategies have been proposed for approaching the yield surface and preventing the element force path from drifting away from it. Orbison [1] used a single polynomial expression for the yield surface and developed a five step procedure for mapping the element forces onto the yield surface. The algorithm has some limitations such as the need to subdivide each increment into several sub-increments in order to prevent large errors. Also, the element response can represent an elastic-perfectly plastic material, but not a material with hardening and it does not account for gradual yielding, since the element ends are either fully elastic or fully plastic.

Several models that improve the shortcomings of Orbison's model were proposed in the last 15 years. The idea of loading and bounding surfaces, introduced by Dafalias and Popov [10] for material plasticity, has been successfully applied to the concentrated and distributed plasticity beam-column elements [4, 5, 11-13]. In these models, the loading and bounding surfaces have the same shape, in order to prevent the two surfaces from overlapping. Once the force point touches the bounding surface (at point A), with continued plastic loading, the force point moves along the line that connects the point A and its conjugate point A' that lies on the bounding surface.

A different algorithm for the gradual, asymptotical approach of the bounding surface for the material plasticity was proposed in the generalized plasticity model by Lubliner and Auricchio [14-16]. The model is simple, does not require an expression for the bounding surface and has a straightforward implementation. It introduces two parameters with clear physical meaning β and δ . With the implementation of the return mapping algorithm, it is computationally very efficient.

The element in this paper adopts the idea of the generalized plasticity material model. The backward-Euler algorithm with general closest point projection [17] is modified to suit the element-based force-deformation relationship. Isotropic and kinematic hardening (or softening) is possible. Because of its quadratic convergence and simplicity, the element is computationally very efficient and overcomes shortcoming of elastic-perfectly plastic elements.

2 ELEMENT FORMULATION

2.1 Basic Framework

The underlying assumption of the generalized plasticity theory is the existence of two continuous real valued functions, the limit function F and yield function f [15, 16]. The yield function f encloses the region with elastic behavior forming the boundary between elastic and inelastic region:

$$\begin{aligned} f < 0 &\Rightarrow \text{elastic state--no inelastic effects} \\ f \geq 0 &\Rightarrow \text{inelastic state--inelastic effects may or may not occur} \\ &\quad \text{depending on loading or unloading} \end{aligned}$$

The basic forces \mathbf{q} of a three-dimensional (3d) frame element without rigid body modes are shown in Figure 1. The corresponding deformations are denoted with \mathbf{v} . Zero-length plastic hinges may form at one or both element ends, while the rest of the element is elastic.

Figure 1: Basic element forces \mathbf{q} .

In beam-column stress-resultant plasticity elements the classical material plasticity rules are modified to represent the axial force, bending moment interaction under inelastic behavior. Therefore, the following equations, that govern the element behavior, are assumed:

1. The element deformations \mathbf{v} are decomposed into the linear elastic contribution \mathbf{v}^e and the plastic contribution \mathbf{v}^p :

$$\mathbf{v} = \mathbf{v}^e + \mathbf{v}^p \quad (1)$$

2. There is a linear elastic relation between basic forces and elastic element deformations:

$$\mathbf{q} = \mathbf{k}_e \mathbf{v}^e = \mathbf{k}_e (\mathbf{v} - \mathbf{v}^p) \quad (2)$$

where \mathbf{k}_e is the elastic element stiffness matrix.

3. The yield function f is expressed in terms of the basic element forces \mathbf{q} , of vector \mathbf{a} which defines the position of the center of the surface and a hardening variable α which models isotropic hardening. H_{iso} and H_{kin} are the isotropic and kinematic plastic hardening (or softening) non-dimensional parameters, respectively. The yield function f distinguishes between elastic and inelastic states.

$$f(\mathbf{q}, \mathbf{a}, \alpha) = \Phi(\mathbf{q} - \mathbf{a}) - H_{iso} \alpha \quad (3)$$

4. The limit function F depends on the nonnegative consistency parameter λ and has the following form proposed for generalized plasticity models:

$$F = h(f) \frac{d}{dt} (\Phi) - \lambda \quad (4)$$

$$h(f) = \frac{f}{\delta(\beta - f) + (H_{iso} + H_{kin})\beta} \quad (5)$$

where δ and β are two non dimensional positive constants (δ measures the speed of approach of the model to the asymptotic behavior, and β measures the distance between the current and the asymptotic yield function). The meaning of surfaces and parameters δ and β is shown in Fig.2.

Figure 2: Basic force \mathbf{q} versus generalized element deformation \mathbf{v} .

5. An associative plastic flow rule is assumed that is described with the following equation:

$$\dot{\mathbf{v}}^p = \lambda \frac{\partial f}{\partial \mathbf{q}}. \quad (6)$$

6. The surface motion (kinematic hardening mechanism) is defined by Ziegler's rule:

$$\dot{\mathbf{a}} = H_{kin} \mathbf{\Pi} \dot{\mathbf{v}}^p = H_{kin} \mathbf{\Pi} \lambda \frac{\partial f}{\partial \mathbf{q}}. \quad (7)$$

where $\mathbf{\Pi}$ is a scaling matrix, that accounts for the different dimensions between \mathbf{a} and \mathbf{v}^p and is adopted here equal to:

$$\mathbf{\Pi} = \text{diag} \left\{ \frac{EA}{L}, \frac{EI_z}{L}, \frac{EI_z}{L}, \frac{EI_y}{L}, \frac{EI_y}{L} \right\}. \quad (8)$$

7. The simplest evolutionary equation for α is adopted corresponding to equivalent plastic strain:

$$\dot{\alpha} = \|\dot{\mathbf{v}}^p\| = \lambda \left\| \frac{\partial f}{\partial \mathbf{q}} \right\|, \quad (9)$$

where:

$$\left\| \frac{\partial f}{\partial \mathbf{q}} \right\| = \left[\left(\frac{\partial f}{\partial \mathbf{q}} \right)^T \mathbf{\Lambda} \frac{\partial f}{\partial \mathbf{q}} \right]^{1/2}, \quad (10)$$

with a scaling matrix $\mathbf{\Lambda}$ defined as:

$$\mathbf{\Lambda} = \text{diag}\left\{\frac{1}{L^2}, \mathbf{I}_4\right\}. \quad (11)$$

Matrix \mathbf{I}_4 is the 4x4 identity matrix.

8. The Kuhn-Tucker complementarity conditions are:

$$\lambda \geq 0, \quad F \leq 0, \quad \lambda F = 0. \quad (12)$$

These conditions reduce the plastic problem to a constrained optimization problem.

9. The limit equation can be written in the following form, $-F=0$:

$$\lambda - h(f) \frac{d}{dt}(\Phi) = 0. \quad (13)$$

Integrating this equation over the time interval $[t_n, t_{n+1}]$, we obtain the discrete limit condition:

$$\Delta\lambda - h(f)(\Phi_{n+1} - \Phi_n) = 0. \quad (14)$$

2.2 Integration Algorithm

The model in the previous section can be transformed into a discrete constrained optimization problem by applying the backward (implicit) Euler numerical integration scheme.

Assuming that the state of the element is known at time step t_n , means that the values $\{\mathbf{v}_n, \mathbf{v}_n^p, \mathbf{a}_n, \alpha_n\}$ are available. The basic forces are also known since they can be found from equation (2):

$$\mathbf{q}_n = \mathbf{k}_e(\mathbf{v}_n - \mathbf{v}_n^p). \quad (15)$$

Suppose that we know an increment in total element deformations $\Delta\mathbf{v}$ at the time step t_{n+1} , so that $\mathbf{v}_{n+1} = \mathbf{v}_n + \Delta\mathbf{v}$. Other state variables \mathbf{v}_{n+1}^p , \mathbf{a}_{n+1} and α_{n+1} should be updated, as well, and this is the problem to be solved.

By applying the backward-Euler method we have:

$$\mathbf{v}_{n+1}^p = \mathbf{v}_n^p + \mathbf{g}_{n+1}(\mathbf{q}_{n+1}, \mathbf{a}_{n+1})\Delta\lambda. \quad (16)$$

$$\mathbf{a}_{n+1} = \mathbf{a}_n + H_{kin} \mathbf{\Pi} \mathbf{g}_{n+1}(\mathbf{q}_{n+1}, \mathbf{a}_{n+1})\Delta\lambda. \quad (17)$$

$$\alpha_{n+1} = \alpha_n + \|\mathbf{g}_{n+1}(\mathbf{q}_{n+1}, \mathbf{a}_{n+1})\|\Delta\lambda. \quad (18)$$

where $\Delta\lambda = \int_{t_n}^{t_{n+1}} \lambda dt$ and $\mathbf{g} = \frac{\partial f}{\partial \mathbf{q}}$. The discrete version of the Kuhn-Tucker conditions (12) is:

$$\Delta\lambda \geq 0, \quad F_{n+1} \leq 0, \quad \Delta\lambda F_{n+1} = 0. \quad (19)$$

The discrete system of equations will be solved by the two-step predictor-corrector return mapping algorithm.

2.3 Return Mapping Algorithm

The return mapping algorithm is an efficient and robust integration scheme, which belongs to the family of elastic predictor - plastic corrector algorithms. In the first, predictor step, a purely elastic (trial) state is computed (\mathbf{q}_{n+1}^{trial}). If this trial state violates the integrated limit in-

equality $F \leq 0$, the element forces are corrected in the second, corrector, step using the trial state as an initial condition. Otherwise, the second step is skipped and the trial solution represents the solution at t_{n+1} .

Since the element has two nodes, and plastic deformations can occur at both of them, the yield functions f_1 and f_2 , limit functions F_1 and F_2 , consistency parameters $\Delta\lambda_1$ and $\Delta\lambda_2$ and hardening variables α_1 and α_2 are lumped into vectors \mathbf{f} , \mathbf{F} , $\Delta\boldsymbol{\lambda}$ and $\boldsymbol{\alpha}$, respectively. The diagonal 2x2 matrix that has nonzero values on the main diagonal, equal to f_1 and f_2 is denoted as $\text{diag}(\mathbf{f})$, and similarly for others: $\text{diag}(\mathbf{F})$, $\text{diag}(\Delta\boldsymbol{\lambda})$, etc.

When both plastic hinges form at element ends, \mathbf{g} is a 3x2 matrix, with the first column equal to $\partial_q f_1 = \mathbf{g}_1$ and the second equal to $\partial_q f_2 = \mathbf{g}_2$. If only one node yields, \mathbf{g} is a 3x1 vector and is equal to \mathbf{g}_1 or \mathbf{g}_2 , depending on which node yields. The parameter $\Delta\lambda$ for the non-yielding node is zero.

1. Predictor step: We consider a purely elastic step obtained by freezing the plastic flow, so that $\Delta\lambda=0$.

$$\mathbf{q}_{n+1}^{trial} = \mathbf{k}_e (\mathbf{v}_{n+1} - \mathbf{v}_n^p) \quad (20)$$

$$\mathbf{v}_{n+1}^{p, trial} = \mathbf{v}_n^p \quad (21)$$

$$\mathbf{a}_{n+1}^{trial} = \mathbf{a}_n \quad (22)$$

$$\boldsymbol{\alpha}_{n+1}^{trial} = \boldsymbol{\alpha}_n \quad (23)$$

$$\mathbf{f}_{n+1}^{trial} = \mathbf{f}(\mathbf{q}_{n+1}^{trial}, \mathbf{a}_{n+1}^{trial}, \boldsymbol{\alpha}_{n+1}^{trial}) = \Phi_{n+1}^{trial} - H_{iso} \boldsymbol{\alpha}_{n+1}^{trial} \quad (24)$$

$$\Phi_{n+1}^{trial} = \Phi(\mathbf{q}_{n+1}^{trial} - \mathbf{a}_{n+1}^{trial}) \quad (25)$$

Once the trial state is computed, we check the limit condition $F \leq 0$, which due to $\Delta\lambda=0$, reduces to the condition $\mathbf{f}_{n+1}^{trial} (\Phi_{n+1}^{trial} - \Phi_n) \leq 0$.

If this condition is not violated, the trial state is admissible state and:

$$\mathbf{v}_{n+1}^p = \mathbf{v}_n^p \quad (26)$$

$$\mathbf{a}_{n+1} = \mathbf{a}_n \quad (27)$$

$$\boldsymbol{\alpha}_{n+1} = \boldsymbol{\alpha}_n \quad (28)$$

$$\mathbf{q}_{n+1} = \mathbf{q}_{n+1}^{trial} \quad (29)$$

$$\mathbf{k} = \mathbf{k}_e \quad (30)$$

If the condition $\mathbf{f}_{n+1}^{trial} (\Phi_{n+1}^{trial} - \Phi_n) \leq 0$ is not satisfied, the trial state is nonadmissible state and the correction should be done in the corrector step.

2. Corrector step: We require the residuals $\mathbf{R}_{1,n+1}$, $\mathbf{R}_{2,n+1}$ and $\mathbf{R}_{3,n+1}$ and the limit condition (14) to be zero.

$$\mathbf{R}_{1,n+1} = -\mathbf{v}_{n+1}^p + \mathbf{v}_n^p + \mathbf{g}_{n+1} \Delta\lambda \quad (31)$$

$$\mathbf{R}_{2,n+1} = -\mathbf{a}_{n+1} + \mathbf{a}_n + H_{kin} \Pi \mathbf{g}_{n+1} \Delta\lambda_{n+1} \quad (32)$$

$$\mathbf{R}_{3,n+1} = -\boldsymbol{\alpha}_{n+1} + \boldsymbol{\alpha}_n + \|\mathbf{g}_{n+1}\| \Delta\lambda_{n+1} \quad (33)$$

After linearization of equations (31)-(34) and the limit equation (14) and after some numerical manipulations, we get the following nonlinear system of equations for determining the parameter $\Delta\lambda$:

$$(\mathbf{a}\Delta\lambda)(\mathbf{b}\Delta\lambda) + \mathbf{c}\Delta\lambda + \mathbf{d} = \mathbf{0} \quad (34)$$

The smallest positive solution $\Delta\lambda$ (the increment of the consistency parameter in the k -th iteration) corresponds to the physically correct solution.

The system can be solved, for example, with the Newton method or another algorithm for a nonlinear equation system. The solution of the linear equation system $\mathbf{c}\Delta\lambda + \mathbf{d} = 0$ can be used as initial value. The coefficients \mathbf{a} , \mathbf{b} , \mathbf{c} and \mathbf{d} are:

$$\mathbf{a} = \text{diag}(\boldsymbol{\delta}) - \boldsymbol{\Phi}2 \quad (35)$$

$$\mathbf{b} = \mathbf{f}2 \quad (36)$$

$$\mathbf{c} = \text{diag}(\Delta\lambda\boldsymbol{\delta})\mathbf{f}2 + \text{diag}(\boldsymbol{\delta}(\boldsymbol{\beta} - \mathbf{f}1) + (H_{iso} + H_{kin})\boldsymbol{\beta}) + \text{diag}(\mathbf{f}1)\boldsymbol{\Phi}2 + \text{diag}(\boldsymbol{\Phi}1 - \boldsymbol{\Phi}_n)\mathbf{f}2 \quad (37)$$

$$\mathbf{d} = \text{diag}(\Delta\lambda(\boldsymbol{\delta}(\boldsymbol{\beta} - \mathbf{f}1) + (H_{iso} + H_{kin})\boldsymbol{\beta})) - \mathbf{f}1(\boldsymbol{\Phi}1 - \boldsymbol{\Phi}_n) \quad (38)$$

where

$$\mathbf{f}1 = \mathbf{f}^{trial} + \mathbf{g}^T (\mathbf{M} - \mathbf{P}) - H_{iso} \mathbf{T} \quad (39)$$

$$\mathbf{f}2 = \mathbf{g}^T (\mathbf{N} - \mathbf{S}) - H_{iso} \mathbf{L} \quad (40)$$

$$\boldsymbol{\Phi}1 = \boldsymbol{\Phi}^{trial} + \mathbf{g}^T (\mathbf{M} - \mathbf{P}) \quad (41)$$

$$\boldsymbol{\Phi}2 = \mathbf{g}^T (\mathbf{N} - \mathbf{S}) \quad (42)$$

$$\mathbf{M} = \mathbf{C}(-\mathbf{R}_1 + \mathbf{Q}\Delta\lambda\mathbf{B}\mathbf{R}_2) \quad (43)$$

$$\mathbf{N} = \mathbf{C}(\mathbf{g} - \mathbf{Q}\Delta\lambda\mathbf{H}_{kin} \boldsymbol{\Pi}\mathbf{g}) \quad (44)$$

$$\mathbf{P} = \mathbf{B}(\mathbf{R}_2 + H_{kin} \boldsymbol{\Pi}\mathbf{Q}\Delta\lambda\mathbf{M}) \quad (45)$$

$$\mathbf{S} = \mathbf{B}H_{kin} \boldsymbol{\Pi}(\mathbf{Q}\Delta\lambda\mathbf{L} - \mathbf{g}) \quad (46)$$

$$\mathbf{T} = \mathbf{R}_3 + \Delta\lambda(\mathbf{Q}\mathbf{n})^T (\mathbf{M} - \mathbf{P}) \quad (47)$$

$$\mathbf{L} = \Delta\lambda(\mathbf{Q}\mathbf{n})^T (\mathbf{N} - \mathbf{S}) - \|\mathbf{g}\| \quad (48)$$

with

$$\mathbf{A} = (\mathbf{k}_e^{-1} + \mathbf{Q}\Delta\lambda)^{-1}, \mathbf{Q} = \partial_{\mathbf{q}\mathbf{q}}^2 \mathbf{f}, \mathbf{B} = (\mathbf{1} + H_{kin} \boldsymbol{\Pi}\mathbf{Q}\Delta\lambda)^{-1}, \mathbf{n} = \frac{\Delta\mathbf{g}}{\|\mathbf{g}\|} \text{ and}$$

$\mathbf{C} = (\mathbf{A}^{-1} - \mathbf{Q}\Delta\lambda\mathbf{H}_{kin} \boldsymbol{\Pi}\mathbf{Q}\Delta\lambda)^{-1}$. In the equations (34) to (48) the superscript k , denoting the iteration, and subscript $n+1$, denoting the value at t_{n+1} , are omitted for simplicity.

For $\boldsymbol{\delta} = \mathbf{0}$ and $H_{iso} = H_{kin} = 0$ the model reduces to elastic-perfectly plastic behavior with the solution:

$$\Delta\lambda_{n+1}^{(k)} = \left(\left(\mathbf{g}_{n+1}^{(k)} \right)^T \mathbf{A}_{n+1}^{(k)} \mathbf{g}_{n+1}^{(k)} \right)^{-1} \left(\mathbf{f}_{n+1}^{(k)} - \left(\mathbf{g}_{n+1}^{(k)} \right)^T \mathbf{A}_{n+1}^{(k)} \mathbf{R}_{1,n+1}^{(k)} \right) \quad (49)$$

The elastic-perfectly plastic solution is also recovered when $\beta=0$ and $H_{iso}=H_{kin}=0$. In the case when only one node yields, the system of nonlinear equations transforms into a single quadratic equation.

After finding the increment $\Delta\lambda$, either as a solution of a system of nonlinear equations or a single equation, the consistency parameter is updated:

$$\Delta\lambda_{n+1}^{(k+1)} = \Delta\lambda_{n+1}^{(k)} + \Delta\lambda_{n+1}^{(k)} \quad (50)$$

2.4 Tangent Stiffness Matrix

The tangent stiffness can be obtained by enforcing the satisfaction of the linearized discrete limit condition. After some manipulation the following expression for the tangent stiffness matrix \mathbf{k}_{n+1} results

$$\begin{aligned} \mathbf{k}_{n+1} &= \frac{d\mathbf{q}}{d\mathbf{v}}|_{n+1} = \mathbf{C}_{n+1} - \mathbf{N}_{n+1}(\mathbf{Y}_{n+1})^{-1}\mathbf{Z}_{n+1} \\ \mathbf{Y}_{n+1} &= \text{diag}(\delta(\beta - \mathbf{f}_{n+1}) + (H_{iso} + H_{kin})\beta) + \text{diag}(\mathbf{f}_{n+1} + \Phi_{n+1} - \Phi_n + \Delta\lambda_{n+1}\delta)\mathbf{g}_{n+1}^T\mathbf{X}_2 - \\ &\quad - \text{diag}(H_{iso}(\Phi_{n+1} - \Phi_n + \Delta\lambda_{n+1}\delta))\mathbf{L}_{n+1} \\ \mathbf{Z}_{n+1} &= \text{diag}(\mathbf{f}_{n+1} + \Phi_{n+1} - \Phi_n + \Delta\lambda_{n+1}\delta)\mathbf{g}_{n+1}^T\mathbf{X}_1 - \text{diag}(H_{iso}\Delta\lambda_{n+1}\delta)\Delta\lambda_{n+1}(\mathbf{Q}_{n+1}\mathbf{n}_{n+1})^T\mathbf{X}_1 - \\ &\quad - \text{diag}(H_{iso}(\Phi_{n+1} - \Phi_n))\Delta\lambda_{n+1}(\mathbf{Q}_{n+1}\mathbf{n}_{n+1})^T\mathbf{X}_1 \end{aligned} \quad (51)$$

We used the substitutions \mathbf{X}_1 and \mathbf{X}_2 with the following definition

$$\begin{aligned} \mathbf{X}_1 &= \mathbf{C}_{n+1} - \mathbf{B}_{n+1}H_{kin}\Pi\mathbf{Q}_{n+1}\Delta\lambda_{n+1}\mathbf{C}_{n+1} \\ \mathbf{X}_2 &= \mathbf{N}_{n+1} - \mathbf{S}_{n+1} \end{aligned} \quad (52)$$

As for the consistency parameter $\Delta\lambda$, for parameters $\delta=0$ and $H_{iso}=H_{kin}=0$ or $\beta=0$ and $H_{iso}=H_{kin}=0$, the consistent tangent stiffness matrix reduces to the expression for the elastic-perfectly plastic case:

$$\mathbf{k}_{n+1} = \mathbf{A}_{n+1} - \mathbf{A}_{n+1}\mathbf{g}_{n+1}(\mathbf{g}_{n+1}^T\mathbf{A}_{n+1}\mathbf{g}_{n+1})^{-1}\mathbf{g}_{n+1}^T\mathbf{A}_{n+1} \quad (53)$$

3 NUMERICAL EXAMPLES

To verify the capabilities of the new element, two simple examples are studied. The response of the new element, named GPMNYS element (from Generalized Plasticity N-M Yield Surface), is compared with the solution of the elastic-perfectly plastic concentrated plasticity element (EPPNMYS element) [18] and the fiber hinge element [19] whose solution is denoted as FIBER and represents the benchmark solution. FEDEASLab, a Matlab toolbox for nonlinear static and dynamic analysis [20], was used for the simulation.

3.1 Cantilever Column

The first example refers to the cantilever column shown in Figure 3(a) which is used before in a study of efficient cross section discretization of fiber beam-column element [21]. In tests B6 and B8_7, the column was subjected to uniaxial and biaxial tip translation history with variable axial force (Figure 3(b-c)). In Test B6, the column tip is subjected to lateral displacements in the strong axis direction, with variation of axial force between -0.05Np and -0.45Np. In Test B8_7, the column tip is subjected to displacements in the Y and Z directions so that normalized bending moments about strong and weak axis are in the ratio 0.5, with variation of axial force between -0.05Np and -0.45Np.

The response of a homogeneous column with elastic perfectly plastic material, obtained with the distributed inelasticity fiber model with fine section discretization (108 fibers) and five Gauss-Lobatto integration points along its length, is compared with the response of the two concentrated plasticity elements, GPNMYS and EPPNMYS elements.

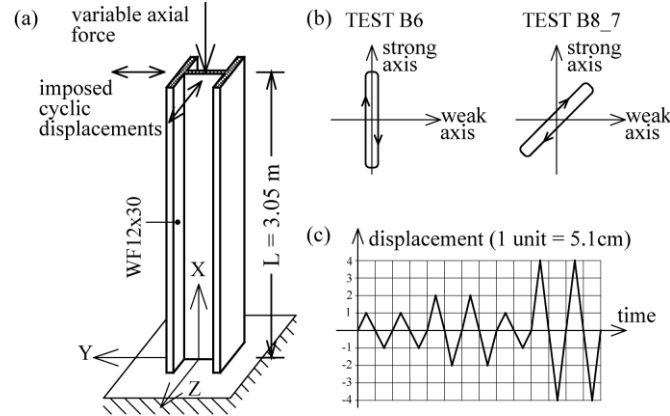

Figure 3: (a) Cantilever column; (b) B6 and B8_7 tip displacement pattern; (c) tip displacement history.

The assumed yield function, i.e. N - M_z - M_y interaction curve, for each end of the beam is:

$$f(p, m_z, m_y) = 1.15p^2 + m_z^2 + m_y^4 + 3.67p^2m_z^2 + 3p^6m_y^2 + 4.65m_z^4m_y^2 - c \quad (54)$$

Where p is the normalized axial force $p = (N - a_p)/N_p$ and $m_z = (M_z - a_z)/M_{pz}$ and $m_y = (M_y - a_y)/M_{py}$, respectively, are the normalized bending moment about strong and weak axis. The variables a_p , a_z and a_y are components of the vector that describes the displacement of the yield surface in the N - M_z - M_y space due to kinematic hardening mechanism. The variable c determines dimensions of the yield surface. Coefficients in the equation (54) are determined to fit the best yield surface for W12x30 US steel cross section with $c = 1.0$ [1]. In GPNMYS and EPPNMYS models, both nodes are assumed to have the same properties. The coefficient c is taken equal to 0.3 in GPNMYS and 1.0 in EPPNMYS model. Additional parameters of the GPNMYS model are: $\delta = 0.15$, $\beta = 0.70$ and $H_{iso} = H_{kin} = 0$. The results are shown in Figures 4-5 for Test B6 and in Figures 6-9 for Test B8_7.

It should be emphasized that the elapsed time during these tests were, approximately, in the ratio 1:1.15:21 for EPPNMYS: GPNMYS: FIBER element, respectively.

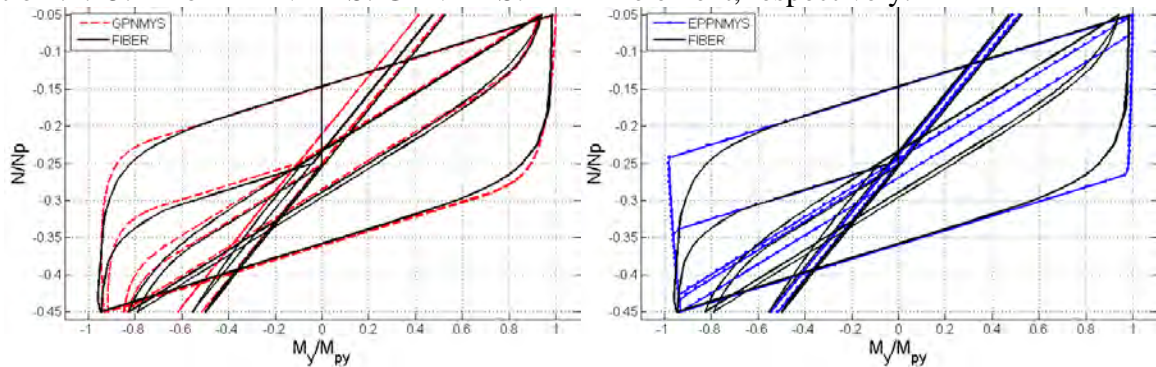

Figure 4: Test B6: normalized bending moment – normalized axial force path

Figure 9: Test B8_7: normalized bending moment about Y – rotation relation
(a) GPNMYS and FIBER; (b) EPPNMYS and FIBER element.

To verify the capabilities of the GPNMYS element to simulate hardening behavior, the Test B6 is conducted again. The material is assumed to have 3% kinematic hardening in FIBER model. Parameter H_{kin} of the GPNMYS model is taken equal to 0.08, while other parameters are the same as in the Test B6 without hardening. Results are shown in Figure 10.

Figure 10: Test B6 with hardening - GPNMYS and FIBER element: (a) normalized bending moment – normalized axial force path; (b) normalized bending moment about Y – rotation relation.

3.2 Portal frame example

The second example refers to the portal frame shown in Figure 11, previously studied by El-Zanaty [22]. Gravity loads are applied first and then kept constant while lateral load is gradually increasing. The residual stresses are not considered since this effect cannot be captured with the EPPNMYS element. In the GPNMYS element this effect can be included by specifying the size of the elastic domain (loading surface) [23].

The nonlinear geometry under large displacements is accounted for with the corotational formulation [24]. In each of the three models (GPNMYS, EPPNMYS and fiber) each member of the portal frame is represented with one element. The material model is assumed elastic-perfectly plastic. Three different levels of vertical load are studied: 20%, 40% and 60% of the ultimate vertical load of the frame and results for bending about the major axis are given in Figure 12.

Figure 11: El-Zanaty portal frame.

The following yield function is used:

$$f(p, m_z) = p^2 + m_z^2 + 3.5 p^2 m_z^2 - c \quad (55)$$

Where p and m_z are as defined before. The parameter c equal to 1.0 is used in EPPNMYS element, and $c=0.71$ for GPNMYS element. Additional parameters of the GPNMYS model are: $\delta=0.1$, $\beta=0.27$.

Figure 13: Load-displacement response of El-Zanaty frame.

As can be seen from the results, the response of the GPNMYS element is closer to the exact – FIBER solution due to its capability to describe the gradual yielding of the cross section.

4 CONCLUSION

In the paper, a new three-dimensional nonlinear beam-column element, called GPNMYS, for the simulation of the global and local response of frames under monotonic and cyclic loading conditions is presented. The element belongs to the family of concentrated plasticity elements, with plastic hinges located at the ends of the element and described with yield and limit surfaces. The concepts of generalized material plasticity are extended to force resultants and used in the element formulation. The element takes into account the interaction of the axial force and the bending moments about the principal axes of the cross section and the hardening behavior. The gradual yielding of the cross section is described by the asymptotical approach to the limit surface. The model is relatively simple and introduces parameters with clear physical meaning. With the implementation of the return mapping algorithm and quadratic convergence it is, also, computationally very efficient.

The capability of the new GPNMYS element is verified with two examples by comparing its response with that of an elastic perfectly plastic element resultant plasticity element, which is also based on the return map algorithm, and with the results of a fiber beam-column element. In comparison with perfectly-plastic element, the GPNMYS element proves significantly more versatile in the simulation of frame response under complex loading conditions without significant increase in calculation time, which remains equal to approximately 15% of the time required by the fiber beam-column with an adequate level of discretization.

Keywords: Earthquake, Finite Element Method, Shear deformation, Passive Energy Dissipation, Yielding Shear Panel Device.

Abstract. *Yielding Shear Panel Device (YSPD) is a newly proposed passive energy dissipation device to make structures more sustainable against earthquakes by exploiting the shear deformation capacity of metallic plates. YSPD is easy to install using simple bolted connections and is significantly less expensive than currently available passive energy dissipation devices. If required, damaged YSPDs could be replaced easily after an earthquake causing minimum disruption to a structure. The current research explains the development of finite element models for the pilot experiments carried out on YSPD. The developed FE models include both material and geometric nonlinearities and use nonlinear spring elements to model appropriate support conditions observed in the experiments. Overall, good agreement is noticed between the FE models and the test results in regards to force displacement response and energy absorption. The developed FE models are validated for both monotonic and cyclic loading. This verification paves the way for generating further reliable set of data to develop appropriate design rules for YSPD.*

1 INTRODUCTION

Recent catastrophic earthquakes occurring in different parts of the world demonstrate the severity of this natural phenomenon on human civilization and points out the significance of further research to develop efficient cost-effective tools to minimise the resulting loss. Minimization of structural damages due to earthquake is a major area of research which contributed to the development of a number of active, semi-active and passive control mechanisms during the last few decades. The current research investigates the structural performance of a newly proposed yielding shear panel device (YSPD) for passive energy dissipation. YSPD is very simple to manufacture and is economical when compared against currently available devices. Pilot tests carried out on the device demonstrates its potential for considerable energy absorption [1]. Appropriate design rules for YSPD would require more understanding of its structural response when subjected to different types of loading. Finite element models are developed herein and verified against available monotonic and cyclic test results to pave the way for thorough parametric analysis leading to design rules. The scope of this paper covers details of the FE modelling technique using the general purpose FE package ANSYS.

2 YIELDING SHEAR PANEL DEVICE (YSPD)

Diagonal tension field that develops in the post-buckling regime of a thin steel plate under shear, which offers significant strength and ductility, can be utilized to dissipate energy. This concept led to the development of a new metallic passive energy dissipating device ‘Yielding Shear Panel Device’ (YSPD). YSPD was introduced by Williams and Albermani [2] based on the proposed design by U. Dorka at the University of Kassel, Germany to exploit the energy dissipative capability of steel plates through in-plane shear deformation and the concept was further explored by Schmidt et.al. [3] and Williams and Albermani [4]. YSPD relies on the in-plane shear deformation of a thin diaphragm steel plate welded inside a square hollow section (SHS). This device can be placed below a structural beam using a V-brace, as shown in Figure 1, so that it automatically comes into play in the event of any horizontal excitation.

Figure 1: Typical YSPD-brace assembly.

Chan et. al. [1] conducted a series of monotonic and cyclic tests using various plate thicknesses and device configurations for YSPD. The tested specimens were fabricated using a short segment of a square hollow section (SHS) with a steel diaphragm plate welded inside it as shown in Figure 2. Four bolt holes spaced at a centre-to-centre distance ‘s’ were drilled on

each of the two opposite SHS flanges for connecting the device to the test setup; this connection is analogous to the practical assembly where YSPDs are proposed to be connected using bolts to ensure easy installation and replacement. The SHS provides a boundary to the diaphragm plate so that shear forces can be applied to the plate, in addition to providing necessary detail for connections to the parent structural frame. Most importantly, the SHS serves as a boundary element allowing the tensile strips to be formed and the tension field to be developed following the post-buckling of the thin diaphragm plate. As a result of sufficiently large displacements occurring in the diaphragm plate, the input energy originating from an earthquake could be dissipated through plastic deformation.

(b)

Figure 2: (a) Yielding shear panel device (YSPD) (b) Schematic diagram showing the geometric parameters of YSPD [5].

Chan et. al. [1] tested two different sizes of YSPD, $100\text{mm} \times 100\text{mm}$ and $120\text{mm} \times 120\text{mm}$, with three different thickness of 2 mm, 3 mm and 4 mm for the diaphragm plate. Bolt spacing of 50 mm was used for four M16 bolts on each side of the SHS to install the test specimen between a ground beam and L-beam. Geometric dimensions of the test specimens are given in Table 1 and reported material properties are summarized in Table 2.

YSPD Designation (D × D × t)	Diaphragm Thickness, t (mm)	SHS Size, D (mm)	SHS Thick- ness, T (mm)	Bolt Spacing, S (mm)
100×100×2	1.86	100	3.76	50
100×100×3	2.83	100	3.76	50
100×100×4	3.78	100	3.76	50
120×120×2	1.86	120	4.91	50
120×120×3	2.83	120	4.91	50
120×120×4	3.78	120	4.91	50

3 FINITE ELEMENT MODELLING OF YSPD

3.1 Material modelling

An appropriate material model is a prerequisite to obtain accurate predictions from a finite element model. Williams and Albermani [4] and Chan et. al. [1] used ordinary carbon steel plates and steel SHS sections to manufacture the tested YSPD specimens. Stress-strain response of ordinary steel shows a steep initial elastic response followed by strain hardening up to the ultimate stress followed by strain softening before failure. Most widely adopted material modelling technique for carbon steel is, however, the bilinear elastic, perfectly-plastic idealization. Alinia et. al. [6] recently used bilinear hardening model to analyze the plastic shear buckling capacity of unstiffened steel plates. Eurocode 3 [7] provides the following guideline for assuming the bilinear material behaviour – material behaviour can be modelled without strain hardening, with a nominal plateau slope or with linear strain hardening depending on the accuracy and the allowable strain required. The Code suggests that the tangent modulus after yielding can be reasonably assumed as 1% of the Young's modulus of elasticity for a bilinear idealization to include the effects of strain hardening. Chan [5] reported two coupon tests for the 100×100×4 SHS. Figure 3 compares the reported coupon test results and

the idealized bilinear material model. Young's modulus of elasticity $E = 200$ GPa and Poisson's ratio $\nu = 0.3$ for mild steel is used in material modelling.

Figure 3. Material properties of the SHS plate of YSPD 100x100x4 [5]

An isotropic hardening model may be used to simulate the material behaviour only for monotonic loading, whilst cyclic behaviour would require a kinematic hardening model as the yield surface can translate in the direction of loading. A bilinear kinematic hardening model available in ANSYS assumes that the total stress range as twice the yield stress which eventually results in von Mises yield criteria with an associative flow rule. The yield surface is assumed to have a cylindrical shape in three-dimensional stress space as shown in Figure 4. This model represents the stress-strain response in two stages – the initial linear elastic part where the material follows the Hook's law and in the following linear plastic part where the material exhibits a constant strain hardening behaviour. The bilinear kinematic hardening model is used in the current study as the constitutive model for the steel plates used in the diaphragm plate as well as the SHS of YSPD for both monotonic and cyclic loading.

Figure 4: von Mises yield surface in the three-dimensional stress space.

3.2 Analysis technique and selection of element type

Developed FE models were analysed elastically to obtain appropriate Eigenmodes, which were used to model initial geometric imperfections in the subsequent nonlinear analysis. The 'BUCKLE' option available in ANSYS was used to obtain the required Eigenmodes followed

by a nonlinear ‘STATIC’ analysis to simulate the force-displacement response of YSPD. To take appropriate account of the geometric nonlinearity effects arising as a result of excessive deformation of the thin diaphragm plate, the ‘NLGEOM’ option was adopted.

A number of techniques for solving the global system of simultaneous equations are available in the ANSYS program such as sparse direct, preconditioned conjugate gradient (PCG), Jacobi conjugate gradient (JCG), frontal direct etc. Among these available options, PCG solver is an iterative equation solver that can handle ill-conditioned problems and provide faster solution for large models when compared against the performance of sparse and frontal solvers. Line search option, accessed with ‘LNSRCH’ command, can further improve the performance of the solution technique [8]. The current FE modelling uses PCG solver with the line search option to obtain an accurate response of YSPD, whilst minimising computational time.

Shell elements are widely used to model thin-walled structures. In recent times, Alinia et. al [6] used four noded quadrilateral shell elements to investigate the plastic shear buckling capacity of unstiffened steel plates, whilst De Matteis et. al. [9] employed shell elements to model stiffened aluminium shear panels. Soo Kim and Kuwamura [10], Ashraf et. al. [11], Ellobody and Young [12] used general purpose shell elements to analyze the behaviour of thin-walled stainless steel members. ANSYS offers a range of shell elements including both general purpose and special purpose elements. ‘SHELL43’ and ‘SHELL181’ are two general purpose shell elements suitable for thin to moderately thick shell structures incorporating nonlinear, large deflection and large strain capabilities. Special purpose shell element ‘SHELL41’ is a membrane only element having only membrane stiffness, whilst ‘SHELL63’ is an elastic shell element. General purpose shell element ‘SHELL181’ is used in the current research to model both the diaphragm plate and the SHS. ‘SHELL181’ is a four-noded full integration quadrilateral shell element with six degrees of freedom at each node, which is well-suited for linear, large rotation, and/or large strain nonlinear applications [8]. It includes both bending and membrane stiffnesses.

3.3 Support conditions for YSPD

Modelling appropriate support conditions for YSPD has been one of the challenging tasks in the current research as it significantly affects the overall load-deformation response and the amount of dissipated energy. The current proposal is to connect YSPD to the parent structure using bolts to ensure easy installation and to facilitate replacement of damaged devices after an earthquake, if required.

3.3.1. Stiffness of the SHS

Chan et al. [1, 5] installed the test specimens between a ground beam and an L-beam, securely fastened by four M16 bolts on each side.. The left flange of the YSPD was connected to the ground beam, whilst the right flange was connected to the L beam. Forced displacements were applied using a 100kN capacity MTS actuator to the YSPD through the L-beam, which moved vertically downward and upward to simulate the horizontal displacement that would occur in a V-brace assembly due to an earthquake excitation.

Displacement measurements obtained from LVDT 2 and LVDT 3 showed some initial in-plane rotation of the L-beam (Figure 5a). Considerable deformations were observed in YSPD specimens. The upper flange of the YSPD moved rightward, whilst the lower flange moved leftward due to this in-plane rotation of the L-beam caused by the downward movement of the actuator. These movements caused the support end flange (left flange) and the loading end flange (right flange) to experience bending in upper and lower portions respectively. The up-

per two bolts of support end and the lower two bolts of loading end experienced minor deformations due to this bending. Opposite movements and deformations were observed when the actuator moved upwards. Figure 5(b) shows the deformed shape for YSPD 100×100×3 after the monotonic test. Noticeable bending observed at the flanges is highlighted by circles.

Figure 5: (a) In-plane rotation of the L-beam of YSPD 100X100X3 under monotonic loading (b) Deformed shape of YSPD 100X100X3 under monotonic loading [5]

3.3.2. FE modelling of the boundary conditions

The developed FF models of the YSPD have the same orientation that would occur when YSPD will be placed in a V-brace assembly (Figure 6). In actual practice the upper flange will be connected to the beam, whilst the bottom flange will be connected to the V-brace. Both the upper and the lower bolted flanges will experience bending due the horizontal movement of the V-brace, which is simulated by applying horizontal nodal displacements to the nodes around the bolt holes of the lower flange. Bolts nearer to the bent flange plates will experience minor deformations due to bending effects originating from these movements. The other two edge lines are supported by the beam and the V-brace end plate.

Figure 6: Spring elements (ANSYS) used to model appropriate boundary conditions for YSPD.

The deformations and movements observed in the bolts and the edges of YSPD were modelled using a combination of hinge and spring supports as shown in Figure 6. All nodes along four edge lines are supported by ‘COMBIN39’ spring elements, which act as a tension-compression element. Both tension and compression will occur due to the bending effects resulting from horizontal movements. Tension and compression stiffnesses are defined separately to allow the elements exhibit different force-displacement responses in tension and compression. The compression stiffness K_{ec} of the edge springs are taken equal to the stiffness of the flange plate. The cross-sectional area between two nodes constitutes the stiffness for a single spring. These springs resist the edge nodes to move beyond the support and the loading planes. The stiffness for the edge springs at the loading side is reduced by multiplying with a reduction factor λ to incorporate the effects of in-plane rotation observed at the loading side. The tension stiffness K_{et} is taken as a very small positive magnitude to eliminate the numerical singularity that allows the edge nodes to move freely in both directions but resists them to go away from the support and the loading planes.

Bolted connections are simulated using circular holes with appropriate boundary conditions around the perimeter. The nodes around the circular hole are divided into two categories - inner nodes and outer nodes as shown in Figure 7. At the support end, the translational degrees of freedom for the inner nodes are fully restrained, whilst the outer nodes are restrained only against the in-plane movements. To simulate the out of plane displacements, these nodes are supported by ‘COMBIN39’ spring elements with stiffness (K_b) whose combined stiffness is equal to the stiffness of the M16 bolts as used in the experiment. At the loading end, both the inner and the outer nodes are supported by ‘COMBIN39’ spring elements with stiffness equal to a fraction of the stiffness of M16 bolts λK_b . These nodes are free against in-plane displacements to simulate the observed horizontal movement of the V-brace end plate during testing. Table 3 presents a summary of the magnitudes of appropriate stiffness for spring supports used at the support and at the loading end.

Figure 7: Definition of inner and outer nodes around the bolt hole.

	Stiffness
Tensile stiffness of the edge springs, K_{et}	0.0001
Compressive stiffness of the edge springs, K_{ec}	$T \times S_n \times E_{SHS}$
Stiffness of the springs at bolt holes, K_b	$\frac{A_b \times E_b}{N_b}$

Table 3: Spring stiffness values used for modelling boundary conditions of YSPD.

Where,

- T = Thickness of the SHS plate
- S_n = Nodal spacing in the SHS plate
- E_{SHS} = Modulus of elasticity of SHS plate
- A_b = Cross section area of bolt
- E_b = Modulus of elasticity of bolt
- N_b = Number of nodes per bolt hole

The reduction factor λ allows the in-plane rotation and degradation of the initial stiffness of YSPD, which are inevitable phenomenon as observed during testing (Figure 5a). The rotation at the loading end is significantly affected by the value of λ ; a higher value of λ contributes to a smaller rotation. The support end and the loading end will be parallel if λ is taken as 1.0; this will eventually make the initial stiffness of the YSPD equal to that proposed by Chan et. al. [1]. The test results, however, show a significantly lower initial stiffness as a result of the observed rotation at the loading end. Test results showed noticeable in-plane rotation of the L beam despite its high stiffness. A parametric study was conducted to find an appropriate value for λ . Figure 8 shows the load-deformation responses of YSPD for different values of λ against test results. Comparisons show that only a small fraction of K_b and K_{ec} produces good agreement with test results and hence a value of $\lambda = 0.002\%$ has been adopted in the current research to allow for the in plane rotation.

Figure 8: Load-deformation response of YSPD 100×100×4 with different values for λ .

3.4 Convergence study – selecting a suitable mesh

Selecting an appropriate mesh is one of the most important aspects of FE modelling. No general guidelines are available to choose a suitable mesh as it largely depends on the type of structure and the corresponding analysis involved. Finer mesh generally provides better predictions but require higher computational time. A convergence study was carried out to choose a suitable mesh to obtain an optimum balance between accuracy and computational time.

Figure 9. Convergence study of YSPD ($100 \times 100 \times 4$). (a) Coarse mesh (492 shell elements), (b) Medium mesh (1516 shell elements), (c) Fine Mesh (5238 shell elements)

Three different mesh sizes were used to simulate the load-deformation response of YSPD as shown in Figure 9. The size of element in the finer mesh was half of the size of medium mesh and one-fourth of the size of coarse mesh. Fig 10 shows a typical force-displacement response for different mesh densities. Results showed that both the finer mesh and the medium mesh give reasonable agreement with test result. No further refinement was attempted since the predictions were found to be in line with the test results and the finer mesh has been adopted in subsequent finite element models to ensure better accuracy.

Figure 10: Typical force-displacement response due to different mesh sizes (YSPD $100 \times 100 \times 4$)

3.5 Initial Imperfections

Yielding shear panel device consists of two main parts – a steel diaphragm plate and a square hollow section (SHS). The diaphragm plate is placed inside the SHS at mid depth and welded along the four sides of the diaphragm plate; this process induces residual stresses. In addition, the steel plates used to fabricate YSPD are not perfectly plane as they always inherit some geometric imperfections i.e. out-of-plane deformations. Effects of geometric imperfections and residual stresses are, therefore, investigated in this section as part of the FE modeling of YSPD.

3.5.1. Geometric Imperfections

Initial geometric imperfections are an inevitable property of steel structures because of the typically high width-to-thickness ratio, which influences their structural response. The impor-

tance of modelling initial imperfections attracted attention amongst researchers during the last few decades. In spite of its observed significance, there is no general guideline to model the magnitude and distribution of the initial geometric imperfections, largely due to the high degree of uncertainty associated with its formation process. Generally, an assumed shape and magnitude for the out-of-plane deformation is incorporated or an assumed transverse force is applied to simulate the effects of initial geometric imperfections. In recent times, the most commonly used technique for modelling imperfection distributions is either to adopt a sinusoidal wave or to use one of the Eigenmodes obtained from elastic buckling analysis; a number of recent approaches adopted for modelling thin-walled structural elements are discussed below.

Dawson and Walker [13] studied the geometric imperfections of cold-formed steel cross-sections and proposed the following relationships for geometrically imperfect plates with free edges under compression and bending,

$$\omega_0 = \alpha t \quad (1)$$

$$\frac{\omega_0}{t} = \beta \left(\frac{\sigma_y}{\sigma_{cr}} \right)^{0.5} \quad (2)$$

$$\frac{\omega_0}{t} = \gamma \left(\frac{\sigma_y}{\sigma_{cr}} \right) \quad (3)$$

Where, ω_0 is the amplitude of initial imperfection, t is the thickness of the plate, σ_y is the material yield stress, σ_{cr} is the critical plate buckling stress, whilst α , β and γ are constants. In addition, a conservative fit of the maximum imperfection amplitude was reported to be equal to $0.2t$. Gardner [14] adopted Equation 7 with a proposed value of $\gamma = 0.023$ for roll-formed stainless steel hollow sections under compression and used the 1st Eigenmode for imperfection distribution.

Schafer and Pekoz [15] proposed the following two simplified regression based relationships to determine the imperfection amplitude ω_0 for cold formed steel lipped channel sections and assumed that the magnitude of imperfections in the lowest Eigenmode is sufficient to characterize the influence of imperfections. In the first formulation, the imperfection amplitude is linearly varied with the width (w) as follows,

$$\omega_0 = 0.006w \quad (4)$$

The second formulation is based on an exponential curve fit to the plate thickness as,

$$\omega_0 = 6te^{-2t} \quad (5)$$

EN 1993-1-5 [7] recommends to apply the equivalent local geometric imperfection for finite element models panels or sub panels based on the shape of the critical plate buckling modes with amplitude of $w/200$, which is linearly proportional to the minimum dimension of the panel. It gives lower imperfection magnitudes than Schafer and Pekoz's [15] proposed Equation 8.

Zhang et.al. [16] measured the maximum imperfections observed in cold formed steel channel columns and the obtained magnitudes varied from $0.03t$ to $0.25t$, whilst the distribution of imperfections showed reasonable resemblance with the 1st Eigenmode. Sun and Butterworth [17] used imperfection magnitude of $0.167t$, $0.333t$, $0.5t$ and $0.667t$ to model the behaviour of steel single angle compression members eccentrically loaded through one leg; the use of amplitude $0.333t$ produced best predictions. Pokharel and Mahendran [18] investigated the sensitivity of imperfection for sandwich panels by varying the amplitude between $0.1t$ and $0.4t$. The 1st Eigenmode was used to model imperfection distribution in all cases; the overall effect on the ultimate compressive strength was observed to be insignificant. Pavlovic et.al. [19] investigated the reduction in shear resistance of longitudinally stiffened panels due to a range of local and global geometric imperfections within the prescribed limit according to EN 1993-1-5 [7]. Global imperfections were defined using the stiffener out-of-

plane deflections in half-sine wave, whilst local imperfections in sub panels were modelled with critical local buckling modes for panels with trapezoidal stiffeners. Results obtained using combined imperfections showed that the reduction in panel shear resistance capacity has a small influence due to imperfections. Ashraf et.al. [11] reported a detailed review of different techniques adopted for modelling geometric imperfections observed in thin-walled structural components. The degree of uncertainty associated with geometric imperfections make it almost impossible to come up with a generalised formulation which can be adopted directly in FE modelling.

The current research adopts the most commonly used technique of obtaining Eigenmodes through elastic buckling analysis of the developed FE model, which are subsequently used as the initial shape in nonlinear analysis. Figure 11 shows some typical Eigenmodes of YSPD obtained through elastic buckling analysis. The distribution of the initial geometric imperfections is assumed to have the same shape as one of the obtained Eigenmodes. In ANSYS, the nodal displacements of an Eigenmode are normalised using the maximum displacement that occurs within a structure and thus the maximum displacement is set equal to unity. By specifying an appropriate multiplying factor, which is the maximum magnitude of imperfection, the nodal co-ordinates are scaled accordingly. This magnitude of the maximum initial geometric imperfection, commonly known as amplitude, is generally taken as a fraction of the plate thickness. A parametric study has been conducted to identify a suitable distribution and the corresponding amplitude of initial geometric imperfection. Figure 12 shows typical force-displacement response for variation in imperfection amplitude and distribution. Obtained results showed insignificant effect of initial geometric imperfections on the force-displacement response of YSPD. Diagonal tension in the diaphragm plate makes the incorporated initial imperfections less effective when compared to its significance in other types of loading e.g. members subjected to longitudinal compression. In the current research, the 1st Eigenmode is used to define the distribution of initial imperfections as this normally represents the lowest buckling capacity. An amplitude of $0.2t$, where t is the thickness of the diaphragm plate, has been used to obtain a reasonable imperfection distribution for YSPD.

Figure 11: Eigenmodes 1, 2, and 3 for YSPD 100×100×4 obtained through elastic buckling analysis.

Figure 12: (a) Typical force-displacement responses of YSPD (100×100×4) as a result of using different imperfection distributions (Eigenmodes) for imperfection amplitude, $w_0 = 0.2t$, (b) Typical force-displacement responses due to different imperfection magnitude (w_0) for the 1st Eigenmode.

3.5.2. Residual stresses

High thermal gradient involved in the welding process induces residual stresses; the magnitude and distribution of residual stresses are, however, quite complex in nature. Masubuchi [20] reported an extensive review on the distribution of residual stresses in different welded shapes. Odar et.al. [21] investigated the magnitude and distribution of residual stresses due to welding process on H and T sections using a method of sectioning, whilst Murugan et.al. [22] measured residual stresses in welded Tee-joint using contour method. Cruise and Gardner [23] conducted experiments for determining imperfections in long austenitic stainless steel sections and proposed simple predictive tools for both local and global imperfections. All experimental results show that tensile residual stress is induced nearer to the welded region, whilst compressive residual stresses are present in the remaining part of the cross-section.

Although the actual distribution of residual stresses is somewhat complicated, a number of simplified guide lines have been proposed by researchers. ECCS publication no. 33 [24] presents a simplified method to model thermally induced residual stresses for welded I sections – the tensile stresses nearer to the welded region and the compression stresses in the other part of the plate are assumed to have trapezoidal distributions. The magnitude of the tensile stress is assumed equal to the yield strength, whilst that for the compressive stress is equal to 25% of the yield strength; the resultant of the tensile and compressive stresses is self-balanced. Ueda et.al. [25] proposed a more simplified rectangular distribution for residual stresses in welded square plates. Liang et.al. [26] adopted the rectangular stress block approach to model residual stresses in concrete-filled welded steel box columns.

In the case of YSPD, a thin diaphragm steel plate is welded inside a square hollow section (SHS). The welding process induces residual stresses both in the diaphragm plate and the square hollow section. To investigate the effects of this residual stress, a simplified rectangular stress distribution is assumed with the magnitudes taken following ECCS specification i.e. the tensile stress is set equal to the yield strength, whilst the compressive stress is taken as 25% of the yield strength. The details are given in Figure 13. The force-displacement responses obtained for YSPDs with and without residual stresses are compared in Figure 14, which shows that residual stresses have negligible effect on the force-displacement response. Residual stress is incorporated for the exact finite element modelling of YSPD though it has an insignificant effect.

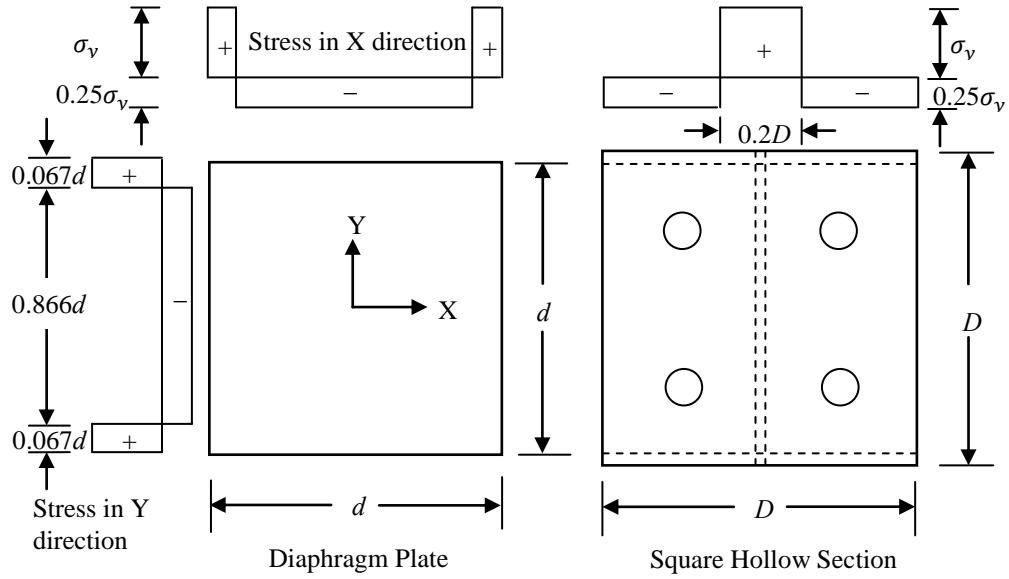

Figure 13: Residual stress Distribution in YSPD

Figure 14: Typical force-displacement response with and without residual stress (YSPD 100×100×4)

4 LOAD-DEFORMATION RESPONSE OF YSPD UNDER MONOTONIC LOADING

A finite element model is developed for yielding shear panel device. Figure 15 compares the force-deformation response of YSPDs obtained from test results to those obtained from FE simulation. The developed FE model with 2 mm diaphragm plate significantly underpredicts the test behaviour; this discrepancy is due to a higher strength shown by the material after a low yield strength (211.3 N/mm^2).

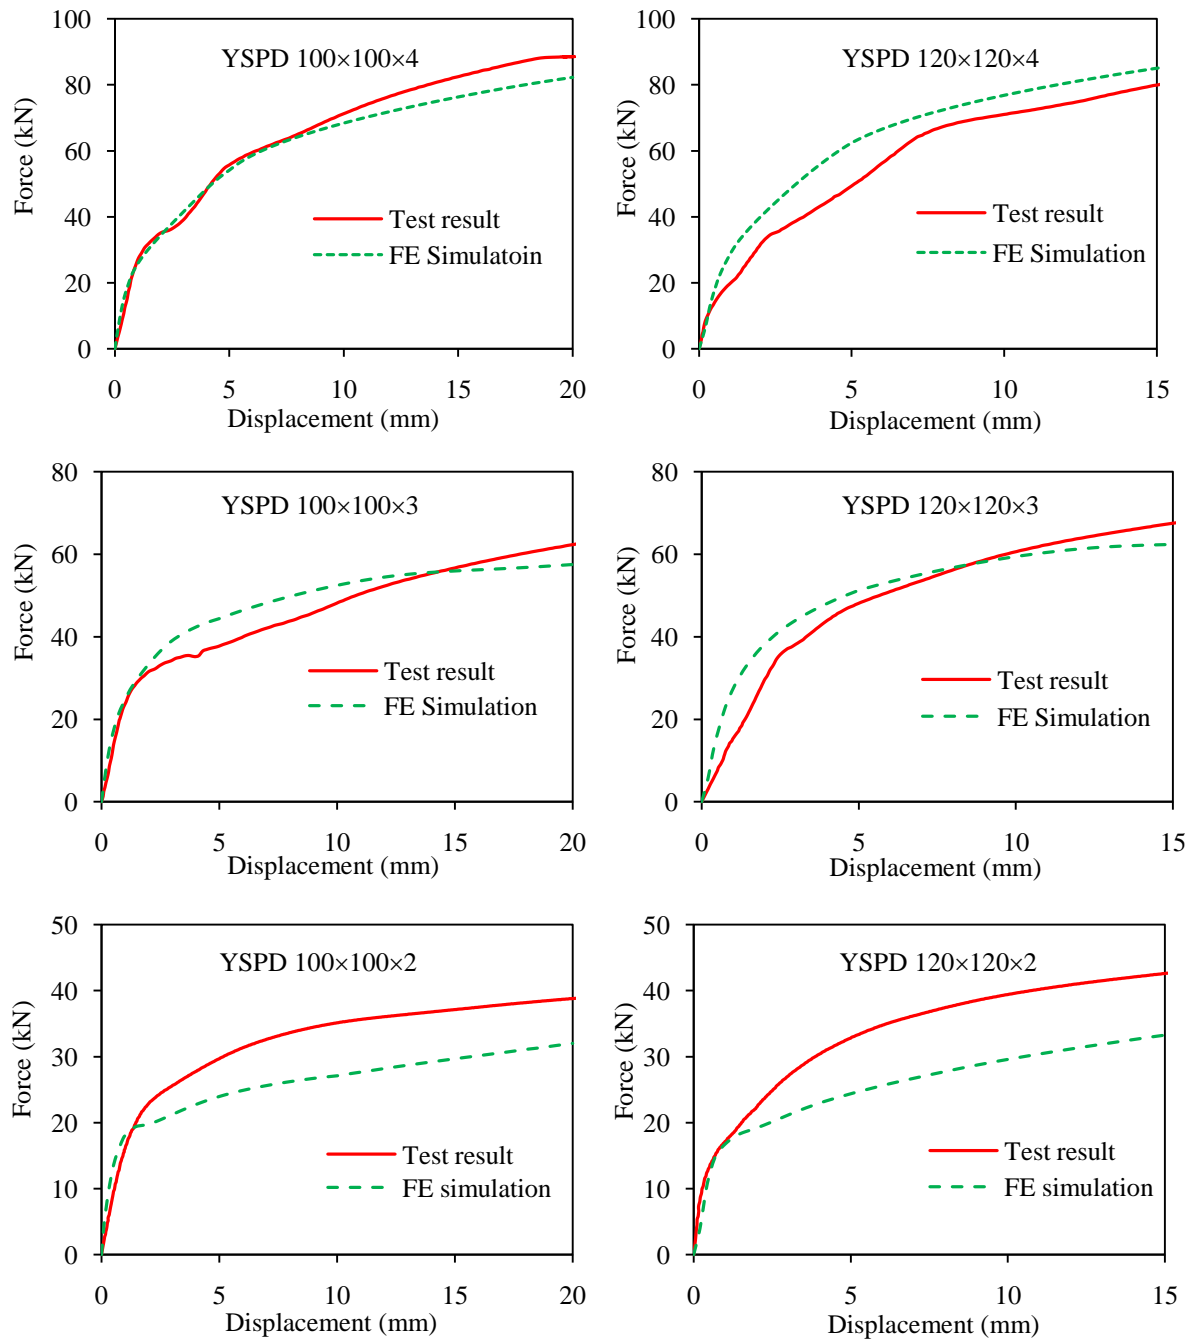

Figure 15. Force-displacement response of YSPDs.

Table 4 compares the amount of energy required to achieve specified displacements during the monotonic loading tests of YSPDs to those obtained from finite element simulation. The ratio of energy required for different displacements indicates that the developed finite element models can predict the required energy with reasonable accuracy.

YSPD Designation	Ratio of Energy for different displacements (FE/Test)			
(D × D × t)	5 mm	10 mm	15 mm	20 mm
100×100×2	0.89	0.83	0.81	0.81
100×100×3	1.13	1.14	1.09	1.05
100×100×4	1.01	0.99	0.97	0.95
120×120×2	0.81	0.77	0.77	-
120×120×3	1.22	1.09	1.03	-
120×120×4	1.29	1.17	1.13	-

Table 4: Comparison of energy required in monotonic loading.

5 LOAD-DEFORMATION RESPONSE OF YSPD UNDER CYCLIC LOADING

Developed FE models were subjected to cyclic loading to validate their accuracy so that reliable results could be generated to develop design rules for YSPD. Figure 16 shows the force-displacement response of YSPDs when subjected to a displacement controlled cyclic loading. Cyclic response, overall, shows a good correlation between the test results and finite element simulation.

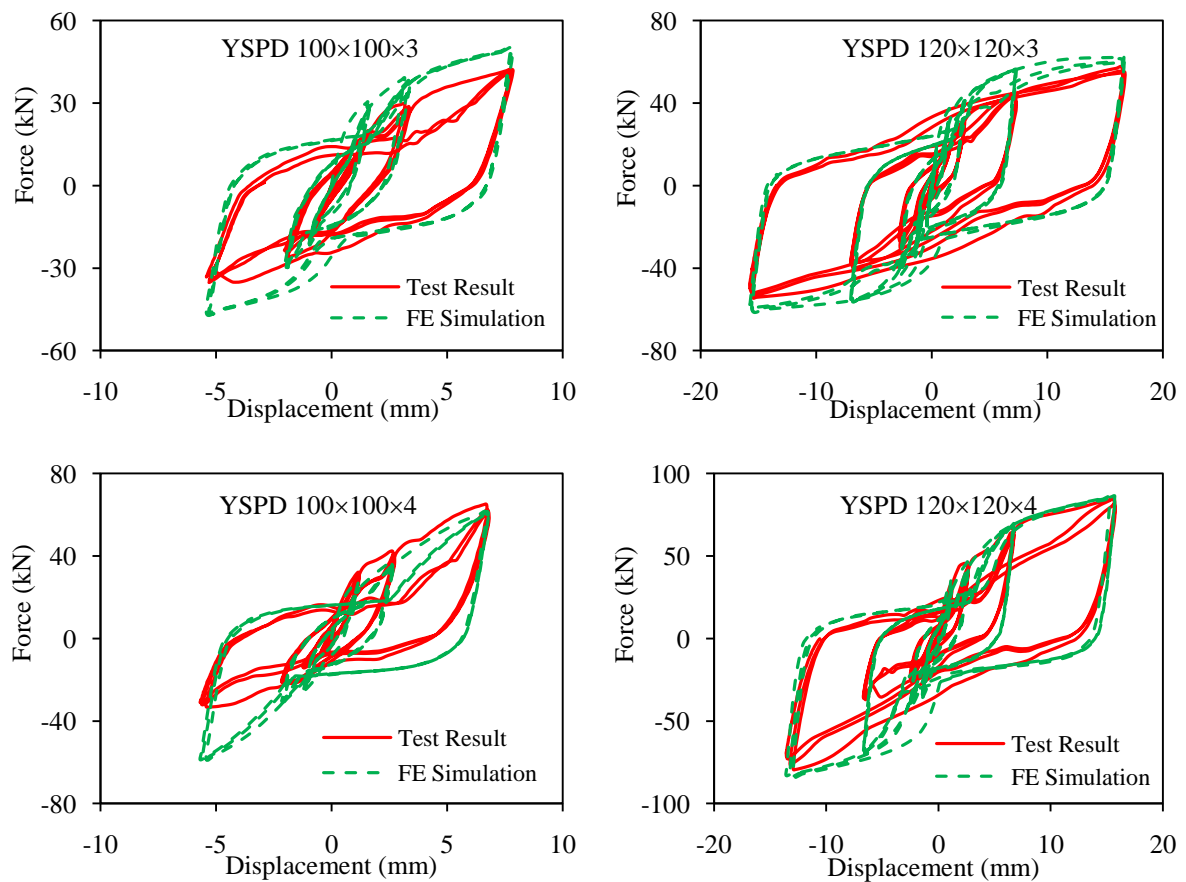

Figure 16. Cyclic response of YSPDs

The energy dissipated in one cycle can be measured by calculating the area bounded by the cyclic response. Total energy dissipation for both test results and finite element simulation are calculated. Comparisons of energy dissipation with the cumulative number of cycles are plotted in Figure 17. The comparison shows that the developed FE models are able to predict the amount of energy absorbed with reasonable accuracy.

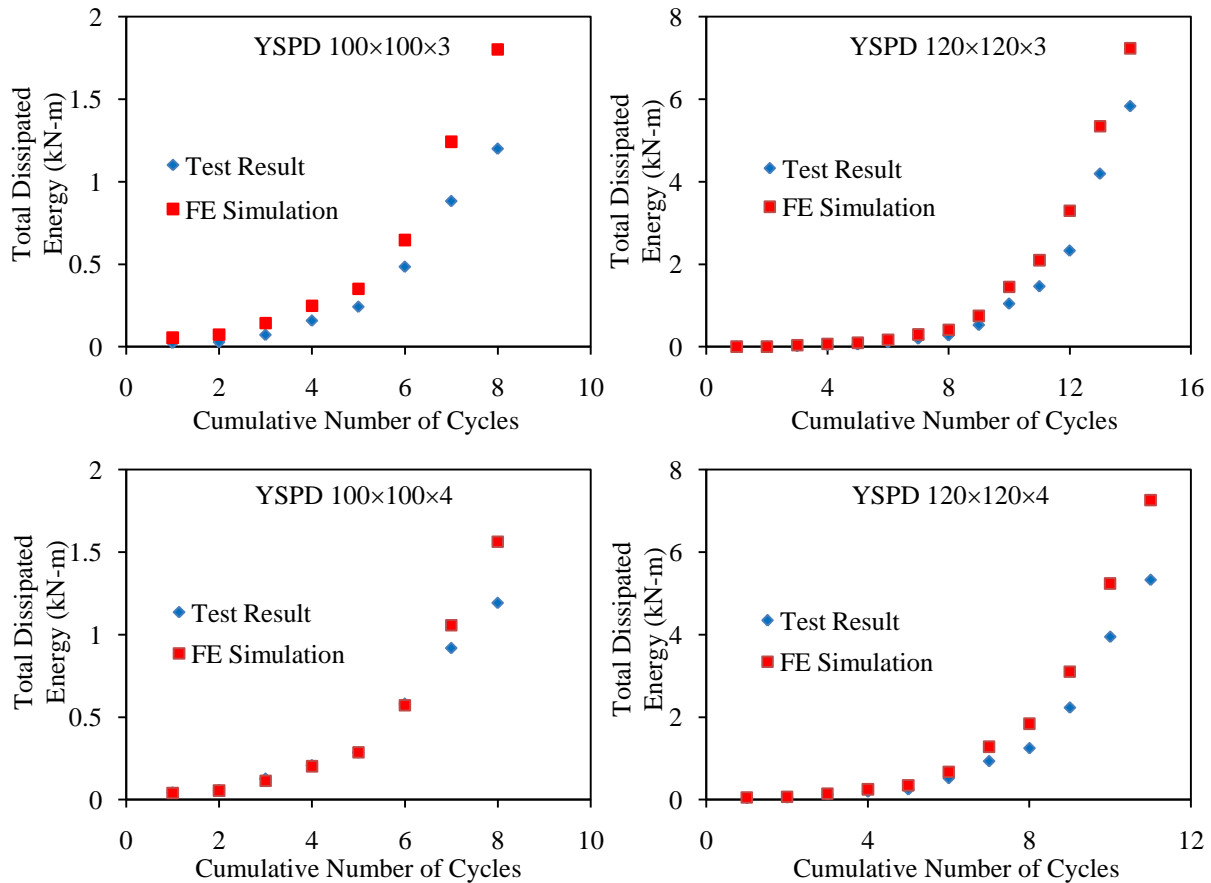

Figure 17. Comparison of hysteretic energy dissipation due to cyclic loading of YSPDs

6 CONCLUSION

Numerical modelling techniques for a newly proposed passive energy dissipation device YSPD is explained in detail, giving special significance of appropriate support conditions, initial geometric imperfections and residual stresses. Modelling of support conditions requires use of nonlinear spring elements with appropriate linear stiffness in both tension and compression. The out-of-plane rotation of the loading beam is observed to play a significant role in determining the initial slope of the load-deformation behaviour. Developed FE models were subjected to both monotonic and cyclic loading and the obtained results showed good agreement with the test results.

Abstract. *Assessment of the structural and functional integrity of civil engineering structures is an essential design issue and of continuous concern during the process of maintenance, repair and upgrading of such structures. The concept of Structural Health Monitoring (SHM) offers means to predict the structural behavior of a particular structure under operating conditions that differ from those taken into consideration in the initial design cycle. Employment of the aforementioned concept requires computational models that are verified, refined and adjusted with respect to actual measurements. In this paper, a finite element updating methodology is presented, which aims to reduce the discrepancies between the dynamic model parameters of the structure and the measurements. A successful finite element updating approach must rely on physically meaningful criteria for selecting the updating parameters and the most suitable method in order to modify the mass and stiffness matrices of the computational model. The proposed iterative method is based on a generalized variational principle, a modified version of the Hu-Washizu principle of elastodynamics, which treats displacements, rotations, strains and stresses as independent variables that can be treated as updating parameters. Thus, a more efficient and direct implementation of measurements is possible. Furthermore, the discretization yields simple and effective finite elements especially suited to repetitious computations required in dynamic finite element updating. Different parameter sensitivities are studied. Single and multi-objective optimization processes are carried out using objective functions that include the eigenfrequencies and the strain modal energy of the structure. Finally, some alternative damage scenarios are presented in order to validate the proposed formulation for the case of hyperbolic paraboloidal shell structures.*

1 INTRODUCTION

Assessment of the structural and functional integrity of civil engineering structures is an essential design issue and of continuous concern during the process of maintenance, repair and upgrading of such structures. The concept of Structural Predictive Maintenance (SPM) offers means to predict the structural behavior of a particular structure under operating conditions that differ from those taken into consideration in the initial design cycle. Employment of the aforementioned concept requires computational models that are verified, refined and adjusted with respect to actual measurements. The finite element updating method is employed to minimize those differences. Over the past decades, significant research has been performed in this area [1]. The monograph by Friswell [2] and the review article [3] mainly deal with the different steps in the updating procedure. Furthermore, Brownjohn *et al.* [4] focus on those steps by using a controlled laboratory-based study of a simple structure. Finite element modelling for updating is the first phase. In case of an updating process, the development of a finite element model for a civil engineering structure, differs from the finite element models used for common structural analysis purposes. Some important issues must be taken into consideration [5]: type of elements, boundary conditions and the presence of damage. Civil engineering structures are modelled by beam, plate, shell, and solid elements with thousands of degrees of freedom (displacements and rotations). An important issue is that not all degrees of freedom can be measured; also rotations are difficult to assess. Therefore, it is vital to employ finite elements that restrict the number of rotational degrees of freedom to a minimum. Furthermore, the element formulation should contain physically meaningful updating parameters. Selection of the appropriate updating parameters is crucial to the finite element updating process. A small perturbation of some parameters may affect the behavior of the structure, while other parameters not. The former may not necessarily be the ideal candidates for an updating process. Therefore, it is necessary to develop a sensitivity analysis preceded by an error localisation investigation. If some damage is present, the model has to take it also into account in order to realistically model the structure. The Force Balance Method [6] calculates a residual force vector, that if plotted can represent the non-equilibrated forces/moments in direction of the degrees of freedom; a fact that points to an error in the modelling phase. Sensitivity analysis represents the variation of an objective function with respect to structural parameters [7, 8]. The derivation of the objective functions can be performed by four different methodologies [9]: overall finite differences, discrete derivatives, continuum derivatives, and computational or automatic differentiation. The selection of a proper objective function can ensure an efficient sensitivity analysis [10]. The objective function establishes a relationship between the measurement results and the numerical predictions. Modal properties such as eigenfrequencies and mode shapes of a structure are normally employed in these objective functions. An optimization process serves to minimize the differences between experimental and numerical results [11–14]. Finally, to ensure the agreement of the updating results it is necessary to validate them. Towards this aim, some validation techniques are employed (e.g., Modal Assurance Criterion [15]).

In this paper, a finite element updating methodology is presented, which aims to reduce the discrepancies between the dynamic model parameters of the structure and the measurements. An effective finite element updating approach must rely on physically meaningful criteria for selecting the updating parameters and the most suitable method in order to modify the mass and stiffness matrices of the computational model. The proposed iterative method employs finite elements that are derived using a generalized variational principle, a version of the Hu-Washizu principle of elastodynamics. This variational principle treats displacements, rotations, strains,

and stresses as independent variables that can be selected in a direct manner as updating parameters. The changes of these parameters are estimated by employing both single- and multi-objective optimisation processes. The application of the method is illustrated by employing four-noded doubly-curved shell elements with a total number of twenty degrees of freedom to study different cases such as damaged or undamaged models. Numerical examples demonstrate that the proposed approach is stable and produces accurate results.

2 FINITE ELEMENT MODELLING

2.1 Hyperbolic Paraboloidal shell

The accuracy of the method is demonstrated for the case of a homogeneous, isotropic, and thin hyperbolic paraboloidal shell (hypar shell) of rectangular planform with length a , width b , thickness h , and radii of curvature R_x and R_y , (see figure 1). The dimensions of the hypar shell are:

$$a = 20 \text{ m} \quad b = 20 \text{ m} \quad R_y = \frac{b}{0.1} \quad R_x = -R_y \quad h = 0.2 \text{ m} \quad (1)$$

Young's modulus and Poisson's ratio are taken as $2 \cdot 10^{10} \text{ N/mm}^2$ and 0.3, respectively.

Figure 1: Hyperbolic paraboloidal shell with rectangular planform.

A damage scenario is considered with a stiffness reduction in two parts of the hypar (see figure 2). A uniform mesh with 8×8 elements is used. Eigenfrequencies and mode shapes obtained from computational methods for the damaged model of this hypar shell are considered to be the experimental results to be validated.

Figure 2: Damage scenario for the hyperbolic paraboloidal shell.

2.2 Finite element formulation

The shell element derived in the present study is a four-noded, doubly-curved isoparametric finite element with five degrees of freedom at each node: three physical components of the displacements u_1, u_2, u_3 and two components of the rotations φ_1, φ_2 . Bilinear shape functions N_k are chosen for the physical components of the displacements and rotations:

$$u_i = \sum_{k=1}^4 u_i^k N_k \quad \varphi_\alpha = \sum_{k=1}^4 \varphi_\alpha^k N_k \quad (2)$$

with $N_k = \frac{1}{4} (1 + \xi_k \xi) (1 + \eta_k \eta) \quad i = 1, 2, 3 \quad \alpha = 1, 2$

Denoting by $\mathcal{U}(\boldsymbol{\gamma})$ the strain energy and by $\boldsymbol{\gamma}$ and $\boldsymbol{\sigma}$ the vectors containing the strain and stress components, respectively, a version of the generalized Hu-Washizu principle assumes the form [16]:

$$\Pi_{HW} [\mathbf{v}, \boldsymbol{\gamma}, \boldsymbol{\sigma}] = \int_V [\mathcal{U}(\boldsymbol{\gamma}) - \boldsymbol{\sigma}^T (\boldsymbol{\gamma} - \mathbf{D} \mathbf{v}) - \Pi_b] dV - \int_{S_{\hat{\mathbf{v}}}} (\mathbf{v} - \hat{\mathbf{v}}) \boldsymbol{\sigma} \mathbf{n} dS - \int_{S_t} \Pi_t dS \quad (3)$$

In the variational principle (3), \mathbf{v} represents the displacement vector and the index b refers to the body forces. The vector $\hat{\mathbf{v}}$ denotes prescribed displacements on the part of the boundary, where displacements are prescribed ($S_{\hat{\mathbf{v}}}$). If the body forces in V and surface tractions on S_t are conservative, then Π_b and Π_t denote the corresponding potentials.

As mentioned before, the use of the Hu-Washizu principle and the independent approximation of strain and stress yields a series of desirable features important for the reliability,

convergence behavior, and efficiency of the elemental formulation, e.g., avoidance of superfluous energy and zero energy modes. Furthermore, the discrete approximation is drawn in a consistent manner from the general theory of the continuum and the mechanical behavior of the finite element, without resource to special manipulations or computational procedures. Also, it has been shown (see [16, 17]) that essential prerequisites for the achievement of these goals are: The identification of the constant and higher-order deformational modes that are contained in the displacement/rotation assumptions, the realization that constant terms are necessary for convergence and that higher-order terms reappear in different strain components. Therefore, our approximations need not retain the higher-order terms in two different strain components (they are needed only to inhibit a mode). Suppressing such terms serves to reduce excessive internal energy and to improve convergence. As an example, the following assumptions for the extensional strains have been shown to serve the aforementioned goals:

$$\begin{aligned}\varepsilon_{11} &= \bar{\varepsilon}_{11} + \bar{\bar{\varepsilon}}_{11} \eta \\ \varepsilon_{22} &= \bar{\varepsilon}_{22} + \bar{\bar{\varepsilon}}_{22} \xi \\ \varepsilon_{12} &= \bar{\varepsilon}_{12} + \bar{\bar{\varepsilon}}_{11} \xi + \bar{\bar{\varepsilon}}_{22} \eta\end{aligned}\quad (4)$$

The higher order modes ($\bar{\bar{\varepsilon}}_{11}, \bar{\bar{\varepsilon}}_{22}$) in the expression for the shear strain ε_{12} appear also in the expressions for the strains ε_{11} and ε_{22} . In order to avoid successive energy, the assumption for the shear strain should not contain the underlined terms.

The eigenvalue problem for the undamped free vibration problem takes the well-known form:

$$\mathbf{K} \mathbf{u}_i = \omega_i^2 \mathbf{M} \mathbf{u}_i \quad (5)$$

where \mathbf{K} is the stiffness matrix of the system, ω_i is the natural frequency in radians of mode i , \mathbf{u}_i represent the corresponding eigenvector, and \mathbf{M} is the mass matrix of the structure. The consistent element mass matrix is derived by discretizing the kinetic energy:

$$\delta \mathcal{U}_K = \frac{1}{2} \int_V \rho \mathbf{v} \delta \ddot{\mathbf{v}} dV \quad (6)$$

$$(7)$$

In table 1, numerical results are presented for the nondimensional frequency parameter λ given by:

$$\lambda = \omega a b \sqrt{\frac{\rho h}{D}} \quad D = \frac{E h^3}{12 (1 - \nu^2)} \quad (8)$$

that demonstrate the convergence behavior for different meshes.

Damage identification based on changes in vibration characteristics requires that those changes are reliable. In table 2, the variation of λ for various ratios b/h is presented. These results are illustrated graphically by figure 3. From these results it can be concluded that the frequency vibration characteristic could not be used alone in a damage identification process due to its relatively low variation with thickness changes.

3 CORRELATION

Analytical results from a finite element model must be validated with respect to those obtained by experimental measurements. Towards this aim, several techniques may be employed [19]. One of the simplest methods for data correlation is to calculate the percentage differences between the natural frequencies obtained by analytical and experimental techniques (see fourth column of table 3 and figure 4).

Mode	Undamaged hypar (Hz)	Damaged hypar (Hz)	Differences (%)	MAC (%)
1	3.60	3.59	0.28	0.99
2	6.02	5.98	0.73	0.008
3	6.02	6.02	-0.01	0.008
4	8.47	8.38	1.01	0.99
5	11.83	11.54	2.45	0.64
6	11.88	11.78	0.78	0.64
7	13.96	13.69	1.91	0.11
8	13.96	13.80	1.17	0.11
9	18.71	18.45	1.38	0.97
10	22.93	22.06	3.83	0.71

Table 3: Differences in the first ten natural frequencies between the undamaged and damaged model for the CCCC hypar (8×8 mesh) of figure 1.

Figure 4: Percentage differences between analytically and experimentally obtained natural frequencies.

The modal assurance criterion (MAC) is another commonly used method to establish a correlation factor for each pair of analytical and experimental mode shapes:

$$MAC_{ij} = \frac{|\phi_{ai}^T \phi_{ej}|^2}{(\phi_{ai}^T \phi_{ai}) (\phi_{ej}^T \phi_{ej})} \quad (9)$$

A high correlation yields a MAC value close to 1, whereas a low correlation assumes values near 0. The fifth column of table 3 presents MAC values for the undamaged model of the hypar (analysis using doubly-curved shell elements) and those for the damaged hypar scenario (considered as experimental data). Furthermore, figure 5 represents the MAC-matrix for the first ten mode shapes.

Figure 5: Representation of Modal Assurance Criterion (MAC) matrix between the undamaged and damaged models for the CCCC hypar.

4 OBJECTIVE FUNCTIONS AND SENSITIVITY ANALYSIS

Jaishi [11] proposed the use of two objective functions comprised of the discrepancies between experimental and numerical results. The modal strain energy residual function (Π_1) and the eigenfrequency residual function (Π_2) are defined as:

$$\Pi_1(p) = \frac{1}{\Pi_1(p_0)} \sum_{i=1}^m \left(\frac{\phi_{ai}^T \mathbf{K} \phi_{ai}}{\phi_{ei}^T \mathbf{K} \phi_{ei}} - 1 \right)^2 \quad \Pi_2(p) = \frac{1}{\Pi_2(p_0)} \sum_{i=1}^m \left(\frac{\lambda_{ai}}{\lambda_{ei}} - 1 \right)^2 \quad (10)$$

where λ and ϕ denote the m eigenfrequencies and modal vectors of the eigenvalue problem, the subindices ai and ei refer to the analytical and experimental results that in this case correspond to the undamaged and damaged models. Matrix \mathbf{K} represents the stiffness matrix of the system and the variable p is defined as a normalization of model parameters (i.e., the thickness h of the bridge) between the initial (h_0) and updated values (h):

$$p_h = -\frac{h - h_0}{h_0} \quad h = h_0(1 - p_h) \quad (11)$$

Sensitivity analysis of these objective functions with respect to the model parameters is carried out by forming the gradients of the objective functions Π_1 and Π_2 , respectively (derivatives of Π_1 and Π_2 with respect to the parameter p_j):

$$\frac{\partial \Pi_1}{\partial p_j} = \frac{1}{\Pi_1(p_0)} \sum_{i=1}^m \left[2 \frac{A}{(\phi_{ei}^T \mathbf{K} \phi_{ei})^2} \left(\frac{\phi_{ai}^T \mathbf{K} \phi_{ai}}{\phi_{ei}^T \mathbf{K} \phi_{ei}} - 1 \right) \right] \quad (12)$$

$$A = \left[\left\{ (\phi_{ei}^T \mathbf{K} \phi_{ei}) \left[2 \frac{\partial \phi_{ai}^T}{\partial p_j} \mathbf{K} \phi_{ai} + \phi_{ai}^T \frac{\partial \mathbf{K}}{\partial p_j} \phi_{ai} \right] \right\} - \left\{ (\phi_{ai}^T \mathbf{K} \phi_{ai}) \left(\phi_{ai}^T \frac{\partial \mathbf{K}}{\partial p_j} \phi_{ai} \right) \right\} \right] \quad (13)$$

$$\frac{\partial \Pi_2}{\partial p_j} = \frac{1}{\Pi_2(p_0)} \sum_{i=1}^m \left[2 \left(\frac{\lambda_{ai}}{\lambda_{ei}^2} - \frac{1}{\lambda_{ei}} \right) \frac{\partial \lambda_{ai}}{\partial p_j} \right] \quad (14)$$

For the derivatives:

$$\frac{\partial \lambda_i}{\partial p_j} \quad \frac{\partial \phi_i}{\partial p_j} \quad (15)$$

in equations (13) and (14), the expressions derived by Fox and Kapoor [18] are employed:

$$\frac{\partial \lambda_i}{\partial p_j} = \phi_i^T \left[\frac{\partial \mathbf{K}}{\partial p_j} - \lambda_i \frac{\partial \mathbf{M}}{\partial p_j} \right] \phi_i \quad (16)$$

$$\frac{\partial \phi_i}{\partial p_j} = \sum_{q=1}^d \beta_{jiq} \phi_q \quad \beta_{jiq} = \begin{cases} \phi_q^T \left[\left(\frac{\partial \mathbf{K}}{\partial p_i} - \lambda_j \frac{\partial \mathbf{M}}{\partial p_i} \right) / (\lambda_j - \lambda_q) \right] \phi_j & q \neq j \\ -\frac{1}{2} \phi_j^T \frac{\partial \mathbf{M}}{\partial p_i} \phi_j & q = j \end{cases} \quad (17)$$

where d denotes the number of modes that will be considered in the evaluation. Since in a hyar model only few of the modes can be computed and the lower modes are of importance, it is reasonable to consider here only the first ten modes ($m = d = 10$). Furthermore, the derivatives of the stiffness and mass matrix, appearing in equations (16) and (17) are formed rather analytically than numerically using finite differences. This yields a series of advantages in the optimization process.

Figure 6(a) and figure 6(b) illustrate the sensitivity of the objective functions Π_1 and Π_2 with respect to variations of the thickness parameter. It can be observed that the strain modal energy function easily detects both damages. On the other hand, sensitivity of the objective function Π_2 , which is related to the eigenfrequencies, assumes a symmetrical form that can not identify the position of the damages. Nevertheless, eigenfrequencies can be accurately measured by operational modal analysis and therefore are considered useful in the optimization process.

(a) Sensitivity of the objective function Π_1 with respect to thickness.(b) Sensitivity of the objective function Π_2 with respect to thickness.

Figure 6: Sensitivity analysis of objective functions with respect to thickness.

5 SELECTION OF UPDATING PARAMETERS

As mentioned before, selection of the updating parameters is the most difficult step in an updating process and the accuracy of the results strongly depends upon this election. Finite element models with fine mesh configurations may lead to thousands of degrees of freedom. Furthermore, considering material properties of individual elements may lead to a very large number of updated parameters related to Young's modules, thickness, etc. Also, selection of updating parameters would be more difficult, if some damage scenario is considered. For these

reasons, an error localisation approach and substructuring techniques are needed.

5.1 Error localisation

In view of possible damage scenarios, the optimization process would become more effective if a method is established for updating parameters that considers this particular case. The Force Balance Method (FBM) calculates a residual vector [6, 19]:

$$\mathbf{F}_r = (\mathbf{K}_a - \lambda_{er} \mathbf{M}_a) \boldsymbol{\phi}_{er} \quad (18)$$

that represents for each mode r the inaccuracies of the finite element model by plotting the degrees of freedom that are not in equilibrium. For illustrative purposes, non-balanced forces (moments) corresponding to the degrees of freedom of the finite element model for the damaged bridge are represented in figure 7.

Figure 7: Error localisation based on Force Balance Method plotted for the first mode.

5.2 Substructure method for parameter selection

Model updating is a process that could lead to ill-conditioned problems, if the same number of updating parameters with respect to each finite element of the model is selected. A common and physically meaningful approach, the so-called “substructure method,” is to establish updating parameters for different groups of finite elements. Kim and Park [20, 21] proposed an automated parameter selection procedure for multi-objective optimisation problems. This method relies on the fact that two neighboring parameters p_i and p_j can be merged into one updating parameter, if the sensitivity with respect to the objective functions has the same sign. This yields a map in the structure with different areas associated with identical parameters.

In the present work, a new method to implement substructure divisions of the finite element model has been developed. By assuming that high sensitivities are associated with damaged zones, a prioritization selection procedure is established. The sensitivity vector, that stores in each

row the sensitivity of each element with respect to the objective function is classified by zones. These zones correspond to multiples of the semi-difference sensitivity extreme (maximum and minimum) absolut values, called step. To illustrate the method, figure 8 shows a substructure division for ten zones.

Figure 8: Substructure method.

In the case of the current hyar shell, the relationship between the element thickness and the updating parameters assumes the form:

$$\mathbf{H} = \mathbf{H}_0 - h_0 \mathbf{S}_b \mathbf{P}_h \quad (19)$$

where \mathbf{H} is a column vector that contains the hyar element thicknesses, vector \mathbf{H}_0 stores the reference thickness taken as h_0 . Matrix \mathbf{S}_b , called *substructure-matrix*, is defined by the method explained before and assumes the following form:

$$\mathbf{S}_b = \begin{bmatrix} 1 & 0 & \dots & 0 & 0 \\ 1 & 0 & \dots & 0 & 0 \\ 0 & 0 & \dots & 0 & 1 \\ 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & 0 & 0 & \dots & 0 \end{bmatrix} \quad (20)$$

with the number of rows equal to the number of finite elements in the model and with the total number of columns equal to the number of non-dimensional updating variables, p_{h_i} . According to the matrix (20), every row consists of zeros except for a single element equal to one.

6 COMPUTATIONAL PROCEDURE

The computational work, related to the present finite element updating methodology, has been developed by programing several subroutines using MATLAB. Furthermore, “fmincon” and “fgoalattain” gradient-based MATLAB optimization algorithms are employed for single-objective and multi-objective optimization, respectively.

7 NUMERICAL EXAMPLES

In order to demonstrate the applicability of the proposed method, some numerical results are presented for the case of the damaged hyar of figure 2. Two different updating processes are studied, the first one considers a single-objective optimization by using a linear combination of objective functions $\Pi_1(p)$ and $\Pi_2(p)$ defined as follows:

$$\Pi_3(p) = \frac{1}{\Pi_1(p_0)} \sum_{i=1}^m \left(\frac{\phi_{ai}^T \mathbf{K} \phi_{ai}}{\phi_{ei}^T \mathbf{K} \phi_{ei}} - 1 \right)^2 + \frac{1}{\Pi_2(p_0)} \sum_{i=1}^m \left(\frac{\lambda_{ai}}{\lambda_{ei}} - 1 \right)^2 \quad (21)$$

and the second one considers a multi-objective optimisation process using the same objective functions but separately.

The convergence plots (figure 9(a) and figure 9(b)) show that for both, single-objective and multi-objective optimization, convergence is achieved in a similar way after ten iterations. The multi-objective optimization process shows that the results fluctuate in the first iterations due to the particular optimization process of the objective functions Π_1 and Π_2 to find a Pareto optimal. Furthermore, the objective function Π_2 is more difficult to optimize. The reason for such complication is the low sensitivity with respect to damage, as it was shown in figure 6(b).

Figures 10(a)-10(b) and tables 4-5 demonstrate that the proposed method is capable to localize all damaged elements. Additionally, correlation of modal shapes is high since the MAC factor is nearly 1.

7.1 Noisy vibration measurements

Vibration measurements are often contaminated by noise. It could be originated by the wind, the traffic, and also due to the cables that are connected to the accelerometers. This uncertainty can be simulated by adding some noisy-terms to the experimental modal shapes [22]:

$$\phi_{e_j}^{noisy} = \phi_{e_j} + \alpha_j RMS(\phi_{e_j}) \psi \quad (22)$$

where α_j is a random matrix generated by a Gaussian distribution of mean 0 and standard deviation 1, ψ is a scalar that represents the noise level and RMS is the root mean square given by:

$$RMS(\phi_{e_j}) = \sqrt{\frac{1}{N_j} \sum_{j=1}^{N_j} (\phi_{e_j})^2} \quad (23)$$

For illustrative purposes, this methodology is followed for the case of the damaged hyper of figure 2 with a noise level of 0.5 %. In this case, only single-objective optimization is employed (objective function Π_3). The optimization convergence is illustrated in figure 11. Table 6 shows the differences before and after updating the model . Frequency differences are plotted in figure 12. The damage localization, see figure 13, illustrates differences in the percentage of damage severity due to the effect of the noise.

8 CONCLUSIONS

In this paper, a finite element updating methodology is presented. Finite element modelling is carried out by using doubly-curved shell elements based on the variational principal of Hu-Washizu. The formulation possesses some important features that ensure low computational effort and reliable results. A hyper model with different damages is employed to test the accuracy of the proposed methodology. Eigenfrequencies and mode shapes of the damaged model are considered as experimental data that are used in the updating process of the numerical model. In order to study the confidence between the numerical and experimental results, several correlation techniques are employed.

The present methodology makes use of sensitivity for updating parameter selection. Two different objective functions are employed to determine the sensitivity of the model: modal strain energy residual and eigenfrequencies residual. High sensitivity zones are associated with possible damaged elements and are classified by the use of a simple-priorization technique. In order to establish the correspondence between the element parameters in the numerical model and the updating parameters, some matrix operations have been developed.

The performance of the method is demonstrated by presenting case studies for single-objective and multi-objective optimization. In the first case study, a linear combination of modal strain energy and eigenfrequencies residual functions was selected as objective function. On the contrary, in the case of multi-objective optimization process, both objective functions were independently employed. The results with respect to localization and severity of the damage are in good agreement with the damaged model. Furthermore, the convergence of the optimization process is achieved in both cases after a few iterations, thus revealing that the proposed

approach produces an efficient and accurate computational tool suitable for complicated structural systems.

Keywords: fiber beam, mixed formulation, shear, torsion, shear lag

Abstract. *Beam elements are commonly used in the analysis of steel and reinforced concrete structures in earthquake engineering practice. These elements reproduce the global behavior of these structures at a reasonable computational cost. For this type of analysis the force-based fiber beam element has proven an excellent compromise between accuracy and computational cost for the simulation of the inelastic response of structural models of significant size. Recent studies have proposed extensions of the model to account for the effect of shear and torsion under fixed shear strain or stress distributions. These assumptions suffer from shortcomings for the representation of the coupling between shear and torsion, and are not suitable for the representation of local stress and strain distributions at critical sections. To describe such complex stress states, shell finite element models are often used with a significant increase in computational cost. This paper presents the mixed formulation of an enhanced 3d fiber beam element that represents accurately the global and local response of structural members under axial force, flexure, shear and torsion interaction. The proposed 3d fiber beam element determines the shear strain distribution at a section from the satisfaction of local equilibrium equations with the section warping displacements as local parameters. Unlike existing models, the coupling between sections is taken in account. Hence the enhanced fiber beam-column is able to capture the local effects due to constrained warping of the section, such as the flange shear lag effect. The model is also capable of representing accurately the maximum local stress at element boundaries, and of simulating the torsional response of beams under warping constraints.*

The element is validated with several examples involving inelastic response of steel members under high shear force, such as shear links. The simulations are conducted under monotonic and cyclic load conditions for specimens with wide flange and box sections. The accuracy and computational efficiency of the proposed element is demonstrated by comparing the results with experimental values and with local response estimates of shell finite element models.

1 INTRODUCTION

Nonlinear analysis is used increasingly for the evaluation of structures under extreme loading conditions. This type of loads induces high inelastic strains at critical sections and large node displacements. Recent studies have shown that the corotational formulation is a suitable framework for the description of large displacements allowing the nonlinear material response of the basic element to be limited to small deformations. For frame elements the force-based fiber beam element by Ciampi and Carlesimo [4] with its subsequent embedment in a consistent variational framework by Taylor [11] and Lee [7] has proven an excellent choice for describing the interaction between axial force and flexure under inelastic material response.

Recently, research interest has focused on the extension of the force-based beam element to the effect of shear and torsion. In older structures and short span elements the shear affects the failure mode and the member capacity. The first formulation of a beam element with shear was based on Timonshenko beam theory with the assumption of a constant shear stress distribution over the cross-section [12]. Subsequent models by A. Saritas [10], N. Gregori [5] and A. Papachristidis [9], postulate a strain or stress field distribution based on the analytical result for a homogeneous section. These models were used to simulate the inelastic response of shear links and shear walls with success. However, the assumption of a fixed shear distribution is not justified when inelastic deformations spread through the section and render the response inhomogeneous. The model of J.M. Bairan [1] and S. Mohr [8] overcomes this limitation with the addition of degrees of the freedom at the section level to represent the shear distribution while also accounting for section warping. Equations of local equilibrium are used to determine the response parameters at these degrees of freedom.

The model of A. Saritas [10] is limited to 2d applications, whereas the element proposed by N. Gregori [5] and A. Papachristidis [9] apply to 3d response without, however, accounting for the shear distribution due to torsion and the effect of warping. The model of J.M. Bairan [1] accounts for section warping and is thus able to represent the torsional response with accuracy. The model also accounts for the in-plane section deformation, which increases computational cost significantly.

Even though existing models account for a variable shear distribution and section warping, the interaction between sections of the beam element is not directly taken into account. In particular the effect of warping on axial deformation is neglected resulting in the incorrect representation of the local response near boundaries and other important local response phenomena such as shear-lag [13]. While neglecting this effect and decoupling the response of different beam sections has the advantage of maintaining the number of element degrees of freedom and reducing the element computational cost, the inability of representing the local stresses under warping constraints and at element boundaries is a serious limitation.

The proposed 3d enhanced fiber beam element model sets out to address some limitations of earlier formulations by allowing for arbitrary section warping under shear and torsion and by including the effect of boundaries on the warping distribution. This objective is met first with the introduction of warping degrees of freedom at each section, and secondly by imposing equilibrium on the entire element, so as to account for section interaction and thus incorporate the effect of boundary conditions. For simplicity only out-of-plane section displacements are represented by assuming that the section is rigid in its plane.

The paper presents a brief description of the theory of the proposed 3d enhanced fiber beam element and concludes with a few examples that demonstrate its capability for representing the shear stress distribution under combined loadings and the shear lag effect. In these examples

the response of structural model with the proposed element is compared with the response of the model with shell elements, thus permitting for the accurate comparison of the global as well as the local response.

2 BEAM DESCRIPTION

This section presents a brief derivation of the enhanced 3d beam element. The element is formulated in a system without rigid body modes, which are removed with the corotational formulation. The element degrees of freedom consist of local degrees of freedom \mathbf{u}_{IJ} and of warping degrees of freedom \mathbf{u}_{IJ}^w . The warping degrees of freedom describe the out-of-plane displacements of

Figure 1: Basic element kinematics

the section. The number of these degrees of freedom for each section is n_w . These are local degrees of freedom associated with local equilibrium equations. To satisfy displacement compatibility between adjacent elements, the warping displacements of the end sections are retained as element variables.

$$\mathbf{u}_{IJ}^w = [\mathbf{u}_I^w \quad \mathbf{u}_J^w] \quad (1)$$

In the local reference system the element deformations are denoted by \mathbf{v} and consist of the axial deformation, of the rotations θ_y and θ_z at the element ends, and of the angle of twist ϕ . The associated forces \mathbf{q} are the axial force, the bending moments about the y and z axis, and the torsional moment. The deformations are related to the local displacements with the compatibility matrix \mathbf{a}_g :

$$\mathbf{v} = \mathbf{a}_g \mathbf{u}_{IJ} \quad (2)$$

2.1 Section Kinematics

The displacements of any point (y,z) of a section, defined by its x along the element axis, are decomposed as follows:

$$\mathbf{u}_{total} = \mathbf{u}^r + \mathbf{u}^w \quad (3)$$

The rigid displacement of the section is denoted by \mathbf{u}^r and is expressed in terms of the cross-section generalized displacements

$$\mathbf{u}(x) = [u \quad v \quad w \quad \theta_z \quad \theta_y \quad \phi]^T(x) \quad (4)$$

The warping displacements $\mathbf{u}^w(x, y, z)$ are defined everywhere in the beam element by interpolation functions

$$\mathbf{u}^w(x, y, z) = \sum_{ij} M_i(x) N_j(y, z) \mathbf{u}^w(x_i, y_j, z_j) \quad (5)$$

In contrast to the formulation by J.M. Bairan [1], only the axial component of the warping displacement is taken into account by neglecting the in-plane section deformation.

The warping displacements are orthogonal to the section rigid body displacements \mathbf{u}^r . This condition is enforced by removing the rigid body modes from the displacements \mathbf{u}^w with the use of a projection matrix. The details of this matrix are not presented here for the sake of brevity.

The displacement of any material point (y, z) of the cross section at position x along the axis is given by

$$u_x(x, y, z) = u(x) - y\theta_z(x) + z\theta_y(x) + u^w(x, y, z) \quad (6)$$

$$u_y(x, y, z) = v(x) - z\phi(x) \quad (7)$$

$$u_z(x, y, z) = w(x) + y\phi(x) \quad (8)$$

The strains are derived from the definition of the displacements and are expressed in the compact form:

$$\begin{aligned} \boldsymbol{\epsilon}(\mathbf{u}^r, \mathbf{u}^w) = \begin{bmatrix} \epsilon_{xx} \\ 2\epsilon_{xy} \\ 2\epsilon_{xz} \end{bmatrix} &= \begin{bmatrix} 1 & -y & 0 & 0 & z & 0 \\ 0 & 0 & 1 & -z & 0 & 0 \\ 0 & 0 & 0 & y & 0 & 1 \end{bmatrix} \begin{bmatrix} u' \\ \theta'_z \\ v' - \theta_z \\ \phi' \\ \theta'_y \\ w' - \theta_y \end{bmatrix} + \begin{bmatrix} \epsilon_{xx}(\mathbf{u}^w) \\ 2\epsilon_{xy}(\mathbf{u}^w) \\ 2\epsilon_{xz}(\mathbf{u}^w) \end{bmatrix} \quad (9) \\ &= \mathbf{a}_s \mathbf{e}(\mathbf{u}) + \boldsymbol{\epsilon}(\mathbf{u}^w) \quad (10) \end{aligned}$$

where the notation $'$ denotes the derivative of the variable with respect to coordinate x . The notation \mathbf{e} for the generalized section deformations is introduced

$$\mathbf{e} = [\epsilon_0 \quad \kappa_z \quad \gamma_y \quad \kappa_x \quad \kappa_y \quad \gamma_z]^T \quad (11)$$

where ϵ_0 is the axial strain, κ_z and κ_y the two curvatures and γ_y and γ_z the shear strains. According to equation (10), the warping displacement contributes to the axial strain and to the shear strain. This fact is critical in the description of the effect of boundary conditions and the additional stresses due to warping constraints.

2.2 Variational principle

The element formulation is based on the Hu-Washizu variational principle [7]. The potential function of displacements \mathbf{u} and \mathbf{u}^w , section deformations \mathbf{e} and stresses $\boldsymbol{\sigma}$ is defined over the element volume V by

$$\Pi(\mathbf{u}, \mathbf{u}^w, \mathbf{e}, \boldsymbol{\sigma}) = \int_V \boldsymbol{\sigma}^T (\mathbf{a}_s \mathbf{e}(\mathbf{u}) - \mathbf{a}_s \mathbf{e}) dV + \int_V W(\mathbf{e}, \mathbf{u}^w) dV + \Pi_{ext}(\mathbf{u}_{IJ}, \mathbf{u}_{IJ}^w) \quad (12)$$

where W is the internal potential energy. In the form of (12), the element formulation is mixed: the warping strain is derived from the warping displacements, while the section deformations

are imposed in weak form.

The external load is defined by

$$\Pi_{ext} = -\mathbf{u}_{IJ}^T \bar{\mathbf{p}} - \mathbf{u}_{IJ}^{wT} \bar{\mathbf{p}}^w \quad (13)$$

The forces $\bar{\mathbf{p}}$ and $\bar{\mathbf{p}}^w$ are the applied forces at the end nodes of the element. If the end sections are free to warp, the applied warping force is $\bar{\mathbf{p}}^w = \mathbf{0}$. Otherwise, warping displacements \mathbf{u}_{IJ}^w are imposed. The case of element loading is not included for the sake of simplicity.

The variation of potential Π leads to the definition of the associative section forces by integration over the cross-section area A :

$$\mathbf{s} = \int_A \mathbf{a}_s^T \boldsymbol{\sigma} dA, \quad s_x^{wj} = \int_A N_j \sigma_{xx} dA, \quad s_{yz}^{wj} = \int_A \frac{\partial N_j}{\partial y} \sigma_{xy} + \frac{\partial N_j}{\partial z} \sigma_{xz} dA \quad (14)$$

By minimization of the potential Π , we obtain a set of equations:

$$\bar{\mathbf{p}} = \mathbf{a}_g \mathbf{q} \quad (15)$$

$$\mathbf{s}_i = \mathbf{b}(x_i) \mathbf{q} \quad (16)$$

$$\mathbf{v} = \int_0^L \mathbf{b}^T \mathbf{e} dx \quad (17)$$

$$\boldsymbol{\sigma} = \frac{\partial W}{\partial \boldsymbol{\epsilon}} \quad (18)$$

$$p_i^{wj} = \int_0^L \frac{\partial M_i}{\partial x} s_x^{wj} dx + \int_0^L M_i s_{yz}^{wj} dx \quad (19)$$

where \mathbf{b} is a linear interpolation matrix given by

$$\mathbf{b}(x) = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & x/L & 1-x/L & 0 & 0 & 0 \\ 0 & 1/L & 1/L & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & x/L & 1-x/L \\ 0 & 0 & 0 & 0 & 1/L & 1/L \end{bmatrix} \quad (20)$$

The first four equations correspond to the mixed formulation equations for the beam: the equilibrium equations (15-16), the compatibility equation (17) and the constitutive law (18). The additional equations (19) correspond to the equilibrium conditions that need to be satisfied by the warping section forces s_x^w and s_{yz}^w . These equilibrium equations are imposed at each section x_i with warping displacements $\mathbf{u}^w(x_i, \cdot, \cdot)$ as the unknowns (5). The section deformations and the warping displacements are determined during the element state determination by satisfying the equilibrium and compatibility equations.

The tangent stiffness associated with the set of equations (15-19) ensures optimal convergence of the element state determination algorithm.

2.3 Interpolations

The section warping is described by warping parameters denoted with \mathbf{u}_{ij}^w . The warping is then described over the section with the functions $N_j(y, z)$ in equation (5). With Lagrange polynomials for the functions N_j the warping parameters \mathbf{u}_{ij}^w can be interpreted as local warping

values. This approach differs from the fixed strain distribution assumed in earlier studies [10]. The enforcement of the warping equilibrium equations results in an accurate strain distribution. This formulation can be applied to any section geometry and does not require a shear correction factor, as is the case with earlier studies [10] and [9]. To reduce the number of warping parameters, advantage can be taken of the geometric characteristics of the section, such as symmetry and double-symmetry, in the choice of interpolation functions $N_j(y, z)$, as proposed in the report by Setec-Tpi [6].

The determination of the warping distribution over the element length is accomplished with the interpolation functions $M(x)$. For constrained warping, the choice of interpolation functions is critical. Under linear elastic response, the analytical solution consists of an exponential distribution of warping displacements along the element axis. Among the different choices for interpolation functions M are exponential functions, Lagrange polynomials, and quadratic spline functions. In the examples of the following section Lagrange polynomials are used.

3 EXAMPLES

The examples presented below demonstrate the capabilities of the enhanced 3d element. The element is tested on two shear links. Its response is compared to the response of the beam element by A.Saritas[10], which is extended to 3d with the assumption of a fixed shear strain distribution. The link response is also compared with the response of a model consisting of MITC shell elements [2]. The nonlinear material response of structural steel is described with the J2 plasticity model. The studies compare the global force-displacement response as well as the local stress distributions with focus on the axial stress σ_{xx} associated with the warping constraints.

The test configuration for the two shear links is shown in figure 2. Warping is assumed to be constrained at both ends. To demonstrate the coupling between shear and torsion, the element is allowed to twist at one end when the shear force is applied with an eccentricity. The shear link is modeled with one 3d beam element with 5 Gauss-Lobatto integration points along its axis.

Figure 2: Shear Link Configuration

3.1 Example 1

The cross-section of the shear link is shown in figure 3. The length of the shear link is $L = 456$ mm. This example is part of the experimental campaign by Berman and Bruneau [3]. The analysis with beam elements is compared with the experimental results and the results with a shell model by limiting attention to the first three load cycles. The enhanced 3d beam element uses $n_w = 12$ parameters in each section to describe the section warping. Figure 4 shows that the response of the three models is very close in terms of the shear reaction force for an imposed vertical displacement (or shear link rotation) and agrees very well with experimental measurements.

The local stress results are plotted for a link rotation $\gamma = U/L = 0.006$ in the transition to

Figure 3: Cross section properties

Figure 4: Shear link rotation vs. Shear Force

the plastic range. The figures 5 and 6 present the shear stresses of the middle section of the element, where warping is free. The results confirm that the enhanced 3d beam reproduces the shear stress distribution postulated by the fixed shear strain assumption of A. Saritas [10]. The distribution of the shear stresses σ_{xz} in the upper flange is also represented accurately.

The shear lag effect takes place at the boundary of the beam and at the load application points. At this boundary section, the warping constraint creates additional axial stresses. The comparison of the axial stresses in the web and in the flange is presented in figures 7 and 8. The enhanced 3d beam element gives a correct estimation of the maximum axial stress in the web, which is 30% higher than the value predicted by the beam with a fixed shear strain distribution.

Figure 5: Shear stresses in the left web

Figure 6: Shear stresses in the lower flange

Figure 7: Axial stresses in the web

Figure 8: Axial stresses in the lower flange

3.2 Example 2

The dimensions of the I cross-section of the shear link are presented in figure 9. The length of the shear link is $L = 28\text{in}$. The steel material is described by a generalized J2 plasticity Model, as presented in [10].

A shear force is applied on the shear link. To model the effect of torsion, the force is applied with an eccentricity of $e_c = 2$ in from the centroid to create a torsional moment proportional to the shear force. The enhanced 3d beam describes the section warping with $n_w = 28$ parameters. The figures 10 and 11 present the force-displacement response of the shear link: the shear force is plotted against the vertical displacement and the torsion force against the angle of twist ϕ . The enhanced beam model is able to represent with accuracy the lateral and torsional stiffness as well as the yielding force. In comparison, the beam with a fixed shear strain distribution cannot represent the exact elastic torsional stiffness, since warping is not taken into account. The interaction between shear and torsion is demonstrated in 10.

In addition to the global response, the proposed element describes with accuracy the local

$$d=17.88\text{in}$$

$$b_f=5.985\text{ in}$$

$$t_f=0.521\text{ in}, t_w=0.314\text{ in}$$

Material Properties

for the web $E_W = 28300\text{ksi}$, $\nu=0.3$
 $f_{yW} = 39.5\text{ksi}$ $f_{uW} = 60.1\text{ksi}$
for the flange $E_F = 28000\text{ksi}$, $\nu=0.3$
 $f_{yF} = 35\text{ksi}$ $f_{uF} = 58.5\text{ksi}$

response in the plastic range. For a shear force of 88.5 kips, the axial stresses at the boundary section are plotted for the web 12 and the lower flange 13 respectively.

4 CONCLUSIONS

The paper presents a 3d enhanced fiber beam element formulation that includes warping degrees of freedom so as to represent the effect of shear and torsion. No shear correction factor is required with the shear strain distribution determined directly from the section warping. The element is capable of representing accurately the local response of beams under different constraints for which a shell element is usually required. It is also capable of describing accurately the shear lag effect at a significantly lower computational cost than a shell model.

A few examples demonstrate the capabilities of the element for simulating inelastic response of steel structures under flexure, shear and torsion. Studies are under way to extend the element formulation to reinforced concrete frames, for which existing studies demonstrate the importance of shear modeling [8]. Further studies to optimize the element performance for earthquake engineering applications by reducing the number of warping degrees of freedom are under way.

Abstract. *Distributed inelasticity force-based elements, widely used in earthquake engineering modeling, lose objectivity at local and global level of response in the softening range of sectional behaviour. This motivated many researchers in the past to propose various regularization techniques to trace a physically meaningful post-peak curve. However, elements that give regularized response under softening behaviour are too flexible to be used for the hardening branch.*

The present work presents a new adaptive force-based plane element that overcomes the aforementioned limitations. As the name suggests, the element is capable of providing solutions for both hardening and softening response by automatically adjusting the element integration weights when a section undergoes into softening. The latter are computed with theoretically derived closed-form expressions from interpolatory quadrature. The ‘adaptive’ nature of the integration scheme renders it numerically very efficient. Furthermore, the proposed element can directly account for the value of axial force installed on the element in the estimation of the corresponding length of plastification, thus creating a physically sound regularization scheme.

The performance of the proposed adaptive element is first evaluated by comparing its results with those obtained by the standard numerical integration scheme under otherwise similar conditions. It is found that for both monotonic and cyclic response the adaptive model gives good matching at a little computational effort. Moreover, the results from the current model compare well against experimental data, both in the hardening and softening ranges of behaviour.

1 INTRODUCTION

In quasibrittle materials like concrete and rock relatively large fracture zones can occur resulting from progressive growth and coalescence of microcracks, which are usually described by softening laws. Softening behaviour of constitutive law, in general, refers to the descending branch of stress with increasing strain in the stress-strain curve. In continuum mechanics, softening behaviour poses complex mathematical difficulties as the problem becomes ill-posed and the finite element (FE) results become mesh size-dependent – a phenomenon called localization. Localization precludes achieving convergence by refining the mesh size (objectivity). The present study focuses on reinforced concrete (RC) beam elements, which also exhibit similar type of numerical difficulties.

Irrespective of the type of beam formulation, force-based (FB) or displacement-based (DB), the objectivity in response is sought by adopting pre-defined characteristic mesh size within the softening zone, which is widely known as regularization. The vast majority of regularization techniques that can be found in literature for continuum finite elements – of which are particularly relevant those based on integral non-local procedures [1, 2] and gradient models [3] – are generally applied with DB FE formulations. The first proposal applicable to FB fibre-section models was based on ensuring a constant fracture energy release [4]. However, it requires a laborious member-by-member modification of the uniaxial stress-strain relationship of each fibre based on the number of integration points (IPs) and the knowledge of the compressive fracture energy, which may not be easily available. Further, the global force-displacement response needs to be post-processed, using the physical characteristic length, to warrant an objective prediction of the curvature demand in the localized damage zone. On the other hand, the more straightforward regularization proposals by Scott and Fenves [5] and Addessi and Ciampi [6] are likely to produce too flexible solutions for the simulation of the hardening phase of behaviour.

Scott and Hamutcuoglu [7] recently proposed a numerically consistent regularization method that is able to accurately model both hardening and softening ranges of sectional behaviour. This is achieved by adding two additional IPs very close to the element ends, their weights being selected to ensure convergence for both types of sectional behaviours. However, the order of accuracy of their scheme is only of $N - 5$, N being the total number of IPs (including those close to the extremities), which means that for the solution of linear-elastic frame elements at least seven IPs should always be used. Additionally, the element performance is highly sensitive to the position of the two extra IPs.

The present study proposes a novel beam element featuring an adaptive integration method that has the ability of continuously controlling the IP weights, while preserving their positions, in order to maximize accuracy for strain-hardening sectional behaviour and maintain objectivity for strain-softening response. The central idea of the formulation is presented and several numerical verification examples are shown along with pertinent discussion.

2 PROPOSED REGULARIZATION TECHNIQUE

In FB elements, in order to control the beam end sections subjected to larger bending moments, Gauss-Lobatto (GL) quadrature (that includes IPs in the extremities of the integration interval) is commonly used. It has a high order of accuracy of degree $2N - 3$, where N is the number of IPs. On the other hand, the typical regularized integration schemes, restrained by the imposition of some pre-defined weights, have less order of accuracy.

The main idea of the present proposal is to allow the commutation, automatically during the loading history, between different numerical integration schemes in order to ensure high accuracy during hardening and also objective solution during softening response.

In order to monitor the history of section forces and deformations during the analysis, IP positions should not be varied and, consequently, only the corresponding weights are adaptively adjusted. Additionally, in order to pass a patch test, the element has to provide at least the linear-elastic solution; i.e. 2nd degree polynomials need to be integrated exactly.

In the present study, the IP positions considered are same as those of the GL integration scheme. Consequently, throughout the hardening branches, the weights of the several IPs are also defined as those of the standard GL quadrature. The full hardening case is denoted as case (a), for future reference. Whenever a section is softening, the associated integration weight of that section is adjusted to match the appropriate normalized characteristic length. Further, it is assumed that softening can only occur in one or both extremity sections. Once the element starts to soften, the integration weights of the several IPs are recomputed under the condition that the extreme integration weights match λ_{pI} or/and λ_{pJ} (respectively the normalized characteristic lengths of the initial and final sections). In the earthquake engineering modelling context, the characteristic length of a certain IP, L_p , can be assumed to be equal to the plastic hinge length (this term is adopted in the current manuscript, although the correct expression would be ‘length of plastification’). The corresponding integration weight λ_p (i.e. the normalized characteristic length) can thus be computed as $(b - a) L_p / L_0$, where L_0 is the length of the element. In case of softening, one of the following three cases is bound to happen (typically, cases (b) or (c) will occur first, then (d) will follow for larger inelastic demands):

- Case (b): Softening of the initial IP. In this case, the integration weight of the initial IP matches the normalized characteristic length λ_{pI} ($w_1^* = \lambda_{pI}$). The computation of the integration weights of the remaining IPs can be achieved through interpolatory quadrature [8, 9], the goal of which is to select the weights $w_2^*, w_3^*, \dots, w_N^*$ such that the error

$$E(f) = \int_a^b f(x) dx - \sum_{j=1}^N w_j^* f(x_j) \Big|_{w_1^* = \lambda_{pI}} = \int_a^b f(x) dx - \lambda_{pI} f(x_1) - \sum_{j=2}^N w_j^* f(x_j) \quad (1)$$

is zero for $f(x) = 1, x, \dots, x^{N-2}$. It is noted that a general integration interval $[a, b]$ was used. Considering the positions of the GL integration scheme, the following linear system of $N - 1$ equations and $N - 1$ unknown weights $w_2^*, w_3^*, \dots, w_N^*$ is obtained:

$$\begin{aligned} \lambda_{pI} + w_2^* + w_3^* + \dots + w_N^* &= \int_a^b dx \\ \lambda_{pI}a + w_2^*x_2 + w_3^*x_3 + \dots + w_N^*b &= \int_a^b x dx \\ &\vdots \\ \lambda_{pI}a^{N-2} + w_2^*x_2^{N-2} + w_3^*x_3^{N-2} + \dots + w_N^*b^{N-2} &= \int_a^b x^{N-2} dx \end{aligned} \quad (2)$$

or, equivalently:

$$\begin{bmatrix} 1 & 1 & \dots & 1 \\ x_2 & x_3 & \dots & b \\ \vdots & \vdots & & \vdots \\ x_2^{N-2} & x_3^{N-2} & \dots & b^{N-2} \end{bmatrix} \begin{bmatrix} w_2^* \\ w_3^* \\ \vdots \\ w_N^* \end{bmatrix} = \begin{bmatrix} b-a-\lambda_{pI} \\ (b^2-a^2)/2-\lambda_{pI}a \\ \vdots \\ (b^{N-1}-a^{N-1})/(N-1)-\lambda_{pI}a^{N-2} \end{bmatrix} \quad (3)$$

- Case (c): Softening of the final IP. In this case, the integration weight of the final IP matches the normalized characteristic length λ_{pJ} ($w_N^{**} = \lambda_{pJ}$). An analogous rationale to case (b) can be applied and the unknown weights $w_1^{**}, w_2^{**}, \dots, w_{N-1}^{**}$ obtained through the next system of equations:

$$\begin{bmatrix} 1 & 1 & \dots & 1 \\ a & x_2 & \dots & x_{N-1} \\ \vdots & \vdots & & \vdots \\ a^{N-2} & x_2^{N-2} & \dots & x_{N-1}^{N-2} \end{bmatrix} \begin{bmatrix} w_1^{**} \\ w_2^{**} \\ \vdots \\ w_{N-1}^{**} \end{bmatrix} = \begin{bmatrix} b-a-\lambda_{pJ} \\ (b^2-a^2)/2-\lambda_{pJ}b \\ \vdots \\ (b^{N-1}-a^{N-1})/(N-1)-\lambda_{pJ}b^{N-2} \end{bmatrix} \quad (4)$$

- Case (d): Softening of both end IPs. The numerical weights of the initial and final end IPs should match λ_{pI} and λ_{pJ} ($w_1^{***} = \lambda_{pI}$ and $w_N^{***} = \lambda_{pJ}$) respectively. Again, interpolatory quadrature can be used to compute the intermediate integration weights:

$$\begin{bmatrix} 1 & 1 & \dots & 1 \\ x_2 & x_3 & \dots & x_{N-1} \\ \vdots & \vdots & & \vdots \\ x_2^{N-3} & x_3^{N-3} & \dots & x_{N-1}^{N-3} \end{bmatrix} \begin{bmatrix} w_2^{***} \\ w_3^{***} \\ \vdots \\ w_{N-1}^{***} \end{bmatrix} = \begin{bmatrix} b-a-\lambda_{pI}-\lambda_{pJ} \\ (b^2-a^2)/2-a\lambda_{pI}-b\lambda_{pJ} \\ \vdots \\ (b^{N-2}-a^{N-2})/(N-2)-a^{N-3}\lambda_{pI}-b^{N-3}\lambda_{pJ} \end{bmatrix} \quad (5)$$

The order of accuracy for cases (b) and (c) is of $N-2$, while for case (d) is of $N-3$. This implies that the minimum number of integration points to be used in the present adaptive element is five, which matches the approximate minimum number of IPs for objective strain-hardening response. It is recalled that the integration weights are used for the numerical integration required to compute the vector of basic displacements and the tangent flexibility matrix of the element.

The calculation of the IP weights for cases (b), (c) and (d) has to be performed continuously throughout the softening branch(es) if the characteristic length depends on the sectional force. This is however an inexpensive operation from the numerical viewpoint, since closed-form solutions can be easily derived. For example, the closed-form solution for 5 IPs and cases (b), (c) and (d) (taking $a = -1$ and $b = 1$) is, respectively:

$$\begin{bmatrix} w_2^* \\ w_3^* \\ w_4^* \\ w_5^* \end{bmatrix} = \begin{bmatrix} \frac{7}{9} - \frac{7}{3}\lambda_{pI} \\ \frac{4}{9} + \frac{8}{3}\lambda_{pI} \\ \frac{7}{9} - \frac{7}{3}\lambda_{pI} \\ \lambda_{pI} \end{bmatrix}, \quad \begin{bmatrix} w_1^{**} \\ w_2^{**} \\ w_3^{**} \\ w_4^{**} \end{bmatrix} = \begin{bmatrix} \lambda_{pJ} \\ \frac{7}{9} - \frac{7}{3}\lambda_{pJ} \\ \frac{4}{9} + \frac{8}{3}\lambda_{pJ} \\ \frac{7}{9} - \frac{7}{3}\lambda_{pJ} \end{bmatrix}, \quad \begin{bmatrix} w_2^{***} \\ w_3^{***} \\ w_4^{***} \end{bmatrix} = \begin{bmatrix} \frac{7}{9} - \frac{\sqrt{21}}{6}(\lambda_{pI} - \lambda_{pJ}) - \frac{7}{6}(\lambda_{pI} + \lambda_{pJ}) \\ \frac{4}{3}\left(\frac{1}{3} + \lambda_{pI} + \lambda_{pJ}\right) \\ \frac{7}{9} + \frac{\sqrt{21}}{6}(\lambda_{pI} - \lambda_{pJ}) - \frac{7}{6}(\lambda_{pI} + \lambda_{pJ}) \end{bmatrix} \quad (6)$$

Figure 1 schematically describes the representation of a computed distribution of integration weights for the previous cases, considering arbitrary values of λ_{pI} and λ_{pJ} . It should be mentioned that the success of the current adaptive element is dependent on the correct identification of the sectional behaviour (hardening or softening). The description of the technique developed for such purpose, and implemented in an *ad hoc* computer code, as well as the associated state determination algorithm, falls out of the scope of this document. Nevertheless, the interested reader can find it in Almeida *et al.* [10]. Finally, it is noted that linear geometry is assumed.

3 NUMERICAL EXAMPLES

3.1 Laterally loaded cantilever

The performance of the proposed adaptive element is first demonstrated with the help of an idealized multi-linear moment-curvature relationship with initial post-yield hardening followed by a softening branch. Figure 2 shows the normalized moment-curvature relationship, where moment and curvatures are normalized by the ultimate moment (M_u) and the corresponding curvature (χ_u) respectively. Elastic unloading behaviour is considered. Furthermore, it is assumed that the softening branch will continue with the same slope for a higher demand of normalized curvature beyond two.

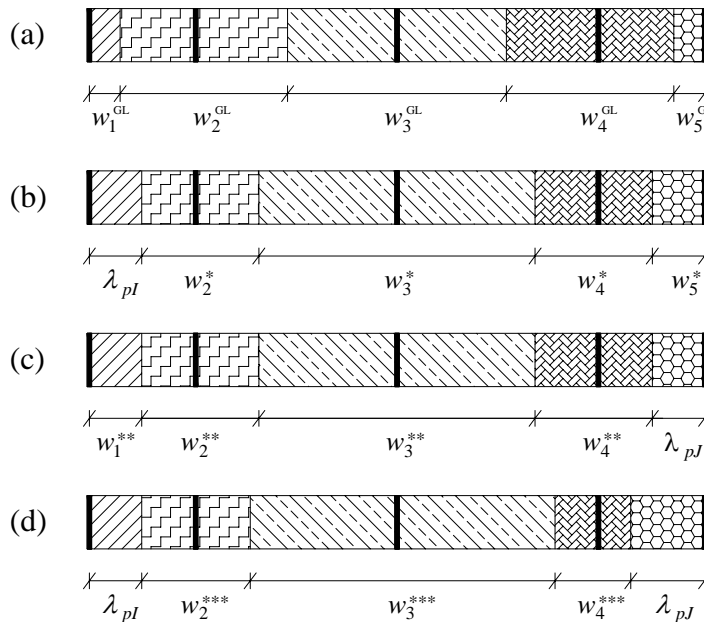

Figure 1: Illustrative example of weight computation: (a) Gauss-Lobatto; (b) softening of initial section; (c) softening of final section; (d) softening of both end sections.

Figure 2: Idealized normalized multi-linear moment-curvature relationship.

Figure 3 shows the top lateral force, normalized by its ultimate value, versus top lateral drift (Δ) ratio of a cantilever column (modelled by a single element). Results for standard GL and for the new adaptive integration schemes with different numbers of IPs are compared. The characteristic length L_p is arbitrarily assumed to be $0.15L$, where L is the shear span associated to the bottom critical section (in the present case it corresponds to the full element length L_0).

Figure 3: Normalized top lateral force versus top lateral drift ratio of the cantilever column in the cases of standard GL and adaptive schemes, for different number of IPs.

It can be observed, as expected, that during the hardening phase of response the new adaptive and the standard GL schemes yield identical results for the same number of IPs because there is a continuous correspondence between the integration weights employed. The difference in responses during the hardening phase is due to the number of IP-dependent spreading of inelasticity within the element, which is however objective. This is also the reason why the peak lateral loads correspond to different values of lateral drift for five and seven IPs. However, for the softening branch, a clear non-objective response is apparent for the standard GL scheme with different number of IPs, while the adaptive scheme produces an objective output.

Figure 4 shows the distribution of curvature at the end of the loading phase along the normalized length of the element. It is clear from the figure that for standard GL scheme the curvature demand at the initial section increases with increasing number of IPs because, during the softening branch, spreading of inelasticity is not possible. However, for the adaptive scheme the curvature demand is objective because it uses regularized integration weight for the initial section.

The ability of the adaptive element to switch the integration weights from those of standard GL to those of interpolatory quadrature, by identifying the type of sectional behaviour, is shown in Figure 5. The variations of the weights for the initial section during the entire loading history and different numbers of IPs are shown for this purpose. It should be noted that the sum of all IP weights adds up to 2, i.e. in equation (1) it is assumed $a = -1$ and $b = 1$.

The previous numerical cases show the results when the column is loaded monotonically. It will also be interesting to see the behaviour under cyclic loading since this will imply a cyclic commutation between the integration weights of standard GL and interpolatory quadrature. Figure 6 shows the general cyclic behaviour of the multi-linear moment-curvature relationship, which has the same monotonic behaviour as that of Figure 2.

Figure 4: Normalized curvatures at the end of loading phase along the normalized length of the element, in the cases of GL and adaptive schemes for different number of IPs.

Figure 5: Variation of integration weight at the initial IP along normalized loading steps (N = total number of loading steps) in the case of adaptive element with different IPs.

Figure 6: Multi-linear cyclic moment-curvature rule for positive and negative initial elastic loadings.

Figure 7 depicts the normalized top lateral force versus top lateral drift ratio for different integration schemes, with five and seven IPs, under cyclic loading. The entire loading phase has three salient parts chronologically, viz., the loading phase (increasing drift ratio), the unloading phase (decreasing drift ratio) and the reloading phase (again increasing drift ratio). At the end of the loading phase the results are identical to the previous monotonic case. When the unloading starts, the sectional response becomes of the hardening type and thus the integration weights for the adaptive scheme change back to those of the standard GL. At the initiation of softening towards the end of the unloading phase they again commute to those of

the interpolatory quadrature, and so on. Consequently, the adaptive scheme yields an objective response for the entire cyclic load history. The commutation of integration weights for the initial section is shown in Figure 8. One thing to be noticed in Figure 7 is that the softening for standard GL with seven IPs is less pronounced in the unloading phase and also the final force level is much lower. This is due to the shift of localization from the extremity section to the adjacent one, a phenomenon that can happen during cyclic behaviour for elements with large number of IPs, and that was observed and explained by Almeida *et al.* [10].

Figure 7: Normalized top lateral force versus top lateral drift ratio for adaptive and standard GL schemes with five and seven IPs.

Figure 8: Variation of integration weights for the initial section during the entire load history in the cases of adaptive element with five and seven IPs.

The effects of such shift can be observed in Figure 9, which shows the curvature distributions along the normalized length of the element at the end of the cyclic loading phase. It is apparent that for GL with 7 IPs, unlike for the 5-IPs' GL case, there is a curvature reversal throughout the element length, which is attributable to the previous numerical occurrence.

3.2 Columns subjected to varying axial loads

The adaptive scheme's ability to continuously adjust the characteristic length can be best utilized by considering response-dependent characteristic length. This feature can be of relevance in real applications, e.g. columns located at the boundary of frame structures subjected to earthquake loading, where the axial load (due to global overturning moment) is expected to fluctuate. For this case-study, two cantilever columns of length L , viz. Column 1 and Column 2, are modelled by one element. A maximum lateral displacement (Δ) of $0.04L$ (4% drift) is imposed, as well as two different axial load ratios that vary during lateral displacement according to Figure 10. The axial load ratio, ρ_A , is defined as the ratio of the axial load to the ultimate axial load capacity of the section. From the figure it is clear that the gravity load and the maximum plus/minus variation correspond to ρ_A of 0.25.

The monotonic moment-curvature relationship with origin-oriented linear unloading, as shown in Figure 11, is adopted for the present case. An elastic constitutive law is assumed for the axial behaviour, which is uncoupled from the flexural response.

Since the characteristic length can depend on the level of axial force (e.g., [11]), a purely illustrative law is considered for the characteristic length. It is a function of ρ_A as:

$$L_p/L = \max[0.5\rho_A, 0.15] \quad (7)$$

where $\max[.]$ indicates the maximum of the two arguments.

Figure 9: Normalized curvatures at the end of cyclic loading phase along the normalized length of the element, in the cases of GL and adaptive schemes for different number of IPs

Figure 10: Variation of axial load ratio in Columns 1 and 2 with lateral drift.

Figure 11: Idealized moment-curvature relationship.

The responses of Column 1 and Column 2 for standard GL and adaptive integration schemes with five and seven IPs are shown in Figure 12. It can be noticed that, once again, the present adaptive element provides objective response for each column and different number of IPs. The difference between both columns depicts obviously the influence of the varying axial force in the computation of the applicable characteristic length, as given by equation (7). Figure 13 shows the evolution of the initial integration weight, for the case of 5 IPs, remaining clear that for Column 2 it is less than for Column 1, due to the lower axial load ratio. It should be mentioned that the integration weight for Column 2 during softening is governed

by the minimum criterion of $L_p = 0.15L$. On the other hand, the integration weight for Column 1 increases in proportion to the increasing axial load. The behaviour of the element with non-regularized GL scheme shows (see Figure 12) not only the typical localization phenomena associated to distinct number of IPs but also the expected insensitivity to the varying values of the axial force.

Figure 12: Responses of Column 1 and Column 2 at different levels of drift, for GL and adaptive integration schemes with different number of IPs.

Figure 13: Variation of integration weight at initial IP for adaptive element with five IPs.

3.3 Experimentally tested column

The previous numerical examples intend to highlight the theoretical aspects of the proposed adaptive numerical scheme. Its application to model reinforced concrete member behaviour is now briefly addressed.

The test specimen U-5 of Watson and Park [12] has been used for experimental verification. The equivalent cantilever length of the column specimen is 1.6 m, where the cross section is 400 by 400 mm. The uniaxial concrete properties are $f_{c0} = 41$ MPa, $f_{cc} = 53.3$ MPa, $\varepsilon_{c0} = 0.0027$ and $\varepsilon_{cc} = 0.00675$ and the yield stress for longitudinal steel is 474 MPa. The column is subjected to a constant axial force of 3280 kN (axial load ratio of 0.5).

The cantilever is modelled by a single FB element and the sectional response is given by a classical concrete/steel fibre discretization approach. The uniaxial laws considered for concrete and steel are due to Martinez-Rueda and Elnashai [13] and Menegotto and Pinto [14] respectively. For concrete in traction an exponential decay was used to account for tension-stiffening effects. Moreover, two different formulae for plastic hinge length, representative of the characteristic length, due to Paulay and Priestley [15] and Bae and Bayrak [11] have been considered.

Figure 14 shows the monotonic envelopes predicted by the standard GL scheme with five and seven IPs, by the adaptive scheme with five IPs and different formulae for the plastic hinge length, as well as the experimental cyclic curves. The lateral force that equates the moment due to P- Δ effect is added to the experimentally applied horizontal force at each step for comparison with numerical results. It is clear from the figure that the adaptive schemes predict the monotonic backbone curve quite accurately while those predicted by the standard GL scheme are not acceptable (in the softening range). It is recalled that in the case of standard GL scheme, a steeper softening slope is due to an unrealistic concentration of curvature demand at the base for a specified lateral displacement at the column top.

Figure 14: Comparison of experimental (cyclic) and numerical (monotonic) curves in the cases of standard GL and adaptive scheme (with different formulae of plastic hinge length), for different number of IPs.

The values of curvature demand along the length for the different cases are shown in Figure 15. For the GL scheme with five and seven IPs the curvature is unrealistically high (respectively around three and six times the objective value provided by the adaptive scheme). Figure 16 shows the moment-curvature demands for the adaptive scheme (with Bae and Bayrak's formula for plastic hinge length) and the standard GL scheme, with five IPs. Only the results corresponding to regular increments of the top node lateral displacement are depicted. As expected, it can be seen that the demands are identical up to the onset of softening, after which the rate of curvature increase is higher for the GL scheme than for the adaptive one.

Figure 15: Curvature distribution along the normalized column length at the end of the loading phase, in the cases of standard GL and adaptive scheme (with different formulae of plastic hinge length).

Figure 16: Comparison of monotonic curvature demands for Watson and Park's test specimen in the cases of standard GL and adaptive scheme (using Bae and Bayrak's formula for plastic hinge length) with 5 IPs.

4 CONCLUSIONS

A new load adaptive FB frame element was proposed, the integration scheme of which can automatically commute between the integration weights of standard GL and characteristic length-based interpolatory quadrature, depending on the type of sectional behavior (hardening or softening). This enables the element's integration scheme to maintain the high order of accuracy of the standard GL scheme during the hardening phase(s), while guaranteeing objective response during the softening part(s) of the response.

A number of numerical applications have been carried out to show the different features of the newly developed adaptive element and to emphasize its advantages over the standard GL integration scheme. It has been found that, although being computationally light, the proposed element can produce objective responses for distinct number of IPs. Additionally, this regularization technique also accounts directly for the axial load variation during softening response – an aspect that cannot be addressed by the currently existing regularization methods, based on pre-defined integration schemes. Finally, the current proposal was also verified against an experimental test, where it proved to yield accurate and realistic results.

Abstract. *This paper aims at identifying suitable approaches for the numerical modelling of stone masonry arch bridges with the purpose of estimating the traffic effects by means of moving loads and taking in account the surface roughness of the pavement. For this purpose two ancient stone masonry arch bridges located near Porto are addressed. The bridge numerical analyses are performed based on detailed finite element models. Suitable nonlinear constitutive models are considered for the joints elements, while the Drucker Prager model is adopted for the infill. The interaction between the wheel and the pavement is considered through a simplified methodology comprising three phases of analysis where the bridge and the vehicle are studied separately. The bridge response shows that the activation of the material nonlinear behaviour has significant influence on the bridge effects (increase), however comparing the results with irregularities and without less influence is shown.*

1 INTRODUCTION

The study presented in this paper is included within the analysis framework of Portuguese masonry arch bridges, particularly for the S. Lázaro bridge and the Lagoncinha bridge herein addressed, aiming at calibrating analysis procedures for this type of structures, specifically by considering different types of materials and strategies for traffic load modelling.

3D and 2D structural numerical models, including the contribution of the backfill and the spandrel walls, were adopted resorting to the computer code CAST3M [1], based on the finite element method. Nonlinear constitutive models were considered both for the joint elements of the masonry structure and for the infill material.

The study included in-situ and laboratory tests on material samples for parameterization and calibration of numerical models fully presented elsewhere [2]. Additionally, ambient vibration tests on the bridge and its numerical modelling allowed for the model calibration, supported also by material calibration tests according to the adopted types of numerical models.

2 GENERAL DESCRIPTION OF THE CASE STUDIES

The S. Lázaro Bridge crosses the Leça river in Alfena, Valongo (nearby Porto) and it is a granite stone masonry bridge supposedly built in the Middle Age [3]. The bridge is about 28m long with two different perfect arches, one with 7.5m span and a smaller one with 2.3m. The deck is about 3.3m wide and the pavement is made of granite slabs (see Figure 1). During the year 2008 the bridge was consolidated by cement grout injection in the backfill as well as by injecting and repointing the masonry joints with appropriate mortar.

Figure 1: S. Lázaro bridge.

The granite masonry arch bridge of Lagoncinha, Lousado (nearby Porto), is classified as a National Monument and its construction dates back to the medieval period [4]. The bridge with about 150 m long and 3.5 m wide consists of six arches, three full turn and the others slightly ogival, as shown in Figure 2.

Figure 2: Lagoncinha bridge.

3 CHARACTERIZATION OF THE BRIDGES NUMERICAL MODELS

3.1 FEM mesh

As aforementioned, the FEM modelling was made in the CAST3M [1] computer code considering the stone masonry blocks (arches, spandrel walls and pavement) discretized using solid finite elements individualized from the adjacent blocks by considering zero thickness joint elements at their interfaces (stone-to-stone joint type). The backfill material was also modelled with solid finite elements connected to zero thickness joint elements in the

interfaces between the infill and blocks of arches, spandrel walls and pavement; in this case, different characteristics were used for this infill-to-stone joint type.

The simulation of the bridges behaviour under the traffic loading was based on 2D and 3D models. The 3D modelling allowed simulating the structural behaviour in both bridge directions (longitudinal and transversal) whereas the 2D modelling aimed at representing the bridge behaviour in the longitudinal direction considering the arch zone under the backfill (central zone, along the bridge longitudinal axis).

3D and 2D finite element meshes of S. Lázaro bridge are illustrated in Figures 3 and 4. The Lagoncinha bridge 3D finite element model is shown in Figure 5.

Figure 3: 3D model of the S. Lázaro bridge. a) Solid and b) joint finite elements.

Figure 4: 2D model of the S. Lázaro bridge. Plane (2D) elements (gray) and joint elements (black).

Figure 5: 3D model of the Lagoncinha bridge.

The boundary conditions were set using rigid support to fix the displacements at the bridges base in contact with the riverbed. The horizontal displacements were blocked in the vertical boundary of the abutments.

3.2 Material properties and constitutive models

The S. Lázaro bridge study aimed at calibrating analysis procedures for this type of structures, particularly by considering different types of materials and strategies for traffic load modelling. In this context, three scenarios were considered for the structural materials' constitution in terms of the type of joints and backfill materials. For one of the scenarios (scenario 1), the analysis aimed at simulating the bridge behaviour after rehabilitation, thus considering the stone block interfaces with filling mortar and the backfill (supposedly) composed by the initially existent granular material and by the added material through cement grout injection. The second scenario (scenario 2) intended to approximate the bridge conditions before a recently made rehabilitation intervention considering the stone block interfaces without filling mortar and the backfill (supposedly) composed by granular material. As for the third scenario (scenario 3), it was intended to simulate the bridge behaviour considering the material constitution with degradation.

Since no specific laboratory tests were carried out for the S. Lázaro bridge materials, the definition of numerical model parameters, including the mechanical properties of the materials, was based on the results of the laboratory tests performed on samples of materials used in other granite stone masonry constructions also from the North of Portugal as found in LNEC [5] and Costa [2]. These parameters were however adjusted to reach a suitable agreement between the in-situ measured frequencies and vibration modes and those numerically calculated through linear modal analysis of the bridge; such values were also compared with other results of materials tests existing in the literature. Observations recorded from visual inspections carried out before and after intervention were also taken in account.

In accordance with the scenarios' definition, Table 1 lists the physical and mechanical parameters assigned to the solid and the joint elements for the three above mentioned scenarios, namely the unit weight (γ), elastic modulus (E) and Poisson ratio (ν) for the solid elements and normal and shear stiffness (k_n and k_s , respectively) for the joints.

Material	γ (kN/m ³)	E (GPa)	ν	Material	k_n (MPa/mm)	k_s (MPa/mm)
Scenario 1 (after rehabilitation)						
Stone blocks	26.0	35.0	0.20	Stone-to-stone joints	6.24	0.56
Infill	21.5	0.03	0.33	Stone-to-infill joints	6.24	0.56
Scenario 2 (before rehabilitation)						
Stone blocks	26.0	35.0	0.20	Stone-to-stone joints	7.20	0.56
Infill	21.5	0.03	0.33	Stone-to-infill joints	0.53	0.28
Scenario 3 (before rehabilitation with material degradation)						
Stone blocks	26.0	15.5	0.20	Stone-to-stone joints	6.24	0.56
Infill	18.0	0.003	0.33	Stone-to-infill joints	0.53	0.28

Table 1: Physical and elastic properties of the materials of the S. Lázaro bridge.

Parameters' definition of Lagoncinha bridge materials were based on results of laboratory tests on stone and infill samples collected from the bridge, as well on the observations recorded during visual inspections, then adjusted to obtain good agreement between the frequencies and vibration modes in-situ measured and numerically determined through linear modal analysis [6]. Table 2 include the material parameters assigned to the solid and joints elements of the Lagoncinha bridge model.

Note that in S. Lázaro bridge all masonry structural elements (arches, spandrels, pavement) were defined as a micro-mechanical material, while for the Lagoncinha bridge the spandrel walls and the infill were considered as a macro-element with homogeneous properties; therefore higher values of E and γ were assigned in this bridge zone.

Material	γ (kN/m ³)	E (GPa)	ν	Material	k_n (MPa/mm)	k_s (MPa/mm)
Stone blocks of the arches	25-35	26	0.2	Stone-to-stone joints	4.46-6.24	0.48-0.69
Infill and spandrel walls	0.4-6.5	18-21	0.2-0.33	Stone-to-infill joints	4.00-65.0	1.67-27.1

Table 2: Physical and elastic properties of the materials of the Lagoncinha bridge.

The solid elements simulating the blocks of the masonry structure of the both bridges were considered linear elastic with the parameters included in Table 1 and Table 2. For the infill material it was used the Drucker Prager model with dilatancy available in CAST3M [1] considering the elastic parameters also included in Table 1 and Table 2. The yield surface was defined in correspondence with the parameters measured by triaxial tests [2] on a granular type material used in the Vila Fria bridge [7] which exhibited values of 30° for the friction

angle, 13kPa for the cohesion and 6° for the dilatancy angle. Constitutive parameters assigned of the infill materials of the S. Lázaro and Lagoncinha bridges are shown in Table 3.

Material	ϕ (°)	c (kPa)	ψ (°)
<i>S. Lázaro bridge</i>			
Granular material with grout injections after rehabilitation (scenario 1)	33	50	33
Granular material before rehabilitation (scenario 2)	30	13	6
Granular material before rehabilitation with material degradation (scenario 3)	30	0	6
<i>Lagoncinha bridge</i>			
Granular material	35.5	9.4	6

Table 3: Constitutive parameters of the infill materials of the S. Lázaro and Lagoncinha bridges.

The joint element behaviour was modelled by a nonlinear Coulomb friction model without dilatancy called JOINT_SOFT_CY_T and implemented in the CAST3M package within the context of a previous work [2]. The values considered for the normal stiffness (k_n) and tangential stiffness (k_s) of the joint elements are also included in Table 1 and Table 2.

Regarding the hardening laws of the joint model, a perfect elastic-plastic law was defined in the shear direction because dry joints were considered for the S. Lázaro bridge scenarios 1 and 2 and for the Lagoncinha bridge. The shear strength is computed according to the yield surface defined by the slope $\tan\phi=0.72$ and no cohesion according to the behaviour recorded in laboratorial shear tests performed on samples of dry joints of the Vila Fria bridge [7]. In the normal direction the loading curve is defined by a constant stiffness k_n and bilinear curves were adopted for unloading/reloading laws according to the pattern observed also in cyclic compressive laboratory tests of stone-to-stone block joints.

Figure 6: JOINT_SOFT_CY_T model. a) Yield surface, b) shear and c) normal behaviour laws for dry joints.

For the S. Lázaro bridge scenario 3 (after rehabilitation) the parameter definition has also taken in account the experimental results observed in laboratory tests of mortared block joints. However, the behaviour of joints after repointing showed insignificant increase of cohesion and, therefore, elastic-plastic behaviour was considered also for these joints.

3.3 Dynamic Characteristics

Table 4 includes the values for the first five frequencies and the types of vibration modes calculated and experimentally identified for scenario 1 (after the rehabilitation). Concerning the experimental measurements, the frequency figures are given in terms of range of values, because modal identification was made using more than one method as reported elsewhere [2].

However, it is quite apparent that boundary values for each frequency are very close, thus supporting the validity of experimental findings.

The numerical dynamic characteristics were calculated through the detailed 3D model included in Figure 3.

The dynamic characteristics' results calculated for the scenario 2 (before the rehabilitation) model are also included in Table 4. These results were obtained by the simpler 2D finite element model (Figure 4), therefore not allowing computing transversal modes, but it is clear the frequency drop from scenarios 1 (after the rehabilitation) to 2 (before the rehabilitation).

Table 5 includes the dynamic characteristics' results in-situ measured and numerically calculated for the Lagoncinha bridge.

Identified Frequencies (Hz)	Numerical Frequencies (Hz)		Type of vibration mode
	Scenario 1	Scenario 2	
7.70 – 7.80	7.7	-	1 st mode (transversal)
10.47 – 10.60	11.7	-	2 nd mode (transversal)
12.70 – 12.96	12.9	8.3	3 rd mode (longitudinal)
14.20 – 14.47	14.1	-	4 th mode (transversal + torsion)
15.37 – 15.71	15.5	11.8	5 th mode (vertical)

Table 4: In-situ measured and numerically calculated dynamic characteristics of the S. Lázaro bridge.

Identified Frequencies (Hz)	Numerical Frequencies (Hz)		Type of vibration mode
	Scenario 1	Scenario 2	
3.81	3.92	-	1 st mode (transversal)
4.78	4.69	-	2 nd mode (transversal)
5.48	5.33	-	3 th mode (transversal)

Table 5: In-situ measured and numerically calculated dynamic characteristics of the Lagoncinha bridge.

4 MODELLING OF ROAD TRAFFIC MOVING LOADS

The loads transmitted by vehicles to a bridge consist of moving vertical loads corresponding to each vehicle axel. These loads should be considered as dynamic actions, since, on the one hand, the vehicle traffic with a specific speed on the bridge deck is likely to introduce potentially larger effects than those due to an equal intensity statically applied load (dynamic amplification effects) and, on the other hand, the pavement surface irregularities might trigger impacts on the deck which can further amplify the traffic dynamic effects.

One of the strategies for modelling vehicle loads in the dynamic behaviour of bridges consists on the application of a sequence of vertical concentrated forces. In this case, the vehicle mass is not involved in the numerical model. This load modelling simplification is valid when the vehicle mass is much lower than the total bridge mass and when the speed is not very high. These two conditions are generally met for stone masonry arch bridges but, when this is not the case, the vehicle load model has to be represented by a set of concentrated masses. This procedure implies the system mass updating at each time step of the analysis [8], which renders the numerical simulation more time consuming.

Within the analysis of S. Lázaro and Lagoncinha bridges, the first above mentioned strategy was adopted for studying the dynamic behaviour due to the moving loads. A set of vertical concentrated forces was therefore imposed including the effects of interaction between vehicle wheels and the bridge caused by the pavement surface irregularities and by the vehicle dynamic behaviour.

4.1.1. Bridge-vehicle interaction

The interaction between the wheel and the pavement is considered through a simplified methodology comprising three phases of analysis where the two systems (bridge

and vehicle) are studied separately. The first phase consist on the bridge numerical modelling to simulate the vehicle action through a series of concentrated loads applied on the pavement (phase 1). This phase allows evaluating the time history of pavement settlements in accordance with the moving load application points. In the subsequent phase (phase 2), the dynamic analysis of the vehicle is carried out to determine the influence of the pavement irregularities added-up with the previous pavement settlement on the vehicle dynamic behaviour. Therefore, new values of the moving loads are obtained in phase 2, corresponding to the forces (reactions) in the contact wheel/deck surface to be used in the subsequent bridge analysis. Finally, phase 3 consists on a recalculation of the bridge considering the moving load values amplified due to the dynamic behaviour of the vehicle, thereby involving both the interaction vehicles/bridge and the effect of pavement irregularities [9].

4.1.2. Irregularities of the pavement

The pavement irregularities of S. Lázaro and Lagoncinha bridges (see Figures 7a and 7b) were recorded along two parallel axes in the deck longitudinal direction by performing a scan with a laser profilograph installed in a commercial vehicle as illustrated in Figure 7c. The scan sampling interval was taken as 0.025m and the acquisition was made during the vehicle ride centred in the deck at an approximately constant speed of 20km/h. A low-pass filter was applied during the acquisition with cut-off frequency corresponding to a wavelength of 100m. The measured signals were corrected adopting usual procedures for such applications [9]. The obtained upstream irregularity profiles in the S. Lázaro and Lagoncinha bridges are shown in Figure 8a and b.

The characterization of the profile amplitude of irregularities in the pavement along the deck of the bridges allowed observing the presence of amplitudes with about 0.015m.

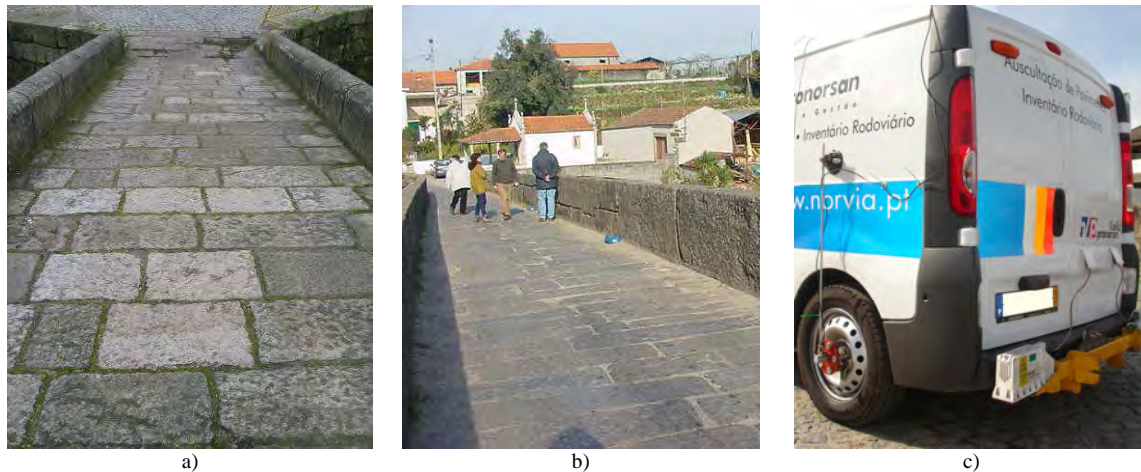

Figure 7: Pavement surface of a) S. Lázaro and b) Lagoncinha bridges. a) Equipment for measuring the irregularity profile.

Figure 8: Profile of in-situ irregularities of a) S. Lázaro and b) Lagoncinha bridges.

4.1.1. Vehicle model

The vehicle modelling was carried out resorting to the CAST3M computer software by using 3D bar elements to discretize the axles of the vehicle (tires and suspension) and the corresponding masses were concentrated in the respective nodes. Thus, the springs corresponding to the vehicle suspensions and the contact between wheels and pavement were replaced by beams with no mass and axial stiffness and damping in accordance with the characteristics of these elements and considering a negligible bending stiffness. The rigid body, composed by the tractor and trailer, was simulated by horizontal plan elements with distributed mass and inertia and high bending stiffness. The connection points between the vehicle body and the axles were simulated by vertical bars with negligible bending stiffness and large axial stiffness.

The dynamic characteristics of the vehicle numerical model correspond to global modes for the first three frequencies: the 1st and 2nd are longitudinal modes while the 3rd is a transverse one, with natural frequencies of 1.6, 2.5 and 3.3Hz, respectively. The remaining modes are local ones involving the vehicle axles with frequencies between 12.7 and 14.4Hz for the 4th and 10th modes, respectively.

Taking into account that higher dynamic effects tend to occur when there is coincidence between natural frequencies of the bridge and vehicles ([10] cited by [8]), Table 6 includes the comparison between the vehicle natural frequencies and the bridge frequencies associated with the first transverse and vertical modes determined by ambient vibration tests.

It is observed that frequencies relevant to the vehicles (between 1.6 and 3.2Hz, associated with vehicle body motions) are lower than those estimated for the natural frequencies of bridges associated with the transverse components of bridge movements.

The range of vehicle higher frequencies (between 12.6 and 14.4Hz, concerning the vibration modes related to vehicle axles motions) is closer to the range of bridge frequencies

relative to vertical modes, but the vehicle response has less energy content for this range of frequencies, which means that the higher energy content recorded in the vehicle response deviates from resonance with the bridge structure.

Mode type: 1 st long. 2 nd long. 1 st trans. 1 st vert. 7 th vert.					Mode type: 1 st trans. 1 st vert.			
4-axle truck	1.6	2.5	3.3	12.7	14.4	Lagoncinha bridge	3.9	11.3
						S. Lázaro bridge	7.7	15.5

Table 6: Frequency (Hz) and mode types of vehicles and masonry arch bridges

Considering the measured roughness distribution, the range of irregularities' wavelengths (λ) likely to contribute for the vehicle excitation in the frequency (f) interval from 1.6 to 14.4 Hz and assuming vehicle speed (v), between 12 and 90 km/h, corresponds to λ within 0.23m and 6.15m as obtained by the expression $\lambda = v / f$).

The observation of the spectral densities determined by Fast Fourier Transform (FFT) of the roughness profile showed that the largest amplitude of the spectra occurs in the range of wavelengths between 0.08m and 0.2m, thus shifted away from the range of wavelengths most significant for the vehicle excitation.

5 RESULTS ANALYSIS OF THE BRIDGES BEHAVIOUR UNDER THE ROAD TRAFFIC CONSIDERING DIFFERENT APPROACHES

5.1 Bridge behaviour under road traffic moving loads

In order to evaluate the result sensitivity of the bridge response to the vehicle speed, effects of irregularities and type of calculation considered in the bridge numerical simulation, particularly concerning static vs. dynamic and linear vs. nonlinear analysis, several analysis were performed to study the influence of moving loads on the bridges.

For the S. Lázaro bridge, in case I linear static analysis was performed in two phases (1 and 3) of the structural calculation. In case II, the dynamic behaviour was activated in both phases, but assuming a linear material. In cases III and IV the material nonlinear behaviour was taken into account, case III involving static calculations and case IV including also the activation of the dynamic behaviour. For each case, the following four speed values were considered: 13, 30, 60 and 90km/h.

For the Lagoncinha bridge in the first calculation phase (phase 1) dynamic analyses were carried out considering the linear velocities of 20, 30, 60 and 90km/h.

In the analyses including the roughness effects (phase 3) three calculation options were considered. One of the options held also linear dynamic analysis. In two cases, the nonlinear behaviour of materials was considered, in one case, performing nonlinear dynamic analysis and, on the other, non-linear static analysis. The speed of 90km/h was considered in the cases where the dynamic behaviour was activated in phase 3. The option for this speed value drive from the fact that a smaller number of steps is needed for the load history and, consequently, the required time for the 3D bridge analysis decreased.

In all cases the study of vehicle response (phase 2) was based on linear dynamic analysis.

Numerical integration of dynamic equations was made resorting to the Newmark scheme and the non-linearity was solved using the classical Newton-Raphson method.

Figure 9 shows the results in terms of the influence lines of the vertical displacement on the principal arch of the S. Lázaro bridge (at the node P1 for which the maximum arch vertical displacement was found). Dynamic linear and nonlinear analyses were performed in the two calculation phases (phase 1 - without irregularities and phase 3 - with irregularities) considering the 2D bridge model shown in Figure 4.

The influence lines show that the maximum arch displacement occurs considering the speed of 30km/h when the vehicle front axle is placed on the section at 22.6m (from the left abutment) which corresponds to a step after the first three axles of the vehicle had passed over the crown section.

Aggravation coefficients were evaluated between the results obtained in phase 1 (without irregularities) and in phase 3 (with irregularities) concerning the maximum displacement in arch 1 for 30km/h speed. Adopting the same analysis type in the two phases and considering the irregularity effects (phase 3), displacements are 1.6 to 6.7% larger than those obtained in the analysis without irregularity effects (phase 1). This aggravation trend observed in the arch occurs also in other bridge elements.

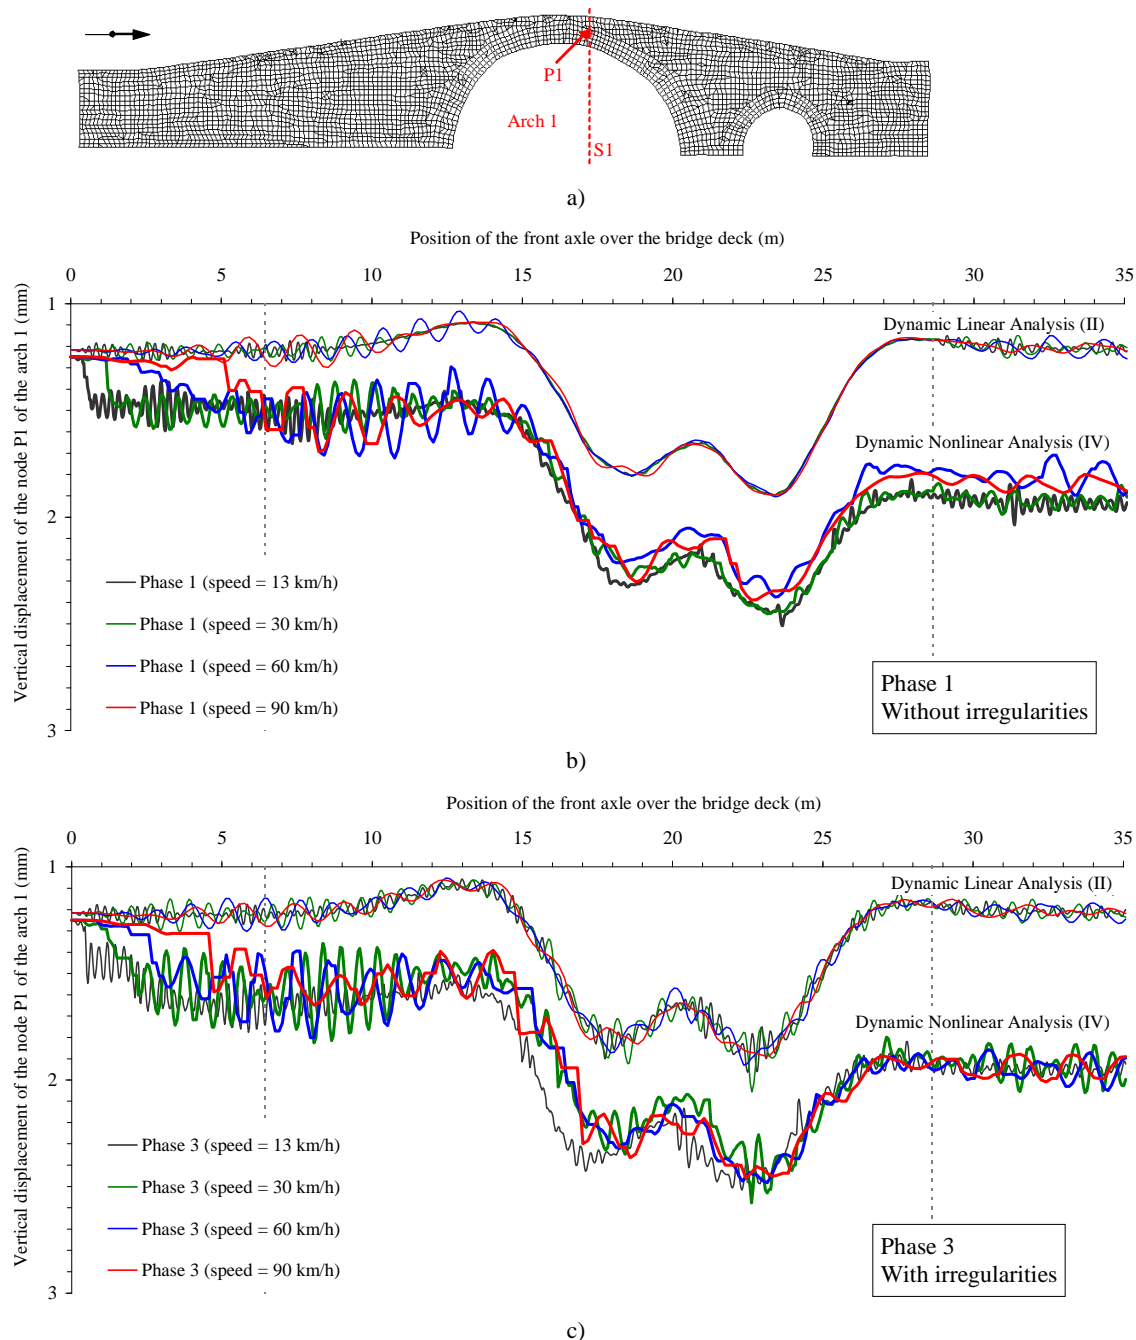

Figure 9: Influence lines of the vertical displacement at the node P1 at Arch 1 (a) for the speed of 13, 30, 60 and 90 km/h, results from cases II and IV of phase 1 (b) and phase 3 (c).

The maximum displacement of 2.6 mm was obtained in phase 3 (with irregularities) considering the analysis where the nonlinear behaviour of materials is activated in the two phases. Comparing the maximum displacement obtained in the nonlinear static analysis with the effects of irregularities (phase 3) and the displacement obtained in the linear static analysis without the effects of irregularities (phase 1) it was found an aggravation of about 37.4%.

The comparison of the influence line obtained from nonlinear dynamic analysis with that obtained from nonlinear static analysis shows that the displacement of node P1 is lower in the latter case only when loads are at the bridge entrance. By contrast, in the remaining path, the results are quite similar to those obtained considering dynamic behaviour, thus showing that the consideration of the dynamic calculation has little influence on the response of this bridge.

The results show also greater dynamic component in the vertical displacement of the node P1 when the moving loads are in the entry and exit zones of the bridge, rather than in the arch neighbourhood. Therefore, considering the position of the moving loads in relation to the node P1, it is concluded that the vibration recorded on the arch follows the vibration transmitted by the infill.

The study of the Lagoncinha bridge behaviour showed that the linear dynamic response of the bridge under the moving loads without including the irregularities in the pavement (phase 1) exhibits very low dynamic components, therefore, the maximum displacement of the arch (at the node P1 where the maximum displacement on that arch is found, see Figure 10) is almost independent of the speed. When the roughness profile is considered in the contact wheel-pavement (phase 3), oscillations appear in the influence line of the vertical displacement denoting the presence of more significant dynamic components, however the aggravation caused by adding the irregularities to the settlements' profile is not significant, increasing only by 2% the vertical displacement for 20 km/h speed (see Figure 10).

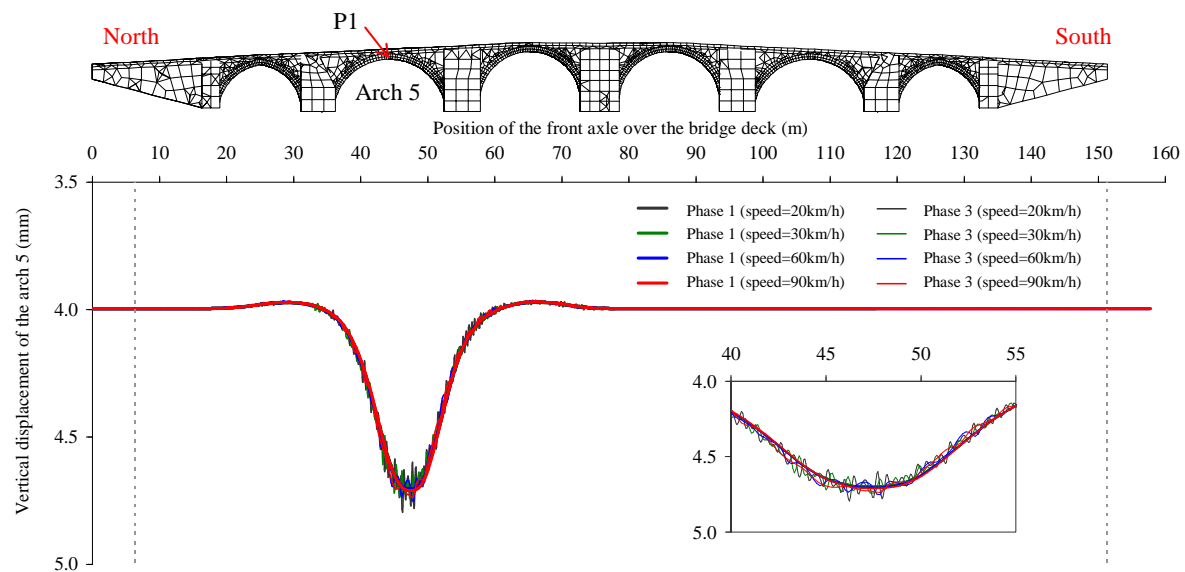

Figure 10: Influence lines of the vertical displacement. Linear dynamic response of the bridge for moving loads with and without the effect of irregularities (Phase 1 and phase 3, respectively).

In the case of nonlinear dynamic response for 90 km/h speed with irregularities, it was found that the value of the maximum vertical arch displacement (7.57 mm) increases about 60% when compared with the value (4.74 mm) obtained from linear dynamic calculation. Through the static nonlinear analysis it was found also that the maximum vertical displacement obtained (7.54 mm) is 0.4% lower than the maximum displacement resulting from the nonlinear dynamic calculation. As in the case study of S. Lázaro bridge, it is

observed that the consideration of material nonlinear behaviour produces a significant effect on the maximum displacement of the bridge main arch and less influence is found when the bridge dynamic behaviour is taken in account.

In order to evaluate the influence of the loading history on the response of the two bridges, the maximum vertical displacement of the arches obtained from the nonlinear dynamic calculation with irregularities $d_v^{dy\ nl}$ are compared in Table 7 with similar results obtained from a nonlinear static analysis $d_v^{est\ nl}$, but considering identical positions and values for the static loads. It is verified that the vertical displacement obtained considering the load history is 22% and 12% larger than that determined by static analysis of the S. Lázaro and Lagoncinha bridges, respectively, allowing to conclude that the entire history of loading is important to evaluate the structural response.

	$d_v^{est\ nl}$	$d_v^{dy\ nl}$
S. Lázaro bridge (arch 1)	2.11	2.58 (+22%)
Lagoncinha bridge (arch 5)	6.70	7.57 (+12%)

Table 7: Maximum vertical displacement of the arch (mm). Static load position vs. moving loading model.

5.2 Bridge behaviour under incremental static loads

Considering the vehicle at the most unfavourable load position for the arch identified previously from the analysis of the bridge considering the moving loading, this section focuses on the relevant aspects of the bridge response considering the nonlinear behaviour of joints and infill and intensity load levels (multipliers) of one and twice the nominal vehicle load.

The evolution of the response parameters in terms of maximum vertical displacement and principal stresses on the arch blocks, concerning the effect of the bridge weight and the intensity levels of the vehicle load of 1P and 2P, can be evaluated through the results included in Table 8. For these load levels, Table 8 includes the response parameters of the joints of the arch in terms of normal and shear stresses (maximum) and the corresponding maximum values of the normal and tangential deformations.

Comparing the results of 2D and 3D simulations, good agreement is observed in the longitudinal direction behaviour parameters. Given the effects of the dead load, it is verified that opening of transverse joints between the arch blocks does not occur. This also means that no incursions occur in the nonlinear range for the normal direction; since these joints have zero tensile strength, shear yielding is not triggered as well.

In the longitudinal joints of the arch (modelled only in 3D models) there were opening deformations. In the bridge transverse direction, that fact indicates the effect on the arch which induces impulses in the spandrels, leading to opening movements and decompression in the transverse direction. This aspect is not represented in 2D modelling and is not well reproduced in 3D linear calculation, because in the latter the stress transmission is kept even when separation occurs at the interfaces between the bridge elements. In the longitudinal arch joints, plastic components of the sliding joint deformation (shear yielding) are also observed.

The inclusion of the vehicle action shows that, in the arch transverse joints, normal opening deformations occur in tensioned areas but without forming a hinge mechanism, which is consistent with the smooth functioning of the arch in this scenario.

The existence of plastic deformations in the infill, only in a limited area under the loading in both 3D and 2D modelling, also adds to the confirmation of the smoothening effect of the infill.

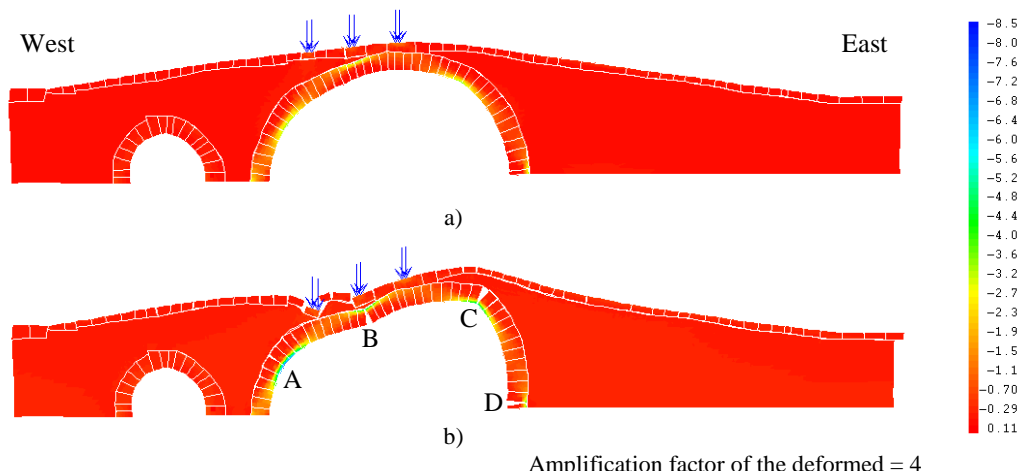

Loads	3D			2D			3D			2D

DL – Dead load; (t) Transversal joints; (l) Longitudinal joints; - joints not considered in the 2D model

Table 8: Principal stresses in blocks and joints (MPa) and maximum displacement (mm) and deformations in joints of arch 1. Results from 3D and 2D models.

Figure 11 shows the distributions minimum principal stresses of the blocks in the deformed configurations corresponding to dead load plus the vehicle loading (at level 2P) considering behaviour scenarios 2 and 3 as reported before. In these conditions, it is possible to identify the formation of a four hinge mechanism when the infill consists of a weak material (scenario 3). The joints where the hinges are formed are identified in the figures with the letters A, B, C and D.

For the scenario 2 the identification of the nodes in which no contact occurs allows recognizing the (potential) location of the hinges corresponding to one mechanism; in this case, the nodes with no contact between blocks are located in the intrados of the arch under the loaded zone and near the abutment of the arch, and in the extrados around the $\frac{1}{4}$ to $\frac{3}{4}$ of the span. It should be noted, however, that the bridge exhibits a high load capacity for the conditions considered in scenario 1. It is noteworthy that the bridge analysis was continued by increasing the loading intensity of the vehicle up to 10P, for which no hinge was formed.

Amplification factor of the deformed = 4

Figure 11: Minimum principal stresses (MPa) and deformed configurations of the bridge under dead loads and vehicle loading for level 2P. a) Scenario 2 e b) scenario 3.

Finally, Figure 12 shows the distributions of the vertical components of the plastic deformation in the infill; the corresponding values of the maximum and minimum plastic strains and total deformations in the infill are included in Table 9.

As evidenced by the values of Table 9b (scenario 3), plastic deformations take place in the infill, for the three load levels. Taking in account the distribution of the vertical components of the plastic deformation shown in Figure 12b, it is verified that such fact influences the interaction between the arch and the infill material. In the arch extrados zone, near the hinges A and C, the filling material yields and, consequently, deformations increase which allows arch joint opening in that zone.

Table 9: Total deformation and plastic deformations in the infill under dead loads and vehicle loading.
a) Scenario 2 e b) scenario 3.

Comparing the response of the bridge with weak infill material (scenario 1) with the bridge response in scenario 2 under identical conditions but with better filling material, it is observed that the presence of the infill material under better conditions restricts the formation of the hinge mechanism in the arch. By contrast, the infill plastic deformation in scenario 1, whose maximum and minimum values are included in the Table 9a and the corresponding distribution of the vertical components are illustrated in Figure 12a, shows that the infill material yielding occurs only in a very limited zone underneath the vehicle axles loading.

These facts explain the good behaviour of the bridge under the conditions considered in scenario 1, because the infill material prevents the formation of the hinges mechanism in the arch, restricting the joint opening in the arch extrados.

6 CONCLUSIONS

Throughout the previous sections some details were presented concerning the numerical simulation of a stone masonry arch bridge by finite element method modelling aiming at estimating the traffic effects due to moving loads and accounting for the pavement roughness.

In order to account for the interaction between the vehicle, the pavement roughness and the bridge, a simplified approach was followed comprising three distinct phases where the two systems (vehicle and bridge) were studied separately.

The bridge response shows that the activation of the material nonlinear behaviour has significant influence on the bridge effects (increase), however comparing the results with irregularities and without less influence is shown. The loading history produces also a significant effect on the maximum displacement of the main arch of the bridges (when comparing with the results from a static load position analysis).

The results show that the dynamic behaviour activation does not produce a significant effect on the maximum displacement of the main arch of the bridges. The study also allowed concluding that the dynamic effects are mainly due to the vehicle dynamic response, with negligible influence on the dynamic response of the bridge.

Keywords: Damage Detection, Finite Element Model, Modal Analysis, Model Updating Method.

Abstract. *Damage Detection in the structure is an active research area since decades. Number of the research studies has been done to meet this objective, particularly, the identification of the damage size and location. The finite element (FE) updating methods have also been used in the literature for the damage size and location identification. However, most of the studies are generally related to the beam type structures with the crack/damage. This concept has now been extended to the plate type structure with damage. Here again, the modal properties (natural frequencies and mode shapes) of the damaged plate have been used to estimate the damage size assuming the location of the damage was known. In the present study, the damage in the plate has been simulated in the FE model of the plate by the reduction in the plate thickness in the small portion of the plate and then the thickness of the plate has been chosen as the updating parameter. The Gradient Search based Sensitivity Model Updating method has then been applied to calculate the plate thickness for the damaged area from the FE model of the healthy plate (without damage). The proposed method has been examined on a simple simulated example of a steel plate. The paper presents the proposed method and the result from a simulated example.*

1 INTRODUCTION

Accurate condition assessment of engineering structures has become increasingly important. Current damage detection methods are either visual or localised experimental methods such as acoustic or ultrasonic methods, magnetic or thermal field methods, etc. [1]. All of these experimental techniques require that the vicinity of the damage is known a priori and that the portion of the structure being inspected is readily accessible. Furthermore, these tests are cumbersome and expensive. The need for quantitative global damage detection methods that can be applied to complex structures, has led to the development of methods that examine changes in vibration. Doebling et al. [2] give an extensive overview of vibration-based detection methods. The vibration characteristics of a structure are the function of its damping, stiffness and mass which in turn are a function of the condition of the structure. Among the various dynamic parameters which are used for damage detection, modal frequency and mode shape are the ones most commonly used. Salawu [3] presents a review on the use of modal frequency changes for damage diagnostics. It was later on confirmed that the modal frequencies are insensitive to the local condition of the structure and as such has limitations for damage isolation. In order to isolate the damage, mode shapes are necessary, which increase the data handling as well as increased instrumentation for accurate measurement. In order to overcome these shortcomings, several different parameters were studied, like the mode shape curvature [4-5], dynamically measured flexibility [6-7], damping [8-9] etc. All the monitored parameters have their set of advantages and disadvantages and the search of an elusive method which can overcome all the problems faced during damage detection is still on.

In recent years, sensitivity-based Finite Element (FE) model updating has been successfully used for damage assessment. In general, FE model updating aims at adjusting the dynamics of the mathematical model so that it becomes close to the experimental model. Many methods have been proposed for the updating of the mathematical model [10]. Some of the methods are direct while others are iterative. The direct methods compute a closed-form direct solution for the global stiffness and/or mass matrices using the structural equations of motion and the orthogonality equations. The changes made in the global matrix do not often make any physical sense. The iterative methods update the physical model variables like the Young's modulus, density, thickness, etc. by minimising the differences between the numerical and experimental vibration data. This gradient based sensitivity approach is an iterative process making use of updating variables to alter the stiffness matrix so as to achieve matching dynamics of the mathematical and the experimental models.

The present paper deal with determination of the extent of damage in plates using the gradient search sensitivity based approach when the location of damage is assumed to be known. The FE model of the plate was developed in the commercial FE code ABAQUS. The computed modal parameters have then been integrated with the computational code developed in the MatLab to calculate the sensitivity matrix and the updating parameter (plate thickness) by minimising the error in the penalty function by the iterative process till the problem converges to the required solution. The proposed method has been examined on a simple simulated example of a steel plate. The paper presents the proposed method, results from a simulated example and possible extension of proposed method to identify damage location as well as its size to meet the requirement of Level 3 in Damage Detection.

2 THEOROTICAL BACKGROUND

The error function at n th iteration is given by [10]

$$\boldsymbol{\varepsilon}_n = \boldsymbol{\delta z}_n - \mathbf{S}_n \boldsymbol{\delta \theta}_n \quad (1)$$

where, $\boldsymbol{\delta z}_n$ is the vectors of the eigen values error between the calculated experimental natural frequencies and corresponding computed natural frequencies from the FE model assuming only modes are used for this purpose.

\mathbf{S}_n is the sensitivity matrix which is the first derivative of the eigenvalues with respect to the updating parameters

$\boldsymbol{\delta \theta}_n$ is the change in the updating parameter at the n^{th} iteration.

The size of the sensitivity matrix depends on the number of updating parameters and number of modes used for this purpose. The penalty function (J) at the n^{th} iteration is given by

$$J(\boldsymbol{\delta \theta}) = \boldsymbol{\varepsilon}_n^T \mathbf{W} \boldsymbol{\varepsilon}_n \quad (2)$$

where \mathbf{W} is the positive diagonal weighing matrix. The vector of the updating parameters can be calculated by minimizing J with respect to $\boldsymbol{\delta \theta}$ which involves differentiating of J with respect to each element of $\boldsymbol{\delta \theta}$ and setting the result equal to 0. The solution obtained at each step is a weighted least square solution. Finally this leads to the following equation for the vector of updating parameters at each iteration.

$$\boldsymbol{\theta}_{n+1} = \boldsymbol{\theta}_n + (\mathbf{S}_n^T \mathbf{W} \mathbf{S}_n)^{-1} \mathbf{S}_n^T \mathbf{W} (\boldsymbol{\delta z}_n) \quad (3)$$

The iterative process will be carried out till the targeted accuracy is reached. The target accuracy determines the computational effort needed to be put in and the target should be optimal to ensure efficient computation. The elements of the sensitivity matrix can be computed as [10-12].

$$\mathbf{S}_{i,j} = \frac{\partial \lambda_{ci}}{\partial \theta_j} = \boldsymbol{\varphi}_i^T \left[\frac{\partial \mathbf{K}}{\partial \theta_j} - \lambda_{ci} \frac{\partial \mathbf{M}}{\partial \theta_j} \right] \boldsymbol{\varphi}_i \quad (4)$$

where, $\mathbf{S}_{i,j}$ is the element of the sensitivity matrix for the computed i th eigenvalue (λ_{ci}) w.r.to the j th updating parameter (θ_j). The system matrix, \mathbf{K} , \mathbf{M} are the stiffness and mass matrices respectively and $\boldsymbol{\varphi}_i$ is the normalized eigenvectors for the i th mode.

3 EXAMPLE

A test plate of 1.2×1.2 m and thickness of 1mm has been considered. The material of the plate was assumed to be steel with Young's Modulus 210GPa, Poisson's ratio 0.33 and density 7800kg/m³. For the simulated example, the plate is divided into 9 elements as shown in Figure 1(a) and all the 4 edges of the plate were assumed to be fixed supports. It has also been assumed that the Nodes 1 to 4 are measured location for vibration during modal testing using tri-axial accelerometers. Hence the measured degree of freedoms (DoFs) at each

measurement node is 3 (2 in plane and 1 out of plane). The thickness of the element 1 is assumed to be 0.8mm (20% less from the original thickness of 1mm) which represents the damage in the plate.

(a) Plate with 4 nodes for vibration measurement

(b) Damage in Element 1 assumed

Figure 1 Simulated example of a damage plate

An FE model of the simulated example of a damage plate shown in Figure 1 has also been constructed in the FE code ABAQUS which is shown in Figure 2. The FE model has then been used to calculate the natural frequencies and the mode shapes related to 12 DoFs at 4 measurement locations shown in Figure 1. The calculated natural frequencies are assumed as the experimental natural frequencies (Target data) which are listed in Table 1.

(a) Plate geometry in FE model

(b) FE mesh

Figure 2 An FE model of the plate shown in Figure 1

3.1. Damage Detection

Now it has been assumed that the damage location is known but the extent of the damage is unknown. Hence the flexural rigidity of the plate $\left(D = \frac{Et^3}{12(1-\nu^2)}\right)$ has been chosen as the updating parameter. It is because the flexural rigidity is nearly proportional to the plate stiffness matrix, \mathbf{K} . A computation program has also been written the MatLab code to calculate the sensitivity matrix using Equation (4) based on the calculated natural frequencies and the modeshapes (eigenvalues) at the measured 12 DoFs and then iterative process as per Equation (3). Initial guess of the damage is assumed to be 0.7mm to start the iteration. The first 6 modes are used for this iterative process. The natural frequencies for initial guess are also listed in Table 1. At the end of each iteration, the change in the updating parameter, dD , is converted to the change in the plate thickness, dt , as

$$dt = \sqrt[3]{\frac{12dD(1-\nu^2)}{E}} \quad (5)$$

The calculated new thickness of the plate is then used into the FE model to estimate natural frequencies and mode shapes for the next iteration. The process is continued still convergence. Table 1 list the updated thickness and natural frequencies with iteration and the

error at each mode with iterations in Table 2 and graphically in Figure 3 which confirms the success of the iterative technique proposed.

Table 1 Updating parameter and the natural frequencies with iterations

Iteration	1	2	3	4	5
Extent	0.8	0.7	0.73	0.75	0.77

4 CONCLUSION

The model updating method has been proposed to find the extent of damage in a plate type structure. The proposed method has been validated through a simple simulated example but it needs further validation through the experimental examples to enhance the confidence level in the proposed method. Currently just one updating parameter has been used but the proposed method can further be extended such that it can identify both location and size of damage in the plate.

Keywords: The analytic hierarchy process, unreinforced masonry building, seismic rehabilitation alternatives

Abstract. *Nowadays, distinctive methods are being used for evaluation of alternatives in making-decision. Among them the analytic hierarchy process (AHP) is one of the most efficient one. The study is set up for the low-rise unreinforced masonry buildings and includes classification of the most important parameters in strengthening of masonry buildings, and the factor analysis is performed to make the preferences of the alternatives. Due to the existence of the large number of unreinforced masonry buildings, and also the great importance of process duration for clients, the application of the AHP method in order to optimize the process and reach to the best alternative of the masonry buildings strengthening are developed. Effective parameters in evaluation of the alternatives are classified and suitable alternatives for rehabilitation are evaluated. Finally, based on the binary concept the model of binary approach decision-making (BADM) is utilized to analyze the decision parameters. Therefore, each criterion is simulated by question texts which appraiser faces two possible answers; yes and no. The results illustrate preference of the strengthening the masonry walls with interior shear wall, compared to the other alternatives. Also, effectiveness of the method is compared to the expert judgment.*

1 INTRODUCTION

Earthquake is an unpredictable phenomenon that the probability of the occurrence can be sensed at any moment. Hence, the study of suitable techniques in earthquake management will be influential in keeping the society safe and declining the losses of this mortal event. The consideration has shown that most of the masonry buildings are vulnerable so in recent years the seismic rehabilitation of the existing buildings has been gained more careful attention. The duration of the theoretical phase is a key point for the decision makers; that is, long process will cause severe economical losses for the clients. That the procedure evaluates the alternatives in the shortened time will decrease the further losses. In this area, different methods as a multi-criteria decision making methods (MCDM), have been used by the decision makers: such as analytic hierarchy process (AHP) a quantitative decision model by using pair-wise comparison, analytic network process (ANP) which is a general form of the AHP method but the elements are not independent and have interaction as a network, multi-attribute utility theory (MAUT) used to combine dissimilar measures of costs, risks, and benefits along with stakeholder preferences, cost-benefit analysis (CBA) a systematic quantitative method of assessing the desirability of government projects or policies, Kepner-Tregoe (K-T decision analysis) in which a team of experts numerically score criteria and alternatives based on individual judgment/assessment [1]. As a matter of the applicability, efficiency, and uniqueness, the analytic hierarchy process (AHP) is used to depict an operative procedure for the decision makers in the optimum alternative selection of the rehabilitation a vulnerable masonry building.

The method has been the subject of many researchers who have tried to optimize the selection process. Among them, the establishment measurement for intangible properties [3], the benefits, opportunities, costs, and risks of a decision [4], the application of the method in risk management [5], a novel approach of cotton fiber selection [6], the result consolidation of the large nominal group of dispersed decision makers [7], the prioritization of road maintenance project [8], structuring remedial decision at contaminated site [9], making decision by using dynamic criteria [10] are appreciative studies in recent years. On the other hand, some papers are discussed about the disadvantages of the applied method [11, 12].

2 THE METHODOLOGY

Decision analysis is a logical process of the ideas, experiences, and information so that the justified decision is resulted from the reasonable procedure. In general, results are described in the qualified appraisal so that an AHP hierarchy provides a comprehensive and rational framework to organize a decision problem, for quantifying its elements. The method includes three main parts, the overall *goal*, a group of options as the *alternatives* for reaching the goal, and the *criteria* that relate the alternatives to the goal which in some cases the criteria can be further broken down into the *sub-criteria* and so on. The design of the hierarchical process depends on the nature of the problem and the appropriate model should be presented. The model consists of five steps which are illustrated in the figure 1. In the first step, based on the nature of the problem, the project objective is defined. The next step deals with the limited assumptions, interfaces, ambiguities, organizational boundaries, and any stakeholders' issues. Therefore, the policy of decision analysis with the circumstances is adopted. In the third step, the appropriate criteria and alternatives are identified. In this regard, the discriminating criteria are introduced and the associated ones are classified in the specific categories. Similarly, those alternatives that

cover the principles are eligible for further consideration. Basically, alternatives vary in their ability to meet the requirements and goal and offer different approaches for changing the initial condition into the desired condition [1]. The next phase includes analyzing criteria and alternatives by using the systematic method in order to handle the information. This part is the main body of the assessment and within this part the weight is assigned to each criteria and alternatives. The optimum option is elicited from the accurate analysis and the level of the accuracy is related to the level of the experience which in this study the consistency ratio is used to restrict the deviation of the preciseness. Finally, the most efficient alternative is chosen with the highest score compared to the others, in the grading process.

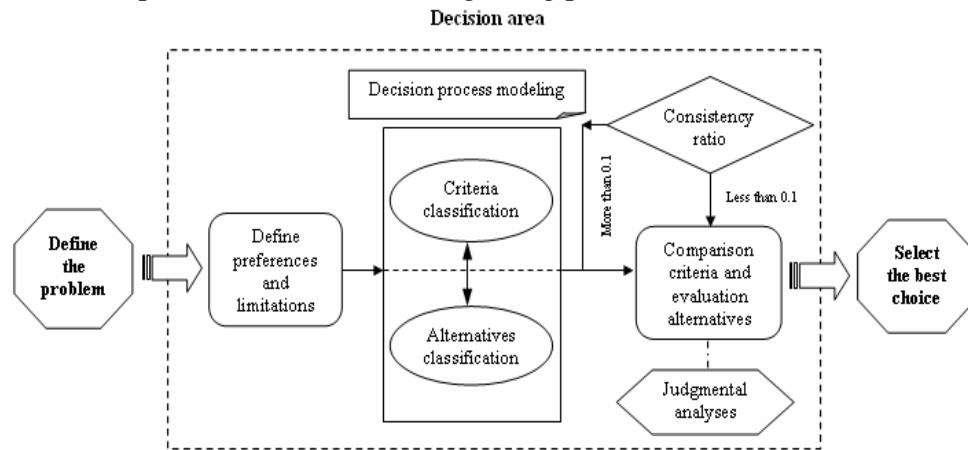

Figure 1: procedure of the decision optimization

2.1 The decision process

Once the hierarchy has been constructed, the pair-wise matrices are configured for each node of the process. The participants establish the two-by-two comparison of the priorities for all nodes, so that the intensity of the relative importance (table 1) is utilized to perform rational analysis of the decision elements. In the completion of each matrix, the array a_{ij} signifies the determinate priority of i-th item over the j-th item. By definition, the array a_{ji} points out the inverse preference of the compared item ($a_{ij} = \frac{w_i}{w_j} \Rightarrow a_{ji} = \frac{1}{a_{ij}}$). In this manner, if the group has N items

then the decision-makers need to fulfill the $\frac{N(N-1)}{2}$ comparisons.

Importance scale	The intensity of relative importance
Equal importance	1
Significantly less importance	3
Somewhat more importance	5
Strong importance	7
Extremely importance	9
The intensity measurement of 2, 4, 6, and 8 are used to explicit the median bound of the importance	

Table 1: Relative scale for pair-wise comparison

A comparison matrix A is said to be consistent if $a_{ij} \cdot a_{jk} = a_{ik}$ for all i, j and k . Mostly, in the multi-criteria problems, the matrices are inconsistent, so the rate which is called the consistency ratio is calculated. Consistency ratio of a matrix with the array $a_{ij} \neq \frac{w_i}{w_j}$ is a deviation that shows the variance of $(\lambda_{\max} - n)$ from the zero, and λ_{\max} is achieved by solving the $AW = \lambda_{\max} \cdot W$ equation. The largest Eigen value is equal to the size of comparison matrix, or $\lambda_{\max} = n$. Following the equation 1 the consistency index and by using the equation 2 the consistency ratio is computed. If the value of consistency ratio is smaller or equal to 10%, the inconsistency is acceptable, and if the consistency ratio is greater than 10%, we need to revise the subjective judgment [14, 15].

$$C.I = \frac{\lambda_{\max} - n}{n - 1} \quad (1)$$

$$C.R = \frac{I.I}{R.I} \leq 0.1 \quad (2)$$

Where

n : Number of elements

λ_{\max} : Maximum eigenvalue

$C.I$: Consistency index

$R.I$: Random consistency index (table 2)

$C.R$: Consistency ratio

The reciprocal matrix using scale, 1/9, 1/8, ..., 8, 9 is randomly generated [3] (similar to the idea of Bootstrap) and get the random consistency index to see if it is about 10% or less. The average random consistency index of sample size 500 matrices is shown in the table below.

n	1	2	3	4	5	6	7	8	9	10
I.I.R	0	0	0.58	0.9	1.12	1.24	1.32	1.41	1.45	1.45

Table 2: random consistency index

To incorporate the results, the process is used to allocate the proportional weight factor for each item. In this regard, there are some mathematical-based methods which lead the process to the desired weight. The methods such as least logarithmic square, Eigen Values and the approximate methods which are the approaches of the Eigen Values are used to figure out the definite weights. By the way, the four approximate methods are evaluated and the result is shown (figure 2) the least deviation of the arithmetic average results; therefore, in this study the weighting factors are obtained by using this routine.

Figure 2: The comparison of approximate methods results

According to this procedure, the weight of the each criterion and also alternatives in every criterion which reveal the priority of the items is computed. Eventually, the final score of the each alternative is acquired using the following equation.

$$Pr eferable (Alternativ e) = \max \sum_{i=1}^n w_{c(i)} \cdot w_{a(i)} \quad (3)$$

Where

$w_{c(i)}$: Indicates the decisive weight of i-th criterion

$w_{a(i)}$: Indicates the decisive weight of i-th alternative

Priorities are absolute numbers between zero and one and they represent the relative weights of the nodes in any group. Due to the different number of the items in the specific groups, the value of each group is normalized to express the same value of distinctive groups. Depends on the problem nature; the final weight refers to the importance, likelihood, capability or whatever factor is being considered by the decision makers.

Beside all the facts, there is a factor that has influence on the final decision and somewhat may change the result. The decision is developed basically on the expert judgment and the decision-makers use their knowledge and experiences to decide, thus, the decision conducted by the group with the more background, more realistic outcome will be concluded. Hence, a coefficient is defined here to take this subject into the consideration which is multiplied to the final result.

	Coefficient of the background
No background	0.9
Less than 3 years	1.0
More than 3 years	1.1

Table 3: proposed coefficient of proportionate study background

3 THE APPLICATION IN THE REHABILITATION OF A MASONRY BUILDING

3.1 Objective

Every year, large amount of money is spent for developing the infrastructural projects in which the allocation of the resources in the right order is the stakeholders' concern. Researches in this area demonstrate that study the optimization methods can bring significant outcome in the time-cost management and the decision-makers are capable to utilize a proper policy to save time and expenditures. Among them the consideration of the effective parameters in seismic rehabilitation [15], assessing the benefits and costs of earthquake mitigation [16], and also the study of affecting issues in the sustainability of buildings by the optimum design [17] can be mentioned. The unreinforced masonry buildings include the large part of the urban constructions and the researches have indicated the vulnerability of the majority numbers. In order to rehabilitate the structure and increase its seismic performance the retrofitting process is conducted, but the remarkable point for the clients is the process duration and the cost of the strengthening which the undesirable management will impose some losses to the project finance. Due to the aforementioned subject, the main purpose of this study is to demonstrate the applied procedure by the comparative algorithm to designate the optimum strengthening alternative with the assessment of the all related criteria in the selection process of unreinforced masonry buildings. As been stated before, to analyze the decision process, the criteria and alternatives are necessitated, so in the following part the appropriate criteria and possible alternatives are identified.

3.2 Criteria and sub-criteria

In the strengthening process of the masonry building, there are some parameters which affect the process and these parameters are identified and classified properly. These parameters are picked out by reviewing the related methodologies, codes, and provisions [18, 19, 20, 21, and 22]. The main criteria which are selected in the procedure include: *building characteristics*, *constructional aspects*, *economical aspects*, *technical aspects*, *architectural aspects*, and *mechanical and electrical equipment*. Each category has some sub-criteria which can be observed in the table 4.

3.3 Alternatives

The vulnerability of a building subjected to an earthquake is dependent on seismic deficiency of that building relative to a required performance objective [23]. Two possible ways are constructive, here. One is to demolish and rebuilt the building and the other one is to rehabilitate which can be the increasing the capacity of structure (add new elements, enhance existing elements; improve connections) or reduction the demand on the building. The rehabilitate techniques are used to enhance the seismic performance of the building and eliminate those deficiencies, subsequently. Different buildings types require different mitigation technique, and depend on the seismic deficiencies alternative recommendation are made to satisfy the performance objective of rehabilitation. In this study, six alternatives are proposed to improve the lateral performance of the unreinforced masonry building. The alternatives include: *strengthening with the shotcrete* (using the shotcrete overlay on the masonry wall), *strengthening with the interior shear wall* (adding the concrete shear wall inside the plan), *strengthening with the FRP*

(using the FRP laminate on the masonry wall), *strengthening with the exterior steel frame* (adding the steel frame outside the plan), *strengthening with the exterior concrete frame* (adding the concrete frame outside the plan), *strengthening with the exterior shear wall* (adding the concrete shear wall outside the plan).

3.4 Concluding remarks

The parameters which affect the selection process of the masonry buildings are categorized. The sort is performed based on the different characteristic of the items and in the term which can be compared, simultaneously. More discussion is provided in detail in the subsequent parts.

3.4.1 Building characteristics

Building characteristics include: *plan dimension, design and construction quality, building area, and vulnerability intensity*. Due to load distribution, using the strengthening with shotcrete and FRP will be more desirable in the buildings with large-sized plan. Some buildings have low design and construction quality, so that the alternatives like the shear wall which absorb the large amount of seismic loads, is desirable.

In some projects, the client may need to increase the building area beside the retrofitting implementation, so the alternatives which are adjunct to the structure (exterior frame or shear wall) will be more effective, and like wise if the existing building has the high vulnerability index which is obtained by the defenselessness analysis, those alternatives such as added-frame or shear wall are more productive. In this case, for a poor quality building, sometimes it is better to employ a method that reduces the transferred seismic force to the building rather than designing a huge new system for it [15].

3.4.2 Constructional aspects

Constructional aspects include: *construction duration, construction difficulties, construction technology, availability of materials, automation possibility, availability of constructional guideline, and level of experience needed for contractors and labors*. Projects related to their occupancy demand a specific duration timeline. In this regard, experiences have indicated the effectiveness of the strengthening with the FRP in comparison with the other alternatives and it is more operable for those projects which have limited time.

Adding the reinforced elements to the existing building is executed with some difficulties (hard accessibility to the structural components, connections, or even foundation) and mostly, it may affect severe impact on the project fund. In execution of shear wall the most troublesome part is the strengthening the foundation and if the wall designed outer part, the excavation and also the construction of new foundation is needed, too. Those alternative in which are added from outside, the adequate connection to the storey diaphragm is so important. However, the interior shear wall and strengthening with shotcrete need some difficulties in connection to the storey diaphragm, if the diaphragm has rigid material. Therefore, the strengthening with the FRP is evaluated the more efficient one.

The mechanized scheme which the required materials and the construction technology are available is more impressive. The level of the experience for the construction team is another important item so that some schemes are more sensitive to the errors and the high-experienced

team is needed. Also, the availability of constructional guideline can be useful for low-experienced contractors to be aware of the executing process.

3.4.3 Economical aspects

Economical aspects include: *effect on the loss reduction, cost of retrofitting, cost of required tools and machinery, cost of labors, current value of building, and presence of occupants in the time of rehabilitation*. The main goal of the rehabilitation process is to decrease the expected losses in the existing building. The losses have direct relation with the stiffness of the building, so the constant-ductile alternatives which increase the global stiffness such as shear wall will be more efficient.

One of the important parts of the evaluation is dedicated to the cost estimation, and it is among the most important parameters, specifically for the clients who should consider selecting the best retrofitting option. The cost of retrofitting comprises the destruction, strengthening, and repair cost which denote a series of items from the cost of removing some components to the cost of adding new material or elements and finally provide a new finishing. In fact, the value of retrofitting costs, including designers, labors, equipments and materials expenditure, compared with the benefit of performing the strengthening plan. The cost of the labors and tool/machinery will be added to the cost of retrofitting which are varying in different area.

According to the lifetime of the building, the retrofitting will increase the value of the building and the amount will be more significant for the older buildings. Also, those alternatives which are added from outside will increase the area and accordingly increase the building value. Some buildings have critical occupancy in which the interruption in the service will bring some losses to the occupants. In this regard, the alternatives which are adjunct to the structure will be preferable, because these approaches have no interference in the existing occupancy.

3.4.4 Technical aspects

Technical aspects include some parameters related to the structural and dynamic attributes such as: *effect on the building weight, or increasing the global stiffness and ductility*. Basically, the seismic load is received by the mass of the building. So, one way to resist the earthquake hazards is to decline the mass of building. Another way is to use an absorption mechanism of the earthquake energy by increasing the stiffness or the ductility of the building. Based on the behavior, the shear wall and frame highly increase the global stiffness of the building. Depend on the design parameters, the shear wall and frame are more ductile and can be more desirable, comparatively.

A discontinuity in the load distribution from diaphragm to the supporting soil brings about the local defect and prevents the seismic system to be effective. The irregularity (plan and vertical) feature has some negative effects on the building performance. The irregularity may place extraordinary demands on elements and the irregular building has more unknown behavior and different modes should be taking into the analysis so that codes are strongly recommended to avoid this feature. The solid movement of the building as grouped components is suggested in leading to the reliable behavior against applied loads. Some alternatives are preferable according to its effectiveness in completing the *load path*, improving the *irregularity*, increasing the overall *solidarity* and *torsional capacity*, like the shear wall, and added frame, respectively. On the contrary, the strengthening with the shotcrete and FRP are preferable in the *minimum strengthening in the foundation* and relative easiness in the *connection to the storey diaphragm*.

These two items are among the most difficult part of strengthening which the ignorance will cause increasing the costs. In supporting of the boundary conditions, the foundations of most masonry buildings are superficial and present noticeable settlements: they are far from the rigid foundations of the structural textbooks. They are unknown, and essentially unknowable, as slight changes of the soil conditions, the sudden action of loads (e.g., storms or earthquakes) could alter the response to the loads [24]. Also, the diaphragm deficiencies are described as inadequate restraints, in-plane strength, and insufficient local shear transfer to lateral-force resisting elements.

Masonry walls are the part of the lateral resisting system which is qualified to endure the seismic loads. Although, the alternatives such as shear wall and frame absorb the high rate of the earthquake energy, but they decrease the portion of masonry walls. If the *using of maximum structural capacity* is the purpose, the strengthening with the shotcrete and FRP are more operative. Diaphragm shall be designed to resist the effects of the seismic forces calculated by dynamic analysis [25]. *The rigidity of the diaphragm* is the key point in the lateral load distribution and reduces the three degree-of-freedom. In buildings with rigid diaphragm the load distribution is based on the stiffness of the elements, so the alternatives with high stiffness such as shear wall are not suitable for the building with flexible diaphragm. Moreover, due to stiffness of the shear walls, the load transmission between diaphragm and shear wall cause stress concentration and the connections are needed strengthen with the resistant materials.

The sensitivity of performance of each scheme *to the technical and constructional errors*, and also the availability of information on performance of such schemes in previous earthquakes is much useful. In all design codes there is a safety factor to consider the indispensable uncertainties in designing where in the rehabilitation process with limited structural information and knowledge factor is certainly much more. The error can be part of the process, but the avoidance or even reduction the errors should be taking into the consideration. The errors include design errors, constructional errors, experiments errors or even the lack of structural information. Conceptually, the shear wall and frame bear the major part of the force, so that they are more sensible to the expected errors. On the other hand, the shotcrete or FRP added-layers are linked to the masonry wall and the combination is assumed to endure the applied force, so the experiments errors and also the lack of structural information have a certain disposition towards the results. Also, in order to design each alternative and lateral capacity appraisal, a design code should be available.

Sometimes, the building under consideration has some weakness in *gravitational load-bearing* which added elements like the shear wall or frame are eligible for improving this deficiency. In using the exterior alternatives, the sufficient area is needed. Due to the strengthening with the shotcrete, interior shear wall, and FRP inside the building, they are evaluated more efficient. Beside the assessment of the structural elements, non structural components which are separated into the displacement-sensitive and acceleration-sensitive should be appraised. The alternative with more stiffness are more effective, so the shear wall, frame, shotcrete, and FRP are preferable, respectively. But the shear wall and somehow the frame increase the diaphragm acceleration, and in this manner the application are not justified.

Occasionally, the local renovation of the masonry walls is needed. In this case, the shotcrete overlay and also the FRP laminate would be preferable compared to the shear wall and frame. These renovations are enhancing the poor condition walls by removing some deteriorated masonries, repointing by using grout and epoxy injection to increase the shear strength. Thus the

deformation-controlled action would be replaced with the force-controlled of the diagonal tension. Masonry wall with height-to-thickness ratio or out-of-plane stresses in excess of the permitted by codes need to be strengthen and the shotcrete and FRP can be proper. Also, the masonry walls are weak in the corner of the opening in which the shear cracks are extended, if the dimension exceeds the allowable values [26, 27, and 28]. Masonry walls with undesirable length or height can not behave properly in earthquake and the maximum value are limited in the related codes [25]. In this order, the application of the shotcrete and FRP are qualified in decreasing the length and height in using as a tie.

According to the resisting system, all connection should have the desirable anchorage. Adequate strength should be provided in the connection between walls, wall to diaphragm and wall to the partition to resist the transfer forces. For local renovations the local scheme can be made to improve the local performance, but either shotcrete overlay or FRP laminate can be applicable.

Finally, *Past experience* is relevant in proving that retrofitting URM buildings reduce damage and loss of life, but also that building configuration and the quality of the evaluation, design and construction makes a substantial difference in the degree of improvement [29].

3.4.5 Architectural aspects

Architectural aspects include: *effect on the building's façade, effect on the building spacing, effect on the building lighting, and changing rooms' occupancy*. In the architectural viewpoint, the optimum alternative is the one which has the least affect on the building architecture and the clients prefer an alternative which has less interference in the aesthetic. In this regard, the most efficient option is the one which does not need to change the spacing, reduce the lighting, or even cause changing some rooms' occupancy. These are some limitations that mostly the designers are faced and are requested to avoid them. Among the proposed alternatives, the adjunct components like the exterior frame or shear wall have significant impact on the façade, or even reduce the lighting. In addition, in many cases the interior shear wall cause changing in some occupancy. Thus, the strengthening with the FRP is more productive.

3.4.6 Mechanical and electrical equipment

The mechanical and electrical equipments are one of the important parts of the building which removing can impose extra costs to the project finance. The effective alternative is defined the less necessity to the equipment removal, and accessibility. The alternatives which are added from the outside, unaffectedly, do not interfere in the building equipments. Also, compared to the strengthening with the shotcrete and FRP, the less shear wall is needed to fulfill the capacity requirements.

3.4.7 Case study

As been mentioned in the prior part, some parameters are constant in comparative evaluation, but some others can be varying in different area, so that different result will be obtained. The study is localized the evaluation of the effective parameter in order to select the best alternative for the rehabilitation of the masonry buildings. The results which is illustrated in the table 4, is accomplished for a masonry building located in the Tehran city to give us a broader perspective of the procedure.

Table 4: relatively weighted criteria, sub-criteria and alternatives

According to the figure.1 the problem is designed in which the model include the goal as a rehabilitation the masonry building. By reviewing the preferences and limitation in the rehabilitation process, the appropriate criteria are explained in the section 3.2, and the qualified alternatives are proposed in the section 3.3 The pair-wise comparative matrices are established and in this order the 5 matrices with different size for the criteria and 56 matrices for alternatives are set up. Using the mathematical syntax of numerical judgments in the decision problem, the absolute weight for the criteria and also for the alternatives is obtained. The consistency of the judgments is checked and the equation 3 is used to gain the final score in determination of the best alternative.

The results are summarized in the table 4 in which the proposed alternatives in the case of each classified criteria are compared and the priority is obtained for each of them. In the analysis the building characteristics, the vulnerability intensity serve the highest rank so the application of those schemes like the shear wall or the frame which can absorb the high rate of the earthquake energy is evaluated more desirable. The assessment of the constructional aspects denotes the importance of the construction duration and the construction difficulties among the other criteria. Based on the experience in this area, the strengthening of the masonry walls with the FRP is judged as a preferable alternative. In proceeding the economical aspects, the cost of the retrofitting and also the presence of the occupants in the time of rehabilitation acquire more effectiveness and the strengthening of the masonry walls with the shotcrete overlay is deserved higher priority. Among all the designated criteria in introducing the technical aspect of the process, the availability of the design codes and then connecting to the storey diaphragm are evaluated the most influential one. In this regard, the outcome indicates the efficiency of the strengthening of the masonry walls with the shotcrete overlay. The analysis of the architectural aspects signifies the precedence of the effect on the building's façade and the strengthening of the masonry walls with the FRP is the privileged alternative. Finally, the three exterior alternatives include strengthening with the steel frame; concrete frame and the shear wall are tending to be more useful in the mechanical and electrical equipment aspect. Whereas, the study of the

effectiveness of different alternatives needs to have the acceptable level of knowledge and experiences in leading to the authentic judgment, the presented study endeavors to be performed precisely. The results illustrate the preference of the strengthening the masonry walls with the shotcrete, compared to the other alternatives.

Figure 3: Final results of the proposed evaluation of the masonry buildings

4 VERIFICATION OF THE PREVIOUS STUDY

Several methods have been proposed in making-decision and in recent years various studies have been developed to analyze the decision problems. The authors presented a procedure to quantify the process for selecting the most advantageous technique, and also a practical method for specifying and prioritizing a criteria and goals for seismic retrofitting of a building [15]. A survey was conducted and some expert's opinions are gathered from some leading authorities, both from academia and profession, to calibrate the method. The aforementioned study was based on the experts' judgment and the criteria and alternatives were compared entirely in a group which it needed more concentration of its larger domain. The comparison of criteria and alternatives in this study is performed with this method again in consideration the final results. In spite of that the evaluation by the experts' judgment is expected to have divergent results but the result which is illustrated in figure 4, has shown the admissible level of outcomes. Due to close assessment, the variance of the combined results is calculated based on the equation 4.

$$\text{If } \mu = E(x) \text{ then } \text{VAR}(x) = E[(x - \mu)^2] \text{ or } \text{VAR}(x) = E(x^2) - [E(x)]^2 \quad (4)$$

Where

Table 6: the expected value and variance for the method-Judgmental

The results presented in the figure 4 and the table 5 and 6 implicate the effectiveness of the experts' judgment and the variance of this method here is less than the AHP method, but the sequence of the priorities is changed. As been mentioned before, the accuracy of decision-makers in analyzing the process and making comparison has a direct relationship with the final result.

5 THE BINARY PROCESS

The productive criteria identified and properly classified and also according to the aforementioned process in the prior section, the relative weight is assigned to each criterion and also the method is used to compare the alternatives to make the preferences in each criterion. In this step, each criterion is simulated by a question tag which covers the intelligible concept of those criteria. In this regard, the only two possible answers are drawn here: “Yes” or “No” which *yes* points the 1 and *no* refers to 0 (eq.5). The main purpose of this study is to draw a simplified flexible procedure in optimization the proposed rehabilitation alternative with consideration the interaction of criteria and alternatives; hence a binary approach decision-making (BADM) is established in this regard. The applied model tries to make a rational conclusion based on the judgmental analysis and its binary utilization authorizes the decision-makers to omit those criteria that are irrelevant to the building under consideration by giving the *no* answer. Finally, the quick survey of building with considering the structural and non-structural components, gathering comprehensive information, limitations and also clients’ objective the alternatives are evaluated by completing the survey.

$$\text{The most efficient alternative} = \max \sum_{i=1}^n CW_i \times \varphi_{bi} \begin{Bmatrix} 0 \\ 1 \end{Bmatrix} \quad (5)$$

Where

CW_i : Indicates the relative weight of i-th criterion

φ_{bi} : The binary coefficient of i-th alternative

The filled cells are those considered as the preferred alternative in the specific criteria, therefore each answer will be evaluated just for these alternatives and the final result will be achieved by summing up the grades. The applied form is presented in table 7 and the result is obtained for a particular building which is considered vulnerable.

[illegible]

The consistency of the judgments is checked and the eq.5 is used to gain the final score in determination of the best alternative. The binary procedure is used as a complementary tool to cover the decision-making process. Depends on what is concluded from the classified criteria analyses by using the AHP method, the high ranked alternatives in each criterion are spotted (blue cells). The relative weights which are assigned in previous evaluation elicited and applied in this table. Based on client's circumstances and project's demand, provided questions; whether it is relevant and needed to consider or not; make a simplified point of view of the most appropriate alternative. Due to the distinctive specifications of different projects, the binary process is added to the decision analysis in order to help the decision makers to come up with their projects with an applicable tool incorporated with the basic concept of the masonry rehabilitation.

6 CONCLUSION

- Unreinforced masonry (URM) bearing wall buildings have shown poor performance in the past earthquakes and the reasons are the inherent brittleness, lack of tensile strength, and lack of ductility. Therefore, the rehabilitation is conducted for those buildings with inadequate capacity in order to improve its seismic performance. Whereas, the high amount of money that spend in this regard, stakeholders are so eager to complete the process in much less timeline and whatever the time duration of decision-making is less, the benefit of the process will be increase. Similar study was conducted by the authors in optimizing the selection process, but the method has a disadvantage that process was rigid model and can not be changeable for different projects in minimum time, so this study brings out the best usage of the model as a flexible model for different projects in a very simple way.
- The presented study helps decision-makers face complex problem with multiple conflicting and subjective criteria. However, explicit comparison of technical characteristics of the retrofitting options is usually conducted by performing linear or nonlinear analyses of the retrofitted building to check the acceptance criteria for structural, non structural and equipments, but the application will be useful in the preliminary evaluation of the alternatives and for buildings with less importance can be appropriate approach to decrease the process timeline.
- Based on the presented study, the method is developed to evaluate the optimum rehabilitation process of the unreinforced masonry buildings. The effective criteria and alternatives for the rehabilitation of these building are introduced and classified and according to the procedure they are evaluated comparatively. The final result indicates the effectiveness of the strengthening of the unreinforced masonry buildings with the shotcrete overlay.
- This paper presents a procedure in leading to select the best rehabilitation alternative of the unreinforced masonry (URM) buildings. The proposed method is carried out in three steps in which the effective criteria are classified and the hierarchical process is used to allot the weight to each criterion. Based on this process the proposed alternatives are compared to make the preferences of each one in different criteria. By using the binary concept the model is developed to select the optimum rehabilitation alternative of the specific unreinforced masonry buildings. The most remarkable characteristic of the applied model is its tendency to be done in minimum time and its simplified structure that will be useful for the decision-makers in this area to choose the optimum option by doing quick survey. The final result

indicates the effectiveness of the strengthening of the unreinforced masonry buildings with adding the interior shear wall.

7 ACKNOWLEDGEMENT

The study was carried out as a research project entitled “Development of the criterion for the vulnerability assessment and the rehabilitation process of the school buildings in Iran” awarded to the state organization of the schools renovation, development, and mobilization; and the support of the structural department of the international institute of earthquake engineering and seismology (IIEES) is appreciated.

SEISMIC RESPONSE OF A STONE MASONRY SPIRE

Keywords: masonry, spire, rocking, heritage structures, discrete element modeling.

Abstract. *Stone masonry spires are vulnerable to seismic loading. Computational methods are often used to predict the dynamic linear elastic response of masonry spires, but this approach is significantly limited to the point when the first masonry joint begins to open. In this paper, analytical and computational modeling methods are used to address the full dynamic response of masonry spires until collapse. An analytical framework is first presented, which addresses both the elastic oscillation response and the rigid rocking response of masonry spires. In this context, the seismic response of the spire of the church of St. Mary Magdalene in Waltham on the Wolds, United Kingdom, which was damaged in the 2008 Lincolnshire Earthquake, is addressed. Both analytical and computational discrete element modeling are applied to predict the response to a variety of base accelerations. Results of both methods are compared to evaluate their utility and to understand the seismic damage which occurred.*

1 INTRODUCTION

Large earthquakes are relatively rare in the United Kingdom, and ensuing damage is often limited to unreinforced masonry spires, chimneys and towers. As spires typically top significant heritage structures, there are numerous recorded examples of spire damage during historic seismic events [e.g. 1,2]. More recently, several stone masonry spires were badly damaged during the 2008 Lincolnshire Earthquake in the United Kingdom, despite the relatively small magnitude of earthquake ground motion. The damage to one such spire, which sat atop the 13th century parish church of St. Mary Magdalene in Waltham on the Wolds, provides the impetus for this research, and will be used as a case study herein.

The stability of masonry spires under static dead load and wind load was addressed by Heyman [3] in the context of ultimate load theory, assuming i) infinite compressive strength, ii) zero tensile strength, and iii) no sliding between masonry units. Heyman [3] assumes that octagonal spires can be modeled as conical shells, and demonstrates the importance of a solid spire tip to resist overturning during high winds.

The dynamic response and collapse of masonry spires has been given relatively little attention. Previous studies concentrate on the onset of cracking due to elastic response, rather than the prediction of post-damage response and complete collapse. In this study, dynamic response is also tackled in the context of rocking structures, for which the literature is extensive. Housner [4] provides the fundamental formulation for investigating the rocking response. Zhang and Makris [5] provide a critical contribution regarding the response of rocking objects to cycloidal pulses which can dominate earthquake ground motions and govern overturning collapse.

The dynamic response of masonry structures can be computationally predicted using Discrete Element Modeling (DEM), which models the contact and separation between individual stones within a masonry structure. In particular, DEM was used to model the dynamic rocking response of the masonry arches by De Lorenzis *et al.* [6], with a more in-depth sensitivity study of modeling parameters provided by DeJong *et al.* [7]. These studies demonstrate the utility of DEM to evaluate analytical models which capture the governing dynamic response.

The aim of this paper is to provide a general approach for evaluating the dynamic response of masonry spires under seismic loading, and then to evaluate that approach by assessment of the damage to the spire of the parish church of St. Mary Magdalene. The general approach is presented first, and makes use of an analytical formulation for predicting damage and rocking response. Subsequently, DEM is used to evaluate the analytical approach through an in-depth computational investigation of the spire in question.

2 ANALYTICAL FORMULATION

The analytical approach for modeling the dynamics of masonry spires will be broken down into three aspects. First, static analysis will be used to obtain a reference point for lateral stability. Second, the linear elastic dynamic response will be approximated. Finally, the rigid rocking response will be considered. A conical shell is assumed to be representative of the octagonal spire, and the three assumptions of ultimate load theory are taken [3].

2.1 Static Analysis

As a starting point, static analysis is useful to determine the minimum horizontal ground acceleration (if applied for infinite duration) necessary to cause overturning of a conical shell. For the geometry in Figure 1(a), the fraction (λ) of gravitational acceleration (g) required for overturning is:

Figure 1: Definition of masonry spire geometry.

$$\lambda = \frac{3r_b}{H} \quad (1)$$

The conical shell has a relatively low center of gravity ($H/3$), and is therefore more resistant to overturning than a solid rectangular prism. However, assuming masonry structures have no tensile capacity, diagonal cracks may open when lateral loads are applied [8]. In reality, the location of these cracks may be limited by interlocking of blocks, but assuming that a diagonal crack can form at any angle β (Figure 1(b)), the fraction (λ) of gravitational acceleration (g) required for overturning is:

$$\lambda = \frac{3r_b}{H} \frac{\left(\frac{1}{\pi^2} h_c^3 - \left(\frac{2}{\pi^2} - \frac{2}{3} \right) h_c^2 H - 2h_c H^2 + 2H^3 \right)}{\left(h_c^3 - 2h_c^2 H + 2H^3 \right)} \quad (2)$$

where h_c is the crack height in Figure 1(b).

2.2 Dynamic Elastic Analysis

The dynamic response of masonry structures involves two stages: an initial elastic stage, during which the entire structure remains in compression, followed by a ‘rocking’ stage, during which masonry units separate and regain contact. The elastic stage will be addressed first, followed by the rocking stage in the next section.

Due to the slender nature of spires, Euler-Bernoulli beam theory can be used to estimate natural frequencies and mode shapes. The mass per unit height, $m(y)$, and bending stiffness, $EI(y)$, of the spire can be written as:

$$\begin{aligned} m(y) &= \left(1 - \frac{y}{H} \right) m_b \\ EI(y) &= \left(1 - \frac{y}{H} \right)^3 EI_b \end{aligned} \quad (3)$$

Figure 2: First two modes shapes of a conical shell [10], and the first mode shape from Equation (5) with $k = 2.2$.

where m_b is the mass per unit height at the base, I_b is the second moment of area at the base, and E is the Young's Modulus.

Therefore, the mass and bending stiffness vary similarly to the solid wedge beam analyzed by Naguleswaran [9], who determined the corresponding natural frequencies:

$$\omega_n = \sqrt{\frac{\Omega_n^2 EI_b}{m_b H^4}} \quad (4)$$

where $\Omega_n = 5.315, 15.21$, and 30.02 for the first three modes. The fundamental mode shapes for the first two modes are depicted in Figure 2.

Alternatively, Rayleigh's principle can be used to estimate the mode shape and compute the corresponding natural frequencies. Assume a mode shape of the form:

$$\bar{x}(y) = \left(\frac{y}{H}\right)^k \quad (5)$$

where $\bar{x}(y)$ is the modal translation at height y , and k is a constant. The fundamental natural frequency is approximated by:

$$\bar{\omega}_1 = \sqrt{\frac{\int_0^H EI(y) \left(\frac{d^2 \bar{x}}{dy^2}\right)^2 dy}{\int_0^H m(y) (\bar{x}(y))^2 dy}} \quad (6)$$

The minimum fundamental frequency $\bar{\omega}_1$ occurs for $k = 2.2$, and the corresponding mode shape compares reasonably well with the actual mode shape derived by Naguleswaran [9] (Figure 2). Modal analysis using equations (5) and (6) can now be applied to determine the point at which elastic oscillation would cause damage and initiate a rocking response.

2.3 Dynamic Rocking Analysis

If the earthquake loading induces a large enough response, the spire would begin to rock as it has no tensile capacity, and the elastic natural frequencies would be completely altered. To investigate whether rocking could cause collapse, consider a rigid conical shell on a rigid foundation.

The rigid conical shell will begin to rock (Figure 1(c)) when the overturning moment exceeds the resisting moment, which occurs at a maximum ground acceleration of $a_{crit} = \lambda g$, where λ is defined in Equation (1) above. Once rocking commences, the response can be treated in a similar fashion to Housner [4], assuming spinning of the cone about its vertical axis does not occur. The equations of motion are:

$$\begin{aligned} I_0 \ddot{\theta} + MgR \sin(+\alpha - \theta) &= -M \ddot{u}_g R \cos(+\alpha - \theta) \rightarrow \theta > 0 \\ I_0 \ddot{\theta} + MgR \sin(-\alpha - \theta) &= -M \ddot{u}_g R \cos(-\alpha - \theta) \rightarrow \theta < 0 \end{aligned} \quad (7)$$

where M is the total mass of the cone, R , α , and θ are defined in Figure 1(c), and I_0 is the mass moment of inertia about point O in Figure 1(c):

$$I_0 = \frac{5}{4} M r_b^2 + \frac{1}{6} M H^2 \quad (8)$$

Assuming small angles, equation (7) can be rewritten in the form:

$$\begin{aligned} \ddot{\theta} - p^2 \theta &= -p^2 \left(\frac{\ddot{u}_g}{g} + \alpha \right) \rightarrow \theta > 0 \\ \ddot{\theta} - p^2 \theta &= -p^2 \left(\frac{\ddot{u}_g}{g} - \alpha \right) \rightarrow \theta < 0 \end{aligned} \quad (9)$$

where $p = \sqrt{MgR/I_0}$ is the frequency parameter of the block.

Still following the formulation of Housner [4], the impact can be modeled by a coefficient of restitution, c_v , defined as the ratio of the angular velocities before and after impact:

$$c_v = 1 - \frac{MR^2}{I_0} (1 - \cos 2\alpha) \quad (10)$$

Equations (9) and (10) now describe the response of the conical shell to horizontal ground motion in general. However, as ground motion impulses often govern overturning collapse, impulse collapse diagrams similar to those presented by Zhang and Makris [5] could directly be plotted.

Finally, the fact that the spire has no tensile capacity must again be considered. Diagonal cracking could result in the rocking response of the ‘cracked cone’ in Figure 2(b) about point O, where point O need not be located at the bottom corner. The crack could occur further up the spire. In this case, equations (7) and (9) could still be used to predict the dynamic response, but the impact formulation must be reconsidered.

3 DISCRETE ELEMENT MODELING

Discrete Element Modeling (DEM) is a tool which can predict the more detailed response of a spire which is actually comprised of numerous separate masonry units. DEM will be used to predict levels of damage and collapse to the spire, rather than to predict precise displace-

ments, which is impossible. In this section, the modeling assumptions are first explained, followed by simulation of static, impulse, and earthquake loading. All simulations were carried out using 3DEC [10].

3.1 Spire Characteristics and Modeling Assumptions

The spire of the church of St. Mary Magdalene in Waltham on the Wolds, UK (Figure 3(a)), was badly damaged during the earthquake, after which the top half of the spire was reconstructed (Figure 3(b)). Construction and survey documents from the dismantling of the spire were used to develop an accurate model of the pre-earthquake spire, in which each stone is individually considered (Figure 3(c)). All earthquake damage was concentrated above the height of the top windows, so only the reconstructed section was modeled. The entire spire is 19.1 meters tall; the model consists of the top 9.4 meters (Figure 3(d)). The top 3.4 meters of spire is solid, with each course tied together by an interior metal rod. This section was modeled as a single rigid block. The average height of each masonry course is 0.3 meters, with an assumed average hydraulic lime mortar joint thickness of 1 cm.

The modeling parameters used for DEM simulations are presented in Table 1. Rigid blocks were specified to limit computational time. The joint stiffness k_j was calculated by lumping all of the stone and mortar deformation in the joints [11]. Stiffness proportional damping was specified to approximate inelastic impact between blocks and to limit unrealistic high frequency vibrations [11]. Mass proportional damping was not used.

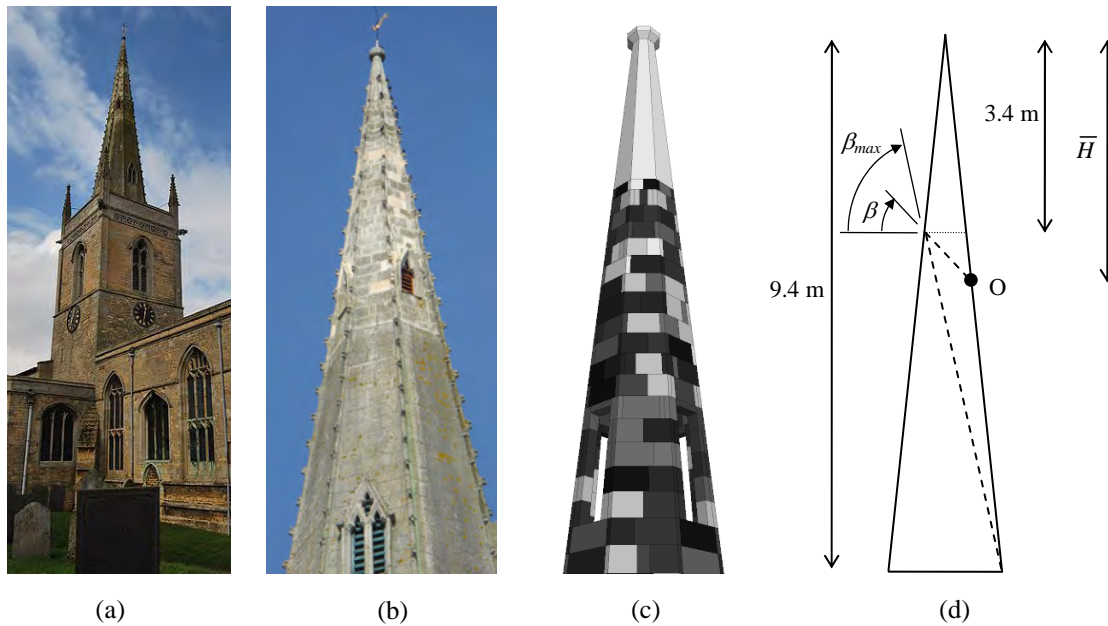

Figure 3: (a) Church of St. Mary Magdalene, (b) repaired masonry spire, (c) DEM model of spire, and (d) model spire geometry.

E_{stone} [GPa]	E_{mortar} [GPa]	Density, ρ [kg/m ³]	k_{joint} [GPa/m]	Friction angle [degrees]	Stiffness proportional damping constant [-]
30	10	2600	98	30	2.1×10^{-5}

Table 1: Modeling parameters.

Figure 4: Progressive collapse under constant horizontal ground acceleration.

3.2 Constant acceleration results

To evaluate the minimum possible acceleration which could cause collapse, an increasing horizontal acceleration was applied until the overturning occurred. As expected, diagonal cracking of the spire occurred (Figure 4). The window openings and the lack of interlocking between blocks above the windows allowed a remarkably vertical crack to form. The collapse acceleration varied from 0.164g to 0.176g in the four horizontal directions, showing some effects of varying block interlock. In general, the spire collapsed with a crack angle of approximately β_{\max} (Figure 3(d)). According to equation (2), $\lambda = 0.192$, which compares well considering the assumption of a perfect conical shell instead of a windowed octagonal spire with vertical joints. A refined analytical model including the solid tip and more precise geometry yields $\lambda = 0.168$.

It is worth noting that even this simple simulation indicates that the poor interlock between blocks limited the ability of the spire to withstand lateral acceleration. Friction due to better interlocking could significantly reduce β .

3.3 Single Impulse Results

The spire was also subjected to a suite of single cycle sinusoidal ground acceleration pulses of maximum amplitude a_p and of duration T_p . The response of the spire was repeatedly simulated to evaluate the pulse characteristics which cause damage (visible residual displacements) and complete collapse. The results are presented in Figure 5, in which the regions above the curves represent regions of damage and collapse respectively. A representative rocking response of the spire is depicted in Figure 6, where the ground moves to the right and the spire rocks to the left (Figure 6(a,b)), recovers and impacts (Figure 6(c)), and then collapses to the right (Figure 6(d)). This mode of collapse will be referred to as Mode I collapse; immediate collapse to the left without impact will be referred to as Mode II collapse (after [5]).

The analytical model presented in §2.3 enables the prediction of Mode I and Mode II rocking collapse. However, the response is sensitive to p . For two identical spires of different scale, the larger will be much more resistant to overturning. The collapse curve for the entire spire (9.4 meters tall), and for the solid spire tip alone (3.4 m tall), are also presented in Figure 5. The region inside the lower loop of the collapse curve represents Mode I collapse, while the region above the upper portion of the collapse curve represents mode II collapse. Clearly the tip alone is more vulnerable.

Figure 5: Damage and collapse diagram for a single sinusoidal base acceleration pulse.

Figure 6: Progressive collapse under for a single sinusoidal base acceleration pulse with $a_p = 1.0$ g and $T_p = 1.0$ s (ground moves to the right).

In addition to considering the entire cracked cone and solely the cone tip, there may be a worse condition. Suppose the spire is allowed to crack, and the cracked portion begins rocking. For this case the maximum p value would shift the collapse curve furthest to the left. If the crack is assumed to initiate just below the solid tip, p is plotted as a function of the cracked height \bar{H} in Figure 7(a). For the spire in question, the maximum value of p occurs for $\bar{H} = 4.1$ meters, which would yield the collapse curve in Figure 7(b).

The results indicate that while rocking of the cracked spire tip is theoretically the worst condition, it may be slightly conservative. In fact, Mode I collapse due to this condition is unlikely due to the inability of the rocking mechanism to reflect without significant dissipation of energy. Instead, an alternate mode of failure may govern, in which the impulse is not large enough to cause Mode II collapse of the cracked spire, but the impulse is large enough to cause significant damage to the non-rocking portion of the spire, which then cannot sustain the impact resulting when the rocking portion of the spire recovers.

Figure 7: Progressive collapse under for a single sinusoidal horizontal base acceleration pulse.

Regardless, Figures 5 and 7(b) indicate that the primary impulse within the earthquake ground motion experienced by the spire was way too small for rocking damage or overturning collapse to occur.

3.4 Seismic Response Results

Unfortunately, ground motion acceleration data from the location of the earthquake was not available near the location of the spire. Instead, ground motion data from a similar epicentral distance was used. Unfortunately, this completely alters the effects of seismic wave directionality and local soil amplification. To compensate, the ground motion was scaled by a range of 2-6 times to account for local site amplification due to differences in soil conditions.

To determine the response of the spire, it is also necessary to consider the amplification of the ground motion by the structure itself. Using a procedure similar to that presented in §2.2, the natural frequency of the combined tower and spire was estimated to be ~ 6.8 Hz. The spectral earthquake data reached its maximum in a similar frequency range, so the fundamental mode was determined to dominate the response, and was used to approximate the horizontal motion at the base of the DEM model.

The DEM model was then used to simulate the seismic response. While assumptions are too numerous to be able to expect to exactly predict the spire response, a few conclusions can be drawn. Because the input acceleration was larger than $0.17g$ for very short durations, overturning mechanisms were repeatedly formed and closed almost immediately, causing the spire to very slightly walk apart, and leaving vertical gaps between stones (Figure 8(b)). Increased amplification of the ground motion input led to increased ‘walking’ and larger vertical gaps between stones. These same vertical gaps appeared above the windows of the actual spire (Figure 8(a)), and led to the need for reconstruction. The duration of the strong motion portion of the earthquake also appears to be critical to evaluate the level of ‘walking’. Generally, it is evident that earthquake ground accelerations must have been amplified locally, by both the soil and the structure, to have caused the observed damage.

Figure 8: Interior view of spire: (a) actual damage, (b) DEM simulation of damage.

4 CONCLUSIONS

The seismic collapse of unreinforced masonry spires is difficult to predict. There is clearly an initial elastic response which must be considered, followed by a rocking response which completely alters the dynamics of the system. The analytical approach presented herein provides a context for dealing with both of these aspects of the dynamic response. However, due to the number of simplifying assumptions involved in the analytical formulation, DEM is critical to evaluate the actual spire response.

Both the analytical and computational results indicate that the damage to the spire of the church of St. Mary Magdalene could not have been caused by the acceleration magnitudes recorded at a similar epicentral distance, or even the ground acceleration scaled due to local soil conditions. Additionally, it was not likely that the damage was caused by a single impulse within the ground motion. Instead, structural amplification seems to have caused large enough accelerations at the top of the spire to cause the spire to walk apart over a longer duration of time, producing the observed damage.

Abstract. *Masonry structures are complicated structures and there is, currently, a lack of knowledge and information concerning the behaviour of their structural system under seismic loading. Successful modeling of a masonry structure is a prerequisite for a reliable earthquake resistant design. However, modeling a real structure to a robust quantitative (mathematical) representation is a very difficult and complicated task. This paper is presenting a contribution toward a solution of the problem. A new methodology for earthquake resistant design of masonry structural systems, either before or after their repair and/or strengthening is presented. The whole process is illustrated using the case study of a typical 4-storey masonry structure of the city of Patras in Greece.*

1 INTRODUCTION

The majority of the main structural systems for historical structures are masonry elements, composed of stone, bricks and mortar. For all types of old historical masonry structures (including monuments) erected in seismic zones of high seismicity, earthquake is always their number one “enemy” due to their very bad response to earthquakes [1]. The responsibility of protecting a historical structure falls mainly on the shoulders of the engineer. A successful intervention on a monument requires a good comprehension of its structural behaviour under static and dynamic (earthquake) loading. For an engineer, taking part to the restoration process of a historical structure, through the analysis of its structural system, means mainly to face the demanding task of equipping the historical structure with the capability to withstand future actions with the minimum possible amount of damage, while bearing in mind the characteristics and values which make this structure unique and worthy of special attention. This has to be carried out within the conditions imposed by current regulations and scientific Charters (e.g. the Athens Charter 1931 [2] the Venice Charter 1964 [3], etc.), which make the process of analysis more complicated.

Masonry structures are complicated structures and there is lack of knowledge and information concerning the behavior of their structural system under seismic loads. What can only be said is that typically these structures are more massive than today’s structures and that they usually carry their actions primarily in compression. It should be noted here that most of these historical structures were built with specific consideration given mainly to their geometry and aesthetic quality and less to their structural integrity.

Successful modeling of a masonry historical structure is a prerequisite for a reliable earthquake resistant design. Recent methods of analysis should be very carefully applied on masonry structures. For modern structures, with new industrial materials used (reinforced concrete, steel, etc.), the development of a reliable mathematical model is usually possible, due to the fact that, materials and member characteristics are uniform and mostly explicitly known. On the other hand, for the case of masonry, and especially for the traditional plain one, it seems that there is a lot to be done on that field, until engineers become confident about the accuracy of the modeling.

For the purpose of masonry analysis and design, an operationally simple strength criterion is essential. Masonry has a mechanical behavior, which has not yet been fully investigated. Systematic experimental and analytical investigations on the response of masonry and its failure modes have been conducted in the last decades. There have been numerous analytical criteria for masonry structures [4][5][6]. The main disadvantage of existing criteria is that they ignore the distinct anisotropic nature of masonry; even if they do not ignore that, they consist of more than one type of surface leading to additional effort in the analysis process of the masonry structures [7]. According to Zienkiewicz et. al [8] the computation of singular points on failure surfaces may be avoided by a suitable choice of a continuous surface, which usually can represent, with a good degree of accuracy, the real condition.

Since reliable experimental data in the combined-stress state are rising rapidly [9][10][11], it is, therefore, timely to examine the validity and utility of existing criteria, and to propose a failure surface of convex shape suitable for the anisotropic nature of masonry material. According to Hill [12] and Prager [13] the failure surface for a stable material must be convex. This, in mathematical terms, is valid if the total Gaussian curvature K of the failure surface is positive.

As can be concluded, various researchers have been working on the earthquake resistant design of masonry structural systems and especially determining a strength criterion, but there is still a lot ongoing research on that field.

2 EARTHQUAKE RESISTANT DESIGN OF MASONRY STRUCTURAL SYSTEMS

2.1 Methodology

The proposed methodology includes six steps for the structural analysis of a historical building. Detailed architectural and structural drawings, describing the existing status of the structure, are always prerequisites for the application of the proposed methodology.

(1) Material characteristics

The characteristics of materials composing the structure are basic input data for structural analysis. Namely, the compressive-tensile strength of the materials, their modulus of elasticity and Poisson ratio are of primary importance. For the estimation of those parameters, combination of analytical or semi-empirical methods and experimental data have to be used. For the determination of the masonry compressive and tensile strength, several semi-empirical expressions exist. Among them the formulae [14]:

$$\begin{aligned} f_{wc} &= \xi \left[\left(\frac{2}{3} \sqrt{f_{bc}} - a \right) + \beta f_{mc} \right] & f_{wt} &= \frac{2}{3} f_{mt} \\ \text{(compressive strength)} & & \text{(tensile strength)} & \end{aligned} \quad (1)$$

are combining all parameters affecting the value of f_w . These parameters are described elsewhere in detail [14].

(2) Structural model

A 3-D finite element model seems to be generally the most suitable for the analysis.

(3) Actions

Different loading cases have to be taken into consideration, including the seismic actions, especially for structures built in seismic areas. Combinations of dead loads, live loads and earthquake loads, is used, following the general rules provided by codes [18][19]. Earthquake has to be considered along all unfavorable directions for the building.

(4) Analysis

Using input data of the previous steps a Finite Element Analysis is performed and moments (normal-shear) - displacements at the joints of the mesh are calculated. Due to the actual behaviour of plain masonry and the high degree of uncertainty in the previous steps, elastic analysis seems to be the most realistic one for the analysis of such structures, especially before any repair and/or strengthening.

(5) Failure criterion

A failure criterion must be established for the definition of the failed regions of the structure. Taking into account the conclusions of step 1 concerning materials' characteristics, such a criterion is proposed, and will be used as an input to carry out the analysis.

(6) Repairing and/or strengthening decisions and reanalysis

According to the results of step 5, all the failed regions are repaired and/or strengthened. The method to be used, the extend of the interventions, the type of the materials, etc., are directly related to the results and are based on semi-empirical expressions for the final mechanical characteristics of masonry [14].

Last, a new structural analysis has to be performed, using the new materials, loadings and structural data. Results of the analysis have subsequently to be used in the process of step 5, leading to a final approval (or rejection) of the decisions already taken for repair or strengthening of the existing structure.

2.2 Failure criterion

The basic step of the proposed methodology is the quantitative damage evaluation of masonry, which is the basic material of historical and monumental structures. The damage is estimated by a cubic polynomial function that is used for composite materials. In this method, the failure surface in the stress space can be described by the equation [15][16].

$$2.27\sigma_x + 9.87\sigma_y + 0.573\sigma_x^2 + 1.32\sigma_y^2 + 6.25\tau^2 - 0.30\sigma_x\sigma_y + 0.009585\sigma_x^2\sigma_y + 0.003135\sigma_x\sigma_y^2 + 0.28398\sigma_x\tau^2 + 0.4689\sigma_y\tau^2 = 1 \quad (2)$$

Their results showed a good correlation with data from the literature. However, this anisotropic failure criterion applies only to the specific masonry material that he was studying. This disadvantage could be reversed if this criterion is expressed in a non-dimensional form, and, as such, can be applied more generally to a plethora of masonry materials. This can be achieved by dividing and multiplying (at the same time) each term in Eq. 2 by one material monoaxial strength raised in the sum of the exponents of the variables σ_x, σ_y, τ (as appeared in each term). It is selected the uniaxial compressive strength Y' to be across the y-axis, which, in terms of the masonry material corresponds to the uniaxial compressive strength denoted with the symbol $f_{wc}^{90^\circ}$. This model was proposed by Asteris et al. [17].

Eq. 2 can thus take the following form:

Figure 1: Non-Dimensional Failure Surface of Masonry in Normal Stress Terms
 $(\tau/f_{wc}^{90^\circ} = 0.00 \text{ up to } 0.45 \text{ by step}=0.05)$ [17]

$$F = 17.15 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right) + 74.57 \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right) + 32.71 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right)^2 + 75.34 \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right)^2 + 356.74 \left(\frac{\tau}{f_{wc}^{90^\circ}} \right)^2 - 17.12 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right) \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right) + 4.13 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right)^2 \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right) + 1.35 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right) \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right)^2 + 122.46 \left(\frac{\sigma_x}{f_{wc}^{90^\circ}} \right) \left(\frac{\tau}{f_{wc}^{90^\circ}} \right)^2 + 202.20 \left(\frac{\sigma_y}{f_{wc}^{90^\circ}} \right) \left(\frac{\tau}{f_{wc}^{90^\circ}} \right)^2 = 1 \quad (3)$$

Fig. 1 depicts the contour map of Eq. 3, that is the non-dimensional failure surface of masonry in normal stress terms (with $\tau/f_{wc}^{90^\circ}$ taking values of 0 up to 0.45 by steps of 0.05).

The resulting F value denotes the type of failure (Table 1), e.g.:

$F < 1$ no failure of the element (type 1)

$F \geq 1$ failure of the element (type 2 to 5)

No	Type of masonry failure		Failure criterion
1	No failure		$F < 1$
2	Failure under biaxial tension/tension		$F \geq 1 \ \& \ \sigma_x > 0 \ \& \ \sigma_y > 0$
3	Failure under biaxial tension/compression		$F \geq 1 \ \& \ \sigma_x > 0 \ \& \ \sigma_y < 0$
4	Failure under biaxial compression/tension		$F \geq 1 \ \& \ \sigma_x < 0 \ \& \ \sigma_y > 0$
5	Failure under biaxial compression/compression		$F \geq 1 \ \& \ \sigma_x < 0 \ \& \ \sigma_y < 0$

Table 1: Non-dimensional masonry failure criterion under biaxial stress state

3 CASE STUDY

The methodology described before is illustrated in a comprehensive form, through the case-study of a 4-storey masonry structure of the city of Patras in Greece. The building was built at the beginning of the 20th century and has been characterized recently as a historical building. The structural system is composed by porous stones and mortar; the floor system is consisted by wooden boards mounted on wooden beams spanning one direction. The building has suffered several earthquakes during its service life, but has never been repaired or strengthened. A typical plan view is shown in Fig. 2.

Figure 2: Typical plan view of the examined building

The new methodology for earthquake resistant design of masonry structural systems either before, or after their repair and/or strengthening is presented, by a short description of all steps.

1. In situ inspection showed that masonry stones were porous stones. Several experiments have been performed in the literature for the determination of the mechanical behavior of stone and mortar; the values shown in Table 2 have been used for the analysis. Taking into account these and using semi-empirical expressions [14], the values of masonry compressive and tensile strength, have been calculated.

Material	Strength		Elastic Modulus	Poisson ratio
	Compressive	Tensile		
porous stone (f_{bc})	10 MPa	-	-	-
mortar (f_{mc} & f_{mt})	0.75 MPa	0.15 MPa	-	-
masonry (f_{wc} & f_{wt})	1.13 MPa	0.20 MPa	1130 MPa	0.3

Table 2: Mechanical characteristics of all materials used

2. For the simulation of the structural characteristics, a 3-D finite element model was built, using the Sofistik design software package (Fig. 3). All masonry walls were model using a 4-noded shell element. About 7800 element were needed to model the structure. For the determination of the strains in each element, six degrees of freedom (6 DoF) were con-

sidered. This refers to the motion of a rigid body in three-dimensional space; translation in three perpendicular axes combined with rotation about three perpendicular axes.

Figure 3: The 3-D FEM model of the building

3. Nominal values of dead and live loads were specified in the Greek Loading Codes [18], which are still in effect today. The seismic loads were also specified in the Greek Earthquake Code [19].

(a) Dead loads (G)

LC1: Self-weight of masonry walls, wooden floor and roof.

LC6: Additional dead load for the roof = 2 kN/m^2

(b) Live loads (Q)

LC2: 1st storey Live load = $3,5 \text{ kN/m}^2$

LC3: 2nd storey Live load = $3,5 \text{ kN/m}^2$

LC4: 3rd storey Live load = $3,5 \text{ kN/m}^2$

LC5: Roof Live load (snow & wind) = $1,0 \text{ kN/m}^2$

(c) Seismic loads (E)

The seismic action was examined at X & Y direction and at 45° of X-direction.

LC7: Seismic load – X direction: $\varepsilon_X = 0,08g / 0,12g / 0,16g$

LC8: Seismic load – Y direction: $\varepsilon_Y = 0,08g / 0,12g / 0,16g$

LC9: Seismic load – 45° of X direction: $\varepsilon_{45^\circ} = \varepsilon_X (\sqrt{2})/2 + \varepsilon_Y (\sqrt{2})/2$

According to the Greek Seismic Code, the seismic zone at the city of Patras is category B, which corresponds to a ground acceleration of $0.08g$. However, in Paragraph 5 of the code

is highlighted that for parapets and independent masonry walls, the stability and seismic analysis, must be carried out considering a value twice the one indicated; hence the ground acceleration is taken 0.16g for the analysis.

Based on the different loads the following combination actions have been used.

Combination with earthquake

LC21: $G + Q = (LC1+LC6) + (LC2+LC4+LC4+LC5)$

Combination with earthquake

LC31: $G + Q + E_x = (LC1+LC6) + (LC2+LC4+LC4+LC5) + E_x$

LC32: $G + Q + E_y = (LC1+LC6) + (LC2+LC4+LC4+LC5) + E_y$

LC33: $G + Q + E_{45}^0 = (LC1+LC6) + (LC2+LC4+LC4+LC5) + E_{45}^0$

LC41: $G + Q - E_x = (LC1+LC6) + (LC2+LC4+LC4+LC5) - E_x$

LC42: $G + Q - E_y = (LC1+LC6) + (LC2+LC4+LC4+LC5) - E_y$

LC43: $G + Q - E_{45}^0 = (LC1+LC6) + (LC2+LC4+LC4+LC5) - E_{45}^0$

X-direction is perpendicular to the front view of the building (longitudinal direction).

Y-direction is parallel to the front view of the building (transverse direction).

4. Carrying out the Finite Element Analysis, biaxial stresses σ_x and σ_y , shear stress τ_{xy} , as well as displacements and rotations have been calculated, using all the different load combinations described previously. The Sofistik software package provides numerical, as well as graphical, output of the results. The results for a typical masonry wall (Wall 6) is shown schematically in Fig. 4 for the biaxial stresses σ_x and σ_y and the shear stress τ_{xy} .

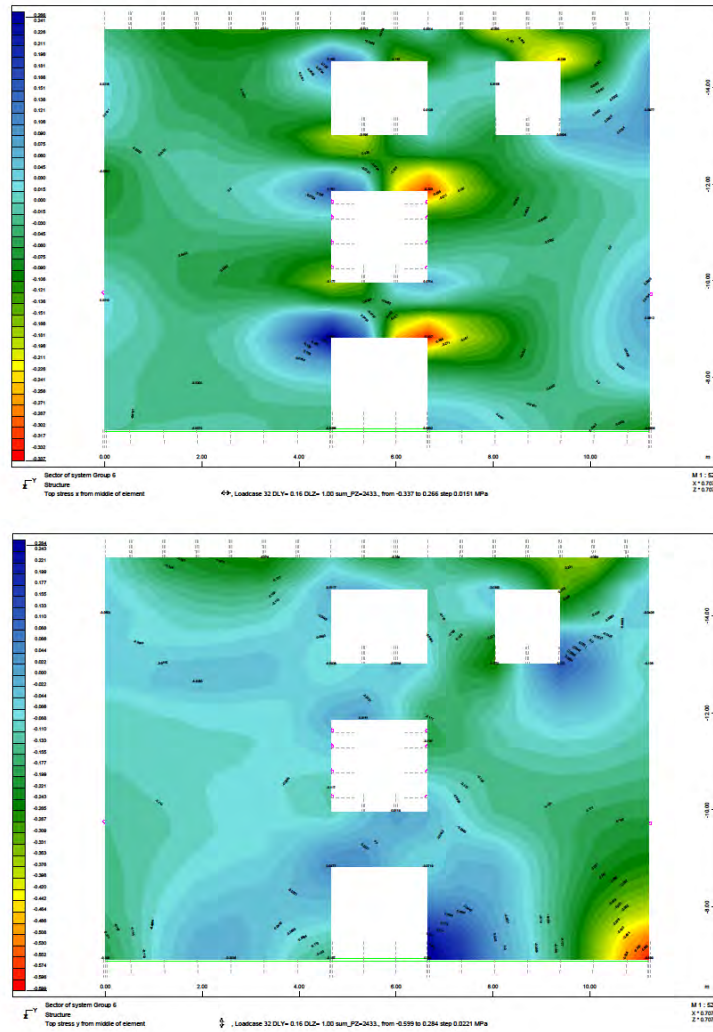

Figure 4: Typical graphical output for biaxial stresses σ_x and σ_y and shear stress τ_{xy} respectively before interventions

5. A spreadsheet has been established for the failure check of each element. 1st column denotes the number of element; 2nd – 9th columns are the internal forces and stress; 10th – 12th columns are the biaxial stresses σ_x and σ_y , shear stress τ_{xy} ; last two columns show the application of the failure criterion proposed by Asteris et. al [17]. This spreadsheet gives also for each of the walls or for the whole structure and for each loading case, statistics for the number of failure points and the type of failure. This information provides a general view for the probable damage level and the main type of damages of the structure. This is shown in Table 3 for a typical masonry wall (Wall 6).

All the different types of failures have been inserted back to the Sofistik model and a corresponding illustration of the walls is obtained (Fig. 6). These diagrams have been proved very useful for the extraction of the required conclusions about the general type of the failures in the structure, as well as for decision making concerning the type and the extent of interventions.

Figure 6: Illustration of failed elements and type of failure for a typical masonry wall before interventions (Wall 6)

	Type of Failure				
	1	2	3	4	5
LC31	42.6	3.9	7.0	3.9	42.6
LC32	58.5	5.6	6.7	2.8	26.4
LC33	55.6	4.9	6.0	2.8	30.6
LC41	39.44	5.28	7.39	3.52	44.4
LC42	46.5	4.9	6.7	3.2	38.7
LC43	47.5	4.9	6.3	5.3	35.9

Table 3: Percentage (%) of failed elements and type of failure for a typical masonry wall (Wall 6)

6. Following the last conclusion, appropriate decisions for the repair and/or strengthening process of the structure have been taken. It was decided to strengthen most of the walls by concrete jacketing the one side of the masonry walls with a thickness of 8 cm and provision of appropriate additional reinforcement (typically $\Phi 10/15$). For the reanalysis of the structure, the new data concerning values of material characteristics, loading and structural layout have been evaluated. The strengths of the new composite materials are modified as following: $f_{wc}=1.51$ Mpa, $f_{wt}=0.35$ Mpa. The results of the analysis after the proposed interventions have shown a significant decrease of the stress levels and thus a significant decrease of the failed elements within the wall.

4 CONCLUSIONS

In this paper, the earthquake resistant design of masonry structural system is discussed, in terms of finding an appropriate failure criterion and then applying an efficient strengthening strategy. A review of numerous failure criteria from various researchers are discussed. A non-dimensional anisotropic masonry failure criterion under biaxial stress state is presented and used in an real masonry structure. The results of the analysis have shown that this crite-

tion is applied successfully and useful conclusions have been provided for the earthquake resistant of the structure. The graphical determination of all failed areas for each wall is important. Especially the categorization of those areas according to the type and intensity of stresses is particularly useful, because the designer can decide on the length and type of intervention. The reason is that some areas may fail due to biaxial compression and others due to biaxial tension and thus different treatment would be need for each case. The case study has shown that the decisions for strengthening each masonry wall separately, based on the failure criterion applied, is successful when comparing the two walls before and after intervention.

Abstract. *Out-of-plane failure is a very common failure mode of unreinforced masonry walls. After earthquake events in Germany (Albstadt 1978, Roermond 1992) damage due to out-of-plane loading was one of the main problems observed. Especially the failure of infill walls and gables was dominated by out-of-plane instability. Since these walls have a relatively low vertical load level, the out-of-plane stability is mainly governed by the slenderness, the thickness of the wall and the bending stiffness parallel and orthogonal to the bed joints, which depend on the bending stiffness of the masonry units, the mortar used, the interconnection between the units as well as the unit geometry and the connection to adjacent constructional elements. In general, current codes only provide limit values for the wall slenderness that are based on experimental results and engineering experience, and simple design concepts based on traditional, force-based design procedures. However, recent research has shown, that masonry walls subject to dynamic out-of-plane loading have deformation reserves exceeding the deformation capacity calculated using traditional, force-based design.*

In order to further investigate the deformation capability of dynamically out-of-plane loaded unreinforced masonry walls, a detailed 3D numerical model on the meso-scale has been developed using the FE toolkit ABAQUS. The model is able to reproduce typical failure modes of single wall panels with different boundary conditions and varying vertical load levels. It is used to investigate and classify the different influence parameters. The results shall be used to define new and refine existing constructional rules. Also, a simplified concept for a dynamic stability check shall be derived.

The paper gives an overview of the current state of the research. It addresses typical problems that arise in the development of numerical models for out-of-plane loaded masonry walls for seismic loading. The numerical model and the results from static and dynamic calculations are presented and - where possible - compared to experimental data.

1 INTRODUCTION

The behavior of out-of-plane loaded, unreinforced masonry wall panels subject to dynamic excitation such as seismic loading is very complex and – up to today – not yet entirely investigated and understood. In 1992 Paulay and Priestly [1] already described this subject accurately with the words:

„one of the most complex and ill-understood areas of seismic analysis“

The out-of-plane failure often happens at earthquake intensities with amplitudes much lower than the ones that are necessary to produce significant in-plane damage. Knowledge about the stability and vulnerability in the out-of-plane direction is therefore absolutely necessary.

Documented experimental investigations in this area of research were carried out as soon as 1802 (Rondot [2]). Recent observations after different earthquake events have shown that in many cases wall failures due to out-of-plane loading resulted in greater damage than in-plane failure mechanisms.

Especially walls with low vertical load levels are vulnerable to out-of-plane loading. Out-of-plane damage can hence often be found in the upper stories and for poorly braced gable walls as shown in Figure 1.

Figure 1: Out-of-plane failure after the earthquake in Albstadt, Germany, 1978 (Photos: Peter Doll)

Traditionally, masonry is regarded as a brittle material with little ductility and is therefore considered to be especially vulnerable to its peak load bearing capacity resulting from the peak ground acceleration. Nowadays it is generally known that the calculated force-based loading capacity plays a subordinate role when it comes to the investigation of the dynamic stability of out-of-plane loaded wall panels. Recent results from current research projects have shown that after the calculated, static, force-based load bearing capacity is achieved, there are still very considerable reserves resulting from the deformation capabilities of the wall ([3], [4], [5]). Dynamically loaded walls are able to withstand accelerations that cannot be achieved with static loading. This discrepancy clearly reveals that the mechanisms leading to out-of-plane wall collapse are not yet entirely investigated and understood.

2 NON-LINEAR WALL BEHAVIOR

The highly non-linear behavior of unreinforced, masonry wall panels subject to out-of-plane loading is mainly governed by stability mechanisms while the calculated static load-

bearing capacity is of fewer relevancies. This complicates the description of the relevant failure modes and the associated kinematic model. Figure 2 shows a typical load-deflection curve of a one-way spanning out-of-plane loaded masonry wall panel.

Figure 2: Qualitative load-deflection-curve of an out-of-plane loaded masonry wall panel

The wall panel exhibits a linear elastic behavior up to the point when the static force-based load bearing capacity is reached. The wall typically develops cracks around its mid-height as well as at its top and its base. It is split into single segments that rock around these pivot points which allows the wall to deform significantly until its point of instability.

It seems reasonable to take these apparently present non-linear reserves in the post-peak domain into account. Clearly, second order effects become more important due to the large deformations. A part from the physical nonlinearity, the geometric nonlinearity is increasingly important and has to be taken into account.

For now the ongoing challenge is the development of simple and feasible models that are able to reproduce this complex behavior and hence the derivation of a modern verification procedure.

3 STATE OF THE ART

The research focus of the past years in Germany was certainly put on the optimization and the determination of the behavior of masonry shear walls and accordingly on the development of a feasible concept for the approximation of in-plane capacity curves opening the way for a deformation based design concept. Consequently, usable verification concepts with a realistic depiction of the actual dynamic behavior of out-of-plane loaded masonry walls are missing until today.

Current design codes usually determine the bending capacity based only on the calculated, static load carrying capacity. E.g. in Eurocode 6 [6] two bending capacities parallel and orthogonal to the bed joints are calculated using the tensile capacity in each direction and the static moment. Beneficial influences of an existing vertical compression may be taken into account by increasing the tensile strength for bending parallel to the bed joints. It should be mentioned that Eurocode 6 [6] clearly excludes the use of this method for seismic design.

It is interesting to notice that Eurocode 8 [7] ignores the subject of the out-of-plane stability of load-bearing masonry walls. There are neither instructions for the determination of the seismic input onto the wall nor a concept for the approximation of the dynamic stability leaving it up to the structural engineer to find a practicable way for the seismic verification. Quite often the seismic input is hence determined by using the definition for non-structural compo-

nents that may be an acceptable approximation in many cases. However, for very important non-structural components and for components that represent a potential risk, a seismic verification using a realistic model and realistic response spectra that take into account the filtering effects of the structure is required. Feasible guidelines for this kind of verification are not included in Eurocode 8 [7].

Some limit values for structural shear walls are included in Eurocode 8 0. In detail these are limits for the thickness, the slenderness and the aspect ratio that are defined in dependence on the seismic zone. Moreover, the national annex of Germany requires all gable walls to be properly braced by transversal walls or pilaster strips if they are not positively anchored to the roof structure. This directive is probably based on the observations after the earthquake in Albstadt in 1978 where these walls were identified to be especially vulnerable to out-of-plane loading.

This clearly shows that further research into this field of seismic engineering is inevitable. The outcome of the research should be a new verification concept that allows for a quick and easy verification based on limit values and also provides guidance for a more advanced investigation of the dynamic stability using displacement-based approaches.

4 NUMERICAL SIMULATIONS

In order to contribute to the development of a feasible deformation-based design concept for unreinforced masonry walls subject to out-of-plane seismic loading, numerical models have been developed. The most recent model was developed using the FEM code ABAQUS [8] which provides powerful material models out-of-the-box. For the current research a 3D model on the meso-scale was chosen. It uses the concrete damage plasticity constitutive law for the bricks and a cohesive contact law to represent the bond between the single bricks [9].

4.1 Assembly

In order to be able to use a 3D model and to fasten up the numerical computations, a few assumptions and simplifications had to be made. All the constraints such as walls or ceilings were reduced to simple concrete beams, which represent the boundary conditions given by adjacent components, with a simplified linear elastic material law. The concrete beam at the top is able to perform vertical movements ensuring a constant vertical load level within the wall. The dimensions of the thin bed mortar joints are neglected.

4.2 Material model

The developed model on the meso-scale consists of individual bricks, which are able to interact between each other and the surrounding concrete beams. Two different materials were used for the bricks in the simulation: calcium silicate and autoclaved aerated concrete. The damaged concrete plasticity material model (CDP), which is included in ABAQUS by default, was used for the material idealization. The masonry bricks are assumed to fail either due to tensile cracking or compressive crushing. The CDP also considers the degradation of the elastic stiffness due to damage and accounts for stiffness recovery effects. It is hence suitable for simulating cyclic loading conditions such as earthquakes.

4.3 Interactions

Each surface needs to be able to interact in every direction with its neighboring surfaces. While pressure and friction can be directly transferred between the surfaces, traction as well as shear forces are delegated through the adhesive effect of the mortar. Since modern high-performance masonry walls in Germany are usually built using precision blocks in combina-

tion with thin-bed mortar joints, there is no need to explicitly model the mortar joints. Consequently, the mechanical properties of the joints were defined as interaction properties between the surfaces. Several interaction forms were used to model contact in the different directions.

Pressure can be transferred directly by using the ‘hard contact’ formulation which propagates forces only when the surfaces are in contact and prevents the penetration of surfaces as ‘pressure overclosure’ is avoided. Shear forces and traction forces are transferred using cohesive interaction behavior. The underlying concept is a traction separation law, which allows the definition of stiffness for each direction. With this, a small elastic deformation of the mortar joint was defined in combination with the specification of maximum strain, damage evolution and failure of the joint.

During the investigations, friction wasn’t taken into account since friction failure is not considered relevant for the investigated walls.

4.4 Gravity

To obtain realistic results, gravity was applied to all models. When using gravity loads in explicit analyses, inertia effects must be taken into account. Otherwise it may occur that the wall bounces slightly, which can be shown by recording the vertical reaction forces at the bottom of the wall. The magnitude of the oscillations of the reaction forces varies depending on the walls’ boundary conditions as well as the used material definitions and the used contact interactions. Especially the use of the ‘hard contact’ formulation amplifies the effect since overclosure of the surfaces is prevented. In order to eliminate such disturbing phenomena induced by the wall’s inertia, the gravity load was applied in a separate analysis step where it was increased in small increments over a period of time.

4.5 Problems during numerical investigations

Within the scope of the of the FE-analysis 8-node-hexaeder elements type C3D8R were used for meshing the walls. During the calculations unrealistically large deformations occurred as shown in Figure 3.

Figure 3: Hourglassing effects

These deformations were classified as hourglassing effects, which often happen when using plastic material behavior in dynamic response analysis combined with reduced integration in explicit analysis steps. Several measures for controlling the hourglassing effect were tested. As a result, a mesh refinement in combination with the use of ‘enhanced hourglass control’ was determined to be the most effective way to reduce such unrealistic deformations. Problems with the enhanced stiffness causing wrong results weren’t encountered.

5 SPECIMEN

5.1 Static specimen

In order to test the quality of the model, static tests were carried out and compared to real life specimen found in literature. In these tests a horizontal distributed load was applied to the wall's back while the wall's horizontal displacement was recorded. An example of the wall's geometry is shown in Figure 4 whereas Table 1 gives an overview of the tested walls' dimensions. All four walls are made of AAC precision blocks in combination with a thin-bed mortar.

Figure 4: Example of unmeshed and meshed tested wall

	H/L	Height [m]	Thickness [mm]	Supports
JW1	0,5	3,0	240	4-sided
JW2	0,5	3,0	175	4-sided
JW3	1,0	3,0	240	3-sided
JW4	2,0	3,0	240	3-sided

Table 1: Overview of tested static walls

5.2 Dynamic / cyclic Specimen

	H/L	Height [m]	Thickness [mm]	Material	Supports	Acceleration
W1a	2,0	3,0	240	AAC	1-sided	ZVL 8
W1b	2,0	3,0	240	AAC	1-sided	El Centro
W1c	2,0	3,0	240	CS	1-sided	El Centro
W2a	1,5	1,5	110	CS	2-sided	El Centro
W2b	2,0	3,0	240	CS	2-sided	ZVL 8
W2c	2,0	3,0	240	CS	2-sided	ZVL 8
W3a	1,0	3,0	240	AAC	3-sided	ZVL 15
W3b	1,0	3,0	240	CS	3-sided	El Centro
W4a	1,0	3,0	240	AAC	4-sided	ZVL 8
W4b	1,0	3,0	240	CS	4-sided	ZVL 8

Table 2: Overview of tested dynamic walls

For research on the behavior of masonry walls subjected to dynamic loading, the geometry of the static walls was used while the distributed load was changed to a horizontal gravity load. The gravity was only distributed to the bricks in order to give conclusion to an equiva-

lent distributed load. Two artificial accelerations (ZVL 8, ZVL 15: $a_{\max} \approx 0,8\text{m/s}^2$) as well as the El Centro accelerogram record ($a_{\max} \approx 3,0\text{m/s}^2$) were used to simulate different input motions. The geometries of the tested walls were derived from the static specimen. Different types of walls such as parapet walls or vertically spanned walls as well as 3-sided and 4-sided constraint walls were tested. A full list of the specimen tested under dynamic gravity load is given in Table 2. The dimension of the bricks as well as the properties of the mortar were chosen according to the experimental test results provided by [10] and [11].

6 RESULTS

6.1 Static specimen

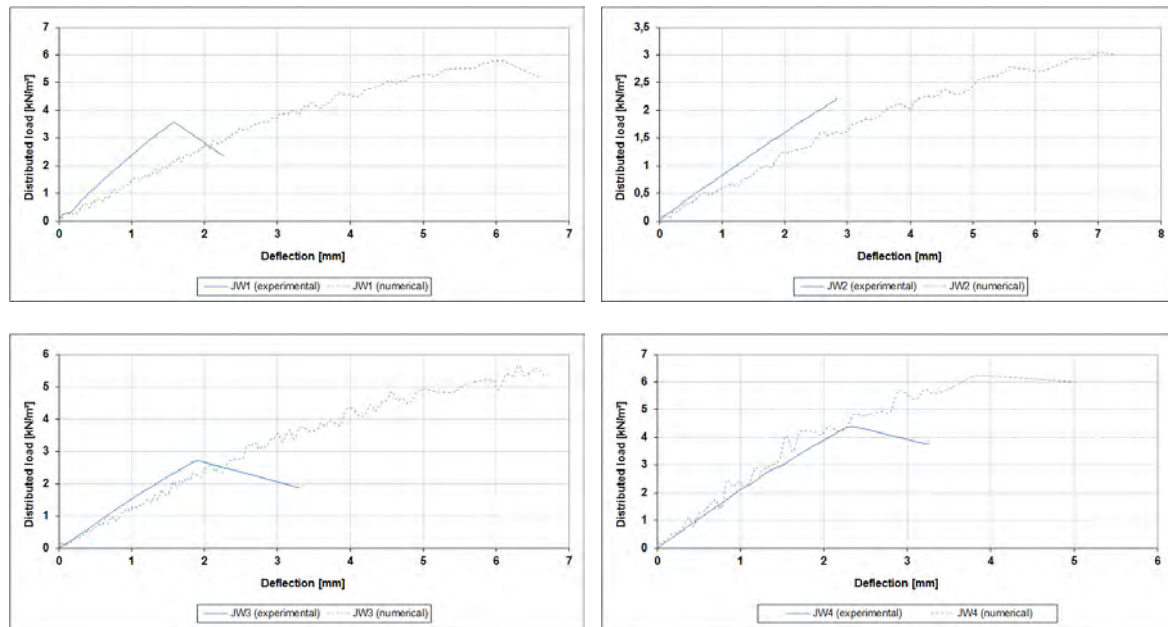

Figure 5: Results of static specimen

Figure 5 gives an overview of the numerical simulations compared to experimental tests found in [11]. In general the results show a good correlation considering the initial stiffness. However, big differences are present for the load bearing capacity and the deformation capability. This may be caused by several reasons. Firstly, the numerical model did not accurately reproduce the boundary conditions of the experimental tests, where the wall was built into a steel frame instead of being held by concrete beams. Moreover, there was no vertical load applied in the experiments while there was a concrete beam at the top charging the wall in the numerical simulations. It is also questionable whether or not the CDP constitutive law correctly described the material behavior since detailed information on the used bricks are not available. There is also a difference in the way the deflection was recorded. While the maximum displacement was used in the numerical model, the experimental testing setup had fixed reference points that did not necessarily provide the exact same deflections.

The failure mechanisms of the numerical walls give the expected results as shown for example in Figure 6. Failure at the 4-sided walls started about mid-height in the middle of the wall whereas the failure of the 3-sided walls started about mid-height of the free side. Crack propagation proceeded to the edges of the constraint sides.

Figure 6: Failure of wall JW1 and wall JW3

6.2 Dynamic specimen

The different wall types showed specific buckling behavior resembling the typical behavior of such walls subjected to dynamic loadings. As an example the results of the parapet wall W1a and the results of the vertically spanned wall W2b are presented. These two walls were subjected to the same excitation. The parapet wall started quickly to buckle. The top of the wall deflected the most as shown in figure 5 while the joints at the bottom of the wall started to open slightly. Complete failure of the wall wasn't achieved, but small plastic strains occurred at about height of the bottom joints. The maximum deflection is about 4 mm as can be seen in Figure 7.

Figure 7: Comparison of (scaled) deformation of wall W1a (left) and wall W2b (right)

The vertically spanned wall has been supplied with an additional vertical load due to the top concrete beam. As a consequence of the added supply, the achieved deformations were smaller, just up to about 0,23 mm as shown in Figure 8. The biggest deflection occurred about mid-height of the wall. No plastic deformations were produced during this conducted test. The upper half of the wall bends due to the excitation.

Again, the results of the presented model show a good approximation of the overall behavior while the maximum deflections differ significantly when compared to experimental results found in [5]. In an attempt to verify the model, one of the walls tested in [5] was modeled. It showed maximum deformations significantly smaller than in the experiment. However, it has to be noted, that the construction type used in the experiments (general purpose mortar) is different from the one that the numerical model is intended for. It is therefore not surprising that the numerical model of the current German construction type with thin bed mortar and modern high performance masonry units has a greater stiffness and hence smaller deformations.

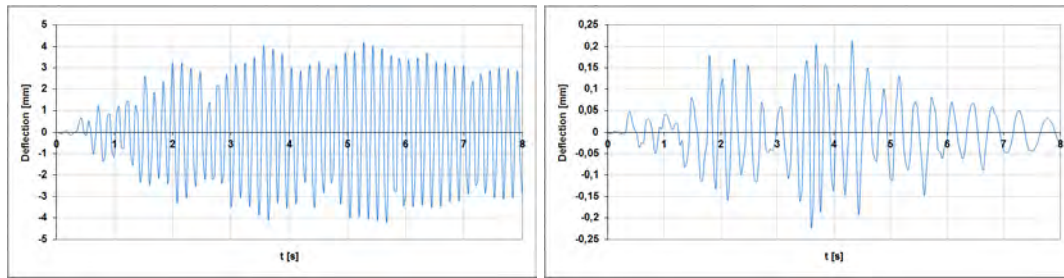

Figure 8: Comparison of deflection of wall W1a (left) and wall W2b (right)

In closing it can be said that the presented model is capable of modeling the failure modes and initial stiffness of an out-of-plane loaded wall made of modern high performance masonry sufficiently well. However, there are still great deficiencies when it comes to predicting the load bearing capacity and the deformation capability.

In its current state, the model cannot yet be used to do parametric tests in order to derive and verify e.g. load-deflection curves. It is already being used to study the typical cracking patterns as a function of the wall and unit geometries and hence the kinematics of cracked wall panels.

7 DISCUSSION

The presented numerical model is able to realistically simulate the typical failure modes of out-of-plane loaded unreinforced masonry walls. It provides a strong basis for comprehensive parametric studies on the influences of the wall geometry, brick dimensions and boundary conditions. Further enhancements are necessary to improve the quality of the results and hence the scope of the model.

The finite element code ABAQUS provides satisfactory results while providing sophisticated material models for brittle material and cohesive contact out of the box.

It is evident, that there is still a high demand for research in the field of seismic verification concepts for out-of-plane loaded unreinforced masonry walls. Basic simplified approaches are already available in European codes but they are very limited and cannot be applied to arbitrary wall configurations. A clear definition for walls not satisfying the provided limit values are still missing.

The development of practicable and efficient verification concepts should result in a multi-stage verification concept.

A more detailed specification of limit values for thickness, slenderness, etc. in dependence on the seismic hazard should be provided along with detailed information on the design of the contact zone between walls and slabs. These values need to be defined for structural as well as non-structural components.

For walls exceeding the limits simplified approaches for a traditional force based design as well as for a typical dynamic stability check is necessary. This requires guidelines for definition of the seismic input as well as a concept for a simplified estimation of the kinematic equivalent system.

The presented numerical model along with future improvements will contribute to this development.

Abstract. *In the framework of a recent EU funded research project, innovative construction systems for clay unit reinforced masonry walls were developed. In particular, one system was developed for low-rise residential buildings. An extensive experimental program was mainly aimed to understand the cyclic in-plane behavior under shear and compression loads. The tests results were compared with code proposed formulations for the evaluation of shear strength, in order to check their reliability in predicting the ultimate load capacity of reinforced masonry walls. A new calibrated formulation is proposed. A FE continuum micro-model was calibrated on the experimental results and then used to carry out parametric analyses of the reinforced masonry system, to investigate the influence of the axial load level, the aspect ratio and the reinforcement ratio on the global in-plane behavior of the tested walls. A new analytical hysteretic model was also developed and used to carry out non-linear dynamic analyses of SDOF systems, to evaluate the reduction of the elastic response of reinforced walls, for a range of natural periods that characterize the elastic phase of load bearing masonry buildings.*

1 INTRODUCTION

Reinforced masonry (RM) was developed to exploit the strength potential of masonry and solve its lack of tensile strength [1] while significantly improving resistance, ductility and energy dissipation capacity with respect to unreinforced masonry (URM) [2, 3]. In the last few decades, a large variety of RM techniques have been made available. Many RM systems around the world are based on the use of hollow concrete [4, 5] and clay units [6], which are reinforced with steel bars and grouted with concrete. Other RM systems, traditionally developed in Europe, make use of perforated clay units combined with concentrated vertical reinforcement, [see, for example 7, 8, 9, 10].

Generally, RM systems are designed for low rise residential buildings in seismic areas, which resist horizontal earthquake actions with the walls parallel to the seismic actions, according to the box-type behavior [1]. Therefore, the main aim of any experimental and numerical study is to assess the behavior under in-plane cyclic actions. In the case that seismic design of this type of buildings is based on linear elastic methods of analysis, the evaluation of the strength capacity (ULS) and the numerical values of the seismic behavior factor (q-factor) to reduce the elastic design spectrum, are crucial. The shear strength of RM is generally evaluated as the sum of the contributions of unreinforced masonry and horizontal reinforcement [11, 12, 13, 14], where many issues regarding the evaluation of masonry strength and horizontal reinforcement efficiency are still open [15]. On the other hand, the q-factor has been recognized in the Italian code [12] to be implementing an “overstrength” ratio also in the case of masonry buildings [16, 17], and its values can be higher if capacity design principles are pursued, whereas the European code [18] does not provide these possibilities. Furthermore, more rational design methods, based on non-linear analyses, are being developed [see, for example 19]. Nevertheless, to adopt them, it is necessary to give deformation/drift limits that should be used, suitably revised on the basis of the more recent construction systems and available experimental information [20].

In this context, a RM systems for use in low rise were recently developed [21] and tested [22]. The main aims of the experimental and numerical work were to study the behavior in relation to the above mentioned issues.

2 STUDIED REINFORCED MASONRY SYSTEM

The RM system developed for low rise residential buildings is based on the use of concentrated vertical reinforcement, similar to confined masonry. Special clay units are laid with horizontal holes, with recesses for horizontal reinforcement on the bed faces (Figure 1 left). Vertically perforated units are used for the confining columns. Vertical reinforcement placed in the cavities of the confining columns is composed of steel bars ($0.130\% \div 0.173\%$); horizontal reinforcement may be made of either steel bars or prefabricated steel trusses (0.045% and 0.040% respectively). The main advantages of the system are related to durability and construction process: placing the horizontal reinforcement inside mortared recesses improves reinforcement durability, makes reinforcement positioning easier and more precise, and allows good bond at the interface unit/ mortar and mortar/reinforcement. In addition, this technique is traditionally adopted in Mediterranean countries to improve thermal insulation. As regards mechanical behavior, this system is conceived to perform as RM, provided that units with horizontal holes are effective in bearing the horizontal loads and transferring them to the confining columns, without showing fragile behavior. More details about this system can be found elsewhere in [22] and [23].

Figure 1: RM system (left) and shear-compression test setup (right).

3 OVERVIEW OF THE MAIN EXPERIMENTAL RESULTS

The seismic performance of the proposed RM system was evaluated by means of in-plane cyclic shear compression tests (Figure 1 right), carried out with cantilever boundary conditions. Fourteen full-scale masonry specimens were tested differentiated by: presence or absence of vertical reinforced confining columns, use of steel bars or prefabricated trusses as horizontal reinforcement, aspect ratio and value of applied axial load, to force both shear and flexural failure modes.

The test results allowed evaluating the influence of the above aspects on the main seismic parameters of RM walls, such as strength and displacement capacity, energy dissipation, viscous damping, stiffness degradation [22, 24, 25].

In general, the failure mechanism strongly influenced all the measured seismic parameters. The tests showed that: the different types of horizontal reinforcement did not cause significant differences in global mechanical behavior, the horizontally perforated units are adequate in bearing the horizontal loads between the confining columns, and the interaction between the inner portion of the wall and the confining columns does not cause premature failure. The ultimate drift θ_u ranged from a minimum value of 0.7% for shear failures to values exceeding 1.7% for flexural failures. These values satisfy the limits associated to ULS for shear (0.6%) and flexural (1.2%) failures of RM walls, adopted by the Italian norms, but the European norms do not provide any drift limit for in-plane response of RM walls. The ductility ratio μ , moves from 2.5 to 4.0 for shear failures and from 3.5 to 6.0 for flexural failures, according to the axial load level. The ratio between dissipated and input energy was around 30%. The values of viscous damping were around 5%, and tended to increase in the post-peak phase.

4 EXPERIMENTALLY BASED MODELING

4.1 Shear strength evaluation

The shear capacity of RM walls is governed by several global and local resisting mechanisms. In general, the combination of vertical and horizontal reinforcement leads to the development of a global mechanism, which lies in between the arch-beam and truss mechanism [1, 26]. While the flexural strength of RM walls is relatively easy to calculate according to theoretical models, the shear strength, due to the complexity of the mechanism, is generally calculated as a sum of contributions, better than on the basis of theoretical models. Four main contributions are usually considered by formulations proposed to predict the nominal shear strength V_R of RM walls: V_m is the shear strength of URM, V_p is the contribution of axial

load, V_s is the contribution due to horizontal reinforcement and V_{dw} is the contribution due to dowel-action of vertical reinforcement.

A crucial issue for the shear strength formulation is the efficiency of the horizontal reinforcement, which vary between 30% and 100% according to the various formulations available in literature [see for example 11, 12, 13, 14, 27, 28, 29, 30]. The shear reinforcement effectiveness, evaluated by means of strain gauges, was about 60%, in the present experimental tests, which is consistent with the values provided by codes such as the Italian and American standards [12, 13], and proposed by researchers such as Tomaževic and Anderson-Priestley [1, 28].

As a consequence of an extensive analyses of the shear strength formulations and the comparison with the present experimental data [22, 15], a calibrated formulation for shear strength evaluation has been proposed:

$$V_R = V_m + V_s = \left(\frac{f_t}{b} \cdot \sqrt{\frac{\sigma_0}{f_t} + 1} \right) \cdot td + 0.6 \cdot \frac{dA_{rh}f_y}{s} \quad (1)$$

The equation (1) is based on the Turnšek and Čačovic criterion [31] for evaluating V_m , which implicitly accounts for the contribution of axial load V_p , and which is consistent with the diagonal cracks experimentally observed. The contribution of horizontal reinforcement V_s , is calculated in equation (1) as for stirrups in reinforced concrete members [as in 12, 13], taking into account the number of stirrups, each of area A_{rh} , across the diagonal crack (with 45° slope, d is the effective length of the wall section and s the spacing of the stirrups). The 0.6 reduction coefficient corresponds to the shear reinforcement effectiveness experimentally evaluated.

The comparison between equation (1) and the experimental data is given in Figure 2.

Figure 2: Shear equation and numerical trend vs experimental data.

4.2 Numerical modeling

A simplified micro-modeling strategy with continuum elements and no unit-mortar interface elements was adopted for modeling the envelope of cyclic behavior of the RM walls under study. The model properties were derived from experimental tests. The Total Strain Rotating Crack isotropic damage model [32] was adopted for mortar and blocks. The steel reinforcement was described by means of elasto-plastic Von Mises yield criterion, and had the shape of a line, full bonded and embedded in all the plane stress elements that define the wall

geometry. Considering the type of model used, it was not possible to make a distinction between the truss and the bar reinforcement used. The analyses were carried out using the code DIANA. Eight-node isoparametric plane-stress elements with Gauss integration scheme were used in the models. The Newton-Raphson iteration procedure was used with a displacement control and an energetic convergence criterion. The values of fracture energy of masonry in tension (G_{ft}^I) and in compression (G_c) were found by means of extensive literature research, summarized into a database valid for masonry structures [33, 34]. Other parameters that were not directly available from the experimental tests carried out are the tensile strengths of the masonry components. The calibration process of the model was carried out starting from uniaxial compression tests, and aiming to solve some defects of the model such as the full-bonded hypothesis used for embedded reinforcement, which is not realistic.

Figure 3 compares the average of the experimental hysteresis loops envelope (H_{med} curve) obtained by the shear compression tests, and the numerical results (Numeric curve), for the specimens failed with shear and flexural mechanism, under axial load of 0.6 N/mm^2 . The models slightly overestimate the initial stiffness and reproduce the maximum horizontal load with an average error of about $\pm 5\%$. Displacements were generally underestimated, but the values of ultimate displacement (when a sudden drop of strength occurs), are in agreement with the experimental ones (average error $\pm 15\%$), as can be seen in Figure 3.

Figure 3: Experimental hysteretic envelopes and numerical pushover analysis: shear failure (left) flexural failure (right).

On the basis of calibrated models, we carried out an extensive parametric study [35, 22] to evaluate the influence of different parameters, such as axial load level, aspect ratio, and amount of vertical reinforcement, on the in-plane behavior of RM walls. The results gave indication about the reliability of the shear strength formulation proposed by equation (1), compared to other formulations available in codes and in the literature. It was possible to confirm the proposed relation between horizontal load and applied axial load, as reported in Figure 2.

In addition, it was found that the contribution of vertical reinforcement is essential for RM walls, since it changes the behavior from rocking mechanism, typical of URM wall, characterized by premature crushing of compressed toe with consequent numerical instability, to a flexural mechanism which leads to higher strength and displacement capacity. When the vertical reinforcement ratio was higher than 0.2%, the walls failed in shear with a limited ductility. This worsening of the wall behavior is more marked for slender rather than for squat specimens.

The parametric analysis on the aspect ratio allowed observing that the maximum shear stress presented a non-linear decrease with increase of H/L ratio.

4.3 Analytical modeling and dynamic analyses

To reproduce the experimental cyclic behaviour, a new hysteretic model was developed. The model was based on the quadri-linear envelope curves defined by the four limit states, and given in [36], and on energy considerations and stiffness degradation rules. Starting from some observation about the shape of the experimental hysteretic cycles [37], the cycles were modelled on the basis of four main points (A; B; C; D) and their symmetrical. These points were found on the basis of the parameters C_1 and C_2 , which depend on the amount of the absorbed and dissipated energy during the cycle, and Z , which is a ductility parameter. Figure 4 (left) shows the geometrical scheme for the loops' construction. The slopes of the various loading and unloading phases are given by stiffness parameters, as in [38]. Other two parameters, R_1 and R_2 , are used to model the repeated cycles on the basis of the ratio between input and dissipated energy in the first and, respectively, the second and the third cycle. Overall, the model uses four independent parameters, and the others are all based on those. A more detailed description of the model features is given in [39]. Figure 4 (right) shows the good agreement between the experimental hysteresis loops and those generated by the model.

Figure 4: Scheme for the loops' construction (left) and experimental vs numerical hysteresis loops (right).

The developed analytical model was used to carry out non-linear dynamic analyses in order to evaluate the reduction of elastic response of RM walls due to their hysteretic behaviour. They were executed on a SDOF system, using a group of 10 synthetic time-histories, compatible with the spectra of national code. The analyses were carried out for a range of natural periods between 0.10 and 0.5 s, and they were repeated for each soil group classified by the Italian code [12]. Analyses were carried out on the basis of the given value of ultimate ductility factor μ , obtained during tests. The aim was to estimate load reduction factor R_μ due to energy dissipation and non-linear behaviour of the RM system, taking into account shear and flexural failure modes. 2160 analyses were carried out and the obtained values for R_μ were variable with the soil type, axial load level and failure mode. The study of the results, obtained from the dynamic analyses [37], allowed to observe that for natural period of 0.15÷0.20 s, characteristic of masonry buildings, the load reduction factors value is confirmed to be of 2.5 and 3.0 that the Italian norm suggests, respectively for RM failing in shear and in flexure, the latter being associated to the application of capacity design principles. It should be pointed out that the same range of values, regardless of the failure mode, is also given by [18], but as final values of q-factors to be adopted (i.e. neglecting overstrength).

5 CONCLUSIONS

- Extensive experimental and numerical investigations were carried out to improve the knowledge of seismic behavior of RM walls and the available design procedures
- New inputs were provided by the tests about the deformation capacity, to be adopted and implemented in non-linear analyses.
- A shear strength formulation derived from the analysis of the available formulations was in good agreement with the experimental results and consistent with the parametric analyses carried out with the developed numerical model
- The role of vertical reinforcement for RM walls was highlighted and a limitation for vertical reinforcement ratio was identified by means of the parametric analyses carried out with the calibrated numerical model.
- An analytical model derived from experimental results was able to account for the cyclic behavior of RM walls. Adopting this model into dynamic analyses, the capability of RM walls of reducing the dynamic response induced by earthquake, was quantified by the load reduction factor. The results confirmed the values reported in Italian code.
- However, taking into account the intrinsic limitation of the present design procedures [40], further analyses are in progress at University of Padova; mainly an analytical fibre model accounting for the shear/flexural interaction has been developed, to be used in direct displacement based design procedures for RM and URM masonry structures.

Abstract. *Pounding between adjacent bridge structures in earthquakes have been investigated by many researchers in the past. However, most of works is performed with an assumption that the considered structures are fixed at their base. If soil-foundation-structure interaction (SFSI) is considered at all then linear soil behaviour is often assumed. Works including nonlinear SFSI is very limited. In this study the influence of non-uniform SFSI is considered. It is assumed that the left bridge structure is fixed at its base, while the soil of the right structure can behave nonlinearly. Each bridge structure with footing and subsoil is described by four degrees of freedom. A macro element is used to describe the dynamic behaviour of the footing and soil. The results show that nonlinear SFSI can have a beneficial effect on the activated forces in the structures. However, compared to bridge structure with linear SFSI more pounding occasions are observed and structural settlement can take place.*

1 INTRODUCTION

In the event of earthquakes seismic waves propagate and arrive at distant bridge support locations with a time delay. Because of the non-uniform development of soil along the bridge the arriving ground motions at adjacent bridge supports are incoherent. This time delay and coherency loss cause then a non-uniform support excitation. During an earthquake interaction between bridge structure, footing and supporting ground occurs. The local soil at adjacent bridge supports is normally not the same. Consequently, unequal soil-footing-structure interaction (SFSI) will take place. Also because of the different dynamic properties of adjacent bridge structures, strong relative movements between neighbouring bridge decks can occur. If the existing gap between the decks is insufficient to cope with the large closing relative movements, pounding will take place. Consequently, damage at girder ends occurs. If the seat length of the bridge deck is inadequately designed then collapse of bridge deck might take place due to insufficient seat length. Even if collapse does not occur, pounding damage can result in a bridge that is functionally disabled.

Bridge damages have been observed in almost all major earthquakes in the past decades, e.g. the 1989 Loma Prieta earthquake [1], the 1994 Northridge earthquake [2], the Kobe 1995 earthquake [3], the 1999 Chi-Chi earthquake [4], the 2008 Wenchuan earthquake [5] and the 2010 Chile earthquake [6]. Figure 1 shows clearly the consequence of strong relative movements at the girder support of the Llacolen Bridge that crosses the Bio-Bio River in Concepcion. The picture is taken by the authors in one of the field investigations of bridge damages due to the 2010 Chile earthquake.

Figure 1. Relative response induced damage of Puente Llacolen in the 2010 Chile earthquake

Researches on the consequence of relative movements for the seismic performance of bridges have been done mainly numerically. Most investigations have been performed under the assumption of uniform ground excitation [e.g. 7] and without considering the effect of SFSI [e.g. 8]. The significance of the influence of the spatial variation of ground excitations has been confirmed [8-14]. Experimental investigations of the effect of spatially non-uniform

ground motions on the development of relative movements between adjacent bridge structures are still very limited [13, 14].

To prevent the occurrence of relative movements most of current design specifications, e.g. JRA [15], Part 2 of Eurocode 8 [16] and most recent CALTRANS [17] recommend that the adjacent bridge structures should have the same or at least similar fundamental frequencies so that the structures will respond to the ground motions mainly in phase. Consequently, relative response between the structures can be avoided or its influence significantly reduces. This is also currently the only suggested measure to prevent pounding damage at the same time to ensure the serviceability of the bridge due to the required small gap of a few centimetres.

Recently, investigations of a possible mitigation measure by installing the so-called modular expansion joints have shown that large relative movements between adjacent bridge structures can be accepted without causing damage to the bridge structures or hinder the functionality of the bridges [10-12].

The significance of nonlinear SFSI has been identified [18-21], however, only very limited works have been performed. This study addresses the influence of unequal SFSI, especially focuses on the consequence of nonlinear SFSI for the development of relative movements between two adjacent bridge structures.

2 SOIL-FOOTING-STRUCTURE SYSTEM AND GROUND EXCITATION

The bridge structures considered are assumed to have the same height of 9 m (Figure 2(a)). Figure 2(b) shows a simplified model of the bridge structures. The multiple bridge piers are described by a collective bridge pier. Each footing is assumed to be rigid with a size of 10 m. The mass of each bridge structure and its footing is assumed to be the same and has the values of 1000 t and 500 t, respectively. The fundamental frequency of the left and right bridge structures with an assumed fixed base is 1.5 Hz and 1 Hz, respectively. Both structures have the same material damping of 5 %.

In the considered cases the supporting ground can be uniform or non-uniform and can behave nonlinearly. The dynamic behaviour of the footing including plastic deformation of sub-soil is described based on soil constitutive models as a macro element with a lumped mass and three degrees of freedom at the centre of the footing [18, 19]. The soil stiffness in the horizontal, vertical and rotational directions is $3.038\text{E}5$ kN/m, $4.594\text{E}5$ kN/m and $9.113\text{E}6$ kNm/rad, respectively. The corresponding damping values are $1.35\text{E}4$ kNs/m, $2.921\text{E}4$ kNs/m and $2.44\text{E}4$ kNms/rad. The soil bearing capacity is described by the strength surface which reflects the soil capability to bear the combined vertical, horizontal and moment loading. In this work a strain-hardening plasticity model for predicting the settlement of shallow foundation on sand proposed by Nova and Montrasio [22] is applied.

Figure 2. Adjacent bridge structures-foundation-soil system.
(a) MDOF systems and (b) simplified two four DOF systems

To limit the influence factors only linear pounding is considered. The pounding element has the stiffness of 5E6 kN/m. It is assumed that the bridge structures and their footings remain elastic during the entire earthquake loading and only uniform ground excitation is considered [Figure 3].

Figure 3. El-Centro ground motions

3 NUMERICAL RESULTS AND DISCUSSION

The effect of linear and nonlinear SFSI on the response of the two adjacent bridge structures can be observed from a comparison of the results with those without considering SFSI. It is assumed that both structures are supported by the same uniform ground. In the case without SFSI, both structures are fixed at their rigid base.

Figures 1(a) and (b) display the time histories of the displacement of the right (u_r) and left (u_l) bridge structures, respectively. The solid grey and dark lines are the displacement without SFSI and with linear SFSI effect while the dash line is the displacement with the influence of nonlinear SFSI.

As mentioned earlier the fundamental frequency of the right and left bridge structures with an assumed fixed base is 1 Hz and 1.5 Hz, respectively. As expected the flexible subsoil has stronger influence on the stiffer left bridge structure. The corresponding fundamental frequency of the structures with subsoil is reduced to 0.79 Hz and 1.16 Hz, respectively. In the considered case SFSI has a strong reduction effect on the displacement of the flexible right bridge structure. The maximum displacement without SFSI is 19.58 cm. The maximum displacement with linear and nonlinear SFSI effect reduces to 14.5 cm and 12.69 cm, respectively. In contrast, linear SFSI has an amplification effect on the left stiffer bridge structure. The maximum displacement without and with linear SFSI effect is 10.09 cm and 10.42 cm, respectively. Nonlinear SFSI has always reducing effect and causes a maximum displacement of only 5.97 cm.

From the displacement time histories one can expect that without a consideration of SFSI a realistic pounding potential of bridges cannot be properly predicted, since supporting ground can alter not only the fundamental frequencies of the adjacent soil-foundation-structure systems but also their response amplitudes and consequently the development of relative responses between the adjacent bridge structures.

Figure 4. Influence of supporting ground condition on the displacement at (a) the right (u_I) and (b) left (u_{II}) bridge girders.

Figure 5. Influence of soil conditions on relative displacement

In Figure 5 the development of the relative displacement u_{rel} is presented. The dash and solid black lines are respectively the development of the relative displacement without and with a consideration of pounding when both bridge structures are assumed to be fixed at their base. The existing gap size of 5 cm can be clearly seen which restricts both girder movements when pounding is considered. The dotted and bold grey lines are respectively the relative displacement with considering nonlinear and linear SFSI effect at the right bridge segment while the left bridge segment is assumed be fixed at the base. Pounding is considered.

From a comparison of the dash and solid thin lines it is apparent that pounding between the adjacent bridge girders reduces the unseating potential of the bridge girders which is indicated by the opening or positive relative girder movement.

The consequence of different soil conditions of the right bridge site can be clearly seen in the pounding development. While an assumption of fixed base bridge structures causes poundings on 18 occasions, when the soil at the right bridge structure remains linear and behaves nonlinearly, poundings only occur on two and five occasions, respectively. It is well known that damage at girder ends is not only influenced by the strongness of the pounding but also by the number of strong poundings. In the considered case SFSI causes a further reduction of the unseating potential which is indicated by smaller positive relative displacement between the adjacent bridge girders. Compared to the linear SFSI case nonlinear soil causes a larger number of pounding occasions and also unseating potential.

Figure 6. Influence of soil conditions on bending moment development.
(a) M_I and (b) M_I and M_{II} due to nonlinear soil

Figure 6(a) displays the influence of soil conditions of the right bridge structure on the bending moment development at the right bridge support. Pounding effect is considered, and it is assumed that the left bridge structure is fixed at the base. The solid thin line indicates the bending moment development when both adjacent structures are assumed to be fixed at their base. The maximum bending moment is 71.5 MNm. The bold grey and dashed lines are the bending moment when the soil at the right bridge site remains linear and can behave nonlinearly, respectively. The corresponding maximum bending moments are 62.08 MNm and 56.58 MNm. In the considered case the simultaneous influence of nonlinear soil and pounding causes the smallest maximum bending moment.

In Figure 6(b) the bending moment at both bridge supports is displayed. Pounding is considered. They have similar development. The maximum bending moment M_{II} at the left bridge support (bold grey line) is only slightly smaller and has the value of 53.9 MNm. However, the consequence of nonlinear soil deformation can be seen in the residual bending moment M_I (dashed line) at the end of the considered time window.

The results show that if the ground is permitted to behave nonlinearly the activated bending moment in the structures can be reduced significantly. In the considered case even though only one bridge site can have nonlinear soil, as long as a large residual settlement of the structures can be avoided, the nonlinear behaviour of soil can be used to reduce the impact of earthquakes on the structures.

4 CONCLUSIONS

In this work numerical analysis of the effect of soil-foundation-structure interaction (SFSI) on pounding behaviour of two adjacent bridge structures is addressed. Three cases are considered: 1) Both structures are fixed at their base; 2) the left bridge structure has a fixed base and the right structure has a linear soil and 3) the soil at the right bridge site can behave nonlinearly. The gap between the bridge girders is 5 cm. It is assumed that both bridge structures remain elastic during the whole spatially uniform earthquake loading. Each of the bridge structures and its supporting soil are described by four degrees of freedom. For the foundation and subsoil a macro element is used.

In the considered cases the study reveals:

- An analysis without considering SFSI effect will produce more conservative results.
- Even if SFSI is considered only on one of the bridge sites the activated forces in the structures can be reduced. This is also the case in terms of pounding occurrence.
- Nonlinear SFSI can further reduce the activated bending moment at the bridge support. However, the number of poundings is larger than that in the case of linear SFSI.

Additional investigations are necessary to have a better understanding of the interrelation between nonlinear SFSI, pounding behaviour and the characteristic of the bridge structures and loading.

Keywords: Earthquake, Passive Energy Dissipation, Shear deformation, Tri-linear model, Yielding Shear Panel Device.

Abstract. *Metal yielding devices have been used in structures for decades to absorb earthquake energy whereby damages to the major structural components could be minimised. A recent technique to exploit the shear deformation of thin metal plates to dissipate energy has given rise to a new yielding shear panel device (YSPD); a thin steel plate is welded within steel a square hollow section (SHS) to form the device. Laboratory test results showed the potential of YSPD in energy dissipation. The behaviour of YSPD is determined by a complex interaction among the thin diaphragm plate, the surrounding SHS and the boundary conditions i.e. the structural elements that connect the device to the parent structure. This paper investigates the load-deformation response of YSPD and proposes a theoretical model to predict the experimental behaviour using the knowledge of the geometry of YSPD and the properties of the material. Previously proposed analytic method based only on the shear deformation of the diaphragm plate is revisited; appropriate modifications are proposed to include the effects of the deformations observed in the SHS and the obvious rotation of the loading plate. A tri-linear load-deformation model is proposed herein and the predictions obtained from the numerical models are compared with the available test results.*

1 INTRODUCTION

Earthquakes cause significant damages to structures resulting in either complete demolition or the affected structures require complex and expensive rehabilitation techniques to be serviceable. Minimization of structural damages due to earthquake is a major area of research which contributed to the development of a number of active, semi-active and passive control mechanisms during the last few decades. The current research investigates the structural performance of a newly proposed yielding shear panel device (YSPD) for passive energy dissipation. YSPD is simple to manufacture and is economical when compared against currently available devices. Tests carried out on the device demonstrate its potential for considerable energy absorption [1]. Hossain et. al. [2] developed finite element models and verified their performance against available monotonic and cyclic test results. An appropriate theoretical model for YSPD is required to understand the effects of this device by analysing structures including different YSPDs. Current paper proposes a tri-linear force-displacement model for YSPD, which is verified against the results obtained from tests and finite element simulation.

2 YIELDING SHEAR PANEL DEVICE (YSPD)

Diagonal tension field that develops in the post-buckling regime of a thin steel plate under shear offers significant strength and ductility and hence can be utilized to dissipate energy. This concept led to the development of a new metallic passive energy dissipating device ‘Yielding Shear Panel Device’ (YSPD). YSPD was introduced by Williams and Albermani [3] based on the design proposed by U. Dorka at the University of Kassel, Germany to exploit the energy dissipative capability of steel plates through in-plane shear deformation and the concept was further explored by Schmidt et.al. [4] and Williams and Albermani [5]. YSPD relies on the in-plane shear deformation of a thin diaphragm steel plate welded inside a square hollow section (SHS). This device can be placed beneath a structural beam using a V-braces so that it automatically comes into play in the event of any horizontal excitation. Figure 1 shows a typical assembly for YSPD.

Figure 1: Typical YSPD-brace assembly.

Chan et. al. [1] conducted a series of monotonic and cyclic tests using various plate thicknesses and device configurations for YSPD. The tested specimens were fabricated using a short segment of a square hollow section (SHS) with a steel diaphragm plate welded inside, as shown in Figure 2. Four bolt holes spaced at a centre-to-centre distance ‘s’ were drilled on

each of the two opposite SHS flanges for connecting the device to the test setup; this connection is analogous to the practical assembly where YSPDs are proposed to be connected using bolts to ensure easy installation and replacement. The SHS provides a boundary to the diaphragm plate so that shear forces can be applied to the plate, in addition to providing necessary detail for connections to the parent structural frame. Most importantly, the SHS serves as a boundary element allowing the tensile strips to be formed and the tension field to be developed following the post-buckling of the thin diaphragm plate. As a result of sufficiently large displacements occurring in the diaphragm plate, the input energy originating from an earthquake could be dissipated through plastic deformation.

Figure 2: (a) Yielding shear panel device (YSPD) (b) Schematic diagram showing the geometric parameters of YSPD [6].

Chan et. al. [1] tested two different sizes of YSPD, $100\text{mm} \times 100\text{mm}$ and $120\text{mm} \times 120\text{mm}$, with three different thickness of 2 mm, 3 mm and 4 mm for the diaphragm plate. Bolt spacing of 50 mm was used for four M16 bolts on each side of the SHS to install the test specimen between a ground beam and L-beam. The geometric dimensions of the test specimens are given in Table 1 and the reported material properties are summarized in Table 2.

YSPD Designation (D × D × t)	Diaphragm Thickness, t (mm)	SHS Size, D (mm)	SHS Thick- ness, T (mm)	Bolt Spacing, S (mm)
100×100×2	1.86	100	3.76	50
100×100×3	2.83	100	3.76	50
100×100×4	3.78	100	3.76	50

3 ANALYTICAL EVALUATION OF YSPD BY CHAN ET. AL. [1]

Chan et. al. [1] classified YSPDs into two different categories based on the slenderness ratio of the diaphragm plate for theoretical evaluation. Material stress-strain response was considered elastic, perfectly-plastic with a von Mises yield criterion. Diaphragm plates were assumed to be simply supported by the SHS and were classified as either compact or slender depending on whether or not the critical shear buckling stress σ_{cr} exceeds the material yielding stress. The critical shear stress for a simply supported plate is given by [7],

$$\sigma_{cr} = k_e \frac{E}{12(1-\nu^2)} \left(\frac{t}{d}\right)^2 \quad (1)$$

where k_e is a coefficient which depends on the aspect ratio and end restraints of the plate e.g. k_e is equal to 9.34 for square plates, whilst E and ν are Young's modulus and Poisson's ratio respectively. It is worth mentioning that the specimens used in the testing program fall within the category of YSPD with compact diaphragm plate.

Assuming an insignificant contribution from SHS, Chan et. al. [1] proposed the theoretical elastic in-plane lateral stiffness of the YSPD, k_{YSPD}

$$k_{YSPD} = Gt \quad (2)$$

where G is the shear modulus of steel and t is the thickness of the diaphragm plate. For a device with compact diaphragm plate, the yield shear strength of YSPD is,

$$F_y = \frac{f_y}{\sqrt{3}}td \quad (3)$$

where d is the width of the steel plate and f_y is the yield strength in tension. Hence the yield displacement of the device becomes,

$$u_y = \frac{F_y}{k_{YSPD}} = \frac{f_y d}{\sqrt{3}G} \quad (4)$$

Figure 3 shows a comparison between the test result and the theoretical predictions proposed by Chan et al [1] for the load-deformation response of YSPD 100×100×4. This comparison clearly demonstrates that there is room for further modifications to the proposed theoretical model. The current research aims to develop FE models and to exploit the numerical results to propose more reliable analytic predictions for the load-deformation response of YSPD.

Figure 3. Comparison between the test result and the predicted force-displacement response of YSPD 100×100×4 based on the model proposed by Chan et al. [1].

4 ANALYTIC FORMULATION OF YSPD

YSPD specimens used in the laboratory testing had compact diaphragms and hence the current paper proposes analytic modelling techniques for such YSPDs so that the proposed model can be verified against test results. Size of the considered YSPDs varies within 100 to 120 mm to avoid the chance of developing large eccentric moment. Development of a tri-linear load-deformation model for YSPD is described in the following sections.

4.1 Evaluation of initial stiffness

When subjected to loading, the YSPD has to resist two equal and opposite forces acting through the bolted connections and hence its initial stiffness would be equal to the force required to produce unit horizontal displacement at the loaded flange. The diaphragm plate and the SHS deform simultaneously due to the applied deformation as shown in Figure 4.

The loading and the supporting ends are assumed to remain parallel for preliminary calculations. The resulting stiffness of YSPD can be obtained by combining the individual stiffness of two constituent elements i.e. the SHS and the diaphragm. Firstly the stiffness of the diaphragm plate is formulated assuming it to be simply supported by the SHS and the diaphragm plate is assumed to deform due to pure shear. In the next step, the stiffness of the SHS is calculated assuming that the diaphragm plate deforms due to in-plane compression. The vertical flanges are also compressed as a result of the flexural deformation of the bolted flanges. The overall stiffness of the YSPD may thus be obtained as follows,

$$\frac{1}{k_{\text{YSPD}}} = \frac{1}{k_{\text{dia}}} + \frac{1}{k_{\text{shs}}} \quad (5)$$

where, k_{YSPD} = Stiffness of YSPD
 k_{dia} = Stiffness of the diaphragm
 k_{shs} = Stiffness of the SHS

Figure 4. Undeformed and deformed shapes of a yielding shear panel device (YSPD).

4.1.1. Stiffness of the diaphragm plate

Figure 5. Undeformed Pure shear deformation of diaphragm plate.

For a unit displacement ($\delta = 1$) of the diaphragm plate (Figure 5), B is displaced to B' and the shear stain is given by,

$$\tan \theta = \frac{\delta}{d} = \frac{1}{d} \quad (6)$$

Considering small strain, it can be reduced to,

$$= \frac{\delta}{d} = \frac{1}{d} \quad (7)$$

For elastic deformation, the shear stress,

$$= G = \frac{G}{d} \quad (8)$$

Hence the elastic stiffness of diaphragm plate in pure shear may be expressed as,

$$k_{dia} = dt = Gt \quad (9)$$

4.1.2. Stiffness of the SHS

The bolted flanges of the SHS undergo flexural deformation due to the in-plane compression of the diaphragm plate and the vertical flanges,. Figure 6 shows the details of assumed deformations with acting forces F_1 and F_2 .

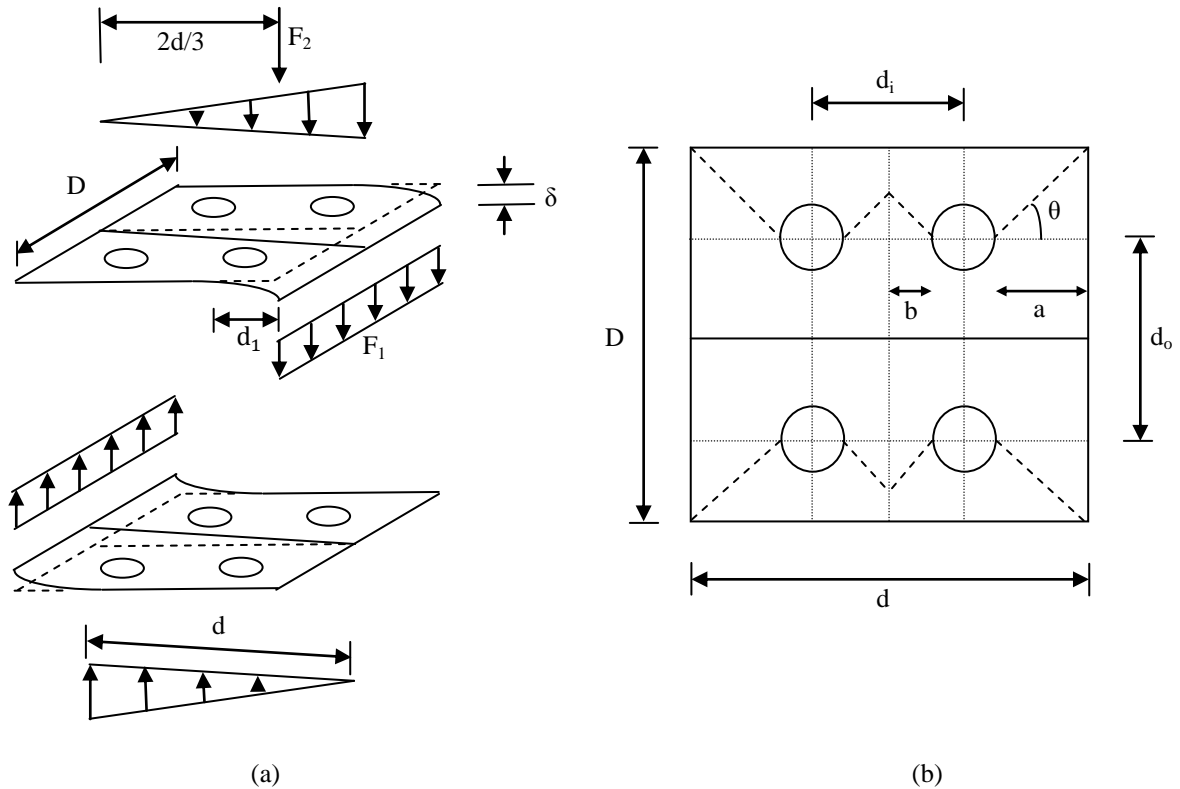

Figure 6. (a) Deformation of bolted flanges, (b) Dimensions of bolted flange.

Bolted flanges experience bending about an axis perpendicular to the loading direction due to the force F_1 . By assuming a zero rotation along the line passing through the centre of nearby bolts and ignoring the effects of bolt holes we can calculate,

$$F_1 = \frac{3EI_1}{d_1^3} = \frac{DT^3E}{4(a+r)^3} \quad (10)$$

$$\text{where, } I_1 = \frac{DT^3}{12}$$

r = Radius of the bolt hole

The compression at the diaphragm plate causes deformation along the line joining the flange and the diaphragm plate. This deformation results in an additional bending to the flange about an axis parallel to the loading direction. The acting force F_2 responsible for this deformation is assumed to have a triangular distribution due to the large in-plane rigidity of the diaphragm plate. This force may be obtained by taking strips in the flange.

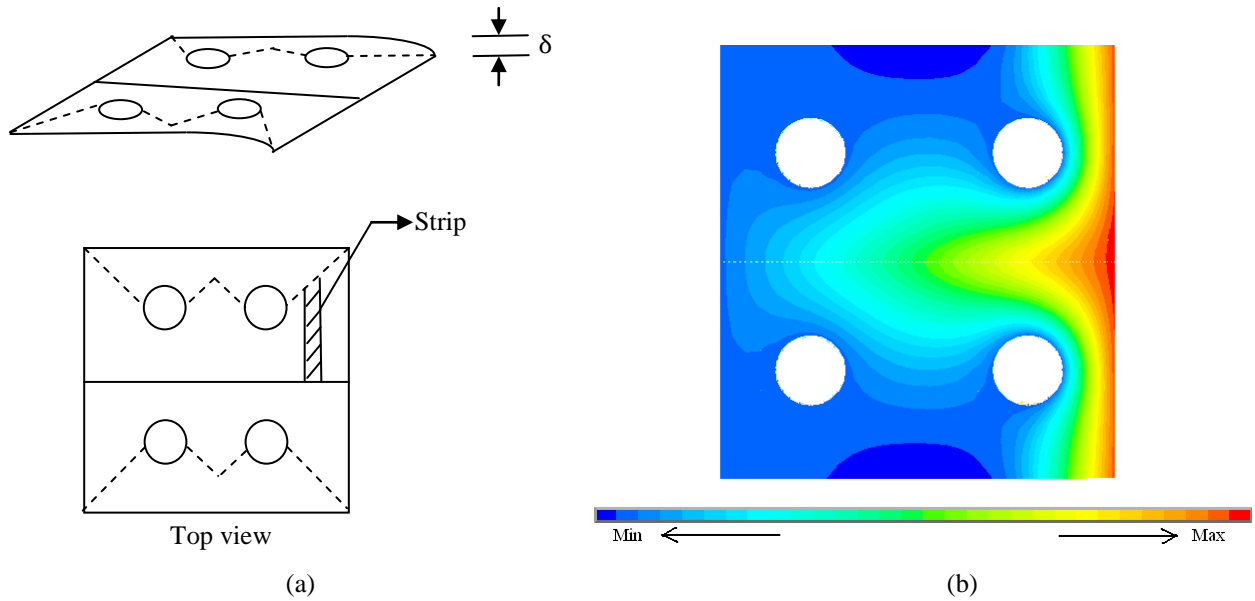

Figure 7. (a) Assumed zero rotation line on SHS flange. (b) Typical contour plot of the out of plane deformation of SHS flange

The zero rotation line is assumed as a zigzag dotted line as shown in Figure 7(a); this pattern is due to the boundary condition provided by the bolted connections. Each strip is considered to be fixed on both sides bounded by the dotted 'zero rotation' line and the line joining the diaphragm to the flange. Figure 7(b) shows a contour plot of the typical out of plane deformation of the SHS flange obtained from FE analysis [2]. The contour plot confirms that the deformation at the right part of the top flange is due to bending about both the orthogonal directions. The deformation pattern due to the compression of the diaphragm plate also verifies the assumed zigzag line for zero rotation.

The zero rotation line is assumed to make an angle of θ (Figure 6(b)) with a plane parallel to the diaphragm. The average distance (d_2) between the diaphragm line and zigzag support line can be calculated as follows,

$$d_2 = \left(\frac{d_0}{2} + \frac{a \cdot \tan \theta}{2} \right) \times \frac{2a}{d} + \left(\frac{d_0}{2} + \frac{b \cdot \tan \theta}{2} \right) \times \frac{2b}{d} + \left(\frac{d_0}{2} - \frac{r}{4} \right) \times \frac{4r}{d}$$

$$\text{or, } d_2 = \frac{d_0}{2} + \frac{a^2 \cdot \tan \theta + b^2 \cdot \tan \theta - r^2}{d} \quad (11)$$

The resultant of the triangular force considering a unit deformation at the end becomes,

$$F_2 = 2 \times \left(\frac{6EI_2/d_2^3}{2} \right) = \frac{6EI_2}{d_2^3} = \frac{dT^3E}{2d_2^3} \quad (12)$$

$$\text{where, } I_2 = \frac{dT^3}{12}$$

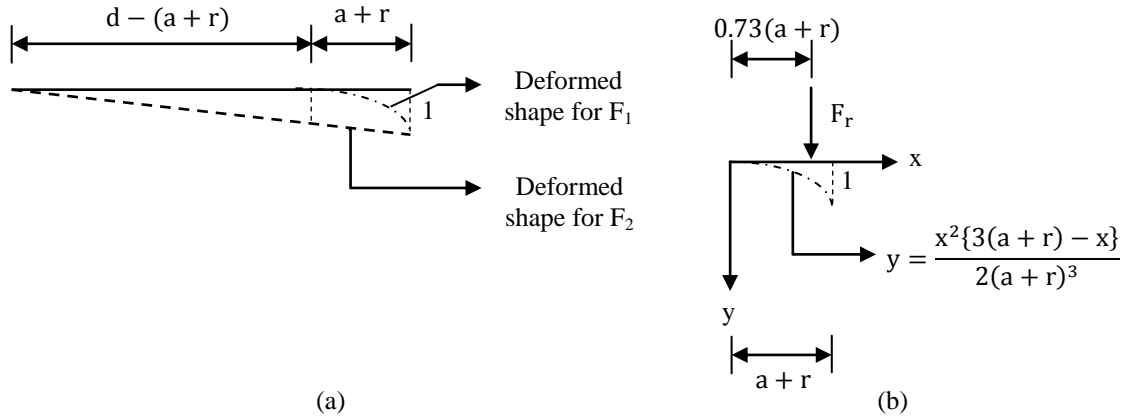

Figure 8. (a) Deformed shapes due to force F_1 and F_2 of SHS flange (b) Equation of the deformed shape for the force F_1 and reduction force F_r

A reduction in the total calculated force is required for bending moments acting at orthogonal directions. Figure 8(b) shows the deformed shape with a unit deformation at the end for F_1 . The average deformation becomes $3/8$ by calculating the area and dividing it with the deformed length $(a+r)$. The common deformation due to force F_1 and F_2 are calculated. Force required to produce this common deformation is the reduction force which can be calculated as,

$$F_r = 2 \times \left(\frac{6EI_3}{d_2^3} \right) \times \frac{3}{8} = \frac{3E(a+r)T^3}{8d_2^3} \quad (13)$$

where, $I_3 = \frac{(a+r)T^3}{12}$

Force F_r acts at a distance of $d_r = \{d - 0.27(a+r)\}$ from the zero deformation end.

Figure 9. Compressive deformation of diaphragm plate and vertical flanges

The compression of the diaphragm plate and the vertical flanges in an YSPD is analogous to the deformation of an I-Section as shown in Figure 9. The force required to make a unit deformation i.e. strain = $1/d$ at the end of the flange,

$$F_3 = DT \times \frac{E}{d} + \frac{dt}{2} \times \frac{E}{d} \quad (14)$$

The distance between the zero deformation and the line of action of the force,

$$d_3 = \frac{DTE+dtE/3}{F_3} \quad (15)$$

The stiffness of the SHS can be calculated by the moment balance of these forces and thus may be expressed as follows

$$k_{SHS} = F_1 + \frac{F_2}{3} - \frac{F_r(2d_r-d)}{d} + \frac{F_3(2d_3-d)}{d} \quad (16)$$

Calculation showed that the contribution of force F_3 is more than 98.5%. The inclination of the zero deformation angle θ , thus, has negligible effect on the overall stiffness of the SHS and hence the angle θ may be taken as 45° whilst calculating the stiffness of SHS.

4.1.3. Combined Stiffness

Test results showed considerable rotation of the loading end within the elastic range [2], which causes the stiffness of the SHS to degrade. Hence the stiffness of the SHS may be taken as ϕk_{shs} , where ϕ is a reduction factor. The modifies stiffness of YSPD (k'_{YSPD}) is thus expressed as follows,

$$\frac{1}{k'_{YSPD}} = \frac{1}{k_{dia}} + \frac{1}{\phi k_{shs}} \quad (17)$$

The value of ϕ can be determined using the initial stiffness of YSPDs obtained from the experimental investigation. Theoretical stiffness of the diaphragm plate and the SHS are calculated individually using Equations 9 and 16 ignoring the effects of rotation. Obtained stiffness magnitudes for the YSPDs and their corresponding diaphragm plates and SHS are used to plot Figure 10. The slope of the straight line is equal to $1/\phi$ according to Equation 17. The obtained value of ϕ is equal to 0.03 ignoring one outlier, which represents significantly low initial stiffness showed by YSPD $120 \times 120 \times 3$ in the monotonic test.

Figure 10. Stiffness plot of SHS to determine the reduction factor ϕ .

4.2 Yield Strength of YSPD

Figure 11. State of elastic stress of the diaphragm plate.

The yielding of YSPD occurs due to the combined action of axial compression and shear deformation of the diaphragm plate. The yield force and the corresponding deformation is initially calculated assuming the loading end and the support end remain parallel. The effect of support rotation is then incorporated to calculate the actual deformation. According to von Mises yield criterion,

$$\sigma_1^2 - \sigma_1\sigma_2 + \sigma_2^2 = \sigma_y^2 \quad (18)$$

where, σ_y is the tensile yield strength

$$\text{Principal stresses, } \sigma_1, \sigma_2 = -\frac{\sigma}{2} \pm \sqrt{\frac{\sigma^2}{4} + \tau^2}$$

The applied horizontal deformation δ can be divided into two components - δ_1 for the pure shear deformation of the diaphragm plate and δ_2 for the deformation of SHS. Thus,

$$\delta = \delta_1 + \delta_2 \quad (19)$$

$$\delta_1 = \frac{k_{YSPD}}{k_{dia}} \delta \quad (20)$$

$$\delta_2 = \frac{k_{YSPD}}{k_{SHS}} \delta \quad (21)$$

The resulting stresses become,

$$= \frac{\delta_1 G}{d} \quad (22)$$

$$= \frac{\delta_2 E}{d} \quad (23)$$

The yield deformation δ_y can be calculated by solving Equation 18. This yield displacement changes due to the rotation of the loading end. By incorporating the effect of end rotation, yield displacement becomes,

$$\delta'_y = \delta_y \frac{k_{YSPD}}{k'_{YSPD}} \quad (24)$$

The yield strength of YSPD can be calculated as,

$$F'_y = k'_{YSPD} \delta'_y \quad (25)$$

Equation 25 gives the same yield strength as calculated by Chan et. al. [1], but the initial stiffness is modified by considering the deformation of the SHS in Equation 24.

The underlying assumption of this calculation is the diaphragm plate is simply supported by the SHS. Practically the diaphragm plate is welded inside the SHS. The thickness ration of diaphragm plate and the SHS plate (t/T) determines the support rigidity. The rigidity of the support increases with the decreasing t/T ratio. Consequently, the theoretical yield strength decreases with the increasing t/T ration. Figure 12 shows the variation of the ration of theoretical yield strength and actual yield strength with the varying td^2/T . The term d^2 is used to normalize the values with different diaphragm size. The graph shows a good correlation and indicates the yield strength reduces with the increasing t/T ration.

Figure 12. Correlation curve for theoretical and actual yield strength.

A strength reduction factor Ω_1 is calculated as follows,

$$\Omega_1 = 0.0003td^2/T \quad (26)$$

Reduced yield displacement and yield strength of YSPD becomes,

$$\delta'_y = \delta_y \frac{k_{YSPD}}{k'_{YSPD}} \quad (27)$$

$$F'_y = k'_{YSPD} \delta'_y \quad (28)$$

4.3 Plastic Buckling Strength in Shear

Early investigations into plastic plate shear buckling were reported by Gerard [8], Stowell [9] and Bijlaard [10]. Stowell [9] and Bijlaard [10] used deformation theory for the analysis of plastic buckling of plates, whilst Gerard [8] followed the secant modulus approach. Stowell [9] derived an expression using the deformation theory and finally suggested a simplified form depending on the secant modulus of elasticity for materials with nearly constant hardening behaviour in the plastic range. Gerard [8] suggested the critical shear stress is rather dependent on the secant shear modulus. Bleich [11] proposed a simplified approximation of Stowell's plastic reduction factor using the tangent modulus concept. Later, Inoue [12] used a Tresca yield criterion [12] based modified incremental theory to analyse the plastic shear buckling of thin plates. Tugcu [13] adopted bifurcation approach to determine the effect of tensile or compressive loading on the critical buckling stress for infinitely long shear plates. Wang and Aung [14] applied the p-Ritz method for the plastic buckling analysis of thick plates based on both deformation theory and incremental theory. Alinia et al. [15] showed that incremental theory based p-Ritz method provides upper bound solutions whereas deformation theory based method predicts lower bound solutions.

Stowell [16] derived a closed form solution for determining the critical shear stress for long plates using the deformation theory. Critical buckling stress may be expressed as,

$$\tau_{cr} = k_e \frac{E}{12(1-\nu^2)} \left(\frac{t}{d} \right)^2 \quad (29)$$

where τ_{cr} is the critical shear stress, k_e is a coefficient which depends on the aspect ratio and the end restraints of the plate, E is the Young's modulus, ν is the Poisson's ratio and η is the coefficient allowing reduction in plastic range. The coefficient η depends on the secant modulus of elasticity, support restraint and the plasticity behaviour of the material. For a linear hardening material Stowell [16] suggested,

$$= \text{Constant} \frac{E_s}{E} \quad (30)$$

For 24S-O aluminium alloy, Stowell [16] found this constant as 0.89 for both simply supported edges and clamped edges. Bleich [11] proposed a simplified conservative approximation for the value of η as

$$= \sqrt{\frac{E_t}{E}} \quad (31)$$

Gerard [8] approximated the value of η incorporating secant shear modulus G_s and shear modulus G as,

$$= \frac{G_s}{G} \quad (32)$$

Gerard [8] further advanced the theory by introducing the concept of critical shear strain γ_{cr} . Using Equation 34, the critical shear strain can be found as,

$$\gamma_{cr} = k_e \frac{2(1+\nu)^2}{12(1-\nu^2)} \left(\frac{t}{b}\right)^2 \quad (33)$$

The expression for critical shear strain γ_{cr} is not dependent on coefficient η and hence γ_{cr} could be easily calculated using the knowledge of the size, the slenderness ratio and the support conditions of a thin plate.

Equation 29 and 33 are used to predict the critical buckling stress and strain for the diaphragm plate and used to calculate the buckling force of a YSPD.

Real et. al. [17] presented a method to identify the critical buckling stress for a metal plate subjected to shear using finite element analysis. The buckling occurs when the stress reversal takes place in the principal stress plot; the compressive principal stress suddenly decreases once the plate starts to buckle. Finite element simulation of YSPD showed the critical buckling force is over predicted. The reduced strength is resulted by the axial compressive stress acting along with the shear stress. Buckling strain is found larger in the FE model. This excessive deformation is resulted from the support rotation. Figure 13(a) shows the variation of the ratio of theoretical critical buckling strength and actual buckling strength with varying slenderness ratio (d/t). The graph shows a good correlation and the buckling strength reduction factor is calculated as,

$$\Omega_2 = 1 + 0.011d/t \quad (34)$$

Critical plastic buckling strain calculated according to the equation 35 can be divided into elastic and plastic parts as follows,

$$\gamma_{cr} = \gamma_{cr}^e + \gamma_{cr}^p \quad (35)$$

The multiplication factor for increasing the value of the plastic shear strain to include the effect of the support rotation depends on the plate area (td). Figure 13(b) shows the variation of the ratio of theoretical plastic shear buckling strain and actual plastic strain obtained from FE models with varying area of the diaphragm plate area (td). The graph showed a good correlation and the plastic strain multiplication factor is calculated as,

$$\Omega_3 = 0.0116td - 1.81 \quad (36)$$

Figure 13. (a) Correlation curve for theoretical and finite element critical plastic buckling strength. (b) Correlation curve for theoretical and finite element critical plastic buckling strain.

4.4 Post Buckling Stiffness

Force-displacement response of YSPD for large deflections after the buckling of the diaphragm plate is necessary to identify its energy dissipation characteristics. A tension field is developed after the shear buckling of diaphragm plate. A typical state of stress of the diaphragm plate with a tension field inclined at an angle α is shown in Figure 14.

Figure 14. Tension field stresses in diaphragm plate after buckling.

The incremental shear strength of the YSPD after buckling becomes,

$$dF = \frac{1}{2} \cdot d \cdot t_y (\sin 2\alpha) td \quad (37)$$

Kharrazi [18] determined the elastic post buckling shear deformation by equating the work done by the post buckling component of the shear forces to the strain energy produced by the tension field. Kharrazi et. al. [19] extended the concept to consider hardening after reaching yield point by replacing the modulus of elasticity (E) with the tangent modulus of elasticity (E_t). Using the same technique, the incremental post buckling shear deformation becomes,

$$d\delta = 2d_{ty}.d/E_t \sin 2\alpha \quad (38)$$

Thus, the post buckling stiffness of the YSPD may be expressed as,

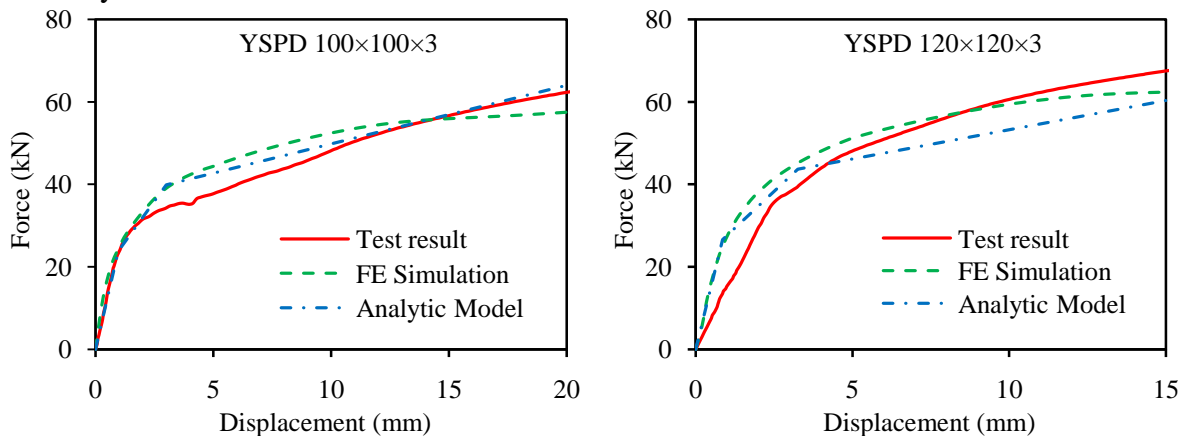

$$k_t = \frac{1}{4}.E_t t \sin^2 2\alpha \quad (39)$$

Equation 39 indicates that the shear deformation behaviour after buckling depends on the inclination angle α of the tension field. A number of research works have been conducted in the last few decades to identify the angle of inclination in tension field action; Shishkin et. al. [20] summarised all available literature relevant to inclination angle. CAN/CSA-S16-01 [21] suggests a limit varying between 38° and 45° for the inclination angle of pin ended strips in steel plate walls. Shishkin et. al. [22] reported that inclination angle values between 38° to 50° gave similar results for calculating the ultimate capacity of steel plate shear walls. An inclination angle of 45° can be reasonably assumed for the tension strips developed within the square diaphragm plate of YSPD. Considering an inclination angle of 45° , the post buckling stiffness may be expressed as follows

$$k_t = \frac{1}{4}.E_t t \quad (40)$$

5 COMPARISON WITH TEST RESULTS AND FE MODELLING

The performance of the proposed tri-linear load deformation response is compared against those obtained from test and FE simulation. Figure 15 compares the load-deformation response for different YSPDs. The developed FE model and analytic model with 2 mm diaphragm plate significantly underpredicts the test behaviour; this discrepancy is due to a higher strength shown by the material although the reported yield strength (211.3 N/mm^2) is unusually low.

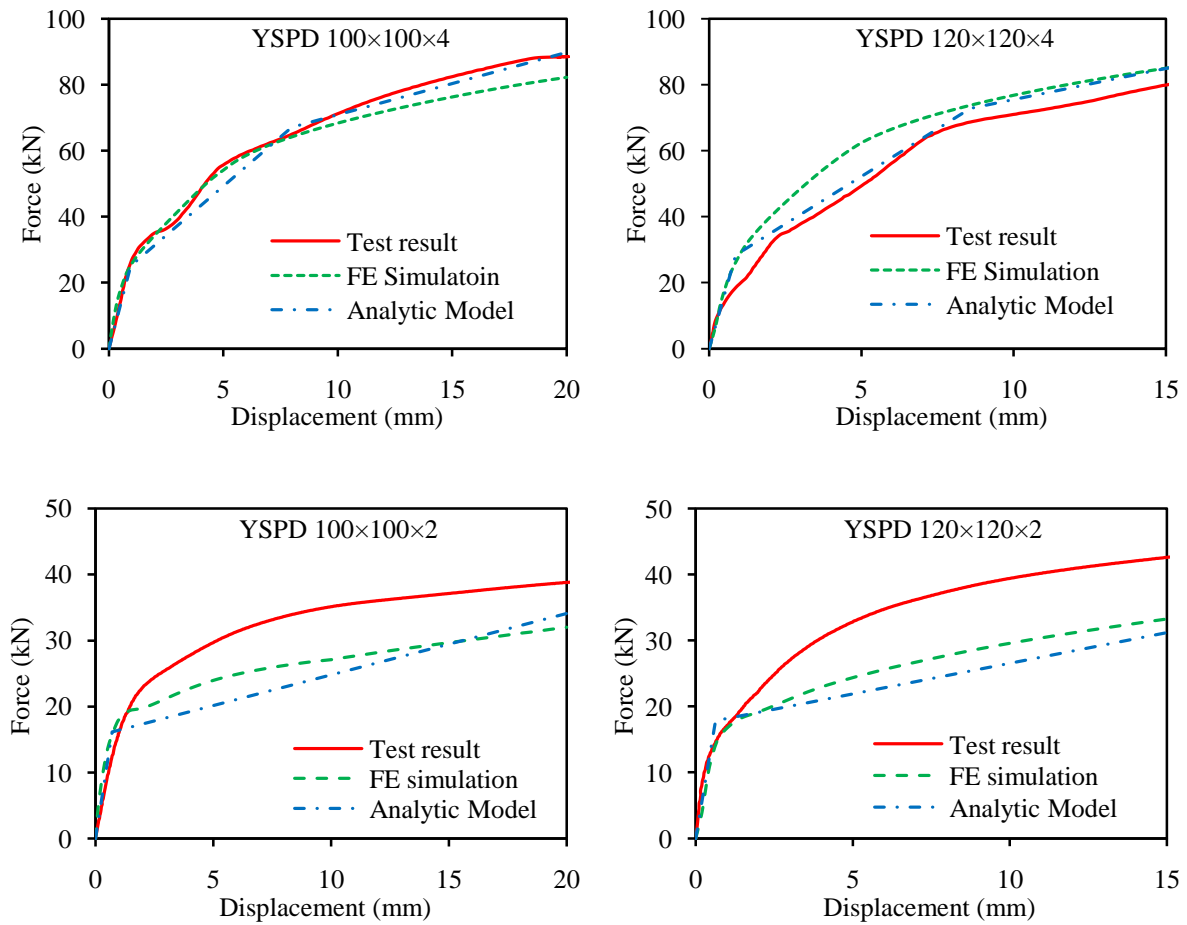

Figure 15. Force-displacement response of YSPDs.

Table 3 compares the amount of energy required to achieve specified displacements during the monotonic loading tests of YSPDs to those obtained from tri-linear models. The ratio of energy required for different displacements indicates that the developed tri-linear model can predict the required energy with reasonable accuracy.

YSPD Designation	Ratio of Energy for different displacements (Theoretical/Test)			
(D × D × t)	5 mm	10 mm	15 mm	20 mm
100×100×2	0.77	0.72	0.73	0.76
100×100×3	1.09	1.08	1.05	1.04
100×100×4	0.91	0.96	0.97	0.97
120×120×2	0.79	0.71	0.71	-
120×120×3	1.15	0.99	0.94	-
120×120×4	1.12	1.07	1.07	-

Table 3: Comparison of energy required in monotonic loading.

6 CONCLUSION

An analytic model for a newly proposed passive energy dissipation device YSPD has been presented in the current paper explaining all necessary theoretical derivations. The force-displacement response of YSPD has been idealized as a tri-linear curve. The first linear segment represents the elastic deformation; the slope of which depends on the individual stiffness of the diaphragm plate and that of the surrounding SHS in addition to the rotation of the support. Yield strength is calculated based on the yield capacity of the diaphragm plate, which is eventually reduced by introducing a yield strength reduction factor to consider the stiffness of the surrounding SHS. Second linear segment corresponds to the plastic deformation of the shear plate. Critical buckling strength is identified using Gerard's plastic buckling theory by calibrating the theoretical values using finite element results. Final linear segment represents the post buckling tension field response. Inclination of the tension field is observed not to play a significant role and hence an angle of 45^0 is adopted. Positive tangential stiffness (k_t) presents a hardening behaviour for post buckling response. The proposed theoretical model is compared with the available test results and the corresponding finite element simulations; overall, the comparisons showed good agreement. Developments of fully nonlinear theoretical formulations for YSPD are currently underway.

Keywords: DFPS, Curved Surface Sliders, Seismic Isolation, Double Friction Pendulum, Construction Defects, Variable Boundary Conditions

Abstract. *Nowadays, the use of seismic isolation within the Italian and European context is gaining more and more acknowledgement, thanks to the high level of protection which can be guaranteed to a structure from the earthquake damage. However, the installation of devices within complex structural systems may influence the actual response due to the random variation of the installation and operating conditions with respect to the theoretical structural scheme. It is then of paramount importance a proper assessment of the overall isolating system response, considering the variability of the construction conditions.*

The main objective of the present work is to study the response of a particular installation system for Double Curved Surface Sliders (DCSS) for buildings with large plan development in case of construction defects related to the non-perfect co-planarity of the devices. A case study is presented, in which the effects of randomly simulated construction defects are analyzed. Preliminary results showed that the simulated construction defects have only limited influence on the global hysteretic behavior of the system and that the contemporary loss of contact may occur only for a limited number of devices. On the other hand, the effects of the vertical and horizontal force redistribution may cause important increase of the actions locally induced in the base connecting slab and create an eccentricity of the resultant horizontal force.

1 INTRODUCTION

Nowadays, the use of seismic isolation within the Italian and European context is gaining more and more acknowledgement [1], [2]. The recent coming into force of the European Code for antiseismic devices [3] witnesses such increasing trend and highlights the importance of a major attention to all the aspects related to the response of installed isolators.

Concerning friction devices, a number of studies has been conducted first on curved surface sliders with single sliding surface ([4], [5], [6], [7], [8], among the others), and then on the most recent double / triple sliding surfaces sliders ([9], [10], [11]). Such studies highlighted features and advantages of such technology, from the theoretical, modeling and experimental point of view, at least for what concerns the single device.

However, complex isolation systems and the actual operating conditions of installed devices often differ from the ideal theoretical design conditions. In particular, when several devices are installed to work in parallel, the possibility of random variations in the installation conditions of each single device may arise issues regarding the response of the entire system.

The main objective of the present endeavor is to study a particular isolation scheme for buildings with large plan development (systems consisting of several isolators and a base connection slab upon which the building is constructed, Fig. 1), in order to evaluate the influence of defects related to non-parallel sliding surfaces. Such kind of defects can be generated by phenomena of deferred concrete creep or simply by construction errors: if isolators sliding plates are non perfectly horizontal, for a given slab displacement each device will encounter a differential vertical displacement, possibly leading some device to loose contact and inducing localized stress in the slab. This in turn causes a redistribution of the vertical reactions and consequently of the horizontal forces throughout the whole system.

Fig. 1 . Schematic model of the isolated system consisting of isolators-base connection slab-building

The first step of the work has been to define the mechanical model of a single isolator, analyzing the geometry of each component, in order to obtain the value of the vertical displacement induced on the slab, for a given value of horizontal displacement. Subsequently, the interaction among the different devices and the base slab has been modeled, by developing a f.e.m. code able to simulate the varying conditions of the system (contact-no contact condition). Finally, a case study has been presented, in which construction defects have been simulated randomly on the different isolators for a large number of analysis, in order to evaluate the consequences at both global and local level.

Preliminary results showed that the simulated construction defects have only limited influence on the reduction of the global hysteretic behavior of the system, and that the simultaneous detachment during the motion may occur only for a limited number of devices. On the other hand, the effects of the vertical and horizontal force redistribution may cause an important increase of the actions locally induced in the slab (shears and moments) and create a global torsion effect on the system, due to the eccentricity of the horizontal resultant force.

2 THE DCSS MECHANICAL MODEL

The geometric model has been developed based on the general case of a DCSS isolator with articulated slider ([9], [10]). The DCSS isolator consists of two sliding surfaces, in general characterized by different values of curvature radius, separated by an articulated slider which allows differential rotations (Fig. 2), and may feature different dynamic friction coefficient at the interfaces with the two sliding surfaces.

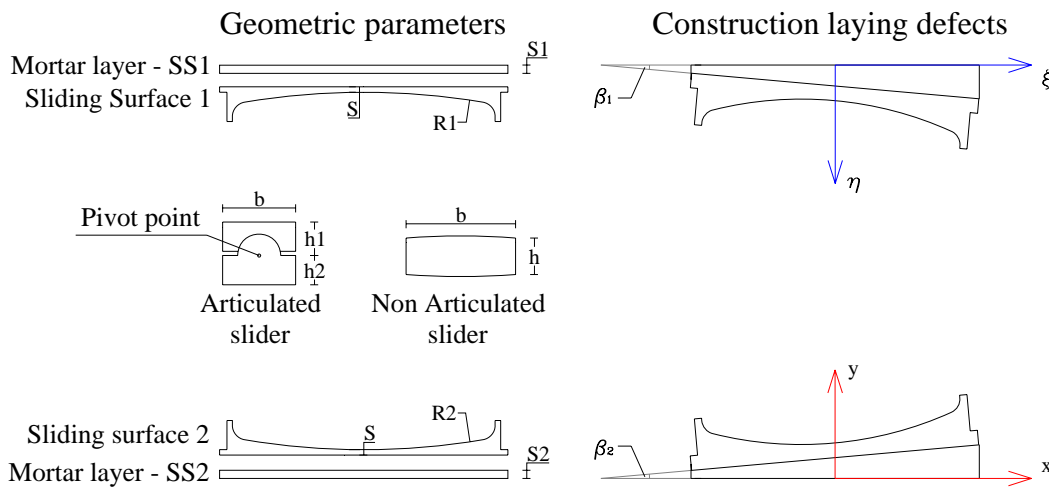

Fig. 2 . section of DCSS with non-articulated slider

The model ([9], [10]) allows to obtain the vertical displacement of the isolator upper surface as a function of the two horizontal displacements between the sliding surfaces and the pivot point of the articulated slider. The equivalent oscillation period of the device is:

$$T = 2\pi \sqrt{\frac{R_{eq}}{g}} = 2\pi \sqrt{\frac{R_1 + R_2 - h_1 - h_2}{g}} \quad (1)$$

When a device is installed, two layers of mortar constitute the interface between the device and the construction system in which it is installed. The construction laying defects can be modeled in terms of non-perfect planarity of such layers of mortar, i.e. as inclinations β_1 and β_2 of the sliding surfaces with respect to the horizontal direction (Fig. 2). The model is plane. In the present work, the model for a DCSS isolator with possible construction defects and with non-articulated slider has been obtained by considering the inclination of the upper and lower plates β_1 and β_2 and imposing no relative rotation between the two units of the slider, thus calculating the vertical displacement only as a function of the total horizontal displacement u between the two sliding surfaces and of the two angles. The inclinations of the sliding surfaces can be described in terms of change of coordinates of the respective center of curvature. Referring to Fig. 3, the angle θ_1 and θ_2 of the two units composing the slide with respect to the vertical axis are thus expressed as:

$$\vartheta_i = \arcsin\left(\frac{u_i - C_{ix}}{R_i - h_i}\right) \quad i = 1, 2 \quad (2)$$

Where C_{1x} and C_{2x} are the x- coordinates of the sliding surfaces centers, and u_1 and u_2 the relative horizontal displacement between the sliding surfaces and the pivot point (Fig. 3).

Fig. 3 . definition for the lower surface

By imposing equal to zero the relative rotation of the two axis of the units composing the slider (i.e. $\theta_1 = -\theta_2$), and with the relation among both the relative displacements u_1 and u_2 and the total horizontal displacement u_{TOT} ($u_2 - u_1 = u_{TOT}$), a linear system is obtained, which allows to express the values of u_1 and u_2 as a function of u_{TOT} and of the geometric characteristics of the device:

$$u_1 = \frac{C_{1x}(R_2 - h_2) + C_{2x}(R_1 - h_1)}{R_1 + R_2 - h_1 - h_2} - u_{TOT} \frac{R_1 - h_1}{R_1 + R_2 - h_1 - h_2} \quad (3)$$

$$u_2 = u_{TOT} + u_1 \quad (4)$$

Once obtained u_1 and u_2 , the height of the extrados of the device can be calculated with the equations of the two sliding surfaces. Fig. 4 shows an example of the profiles of vertical displacement versus horizontal displacement for the device considered in the case study (with characteristics in Table 2), assuming only the upper surface with different inclinations (i.e. $\beta_1 \neq 0$ and $\beta_2 = 0$).

Fig. 4 . example of vertical displacements versus horizontal displacements for inclined upper plate

Regarding the sliding friction coefficient μ , it is well known that for common sliding materials μ is a decreasing function of the acting pressure [12]: a simplified relationship for the variability of the dynamic friction coefficient as a decreasing function of the vertical load is assumed (Fig. 5), based on the several tests carried out at the EUCENTRE TREES Lab (Pavia, Italy) on full scale devices. At this stage of the work, the curve has been assumed linear for sake of simplicity.

Fig. 5 . dynamic friction coefficient – vertical load variation curve

3 VARIABLE BOUNDARY CONDITIONS CODE

Subsequently, the interaction among the different devices and the base slab has been modeled, by developing a f.e.m. code able to simulate the varying contact-no contact conditions of isolators (Variable Boundary Conditions code, VBC).

The code flowchart is illustrated in Fig. 6: at each loading step, the program is able to identify devices still in contact and devices which have lost contact, updating the total system stiffness matrix at each new configuration.

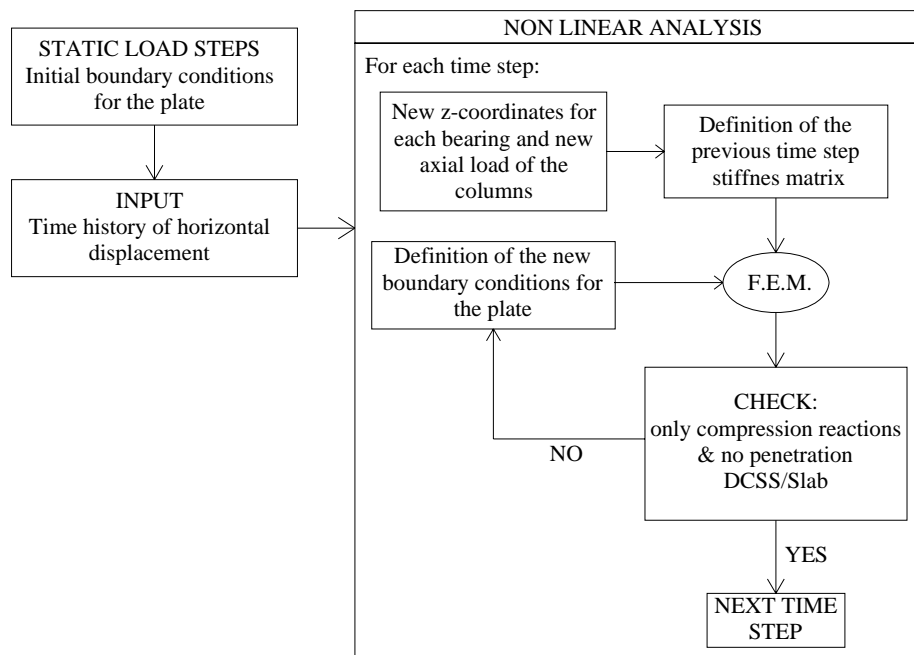

Fig. 6 . Flowchart of the VBC code

The first step of the program is the analysis of the system configuration corresponding to a zero horizontal displacement. The ideal situation of infinitely rigid slab is first studied, with an algorithm able to identify the plane determined by the three devices containing the vertical resultant application point, and with z-coordinate equal or greater than the other isolators (i.e. the three isolators bearing the infinitely rigid plate). Starting from the ideally rigid slab condition, the real deformation of the plate is then obtained by implementing the finite element problem: modeling the plate with its actual stiffness, the vertical load is applied by steps, checking that reactions are purely compressive that there is no penetration between the plate and the isolators. Once defined the zero-displacement deformed shape, the horizontal displacement is stepwise applied to the slab, considering the effects of the dynamic interaction of the building.

The weight of the plate is considered as evenly distributed over the entire surface, while the loads (static and dynamic) transmitted by the building are modeled in terms of concentrated vertical forces imposed on the isolated slab, according to the influence area of each building column. At this stage, the dynamic response of the system has been simulated in a simplified way, by imposing a sinusoidal displacement time history directly to the isolated plate, as during the dynamic testing of the system. The period of the input waveform is taken equal to the oscillation period of the isolation system, calculated as a function of the equivalent radius of the devices.

The dynamic interaction between the building and the isolation system has been simulated by considering the isolated building as an equivalent SDOF of given mass and period. The total base shear V_b is estimated by integrating the equation of motion of a SDOF oscillator. Assuming an equivalent height h_{eq} of the oscillator, the corresponding overturning moment M_{ovt} is computed, which in turn is used to obtain the axial load variation P_i of the building columns acting on the slab, for the x and y motion direction, respectively:

$$M_{ovt}(t) = V_b(t)h_{eq} \quad (5)$$

$$P_{i-X_motion} = \frac{M_{ovt}(t)}{\sum x_j^2} x_i \quad (6)$$

$$P_{i-Y_motion} = \frac{M_{ovt}(t)}{\sum y_j^2} y_i \quad (7)$$

Where x_i and y_i coordinates of isolators are measured with respect to the center of mass of the building columns. For each value of horizontal displacement and axial load variation, the new z_i coordinates of the isolators are calculated based on the DCSS model and imposed to the plate only for the isolators still in contact at the previous time step (compression reactions). Then boundary conditions are newly updated, considering at each iteration only the isolators still in contact.

According to the axial load acting on each isolator and to the actual position, the corresponding reaction force is step by step computed for each device.

4 CASE STUDY

The analyzed case study consists of a reinforced concrete frame structure, built on a slab of thickness 0.5 m, placed on a grid of 10 x 4 DCSS isolators with non-articulated slider. The plan view and a section of the system is shown in Fig. 7. The weight of the plate is 12.5 kN/m², while the building static vertical loads on the base slab are listed in Table 1, according

to the position of the building columns. The geometric and mechanic characteristics of the DCSS are shown in Table 2 (geometric quantities refer to Fig. 2).

Fig. 7 . Schematic view of the studied isolating system

Table 1. static vertical load transmitted by the building columns on the base slab [kN]

Corner column	Edge column	Internal column
280.4	560.8	1121.6

Table 2. Geometric Characteristics of the isolator

$R_1 = R_2$	$s_1 = s_2$	B	h	S	$\mu_1 = \mu_2$
2024 mm	15 mm	335.44 mm	66.31 mm	20 mm	Variable with vertical force

The input for the analysis is a sinusoidal displacement waveform imposed to the plate (as during the dynamic testing of the system), with amplitude of 260 mm and period of 4 s, i.e. equal to the system design displacement and isolation period, respectively. For the dynamic interaction, the building has been modeled as a SDOF with period equal to 0.48 s, 5% damping, and h_{eq} of about 7 m (2/3 of the height).

The construction laying defects have been simulated by considering for each device the parameters β_1 and β_2 , randomly selected within an established range of variation, for a total of 135 and 125 configurations in the x and y direction of motion analysis, respectively. In order to maintain the maximum generality and to minimize the imposed a priori information, parameter distributions are assumed uniform and in general independent. Wide variation ranges are intentionally considered ($\pm 1.5^\circ$, much beyond the allowed installation tolerances) in order to evaluate the consequences in extreme conditions (an inclination of 1.5° corresponds to a total offset of 2 cm over a length of 80 cm).

Results are presented in comparison to the reference configuration, which is the ideal situation with isolators having perfectly horizontal sliding plates. At a global level, results are shown in terms of analysis of devices which loose contact, of global hysteretic response of the system and of eccentricity of the horizontal resultant force, while at a local level the variation

of vertical loads and the moments induced in the slab are analyzed. The isolators labels and groups are illustrated in Fig. 8, according to their position with respect to the building projection. For the considered case study, it has been seen that isolators belonging to the same line (group 1 to 4, Fig. 8) feature similar response.

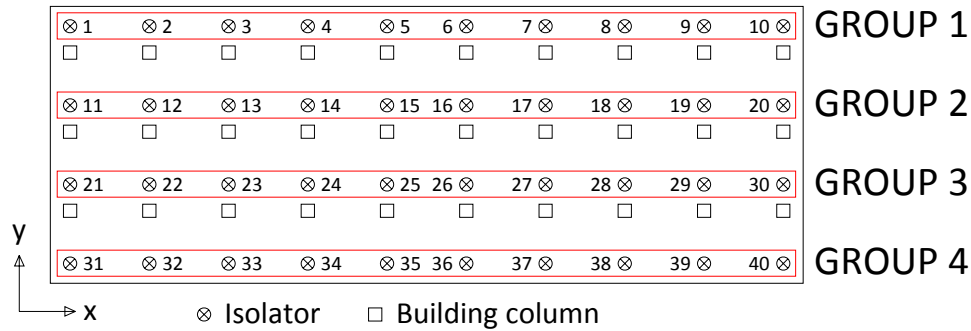

Fig. 8 . Nomenclature of the devices

4.1 Numerical results: global response

Fig. 9 and Fig. 10 show the number of devices which simultaneously lost contact at each value of horizontal displacement: averagely less than 5 DCSS out of 40 have lost the contact at the maximum displacement.

Fig. 9 . Number of isolators simultaneously not in contact (motion in the x direction)

Fig. 10 . Number of isolators simultaneously losing contact (motion in the y direction)

Fig. 11 and Fig. 12 show, for the motion in the x and y direction, the rate of contact loss for each device during the analyses, i.e. the rate of the cases in which an isolator loses contact at least once during motion: it is evident the similar response of isolators belonging to the same alignment. This is due to the position of the building with respect to the base slab. The most external line (group 4) has in fact the highest probability of detachment, while group 2, which is the closest line to the building center of mass, is the most stable. Table 3 shows the values of frequency of contact loss per group of isolators at the maximum displacement.

Fig. 11 . Rate of cases in which an isolator loses contact at least once during the motion (x direction)

Fig. 12 . Rate of cases in which an isolator loses contact at least once during the motion (y direction)

Table 3. Frequency of no-contact across all the analyses, at the maximum displacement

	Motion x	Motion y
Group 1	14.48 %	13.56 %
Group 2	5.75 %	6.44 %
Group 3	9.18 %	9.28 %
Group 4	20.41 %	23.12 %

The total base shear as a function of the horizontal displacement is shown for both directions of motion in Fig. 13: the effects of the construction errors result in a limited reduction of the hysteresis loop. This is due to the redistribution of vertical loads among the isolators still in contact, which increase their reactions but not proportionally, due to the varying friction coefficient. Moreover, isolators not in contact do not contribute to the dissipative behavior.

Fig. 13 . Global hysteresis cycles for the x (left) and y (right) direction of motion

Finally, the horizontal eccentricity of the DCSS resultant reaction with respect to the system center of mass has been evaluated. Fig. 14 illustrates the values of the eccentricity as a function of horizontal displacement. Values of eccentricity are normalized with respect to the correspondent plan dimensions of the base slab (L_x and L_y):

$$E_i = \frac{e_i}{L_i} [\%] \quad (i = x, y) \quad (8)$$

For both directions of motion, at the maximum displacement, the normalized maximum eccentricity is about the 7%.

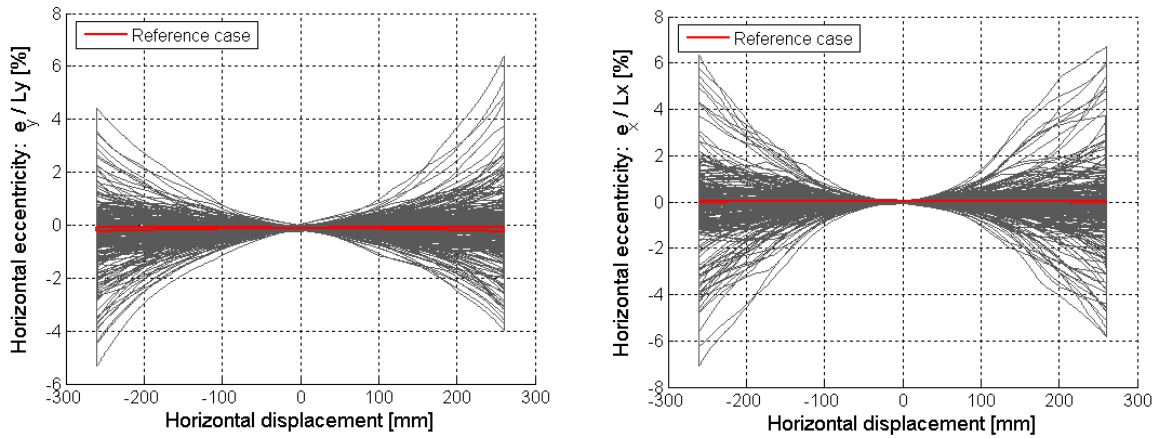

Fig. 14 . Horizontal eccentricity for the x (left) and y (right) direction of motion

4.2 Numerical results: local response

Fig. 15 and Fig. 16 show the distribution of the amount of the vertical load variation for each device at the maximum displacement, for the x and y motion respectively:

$$Var_j = \frac{R_j - R_0}{R_0} [\%] \quad (9)$$

Where R_0 represents the reaction of the reference case, and R_j is the reaction of the j-th analysis. The histograms representing the rate of variation of the vertical reactions with respect to the reference case confirm what already observed: the outer rows of isolators, in particular group 4, are characterized by more dispersed axial load variations, thus by the

highest frequency of contact loss due to the considerable distance from application point of the vertical load resultant, whereas internal groups (e.g. group 2) are less susceptible to important axial load variation and thus to detachment. It is possible to see that compressive load can increase more than twice with respect to the reference situation.

Fig. 17 to Fig. 20 present at a local level, the range of variation of the bending moments induced in the base slab at the isolator locations: results are shown for both the main bending moments and for the two directions of motion. It can be seen that the mean value and the reference value approximately coincide, but the actual values are greatly dispersed, especially for the internal groups of isolators (from isolator #11 to isolator #30). This is due to the fact that, when an isolator loses contact, the plan dimensions of the corresponding slab field doubles, with immediate effects on the induced bending action. Such effect is increased for central devices since they are also subject to greater vertical loads, but are not aligned to the central columns of the building.

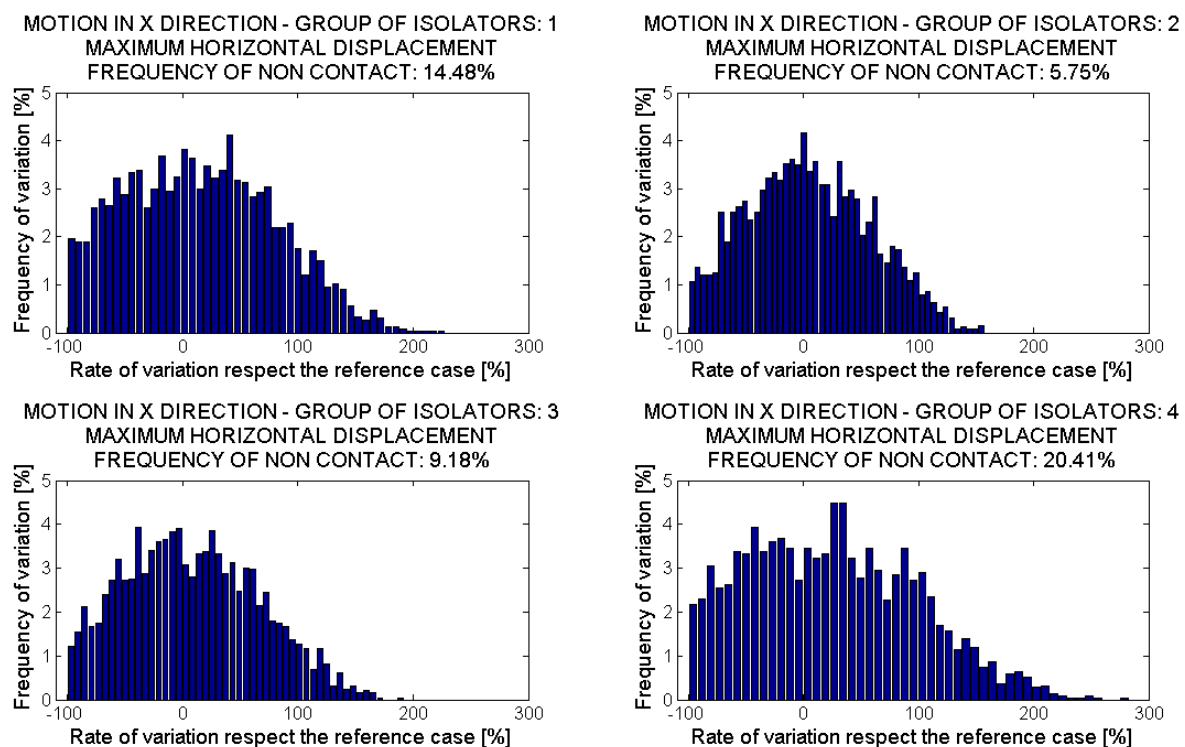

Fig. 15 . Rate of variation of the vertical reactions (motion in the x direction)

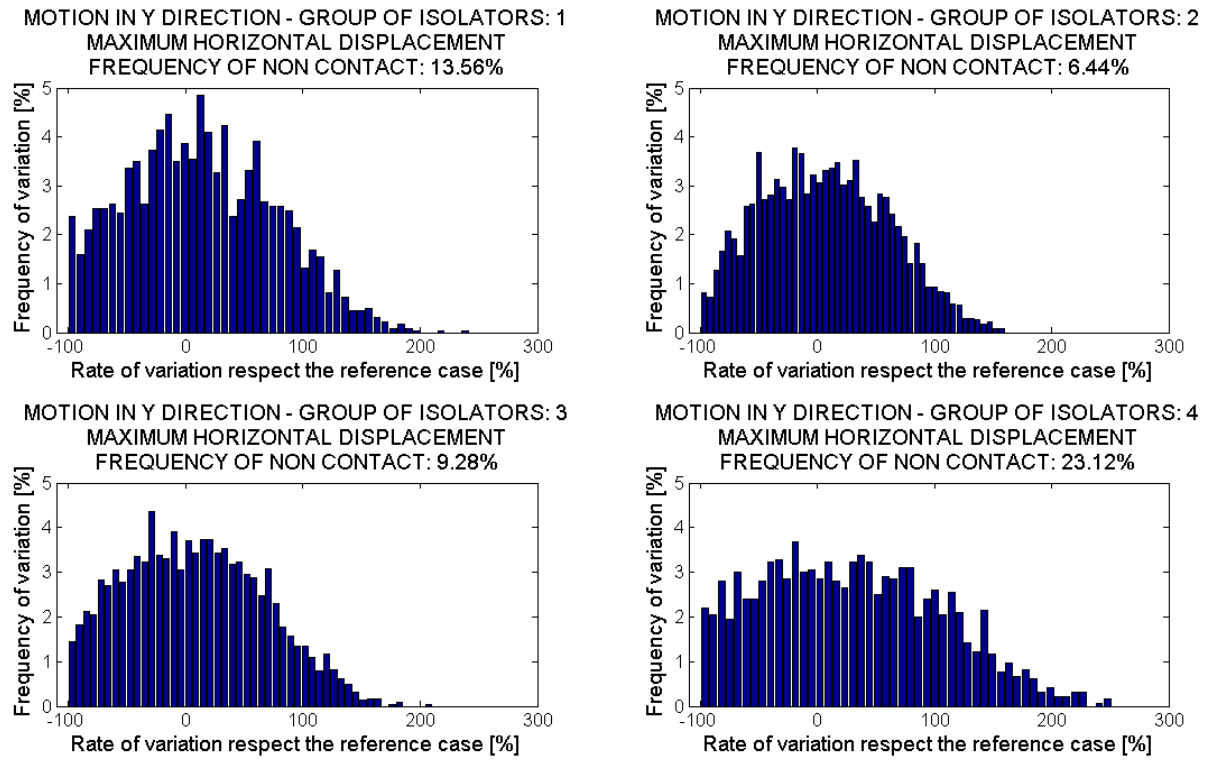

Fig. 16 . Rate of variation of the vertical reactions (motion in the y direction), at the maximum displacement

Fig. 17 . Moment M_{xx} for each isolator (motion in the x direction)

5 CONCLUDING REMARKS AND FUTURE DEVELOPMENTS

In the present paper a particular isolation scheme for buildings with large plan development has been studied, consisting of a connecting base slab isolated by several DCSS devices upon which the structure is built. In particular, it is analyzed the problem of the possibility of construction laying defects of the isolators, in order to evaluate the influence on the system response of non-parallel sliding surfaces and to estimate the effects on the installed system with respect to the idealized configuration with perfectly horizontal sliding surfaces.

In order to study the problem, a plan geometric model of a single device has been first developed, considering the real geometry of each component, and modeling the defects in terms of inclination of the two sliding surfaces of the device. A f.e.m. code has been implemented, able to simulate the interaction between the devices and the base slab upon which the building is constructed, including the variability of the boundary conditions of the plate in case of isolators loosing the contact during the motion.

A case study has been finally analyzed, for which 260 analyses have been run, with different configurations simulating random defects in the isolators. The inclinations of the sliding surfaces of each device constituted the varying parameters of the analyses and were randomly selected within uniform distribution range. Such a range has been assumed intentionally large ($\pm 1.5^\circ$, much higher than admitted tolerances), in order to evaluate the consequences in extreme conditions.

The results of the numerical analyses showed that installation defects can influence the response of the isolated building more importantly at a local rather than at a global level. Results have been compared to the "ideal" reference case, corresponding to isolators with perfectly horizontal sliding surfaces.

From the global point of view it can be observed that:

- the dissipative behavior is only moderately affected, with a general reduction, due to the detachment of some device and to the redistribution of the vertical load among devices still in contact, considering the dependence of the friction coefficient on the vertical load.
- at the maximum displacement, the horizontal eccentricity of the system reaches values close to the 7%. The actual effects of such eccentricity have still to be evaluated, with a proper tridimensional model of the devices.
- the rate of devices loosing contact during the motion is a function of the relative position of the building with respect to the isolating base slab. As expected, the rows of isolators close to the centre of mass of the building have the lowest probability of loosing contact, while external rows are the most susceptible to detachment.
- For the considered case study, featuring some degree of asymmetry of the building location with respect to the plate, no more than 5 devices out of 40 loose contact simultaneously during the motion.

From the local point of view the analysis have shown that:

- the construction defects may result in localized concentration of vertical loads on occasion importantly higher than the reference situation.
- the loss of contact of some device may result in important increase of bending actions locally induced in the base slab.

From a merely structural point of view, the location of columns close to the devices would allow a more direct transmission of the vertical loads, thus reducing the risk of detachment of the isolators and the localization of high stress values in the slab.

AKNOWLEDGEMENTS

Part of the current work has been carried out under the financial support Italian Civil Protection, within the framework of the Executive Project 2008–2011 (Project e2 – Bearings and isolation systems: characterization of existing typologies and development of innovative prototypes). Such support is gratefully acknowledged by the authors. The authors would also like to thank the Cariplo Foundation, for the contribution within the project 2008-2295.

Abstract. *Very often, especially in densely-resided areas and city centers, neighboring buildings are constructed very close to each other, without sufficient clearance between them. Thus, during strong earthquakes, structural poundings may occur between adjacent buildings due to deformations of their stories. The current study presents a simple but efficient methodology that can be used to numerically simulate the incorporation of rubber layers between neighboring buildings with relatively narrow seismic gaps in order to act as collision bumpers and mitigate the detrimental effects of earthquake-induced poundings. The efficiency of this potential impact mitigation measure is parametrically investigated considering the case of two neighboring multistory structures subjected to various earthquake excitations. The results indicate that under certain circumstances the incorporation of rubber bumpers in an existing seismic gap can reduce the amplifications of the peak responses of the structures due to pounding.*

1 INTRODUCTION

Very often, especially in densely-resided areas and city centers, neighboring buildings are constructed very close to each other without sufficient clearance between them. Therefore, during strong earthquakes, structural poundings may occur between adjacent buildings, due to deformations of their stories. Consequences of such pounding incidences, ranging from local light damage to severe structural damage or even collapse, have been observed and reported in past strong earthquakes [1-4]. In case of structural pounding, both floor accelerations and interstory deflections may be significantly amplified, threatening the functionality and the contents of the building [5-7]. The photograph in Figure 1 shows a pounding incidence between two neighboring buildings, as reported from an EERI/PEER reconnaissance team after the L'Aquila Earthquake, which hit Central Italy on April 2009 [8]. During that seismic event, the roof of a 2-story building hit an adjacent 4-story structure causing significant damage to the columns of the latter at that level. Nevertheless, the third and the fourth stories of the building experienced essentially no damage. The confinement of the damage of the 4-story building at the level of impact indicates the destructive effect of structural pounding.

Figure 1: Damage of a four-story conventional building due to pounding with its adjacent two-story building, during the L'Aquila earthquake in Italy, in April 2009

At the pounding floors, short-period impulses of high amplitude are observed in the acceleration response, while their amplitude is affected by the impact stiffness. The presence of high spikes in the acceleration response due to poundings is a very critical issue, especially for buildings that may house sensitive equipment. Therefore, it is very important to consider impact mitigation measures that could be employed in practice.

Certain mitigation measures have already been proposed, by various researchers who investigated this problem in buildings and bridge decks, in an effort to alleviate the detrimental effects of structural poundings [9]. One of the proposed measures is the incorporation of layers of soft material, such as rubber, on certain locations, where impact is likely to happen. Such elastomeric material could act as a shock-absorber. The effectiveness of such an impact mitigation measure is assessed in this paper, through numerical simulations and parametric studies.

2 IMPACT MODELING

Usually, in numerically simulated dynamic systems, such as multistory buildings under earthquake excitations, structural impact is considered using force-based methods, also known as “penalty” methods. These methods allow relatively small interpenetration between the colliding structures, which can be justified by the local deformability at the point of impact. The interpenetration depth is used along with an impact-stiffness coefficient, representing an impact spring, to calculate the impact forces that act on the colliding structures, pushing them apart. Based on the mathematic relation between the impact force and the interpenetration depth, the impact models can be classified as linear and non-linear models. Furthermore, some models assume that an impact dashpot acts in parallel to the contact spring in order to take into account the energy that is dissipated during an impact [10].

2.1 Concrete-to-concrete impacts

In the current study, impacts between concrete surfaces are simulated assuming a linear impact spring and an impact dashpot exerting, in parallel, impact forces to the colliding structures whenever their separation distances are exceeded. In particular, when a contact is detected, the impact force is estimated at each time-step using the following formulas [7]:

$$F_{imp}(t + \Delta t) = \begin{cases} k_{imp} \cdot \delta(t) + c_{imp} \cdot \dot{\delta}(t) & \text{when } F_{imp}(t) > 0 \\ 0 & \text{when } F_{imp}(t) \leq 0 \end{cases} \quad (1)$$

where $\delta(t)$, is the interpenetration depth, $\dot{\delta}(t)$ is the relative velocity between the colliding bodies, k_{imp} is the impact spring's stiffness and c_{imp} is the impact damping coefficient. The later is computed according to the following formulas, provided by Anagnostopoulos [6]:

$$c_{imp} = 2 \cdot \xi_{imp} \sqrt{k_{imp} \cdot \frac{m_1 \cdot m_2}{m_1 + m_2}} \quad (2)$$

$$\xi_{imp} = -\frac{\ln(COR)}{\sqrt{\pi^2 + (\ln(COR))^2}} \quad (3)$$

In the previous formulas, m_1 , m_2 are the masses of the two bodies and COR is the coefficient of restitution, which is defined as the ratio of relative velocities after and before impact ($0 < COR \leq 1$). In particular, the above impact model is a small variation of the classical linear viscoelastic impact model that had been initially proposed by Anagnostopoulos [1], in which the tensile forces that arise at the end of the restitution period are omitted and a small plastic deformation is introduced, which increases the available clearance between the buildings.

2.2 Simulation of rubber bumpers

A significant part of this numerical problem has to do with the simulation of the behavior of rubber bumpers under impact loading. Anagnostopoulos [6] simulated the usage of a soft material that acted as a shock absorber by simply considering a decreased impact stiffness value for the linear viscoelastic impact model that was used for the simulation of poundings of buildings in series. That research work demonstrated that the use of bumpers may reduce, in some cases, the response due to poundings, although the maximum response values remain higher than the corresponding case without poundings.

Jankowski et al [11] numerically simulated the use of several devices to mitigate structural pounding among bridge segments during earthquakes. That research work examined the case of using dampers and stiffeners, as connectors of the segments in series, or rubber bumpers to absorb impact energy between girders. The rubber bumpers in that case were simulated using a linear spring-dashpot element and the results showed that the incorporation of such devices may substantially reduce the overall response due to poundings.

However, the usage of linear impact models for simulating the response of rubber during impact loading does not seem to be the most suitable, considering the stress-strain curves obtained from experiments [12-15]. In particular, static and dynamic compressive tests of rubber reveal an exponential relationship between compressive load and displacement. Therefore, it would be more appropriate to simulate the incorporation of rubber-bumpers by using a non-linear impact model. Furthermore, since a rubber shock-absorber has a finite thickness, there is a possibility to reach its ultimate compressive strain during severe impacts, whereas the impact stiffness should represent the material behind the rubber (e.g. concrete) and not the rubber bumper, since the ultimate strain of the rubber is exceeded.

In a relevant research work [16, 17], regarding the usage of rubber bumpers as an impact mitigation measure for earthquake-induced poundings of seismically isolated buildings, a non-linear impact model with hysteretic damping has been proposed and verified. That simple and efficient impact model is also used in the simulations performed in the present research work. The impact force during the approaching phase is provided by the formula:

$$F_{imp}^A = \begin{cases} k_{imp} \cdot \delta^n & \text{for } \delta < \delta_u \\ k_{imp} \cdot \delta_u^n + k_{imp_PY} \cdot (\delta - \delta_u) & \text{for } \delta > \delta_u \end{cases} \quad \text{when } \dot{\delta} > 0 \quad (4)$$

While during the restitution phase the impact force is computed by the expression:

$$F_{imp}^R = k_{imp} \cdot \delta^n \cdot (1 + C_{imp} \cdot \dot{\delta}) \quad \text{for } \dot{\delta} < 0 \quad (5)$$

In Eq. (4), k_{imp} is the impact stiffness, δ is the indentation and n is the impact exponent ($n > 1$). The impact stiffness is given by the following expression:

$$k_{imp} = \alpha \cdot k_{st} = \alpha \cdot \frac{A \cdot K_r}{d^n} \quad (6)$$

where k_{st} is the bumper's static stiffness and $\alpha > 1$ is a multiplier that ranges usually between the values of 2 to 2.5 as it was found from relevant experiments [15]. A is the contact area of the bumper, d is the bumper's thickness and K_r expresses the material stiffness. The unknown parameters that have to be determined in Eq. (6) is the material stiffness K_r and the exponent n . The values of both parameters depend on the material characteristics and, therefore, their evaluation can be done experimentally. In the current study, those values have been estimated [16-17], based on relevant experiments from the literature [15].

Eq. (4) takes into account the case of exceeding the ultimate compressive strain of the material, during the approach phase, as it is assumed that after a certain indentation, δ_u , which corresponds to the ultimate compressive capacity of the rubber bumper, the exponential trend becomes a linear trend with a linear post-yield stiffness, k_{imp_PY} .

The damping term C_{imp} in Eq. (5) is given by the formula:

$$C_{imp} = 1.55 \cdot \frac{1 - COR^2}{COR^{0.7076} \cdot \left(\frac{m_1 \cdot m_2}{m_1 + m_2} \right)^{0.0025} \cdot v_{imp}^{0.9755}} \quad (7)$$

where v_{imp} is the impact velocity, which is the relative velocity of the two bodies just before impact.

The force-time and force-displacement diagrams of the proposed non-linear model for simulating the response of rubber bumpers under impact loading are shown in Figure 2. Figure 3 demonstrates the same diagrams in the case of exceeding the ultimate compressive capacity of the bumper for three different values of the coefficient of restitution.

Figure 2. Force-displacement diagram of the non-linear impact model with hysteretic damping.

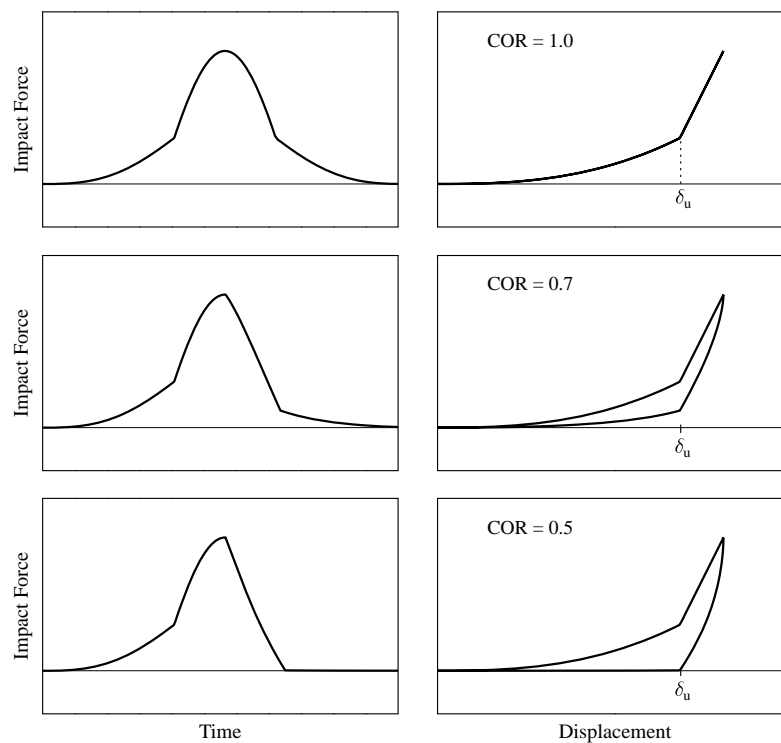

Figure 3: Impact force in terms of time and displacement in the case of exceeding the ultimate compressive strain capacity of the rubber bumper

3 NUMERICAL EXAMPLE CONSIDERING TWO RIGID BODIES

In order to examine the effect of using a rubber shock-absorber on the computed responses after impact, a simple numerical example of two free rigid bodies of equal masses that collide with a constant relative velocity has been performed. Two different circumstances were considered regarding the area of contact. In the first case, concrete-to-concrete impact was con-

sidered and the modified linear viscoelastic impact model was used (Eq. 1). In the second case a rubber bumper 5 cm thick was assumed to be incorporated at the area of contact, which is simulated using the non-linear impact model with hysteretic damping (Eq. 4 and 5). The impact parameters, used in both cases, are provided in Table 1. The masses of the two colliding rigid structures are assumed to be 320 tons each, while two different values of impact velocity were used, specifically 0.5 and 1.0 m/sec.

Property	No Bumper	With Bumper
Impact model	Linear	Non-linear
Exponent (n)	1.0	2.65
Impact stiffness (k_{imp})	2500 kN/mm	0.36 kN/mm ^{2.65}
Coefficient of Restitution (COR)	0.6	0.5
Bumper thickness (d)	-	5 cm
Bumper's max strain (δ_u/d)	-	0.8
Post-yield impact stiffness (k_{imp_PY})	-	2500 kN/mm

Table 1: Impact parameters for the cases without and with rubber bumper.

Figure 4 demonstrates the load-displacement diagrams for the two cases of the impact velocity and for both cases of with and without the use of the rubber bumper. The results show that the indentation, which represents the local deformation at the vicinity of impact, is much larger in the case of having the rubber shock-absorber due to the reduced impact stiffness. Furthermore, in the case of the relatively high impact velocity of 1.0 m/sec, the deformation exceeds the maximum compressive capacity of the 5 cm thick rubber bumper and the impact force begins to rise rapidly, since the post-yield linear impact stiffness is used.

Figure 4: Impact force – displacement diagram for the cases of two impacting rigid bodies, with and without the incorporation of a rubber bumper and for two different values of the impact velocity.

The plots in Figure 5 show the impact force, relative velocity and acceleration time histories for the same cases. It is evident that the use of the rubber bumper elongates the duration of impact and reduces both the maximum impact force and the maximum acceleration. The ratio between the relative velocity after and before impact is equal to the coefficient of restitution used in the corresponding impact model, which verifies the correctness of the two impact models used in the simulations.

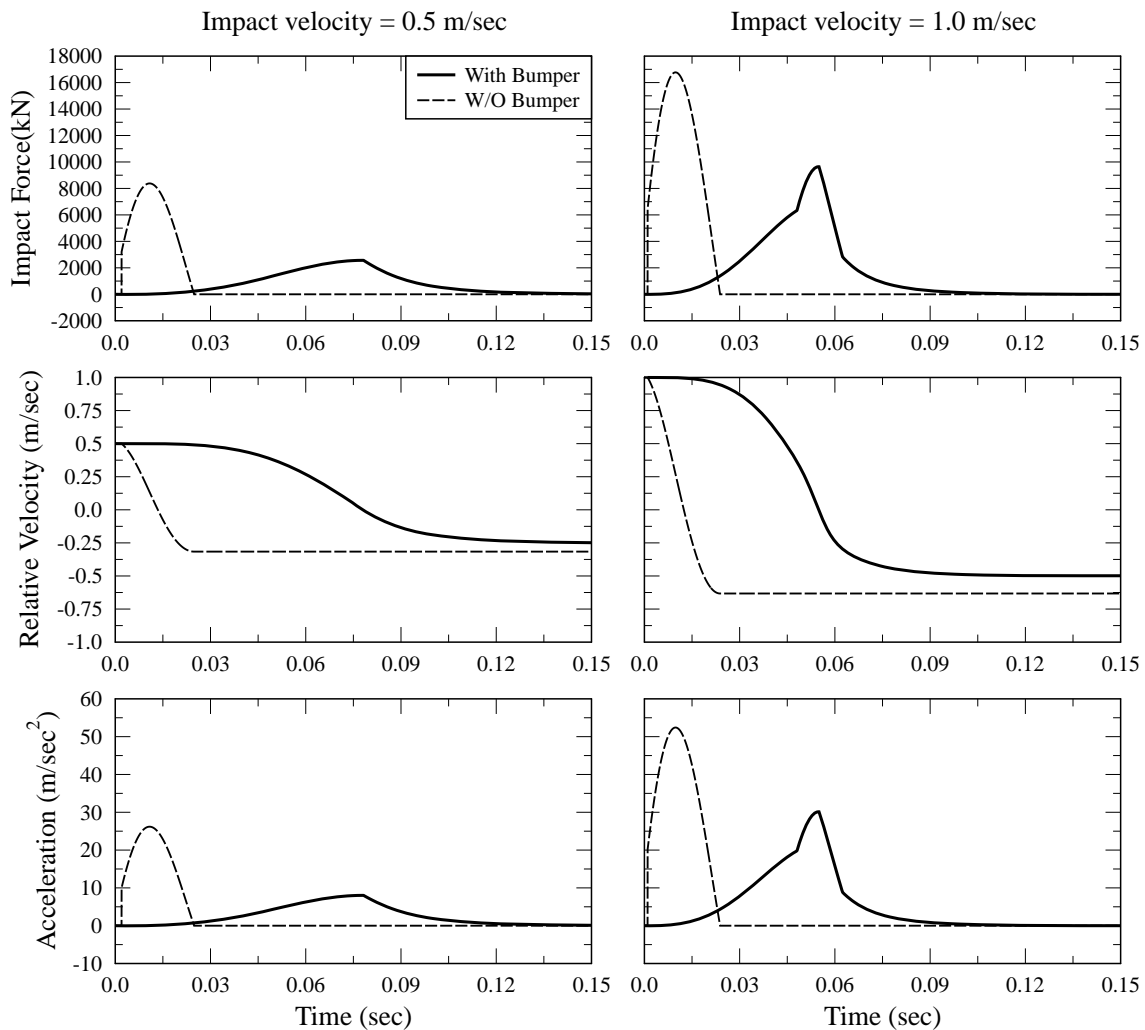

Figure 5: Impact force, relative velocity and acceleration time histories for the case of two impacting rigid bodies, with and without the incorporation of a rubber bumper and for two different cases of the impact velocity.

4 APPLICATION EXAMPLE AND PARAMETRIC ANALYSES

Next, a practical example is presented in order to assess the effectiveness of using rubber shock absorbers as an impact mitigation measure for cases of narrow seismic gap sizes between adjacent multistory buildings. For the numerical simulations, a specialized software application has been specifically developed using modern object-oriented programming in order to efficiently perform dynamic analyses of multistory buildings in two dimensions, modeling the consideration of potential structural pounding. The simulated buildings are modeled as multi-degree of freedom (MDOF) systems, with shear-beam behavior and the masses lumped at the floor levels, assuming linear elastic behavior during earthquake excitations.

A 4-story and a 6-story fixed-supported buildings were considered in series for the performed simulations, as shown in Figure 6. Each floor has a lumped mass of 320 tons, except of the top floor where a mass of 250 tons is considered. Each story has a horizontal stiffness of 600 MN, while a constant viscous damping ratio of 5% has been considered for both buildings. The floors of the neighboring buildings are assumed to be at the same levels.

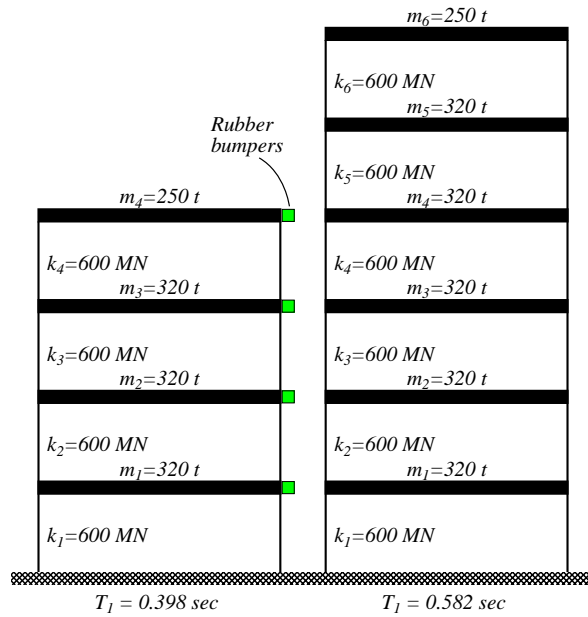

Figure 6: The two multistory buildings considered in the simulations and their structural properties.

For the particular structural system, the performed analysis examined whether the incorporation of rubber bumpers at the locations of potential impacts, which reduces the available seismic gap width, would be beneficial for the colliding buildings or not. For the performed simulations, 5 cm thick bumpers were assumed to be installed at all floor levels, as shown in Figure 6. Therefore, by applying the rubber shock-absorbers at the side of the one of the two buildings, the existing seismic gap size reduces by 5 cm, when compared with the case without the bumper. Consequently, the results obtained from the simulations considering the use of the rubber bumpers are compared with the corresponding results from the case without the bumpers but with a clearance that is 5 cm wider. In the performed parametric analyses, the available seismic gap was varied in the range of 5 to 25 cm, which corresponds to a clearance width of 0 to 20 cm in the case of incorporating rubber bumpers.

In order to investigate the effect of the earthquake characteristics, three different seismic records (Table 2) from relatively strong and widely-known earthquakes were selected as ground excitations.

Earthquake	M_w	Station	PGA (g)
Kobe, Japan 1995	6.9	0 KJMA	0.821
Northridge, USA 1994	6.7	74 Sylmar - Converter Station	0.897
San Fernando, USA 1971	6.6	Pacoima Dam, S16	1.170

Table 2: Earthquake records that were used in the simulations.

Plots in Figure 7 demonstrate the effect of using rubber bumpers on the computed response of the 4-story and the 6-story buildings, in terms of the size of the seismic gap for the Kobe earthquake record. In particular, the plots present the amplification of the peak floor accelerations and peak interstory deflections due to the implementation of the rubber shock-absorbers with a thickness of 5 cm, between the two buildings. The amplification of the response is defined as the ratio of the response obtained after the incorporation of rubber bumpers, which unavoidably reduce the available clearance, to the corresponding response, without the usage

of bumpers. Therefore, the usage of rubber bumpers has beneficial effects on the corresponding response quantity when the amplification ratio value is smaller than 1.0.

The results indicate that the size of the seismic gap affects the effectiveness of the rubber bumper in a different manner on each floor and for each building. For example, the peak floor acceleration at the 4th floor of the 4-story building is reduced after the incorporation of the bumper almost for all seismic gap sizes, while at the same time the peak acceleration at the 2nd floor of the 6-story building amplifies up to 30%. Moreover, the maximum interstory deflections are not affected in the same way with the floor accelerations, since the later may be amplified after the use of the rubber bumper, while the former are reduced for a certain gap size. Nevertheless, peak floor accelerations seem to be more sensitive to the use of bumpers than interstory deflections, since the variations of the curves in the plots of Figure 7 are more pronounced in the former case.

Figure 7: Amplification of the peak floor accelerations and interstory deflections of the 4-story and the 6-story buildings, due to the usage of rubber shock-absorbers, in terms of the width of the seismic gap, considering the Kobe earthquake record.

In order to be able to provide the computed results from all three earthquake records in the same plots, the mean peak responses among all floors of the buildings are computed and plotted in Figure 8. Specifically, these plots demonstrate, in a more general form, the effect of applying rubber bumpers of 5 cm thick inside the available gap on the overall seismic response of the two buildings. It is observed that the characteristics of the earthquake excitation affect the effectiveness of this kind of an impact mitigation measure, in combination with the size of the available clearance. It can be also observed that, under the considered circumstances, the incorporation of such a shock-absorber amplifies, in most of the times, the response, especially in the case of the 6-story building. However there are some cases of relatively narrow gap sizes in which the usage of rubber bumpers seems to be beneficial.

Figure 8: Mean values of the peak responses among all floors of the 4-story and the 6-story buildings, due to the usage of rubber shock-absorbers, in terms of the width of the seismic gap.

In the previously presented simulations, it has been assumed that, after the attachment of rubber bumpers on the side of the seismically isolated building, the reduction of the available clearance from the surrounding moat wall equals to the corresponding thickness of the bumpers. However, the rubber bumpers could be attached in small cavities on the buildings' walls, taking full advantage of the compressible width of the rubber, as shown in Figure 9, without unnecessarily decreasing further the width of the seismic gap. For example, if the thickness of a rubber bumper is 5 cm and its maximum compressive strain equals 0.8, then the compressible width δ_u of the bumper is 4 cm. Therefore, if the particular, 5 cm thick shock-absorber is attached in a cavity that is 1 cm deep, its effective width of 4 cm can be fully utilized, without unnecessarily decreasing further the width of the available seismic gap by 1 cm.

Figure 9: Attachment of a rubber shock-absorber in a cavity on the building's wall.

The above technique seems to be quite efficient since the corresponding amplification ratios due to the incorporation of the bumpers, shown in Figure 10, are substantially reduced in relation to those of Figure 8.

5 CONCLUSIONS

The performed simulations indicate that the incorporation of rubber shock-absorbers to an existing seismic clearance can reduce the peak responses of the pounding structures, under

certain circumstances. The effectiveness of the bumpers depends on the existing gap size in combination with the earthquake characteristics and the structural properties (e.g number of stories). The attachment of the bumper in cavities on the building's wall, taking full advantage of the whole compressible width of the rubber, improves their efficiency.

Nevertheless, it has to be mentioned that the above observations concern only the specific earthquake excitations, structural properties and arrangement of buildings. There is a need for further investigation, performing numerous simulations considering different characteristics of the structures, more buildings and earthquake records, where the effectiveness of such impact mitigation measures will be more generally assessed.

Figure 10: Mean values of the peak responses among all floors of the 4-story and the 6-story buildings, due to the usage of rubber shock-absorbers, in terms of the width of the seismic gap. with 1cm cavity (full advantage of bumper effective thickness, i.e. 4cm)

Keywords: Negative Stiffness Device, Apparent yielding, Passive, True Negative Stiffness

Abstract. *Structural weakening and damping is an approach previously proposed for the reduction of seismic forces and drifts in structures. While this approach is very efficient, it requires a reduction in strength, which will result in inelastic excursions and permanent deformation of the structural system during the seismic event. This paper describes a true Negative Stiffness Device (NSD) that can emulate weakening of the structural system without inelastic excursions and permanent deformations. The Negative Stiffness Device (NSD) is a self contained device that produces a force which is in the same direction as the imposed displacement, thus the name “negative stiffness”. The device is inherently unstable but when installed in a structure transfers a force at its installation level which in turn reduces all forces, drifts and accelerations above that level. The NSD is therefore capable of limiting the forces developed in a structure without any yielding which could lead to permanent deformations. The NSD was developed at the University at Buffalo (UB), Rice University and Taylor Devices Inc. and tested on a shake table by authors in a three storied structural model isolated with elastomeric bearings. The NSD consists of a highly compressed spring in a double negative stiffness magnification mechanism. In order to ensure a considerable amount of positive stiffness of the global system around small displacements to minimize wind vibrations a so called gap spring assembly (GSA) mechanism is implemented which delays the engagement of the device by a prescribed displacement. Moreover, the device employs double containment chevron braces that contain the large vertical forces needed for the development of negative stiffness without transferring these forces to the structure. This paper describes the development of analytical and computational tools that describe the behavior of the device and presents results for the experimental verification of these tools.*

1 INTRODUCTION

Designing structures for ductile behavior and allowing for significant inelastic action in strong earthquakes results in reduction of inertia forces. However, this is accompanied by large drifts, permanent deformations and eventually loss of functionality of the structure after a seismic event. Reinhorn et al. (2005) [1] and Viti et al. (2006) [2] introduced the concept of weakening structures (reducing strength and implicitly stiffness), while introducing supplementary viscous damping to reduce simultaneously total accelerations and inter-story drifts. However, weakening also reduces strength and results in some permanent displacements. An alternative approach is to “simulate yielding” by introducing negative stiffness at prescribed displacements leading to the idea of “apparent weakening”.

The concept of true negative stiffness for structural applications was first introduced by Nagarajaiah et al [3]. True negative stiffness means the force must assist motion, not oppose it as it is in the case of a positive stiffness spring. Pseudo negative stiffness [4] can be accomplished using active or semiactive hydraulic device. True negative stiffness needs no external power supply. The Negative Stiffness Device (NSD) presented herein is entirely composed of springs and generates an elastic nonlinear true negative stiffness.

By engaging the NSD at an appropriate displacement (simulated yield displacement), which is well below the actual yield displacement of the structural system, the composite structure-device assembly, behaves like a yielding structure. The NSD has a re-centering mechanism thereby avoiding permanent deformation in the composite structure-device assembly unless, the main structure itself yields. However, the combined structural system with just the NSD develops increased structural deformations. Addition of passive dampers reduces and controls these deformations without any considerable increase in the base shear. The addition of dampers combined with the reduction of stiffness also lead to an increased damping ratio which presents an additional advantage in controlling the displacements.

In order to visualize the effect of adding true negative stiffness to a structure, consider the force displacement plots shown in Figure 1(a) (green line is structure, magenta is viscous damper and red is negative stiffness device). By adding NSD to the structure, schematically shown in Figure 1(b), the assembly stiffness reduces to $K_a = K_e - K_n$ beyond the displacement x_1 (shown as blue line in Figure 1(b)). If, F_2 and x_2 are the maximum restoring force and maximum displacement of a perfectly-linear system (green line in Figure 1(b)) then for the same load the maximum restoring force and maximum displacement of the assembly are F_3 and x_3 (blue line in Figure 1(b)), respectively. K_n is designed to achieve the desired reduction in base shear. Force exerted by the NSD is shown as red line in Figure 1(b). Although the reduction in base shear is achieved the maximum deformation of the adaptive system is substantially increased in the process when compared with an elastic system. Deformation of this assembly can be reduced by adding a passive damping device in parallel to the NSD, schematically shown in Figure 1(c).

Figure 1: Working Principle of NSD (Nagarajaiah et al 2010)

Photographs of the NSD are shown in Figure 2a (un-deformed) and Figure 2b (deformed). The device itself is inherently unstable. It can be installed in an isolated structure between the ground and the isolation level or in between the floors of any fixed and/ or isolated structure. Its effect is that it reduces the forces that are transferred above its installation level.

In order to ensure a considerable amount of positive stiffness around small displacements in order to minimize wind vibrations and account for some variability in structural and NSD properties, a so called gap spring assembly (GSA) mechanism is implemented which essentially makes the device engage at a larger displacement (displacement x_1 in Figure 1) rather than at the initial position of the structure.

The current paper focuses on the analytical framework and experimental validation of the NSD which uses only a part of the experimental NSD testing program. Complete details and additional analytical and computational issues, further experimental validation together with shake table testing and the verification of the true Negative Stiffness (NS) concept through shake table testing can be found in [5, 6].

2 NSD DESCRIPTION

2.1 NSD Operation

The NSD shown in Figure 2a is composed of a pre-compressed spring shown in the center of the device as well the gap spring assemblies on the bottom. A combination of frame elements and plates hold these pieces together. When the device deforms, the pre-compressed spring is the one that creates the force that assists the motion or the negative force and thus the name negative stiffness for the device. The bottom spring assemblies (gap spring assembly mechanism) provide the device inherently with a bilinear elastic positive stiffness in order to make the device engage at larger displacements (displacement x_1 in Figure 1). More specifically, around equilibrium, the positive stiffness caused by the gap spring assembly mechanism, cancels out the negative stiffness caused by the pre-compressed spring so that essentially the force/stiffness generated by the device is close to zero. After a prescribed

displacement, the gap spring assembly softens drastically so that the pre-compressed spring acts essentially on its own creating the negative stiffness. It is noted that the operation of the gap spring assembly is achieved without any yielding so that there is no inherent permanent deformation in the device.

Figure 2: View of Negative Stiffness Device tested at SUNY Buffalo

Schematic diagram of the device in its deformed configuration is shown in Figure 3 after imposing a displacement on the top of the device. The lever imposes a displacement on the top of the pivot plate (point B) making the pivot plate to rotate about point C. Due to the axial rigidity of the lever and its negligible rigid body rotation, the imposed displacement and the displacement of Point B are approximately equal. Since the pivot plate rotates about C, point D moves in the opposite direction from the imposed displacement. Point E is rigidly connected to the top of the device and therefore has a displacement equal to the one imposed. Due to the kinematics of points D and E, the pre-compressed spring rotates and its pre-compression force facilitates the motion rather than opposing it. Moreover since the “negative force” is generated by a spring whose deformation depends nonlinearly to the NSD imposed displacement, the NSD exhibits nonlinear elastic behavior.

The spring exhibits its minimum length when the device is un-deformed. As the device deforms, the spring extends thus its pre-compression force reduces while its inclination angle increases and the stiffness magnitude generated by the device reduces. This gradual stiffness reduction will eventually lead to positive stiffness at larger displacements and this is termed as “stiffening” throughout this paper. This stiffening part can be very important in the case the maximum considered earthquake has been exceeded since it limits the displacements of the structure or the isolators.

Figure 3: Terminology used for the elements of the Negative Stiffness Device

2.2 Advantages of NSD Tested at SUNY Buffalo

Negative Stiffness in applications other than earthquake has been proposed and used at small scale for the vibration isolation of equipment by Molyneaux (1957) [7], Platus [8-16], Carrella et al [17] and for car suspension systems [18]. It has also been proposed in base isolation [19] with the application of the convex pendulum bearings in parallel with elastomeric bearings. The NSD described in the current paper is a large scale novel design that passively generates negative stiffness and it is not restricted to only base isolation. The NSD presents the following advantages:

- The device changes the **apparent global lateral stiffness** of the structure, without changing the actual stiffness of the structure. The apparent stiffness is reduced to a very low level simulating global lateral yielding without actual yielding in the main structure.
- The device produces **true horizontal negative stiffness** by passively generating a force that assists the imposed displacement. No external power supply is needed since all the elements comprising the device are passive.
- The device is self contained and therefore when installed affects only the horizontal stiffness of the system while leaving the vertical stiffness intact. Stability and buckling limits of the structure are not affected. **The NSD does not participate in transferring the vertical loads.**
- There is no significant hysteresis in the device. The NSD is essentially elastic.
- The device provides variable stiffness which becomes positive at large deformations, therefore its global behavior is “elastic nonlinear”. This is a desired feature as it promotes stability.
- The device employs a double magnification mechanism that allows for easy adjustment of the negative stiffness value. The gap spring assembly (GSA) mechanism allows for adjustable gap opening.

3 OUTLINE OF THE EXPERIMENTAL PROGRAM

The experimental setup is shown in Figure 4a. The 3 story structure –used before as a six story structure [e.g., 20] - is sitting on top of four low damping elastomeric bearings used before in [20]. The elastomeric bearings were tested individually at the single bearing testing machine at UB described in [21]. Two NSD's were installed on the side of the shake table and were connected to the base of the superstructure with rollers in order to accommodate the height loss that they exhibit during deformation. The tests conducted at UB were divided in to two major categories: 1) Displacement controlled tests with and without the gap spring assembly and 2) Shake table tests involving various configurations of the NSD with and without viscous dampers. The displacement controlled tests were achieved by externally bracing the superstructure at the base-mat level through a reaction frame that was constructed on the side of the shake table and shown in Figure 4a on the right while the bracing system is shown in Figure 4b.

Figure 4: Experimental Setup

Each NSD is sitting on top of four load cells [22] and instrumented at points B,C,D,E with string pots and accelerometers. NSD East is also heavily instrumented with Krypton LED's. Krypton is an advanced camera coordinate tracking system described in [23].

Figure 5: Instrumentation for NSD East

4 ANALYTICAL EQUATIONS OF NEGATIVE STIFFNESS DEVICE

In order to derive the force displacement equations of the device, equilibrium at the deformed shape needs to be considered since essentially the operation of the device is based on geometric nonlinearity. Therefore one needs to consider the deformed shape and the device being supported horizontally on top by the application of a force which is essentially the negative force generated by the device. The forces acting on the pivot plate caused by the pre-compressed spring and the lever are shown in Figure 6. From geometry and considering the fact that point C is fixed, the displacements of other points of the device are:

Figure 6: Forces acting on pivot plate

$$u_B = u_E = u_D \frac{l_2}{l_1} = u \quad (1)$$

In Figure 6, θ_s is the angle of the spring θ_p the angle of the pivot plate with respect to vertical. θ_s and θ_p are obtained from equation (2):

$$\theta_s = \arcsin \frac{1}{l_s} u \left(1 + \frac{l_1}{l_2} \right) \quad (2)$$

$$\theta_p(t) = \arcsin \frac{u}{l_2}$$

The spring length at the deformed configuration is given by:

$$l_s = \sqrt{\left(l_p + l_1 - l_1 \sqrt{1 - \left(\frac{u}{l_2} \right)^2} \right)^2 + u^2 \left(1 + \frac{l_1}{l_2} \right)^2} \quad (3)$$

l_p is the length of the spring when the NSD is un-deformed and F_s is the force of the pre-compressed spring:

$$F_s = P_{in} - K_s(l_s - l_p) \quad (4)$$

P_{in} is the pre-compression force of the spring and should have a positive value and K_s is the stiffness of the pre-compressed spring.

Writing the equilibrium equations for the pivot plate for the forces of Figure 6 and using equations (1)-(4) yields the horizontal force at point C. Then from Figure 3 one can see that the total NSD force is simply $F_{NSD} = F_C + F_g$. The final expression for the force generated by the NSD as a function of the imposed displacement is given in equation (5):

$$F_{NSD} = -\left(\frac{P_{in} + K_s l_p}{l_s} - K_s\right)\left(\frac{l_1}{l_2}\right)\left(2 + \frac{l_2}{l_1} + \frac{l_p + l_1}{\sqrt{l_2^2 - u^2}}\right)u + F_g \quad (5)$$

The force displacement of the gap spring assembly for monotonic positive displacement is given by:

$$F_g = \begin{cases} k_{g1}u, & 0 \leq u \leq d_{gap} \\ k_{g1}d_{gap} + k_{g2}(u - d_{gap}), & u > d_{gap} \end{cases} \quad (6)$$

d_{gap} is a prescribed displacement at which the gap spring assembly softens and H is the Heaviside function

Quantity	Value
Distance from spring pin to fixed pin	$l_1 = 10in$
Distance from lever pin to fixed pin	$l_2 = 5in$
Spring length	$l_p = 30in$
Spring rate	$K_s = 0.8 \text{ kips/in}$
Preload	$P_{in} = 3.7 \text{ kips}$
Gap opening	$d_{gap} = 0.65in$
Gap Spring Assembly Stiffness for $u < d_{gap}$	$K_{g,1} = 2.81 \text{ kips/in}$
Secondary spring assembly stiffness $u > d_{gap}$	$K_{g,2} = 0.17 \text{ kips/in}$

Table 1: NSD Properties

The force displacement loops for the derivations above are generated in figure 7 for the properties shown in Table 1.

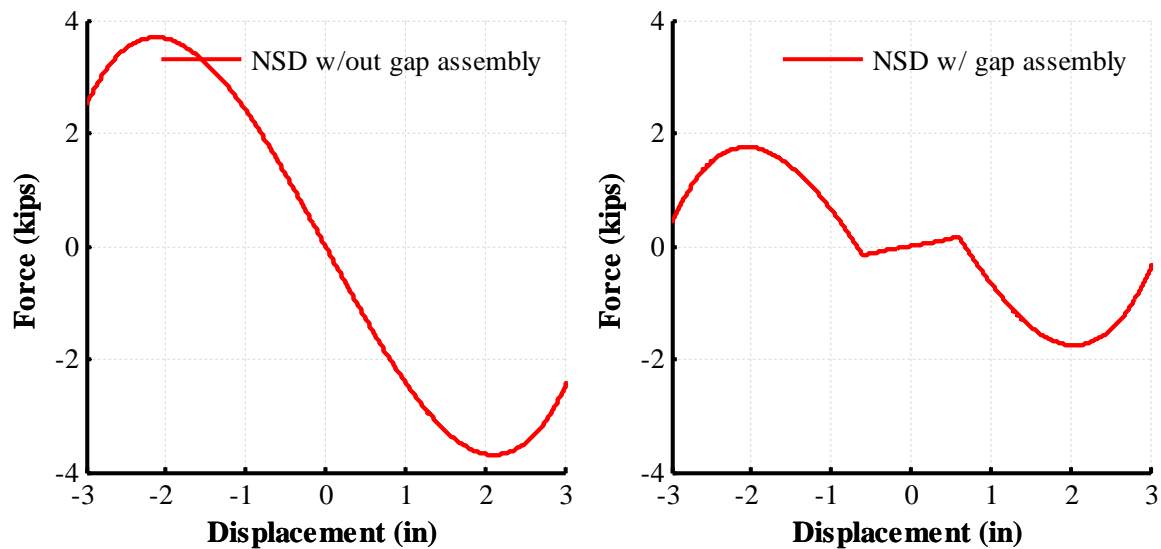

Figure 7: Force versus NSD imposed displacement plots for NSD with and without the gap spring assembly

5 MODELING OF NSD IN SAP2000

Modeling the NSD in user subroutines is straightforward by implementing equations (5) and (6). In SAP2000 [24], the NSD behavior can be modeled using the multi-linear elastic spring element. One can directly import the force displacement loop of the NSD into SAP2000. There is no restriction in SAP2000 for the sign of the stiffness and therefore negative springs can be implemented as well. The gap spring assembly can be also modeled using the same multi-linear element. The NSD model in SAP2000 is therefore a parallel arrangement of two elements 1) a multi-linear elastic element representing the negative nonlinear elastic component from equation (5) with $F_g=0$ and 2) a multi-linear elastic element representing the positive bilinear elastic component generated by the gap spring assembly and given by equation (6).

The configuration as implemented in SAP2000 is shown in Figure 8 on the left. Both elements ML1 and ML2 share the same joints on top and bottom. Comparisons of the results obtained in the SAP2000 model for a displacement controlled test are compared with the analytical equations in Figure 8 on the right. Results match identically.

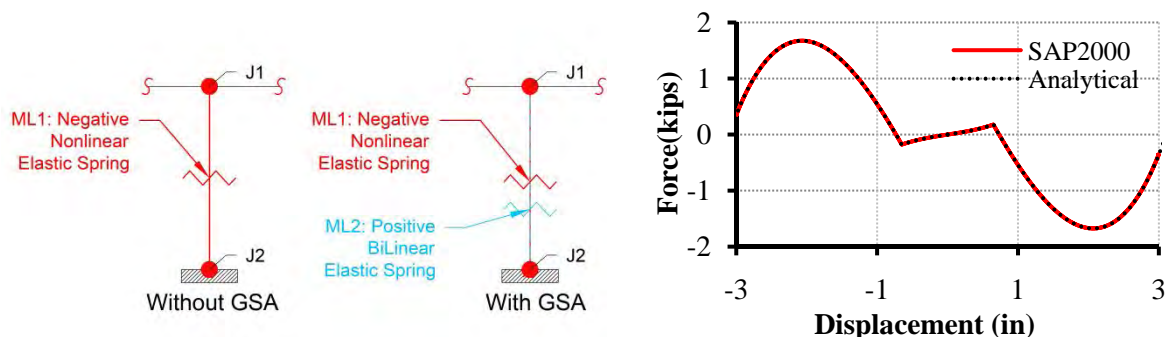

Figure 8: SAP2000 NSD elements for the cases with gap and without gap and comparisons of SAP2000 results with analytical results

6 ANALYTICAL INVESTIGATIONS AND MODELING OF THE DETAILED NSD BEHAVIOR

For most practical applications, the analytical equations and the modeling of sections 4 and 5 is sufficient to provide highly accurate results. The derivations of this section are intended to provide the reader with complete understanding of the detailed mechanics of the NSD. Understanding the complete mechanics of a system is essential in its practical implementation and later on use of the simplified models.

6.1 Analytical Derivations of NSD Dynamics

The rigid body dynamics of the Negative Stiffness are derived here using a Lagrangian formulation. The masses and moments of inertia in the actual device are shown in Figure 9. All frame elements connected to the top channel and the double hinged columns, undergo an inverted pendulum motion around the base and their moment of inertia is lumped at F and H respectively. At point C the mass moment of inertia of the pivot plate is lumped. The center of mass of the spring undergoes both translation and rotation. Its mass m_s is lumped at its center of mass located at point S. Its moment of inertia varies with displacement u .

Figure 9: Discretization of the device

Considering the fact that the rotations of the individual components are coupled to the imposed displacement there is only one degree of freedom. The rotation of the pivot plate and spring is given by equation (2), the horizontal displacement of the center of mass of the spring is the average of the displacements of points D and E from equation (1) while the vertical displacement is half the vertical displacement of point D and can be easily calculated from geometry of Figures 3, 6 and 9 while angle θ can be calculated from the geometry of figure 9. All quantities above are functions of the imposed NSD displacement alone.

The Euler-Lagrange equation for the NSD is:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{u}} \right) - \frac{\partial L}{\partial u} = 0 \quad (7)$$

$$L = K - V$$

Where K is the total kinetic energy of the system and V is the total potential energy of the system with respect to a reference coordinate system given as the sums of the kinetic and

potential energies of the individual moving parts of the device. The total kinetic and potential energies (with reference to C) of the system are given from:

$$K = \frac{1}{2} I_p \dot{\theta}_p^2 + \frac{1}{2} m_s \dot{u}_s^2 + \frac{1}{2} m_s \dot{v}_s^2 + \frac{1}{2} I_s \dot{\theta}_s^2 + \frac{1}{2} I_h \dot{\theta}^2 + \frac{1}{2} I_f \dot{\theta}^2$$

$$V = -m_f g \left(l_p + l_1 - \bar{y} \cos \theta \right) - m_s g \left(l_1 + \frac{v_{DE}}{2} \right) + m_c g \left(h - v_{LB} - \frac{h}{2} \cos \theta \right) + V_{el,s} + W$$
(8)

The potential energy coming from the deformation of the spring in equation (8) is:

$$V_{el,s} = \frac{1}{2} K_s \left[l_s - \left(l_p + \frac{P_{in}}{K_s} \right) \right]^2$$
(9)

The external work done by a restraining force in (8) has to be expressed as a potential so:

$$W = - \int F du = -Fu + C$$
(10)

It is noted that the force above is the force needed to be applied at the top of device in order to hold the device in place and make it stable. Equivalently this is the force generated by the device.

Using equations (7)-(10), (1)-(4) and after performing some tedious algebra which involves the calculation of the derivatives involved in equations (7) and (8) we can get the equation of motion of the NSD which is given by:

$$M_a \ddot{u} + M_v \dot{u}^2 + M_u u = F$$
(11)

The terms M_a , M_v and M_u , are given by complex expressions and final results are omitted for simplicity. The force displacement loops of the device for various driving frequencies are plotted in Figure 10 for the device properties of table 1. The effect of the inherent dynamics is that of increasing the negative stiffness and maximum force generated by the NSD while slightly delaying the initiation of stiffening. The driving frequencies of Figure 10 are only for demonstration purposes. The accelerations and velocities for the higher frequencies shown there are unrealistic and therefore the effect of the inherent dynamics is negligible.

Figure 10: Force Displacement Loops of NSD for various excitation frequencies

6.2 Analytical Derivations of NSD Imperfections

Although the pins are typically assumed to be frictionless and dimensionless, in reality they are not. When a pin is connecting two members, in order for the member to start rotating relatively one to the other, a friction force must be overcome either between one member and the pin, or the other member and the pin, or both. For example consider the assembly shown in Figure 11a:

Figure 11: Pin friction model

In Figure 11a, it is assumed that rotation of the pin occurs because connecting part 1 rotates relatively to the pin while the pin and part 2 are in sticking conditions. In order to have a relative rotation between one of the connecting parts and the pin, we need to apply a torque on the pin of magnitude:

$$M_p = r\mu_p |P_p| \quad (12)$$

r is the radius of the pin, P_p is the resultant force acting on the pin and μ_p is the friction coefficient.

Figure 11b shows the free body diagram of the pivot plate and 11c of the doubled hinged columns considering friction in the pins. Based on Figure 11b, due to the moment at points B and A, the lever now has a shear force equal to:

$$F_{By} = \frac{2M_B}{l_v} \quad (13)$$

Writing the equilibrium equations for Figure 11b the unknown forces can be computed:

$$\begin{aligned}
 F_{Bx} &= -\frac{F_s}{l_s} \frac{l_1}{l_2} \left[1 + \frac{l_p + l_1}{\sqrt{l_2^2 - u^2}} \right] u + \frac{M_D + M_B + M_C + \frac{2M_B}{l_{lv}} \left(l_2 - \sqrt{l_2^2 - u^2} \right)}{\sqrt{l_2^2 - u^2}} \\
 F_{Cx} &= F_{Bx} - \frac{F_s}{l_s} u \left(1 + \frac{l_1}{l_2} \right) \\
 F_{Cy} &= -F_s \frac{l_p + l_1 - \frac{l_1}{l_2} \sqrt{l_2^2 - u^2}}{l_s} + F_{By}
 \end{aligned} \tag{14}$$

From Figure 11c, the end moments caused by the friction in the pins cause a shear force that is constant throughout the height of the double hinged columns:

$$F_{Lx} = \frac{2M_L}{h} \tag{15}$$

The total force of the NSD becomes:

$$F_{NSD} = F_{Cx} + 2F_{Lx} + F_g \tag{16}$$

The equation above can be decomposed into a nonlinear elastic part and a hysteretic part, $F_{NSD} = F_{el} + F_{pl}$. We approximate the hysteretic moment by using the Sivaselvan-Reinhorn [25] hysteretic model:

$$dM = k_o \left\{ 1 - \left| \frac{M}{M_y} \right|^2 \text{sign}(M) \text{sign}(d\theta) \right\} d\theta \tag{17}$$

$d\theta$ is the rotation increment of the pin being different for each pin, du is the increment of the imposed displacement while k_o elastic stiffness of the pin prior to slipping occurring.

According to equation (17), in order to calculate the moments of the pins, we need to calculate the resultant forces as well as the rotation increments of all the pins. The resultant forces can be calculated from the free body diagrams of Figure 11b, c. The pin rotation increments can be calculated by differentiating the pin rotations with respect to the imposed NSD displacement and then solving for the rotation differentials. The pin rotations are given from equation (2) for point C, similarly for point B if the negligible rotation of the lever is ignored, as $\theta_D = \theta_C + \theta_s$ for point D with the help of equation (2) for the spring angle and from the geometry of Figure 9 for the rotation θ of the double hinged columns.

The set of equations (12)-(15) and (17) written for each pin with its corresponding resultant forces and rotation increments represent a system of equations on the unknowns. Consider the unknown vector at time step $n+1$:

$$\mathbf{x}_{(n+1)} = [M_{Bn+1} \quad M_{Cn+1} \quad M_{Dn+1} \quad M_{Ln+1} \quad F_{(n+1)} \quad F_{Bx(n+1)} \quad F_{By(n+1)} \quad F_{Cx(n+1)} \quad F_{Cy(n+1)} \quad F_{Lx(n+1)}]^T \tag{18}$$

Collecting all terms of the equations on the left hand side and define $\mathbf{f}(\mathbf{x}_{n+1}) = 0$, using $\mathbf{x}_{n+1}^{(0)} = \mathbf{x}_n$ as the first iteration, then Newton Raphson iteration follows as:

$$\mathbf{x}_{n+1}^{(j+1)} = \mathbf{x}_{n+1}^{(j)} - D\mathbf{f}^{-1}(\mathbf{x}_{n+1}^{(j)})f(\mathbf{x}_{n+1}^{(j)}) \quad (19)$$

Note that the initial conditions at the first step is $\mathbf{x}_0 = [0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ P_{in} \ 0]$

Results are plotted in Figure 12 for the properties listed in table 1 for various friction coefficients. Hysteresis in the NSD is proportional to the horizontal force exerted by the NSD. At large displacements when the NSD force becomes zero so does the hysteretic force while after that it maintains the same sign.

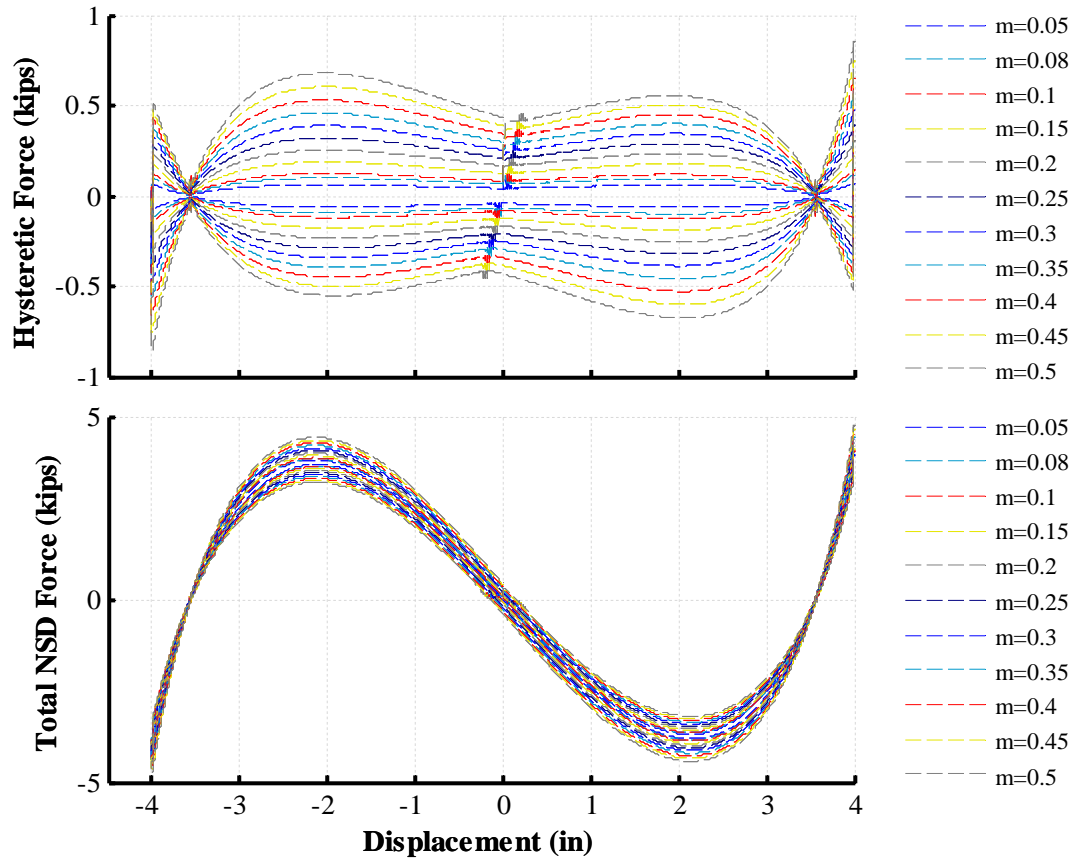

Figure 12: Force Displacement Loops of NSD for various friction coefficients

6.3 Analytical Derivations of NSD Inherent Flexibilities

All the equations up to this point have been derived based on the assumption that point C is fixed and point E undergoes only rigid body motion driven by the top channel of the device. This is only true if the connecting frame elements, namely, the top supporting and the bottom supporting frames are considered rigid. This in most cases is only approximately true.

In order to visualize the flexibility effects, consider an equivalent NSD model shown in Figure 13 in equivalence to the points of Figure 3. Now, at point C a spring k_b is added to approximately represent the flexibilities of the bottom frame together with the bottom supporting channel. Similarly for the top supporting frame, the rigid frame element is no longer assumed to be continuous since a spring k_t is added at its midpoint in order to approximate the flexibilities of the top supporting frame together with the top NSD channel.

$$F_g = \begin{cases} k_{g1}u_E, & 0 \leq u_E \leq d_{gap} \\ k_{g1}d_{gap} + k_{g2}(u_E - d_{gap}), & u_E > d_{gap} \end{cases} \quad (25)$$

Then the total NSD force is given from:

$$F_{NSD} = F_{Cx} + F_g \quad (26)$$

Equations (22)-(26) together with the help of (21) and (4) are a system of 5 nonlinear equations on 5 unknowns which are collected in the following vector $\mathbf{x} = [F_{Cx} \ F_g \ F_{NSD} \ u_C \ u_{fE}]^T$. Then similarly to the hysteresis derivations, all equations are brought on the left hand side, written at step $n + 1$ and iterate based on equation (19).

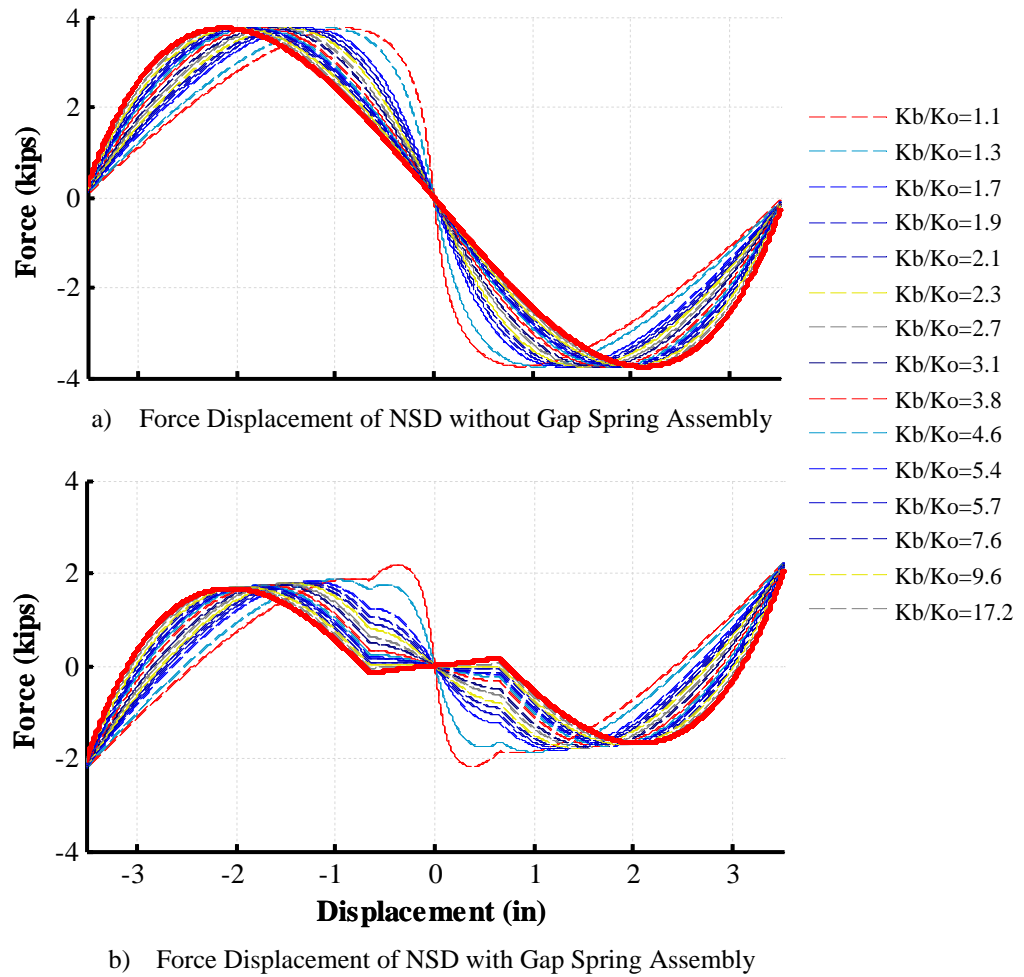

Figure 14: NSD force displacement loops assuming rigid top frame and flexible bottom supporting frame for various stiffness values of the bottom supporting frame

It is noted, that the flexibility of the bottom frame is equivalent to arranging a negative spring in series with a positive spring. Figure 14 shows the results assuming the top frame is rigid and considering various stiffness values for the bottom supporting frame. Legend values are given as ratios of the stiffness of the bottom supporting frame to the Negative NSD stiffness at zero displacement. Flexibility of the bottom frame leads to increased negative stiffness generated by the NSD while the peak force is unchanged and therefore stiffening of the NSD occurs faster than if the bottom frame was rigid. An additional effect of increasing

the Negative Stiffness is the fact the gap spring assembly becomes ineffective since the imposed NSD displacements together with the NSD force becomes inconsistent as shown in Figure 14b.

Results assuming a rigid bottom frame and a flexible top frame are shown in Figure 15a. Due to this flexibility, this case affects the results only when the gap spring assembly is present since point E cannot follow the imposed NSD displacement. This is obvious in Figure 15b which is the force versus NSD imposed displacement of the gap spring assembly.

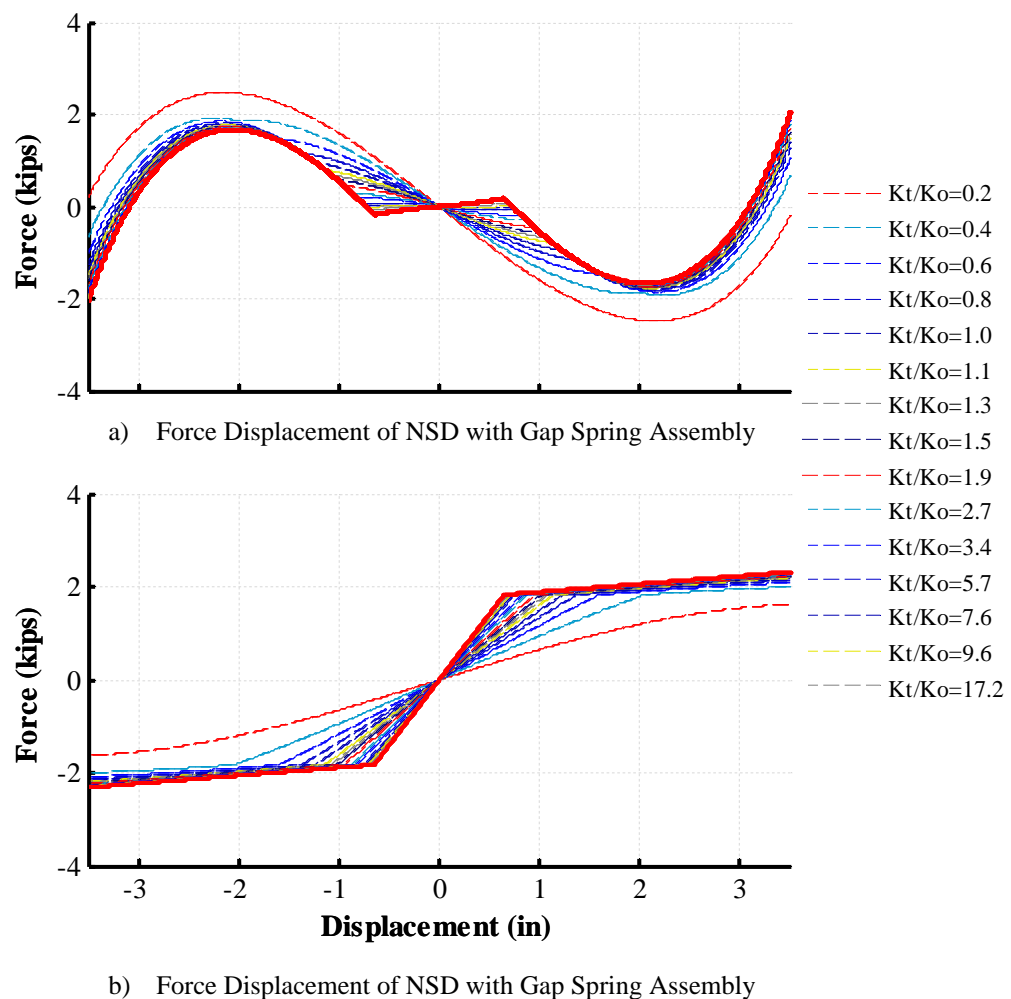

Figure 15: NSD and Gap Spring Assembly force displacement loops assuming rigid bottom and flexible top supporting frame for various stiffness values of the top supporting frame

7 EXPERIMENTAL RESULTS

Results from the experimental study conducted at UB are presented here for the displacement controlled tests. These results are only a minor portion of the complete experimental program. Complete details, additional analytical derivations and results are presented in [5 and 6]. Figure 16 shows the NSD force displacement loops obtained for displacement controlled tests conducted at 0.02Hz as well as comparisons of the forces obtained from the elastomeric bearings, the NSD's and the total base shear. Installing the Negative stiffness device indeed reduces the total base shear and generates a “negative force” if one compares the red line with the blue line. The blue line represents what the base shear would have been in the absence of the NSD.

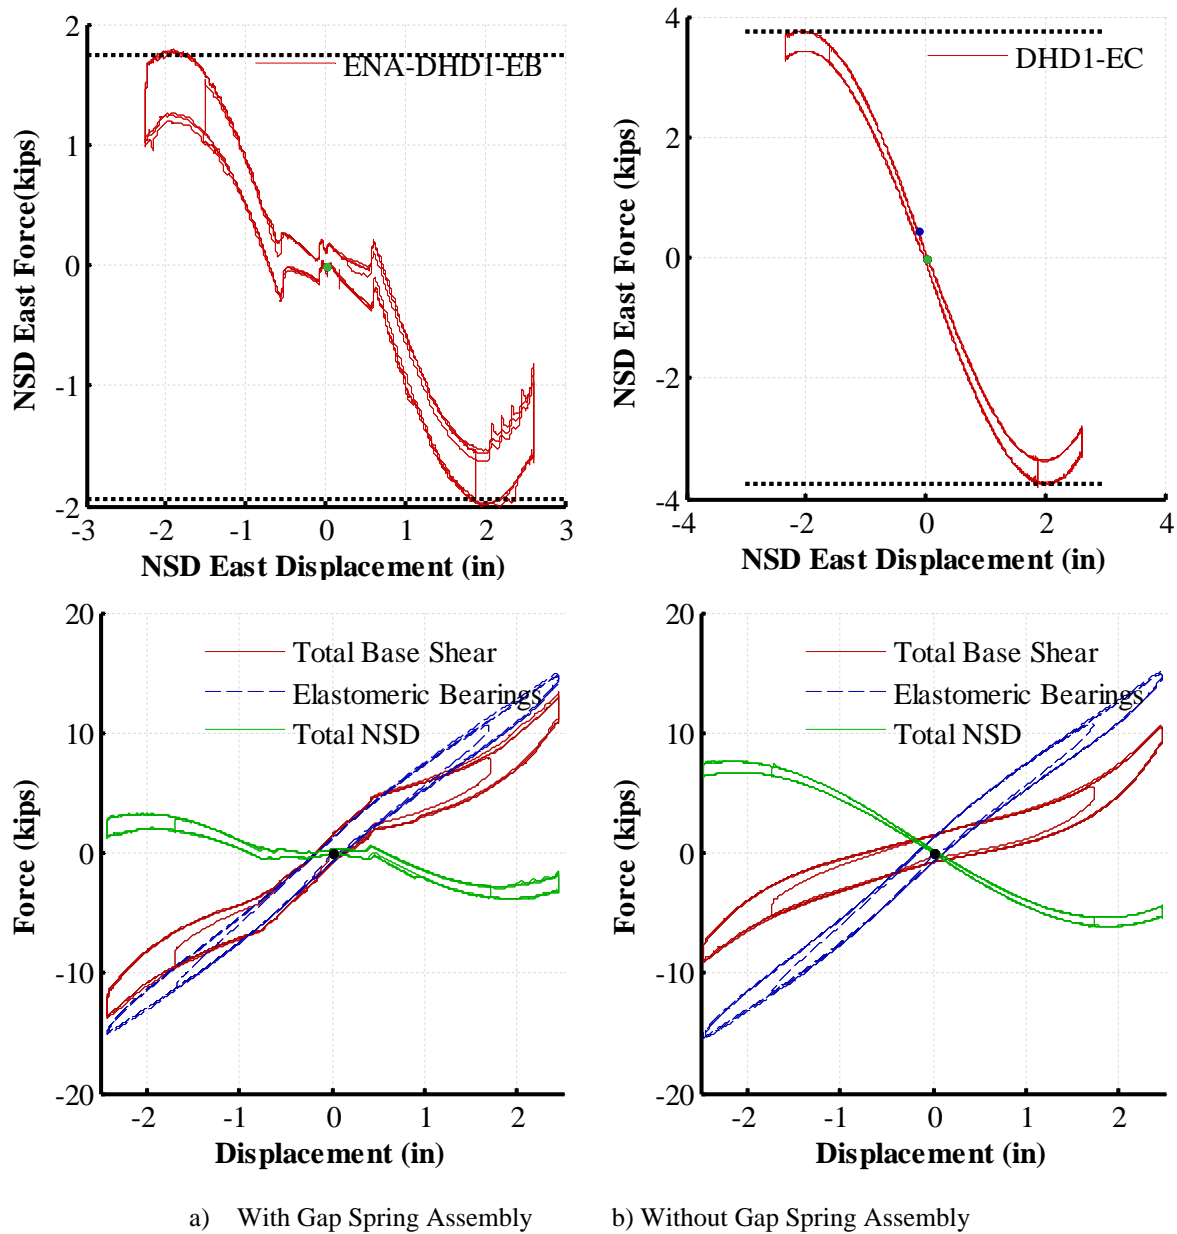

Figure 16: Experimental Results from Displacement Controlled Tests of NSD

Figure 17 shows the results obtained from Krypton for the most significant points of the NSD. As expected, point A which is the displacement imposed on the NSD, point B and point E have approximately equal displacements while point D is double in magnitude and opposite in sign from the displacement of point B. All displacements below are given as the relative displacements between their absolute displacements and the displacement of the shake table.

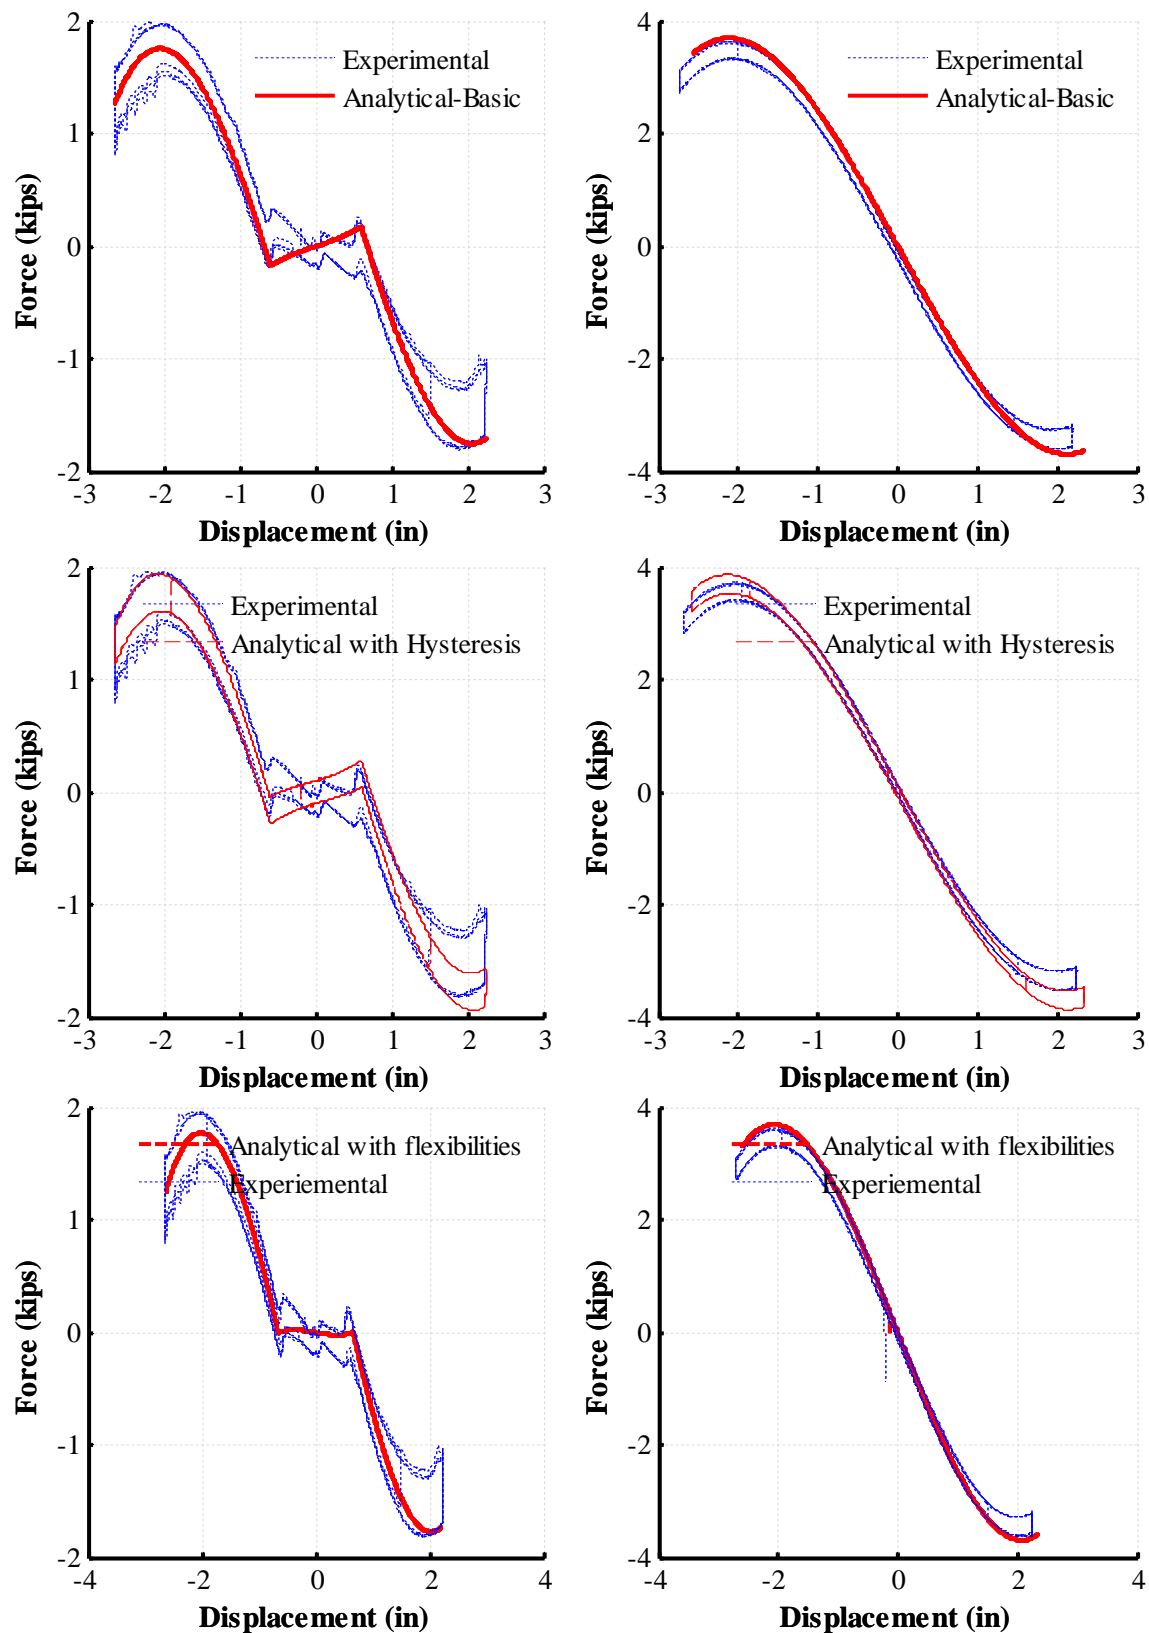

Figure 17: Experimental results from Krypton data acquisition system for displacement controlled tests

8 VERIFICATION OF ANALYTICAL EQUATIONS AND COMPUTATIONAL MODELS

Figure 18 compares all the analytical results described earlier with the results obtained from the experiments. With the exception of the dynamic model comparisons, all other results are shown for static tests conducted at $0.02Hz$ frequency. Analytical results are plotted for the nominal properties of table 1 in order to demonstrate the additional advantage that the NSD exhibits of small variability of its properties. The absence of friction elements and the absolute dependence of the NSD behavior on the pre-loaded spring and geometry make the NSD behavior to be predictable at the design level. Note that inclusion of the flexibilities of the top frame explains the smaller stiffness in the gap spring assembly active region- observed in the experimental results- the dynamics explain the higher “negative force observed during the high frequency tests while the hysteretic element accurately follows the hysteresis trend observed in experiments. Based on these comparisons one can though conclude that the basic analytical equations derived in section 3 are sufficient for accurately capturing the NSD behavior assuming proper design was followed.

Figure 18: Verification of analytical derivations

9 CONCLUSIONS

Based on the material presented above the following may be concluded:

- A novel Negative Stiffness Device (NSD) has been developed. Proof of concept testing was performed at the NEES facility at the University at Buffalo. The NSD was shown to generate negative stiffness and reduce the base shear of a structure.
- Installing a Negative Stiffness Device is an efficient method of reducing the "apparent strength/stiffness" of a structure's floor/story without affecting the vertical stiffness or stability limits of the structure.
- NSD operates with only minor energy dissipation and can be considered to be nonlinear "elastic". Any minor permanent deformations that the NSD might exhibit are eliminated by the gap-spring assembly.
- Basic NSD properties that determine its behavior are adjustable and therefore the NSD can generate a wide range of behaviors by simple adjustments that can be performed even after the installation of the device.
- NSD generates reliable and predictable behavior which can be accurately predicted. This is due to the mechanical nature of the device, consisting of links and springs of well known geometry and of predictable mechanical properties. Note that the comparisons of the analytical versus experimental results are done using the nominal spring properties in order to specifically demonstrate this advantage. No testing was conducted on the individual components (springs).
- Although the NSD behavior might be affected by many factors, the influence of those factors is minor. The NSD behavior can be very accurately predicted by the equations of section 3 and modeling of section 4. Additional complex derivations presented herein help in obtaining understanding of the complete mechanics of the system and provide the designer with additional confidence in using the NSD in practical applications.
- Complete details on the experimental program as well as further analytical and computational work will be enclosed in [5] and [6].

Keywords: Vibration control, Izadkhashast Bridge, Viscous damper, Passive control, Earthquake

Abstract. *Present study addresses the effectiveness of viscous dampers (VDs) in reducing the response of Izadkhashast Bridge under earthquake ground motions. With the length of 485 m, Izadkhashast Bridge is the longest box girder bridge in Iran and is located in Isfahan-Shiraz railway. The bridge is installed with VDs at the two ends. The Finite element model of the bridge is developed. Five pairs of representative earthquake records are selected and scaled using the earthquake code and applied to the model. Nonlinear seismic analyses of the structure without and with VD's are performed and the results are reported. Comparison of the results clarifies VD's effectiveness on seismic response reduction of the bridge. Sensitivity analyses are performed to demonstrate the effects of damper parameters on structural response.*

1 INTRODUCTION

The basic function of passive energy dissipation devices when added to a structure is to absorb and dissipate a portion of the input energy, thereby reducing energy dissipation demand on primary structural members and minimizing possible structural damage. Serious efforts have been devoted to the development and utilization of passive energy dissipation devices [1]. Viscous dampers (VD's) are a kind of these devices which significant efforts have been directed toward their application for structural vibration control. In VDs, energy dissipation occurs via conversion of mechanical energy to heat as a piston deforms a thick, highly viscous substance [1]. In present study, the effectiveness of VD's on response reduction of Izadkhast Bridge under earthquake ground motions is investigated.

With the length of 485 m, Izadkhast Bridge is the longest box girder bridge in Iran. This bridge is located in the central part of Iran, spanning Izadkhast valley on the railway line between Isfahan and Shiraz. The bridge is composed of five 77 m spans in the middle, two side spans having the length of 20 m and 40 m, six piers and two abutments, as shown in Fig. 1. The cross section of piers is shown in Fig. 2. With the width of 6.6 m, the deck is composed of two 4.5 m high box girders (Fig. 3). Seismic considerations were considered in the design of the bridge due to its location. The bridge is equipped with four 100 t VD's (stroke 25 cm) longitudinally directed at both ends (Fig. 4). According to the manufacturer catalogs and design documents, the governing equation of the dampers is $f = cv^\alpha$, where f is force, c is the damping coefficient, v is the velocity, and $\alpha = 0.15$ [2, 3]. Four 21.9×80×80 cm rubber bearings are placed at the top of each pier and two 35.7×80×80 cm rubber bearings at the top of each abutment (Fig. 5).

The Finite element model of the bridge is developed. Five pairs of representative earthquake records are selected and scaled using earthquake code and applied to the model. Nonlinear seismic analyses of the structure without and with VD's are performed and the results are reported. Comparison of the results clarifies VD's effectiveness on seismic response reduction of the structures.

2 MODELLING AND ANALYSES

2.1 Finite element model of the bridge

A finite element model of the bridge is developed in PERFORM-3D [4]. Constraints are applied to restrict the deck from moving horizontally at Piers 2, 3, 4, and 5 and laterally at all piers. According to Caltrans [5], the displacement capacity of the rubber bearings are calculated as following

$$V_x = \tan \gamma T \quad (1a)$$

$$\frac{T}{a} \leq 0.2 : \tan \gamma = 0.7 \quad ; \quad \frac{T}{a} \geq 0.2 : \tan \gamma = 0.9 - \frac{T}{a} \quad (2b)$$

where T is the effective thickness of the rubber bearing which according to the manufacturer catalogs is 14.4 cm for piers and 25.2 cm for abutments; and a is the minimum dimension of the cross section of rubber bearings. Under seismic loading, an increase of 50% should be applied to displacement capacity. As a result, the displacement capacity for the abutment bearings is 22 cm while this value for the pier bearings is 15 cm. The rubber bearing are modeled

as non-linear springs whose initial stiffness are $k_s = GA/T$, where G is shear modulus, A is the area and T is the effective thickness of bearings. This leads to $k_s = 43600$ N/cm for piers and $k_s = 24914$ N/cm for abutments. An increase of 50% to the stiffness should be applied for seismic loading. For the definition of plastic hinge in piers, the famous available models are employed. The length of plastic hinge, Priestley relation is used [6]

$$L_p = 0.08L + 0.0022f_y d_b \quad (\text{MPa}) \quad (2)$$

where L_p is the distance between critical section and inflection point of the member; d_b is the diameter of longitudinal bars and f_y is the yield stress.

According to design documents, the expansion joint between deck and abutments has a width of 25 cm which is taken into account in the model. If the longitudinal displacement of the deck is greater than this value, the deck knocks the abutments.

2.2 Earthquake records used

For the excitation of the bridge, five pairs of earthquake records are chosen (Table 1). These records are scaled according to UBC [7] and then applied to the structure.

Table 1: Earthquake records used

3 RESULTS

3.1 Uncontrolled bridge

Dynamic analyses of the bridge without VD under scaled earthquake time histories are conducted. The first natural period of the bridge is 2.5 sec. The results show that the maximum longitudinal displacement of the deck occurs under scaled Izmit earthquake (PGA=0.546g) which is 51 cm. The time history of the longitudinal displacement response is shown in Fig. 6. The moment-curvature diagram for pier P6 is shown in Fig. 7. It is clear that the piers will exhibit nonlinear behavior. Fig. 8 shows the energy response of the bridge. A significant portion of the energy input to the structure is dissipated with both inelastic hysteretic mechanisms and viscous damping. In this case, the expansion joint will be closed and the deck will knock the abutments which can cause serious damages.

Figure 6: Longitudinal displacement response of the uncontrolled bridge under Izmit earthquake records

Figure 7: Moment-curvature diagram for pier P6 (shortest pier with the height of 11.9 m) for the uncontrolled bridge

Figure 8: Energy response of the bridge under scaled Izmit earthquake

3.2 Controlled bridge

As mentioned before, the bridge is equipped with four 100 t VD's at both ends. Dynamic time-history analyses of the controlled bridge show that the maximum displacement of the bridge reduces to 38 cm but it is still greater than the width of expansion joint and the deck knocks the abutments (Fig. 9). However, a significant portion of the energy input is absorbed and dissipated by the dampers which reduces the nonlinear deformation of the structure. The moment-curvature diagram for pier P6 is shown in Fig. 10.

Figure 9: Longitudinal displacement response of the bridge fitted with four 100 t VD's under Izmit earthquake

Figure 10: Moment-curvature diagram for pier P6 for the case that the bridge is equipped with four 100 t VD's

Figure 11: Longitudinal displacement response of the bridge fitted with four 250 t VD's under Izmit earthquake

Figure 12: Moment-curvature diagram for pier P6 for the case that the bridge is equipped with four 250 t VD's

Proper VD's will prevent structural damages and does not let the deck knock the abutments. A trial and error procedure employed and finally it was concluded that if 100 t dampers are replaced by 250 t dampers, then the maximum longitudinal displacement reduces to 24 cm and piers will remain elastic (Figs. 11 and 12). These dampers are more expensive and off course apply higher values of reaction forces to the abutments which should be taken into consideration in design procedure.

4 SUMMARY AND CONCLUSIONS

- The inclusion of VD's enhances the seismic behavior of the bridge and the dampers dissipate a significant portion of the energy input to the bridge. This reduces the hysteretic energy dissipated by the sub-structural members and decreases damage to the structure and is favorable for earthquake resistant design.

- For the case that the bridge is fitted by 100 t VD's, the maximum longitudinal displacement under design earthquake is 38 cm which is more than the displacement capacity of the damper and expansion joint width and the deck knocks the abutments.
- To overcome the above-mentioned problems and improve aseismic performance of the bridge, 250 t dampers are recommended to be used. In this case the maximum displacement reduces to 24 cm.

ACKNOWLEDGEMENT

The authors are grateful to Tazand Co. for providing them with the bridge design documents and data.

Abstract. *The rock formation at a depth of several thousand meters is exposed to a hydrostatic pressure. Drilling a borehole makes the drill experience same pressure from the walls of the borehole. On fast removing of the drill from the borehole the dynamical process of unloading borehole walls begins. The sharp decrease of normal pressure on the walls of the borehole brings to the increase of ring stresses. The waves of unloading propagate from the borehole, which could cause fragmentation of rock and blocking the borehole with fractured material. The goal of the present paper is to give the problem statement for the dynamical process of unloading the internal walls of the borehole after removing the drill, and successive oil-bearing layer's fracturing. The layer is represented by the model of damageable thermoelastoplastic material with two parameters of damaging (by evolution of micropores and by shear microfracturing). The criterion of the beginning of new free surfaces within the material) uses the principle of the critical value of specific dissipated energy. The problem is treated as two-dimensional (plane deformed state). This task is solved numerical modeling on Lagrangian mesh by method similar to M.L. Wilkins one and on local reconstruction of the Lagrangian grid in the vicinity of the fracture origination.*

1 SETTING OF A PROBLEM

Description of process we will in cylindrical coordinate system which axis Oz is coincide with axis of a hole. Then all parameter of problem depend on space coordinate r, θ and the time t .

Write the mass, momentum and internal energy equations in cylindrical coordinate system r, θ :

$$\frac{\dot{\rho}}{\rho} = -\dot{\varepsilon}_r - \dot{\varepsilon}_\theta; \quad \rho \dot{v}_r = \frac{\partial \sigma_r}{\partial r} + \frac{1}{r} \frac{\partial \sigma_{r\theta}}{\partial \theta} + \frac{\sigma_r - \sigma_\theta}{r}, \quad \rho \dot{v}_\theta = \frac{\partial \sigma_{r\theta}}{\partial r} + \frac{1}{r} \frac{\partial \sigma_\theta}{\partial \theta} + 2 \frac{\sigma_{r\theta}}{r}; \quad (1)$$

$$\rho c_\sigma \dot{T} + \alpha_v \dot{\sigma} T = S_r \dot{\varepsilon}_r^p + S_\theta \dot{\varepsilon}_\theta^p + S_z \dot{\varepsilon}_z^p + 2 S_{r\theta} \dot{\varepsilon}_{r\theta}^p + A \dot{\alpha}^2 + \Lambda \dot{\omega}^2$$

Here and later point under symbol denote the material derivative with respect to time; ρ - density; v_r, v_θ - velocity components; $\sigma_r, \sigma_\theta, \sigma_{r\theta}$ - stress tensor components (σ_θ - ring stress), which decompose on spherical $\sigma = (\sigma_r + \sigma_\theta + \sigma_z)/3$ and deviator parts $S_r, S_\theta, S_{r\theta} = \sigma_{r\theta}; S_r + S_z + S_\theta = 0; \dot{\varepsilon}_r, \dot{\varepsilon}_\theta, \dot{\varepsilon}_{r\theta}$ - velocity strain tensor components; $\dot{\varepsilon}_r^p, \dot{\varepsilon}_\theta^p, \dot{\varepsilon}_z^p, \dot{\varepsilon}_{r\theta}^p$ - plastic components of velocity strain tensor; T - temperature; ω, α - scalar damage parameters; c_σ - is the heat conductivity at constant stress; α_v - is the coefficient of cubic expansion; Λ, A - constants of materials, connected with damage parameters ω and α ; $\dot{\varepsilon}_r^p, \dot{\varepsilon}_\theta^p, \dot{\varepsilon}_z^p, \dot{\varepsilon}_{r\theta}^p$ - plastic components of velocity strain tensor; T - temperature; ω, α - scalar damage parameters of medium; c_σ - is the heat conductivity at constant stress; α_v - is the coefficient of cubic expansion; Λ, A - medium parameters connected thermal and damage processes.

Velocity strain tensor components are expressed over velocity components:

$$\dot{\varepsilon}_r = \frac{\partial v_r}{\partial r}, \quad \dot{\varepsilon}_\theta = \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r}, \quad \dot{\varepsilon}_{r\theta} = \frac{1}{2} \left(\frac{\partial v_\theta}{\partial r} + \frac{1}{r} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r} \right), \quad (2)$$

and decompose on elastic and plastic components:

$$\dot{\varepsilon}_r = \dot{\varepsilon}_r^e + \dot{\varepsilon}_r^p, \quad \dot{\varepsilon}_\theta = \dot{\varepsilon}_\theta^e + \dot{\varepsilon}_\theta^p, \quad \dot{\varepsilon}_{r\theta} = \dot{\varepsilon}_{r\theta}^e + \dot{\varepsilon}_{r\theta}^p, \quad \dot{\varepsilon}_z = \dot{\varepsilon}_z^e + \dot{\varepsilon}_z^p \equiv 0. \quad (3)$$

Plastic flow are incompressible: $\dot{\varepsilon}_r^p + \dot{\varepsilon}_\theta^p + \dot{\varepsilon}_z^p \equiv 0$.

The system of constitutive equation for a model of damageable thermoelastoviscoplastic medium is as follows [1-3]:

$$\begin{cases} \dot{\sigma}' = K_0 \left(\dot{\varepsilon}_r + \dot{\varepsilon}_\theta - \alpha_v \dot{T} - \frac{\Lambda}{3} \dot{\omega} \frac{\partial \dot{\omega}}{\partial \sigma} \right) \\ (S'_{ij})^{\nabla} + \lambda S'_{ij} = 2 \mu_0 \dot{\varepsilon}_{ij} - 2 A \dot{\alpha} \frac{\partial \dot{\alpha}}{\partial S_{ij}} \\ S'_{ij} S'_{ij} \leq \frac{2}{3} Y_0^2(\sigma) \\ Y_0 = c_1 \sigma + c_2 \end{cases} \quad (4)$$

Here symbol ∇ - Yaumann derivative of deviator components stress tensor; $\dot{\epsilon}_{ij}$ - deviator of velocity strain tensor; $\sigma' = \frac{\sigma}{(1-\omega)}$ $S'_{ij} = \frac{S_{ij}}{(1-\omega)(1-\alpha)}$; K_0 and μ_0 - volume and shear module for an undamaged material; ω_{ij} - tensor of rotation:

$$\omega_r = \omega_\theta = 0, \quad \omega_{r\theta} = -\omega_{\theta r} = \frac{1}{2} \left(\frac{1}{r} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r} - \frac{\partial v_\theta}{\partial r} \right). \quad (5)$$

The last relation from (4) – Misses-Shlexer rule, connecting limit of elasticity under simple tension Y_0 and pressure in layer $(-\sigma)$; c_1, c_2 – material constants.

System of equations (1) - (5) close by kinetic equations for damage parameters ω, α :

$$\begin{aligned} \frac{\dot{\omega}}{\omega} &= B \left(\frac{\sigma}{1-\omega} - \sigma_* \right) H \left(\frac{\sigma}{1-\omega} - \sigma_* \right) + \frac{\sigma - \sigma^+}{4\eta_0} H(\sigma - \sigma^+) + \frac{\sigma - \sigma^-}{4\eta_0} H(\sigma^+ - \sigma), \\ \sigma^+ &= -\frac{2}{3} Y_0 \ln \omega - p_0 \left(\frac{\omega_0}{\omega} \right)^\gamma, \quad \sigma^- = +\frac{2}{3} Y_0 \ln \omega - p_0 \left(\frac{\omega_0}{\omega} \right)^\gamma, \\ \dot{\alpha} &= C \left(\frac{S_u}{(1-\omega)(1-\alpha)} - S_u^* \right) H \left(\frac{S_u}{(1-\omega)(1-\alpha)} - S_u^* \right). \end{aligned} \quad (6)$$

Here η_0 - dynamic viscosity for an undamaged material; p_0 – initial pressure in pore («горное» pressure); γ - index of adiabatic curve for medium, filling pore; ω_0 - initial porosity; $S_u = \sqrt{S_{ij} S_{ij}}$ - intensity of stress deviator; S_u^*, σ_*, B, C - constants of material; $H(x)$ - Heaviside unit function.

From equations (6) we see that the first term describing the viscous growth in domains of tension of the material comes into play. The second term describes the viscoplastic flowing in pores when the material is compressed. Note that the equation for ω taken without the dynamical problem on a single spherical pore of inner radius a and other radius b in a viscoplastic incompressible material. Damage parameter α connect with intensity of stress deviator and describe fracture shear.

The evolution of the intensive plastic flow and accumulation of microstructure damages may be considered as a process of prefracture of the material. The entropy criterion of limiting specific dissipation [1, 3]:

$$\begin{aligned} D &= \int_0^{t_*} \frac{1}{\rho} (d_M + d_F + d_T) dt = D_*, \\ d_M &= S_{ij} \dot{\epsilon}_{ij}^p, \quad d_F = \Lambda \dot{\omega}^2 + A \dot{\alpha}^2, \quad d_T = \kappa \frac{(\text{grad } T)^2}{T} \end{aligned} \quad (7)$$

is proposed as the criterion of the beginning of macrofracture (i.e., the beginning of formation of cracks (new free surfaces) in material). Here t_* is the time of the beginning of fracture; D_* is a constant of the material (the limiting specific dissipation); d_M, d_F and d_T are

mechanical dissipation, dissipation of continuum fracture and thermal dissipation. Similar model used for decision problem of hydraulic fracturing of oil layer ([2] etc.).

2 INITIAL AND BOUNDARY CONDITIONS

Initial rock layer be in rest: $v_r = v_\theta = 0$ in time $t = 0$. Additionally we must define initial description of stresses in layer $\sigma_r, \sigma_\theta, \sigma_{r\theta}$, value of damage parameters ω and α as functions of space coordinates r and θ .

As initial distribution for stresses in rock layer we use decision of next static elasticity problem: consider infinite cylindrical solid with circular cut; on infinitum in two mutually perpendicular directions applied contractive stresses Σ_1 and Σ_2 corresponding known as “rock pressure”. In common case $\Sigma_1 \neq \Sigma_2$ that modeling no homogeneity stress state of rock layer. On surface of circular cut applied pressure $\Sigma_3 \geq 0$.

Distributions of initial stresses for this problem are [4]:

$$\begin{cases} \sigma_r = \frac{\Sigma_1 + \Sigma_2}{2} + \frac{\Sigma_1 - \Sigma_2}{2} \cos 2\theta + \frac{a^2}{r^2} \left(-\Sigma_3 - \frac{\Sigma_1 + \Sigma_2}{2} - 2(\Sigma_1 - \Sigma_2) \cos 2\theta \right) + \\ + \frac{a^4}{r^4} \left(\frac{3}{2} (\Sigma_1 - \Sigma_2) \cos 2\theta \right) \\ \sigma_\theta = \frac{\Sigma_1 + \Sigma_2}{2} - \frac{\Sigma_1 - \Sigma_2}{2} \cos 2\theta + \frac{a^2}{r^2} \left(\Sigma_3 + \frac{\Sigma_1 + \Sigma_2}{2} \right) + \frac{a^4}{r^4} \left(-\frac{3}{2} (\Sigma_1 - \Sigma_2) \cos 2\theta \right) \\ \sigma_z = \nu (\sigma_r + \sigma_\theta) \\ \sigma_{r\theta} = -\frac{\Sigma_1 - \Sigma_2}{2} \sin 2\theta - \frac{a^2}{r^2} (2(\Sigma_1 - \Sigma_2) \sin 2\theta) + \frac{a^4}{r^4} \left(\frac{3}{2} (\Sigma_1 - \Sigma_2) \sin 2\theta \right) \end{cases} \quad (8)$$

Here ν - Poisson coefficient, a - radius of hole.

At moment $t = 0$ happen sharply drop of pressure in hole from value Σ_3 to 0.

3 EXPLICIT SEPARATION OF MACRO FRACTURE ZONES

The entropy criterion of limiting specific dissipation is proposed as the criterion of the beginning of macro fracture (i.e., the beginning of formation of cracks (new free surfaces in material) (7). When criterion (7) is fulfilled at some point of material, a macro crack should be formed there, i.e., a new free surface that will spread over the body. In point where criterion of fracture fulfilled is realized explicit coasts of macro discontinuity. For this we construct separation of nodes of network on cells boundary – internal nodes and corresponding them edges of cells are boundary on this put condition of free surface or contact condition depending on situation [5]. Note that earlier we used procedure of bifurcation of Lagrangian network ([1, 3, 6, 7] et al).

Figure 1: Types of “primary” cracks.

Procedure of decomposition for nodes of network consists of construction “primary” cracks for each node and their combination with already existing cracks. Interaction between “primary” cracks formation cracks biggest scale. On figure 1 show variants of construction “primary” cracks for internal node. Type of “primary” crack determine from analysis strain state on adjacent edges for present node.

4 RESULTS OF COMPUTATIONAL SIMULATION

This task is solved by numerical modeling on Lagrangian mesh by method similar to Wilkins one [18]. In calculation we used next value of parameters: $\rho_0=2000 \text{ kg/m}^3$; $K_0=14000 \text{ MPa}$; $\mu_0=8400 \text{ MPa}$; $\eta_0=100 \text{ Pa}\cdot\text{s}$; $\Lambda=1500 \text{ Pa}\cdot\text{s}$; $c_1=-0,09$; $c_2=40 \text{ MPa}$; $\gamma=1,4$; $D^*=334,4 \text{ kJ/kg}^3$; $\omega_0=0,05$; $A=250 \text{ Pa}\cdot\text{s}$; $C=0,00022(\text{Pa}\cdot\text{s})^{-1}$; $B=0$; $S_u^*=32,5 \text{ MPa}$. Radius of borehole is $a=1\text{m}$, initial “rock” pressure, depending from coordinates r, θ , defined from formula (8) - $p_0 = -(\sigma_r + \sigma_\theta + \sigma_z)/3$.

Value of stresses, depending initial strain state are: $\Sigma_1 = -50 \text{ MPa}$ or $\Sigma_1 = -65 \text{ MPa}$; $\Sigma_2 = -75 \text{ MPa}$ and $\Sigma_3 = 35 \text{ MPa}$.

On figure 2 present dependence of velocities different borehole points, which position depended angle θ , from time t .

On figure 3 present process of origin and growth of cracks for different value of Σ_1 . In left part of figure present sequential moments of time for $\Sigma_1 = -50 \text{ MPa}$, in right part - for $\Sigma_1 = -65 \text{ MPa}$. Intensity of grey color defines level of energy dissipation, white color correspondence limited dissipation in criteria of fracture (7) - $D_* = 334,4 \text{ kJ/kg}^3$.

Figure 2: Velocity of different points of borehole.

As it show from figure 3, cracks in material origin and growth on internal surface of borehole and propagate deep into rock under angle near 45° to tangent of borehole contour. Further development of fracture process takes place on two scenarios: either crack continues your growth in initial direction or after some time moments it turns under angle near 90° to your initial moving. As it followed wait, in case $\Sigma_1 = \Sigma_2$ observed symmetrical not depended from angle θ situation of fracture shear type near surface of borehole with dispersion of rock fragments.

5 CONCLUSIONS

The authors would like to thank Russian Foundation of Basic Research (09-01-00144a) for financial support.

Keywords: Reinforced soil, Geosynthetics, Numerical modelling, Seismic loading.

Abstract. *In recent earthquakes the performance of reinforced soil retaining walls was diverse. The Hyogoken-Nambu (Kobe) Earthquake caused serious damage to conventional masonry retaining walls, unreinforced concrete gravity-type retaining walls and cantilever-type steel-reinforced concrete retaining walls, while geogrid-reinforced soil retaining walls, having a full-height concrete facing, performed very well during the earthquake [1]. On the other hand, the Chi-Chi earthquake, in Taiwan, caused serious damage to reinforced-soil retaining walls using keystones as facing [2].*

In this work the two-dimensional finite difference program Fast Lagrangian Analysis of Continua FLAC [3] was used to model the seismic response of a geogrid reinforced steep slope constructed in the North of Portugal. This structure was built in the Portuguese main itinerary, IP3, and is part of a reestablishment. The reinforced slope has an extension of about 206.2 m and the reinforced soil area reaches a maximum height of about 19.6 m. The slope behaviour was observed during 13 months, which includes three months of construction period.

The analysis of monitoring information of this geogrid reinforced steep slope and the numerical simulation of its construction are briefly presented. The seismic behaviour of this structure is analysed using FLAC program. Earthquake ground motions artificially generated with the program SIMQKE [4] were considered as seismic loading. The permanent displacements and reinforcement tensile forces are analysed and compared.

The numerical simulation of seismic loading showed a good performance of the reinforced steep slope. Since the structure is an overpass embankment, permanent vertical settlements can be the most disquieting factor. The residual reinforcement tensile forces remain smaller than the long term design strength of the geogrids.

1 INTRODUCTION

In recent earthquakes the performance of reinforced soil retaining walls was diverse. The Hyogoken-Nambu (Kobe) Earthquake caused serious damage to conventional masonry retaining walls, unreinforced concrete gravity-type retaining walls and cantilever-type steel-reinforced concrete retaining walls, while geogrid-reinforced soil retaining walls, having a full-height concrete facing, performed very well during the earthquake [1]. On the other hand, the Chi-Chi earthquake, in Taiwan, caused serious damage to reinforced-soil retaining walls using keystones as facing [2].

Usually reinforced soil retaining walls are designed using limit-equilibrium pseudo static methods. These methods are dependent only on peak ground acceleration, and disregard the effects due to duration of seismic action, frequency, foundation condition, stiffness of the reinforcement, facing type and others factors.

In this work the two-dimensional finite difference program *Fast Lagrangian Analysis of Continua* - FLAC [3] was used to investigate the seismic response of a geosynthetic reinforced steep slope. This code, suitable for modelling large distortions and dynamic response of earth structures, has also been used to investigate seismic response of reinforced soil retaining walls by other authors [5, 6].

2 BRIEF DESCRIPTION OF FLAC CODE AND SEISMIC LOADING

FLAC is an explicit finite difference program that performs a Lagrangian analysis. The finite difference method is perhaps the oldest numerical technique used for the solution of sets of differential equations, given initial values and/or boundary values [3]. For dynamic analyses the full equations of motion are solved using lumped gridpoint masses derived from the real density of surrounding zones (rather than fictitious masses used for static solution). Each triangular sub-zone contributes one-third of its mass (computed from zone density and area) to each of the three associated gridpoints. The final gridpoint mass is then divided by two in the case of a quadrilateral zone that contains two overlays. In finite-element terminology, FLAC uses lumped masses and a diagonal mass matrix [3].

In FLAC, the dynamic input can be applied as an acceleration history, as a velocity history, as a stress (or pressure) history or as a force history. Dynamic input can be applied either in the x or y directions corresponding to the xy axes for the model, or in the normal and shear directions to the model boundary.

Figure 1(a) presents one of the earthquake ground motions artificially generated [2] according to Portuguese National Annexes (PNA) of Eurocode 8 [7] for the greatest seismicity area of Portugal, considering seismic action type 2 (earthquake with moderate magnitude and small focal distance – close earthquake) and ground type B (deposits of very dense sand, gravel or very stiff clay). According to the PNA of Eurocode 8 [7], for the greatest seismicity area, the peak ground acceleration on type B ground is 2.5m/s^2 and 1.7m/s^2 for seismic action type 2 and type 1, respectively. The duration of the stationary part of the accelerograms are equal to 10 seconds and 30 seconds. The Fourier spectrum for the accelerogram presented in Figure 1(a) is plotted in Figure 1(b).

Figure 2 shows the horizontal displacements obtained by double integration of the earthquake ground motion presented in Figure 1(a). Without correction, significant residual displacements occur at the end of the motion. To avoid these unreal large displacements at the end of the dynamic action, a baseline correction should be performed. A low frequency wave is determined which, when added to the original history, produces a final displacement equal

to zero (Figure 2). The velocity and acceleration time histories with and without baseline correction remain similar.

Figure 1: Example of one seismic action (type 2): a) artificial accelerogram [4]; b) Fourier spectrum.

Figure 2: Effect of baseline correction on the imposed displacements.

To analyse the behaviour of this reinforced steep slope, earthquake ground motions artificially generated with the program SIMQKE [4] were considered as seismic loading. Two

types of seismic action were considered: an earthquake with moderate magnitude and small focal distance - “close” earthquake (seismic action type 2) and an earthquake with greater magnitude and greater focal distance – “distant” earthquake (seismic action type 1). Although the embankment was constructed in the lower seismicity area (North of Portugal), the most adverse scenery in terms of seismicity was considered. Ten accelerograms were analysed for each seismic action type.

3 GENERAL OVERVIEW OF THE STRUCTURE

The geogrid-reinforced steep slope was built (in 1998) in the Portuguese main itinerary (IP3) and is part of a reestablishment. The embankment has an extension of about 206.2 m and the reinforced soil area reaches a maximum height of about 19.6 m. On sections higher than 10 m, a bench with variable width parallel to the road pavement was built. The inclination of the reinforced slope is about 60° (Figure 3).

Figure 3: Overview of the embankment at the end of construction [8].

The foundation of the structure is a natural compact granite residual soil. Due to the local morphology, a rockfill was executed. The backfill is, also, a residual soil from granite. The reinforcements are high density polyethylene (HDPE) uniaxial geogrids, placed horizontally and spaced 0.60 m on vertical direction. In the analysed cross section, 31 layers of HDPE geogrids with nominal tensile strength of 160 kN/m (7 layers), 120 kN/m (10 layers), 90 kN/m (4 layers) and 60 kN/m (10 layers) were placed. The geogrids length is about 12.8m. The face units were constructed using welded wire net with quadrangular openings (Figure 4). A biodegradable mat was placed inside the face elements to prevent surface erosion and promote the vegetation growth (Figure 4b).

The reinforcement strains were measured in three reinforcement layers using linear extensometers spaced of 0.50 m (20 extensometers per monitored geogrid). Vertical stresses were recorded using load cells placed near the three monitored geogrids. The internal horizontal displacements were recorded using two inclinometer tubes [8, 9]. The inclinometer I_1 , also

called bench inclinometer, was placed at the middle of the bench width. The inclinometer I_2 was placed approximately at the middle of the higher bench (Figure 5). The displacements of the slope face were measured topographically. The analysed slope cross section, the monitoring devices and their positions are schematically represented in Figure 5.

The slope behaviour was observed during 13 months, which includes three months of construction period.

Figure 4: Detail of slope face: a) during the construction period [8]; b) August 2003 [9].

Figure 5: Analysed cross section and location of monitoring devices [9].

4 NUMERICAL MODELING OF THE CONSTRUCTION

4.1 Details of numerical modelling

The construction of an embankment is a progressive placement of soil layers. Consequently, the monitoring results are relative values. So, in order to compare the monitoring results with those obtained by the numerical analyses, the knowledge of the construction

sequence is imperative. An estimate was made, based on data from the instrumentation and some photographs found in [8, 10].

The fill was modelled as a purely frictional elasto-plastic material, with a Mohr-Coulomb yield function and a non-associated flow rule. The friction angle of the soil was taken equal to 35° and the unit weight $\gamma = 21.5 \text{ kN/m}^3$. Young modulus and Poisson ratio of the soil were taken equal to 30 MPa and 0.3, respectively. After conducting a parametric study [9], it was considered a value of 5 kPa for the soil cohesion. This value has not a great physical significance but improves the performance of the numerical model, eliminating some numerical instability, particularly in the slope face.

The reinforcement layers were modelled using linear elasto-plastic cable elements with negligible compressive strength. The linear elastic stiffness of the reinforcement layers depends on the reinforcement strength and strain level. So, it was considered the value for 2% of geogrids strain. The interface between the reinforcement and the soil was modelled by a grout material [3] with an interface friction angle of 19.5° and a bond stiffness of $3 \times 10^3 \text{ kN/m}$. These values were achieved from the numerical simulation of an in-situ pullout test [9].

The wrap-around face was modelled with cable elements with compressive strength not null (equal to 20% of reinforcement tensile strength) and an interface friction angle equal to 35° .

After the clearing of natural ground, it was decided [8] to place a rockfill under and in front of the reinforced soil mass (see Figure 5). The foundation and the rockfill were modelled as elastic materials with Young modulus of 200 MPa. Over the rockfill foundation, it was considered a thin layer of soil, with similar properties to those of the backfill, which is the base for the first reinforcement layer.

In order to model, as closely as possible, the real construction sequence, the embankment was simulated by the placement of successive soil layers of 0.30 m thick. The pavement was simulated by a layer with increased density. When the position of the reinforcement layer “i” is achieved, the horizontal displacement of the face at this level is prevented, being allowed only in the next stage, ie the reinforcement layer “i” is only loaded in the following construction stage.

4.2 Comparison of numerical results with monitoring data

Taking into account the reference values of the topographic targets and the construction sequence, intermediate measurements of the face displacements were performed in the numerical analyses. With these intermediate values it was possible to obtain relative displacements comparable with those obtained with monitoring. To make possible the comparison between the internal displacements of the embankment obtained with the numerical analyses and the values recorded in the inclinometer tubes, intermediate measurements of the horizontal displacements along two vertical planes (coincident with the inclinometer tubes position - see Figure 5) were also performed.

Figure 6 compares the relative displacements of the slope face achieved in the numerical analyses with those from the topographic measurements. The analysis of this figure shows that the numerical model captures the real behaviour of the reinforced embankment. In the four targets placed nearest the top, the horizontal displacements of the model are very close to values recorded in-situ. In the remaining targets, the numerical model tends to overestimate the horizontal displacements of the slope face. The model reproduced very closely the vertical displacements of the slope face. Note that the targets were fixed to the welded wire net, which means, their movements may be related to a punctual displacement of the wire net and not to

the behaviour of slope face. The numerical modelling of the real conditions of the slope face is not easy, since the system face is complex (geogrid+ biodegradable mat+ welded wire net).

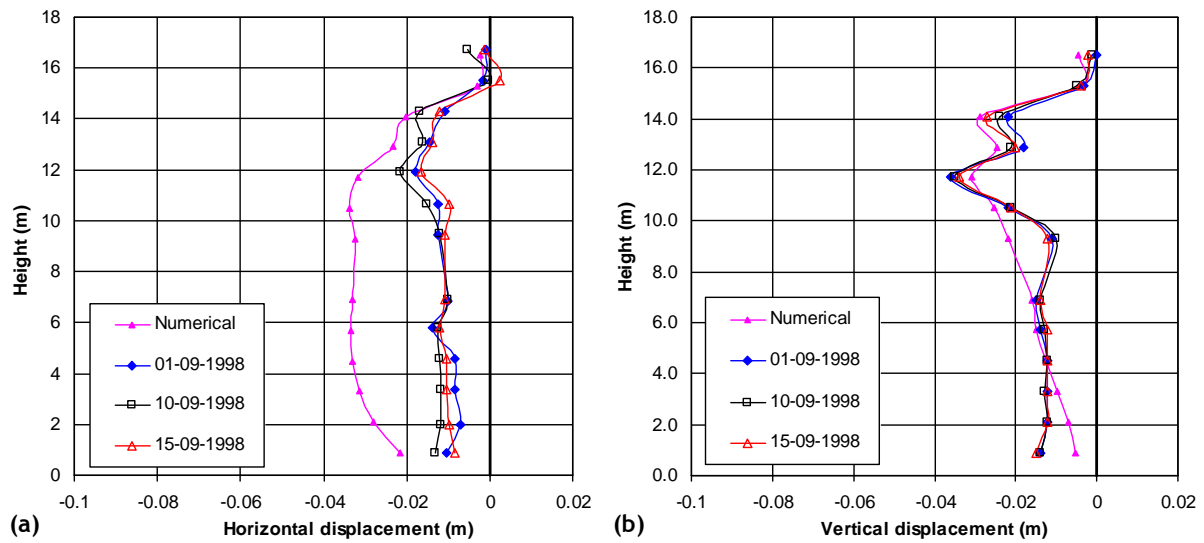

Figure 6: Comparison of numerical and monitoring results: a) horizontal displacements of the slope face; b) vertical displacements of the slope face.

Figure 7 presents the internal horizontal displacements along two vertical planes coincident with the inclinometer tubes position. The numerical results are compared with those obtained from the monitoring.

Figure 7 shows that the numerical analysis seems suitable for the internal horizontal displacements, particularly those relating to the inclinometer I_2 (Figure 7b). For the bench inclinometer (or inclinometer I_1), located near the slope face, the numerical analysis did not show the same effectiveness. For this inclinometer, the numerical model tends to overestimate the internal displacements in the upper part of the inclinometer. This may be partly justified by the influence of the complex face system.

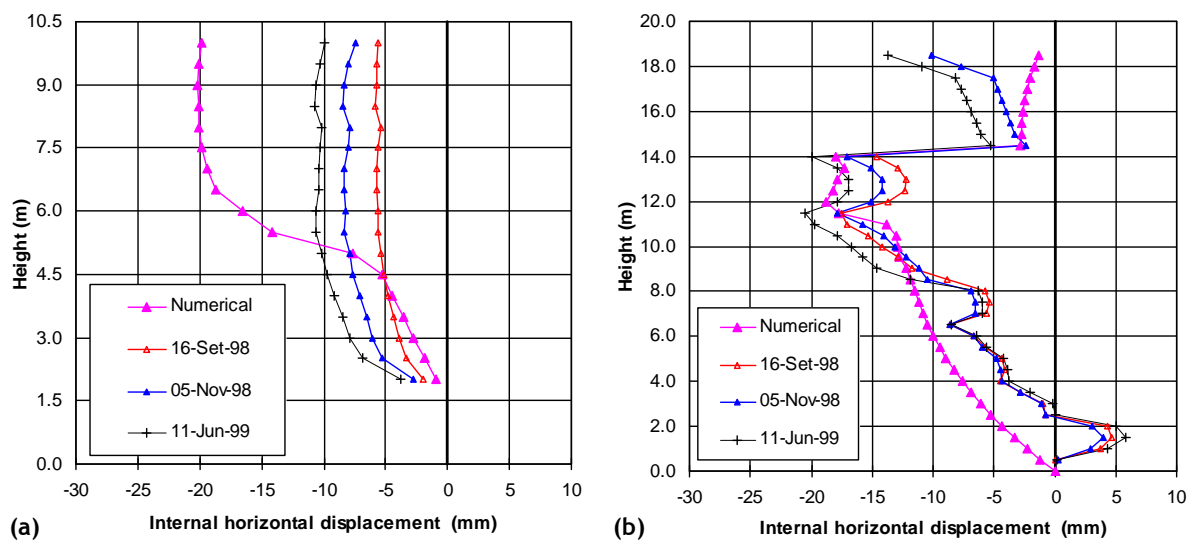

Figure 7: Comparison of internal horizontal displacements reached with numerical analyses and monitoring results: a) inclinometer I_1 ; b) inclinometer I_2 .

5 SEISMIC BEHAVIOUR OF THE STRUCTURE

5.1 General

As mentioned, two types of seismic action were considered: an earthquake with moderate magnitude and small focal distance - “close” earthquake (seismic action type 2) and an earthquake with greater magnitude and greater focal distance - “distant” earthquake (seismic action type 1). In order to select 10 accelerograms representative of seismic action type 2 and 10 accelerograms representative of seismic action type 1, several series were artificially generated. Time increments of 0.01 seconds were considered. For seismic action type 2 and type 1, the duration of the stationary part of the accelerograms are equal to 10 seconds and 30s seconds and the duration of the transitory sections, before and after the stationary part, are equal to 1 second and 3 seconds, respectively.

To avoid the reflection of the waves back into the model, absorbing boundaries (free-field conditions [3]) were considered at the lateral limits of the mesh.

The hysteretic damping of the foundation and rockfill was represented by an equivalent Rayleigh damping with damping coefficient of 10%. In addition to the damping associated to the elasto-plastic behaviour of the backfill, no additional damping was considered.

5.2 Results for seismic action type 2 – “close” earthquake

Figure 8 presents time histories of horizontal displacements recorded at three points located at the slope face. The horizontal displacement at the base of reinforced slope (Point 1) follows closely the imposed displacement at the foundation. Note that, a rockfill was placed in front of the first reinforcement layers (up to 1.5 m high). The horizontal displacement at the crest of the upper slope (Point 3) in outside direction (negative values in Figure 8), tends to be smaller than those recorded at the crest of the lower slope (Point 2).

As an example, Figure 9 shows the geometry of the reinforced steep slope at the end of the seismic action Ac2_6. Note that the displacements were enlarged 10 times. It is evident some instability at the bench, including swelling of the soil. Vertical displacements with some significance are also shown at the top.

Figure 10 presents the reinforced load developed in a cable element of the 4th reinforcement layer. This element is located about 3 m from the slope face. The seismic horizontal displacement of one node of the same element is also plotted. In the time history of this reinforcement load, three sudden increases are visible. These increases occur when the accelerogram inverts the sign. In the horizontal displacement time history, positive values mean displacements inwards of reinforced slope.

Figure 11 shows the average curves of horizontal and vertical displacements of the slope face and those obtained by adding and subtracting the respective standard deviation, for the ten accelerograms considered (seismic action type 2). The analysis of this figure shows that, on the slope below the bench, the maximum horizontal displacement occurs in the upper half of the slope. In the slope above the bench the horizontal displacements in the upper half are lower. The maximum vertical displacement occurs at the crest of the embankment.

Figure 12 presents the average values of residual reinforcement tensile forces in all reinforcement layers and those obtained by adding and subtracting the respective standard deviation. To understand the sudden changes shown, it was included the reference to geogrids with distinct properties. Note that, geogrids with nominal strength of 160 kN/m and 120 kN/m

Figure 8: Horizontal displacements time histories of 3 points located at the slope face:
a) accelerogram Ac2_1; b) accelerogram Ac2_6.

Figure 9: Deformed slope at the end of seismic action Ac2_6.

Figure 10: Time histories of reinforcement load and horizontal displacement recorded in one element of the 4th geogrid level (Ac2_6).

Figure 11: Pattern of mean residual displacements for seismic action Type 2: a) horizontal residual displacements of slope face; b) vertical residual displacements of slope face.

were placed on the embankment below the bench and geogrids with nominal strength of 90 kN/m and 60 kN/m were installed on the embankment above the bench. The presence of the rockfill in front of the lower reinforcement layers reduces, significantly, the tensile forces mobilized at these layers.

Although not presented in this work, it is important to mention that the maximum tensile loads recorded in the reinforcement elements located on the upper slope are very close to the residual values (at the end of motion). On the slope below the bench, the maximum tensile loads exceed the residual values, particularly in the 4th reinforcement layer (the first layer placed above the rockfill), where the difference can be substantial (around 50%).

Figure 12: Pattern of mean residual reinforcement tensile forces for seismic action Type 2.

5.3 Results for seismic action type 1 – “distant” earthquake

Figure 13 shows time histories of horizontal displacements recorded at three points located at the slope face for the artificial accelerogram Ac1_9. As observed for the “close” earthquake, the horizontal displacement at the base of reinforced slope (Point 1) follows closely the imposed displacement at the foundation.

The horizontal displacements recorded during the simulated earthquakes are quite distinct (compare Figure 8 and Figure 13). Even so, the permanent horizontal displacements at the end of ground motion are not very different.

Figure 13: Horizontal displacements time histories of 3 points located at the slope face for the accelerogram Ac1_9.

Figure 14 illustrates the reinforced load recorded in a cable element of the 4th reinforcement layer during the numerical simulation relating to the accelerogram Ac1_9. The seismic

horizontal displacement of one node of the same element is also plotted. As noted for the seismic action type 2, the reinforcement load tends to experience sudden increases. Although, for the accelerograms representative of seismic action type 1, after some seconds, the changes in the reinforcement load are very small (Figure 14).

Figure 14: Time histories of reinforcement load and horizontal displacement recorded in one element of the 4th geogrid level (Ac1_9).

The average curves of horizontal and vertical displacements of the slope face, and those obtained by adding and subtracting the respective standard deviation, for the accelerograms representative of the seismic action type 1 are presented in Figure 15. As verified for the seismic action type 2 (Figure 11), the maximum horizontal displacements occur in the upper half of the slope below the bench and in the lower half of the slope above the bench. The maximum vertical displacement occurs at the crest of the embankment.

Figure 15: Pattern of mean residual displacements for seismic action Type 1: a) horizontal residual displacements of slope face; b) vertical residual displacements of slope face.

Figure 16 illustrates the average values of residual tensile forces in all reinforcement layers, and those obtained by adding and subtracting the respective standard deviation. The residual tensile forces distribution through the structure height is similar to that presented in Figure 12 for “close” earthquakes.

Figure 16: Pattern of mean residual reinforcement tensile forces for seismic action Type 1.

5.4 Influence of seismic action type

Figure 17 compares the average curves of horizontal and vertical displacements of the slope face for the two seismic actions considered. The first conclusion to be drawn, from the analysis of this figure, is that the “distant” earthquake is more adverse for the performance of this reinforced steep slope.

Figure 17: Influence of seismic action type on residual displacements of slope face: a) horizontal displacements; b) vertical displacements.

On average, the horizontal and vertical displacements recorded for “distant” earthquakes are, respectively, 7.1% and 9.1% greater than those recorded for “close” earthquakes. Even so,

the horizontal displacements of the slope face near the top tend to be lower when the structure is subjected to distant earthquakes. The vertical displacements of the slope below the bench are quite small and they are not influenced by the seismic action type.

Figure 18 illustrates the average values of maximum reinforcement tensile loads at the end of ground motion (residual values) for the two seismic actions. The distribution of residual reinforcement tensile loads through the structure height is similar. However the seismic action type 1 generates greater reinforcement loads.

The maximum values of the residual reinforcement tensile loads remain smaller than the long term design strength of the geogrids. These latter values are, according to [8], 46.1 kN/m, 35.0 kN/m, 25.9 kN/m and 17.5 kN/m for the geogrids GG160, GG120, GG90 and GG60, respectively.

Figure 18: Influence of seismic action type on residual reinforcement tensile forces.

6 MAIN CONCLUSIONS

Despite some limitations related to the characterization and real progress of the embankment construction, resulting from the fact that the first author of this work did not follow the design and construction of the structure, the obtained results fit reasonably with the monitoring data. It was found that:

- with respect to distribution of slope face displacements through the structure height, either horizontal or vertical, the numerical model captures the real behaviour of the embankment;
- numerical modelling also seems appropriate for the internal horizontal displacements.

The numerical simulation of seismic loading showed a good performance of the reinforced steep slope. Since the structure is an overpass embankment, permanent vertical settlements can be the most disquieting factor. However, it should be noted that, according to the philosophy of safety codes, under the action of intense earthquakes, the occurrence of damages is allowed, provided they do not produce the rupture of the structure.

The residual reinforcement tensile forces remain smaller than the long term design strength of the geogrids.

The occurrence of a “distant” earthquake seems to be more adverse for the seismic performance of this structure. Nevertheless, numerical modelling of other geosynthetic reinforced soil structures has shown that “close” earthquakes can be critical. The fundamental frequencies of these structures will have, certainly, its influence.

Keywords: seismic isolation, bridge, partial restraint, free vibrations, non-classical damping.

Abstract. *This paper analyzes the dynamic behavior of partially restrained seismically isolated (PRSI) bridges. These are a particular class of multi-span seismically isolated bridges in which isolation bearings are posed only at the top of the piers, while seismic stoppers restrain the transverse motion of the superstructure at the abutments.*

The transverse dynamic behavior of these partially-restrained bridges is described analytically by considering a two-dimensional simply supported beam model, with intermediate visco-elastic restraints whose properties are calibrated to describe the substructures' behavior. Particular simplified configurations are considered which allow to identify a minimal set of characteristic problem parameters that completely describe the dynamic response. The properties of the dynamic systems are analyzed by considering separately the undamped and the damped case.

The results of the study contribute to improve the understanding of the dynamic behavior of partially restrained seismically isolated bridges and allow to draw some conclusions useful for their preliminary assessment and design.

1 INTRODUCTION

Seismic isolation in bridges has proven to be an effective method for the mitigation of the forces induced by the seismic actions ([1],[2]). It usually consists in the introduction of isolation/dissipation devices between the bridge substructures and the superstructure, in order to decouple their motion, shift the natural period of vibration away from the dominant period of earthquake excitation and introduce additional sources of damping.

Partially restrained seismically isolated (PRSI) bridges ([3]) are a particular class of isolated bridges in which isolation bearings are posed only at the top of the piers, with seismic stoppers restraining the transverse motion of the superstructure at the abutments. This restraint is usually introduced in order to avoid the use of bi-directional joints at the abutments and to exploit the abutment contribution in resisting the inertia forces, thus reducing the forces acting on the piers.

Recently, many authors have investigated the dynamic behavior of PRSI bridges ([3], [4], [5]). Tsai [3] evaluated the effectiveness of the partially restrained seismic isolation and describes the difference of the behavior of PRSI bridges with respect to fully isolated bridges. Analytical expressions were also proposed for estimating the transverse effective period and composite damping ratio of PRSI bridges. Makris et al. [4] examined the eigenvalues of PRSI bridges under transverse and longitudinal vibration, by considering the two cases of elastomeric bearings and friction-pendulum bearings. They concluded that regardless of the value of the isolation period along the longitudinal direction, there is a certain length beyond which the transverse period of the deck will exceed the longitudinal isolation period. Tubaldi and Dall'Asta [5] analyzed the dynamic problem of PRSI bridges in a variational form, in order to obtain a simplified solution based on assumed vibration shapes which coincide with the Fourier sine-only series terms. They also defined a design procedure for dimensioning the properties of the isolation system, with the objective of controlling the internal actions on the piers. The applications to realistic PRSI bridges allowed to highlight the following results: a) the response in terms of some quantities of interest in the seismic analysis (e.g., the abutment reactions and the superstructure transverse bending moments) can be strongly influenced by higher vibration modes, b) the response according to the higher modes of vibration is less affected by the pier-bearing restraint action and depends mostly on the superstructure properties, c) neglecting the non-classically damped nature of the problem may induce some inaccuracies in the assessment of the seismic response of this particular type of system.

In summary, PRSI bridges show a complex dynamic behavior in the transverse direction and many modal properties related to the seismic response, such as modal shapes and extent of non classical damping, significantly change by varying the properties and geometry of the deck and properties and location of the intermediate supports.

This study aims at providing some contribution to the further advancement in the understanding of the dynamic behavior of PRSI bridges. Under a qualitative point of view, the dynamic properties of a linear system, such as the ones analyzed in the present study, can be measured by solving the free vibrations problem. Thus, the focus of the paper is on the free-vibration response of PRSI bridges only.

The transverse dynamic behavior of PRSI bridges is described [5] by considering a model which consists in a continuous 2-dimensional simply supported beam resting on discrete visco-elastic supports. The properties of the intermediate supports can be calibrated to represent the behavior of the pier-bearing systems. Numerous studies are devoted to the analysis of the free vibration problem of continuous beams elastically restrained by intermediate linear springs ([6],[7],[8]) or dampers ([9],[10]). However, many of these studies analyze the problem from a purely mathematical perspective and are mostly focused on the

influence of the restraint on the eigenvalues or in the observation of the transition condition in which multiple coincident eigenvalues are observed. Thus, there is a need for an engineering interpretation of the complex behavior of PRSI bridges in terms of physical quantities which can be of interest in the seismic analysis, e.g., displacement and bending moment shapes, participation factors, abutment reactions, vibration periods, damping properties and extent of non classical damping.

In this paper, the free vibration problem of a set of simplified PRSI bridges configuration is considered, assuming constant stiffness, mass and support spacing for the superstructure. This allows to identify a minimal set of characteristic problem parameters that completely describe the dynamic response of partially restrained bridges and to shed light on the relationship between these parameters and the response quantities of interest in the seismic analysis. Furthermore, the consideration of the simplified cases permits deriving an analytical solution of the free-vibrations problem and developing analytical relationships between the characteristic parameters and the system response.

The influence of the characteristic problem parameters on the free vibrations is analyzed through an extensive parametric analysis by considering separately the case of support systems without damping, and the case of support system with damping, thus generating a non-classical dynamical system. The results of the parametric analysis undertaken permit to draw important information which can be useful for the preliminary assessment and design of the particular class of bridges analyzed.

2 DYNAMIC BEHAVIOR OF PRSI BRIDGES

The continuous isolated bridge with partial restraint can be modeled as a 2-dimensional simply-supported beam resting on intermediate discrete visco-elastic supports that represent the pier-bearing systems (Fig. 1).

Fig. 1. Analytical 2-dimensional model for bridges with partial restraint.

Let $V = \{v(x) \in H^2[0, L] : v(0) = v(L) = 0\}$ ¹ be the space of displacement functions defined along the bridge length L and satisfying the kinematic (essential) boundary conditions and $u(x; t) \in U = C(V; [t_0, t_1])$ be the motion, defined in the time interval considered $[t_0, t_1]$.

The differential dynamic problem can be derived from the D'Alembert principle [11] and can be posed in the following form, $\forall \eta \in V; \forall t \in [t_0, t_1]$:

$$\begin{aligned} & \int_0^L m(x) \ddot{u}(x, t) \eta(x) dx + \int_0^L c_d(x) \dot{u}(x, t) \eta(x) dx + \sum_{r=1}^N c_{c,r} \dot{u}(x_r, t) \eta(x_r) + \\ & + \int_0^L b(x) u''(x, t) \eta''(x) dx + \sum_{r=1}^N k_{c,r} u(x_r, t) \eta(x_{c,r}) = - \int_0^L m(x) \ddot{u}_g(t) \eta(x) dx \end{aligned} \quad (1)$$

¹ The form $H^m(\Omega)$ denotes the space of functions defined on Ω for which the derivatives with respect to x of order less than or equal to m are on $L^m(\Omega)$.

The functions $m(x)$, $b(x)$ and $c_d(x)$ are piecewise continuous and denote the mass per unit length, the transverse stiffness per unit length and the distributed damping constant. The constants $k_{c,r}$ and $c_{c,r}$ are the stiffness and damping constant of the visco-elastic support located at the r -th position $x=x_r$. Finally, $\ddot{u}_g(t)$ denotes the ground motion input. It is noteworthy that although various models are available for describing the dissipation of energy in the deck [12],[13], in the present study the deck damping is simply described in terms of a force proportional to velocity. More cumbersome descriptions are avoided since the deck damping is usually smaller than the intermediate supports' damping and, moreover, the focus of the paper is on the influence of the intermediate supports on the response.

In the present work, particular simplified configurations of bridges are analyzed in order to identify the parameters which influence the most the bridges' dynamic properties. In these configurations, the mass per unit length, the beam transverse stiffness and the external damping coefficient are assumed constant and equal respectively to m_d , EI_d , c_d . Furthermore, the values of $k_{c,r}$ and $c_{c,r}$ at the N different intermediate supports are assumed constant and equal to $k_{c,r}=k_T/N$. Finally, the intermediate restraints are assumed equally spaced and the length of each span is set equal to $L/(N+1)$, where L is the total length of the bridge.

After these positions, the equation of motion can be expressed as:

$$\begin{aligned} m_d \int_0^L \ddot{u}(x,t) \eta(x) dx + c_d \int_0^L \dot{u}(x,t) \eta(x) dx + \sum_{r=1}^N \frac{c_T}{N} \dot{u}(x_r,t) \eta(x_r) + EI_d \int_0^L u''(x,t) \eta''(x) dx + \\ + \sum_{r=1}^N \frac{k_T}{N} u(x_r,t) \eta(x_r) = -m_d \int_0^L \ddot{u}_g(t) \eta(x) dx \quad \forall \eta \in V; \forall t \in [t_0, t_1] \end{aligned} \quad (2)$$

Both the members of Eqn. (2) are divided by m_d , as usual, thus yielding:

$$\begin{aligned} \int_0^L \ddot{u}(x,t) \eta(x) dx + 2\omega_d \gamma_d \int_0^L \dot{u}(x,t) \eta(x) dx + \sum_{r=1}^N \frac{c_T}{m_d N} \dot{u}(x_r,t) \eta(x_{c,r}) + \frac{\omega_d^2 L^4}{\pi^4} \int_0^L u''(x,t) \eta''(x) dx + \\ + \sum_{r=1}^N \frac{k_T}{m_d N} u(x_r,t) \eta(x_{c,r}) = - \int_0^L \ddot{u}_g(t) \eta(x) dx \quad \forall \eta \in V; \forall t \in [t_0, t_1] \end{aligned} \quad (3)$$

In deriving eqn.(3) the two following parameters have been introduced:

$$\begin{aligned} \omega_d &= \sqrt{\frac{\pi^4 EI_d}{m_d L^4}} \\ \gamma_d &= \frac{c_d}{2\omega_d m_d} \end{aligned} \quad (4)$$

The first one, ω_d , denotes the circular frequency of the first mode of vibration of the deck alone, i.e., the deck without intermediate supports [13]. The second one, γ_d , denotes the corresponding damping factor, i.e., the ratio between the energy dissipated by the external damping and the maximum strain energy attained due to deck bending, for an harmonic motion at the frequency ω_d , whose shape coincides with the first sinusoidal modal shape [13].

The properties of the system of visco-elastic intermediate supports can be conveniently described by introducing three non-dimensional parameters α , β and γ_c , defined as follows:

$$\begin{aligned}
 \alpha^2 &= \frac{k_T L^3}{\pi^4 E I_d} = \frac{k_T}{\omega_d^2 L m_d} \\
 \beta &= \frac{1}{N} \\
 \gamma_c &= \frac{c_T}{2\alpha^2 \omega_d m_d L} = \frac{c_T \omega_d}{2k_T}
 \end{aligned} \tag{5}$$

The parameter α expresses the relative importance of the total spring stiffness with respect to a generalized measure of the global deck transverse stiffness. Low values of α^2 correspond to a stiff deck relative to the springs while high values correspond to a slender deck relative to the springs. The limit case $\alpha^2 = 0$ corresponds to the simply supported beam with no intermediate restraints.

The parameter β measures the degree of regularity of the total support stiffness' distribution along the bridge. It is inversely proportional to the number of intermediate springs and assumes values spanning from 0 to 1. The case $\beta = 1$ corresponds to the case of support stiffness concentrated at a single point while the limit case $\beta = 0$ ($N \rightarrow \infty$) corresponds to a beam resting on continuously distributed springs (Winkler beam).

The parameter γ_c describes the energy dissipation in the piers or the pier/bearing systems and it has the following physical interpretation: it is the ratio between the energy dissipated by the dampers and the maximum strain energy in the springs, for a rigid transverse harmonic motion of the deck with frequency ω_d .

After substituting eqn.(5) into eqn.(3) one obtains, $\forall \eta \in V; \forall t \in [t_0, t_1]$:

$$\begin{aligned}
 &\int_0^L \ddot{u}(x, t) \eta(x) dx + 2\omega_d \gamma_d \int_0^L \dot{u}(x, t) \eta(x) dx + 2\alpha^2 \beta \gamma_c \omega_d L \sum_{r=1}^N \dot{u}(x_r, t) \eta(x_r) + \\
 &+ \frac{\omega_d^2 L^4}{\pi^4} \int_0^L u''(x, t) \eta''(x) dx + \alpha^2 \beta \omega_d^2 L \sum_{r=1}^N u(x_r, t) \eta(x_r) = - \int_0^L \eta(x) dx \cdot \ddot{u}_g(t)
 \end{aligned} \tag{6}$$

In order to cut off also dimensional aspects related to the length, the variable $y=x/L$ can be introduced and accordingly the motion can be described by

$$\tilde{u}(y, t) = u(x, t) \tag{7}$$

Upon substitution in eqn.(6), one obtains:

$$\begin{aligned}
 &\int_0^1 \ddot{\tilde{u}}(y, t) \tilde{\eta}(y) dy + 2\omega_d \gamma_d \int_0^1 \dot{\tilde{u}}(y, t) \tilde{\eta}(y) dy + 2\alpha^2 \beta \gamma_c \omega_d \sum_{r=1}^N \dot{\tilde{u}}(y_r) \tilde{\eta}(y_r) + \frac{\omega_d^2}{\pi^4} \int_0^1 \tilde{u}''(y, t) \tilde{\eta}''(y) dy + \\
 &+ \alpha^2 \beta \omega_d^2 \sum_{r=1}^N \tilde{u}(y_r) \tilde{\eta}(y_r) = - \int_0^1 \tilde{\eta}(y) dy \cdot \ddot{u}_g \quad \forall \tilde{\eta} \in \tilde{V} = \{ \tilde{v}(y) \in H^2[0, 1] : \tilde{v}(0) = \tilde{v}(1) = 0 \}; \forall t \in [t_0, t_1]
 \end{aligned} \tag{8}$$

The corresponding local form of the problem is obtained by integrating by parts and can be written as:

$$\begin{aligned}
 M \ddot{\tilde{u}}(y, t) + C \dot{\tilde{u}}(y, t) + K \tilde{u}(y, t) &= -M \ddot{u}_g(t) \\
 \tilde{u}''(y, t) \tilde{\eta}'|_0^1 &= 0
 \end{aligned} \tag{9}$$

where M, C, K are formal linear operator related to the mass, damping and stiffness:

$$\begin{aligned}
 M &= 1 \\
 K &= \left[\frac{1}{\pi^4} \frac{\partial^4}{\partial x^4} + \alpha^2 \beta \sum_{r=1}^N \delta(y - y_r) \right] \omega_d^2 = K_1 \omega_d^2 \\
 C &= 2 \left[\gamma_d + \alpha^2 \beta \gamma_c \sum_{r=1}^N \delta(y - y_r) \right] \omega_d = C_1 \omega_d^2
 \end{aligned} \tag{10}$$

and $\delta(\cdot)$ denotes the Dirac delta function.

3 FREE VIBRATIONS PROBLEM

3.1 Form of the characteristic equation

Under a qualitative point of view, the dynamic properties of a linear system, such as the ones analyzed in the present study, can be measured by solving the free vibrations problem that corresponds to eqn.(9) for $\ddot{u}_g = 0$. Thus, the study will proceed with the assessment of the influence of the parameters α , β , γ_d on the response in the most significant vibration modes. For this purpose, the differential boundary problem of eqn.(9) is reduced to an eigenvalue problem through the separation of variables technique. The transverse displacement \tilde{u} is decomposed into the product of a spatial function and a time-dependent function, thus yielding:

$$\tilde{u}(y, t) = \psi(y) Z(t) \tag{11}$$

where $\psi(y)$ is a space-only dependent function while $Z(t)$ is a time function, whose expression is:

$$Z(t) = Z_0 e^{\lambda t} \tag{12}$$

After substituting eqns.(10), (11) and (12) into eqn.(9), one obtains the characteristic equation for the free-vibration problem:

$$\left\{ \lambda^2 + 2 \left[\gamma_d + \alpha^2 \beta \gamma_c \sum_{r=1}^N \delta(y - y_r) \right] \omega_d \lambda + \left[\frac{1}{\pi^4} \frac{\partial^4}{\partial x^4} + \alpha^2 \beta \sum_{r=1}^N \delta(y - y_r) \right] \omega_d^2 \right\} \psi(y) = 0 \tag{13}$$

It is noteworthy that if λ_1 and $\psi(y)$ are solutions of eqn. (13) for a particular value of the deck circular frequency $\omega_d = \omega_{d1}$ then $\sigma \lambda_1$ and $\psi(y)$ are solution of eqn.(13) for $\omega_d = \sigma \omega_{d1}$. Thus, the particular choice of the characteristic parameters leads to a formulation such that the vibration shape $\psi(y)$ does not depend on the particular value of ω_d but it only varies by varying the parameters α , β , γ_d and γ_c . This makes it possible to obtain qualitative results that are not dependent on the deck stiffness or on the deck mass.

3.2 Analytical solution of the eigenvalue problem

In order to solve analytically the free vibrations problem it is convenient to divide the beam into a set of N_s segments, each bounded by two consecutive restraints (external or intermediate). The motion of the s -th segment is described by the function $\ddot{u}_s(z_s, t)$ as follows:

$$\ddot{u}_s(z_s, t) + 2\gamma_d \omega_d \dot{u}_s(z_s, t) + \frac{1}{\pi^4} \omega_d^2 \tilde{u}_s(z_s, t) = 0 \quad \text{with } z_s \in [0, 1/N_s] \tag{14}$$

The transverse displacement \tilde{u}_s is decomposed into the product of the spatial function $\psi_s(y)$ and the time-dependent function $Z(t)$ of eqn.(12), thus yielding the following equation of motion:

$$(\lambda^2 + 2\gamma_d \omega_d \lambda) \psi_s(y, t) + \frac{\omega_d^2}{\pi^4} \psi_s^{IV}(y, t) = 0 \quad (15)$$

which is rewritten as:

$$\psi_s^{IV}(y, t) = \Omega^4 \psi_s(y, t) \quad (16)$$

having posed $\Omega^4 = -\frac{\pi^4 (\lambda^2 + 2\gamma_d \omega_d \lambda)}{\omega_d^2}$, or $\lambda = -\gamma_d \omega_d + i \sqrt{\left(\frac{\Omega^4 \omega_d^2}{\pi^4}\right) - (\gamma_d \omega_d)^2}$.

The solution to eqn.(15) is:

$$\psi_s(y) = C_{4s-3} \sin(\Omega y) + C_{4s-2} \cos(\Omega y) + C_{4s-1} \sinh(\Omega y) + C_{4s} \cosh(\Omega y) \quad (17)$$

with C_{4i-3} , C_{4i-2} , C_{4i-1} , C_{4i} to be determined based on the boundary conditions at the external supports and the continuity conditions at the intermediate restraints. This involves the calculation of higher order derivatives up to the third order.

In total, a set of $4N_s$ conditions is required to determine the vibration shape along the whole beam. At the first span, i.e., for $s=1$, the conditions $\psi_1(0) = \psi_1''(0) = 0$ apply while at the last span, i.e., for $s=N_s$, the support conditions are $\psi_{N_s}(1/N_s) = \psi_{N_s}''(1/N_s) = 0$. The boundary conditions expressing the continuity of the functions ψ_{i-1} and ψ_i at each of the N_s-1 spring locations can be expressed as:

$$\begin{aligned} \psi_{s-1}(1/N_s) &= \psi_s(0) \\ \psi_{s-1}'(1/N_s) &= \psi_s'(0) \\ \psi_{s-1}''(1/N_s) &= \psi_s''(0) \\ [\psi_{s-1}'''(1/N_s) - \psi_s'''(0)] - \beta \left(\pi^4 \alpha^2 + \frac{2\lambda \pi^4 \alpha^2 \gamma_c}{\omega_d} \right) \psi_s(0) &= 0 \end{aligned} \quad (18)$$

By substituting eqn. (17) into the boundary (supports and continuity) conditions, a system of $4N_s$ homogeneous equations in the constants C_1, \dots, C_{4N_s} is obtained. Since the system is homogeneous, the determinant of coefficients must be equal to zero for the existence of a nontrivial solution. This procedure yields the following frequency equation in the unknown Ω :

$$G(\Omega, \alpha^2, \beta, \gamma_d, \gamma_c) = 0 \quad (19)$$

It is noteworthy that the particular choice of the set of characteristic adimensional parameters results in an function G which is independent from ω_d .

In the general case of non-zero damping, the solution of the equation must be sought in the complex domain. Since the system is continuous, an infinite set of Ω values satisfying eqn.(19) is obtained. However, only selected values of Ω are significant, because they correspond to the first vibration modes which are usually characterized by the highest participation factors. For a given value of Ω satisfying eqn. (19), the corresponding modal

shape can be calculated, together with the corresponding circular frequency ω and damping factor ζ . It is remarked that the eigensolutions Ω are complex conjugate. Thus, if the couple $\Omega = \Omega_r + i\Omega_i$ and $\lambda = \lambda_r + i\lambda_i$ is a solution of eqn.(19), then the couple $\bar{\Omega} = \Omega_r - i\Omega_i$ and $\lambda = \lambda_r - i\lambda_i$ is a solution, too. The corresponding eigenvectors are complex conjugate, too. Finally, for zero-damping $\lambda = i\omega$ where $\omega = \Omega\sqrt{EI_d / m_d}$.

3.3 Generalized orthogonality conditions for vibration modes and modal properties

Eqn.(13) for mode i is multiplied by ψ_j and eqn.(13) for mode j is multiplied by ψ_i . After integrating over the entire length of the beam one obtains:

$$\begin{aligned} & \lambda_i^2 \int_0^1 \psi_i(y) \psi_j(y) dy + 2\omega_d \lambda_i \left[\gamma_d \int_0^1 \psi_i(y) \psi_j(y) dy + \alpha^2 \beta \gamma_c \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) \right] + \\ & + \frac{\omega_d^2}{\pi^4} \int_0^1 \psi_i^{IV}(y) \psi_j(y) dy + \alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \end{aligned} \quad (20)$$

$$\begin{aligned} & \lambda_j^2 \int_0^1 \psi_j(y) \psi_i(y) dy + 2\omega_d \lambda_j \left[\gamma_d \int_0^1 \psi_j(y) \psi_i(y) dy + \alpha^2 \beta \gamma_c \sum_{r=1}^N \psi_j(y_r) \psi_i(y_r) \right] + \\ & + \frac{\omega_d^2}{\pi^4} \int_0^1 \psi_j^{IV}(y) \psi_i(y) dy + \alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_j(y_r) \psi_i(y_r) = 0 \end{aligned} \quad (21)$$

By integrating twice by parts the terms with the fourth order derivative and recalling the support boundary conditions, one finally obtains:

$$\begin{aligned} & \lambda_i^2 \int_0^1 \psi_i(y) \psi_j(y) dy + 2\omega_d \lambda_i \left[\gamma_d \int_0^1 \psi_i(y) \psi_j(y) dy + \alpha^2 \beta \gamma_c \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) \right] + \\ & + \frac{\omega_d^2}{\pi^4} \int_0^1 \psi_i''(y) \psi_j''(y) dy + \alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \end{aligned} \quad (22)$$

$$\begin{aligned} & \lambda_j^2 \int_0^1 \psi_j(y) \psi_i(y) dy + 2\omega_d \lambda_j \left[\gamma_d \int_0^1 \psi_j(y) \psi_i(y) dy + \alpha^2 \beta \gamma_c \sum_{r=1}^N \psi_j(y_r) \psi_i(y_r) \right] + \\ & + \frac{\omega_d^2}{\pi^4} \int_0^1 \psi_j''(y) \psi_i''(y) dy + \alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_j(y_r) \psi_i(y_r) = 0 \end{aligned} \quad (23)$$

By subtracting eqn.(23) from eqn.(22), for $\lambda_i \neq \lambda_j$, one obtains the first orthogonality condition:

$$(\lambda_i + \lambda_j) \int_0^1 \psi_i(y) \psi_j(y) dy + 2\omega_d \gamma_d \int_0^1 \psi_i(y) \psi_j(y) dy + 2\alpha^2 \beta \omega_d \gamma_c \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \quad (24)$$

By subtracting eqn.(23) multiplied by λ_i from eqn.(22) multiplied by λ_j and dividing by $(\lambda_j - \lambda_i)$ one obtains the second orthogonality condition:

$$\frac{\omega_d^2}{\pi^4} \int_0^1 \psi_i''(y) \psi_j''(y) dy - \lambda_i \lambda_j \int_0^1 \psi_i(y) \psi_j(y) dy + 2\alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \quad (25)$$

which upon substitution of eqn.(24) may also read as follows:

$$\begin{aligned} & \frac{\omega_d^2}{\pi^4} (\lambda_i + \lambda_j) \int_0^1 \psi_i''(y) \psi_j''(y) dy + 2\omega_d \gamma_d \lambda_i \lambda_j \int_0^1 \psi_i(y) \psi_j(y) dy + \\ & + 2\alpha^2 \omega_d \beta \gamma_c \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) + 2\alpha^2 \beta \omega_d^2 (\lambda_i + \lambda_j) \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \end{aligned} \quad (26)$$

For the case of zero damping, the two orthogonality conditions reduce to the well expression already derived in [8]:

$$\int_0^1 \psi_i(y) \psi_j(y) dy = 0 \quad (27)$$

$$\frac{\omega_d^2}{\pi^4} \int_0^1 \psi_i''(y) \psi_j''(y) dy + 2\alpha^2 \beta \omega_d^2 \sum_{r=1}^N \psi_i(y_r) \psi_j(y_r) = 0 \quad (28)$$

Similarly to [14], the generalized orthogonality conditions are employed to derive the analytical expressions of the circular frequency of vibration ω_i and of the damping factor ξ_i for the i -th vibration mode. By setting $\lambda_j = \bar{\lambda}_i$ in eqn.(25) and in eqn.(24), and recalling that $\lambda_i \bar{\lambda}_i = \omega_i^2$ and $\lambda_i + \bar{\lambda}_i = -2\xi_i \omega_i$, one obtains:

$$\frac{\omega_i^2}{\omega_d^2} = \frac{\frac{1}{\pi^4} \int_0^1 [\psi_i''(y)]^2 dy + 2\alpha^2 \beta \sum_{r=1}^N \psi_i^2(y_r)}{\int_0^1 \psi_i^2(y) dy} \quad (29)$$

$$\xi_i = \frac{\gamma_d \int_0^1 \psi_i^2(y) dy + \alpha^2 \beta \gamma_c \sum_{r=1}^N \psi_i^2(y_r)}{\int_0^1 \psi_i^2(y) dy} \cdot \frac{\omega_d}{\omega_i} \quad (30)$$

The circular frequency ω_i , normalized in eqn.(29) with respect to ω_d , is simply expressed in terms of the ratio between the potential energy of the deck and the restraints, and the kinetic energy of the deck mass. It can be observed that the contribution to the potential energy of the deck is proportional to the deck curvature and becomes more and more important with respect to the other term when the number of the vibration mode increases.

The modal damping factor in eqn.(30) corresponds to the ratio between the energy dissipated by the deck and by the restraints and the kinetic energy of the deck. It should be stressed that the term of the dissipation related to the intermediate dampers qualitatively acts a mass-proportional similarly to the deck damping and, thus, the damping factor is expected to reduce significantly when the number of the vibration mode increases. Furthermore, damping factor ξ_i is not sensitive to ω_d .

4 PARAMETRIC ANALYSIS

4.1 Undamped free vibrations

This paragraph analyzes the free vibrations problem of the beam with intermediate restraints, disregarding the damping exerted by both the deck and the restraints. The values of γ_d and γ_c are assumed equal to zero at this stage, in order to describe the influence of the global stiffness of the supporting system, described by α^2 , and the effects related to the distribution of its stiffness, described by β .

Different configurations of beams with intermediate restraints are considered which are representative of common short and medium span bridges (Fig. 2). They correspond to different values of the parameter β , i.e., $\beta=1$ (Fig. 2a), $\beta=1/2$ (Fig. 2b), $\beta=1/3$ (Fig. 2c). Moreover, the limit case of a beam simply supported at its extremes with no intermediate restraints (corresponding to $\alpha^2=0$) (Fig. 2d), and a beam resting on elastic continuous transverse restraints (corresponding to $\beta=0$) are also analyzed.

Fig. 2. Different configurations of beams with intermediate restraints analyzed.

The parameter α^2 is varied between about zero (stiff deck, flexible supports) and 10, that may be regarded as a realistic upper limit for slender superstructures on stiff supports. The results presented in the following include the modal shapes and periods of vibration. As previously shown, in the considered formulation the modal shapes depend on the parameters α and β only, and they are invariant with respect to the deck circular frequency ω_d . The vibration periods depend on the deck circular frequency, but they are divided by ω_d in order to make them independent from ω_d , too. Thus, the particular choice of the deck does not affect the following results. For the sake of completeness, the numerical results have been obtained by considering as reference the deck reported in [5], whose parameters are: $L=200\text{m}$, $m_d=16.24\text{t}$, $EL_d=1100307114\text{ kN/m}^2$, and $\omega_d=2.03\text{Hz}$. Before discussing the results, it may be useful to recall that, in the limit case corresponding to $\beta=0$, the vibration modes are purely sinusoidal, irrespectively of the value of α^2 (see Appendix for the proof).

Fig. 3 reports the first three modal shapes for different values of α^2 and of β , normalized with respect to the L2 norm, i.e. $\|\psi_i\|_2 = \left(\int_0^1 |\psi_i(y)|^2 dy \right)^{1/2} = 1$. It is recalled that the even modes of vibration are characterized by an anti-symmetric shape and a participating factor equal to zero, and thus they do not affect the seismic response of the considered configurations.

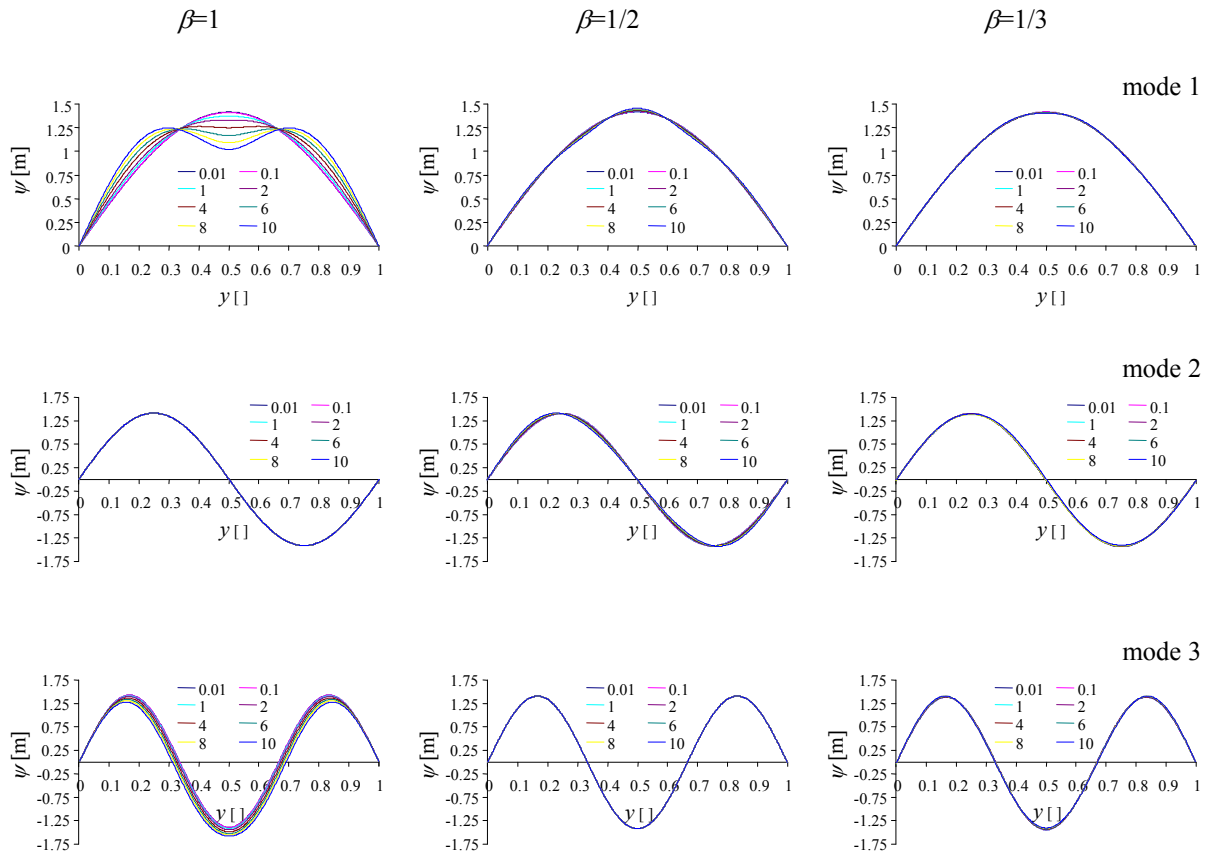

Fig. 3. Normalized first three modal shapes for different values of α^2 and for β .

The intermediate restraints have a remarkable influence on the first mode shape only for $\beta=1$. In this case, the first mode vibration shape significantly deviates from the shape of the deck vibrating alone ($\alpha^2=0$), for high values of α^2 . On the other hand, for $\beta=1/2$ and $\beta=1/3$, the vibration shape is very close to the shape of the deck vibrating alone, even for high values of α^2 . This can be explained recalling that the vibration shape tends, for decreasing β values, to the sinusoidal shape of a simply-supported beam on continuous elastic restraints.

Globally, the influence of the restraints on the higher modes shapes is almost negligible, for any case of β , although a uniform trend is not observed, since the influence of the intermediate supports depend on their distance from the shape mode nodes.

In order to have a full insight into the influence of the restraints on the response along the deck, it is of interest to analyze the effects of the variation of the support properties on the second order derivative $\psi_i''(y)$ of the displacement shape, since this quantity is related to the deck's bending moments and strain energy distribution. Fig. 4 reports the normalized shape of $\psi_i''(y)$, for the first three vibration modes and for different values of the parameters α^2 and β .

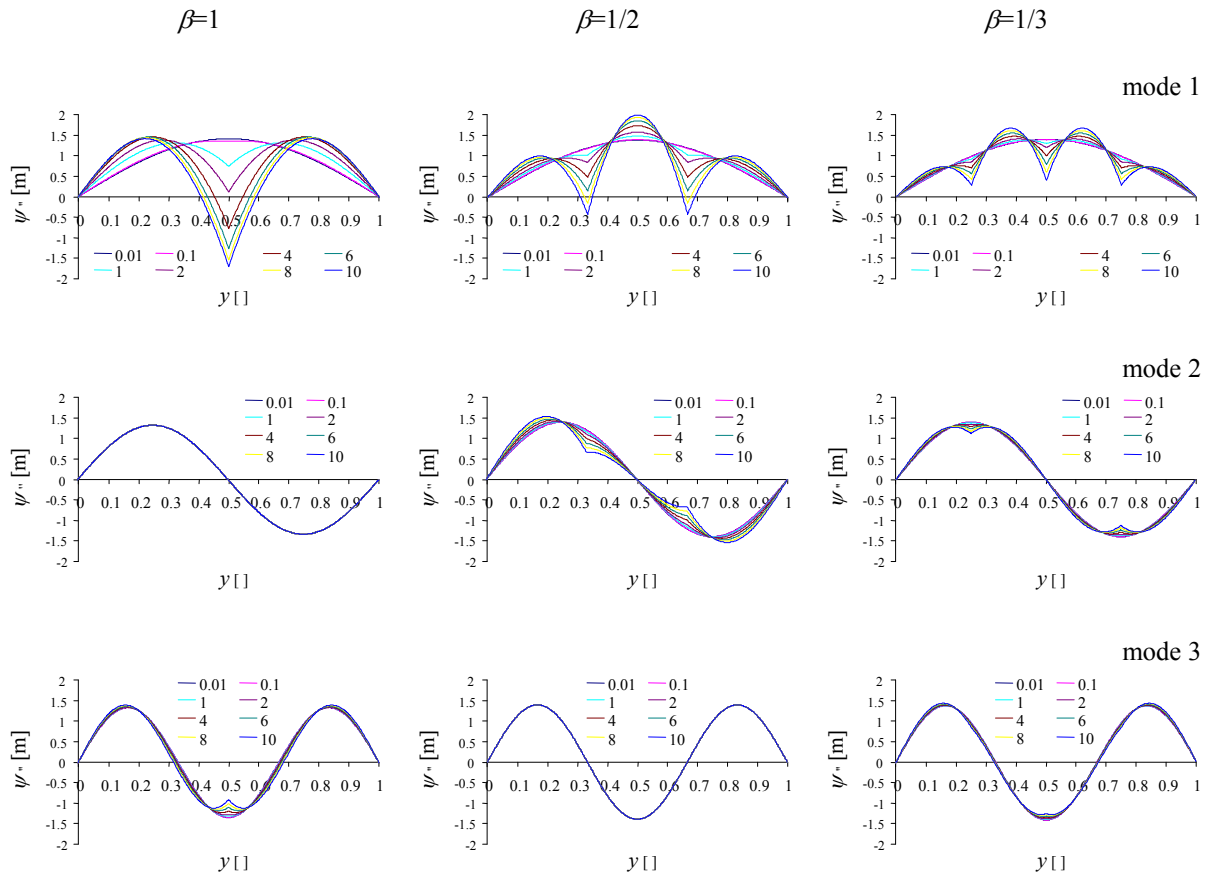

Fig. 4. Normalized second order derivatives of the first three modal shapes for different values of α^2 and β .

The intermediate supports influence more significantly the shape of the second order derivative than the displacement shape itself. Notable variations (with respect to the case corresponding to $\alpha^2=0$) are observed in the first mode shape, for all the three configurations considered. The variations in the higher modes are less significant and different from configuration to configuration.

In conclusion, the variation of the intermediate supports' properties induces minor variations in the distribution of the modal shapes, and thus in the distribution of the piers shear and inertia forces, directly related to them. Significant variations are limited to the first mode and to the configuration with a single support. On the other hand, the distribution of internal actions in the deck is strongly affected by the intermediate restraints, for the modes and configuration reported.

In order to describe synthetically the variation of the functions ψ_i and ψ_i'' defined along the bridge, the following scalar variation index is introduced:

$$\delta_{f_i} = \frac{\|f_i - f_{d,i}\|_2}{\|f_{d,i}\|_2} \quad \text{for } f_i = \psi_i, \psi_i'' \quad (31)$$

where the subscript “ i ” denotes the i -th vibration mode while the subscript “ d ” refers to the limit case corresponding to $\alpha^2=0$.

Other scalar quantities are of interest in the assessment of the system's seismic response and their variation due to the intermediate supports can be described synthetically in a similar way. In particular, the following results report the variation of the vibration periods T_i , of the

participation factors ρ_i , and of the values of the third order derivative at the beam ends $R_i = |\psi_i'''(0)| = |\psi_i'''(L)|$, that is proportional to the transverse reaction at the abutments. The variation indexes for these quantities are defined as:

$$\delta_{f_i} = \frac{f_i - f_{d,i}}{f_{d,i}} \quad \text{for } f_i = R_i, \rho_i, T_i \quad (32)$$

Fig. 5 shows the influence of parameters α^2 and β on the first-mode variation indexes. Fig. 5a highlights the different trend of the mode shape (displacement) and of its second order derivatives (bending moments). The variation index of the abutment reactions (Fig. 5b) assume positive and negative values spanning from -10% to around 40%-50%. Similar trends are observed for all the configuration considered. Finally, minor variations are observed for the participation factor while the vibration period strongly decreases with increasing α^2 . Its sensitivity to α^2 is very high in the initial part of the range explored.

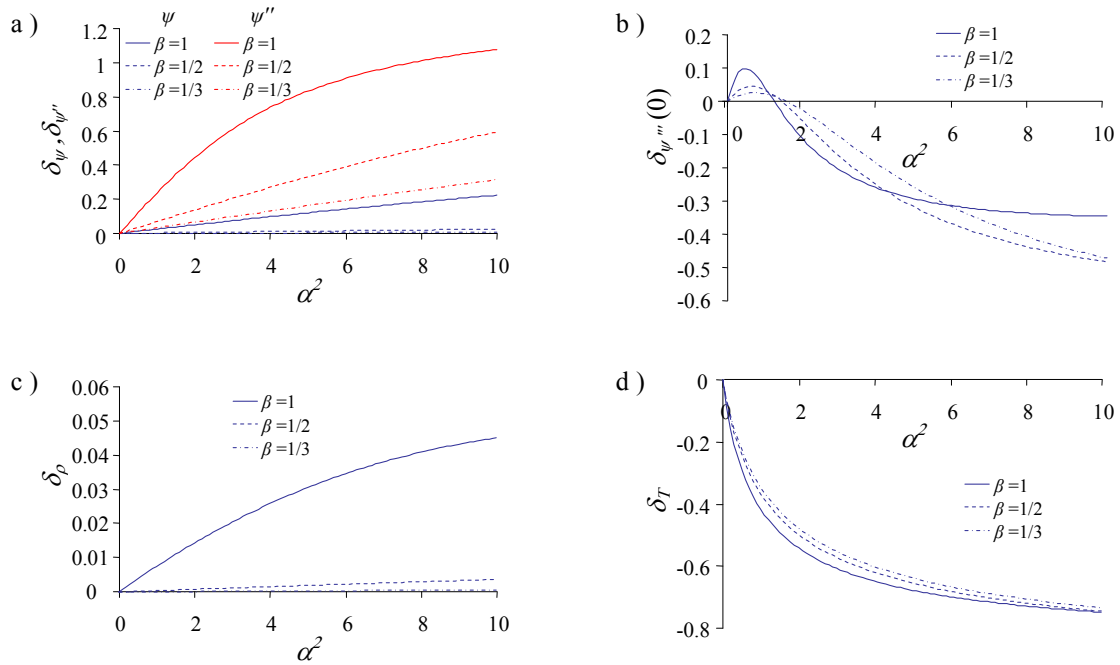

Fig. 5. Variation of δ with α^2 and β for mode 1 and relative to: a) displacements $\psi(y)$ and bending moments $\psi''(y)$, b) abutment shear $\psi'''(0)$, c) participation factor ρ , and d) vibration period T .

Fig. 6 and Fig. 7 show the influence of parameters α^2 and β on the variation indexes of the third and fifth mode. As previously noted, even modes are not of interest. Thus, the results concern odd terms only.

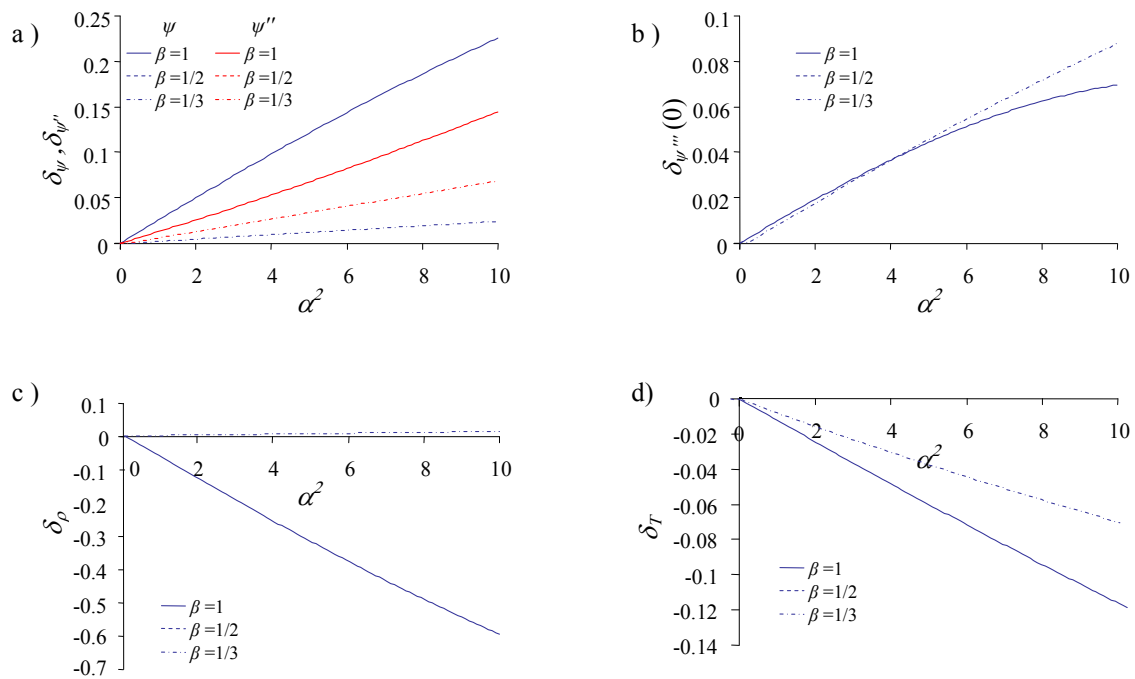

Fig. 6. Variation of δ with α^2 and β for mode 3 and relative to: a) displacements $\psi(y)$ and bending moments $\psi''(y)$, b) abutment shear $\psi'''(0)$, c) participation factor ρ , and d) vibration period T .

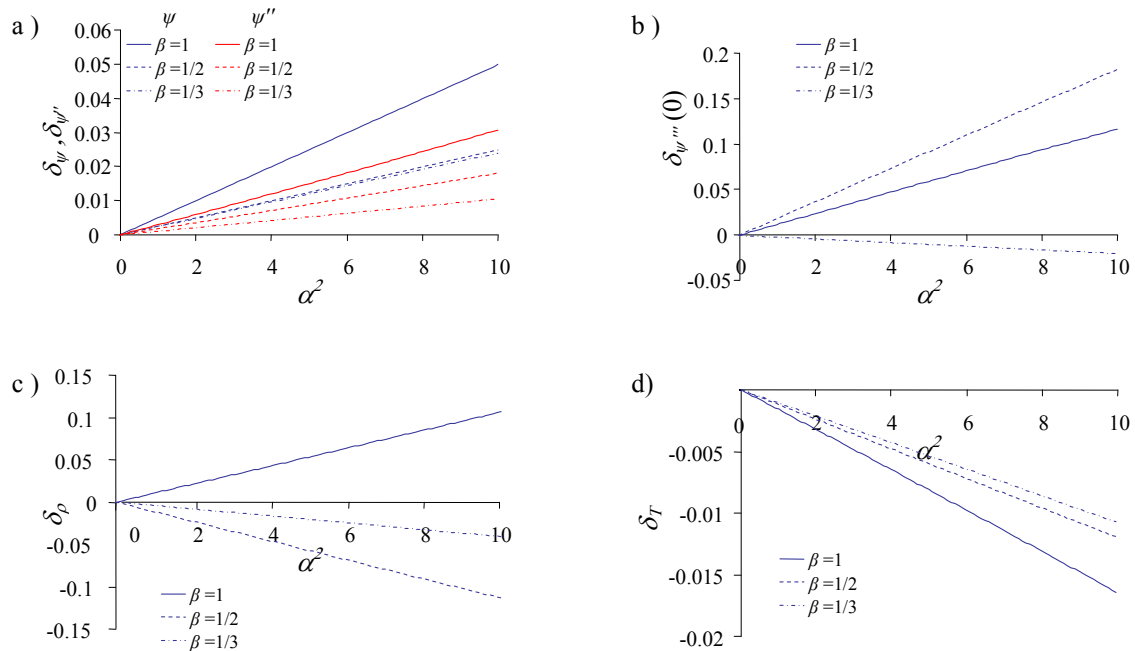

Fig. 7. Variation of δ with α^2 and β for mode 5 and relative to: a) displacements $\psi(y)$ and bending moments $\psi''(y)$, b) abutment shear $\psi'''(0)$, c) participation factor ρ , and d) vibration period T .

Generally, different trends can be observed in the higher-modes variation indexes. Variations in displacement and bending decrease for higher modes and higher number of supports. The reaction at the abutments, related to the third order derivative, is strongly influenced by the presence of intermediate supports, without distinction for the considered

configurations, and it shows large variations with different sign. The intermediate supports in general reduce the vibration period but their influence is lower and lower for increasing order of modes. Finally, the participation factors are not significantly influenced by the intermediate restraints, with the exception of the second mode's participation factor, for $\beta=1$.

4.2 Non-classically damped free vibrations

This paragraph analyzes the damped free vibrations problem which corresponds to considering the deck damping and intermediate restraints with visco-elastic behavior. The solution to this problem is reported in Appendix A. A damping factor $\gamma_d = 0.02$ is employed to describe the dissipation in the deck [5] while different values of γ_c from 0 to 0.25 are considered to describe the dissipation of the intermediate restraints. It is noteworthy that only the intermediate dampers are the cause of the non-classical damping, since the deck damping is assumed proportional to the mass. The most relevant effects of the variation of the intermediate dampers properties on the system free-vibration response are discussed below.

Fig. 8 shows the influence of the intermediate supports damping γ_c on the global dissipative properties, described by the damping factor ζ , for vibration modes 1, 3 and 5. The definition and the analytical expression of ζ are reported in Appendix A. Different values of the parameters describing the intermediate supports stiffness (α^2) and the bridge configuration (β) are considered.

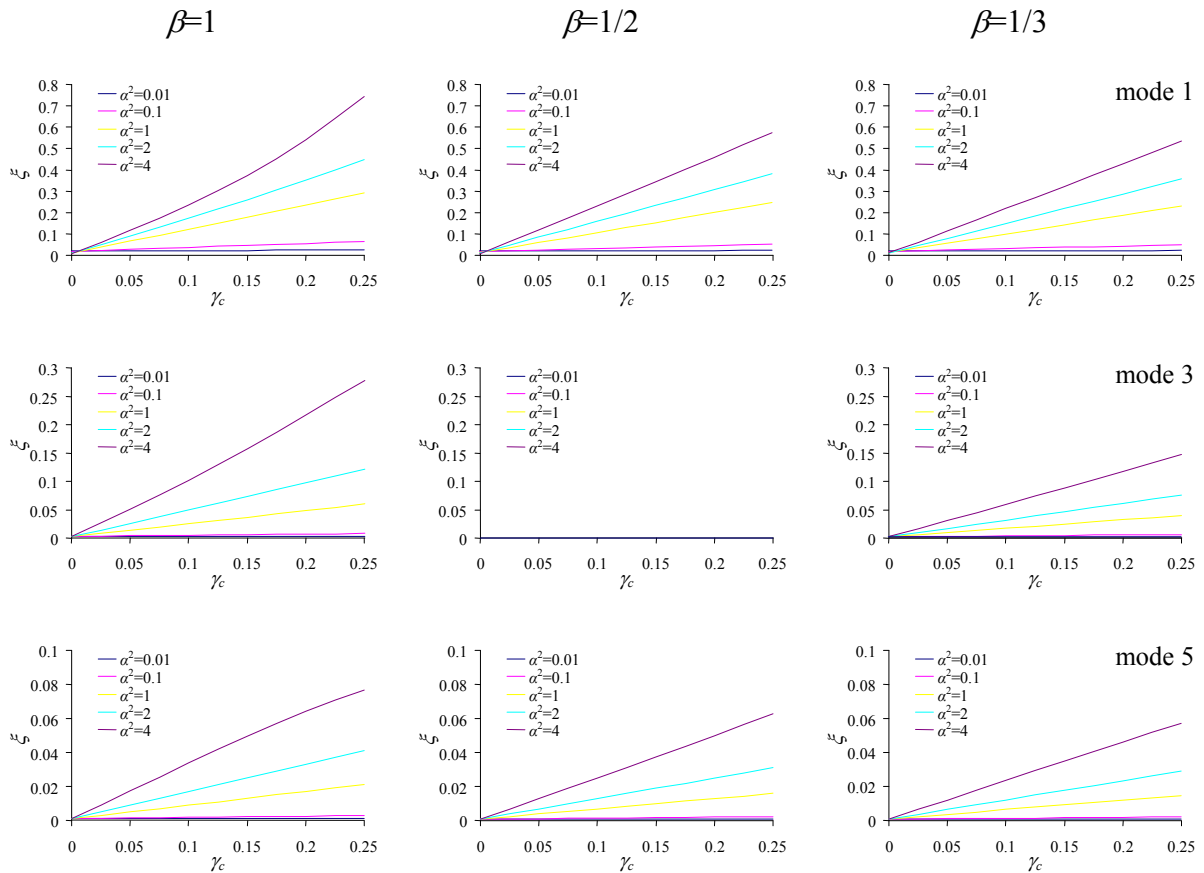

Fig. 8. Damping factor ζ vs. γ_c for different values of α^2 and β .

In general, the values of ζ corresponding to the first vibration mode (maximum value of 0.7 for $\gamma_c=0.25$) are significantly higher than those corresponding to the third (maximum value of 0.3 for $\gamma_c=0.25$) and the fifth vibration mode (maximum value of 0.08 for $\gamma_c=0.25$). It is also observed that the intermediate supports damping, which is proportional to the displacement, have a reduced efficiency in damping the higher modes and its decay rate is approximately proportional to $1/i^2$ (i denotes the mode index). Furthermore, the above figures demonstrate that the value of ζ increases almost linearly for increasing γ_c and for increasing α^2 while decreases slightly for decreasing β .

In a non-classically damped system such as those analyzed, the dampers may significantly affect the modal shape and the vibration motion may considerably vary with respect to the undamped case. In order to illustrate the modifications introduced by the intermediate dampers on the vibration shape with respect to the undamped case, a particular configuration is firstly analyzed which corresponds to the values of $\alpha^2=4$, $\beta=1$ and $\gamma_c=0.13$, leading to $\zeta=0.3$. Fig. 9 shows the real and imaginary part of the normalized first modal shape ($\psi_{1,ncd}^R$ and $\psi_{1,ncd}^I$) and of its second order derivative ($\psi_{1,ncd}^{''R}$ and $\psi_{1,ncd}^{''I}$) for the non-classically damped case. In the same figure, the normalized shape ($\psi_{1,cd}$) and its second order derivative ($\psi_{1,cd}^{''}$) corresponding to the classically-damped case ($\gamma_c=0$) are also shown for comparison.

Fig. 9. (a) Real and imaginary part of the normalized first modal shape and (b) of the second order derivative for the non-classically damped case and for the classically-damped case ($\gamma_c=0$).

The intermediate dampers influence not only the imaginary part of the eigenvector and of its derivatives, but also, to a less extent, the real part. Furthermore, the imaginary part is quite small with respect to the corresponding real part in the displacement shape, but it assumes an high relevance in the moment shape.

For design purposes, it can be interesting to analyze the envelope of the free vibration response in the first classically ($\psi_{1,cd}$) and non-classically damped ($\psi_{1,ncd}$) modes obtained neglecting the amplitude decay term.

$$\psi_{1,ncd} = \max_t \{ \psi_1^R \cos(\omega_1 t) - \psi_1^I \sin(\omega_1 t) \} \quad (33)$$

Fig. 10a plots the envelope (acronym “env”) of the modal shape. The envelope of the second-order derivative, derived in a similar manner, is also reported in Fig. 10b.

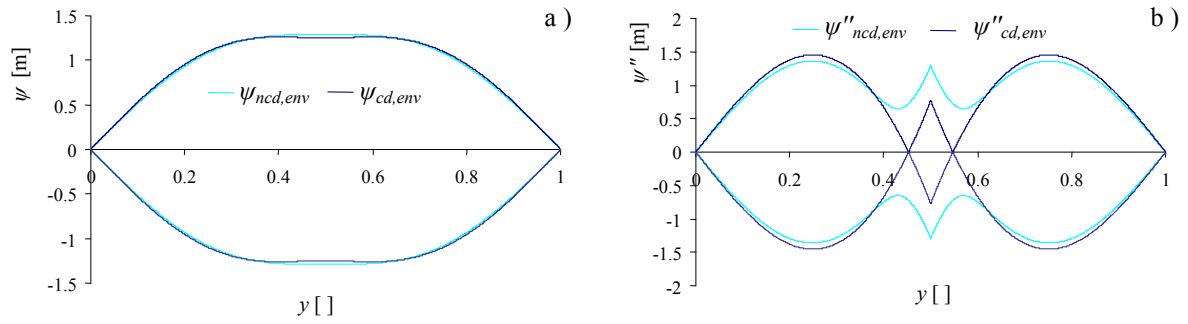

Fig. 10. Envelope of a) the first modal shape and b) of its second-order derivative for the non-classically damped case and the classically-damped case.

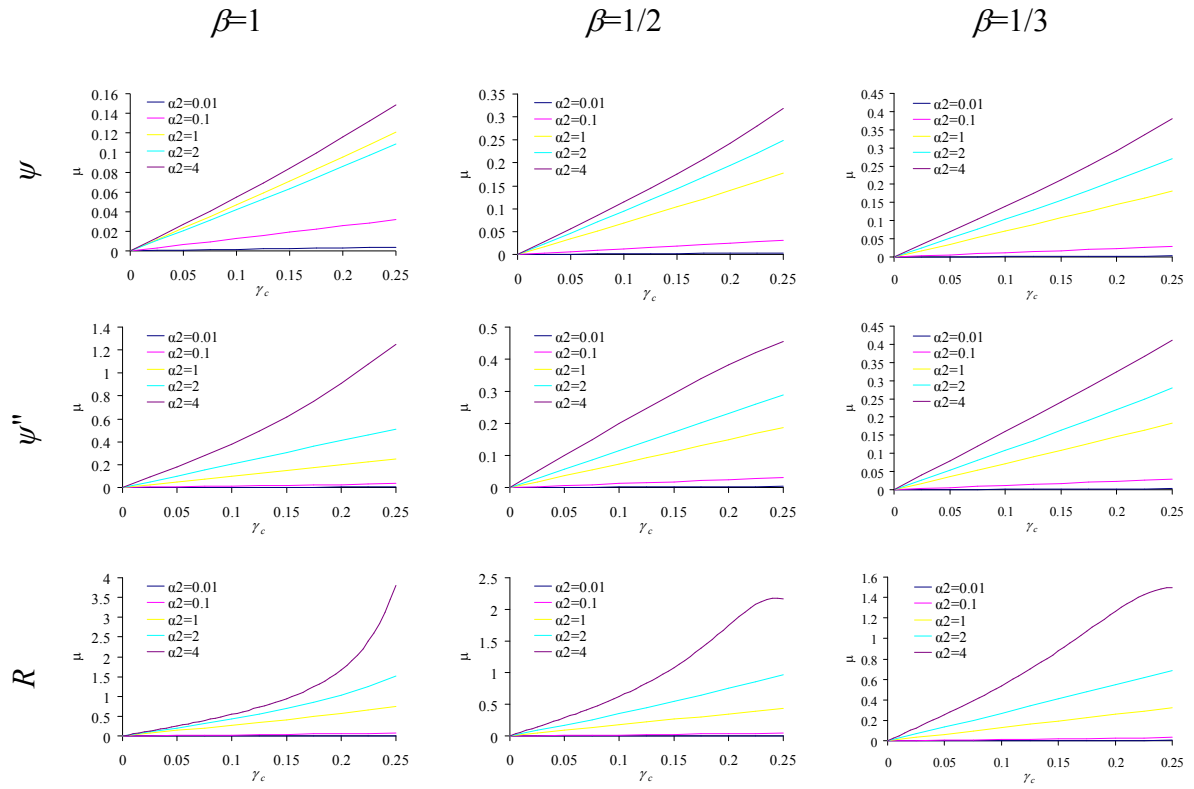

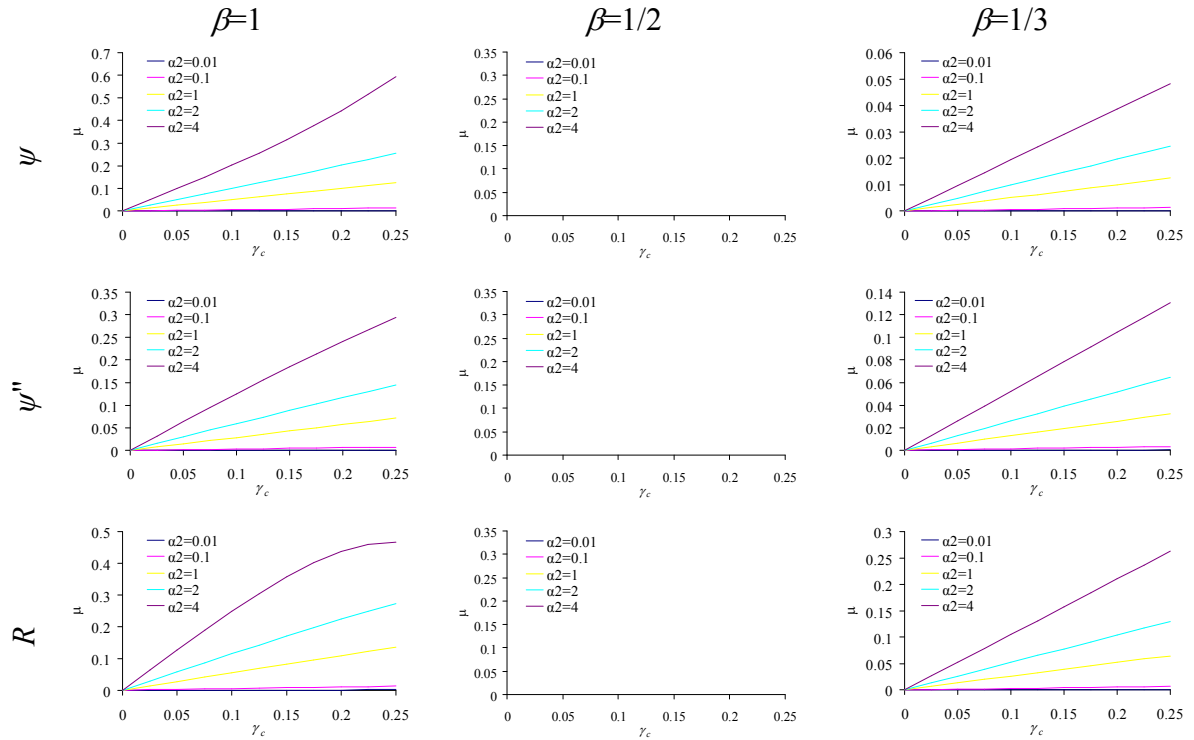

It is interesting to observe that the displacements envelopes accounting for and disregarding damping are very similar. On the other hand, the envelope of the curvatures for the non-proportionally damped case significantly differs from the corresponding envelope for the proportionally damped case. In conclusion, with reference to this case it is observed that neglecting the non proportionality of the damping yields sufficiently accurate estimates of the displacement shape but inadequate estimates of the maximum values of the internal actions attained during the vibration motion.

In order to provide information about the extent of non proportionality in the response, the following non-proportionality indexes are introduced for displacements, second order derivatives and end reactions:

$$\mu_{f_i} = \frac{\|\text{Im}(f_i)\|_2}{\|\text{Re}(f_i)\|_2} \quad \text{with } f_i = \psi_i, \psi_i''$$

$$\mu_{R_i} = \frac{\text{Im}(R_i)}{\text{Re}(R_i)}$$
(34)

The non-proportionality indexes generally increase for increasing α^2 and increase almost linearly for increasing γ_c , except for the variation index of ψ in case $\beta=1$, mode 1. They also decrease for increasing β as expected, since when β tends to zero the system tends to a simply supported beam resting on continuously distributed visco-elastic restraints, whose damping is proportional and whose vibration modes are real.

 Fig. 11. Variation with γ_c of non-proportionality indexes relative to mode 1, for different values of α^2 .

 Fig. 12. Variation with γ_c of non-proportionality indexes relative to mode 3, for different values of α^2 .

CONCLUSIONS

This paper examines the dynamic behavior of partially restrained seismically isolated bridges by studying the transverse free vibrations of a two-dimensional simply-supported beam model resting on intermediate visco-elastic supports.

Particular simplified configurations with constant deck properties and uniform equally spaced supports are considered, with two main aims: to seek a reduced set of characteristic parameters describing completely the dynamic system and to obtain analytical solutions useful to make explicit the relationship between the bridge properties and the dynamic response. Three parameters are identified that describe a) the global ratio between deck and supports stiffness (α), b) the regularity of the support stiffness distribution (β), and c) the global dissipative properties of the supports (γ_c).

A parametric analysis is carried out by varying the values assumed by these parameters, in order to highlight their influence on the dynamic properties of interest for the seismic response assessment. The reported results show that (a) variations in the distribution of displacements, related to the piers and inertia forces, are remarkable only for the first mode of the configuration with only one intermediate support, while minor variations are observed in the other cases; (b) variations in the curvatures' shape, related to the deck bending moments, are very significant and cannot be neglected for all the modes and configuration reported; (c) the abutment reactions are also strongly affected to the presence of intermediate supports, without distinction for the considered configurations; (d) the damping promoted by the intermediate supports is proportional to the displacements, and its effectiveness decreases rapidly with increasing mode order; (e) for certain values of the characteristic parameters the non classical damping induced by the intermediate supports can play an important role in the dynamic response and, thus, simplified approaches neglecting it can lead to not accurate estimates of the maximum values of the response parameters attained during the motion; (f) non-classical damping induces minor variations on the displacement shape and on related quantities rather than on higher order derivatives.

Keywords: Bridge, Abutment, Earthquake Resistance, Restraining System, Steel Tube, Serviceability, Seismic Movement

Abstract. *The present study proposes an alternative to seismic isolation practice, which aims at the reduction in the bridge seismic actions mainly for the longitudinal design earthquake, which is more critical than the transverse one. The aforementioned purpose is achieved through the improved seismic participation of the bridge abutments. The deck slab is extended onto the embankments and is rigidly connected either with transversely directed RC walls or with transversely directed rows of hollow section steel tubes. This system is constructed into a concrete box-shaped substructure which replaces the conventional wing-walls. As a result the approach embankment does not affect the response of the proposed system. The efficiency of the proposed system was assessed by utilizing a conventional seismic isolated railway bridge. The analytical investigation was performed by means of non-linear dynamic time history analysis implemented with the FE commercial code SAP 2000. The bridge systems were subjected to artificial earthquake motion that is compatible to Eurocode 8 elastic spectra. The assessment of the efficiency was mainly carried out by comparing the response of the resulting modified bridge system with the response of the initial bridge system. The proposed system has the ability to accommodate the in-service movements of the deck, by means of the flexibility of the restraining members. The seismic response of the bridge is also enhanced. The displacements of the deck in the longitudinal direction of the bridge were found to be significantly reduced. The restraining effect also reflects on the seismic actions of the piers (shear actions and bending moments) leading to cost-effective bridge design.*

1 INTRODUCTION

Many countries around the world suffer from earthquakes and people expect that structural engineers will design structures so that they can survive the effects of these earthquakes. The basic requirement that the engineer work to meet during the design process is the ensuring that the capacity of the structure is greater than the demand [1,2]. The earthquake causes inertial forces proportional to the structure's mass and the earthquake ground accelerations. As the ground accelerations increase, the capacity of the structure must be increased to avoid structural damage. However it is not practical to continue to increase the strength of the structure indefinitely as this also increase the structural cost. So the Codes [3] allow engineers to use ductility to achieve the capacity. Ductility is a concept of allowing the structural elements to deform beyond the elastic limit in a controlled manner. Beyond this limit, the displacements increase with only a small increase in force.

Seismic isolation represents an opposite, to the aforementioned, approach, as it attempts to reduce the demand rather than increase the capacity of a structure [4-6]. In this framework, the effort on protection of bridges against earthquakes is mainly focused on minimizing the forces to be carried by the piers, in particular the shears. Isolation systems are basically typified into bearings and energy dissipation devices. Rubber bearings with high lateral flexibility are meant to shift the vibrational periods of the structures so as to avoid resonance with the excitations [7]. They are usually combined with high damping material and fluid dampers to increase the in-structure damping and to reduce the lateral movements of the bridge due to the seismic loading. Sliding bearings are introduced to filter out the imparting earthquake forces through the frictional interfaces. The support of the deck to the piers and abutments through bearings also accommodates the in-service induced movements of the deck due to shrinkage creep and thermal effects [8]. However, although seismic isolation is considered one of the most promising practices worldwide, the high purchase cost of the devices, which increases the total construction cost of the bridge constitutes a major disadvantage of this practice.

In this regard, concerning the reduction on the demand rather than the increase on the capacity of a structure, the seismic performance of bridges can also be enhanced by the abutment and backfill soil participation. Current research [9-11] focuses on the known problem of embankment-bridge interaction which can contribute to the enhancement of the seismic response of bridge structures. Specifically, recent studies have investigated the problem and came up to the conclusion that the dynamic participation of these elements results in significant displacement reductions [12]. Furthermore the seismic participation of the abutment was found to lead to cost-effective bridge design according to Nutt [13].

In the present study the seismic performance of bridges is enhanced through an external restraining system consisting of steel tubes which are arranged in rows behind the abutment's web. The efficiency of the proposed restraining system is examined by analyzing the seismic response of a railway bridge in Greece which is considered to be the "reference" bridge.

2 DESCRIPTION OF THE PROPOSED SYSTEM

The aim of the present study is the investigation on the efficiency of an external restrainer which has the ability to reduce the bridge seismic movements. The proposed restrainer is located behind the abutment's web and is consisted of transversely directed members which are either pairs of concrete walls or rows of pairs of steel tubes. The efficiency of the system consisting of pairs of concrete walls was extensively investigated in previous works [14]. In this study the investigation is extended in the field of the composite steel and concrete structures. The proposed system is given in Figure 1. Each pair of steel tubes is encased in the pile- cap

while their heads are connected in the longitudinal and transverse direction through steel plates which are welded around their perimeter, see Detail 1 in Figure 1. The head of the pairs of the steel tubes is properly connected with the extension of the deck slab. As a result the in-service as well as the seismic loading causes the activation of the system. This system is constructed into a concrete box-shaped substructure which replaces the conventional wing-walls. Therefore the approach embankment does not affect the response of the proposed system.

Figure 1:(a) Longitudinal section of the proposed restraining system, (b) Plan view of the proposed restraining system and (c) Restraining members' model.

Any relevant movement between the tube's head and base causes (a) linear variant bending moments along the height of the tube (the zero point is at the middle of the height), (b) constant shear forces along the height of the tube which resist to the movement of the extension of the deck's slab, (c) tension and compression axial forces corresponding to the direction of the head's movement (every pair has one tensile and one compressive tube), (d) second-order effects due to the aforementioned axial loading. The additional bending moment due to these effects increases the initial bending moment at the base of the tensile member and decreases the bending moment at the base of the compressive one. It is also notable that the second-order effects affect the performance of the tube's pair and induce the synchronous yielding at the critical region of the tubes' bases. Otherwise the absence of the second-order effects causes the yielding at the base of the member subjected to tensile axial loading before the corresponding one at the compressive member. Although the aforementioned assumption cannot reasonably be made in the case of the members' heads, the inversion of the loading direction due to the cycling event leads to the acceptance of the asynchronous yielding at the members' heads. The aforementioned analysis regarding the behavior of the proposed restraining system rationalize the consideration of the restraining tubes as fixed members in the computational framework.

The steel tubes used in this system can either be rectangular or square cross-section [15]. The choice of the tube's cross-section determines the number of the steel tubes which can be used as the distance between the wing-walls is given. The response of the proposed system is strongly dependant on the dimensions of the aforementioned members which also affect the constructability of the system. The use of steel tubes with big dimensions complicates the constructability but increases the efficiency of the system. In this study has been chosen rectangular steel tubes whose dimensions are 200x400mm. Each row consists of 25 steel tubes whose weak axis is oriented parallel to the longitudinal direction of the bridge.

The proposed restraining system is rationally combined with sliding bearings which permit the free movement of the deck in the longitudinal direction of the bridge. The support of the deck to the piers through rubber bearings in bridge systems which develop the aforementioned system is in slight contrary to this proposal as on one hand the period of the system is reduced and on the other hand is attempted its increase through the flexibility of the system due to the presence of the bearings. However a solution with rubber bearings is quite interesting even for reasons concerning its economic efficiency and is presented in this study.

Finally, based on the aforementioned assumption concerning the static behavior of the restraining members, it is necessary to be mentioned an significant characteristic of the proposed system. The investigation on the efficiency of the system showed that two pairs of rows of steel tubes (one pair per abutment / 25 steel tubes per row) with a RHS cross-section 200x400x10mm and a height $H_t=4.50\text{m}$, have the same seismic resistance as five concrete piers monolithically connected to the deck. These piers have circular cross-section with a diameter $d_c=1.5\text{m}$ and a height $H_c=13.0\text{m}$. The aforementioned conclusion derives from the equation of the resistances of the above members. The seismic resistance of a steel tube is calculated according to Equation (1). Equation (2) gives the seismic resistance of a pier. The resistance of two pairs of rows of steel tubes is 214 071 kN/m and is about five times the resistance of a pier with the above properties:

$$R_t = \frac{12E_s \cdot I}{H_t^3} \quad (1)$$

$$R_c = \frac{12E_c \cdot \pi \cdot d_c^4}{64H_c^3} \quad (2)$$

Respectively, 20 piers with the aforementioned properties, which are connected to the deck through bearings and their longitudinal movements are restrained through seismic links have the same resistance as two pairs of rows of steel tubes.

3 OVERVIEW OF THE BRIDGE STUDIED

In order to investigate the efficiency of the proposed practice a seismic isolated railway bridge located at Northern Greece was chosen as the case study. This bridge is straight, has four-spans and a total length equal to 168.0m, Figure 2. The end spans have a length equal to 39.0m, while the two intermediate spans are 45.0m long. The prestressed deck, Figure 3(a), has a hollow T-beam-like section, is 13.60m wide and 3.60m high, is supported through LRB bearings placed on the two abutments and the three middle piers and is separated from the backwall through an expansion joint. Seismic forces are also resisted by the activation of stoppers (in the transverse direction) which are constructed at the seating of the abutments. Each abutment is equipped with two fluid dampers. The piers have a 3.00 x 5.50m hollow cross-section, 0.45m wall thickness and heights equal to 20.35m, 23.80m and 14.35m, Figure 3(b). The pier foundation consists of a 4x4 pile group of 15.0m long piles, connected with a 2.0x11.0x11.0m pile cap, while the abutments are supported on a 3x4 pile group of 12.0m long piles connected with a 2.0x7.5x11.0m pile cap. The axial spacing between all piles is 3.0m.

Figure 2: Longitudinal section of the seismic isolated bridge used for the purposes of the present study.

Figure 3: (a) The cross-section of the deck in the middle and (b) the cross-section of the pier.

The bridge was designed for normal loads according to the German Norms [16] while the seismic design was carried out according to the Greek Seismic Code [17] and the relevant Greek standards [18] for the seismic design of bridges. The bridge is founded on a ground type B according to the Greek Seismic Code [17]. The corner periods of the spectrum used are 0.15s and 0.60s for ground type B. The site of the bridge belongs to Seismic Zone II according to the Greek Seismic Code, which is characterized by a Peak Ground Acceleration of 0.24g. The behavior factors of the system adopted for design according to the relevant Greek standards were $q_x=q_y=q_z=1.0$ for the response in the three principal directions, respectively.

4 COMPUTATIONAL FRAMEWORK

The proposed restraining system is implemented in the bridge described in the previous section. The modified bridge doesn't have hydraulic dampers and the LRB bearings are replaced by low-damping rubber bearings whose dimensions are calculated according to the Codes provisions [7]. The steel tubes are rectangular hollow sections 200x400mm with a wall thickness 10mm. Four rows of 25 steel tubes are considered per abutment as shows Figure 1. These tubes have a height equal to 4.5m and their weak axis is oriented parallel to the longitudinal direction of the bridge.

The numerical simulations of the two bridge systems (initial and modified) studied in the present investigation were carried out with the FE- Code SAP 2000 [19]. The aforementioned bridge systems were subjected to corresponding artificial Earthquake motions that are compatible to Eurocode 8 elastic spectra [3] and two different peak ground accelerations $a_g=0.24g$, $a_g=0.36g$ were considered. In Figure 4 are given the response spectra of the artificial earthquake motions used in the present investigation. Dynamic non-linear time history analysis was implemented and the direct integration, known as β -Newmark method, was used [20] as this method is the most robust to be used for the step-by-step dynamic analysis. The mass and stiffness proportional damping was chosen and critical damping ratios equal to 5% were considered for the first and the second period of the analyzed bridge systems [21].

Figure 5(a) gives the stick model of the initial bridge system. The deck of the bridge was modeled by frame elements, which have the section properties of the deck, Figure 3(a). The piers were also modeled by frame elements. The flexibility of their foundations was taken into account by assigning six spring elements -three translational and three rotational- whose stiffness values are given in Figure 5(a). These spring values were obtained by the in-situ geotechnical tests conducted for the design of the as-built bridge given in Figure 2. The LRB bearings which have a non-linear force-displacement relationship in the two horizontal directions were modeled by rubber isolator link elements. Their stiffness values were calculated according to Naeim and Kelly model [5]. Damper elements which are available in SAP 2000 were used for the modeling of the four fluid dampers of the bridge. These elements have a non-linear force-velocity relationship and their damping properties are based on the Maxwell model of viscoelasticity [22].

Figure 5(b) gives the stick model of the modified bridge system. The modeling of this bridge system developed the modeling of the initial bridge. The deck and the piers have the same cross-sections in the two bridge systems. As mentioned above the modified bridge doesn't have hydraulic dampers and the LRB bearings were replaced by low-damping rubber bearings. These bearings were modeled by link elements and their stiffness values were calculated according to Naeim and Kelly model [5]. The restraining system consists of two parts: (a) the extension of the deck slab, namely the continuity slab, which was modeled by frame elements. This slab has a width equal to 13,50m and a thickness equal to 0,40m and (b) the group of the steel tubes. The tubes were modeled by frame elements, which have an RHS

cross-section 200x400x10mm. The steel tubes have a length equal to 4.5m and were considered to be fixed at the pile-cap of the foundation.

Figure 4: Response spectra of the artificial earthquake motions used in the present study and Eurocode 8 target spectrum (Soil Class B).

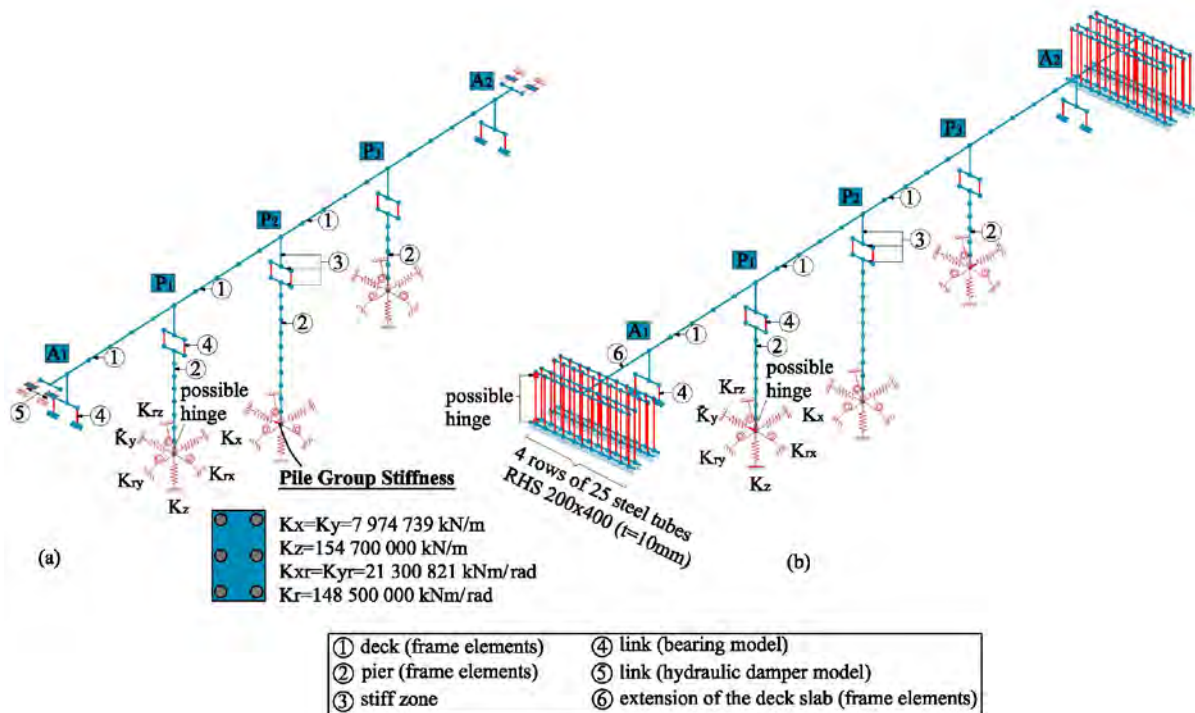

Figure 5: (a) Overview of the finite element models developed: (a) seismic isolated bridge system and (b) modified, according to the proposal of the present study, bridge system.

The possible plastic hinges at the piers' feet as well as at the restraining members' feet and heads were also modeled. The moment-curvature ($M-\phi$) curves were calculated by means of RCCOLA-90 [23]. The model involves beam elements with inelastic springs located at their

ends. Based on the members' geometry and the moment-curvature curves derived from the analysis of the cross-sections, the constants for the rotational springs are calculated. These springs are activated only whenever the developed bending moment exceeds the yield moment of the section and follows a non-linear force-rotation law that is a function of the cross-section properties.

5 EVALUATION ON THE EFFICIENCY OF THE PROPOSED SYSTEM

For the above two finite element models, non-linear dynamic analysis was performed using the 5 artificial earthquake motions. All analyses were conducted in the inelastic range and the excitation was performed in the longitudinal direction. As mentioned in the previous sections the proposed system is expected to dissipate part of the induced seismic energy through the flexural response of the restraining members. Figure 6(a) illustrates the hysteresis loop of a restraining member for a design ground acceleration $a_g=0.24g$. This figure shows that the restraining members respond in an inelastic manner. Consequently, the steel tubes are not only resisting with their stiffness, but also dissipate energy through hysteretic behavior. Figure 6(b) depicts the total input energy in the bridge system as well as the energy absorbed through the hysteretic behavior of the steel tubes for the same design ground acceleration. It can be deduced that a part of the input energy, about 35%, is absorbed through the hysteretic behavior of the restraining members.

The restrain of the bridge by the proposed system leads to an increase in the overall stiffness of the bridge. Specifically, the period of the first longitudinal mode shape is up to 73% reduced in the modified bridge system, in comparison to the period of the initial one. The reduction in the modal period of the modified bridge was found to lead in increases in its seismic loads, due to the fact that the modal periods are closer to the dominant periods of the elastic response spectrum. Despite this fact, the investigation showed that the movements of the deck of the modified bridge system are effectively reduced, in comparison to the corresponding ones of the initial bridge. Figure 7 shows the time histories of the longitudinal seismic displacements of the joint of the deck over the pier P_2 for the two bridge systems. From this figure it can be derived that the modified bridge system responds with smaller displacements in the longitudinal direction. The time histories also show that the overall resisting system of the modified bridge becomes stiffer. Both time histories given in Figure 7 correspond to an artificial accelerogram, which is compatible to Eurocode's 8 [3] elastic spectrum for a ground acceleration equal to 0.24g.

The efficiency of the proposed practice was mainly determined by calculating the percentage reductions in the longitudinal movements and seismic actions of the initial bridge system, Figure 5(a), compared with the corresponding ones of the modified bridge system, Figure 5(b). The ratio of this percentage reduction (P.R.) is given in Equation (3). In this equation $P.R.$ is the ratio of the percentage reduction of the movements of the deck or the seismic actions, $A_{,E1}$ is the seismic movement or the seismic action of the initial bridge system and $A_{,E2}$ is the seismic movement or the seismic action of the modified bridge system.

$$P.R. = \left[1 - \frac{A_{,E2}}{A_{,E1}} \right] \cdot 100 \quad (3)$$

In Figure 8 the percentage reductions in the longitudinal movements of the deck are illustrated for the two ground accelerations 0.24g and 0.36g. It is deduced that the proposed restraining system has the ability to reduce by up to 27% the longitudinal movements of the deck when the ground acceleration is 0.24g, while its efficiency is greater in higher ground

acceleration ($a_g=0.36g$) as the aforementioned reduction is 33%. This can be attributed to the energy dissipation through the hysteretic behavior of the restraining members.

In Figure 9 the percentage reduction in the bending moments M_{yy} at the base of the piers due to the longitudinal seismic action is illustrated for two different design ground accelerations 0.24g and 0.36g. The analysis showed that the M_{yy} moments were reduced up to 28% when the ground acceleration is 0.24g. The corresponding percentage reduction is greater when the bridge system is subjected to greater ground accelerations. Finally it seems that the restraining effect of the proposed restraining system is limited in the central pier of the bridge which is the tallest one.

Figure 6: (a) The hysteresis loop of the steel tubes and (b) The input energy and the energy absorbed through the hysteretic flexural behavior of the steel tubes (Link Hysteretic Energy) for design ground acceleration $a_g=0.24g$.

Figure 9: The percentage reductions in the bending moment actions M_{yy} at the base of the piers for two ground accelerations 0.24g and 0.36g.

6 CONCLUSIONS

In this study the seismic efficiency of an alternative to seismic isolation practice is investigated. The aforementioned purpose is achieved through the improved seismic participation of the bridge abutments. The deck slab is extended onto the embankments and is rigidly connected with transversely directed rows of hollow section steel tubes. Based on the results of this study, the following conclusions are drawn:

- The system is significantly efficient is seismic isolated bridge systems as a great part of the induced seismic energy is dissipated through the hysteretic behavior of the restraining members.
- The proposed seismic restrainer effectively reduces the movements of the deck and by extension the seismic actions of the piers, their foundations and the actions of the bearings. The aforementioned reduction is of the order of 27% for the longitudinal design earthquake.
- The ground acceleration influences the efficiency of the proposed restraining system as the restraining members dissipate greater part of the induced seismic energy through their hysteretic behavior.
- The restraining effect also reflects on the seismic actions of the piers (shear actions and bending moments) as well as on the bearings type and dimensions leading to cost-effective bridge design.
- The restraining effect of the proposed system is significant even in stiffer bridge resisting systems. The resulting bridge system is jointless, and has explicit advantages concerning durability and driving convenience.

ACKNOWLEDGEMENTS

This research is co-funded by the European Union (European Social Fund- ESF) and National Resources, in the framework of the program “HRAKLEITOS II” of the “Operational Program for Education and Initial Vocational Training”.

The authors wish also to thank METE SYSM S.A., for kindly providing the original study of the seismic isolated railway bridge used for the purposes of the present study.

Keywords : Subway, tunnels, metro stations, earthquake response

Abstract. The seismic response of structures overlaying soil strata has been extensively studied. Also, numerous studies can be found in the literature regarding the deformations imposed on structures during the excavation of tunnels in suburban areas. However, the impact of the presence of a tunnel on the seismic response of overlaying structures has drawn very limited attention.

The goal of this study is to examine the considerable influence that the existence of a tunnel has on ground acceleration, as well as to point out the limits of parameters, such as the tunnel depth and the horizontal distance of a structure from the axis of the tunnel, beyond which the difference in ground acceleration cannot be neglected.

The corrected accelerograms of the Athens(Greece), Kobe(Japan) and Duzce (Turkey) earthquakes are used in this investigation. The geotechnical data has been drawn from the drillings that took place during the construction of the subway in Athens. For the Athens earthquake two approaches were applied. In the first approach the soil stratum with the tunnel were modeled as a linear system with the finite element software called Plaxis. In the second approach the part of the soil stratum over the bedrock and up to a distance of 2.5 m below the lower part of the tunnel were modeled with software capable to account for nonlinear soil behavior, while the upper part including the tunnel were modeled as a linear system using Plaxis. The second approach is considered as more realistic especially for the latter two seismic excitation cases.

The results of this study showed that the presence of the shallow tunnels considerably modify the surface ground motion within a range that depends on their geometrical characteristics. Even though this is a limited study, the results clearly indicate that the phenomenon should be considered when : i) evaluating the anticipated seismic behavior of overlaying structures, ii) deciding on strengthening measures in order to protect structures with inferior strength, iii) specifying the design spectra of new buildings to be constructed in the vicinity of such tunnels and iv) making decisions regarding relocation of a tunnel to be constructed.

INTRODUCTION

In recent years there have been considerable advances on techniques of bored tunnel construction in any type of ground. This has led to a plethora of tunnelling projects being instigated, frequently in urban areas, in order to deal with increasing traffic congestion problems. As a consequence, there is respectable international interest in predicting the impact that tunnels have on the behaviour of overlaying and neighboring structures.

Even though the presence of tunnels in urban environments, such as low-depth subway tunnels is very common in countries with high seismicity, there are indeed very few studies reported in the literature on this topic. It should be noted that many of the overlaying structures are old and in many cases constructed without seismic provisions. The influence of the presence of a subway tunnel on the seismic response at the ground surface supporting a structure is investigated in this study.

This paper summarizes the methodology adopted to predict the critical area around a tunnel, depending on its depth, where the acceleration from an earthquake is increased due to the presence of the tunnel.

ANALYSIS PROCEDURE

Firstly, the soil profile is specified.

The soil profile has been obtained from the drillings during the construction of the metro at a location of central Athens. The soil profile with the corresponding characteristics is shown in Figure 1.

Figure 1 – The soil profile and characteristics

Where:

γ : bulk density, E : Young's modulus, c : effective cohesion, ϕ : effective internal angle of friction.

Ground motions for three well-known earthquake records were used, i.e. the Athens, the Kobe and the Duzce earthquakes. All records present near source directivity phenomena ([3], [4]). The earthquake records were used as is described in the following: For the Athens earthquake two approaches were applied. In the first approach the soil stratum with the tunnel were modeled as a linear system with the finite element software called Plaxis ([1], [5]). In the second approach the part of the soil stratum over the bedrock and up to a distance of 2.5 m below the lower part of the tunnel were modeled with software capable to account for nonlinear soil behavior, while the upper part including the tunnel were modeled as a linear system using Plaxis. The second approach is considered as more realistic. The models used in these approaches are dedicted in figures 2a, 2b and 3. Specifically, *figure 2a* :shows the model using Plaxis for the linear analysis of the soil stratification with the tunnel, *figure 2b* :shows the finite element mesh of the model using Plaxis, *figure 3*: shows the soil strata model using the Shake2000 ([2]) for the lower part and Plaxis for the upper part that includes the tunnel.

In all cases a tunnel with a diameter of 2.5 m is used.

Figures 4, 5, 6 show horizontal accelerations of the records at Syntagma (Athens) 1999, Kobe (Japan) 1995 and Duzce (Turkey) 1999 respectively.

Figure 4 – Syntagma (Athens) 1999 earthquake record on the bedrock,
maximum acceleration : $1.08 \text{ (m/s}^2\text{)}$, estimated effective acceleration (EDA) : $0.37 \text{ (m/s}^2\text{)}$

Figure 5 – Kobe (Japan) 1995 earthquake record on the bedrock,
maximum acceleration : $3.09 \text{ (m/s}^2\text{)}$, estimated effective acceleration (EDA) : $3.09 \text{ (m/s}^2\text{)}$

Figure 6 – Duzce (Turkey) 1999 earthquake record on the bedrock,
maximum acceleration : $7.14 \text{ (m/s}^2\text{)}$, estimated effective acceleration (EDA) : $5.99 \text{ (m/s}^2\text{)}$

The locations where the response of all analyses for the models of both approaches have been calculated are showed in figure 7.

Figure 7 – Locations where ground acceleration values are calculated.

In the following all the results of the analyses are given in a table form for the locations presented in figure 7 and for each case of tunnel depth. In Tables 1a, 2a, 3a, 4a, 5a, 6a and 7a the results from the first method using Plaxis are showed, while in Tables 1b, 2b, 3b, 5b, 6b and 7b the results from the second method using Shake2000 & Plaxis are presented. Red ink is used to point out when the increase of surface acceleration exceeds a limit of 5%.

Table 5b – Results from Shake & Plaxis model

Athens earthquake 1999

The horizontal distance from the tunnel center is taken as 70 m.

Noticing the results showed in the tables above one could make the following remarks: In Table 1b (location B) it is observed that ground acceleration after the construction of a tunnel is increased by 15.5% : when the tunnel depth is 5m, by 9.1% : when the tunnel depth is 10m and less than 5% : when the tunnel depth is more than 10m. In Table 2b (location C) the increase is 13.0% when the tunnel depth is 5m, 8.9% when the tunnel depth is 10m and less than 5% when tunnel depth is more than 10m. In Table 3b (location E) the ground acceleration is increased because of the tunnel presence by 8.9% when the tunnel is located 5m below the surface, by 5.6% when it is located 10m below the surface and by less than 5% when it is located more than 10m below the surface. Finally, in Tables 4b (location G) and 5b (location I) the increase is less than 5% for any case of tunnel depth.

For the Kobe and Duzce earthquake records the combined method is used.

The results for the Kobe analysis are showed in a table form while red ink is used to point out when increase of surface acceleration exceeds the limit of 5% (Tables 6, 7, 8, 9).

depth=25	1.67	0.00	0.00

*Table 12 – Results from Shake&Plaxis model Table 13 – Results from Shake&Plaxis model
Kobe earthquake 1995*

The horizontal distance from the tunnel center is taken as 20 m for Table 12 and 40m for Table 13.

In Table 10 (location B) the ground acceleration is increased because of the tunnel presence by 19.0% when the tunnel is located 5m below the surface, by 9.2% when it is located 10m below the surface and by less than 5% when it is located more than 10m below the surface. Table 11(location C) shows that increase of acceleration is 22.1% when the tunnel depth is 5m, 11.7% when the tunnel depth is 10m, 6.6% when the tunnel depth is 15m and less than 5% when the tunnel depth is more than 15m. In Table 12 (location E) the acceleration is increased by 12.1% when the tunnel depth is 5m, by 6.8% when the tunnel depth is 10m and by less than 5% when the tunnel depth is more than 10m. In table 13 (location G) the increase is less than 5% for any case of tunnel depth.

CONCLUSIONS

- In general, in Plaxis2d higher acceleration results were obtained in comparison with the ones from the combined Shake2000&Plaxis2d models. This difference is attributed to the fact that Shake accounts for nonlinear soil behavior
- The impact of the tunnel presence on the ground acceleration could be considerable, since the ground surface acceleration can be increased even by 22%.
- As the horizontal distance of the foundation of a structure from the tunnel center and the tunnel depth increase, the influence of the presence of the tunnel on the acceleration at the surface diminishes.
- When the horizontal distance from the tunnel center is 20m or less and the tunnel depth is 5m, the increase of the ground acceleration ranges from 7% to 22%. Furthermore, when the horizontal distance from the tunnel center is 20m or less and the tunnel depth is 10, the increase of the ground acceleration ranges from 5% to 15%.

The results indicate that the presence of the tunnel should be considered when the following two conditions are present:

- **1st Condition:** Tunnel depth must be less than 10 meters.
- **2nd Condition:** Horizontal distance from the tunnel center must be less than 20 meters.

Those conclusions were drawn from the analyses based on specific data (the soil profile from central Athens, Athens, Kobe and Duzce earthquakes, tunnel diameter 5.0 m).

Even though the conclusions are based on limited results, they clearly indicate that the impact of the tunnel presence on ground acceleration should be taken into consideration when:

- i) specifying the design spectra of structures to be built at the area near the subway tunnel.
- ii) selecting strengthening measures in order to strengthen structures that are vulnerable.
- iii) deciding on the location of a tunnel to be constructed.
- iv) evaluating the anticipated seismic behavior of overlaying structures.

Keywords: Incremental dynamic analysis, Precedence list, Ground motion selection, Computational efficiency, PBEE toolbox.

Abstract. *Progressive incremental dynamic analysis involves precedence list of ground motion records aiming of selecting the most representative ground motions from a set of ground motions. The precedence list of ground motion records provides the advantage of a simple mathematical model, which is not computationally demanding, and it is defined as an optimization problem, which can be solved with sufficient accuracy by means of a simple procedure. Therefore, the seismic response parameters are computed progressively, starting from the first ground motion record in the precedence list. After an acceptable tolerance is achieved, the analysis can be terminated. Such approach facilitates practical application of incremental dynamic analysis (IDA), especially, if the number of ground motions in a set of ground motions is large, and its computational efficiency is higher than ordinary IDA. In the paper the precedence list of ground motion records is determined for three reinforced concrete frame structures in order to evaluate computational efficiency of the progressive IDA. The results indicate that 16th, 50th and 84th fractiles of seismic response parameters of frame structures can be determined with sufficient accuracy if about 12 to 15 records out of 30 are used in the analysis, this indicating that progressive IDA requires much less computational time than IDA.*

1 INTRODUCTION

Incremental dynamic analysis (IDA) [1] is widely used parametric analysis method for seismic performance assessment of structures. It enables direct evaluation of record-to-record variability in structural response through a set of ground motion records. If the set of ground motions is large, IDA becomes computationally demanding. In order to accommodate its practical application, precedence list of ground motions has been introduced [2, 3], aiming at selecting the most representative ground motion records for IDA analysis.

In progressive IDA the “selected” IDA curves are computed progressively from the first ground motion in the precedence list till the acceptable tolerance is attained. Therefore seismic response parameters are estimated by using the nonlinear dynamic analysis, which is performed for a limited number of records from a list. Such approach can significantly reduce computational efforts and consequently facilitate the use of nonlinear dynamic analysis for practical applications.

Since precedence list of ground motion records is based on dynamic response of equivalent SDOF model the computational efficiency of the progressive IDA varies from structure to structure and depends also on the set of ground motion records used in analysis. The objective of this study is to assess the computational efficiency of progressive IDA for different reinforced concrete frames, which were modeled by using the PBEE toolbox [4] in conjunction with OpenSees [5]. The toolbox was developed in Matlab [6] and provides functions for the rapid determination of simplified nonlinear structural models, performance assessment by employing different methods and the post-processing of analysis results. Since the PBEE toolbox is focused on simple nonlinear models, material nonlinearity is modeled only with the moment-rotation relationship in the plastic hinges of the columns and beams.

2 SUMMARY OF PROGRESSIVE INCREMENTAL DYNAMIC ANALYSIS

Progressive IDA was recently proposed [3] aiming at minimizing the computational time, which is required for prediction of seismic response parameters in the case if they are estimated with nonlinear dynamic analysis. For that reason a precedence list of ground motion records was introduced. The determination of such a list is an optimization problem and can be sufficiently solved by minimizing the defined fitness function, which is determined based on response of a simple model, e.g. the single-degree-of-freedom (SDOF) model.

The methodology was originally proposed for prediction of median seismic response (i.e. median IDA curve) [2]. However its use was extended for prediction of 16th, 50th and 84th fractile response [3]. In progressive IDA the so-called “selected” IDA curves are computed progressively starting from the first ground motion record in the precedence list. When the required tolerance in the prediction of seismic response is achieved, the analysis can be terminated. The benefit of progressive IDA, in comparison to the IDA, is the reduction of the computational effort. However, determination of the precedence list of ground motion records also requires some computational time, firstly, for IDA analysis of the simple model (e.g. SDOF system), which is needed in order to determine a precedence list, and secondly, for the optimization of the precedence list of ground motion records. Computational time needed for determination of precedence list is usually shorter than time needed for one IDA analysis of a structure.

The input data for determination of the precedence list of ground motion records are IDA curves for the simple (e.g. SDOF) model. The next step is definition of the so called fitness function, which incorporates IDA curves of the simple model, and it is defined in a way that its value changes if the position of the ground motions identification numbers (IDs) in a list

are rearranged. The precedence list is determined when the ground motions IDs are arranged in the order that the fitness function takes on a minimum value.

In general, the fitness functions can be defined for different purposes. However, for the precedence list of ground motions aiming at predicting the fractile IDA curves, it was found [2, 3], that a good measure for defining the fitness function is the area between the “original” fractile IDA curve and the “selected” fractile IDA curve, where the term “original” is used for the case if fractile IDA curve is obtained from all the IDA curves while the term “selected” is used if the fractile IDA curve is determined only for the first s ground motions from the precedence list. If this area is normalized with the area defined by the “original” fractile IDA curve then the dimensionless measure for the error between the two types of the fractile IDA curves can be defined as follows [3]

$$Error(s, f) = 100 \times \frac{\int_0^{EDP_{\max}(s, f)} |\Delta IM(s, f)| dEDP}{\int_0^{EDP_{\max, or}(f)} IM_{or}(f) dEDP} \quad (1)$$

where s is the number of selected subsets of three ground motions, IM and EDP are usual notations for intensity measure and engineering demand parameter, respectively, $IM_{or}(f)$ is the intensity measure of the “original” f -th fractile IDA curve, $EDP_{\max, or}(f)$ is the engineering demand parameter corresponding to the capacity point of the “original” f -th fractile IDA curve, $\Delta IM(s, f)$ is the difference in the IM corresponding to the “original” and “selected” f -th fractile IDA curve, and $EDP_{\max}(s, f)$ is the maximum of the engineering demand parameters corresponding to the capacity point of the “selected” and “original” f -th fractile IDA curves. The error as defined in the Eq. (1) is not yet the fitness function since it depends only on the first s selected number of records from the precedence list and on the selected f -th fractile IDA curve. In order to define the fitness function the sum of $Error(s, f)$ over all values is required. In the case if the precedence list of ground motions is determined in order to predict the three fractile IDA curves it was found [3], that the best precedence list is obtained if the fitness function is defined in a way to give a preference to those ground motions, which IDA curves are close to the “original” fractile curves. Therefore, the fitness function Z is defined by sum of $Error(s, f)$ over the m number of subsets of ground motion records and over all f -th fractile IDA curves

$$Z = \frac{1}{m} \sum_{s=1}^m \sum_{f=1}^3 Error(s, f) \quad (2)$$

Different techniques can be used to minimize the fitness function. The simplest possible way, which actually does not require optimization method, is gradual minimization of $Error(s, f)$. It was proven that gradual minimization of $Error(s, f)$ results in a value of the fitness function, which is close to the global minimum [3]. The first ground motion in the precedence list corresponds to the minimum value of errors (Eq. (1)) that are calculated for $s=1, f=1$ and for all n records in the given set of ground motion records. The second and third ground motion in the precedence list correspond to minimum error calculated for $s=1, f=2$ and $f=3$ for $n-1$ and $n-2$ records left to be placed in the precedence list, respectively. The following ground motion IDs in the precedence list are defined with repeating described procedure until all ground motion IDs are placed in the precedence list of ground motions.

Once the precedence list of ground motions is known, the difference between the fractile curve determined for $s-1$ and s subsets of ground motions can be obtained. This measure is called the tolerance function and is defined as follows [3]

$$Tolerance(s, f) = 100 \times \frac{\int_0^{Max[EDP_{max}(s, f), EDP_{max}(s-1, f)]} |IM(s, f) - IM(s-1, f)| dEDP}{\int_0^{EDP_{max}(s-1, f)} IM(s-1, f) dEDP} \quad (3)$$

where $IM(s, f)$ and $IM(s-1, f)$ are the values of the intensity measures for the f -th fractile IDA curves, which are determined, respectively, on the basis of the first s and $s-1$ subsets of ground motion records. The additional parameters introduced into Eq. (3) are the engineering demand parameters $EDP_{max}(s, f)$ and $EDP_{max}(s-1, f)$, which correspond to the capacity point of the f -th fractile curve determined from first s and $s-1$ subsets of ground motion records.

In progressive IDA “selected” IDA curves are computed progressively starting from the first ground motion in the precedence list as long as required tolerance in the prediction of seismic response is achieved.

3 EXAMPLE: SEISMIC PERFORMANCE ASSESSMENT OF DIFFERENT REINFORCED CONCRETE FRAMES USING PROGRESSIVE IDA

Computational efficiency of progressive incremental analysis is studied by means of a seismic performance assessment of three reinforced concrete frame structures and a set of 30 ground motion records. The structural performance is assessed for two limit states, which were defined on the basis of the damage observed in the beams and columns. The peak ground acceleration and the maximum top displacement were adopted, respectively, as the intensity measure and the engineering demand parameter.

3.1 Description of the structures and the structural models

The eight-storey RC frame [7], six-storey building [8] and the eight storey building [9, 10] were selected from literature. Elevation and the plan views of the structures as well as typical reinforcement of columns and beams are shown in Figure 1. All the structures under consideration are symmetrical reinforced concrete frames, but there appear differences in the number of stories, height of the stories, position of columns, dimensions and reinforcement of columns and beams cross-sections, thickness of slabs, strength of concrete and reinforcement. In addition, these structures were designed according to different design requirements.

The first structure (S1), which was designed for gravity loads only, is eight-storey RC frame with constant storey height of 2.8 m. Typical cross-sections as shown in Figure 1a are equal for all beams and columns, except for inner two columns in lower two storeys and outer two columns in the top storey, where for the longitudinal reinforcement 4Φ20 bars are used instead of 4Φ16 bars. Mean strength of the concrete is 25 MPa and the mean yield strength of the steel is 400 MPa.

The second structure (S2) is six-storey RC frame and is shown in Figure 1b. The bottom storey is 4 m high, while the height of other storeys is 3 m. The dimensions of cross-sections and steel reinforcement in the beams and columns do not change from element to element. The structure was probably design according to Eurocode 8 [11] provisions for high seismic hazard area, since the amount of longitudinal and shear reinforcement in the cross-sections of the columns and beams is high. The concrete strength class is C20/25, while the steel strength class is S500.

The third structure (S3), i.e. an eight-storey building (Figure 1c), was designed according to the European standard Eurocode 8. The building's height of the first or second storeys is 5 m, whereas the other storeys are 3.1 m high. The building has three bays in each horizontal direction and therefore the largest structure considered in the presented study. All the cross-sections of the columns and beams of the structure have dimensions of 60/60 cm and 40/60 cm, respectively. For the columns, the steel reinforcement is the same for all sections, except for the cross-sections at the base, where the density of the stirrups is greater ($\Phi 8/5$ cm and $\Phi 10/5$ cm). The steel reinforcement for the beams is the same for all cross-sections, except for the beams in first two storeys, where at the top of the beams there are 6 instead of 4 $\Phi 20$ bars. The concrete strength class of the building is C30/37, and the steel strength class is B500.

Figure 1: The elevation, plan view and the reinforcement in typical cross-sections of the columns and beams for a) eight storey frame, b) six-storey and c) eight-storey RC building.

Structural models of the buildings were prepared in the PBEE toolbox [4]. Structures S2 and S3 were modelled as 3D frame structures although they are symmetric. The height of the storeys was determined by the distance between the centrelines of the beams. The masses were concentrated at the storey levels, at the centre of gravity and the effective width of the beams was modelled as described in Eurocode 2 [12], assuming zero moment points at the midpoint of the beams. The effective width of all the beams in structure S1 was considered equal to 1.65 m, while the effective width of the beams of the structure S2 differed and amounted to 0.65 m, 0.75 m and 1.85 m. In the case of the structure S3, the effective width of the beams in the exterior and interior frames amounted 1.2 m and 2 m, respectively.

Beam and column flexural behaviour was modelled by one-component lumped plasticity elements, consisting of an elastic beam and two inelastic rotational hinges. The moment-rotation relationship before strength deterioration was modelled by a bi-linear relationship,

whereas the post-capping stiffness was assumed to be linear, with a descending branch. The yield and maximum moment in the columns were calculated taking into account the axial forces due to the vertical loading. The ultimate rotation Θ_u in the columns at the near collapse (NC) limit state corresponded to 80% of the maximum moment measured in the post-capping range of the moment-rotation relationship. It was estimated by means of the Conditional Average Estimate (CAE) method [13]. For the beams, the EC8-3 [14] formulas were used to compute the ultimate rotations in the plastic hinges. In case of structure S1 ultimate rotations were multiplied by a factor of 0.85, because there was no seismic detailing considered in the design of the frame. The parameter β_u , which controls the unloading stiffness in the plastic hinges, was assumed to have a value of 0.8. Note, that computation of the moment-rotation envelopes in plastic hinges is embedded in the PBEE toolbox. Nonlinear dynamic analyses were performed by assuming 5 % damping proportional to mass.

3.2 Ground motion records

A set of 30 ground motion records [15] was used for seismic loading. The peak ground acceleration of the ground motions varies between 0.05 - 0.52 g. The records have been selected within events having a magnitude of between 6.5 and 6.9. All the ground motion records have been recorded on firm soil, with a distance range from the epicentre of 12 - 55 km. The acceleration spectra for each of the 30 ground motion records, and the corresponding 16th, 50th and 84th fractiles, are presented in Figure 2.

Figure 2: Acceleration spectra for all 30 ground motion records and corresponding 16th, 50th and 84th fractile.

3.3 Seismic performance assessment using progressive IDA

The seismic response parameters, the top displacement and the corresponding peak ground acceleration, were estimated for the significant damage (SD) and near collapse (NC) limit states (LS). It is considered that the SD limit state is violated at the structural level when the rotation in the plastic hinge of the first column or in all the beams in one of the storeys exceeds the rotation which corresponds to the maximum moment in the columns or beams, respectively. Similarly, it is considered that the NC limit state is violated when the rotation in the plastic hinge of the first column or all the beams in one of the storeys exceeds the ultimate rotation in the columns or beams, respectively. The NC limit state is also violated if the average residual top displacement in last five seconds of the analysis exceeds the height of a

building by more than 1 %, or if global dynamic instability is reached before other conditions for near collapse limit state are violated.

In order to assess seismic performance of structure by using progressive IDA, a precedence list of ground motion records need to be determined based on the IDA, which is performed for a simple model, e.g. equivalent single-degree-of-freedom (SDOF) model. The equivalent SDOF models were therefore defined from results of pushover analyses. The pushover analyses were performed by assuming a modal distribution of the horizontal forces for all structures. The analysis is limited to horizontal direction X (Figure 1) since the structures are symmetric, pushover analyses were performed in positive X direction only. The pushover curves, together with the points which indicate the defined limit states, are presented in Figure 3. Pushover curves were idealized with the tri-linear force-displacement relationships as presented in Figure 3. The strength of the idealized force-displacement relationship was set equal to the maximum strength determined by the pushover analysis. In Table 1 mass of the equivalent SDOF model m^* , the transformation factor Γ , period of the equivalent SDOF model T^* , which is equal to fundamental period of MDOF structure in the analysed direction, and the ratio between the maximum base shear and weight of the structure F_b/W are presented for the three structures.

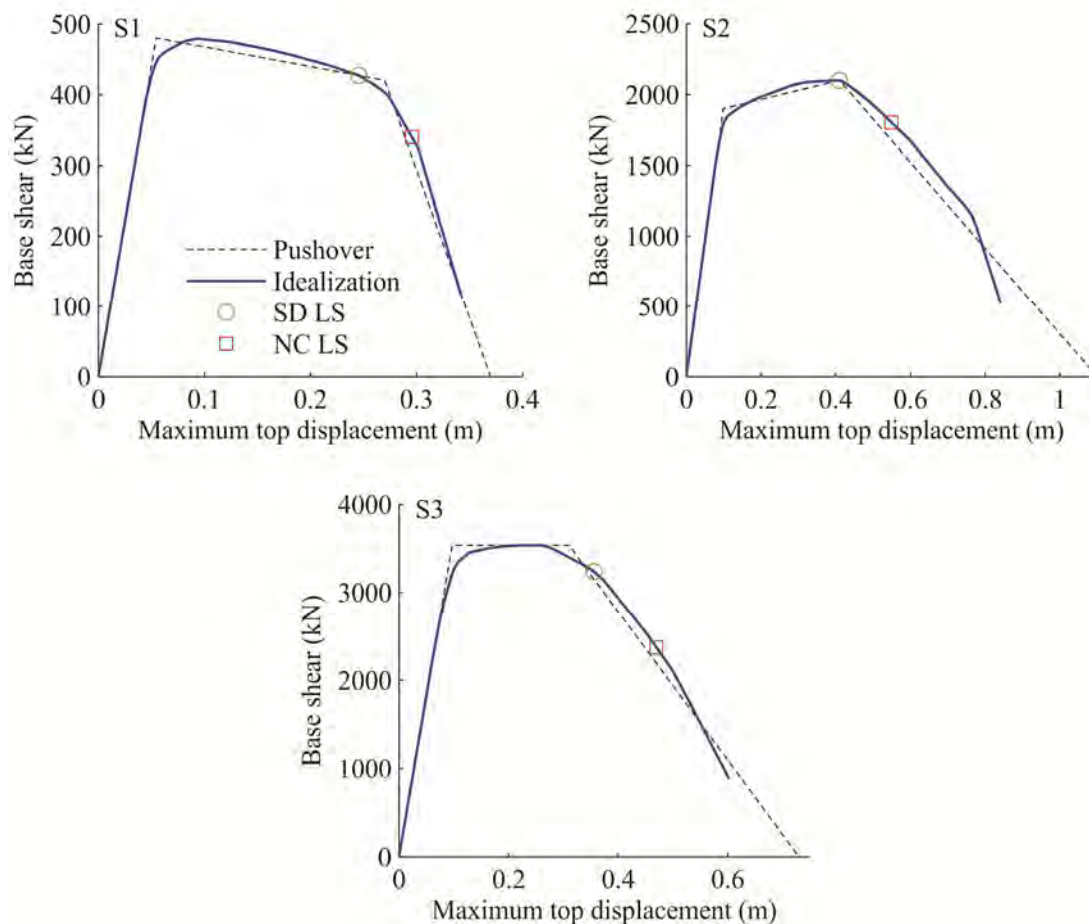

Figure 3: Pushover curves, showing the displacements which correspond to the SD limit state and NC limit state, and the idealized force-displacement relationships for structures S1, S2 and S3.

Table 1: Mass of the equivalent SDOF model m^* , the transformation factor Γ , period of equivalent SDOF model T^* and the ratio between the maximum base shear and weight of the structure F_b/W for structures S1, S2 and S3.

Structure	m^* (t)	Γ	T^* (s)	F_b/W
S1	606	1.27	1.65	0.05
S2	327	1.28	0.82	0.44
S3	2860	1.21	1.76	0.09

The damage at the plastic hinges of the beams and columns at NC limit state, which is obtained based on the pushover analysis, is presented in Figure 4. Note that, green, yellow and red colours represent, respectively, yielding of reinforcement, the state of exceeding the maximum moment, and the state of exceeding the ultimate rotation, whereas the grey part of the structure does not suffer any damage. The majority of the damage is concentrated in first and second storeys, while the upper stories remain almost undamaged.

Figure 4: The distribution of damage for pushover analysis at NC limit state for structures S1, S2 and S3.

Precedence lists of ground motion records for all structures were determined from the IDA curves for the equivalent SDOF models by utilizing the simple optimization procedure [3]. Single record IDA curves were then computed progressively, starting from the first ground motion record in the precedence list for each structure. Progressive IDA was terminated after an acceptable tolerance for 16th, 50th and 84th fractile IDA curves was achieved. It was recognized the fractile IDA curves are predicted with sufficient accuracy with first 4, 5 and 4 subsets of ground motion records form the precedence list of records, respectively, for structure S1, S2 and S3. Note that each subset of ground motion records consists of three records.

The global dynamic instability of each computed IDA curves was estimated with a precision of 0.02 g. The largest interval between the peak ground acceleration, for which the seismic response parameters were computed, was defined as being equal to 0.05 g. However, if the peak ground acceleration, which corresponds to global dynamic instability, was large, the IDA curves were computed for only 20 points. Each nonlinear dynamic analysis within the IDA was calculated by employing the Newmark integration scheme, assuming $\gamma_n = 0.5$, $\beta_n = 0.25$ and an integration time interval of 0.005 s.

The “selected” IDA curves for the ground motion records from the precedence list of records and the corresponding 16th, 50th and 84th fractile response, with indication of the significant damage (SD) and near collapse (NC) limit states, are presented in figures 5a, 5c and 5e for all three structures.

In order to demonstrate the accuracy of results for 16th, 50th and 84th fractile response obtained with progressive IDA, IDA was performed for all 30 records. The comparison of fractile response obtained by progressive IDA and IDA is presented in figures 5b, 5d and 5f for

all considered structures. The differences between the fractile IDA curves is practical negligible, even in the range close to the NC limit state, where the structures are already severely damaged. The indicated points in figures 5b, 5d and 5f represent the 16th, 50th and 84th fractiles of the peak ground acceleration, which cause the median top displacement corresponding to the SD or NC limit state for IDA and progressive IDA, and are also presented in Table 2. It can be observed that the error between the presented median estimates based on progressive IDA and IDA is always less than 10 % in all cases, while a mean error is only 3 %. Progressive IDA produces practically the same results as IDA. However, a bit larger errors are observed in the case of the prediction of global dynamic instability (figures 5b, 5d and 5f).

Table 2: The 16th, 50th and 84th fractiles of peak ground acceleration (PGA) causing the SD and NC limit states, and the corresponding median top displacement (MTD) for IDA and progressive IDA for all three structures.

The values in brackets represent an error with respect to results of the IDA.

Structure	Method	Fractile	SD limit state		NC limit state	
			MTD (m)	PGA (g)	MTD (m)	PGA (g)
S1	IDA	16	0.24	1.01	0.34	1.24
		50		0.38		0.55
		84		0.18		0.27
	Progressive IDA	16	0.23 (2%)	0.97 (3%)	0.37 (9%)	1.28 (3%)
		50		0.37 (3%)		0.59 (7%)
		84		0.18 (3%)		0.27 (0%)
S2	IDA	16	0.40	1.99	0.53	2.32
		50		1.22		1.43
		84		0.82		0.91
	Progressive IDA	16	0.40 (1%)	2.02 (2%)	0.53 (1%)	2.29 (2%)
		50		1.26 (3%)		1.44 (1%)
		84		0.82 (0%)		0.90 (1%)
S3	IDA	16	0.32	1.23	0.45	1.87
		50		0.54		0.74
		84		0.24		0.32
	Progressive IDA	16	0.33 (4%)	1.26 (2%)	0.44 (2%)	1.82 (3%)
		50		0.55 (2%)		0.72 (2%)
		84		0.26 (6%)		0.33 (3%)

The seismic performance assessment by using progressive IDA requires significantly less computational time. It is shown that, by using progressive IDA, computational time can be reduced for about 50 % compared to that needed to perform IDA. It was proved, at least for the presented examples, that the seismic response parameters are sufficiently accurate when determined by progressive IDA, which requires only 12 to 15 IDA curves instead of 30, which was the number of records used in the IDA. Nevertheless there is some additional work with the preparation of the precedence list. Note that the method provided sufficiently accurate results, although it is based on response of an equivalent SDOF model.

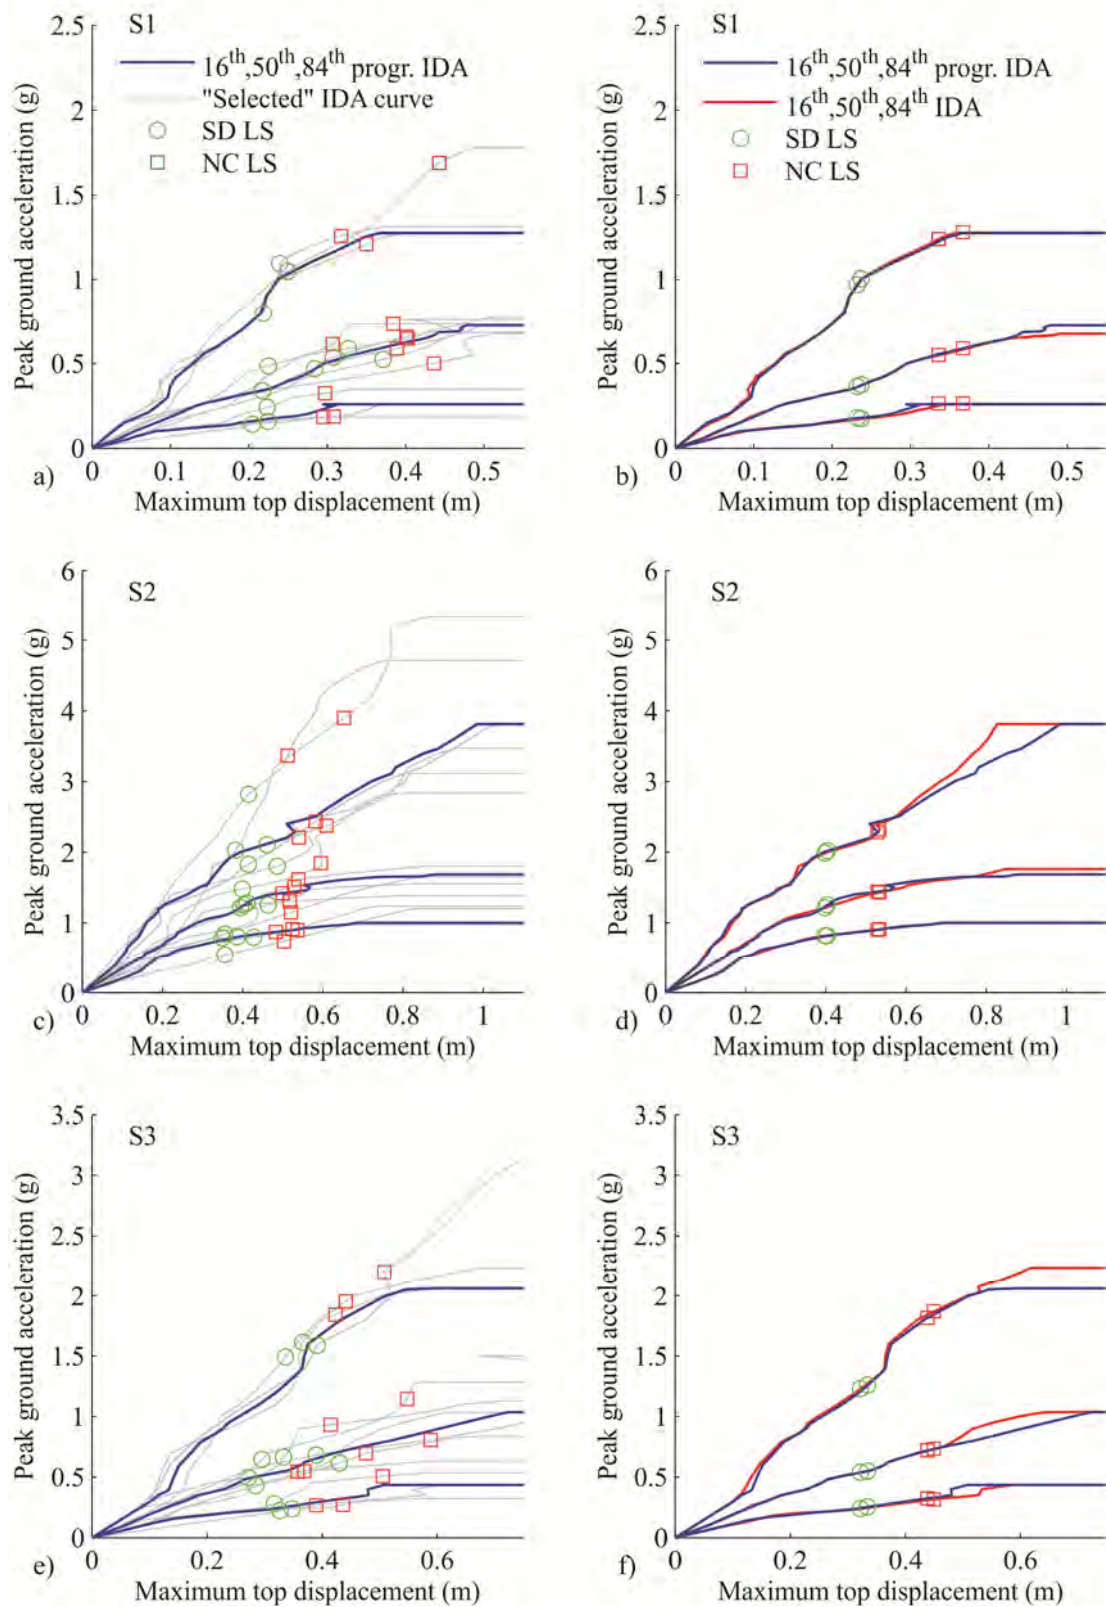

Figure 5: The “selected” IDA curves with the corresponding fractile response determined by progressive IDA and the comparison of the 16th, 50th and 84th fractile response determined by IDA and progressive IDA for structures S1, S2 and S3. Significant damage (SD) and near collapse (NC) limit states are indicated.

4 CONCLUSIONS

Computational efficiency of progressive IDA was assessed by means of seismic performance assessment of three symmetrical reinforced concrete frame structures. The considered structures differed in geometry, material, design requirements and consequently in period and ratio between the maximum base shear and weight of the structure significantly. However, it was shown that it is possible to predict the 16th, 50th and 84th fractiles of seismic response parameters for the significant damage and near collapse limit state by using the progressive IDA with minor errors in comparison to IDA for all three structures.

The differences in 16th, 50th and 84th fractiles of peak ground acceleration causing the significant damage and near collapse limit states, and in the corresponding median top displacement for progressive IDA and IDA are smaller than 10 %, for most cases only about 3 %. Progressive IDA produces practically the same results as IDA if compared in the range up to the near collapse limit state, although the results of progressive IDA are based on only 12 to 15 ground motion records. Therefore progressive IDA requires only about 50 % of computational time with respect to the computational time needed for the IDA. However, there is some additional work with determination of precedence list of ground motion.

Keywords: seismic screening methods, vulnerability, schools.

Abstract. *An ongoing project at McGill University is aimed at designing an adapted seismic screening method for schools in the province of Québec, Canada. As part of this project the “FEMA154 Rapid Visual Screening of Buildings for Potential Seismic Hazard” and the “NRC92 Manual for Screening of Buildings for Seismic Investigation” were used to assess the potential performance of 100 school buildings located in the city of Montréal. Results for both methods are in reasonable agreement, with 65% of the buildings requiring a detailed evaluation according to FEMA154 and 50% according to NRC92. The evaluation highlighted particular characteristics of the structures. School buildings are generally low-rise, of a limited number of structural types and have a high incidence of features that could affect seismic performance, such as steps in elevation and re-entrant corners. Findings were also used to identify advantages and shortcomings of each screening method. NRC92 is largely based on expert opinion, which makes the method difficult to update. FEMA154 uses a more rational methodology for calculating the vulnerability scores; however the nonlinear static seismic analysis procedure employed doesn’t consider latest improvements in building codes. Updating the procedure increases the basic scores on average by 24%, with higher scores indicative of better performance. When using FEMA154 it has to be considered that seismicity and soil amplification factors were developed for the United States. NRC92, although conceived for the Canadian context, has to be updated to include latest findings in seismic hazard parameters and soil classification. Since schools typically have a high incidence of irregularities, accounting for them in the screening phase is essential. FEMA154 only considers vertical and plan irregularities and it was found that this is insufficient to capture the characteristics of the evaluated schools. NRC92 partially overcomes this shortcoming by specifying seven different types of irregularities. In conclusion it was recognized that the clear analytical procedure behind FEMA154 allows updating and adapting the method to its use outside its intended scope. Therefore the screening procedure currently under development is largely based on this method, incorporating key characteristics of NRC92.*

1 INTRODUCTION

Schools deserve special attention regarding earthquake performance because of their unique occupancy and important post-earthquake role. However experience in the past has demonstrated that they are especially vulnerable. This was illustrated by the effects of the 1997 Cariaco earthquake in Venezuela. Two out of five collapsed buildings were schools, and more than half the casualties were students [1]. There have been many other examples that have demonstrated that school buildings are especially vulnerable to damage in moderate to strong earthquakes (e.g. [2, 3]). Different reasons have been proposed to explain the observed poor performance, including the age of school buildings and that their complex structural features compromise seismic safety [4].

The protection of children is paramount in society because they provide for future generations and represent an especially vulnerable segment of society. It has also been argued that safe schools must be considered a basic right in countries where school attendance is obligatory [5]. In addition, school buildings play a key role in restoring the normal functioning of society after an earthquake. Immediately following a seismic event they can be used as shelters, and their operation permits parents to return to work. In 2005 the Organization for Economic Co-operation and Development, acknowledging these facts, published recommendations on the earthquake safety of schools. In this document, the organization suggests that "Member countries take steps to establish and implement programs of school seismic safety" [6]. The first step to ensure effective risk reduction in existing buildings is the assessment of this risk.

Seismic screening methods for schools are needed as the first phase in vulnerability assessment projects. One example of the successful application of the technique is the evaluation of all schools located in zones with high seismicity of the province of British Columbia, Canada. This study, conducted in 2004, found that 82% of the more than 850 evaluated schools were at moderate or high risk, and consequently a state of the art tool for the detailed evaluation and strengthening of the province's schools was developed [7]. Presently the schools identified to be the most critical are being reassessed and retrofitted [8, 9].

2 SEISMIC SCREENING METHODS

Seismic screening methods, more specifically rapid visual screening or score assignment procedures, are intended to be coarse screening procedures using little resources per building. This is achieved by evaluating a limited number of features that influence seismic performance and assigning an overall score to each building. An ideal screening method will identify all those buildings that are potentially seismically hazardous, while limiting the number of buildings that will pass a more detailed evaluation [10].

Seismic screening methods can be classified as observed or predicted vulnerability procedures, or hybrid methods, depending on the type of source information used. Observed vulnerability procedures use statistics of damages in past earthquakes, sometimes combined with expert opinion, to determine the probable behavior of structures under future seismic events. The main setback of this approach is the possible insufficiency of observational data, and the subjectivity in judging data. The method also lacks analytical justification. Predicted vulnerability methods try to overcome these shortages by using analytical procedures to determine the probable behavior of a structure subjected to earthquake loading. The limitation of this approach is the time and computational effort required by detailed analytical analyses. Therefore a balance between effort and precision has to be found [11].

The first comprehensive rapid visual screening method was developed in the United States by the Applied Technology Council under contract to the Federal Emergency Management Agency [12, 13]. This method, published as the FEMA154 report, *Rapid Visual Screening of*

Buildings for Potential Seismic Hazard, is probably the most widespread RVS tool, and there is considerable guidance on its application (e.g. [14, 15]). The method has served as a prototype for the development of screening tools in other countries, as for example in Switzerland [16] and Italy [17]. The current Canadian seismic screening method, *Manual for Screening of Buildings for Seismic Investigation* (NRC92) [18], is also largely based on the first edition of FEMA154. There are other methods, developed independently, such as the procedure of the New Zealand Society for Earthquake Engineering [10]. This method judges existing buildings by comparing them to current New Zealand standards. Another example is the Japanese Seismic Index Method, a multiphase screening procedure that estimates the vulnerability of an existing building by a seismic performance index calculated for every story in each main direction and based on key characteristics of the building. This method has been used to evaluate low- and mid-rise reinforced concrete buildings in Japan since 1975 [19].

For the present research FEMA154 and NCR92 were evaluated, due to their relevance at the global and national level, respectively. A more detailed description of the two methods follows.

2.1 FEMA154

FEMA154 was first published in 1988 [20, 21], but was significantly improved in 2002 with the release of its second edition. The screening is done by visual observation of the building, and can be completed by means of a sidewalk survey, although entering the building and consulting existing plans and other documentation is recommended. Based on this inspection a data collection form is completed. Initially the lateral load resisting system has to be identified and related to one of the 15 predefined building types. A basic structural hazard score is provided for each building type. To consider specific characteristics of the building that could affect its seismic performance, the score is then altered by adding or subtracting score modifiers to obtain the final structural score. Score modifiers related to building height, vertical and horizontal irregularities, year of construction and soil type are provided. Higher final structural scores correspond to a better seismic performance, and usually they range from 0 to around 6. It is recommended that buildings with a score of 2 or less should be evaluated in more detail.

The basic structural hazard score (*BSH*) for each building type is defined as the negative of the logarithm (base 10) of the probability of collapse (*P*) of the building, given a ground motion corresponding to the maximum considered earthquake (*MCE*), as shown in Equation 1.

$$BSH = -\log_{10}[P(\text{collapse given } MCE)] \quad (1)$$

The probability of collapse is the probability of the building being in complete damage state times the fraction of the buildings in complete damage state that collapse.

To determine the probability of being in complete damage state first the spectral displacement is calculated using a nonlinear static seismic analysis procedure. The technique used is the capacity spectrum method [22], depicted in Figure 1.a. The capacity spectrum method, an equivalent linearization technique, is based on the assumption that the maximum inelastic deformation of a nonlinear single degree of freedom system can be estimated from the maximum elastic deformation of a linear elastic single degree of freedom system which has natural period and damping values higher than the original one. The inputs of the method are the force-deformation relationship of the structure, commonly known as push-over curve, and the seismic demand. Both are plotted in acceleration-displacement response spectrum format. In this format periods can be represented by radial lines, and the equivalent period is assumed to be the secant period at the intersection of the capacity spectrum and the seismic demand spectrum reduced for equivalent damping. The equivalent damping is estimated based on the area

under the capacity curve. Since both equivalent period and damping are dependent on the estimated maximum spectral displacement, an iterative process is followed for its calculation.

The estimated spectral displacement is used to determine the probability of complete damage state from a fragility curve corresponding to the building type, as can be seen in Figure 1.b. This value is multiplied by the fraction of buildings that will collapse being in complete damage state to obtain the probability of collapse and calculate the basic structural hazard scores. A similar procedure is used to calculate the score modifiers.

Figure 1: Estimation of the probability of complete damage state of a building class [13].

2.2 NRC92

The NRC92 procedure was developed in Canada in 1992. Similar to FEMA154, the practical implementation of NRC92 relies on a data collection form that can be filled out by visual inspection of the building. It is expected that the exterior as well as the interior is evaluated, and recommended that building plans are considered. The user first has to identify the lateral load resisting system and correlate it to 15 different building types, very similar to those of FEMA154. High importance is given to the identification of building irregularities, differentiating between seven different types. Non-structural hazards also have to be identified.

A structural index is computed by multiplying five factors. They are related to local seismicity, soil conditions, lateral load resisting system, vertical and horizontal irregularities and building importance. A non-structural index is also computed, based on the observed non-structural hazards, the soil conditions and building importance. The final score, called the seismic priority index, is the sum of a structural index and a non-structural index. In contrast to FEMA154, a high final score indicates high priority for refined seismic vulnerability analysis of the building. It is suggested that buildings with a score less than 10 be treated as low priority, 10 to 20 as moderate priority, 20 to 30 as high priority and more than 30 as potentially hazardous requiring immediate attention.

NRC92 is largely based on the first edition of FEMA154. In this first edition the same types of scores and modifiers as the second edition are used, however calculations are mainly based on engineering expert opinion. The basic structural hazard scores were calculated as the negative of the logarithm (base10) of the probability of damage (D) exceeding 60% of the building value, given a ground motion represented by the NEHRP effective peak acceleration, as shown in Equation 2.

$$BSH = -\log_{10}[P(D \geq 60\%)] \quad (2)$$

To determine the probability of occurrence of different levels of damage given a specified ground motion, expert opinion was used (ATC-13 report [23]). This report was concerned exclusively with buildings constructed according to Californian building practices, and again expert opinion was sought out to make the results applicable to other regions of different seismicity. The score modifiers were also calculated based on expert criteria.

To develop NRC92 the method was adapted to Canadian seismicity and building practice. The scoring system was also modified to consider structural and non-structural components in the evaluation, and the importance of the building, related to occupancy and use.

3 BACKGROUND: SCHOOLS IN QUÉBEC

The present study is conducted in the province of Québec, Canada, considered a moderate seismic zone. Most of the population is located in the St. Lawrence River valley, the province's most active seismic zone. The region with highest seismicity, LaMalbaie, has spectral accelerations response values of $S_a(0.2s) = 2.3g$ for short periods and of $S_a(1.0s) = 0.6g$ for long periods, with a probability of exceedence of 2% in 50 years. More typical values are those of the two largest cities of the province, Montréal with $S_a(0.2s) = 0.69g$ and $S_a(1.0s) = 0.14g$, and Québec City, with $S_a(0.2s) = 0.59g$ and $S_a(1.0s) = 0.14g$. These two cities account for half of the province's population.

In Québec moderate and strong earthquakes have occurred in the past, and they will most certainly occur in the future. The large events have a relatively long return period (several centuries) and hence the general population has the impression that earthquakes are not likely in the region. Although Québec's earthquakes in the past have not caused loss of human life, extensive property damage has been reported. Some examples are the 1935 Timiskaming earthquake (magnitude 6.2) and most recently the 1988 Saguenay earthquake (magnitude 6.0) [24].

Since experience in strong earthquakes is limited in Eastern Canada, reported seismic damage to schools has been mostly to non-structural elements. There was considerable damage reported to one Collegiate and Vocational School in Cornwall after the 1944 Cornwall-Massena earthquake [24]. The 1988 Saguenay earthquake produced architectural damage to 33 out of 42 public schools of the two most affected communities [25]. The site visit team also drew attention to the dangers of unreinforced masonry infill walls, and warned about the abundance of them particularly in schools and hospitals [26].

A school inventory report from the Québec Ministry of Education [26] has classified all the provincial public school buildings into five main structural/architectural categories and determined their general seismic vulnerability features relating the structural type to the construction year. The five categories and their province-wide occurrence are presented in Figure 2, totaling approximately 3600 schools. No distinction between different buildings at each location was made. About one half of the schools were built before 1960, i.e. before modern earthquake-resistant design procedures were introduced in the *National Building Code of Canada* (NBCC), and were therefore classified as the more vulnerable schools of the province. This inventory was a first step in the vulnerability assessment of schools in Québec and its results highlighted the need for more detailed studies. Clearly, a detailed school-by-school evaluation is not feasible on a large scale and the development of a screening method adapted to address the specific characteristics of the building inventory is necessary.

Figure 2: Initial classification of school buildings in Québec [26].

4 EVALUATION OF SCHOOL BUILDINGS

The goal of this research is to design such an adapted seismic screening method for school buildings of the province of Québec. As part of the study the seismic vulnerability of sixteen high schools (secondary education level) comprising a total of 102 individual buildings is being studied. These schools are designated as post-critical shelters on the island of Montréal, mostly based on their location and their capacity to shelter a large number of disaster victims. A detailed database of the characteristics of the school buildings was created. Information from plans, site visits and the city's seismic microzonation map [27] was used.

It was found that most school buildings are low rise: over 3/4 of them are three stories high or less, with the tallest being six stories high. The floor area varies between 200 and 5300m², with an average value of 2000m². It is noted that 87% of the structures were built in the 1960s and 1970s. The most common lateral load resisting systems, which account for 80% of the studied buildings, are: concrete frames with infill masonry shear walls, concrete shear walls and steel moment frames. As expected the evaluated schools are complex structures, with features that could potentially affect their seismic behavior. Buildings with re-entrant corners, steps in elevation, potential for pounding, exterior cladding and heavy partition walls are common. Table 1 summarizes the most common features and their percentage of occurrence. According to the seismic microzonation map of Montréal, eight of the 16 school campuses are located on soils prone to ground motion amplification [28].

Feature	% of Buildings
Irregular building plan	40%
Steps in elevation view	40%
Heavy masonry partition walls	90%
Potential for pounding	99%
Exterior cladding	80%
Site effects	50%
Deterioration	35%

Table 1: Features that could affect seismic performance and their occurrence in evaluated schools buildings.

Preliminary assessments using the FEMA154 and NRC92 seismic screening procedures were performed. Cut off scores were used as recommended for each method. Results of FEMA154 suggested that 65% of the buildings should undergo a detailed evaluation. NRC92 results were similar, finding 12% of the buildings with low priority for future interventions, 38% moderate priority, 34% high priority and 16% potentially hazardous. There is relatively good agreement in the results obtained with the two methods given that 80% of the buildings

that didn't comply with the screening of FEMA154 were classified as having high priority of intervention or being potentially hazardous by NRC92. The large proportions of buildings requiring detailed evaluation (65% according to FEMA and 50% according to NRC92) appear somewhat alarmist for a moderate seismicity environment and provide further motivation for the development of better adapted screening methods that can identify more precisely the installations that need detailed seismic vulnerability assessment.

A companion study evaluated the seismic risk of operational and functional components of fourteen of the sixteen schools [29], according to the procedure in CAN/CSA S832-06 standards, *Seismic risk reduction of operational and functional components (OFCs) of buildings* [30]. Around 450 typical components were evaluated in total, from which 20% were rated high and 54% moderate risk. The most common problem identified was lack of restraint of the non-structural components.

5 ADVANTAGES AND SHORTCOMINGS OF EACH METHOD

5.1 Procedures behind score calculations

Supporting documentation for NRC92 is limited and this creates challenges for any attempt of updating the procedure. An update of NRC92 is needed because it was largely based on the first edition of FEMA154, which has been thoroughly revised. On the other hand, FEMA154 uses a more sound methodology for calculating the vulnerability scores than NRC92, with the calculations based on the capacity spectrum method as described in ATC-40 [22]. However the application of ATC-40 has raised concerns in the past, compared with other simplified analysis methods with poor agreement. Furthermore, when comparing to results of response history analysis, significant differences could be found [31]. Some studies demonstrated that the estimated maximum deformations can be underestimated by as much as 50% [32]. Recognizing this concern, in 2004 a thorough evaluation of the existing method was conducted and an updated procedure was published in the FEMA440 report [33]. In this evaluation it was found that for short-period structures, with period less than 0.5s approximately, the peak displacements are largely overestimated. For higher periods the ATC-40 methodology can either overestimate or underestimate the displacements, depending on the assumed hysteretic behavior of the evaluated building. The main modification of the method was the update of the expressions for the calculation of the equivalent or effective period (T_{eff}) and damping (β_{eff}). Approximate equations, that are independent of the hysteretic curve and post-elastic stiffness ratio of the capacity curve used, are repeated in the Equations 3 to 5, where μ is the ductility demand, T_0 and β_0 are the elastic damping and period, respectively.

For $1.0 < \mu < 4.0$:

$$\begin{aligned}\beta_{eff} &= 4.9(\mu - 1)^2 - 1.1(\mu - 1)^3 + \beta_0 \\ T_{eff} &= [0.20(\mu - 1)^2 - 0.038(\mu - 1)^3 + 1]T_0\end{aligned}\tag{3}$$

For $4.0 \leq \mu < 6.4$:

$$\begin{aligned}\beta_{eff} &= 14.0 + 0.32(\mu - 1) + \beta_0 \\ T_{eff} &= [0.28 + 0.13(\mu - 1) + 1]T_0\end{aligned}\tag{4}$$

For $\mu > 6.5$:

$$\beta_{eff} = 19 \left[\frac{0.64(\mu - 1) - 1}{[0.64(\mu - 1)]^2} \right] \left(\frac{T_{eff}}{T_0} \right)^2 + \beta_0$$

$$T_{eff} = \left\{ 0.89 \left[\sqrt{\frac{(\mu - 1)}{1 + 0.05(\mu - 2)}} - 1 \right] + 1 \right\} T_0 \quad (5)$$

Based on these equations, scores for FEMA154 were recalculated in the present study. Figure 3 shows a comparison between the basic structural hazard scores presented in FEMA154 and the updated values. On average the values increased 14% for high seismicity, 29% for moderate seismicity and 28% for low seismicity. Increased values are related to a better earthquake performance. This result was expected, since the basic structural hazard scores are calculated for low rise buildings with relatively short periods, and the capacity spectrum method as presented in ATC-40 tends to overestimate the predicted maximum displacement values for short periods.

Figure 3: Comparison between the basic structural hazard scores of FEMA154 and recalculated values with updated capacity spectrum method.

5.2 Spectral response acceleration values

FEMA154 targets seismicity of the United States. Three seismicity regions (high, moderate and low) are defined based on design spectral acceleration values for periods of 0.2 and 1.0 seconds, $S(0.2s)$ and $S(1.0s)$. Limiting values were taken from FEMA310 [34], ignoring local site effects. To determine the median spectral acceleration response values for each seismic region first each county was classified based on the maximum $S(0.2s)$ and $S(1.0s)$ values. The median of these maximum values was calculated for each region and used for the score calculations. The median values and the basic structural hazard scores and modifiers were recalculated [35] considering the seismicity of Québec's cities as specified in the 2005 edition of the NBCC [36], considering the same boundaries for the seismicity regions.

Although the spectral accelerations in Canada and the United States are calculated with the same probability level, 2% in 50 years, there are differences in the calculations that account for cross-border inconsistencies, as for example the use of the median seismicity values in Canada versus the mean values in the United States. Furthermore when using FEMA154 in Canada, one difference in philosophy has to be addressed: in the United States the spectrum is

reduced by 2/3 for design purposes [37], while in Canada this reduction is not used. This will have an impact on the calculated scores, and the use of the same limiting values that define the three seismicity regions is questionable, since they were conceived considering the reduction factor. When analyzing the case of the city of Montréal for example, a city identified as having moderate seismicity, with $S(0.2s) = 0.69g$ and $S(1.0s) = 0.14g$ for Site Class C, it was found that it would be classified by FEMA154 as moderate seismicity if applying the 2/3 reduction factor and high seismicity if not.

NRC92, although conceived for the Canadian context, has yet to be updated to consider the latest findings regarding seismic hazard. The seismicity used by the method is specified in the 1990 NBCC [38], with seismic hazard maps developed in 1985. The effective seismic zone of the site of interest is calculated according to the peak ground acceleration and peak ground velocity with probability of being exceeded of 10% in 50 years. New models were developed for the 2005 NBCC, which include latest findings related to historical seismic events, new attenuation laws, a better description of the site conditions and the explicit consideration of uncertainty [39].

5.3 Site classification

Design spectral accelerations are determined by the expected seismic excitation and local geotechnical conditions at the site. Both in the US and in Canada soil is classified into six categories, from type A to F, ranging from hard rock (type A) to poor soil (type F). For the classification of each type, the parameters used are the measured shear wave velocity or standard blow count. Ground motion amplification factors for short and long periods, F_a and F_v , dependent on the expected intensity of shaking, are defined for each site class. For the US, the reference soil is type B, meaning that F_a and F_v values are equal to one for soil type B [37]. In the seismic provisions of the 2005 NBCC, the American classification system was adopted with small changes. However the reference soil in Canada was defined as type C, to be consistent with previous editions of the NBCC [40]. Therefore F_a and F_v values for the same soil type are lower in Canada. This implies that when using FEMA154 with spectral acceleration values and soil definitions from Canada the site effects are overestimated.

The four different soil types considered by NRC92 have foundation factor F , ranging from 1.0 to 2.0. These factors, based on design practice of the time, do not consider the differences between short and long period responses and the influence of the intensity of shaking.

5.4 Configuration irregularities

The findings of the initial evaluation demonstrated that schools are complex structures: it was found that 80% of the examined buildings have some type of irregularity, with almost 40% having at least one vertical and one plan irregularity. While FEMA154 only differentiates between vertical and plan irregularities, NRC92 identifies seven different types of irregularity: vertical and horizontal irregularity (torsion), short concrete columns, soft story, pounding, major modifications and deterioration. The effect can be appreciated when studying the influence of different irregularities that can be classified as vertical (e.g., steps in elevation view, building on hill, soft story) on the score results. NRC92 classified 40% of school buildings with only one vertical irregularity as high priority and 70% with two vertical irregularities as high priority. Using FEMA154 the percentage of buildings in need of a detailed assessment was 90% and 100% for each these two case. This demonstrates that the NRC92 approach gives greater differentiation when more than one irregularity exists.

In FEMA154 score modifiers for vertical irregularities were based on engineering judgment. For high and moderate seismic zones, the modifiers were chosen so that if it were the

only modifier considered, the final score would be below the cut-off score of 2. For low seismicity, modifiers similar to those of moderate seismic zone were adopted. For the calculation of the plan irregularity modifiers, an increase of 50% in the spectral acceleration response values was used. This approach seems appropriate when evaluating general building stock, where irregularities in plan and elevation should be rather uncommon. When evaluating schools however, due to the prevalence of configuration irregularities, a more detailed evaluation is desirable. Finding a balance between the simplicity of the method and the detailed identification of irregularities is challenging. An example on how this can be achieved can be found in the screening procedure of New Zealand [10]. Even in a first phase evaluation, four critical structural features have to be identified (plan and vertical irregularities, short columns and pounding potential) and the effect on the structural performance of each has to be classified as severe, significant or insignificant. Guidance on how to classify the severity is provided. For buildings with an L-shape plan, for example, the effect on structural performance is determined by comparing the length and the width of the wings.

5.5 Potential for pounding

When insufficient or no separation is provided between adjacent buildings they will likely suffer from pounding during a strong earthquake. This will induce high amplitude shock loadings, and experience in past earthquakes has demonstrated that this problem can even cause buildings to collapse. During the 1985 Mexico City earthquake, 15% of building collapses could be attributed to these severe pounding effects [41].

While FEMA154 doesn't consider pounding, NRC92 incorporates it in calculating the score, and the limiting distance between buildings is defined in terms of the velocity related seismic zone (dependent on the expected peak ground velocity) and number of stories. Since the 2005 edition of NBCC stipulates the seismic demand in terms of spectral acceleration values only, other expressions have to be found.

Experience in past earthquakes has demonstrated that there are special circumstances where the effect of pounding is most critical. Adjacent buildings with different heights, periods and masses are the most vulnerable. Floors at different elevations will allow the slabs of one building to impact columns of the other building generating shear failure and partial or total collapse. In absence of these adverse factors, pounding usually will only induce local damage [42]. Given the high incidence of potential for pounding in the evaluated schools, the identification of the probable severity of damages is important in the rapid visual screening phase.

5.6 Non-structural components

Another important aspect considered by NRC92 while ignored by FEMA154 is the evaluation of non-structural components. Solving non-structural component related problems is not only a cost-effective first step for retrofit, these problems can also be life-threatening or produce injuries while not leading to collapse of the structure. Furthermore, if the installations should be operational immediately after the event, as is the case with post-critical shelters, non-structural damage should be limited. In a moderate seismic zone non-structural damage can be more widespread than structural damages or collapse, as has been demonstrated by experience in past earthquakes in Québec [26].

The initial evaluation highlighted the extensive use of heavy partition walls in schools, many of them made of unreinforced masonry blocks and often without restraint at the top of the walls. This is especially worrisome considering the potential life safety hazard that out-of-plane failure can cause even in a moderate earthquake. A detailed inventory of these walls

must be made to better assess the risks. Key characteristics for wall performance include thickness, height and effective lateral support. The wall density and location will furthermore help to prioritize the cases where corrective measures are necessary.

5.7 Building importance

Schools fall into two distinct classes regarding importance: post-disaster shelters and ordinary schools which all belong to the post-critical building category according to NBCC. The different performance objectives should be acknowledged by the seismic screening method used. While ignored by FEMA154, NRC92 asks for the calculation of a building importance factor based on the occupancy and use of the building. For school buildings, the structural index is increased between 20 and 50%, compared with a normal occupancy building. For post-disaster buildings which have to remain fully functional after the earthquake, the increase is between 50 and 100%.

5.8 Cut-off scores

While FEMA154 only suggests one cut-off score, classifying a building either as safe or as requiring an in depth examination, NRC92 has four distinct categories: low, moderate or high priority for future intervention or potentially hazardous. This more detailed classification gives a better sense of the hazard of each building and the need for detailed evaluation.

The scores of FEMA154 are directly related to the probability of the building to collapse given the maximum considered earthquake. A score of 1 indicates a probability of collapse of 1 in 10 or 10%, a score of 2 a probability of 1%, a score of 3 a probability of 0.1%, etc. Based on these numbers a detailed ranking system is presented in Table 2, as used in the evaluation of schools and other critical public facilities in Oregon [43].

Classification	Probability of collapse	Score
Very high	100%	≤ 0.0
High	$\geq 10\%$	0.1 – 1.0
Moderate	$\geq 1\%$	1.1 – 2.0
Low	$< 1\%$	> 2.0

Table 2: Proposed ranking to be used with FEMA154 [43].

6 IMPROVED SCREENING METHOD

The clear analytical procedure behind the score calculations of FEMA154 makes it possible to update and adapt the method to its use outside its intended scope. NRC92 on the other hand, based largely on expert opinion, is difficult to modify. The RVS method under development therefore uses FEMA154 as a template, modifying it to serve the purpose of evaluating schools in Québec. Some key features of NRC92 are being incorporated.

The scores and modifiers are being recalculated according to Equation 1, with spectral displacements estimated by the capacity spectrum method of FEMA440. The classification of lateral load resisting systems used is that of NRC92, analogous to FEMA154. The seismicity is represented by Montreal's acceleration response spectrum and local site conditions are considered by using the corresponding Canadian ground motion amplification factors F_a and F_v specific to Montréal's seismicity.

Major changes will be introduced in the treatment of irregularities. The classification used in the NRC92 procedure will be adopted, since it covers the findings of the initial evaluation

of the schools. Furthermore, the effect of each type of irregularity on the seismic performance was classified as severe, significant or insignificant. The detrimental effect of the irregularities will be represented by increased spectral response acceleration values.

The evaluation of architectural components (partitions, cladding and exterior finishes) will be included, using the findings of the detailed examination of the unreinforced heavy partition walls to define the appropriate screening mechanism.

7 CONCLUSIONS

The following conclusions were made from this preliminary study:

- The importance of having earthquake resistant schools has been discussed. Not only do schools have unique occupancy characteristics, but they play a key role in response and recovery efforts after a seismic event. Unfortunately they tend to be especially vulnerable.
- In the province of Québec, a moderate seismic zone located in eastern Canada, efforts are currently being made to assess the potential performance school buildings. Seismic screening is appropriate as a first phase of the vulnerability assessment, since with around 3600 schools, a detailed evaluation for each building is not feasible.
- Two seismic screening methods are relevant when evaluating seismic vulnerability of buildings in Canada: NRC92, developed nationally and FEMA154, developed in the US, having similar construction and design practices. Both methods were used to evaluate 16 school campuses comprising around 100 independent buildings located in the city of Montréal. According to the method in FEMA154, 65% of the buildings should undergo a detailed evaluation. With the NRC92 method, 34% of the buildings were classified as having high priority for future intervention and 16% as potentially hazardous. Results of both evaluations are in reasonable agreement.
- Data indicates that school buildings are generally low-rise and have a limited number of types of lateral load resisting systems. Features that could affect seismic performance are common. This characterization is in accordance with findings of similar studies in other countries, and could explain the large proportion of damage to schools observed in past earthquakes.
- The methodologies employed for the score calculation of both evaluated screening methods are outdated. NRC92 is largely based on expert opinion and therefore difficult to update. On the contrary FEMA154, based on the capacity spectrum method, can be revised to include latest findings. An average increase of 24% on the basic structural hazard scores was obtained when updating FEMA154, with higher scores indicative of a better performance. The clear analytical procedure behind FEMA154 also makes it possible to adapt the method to its use to other countries.
- The high incidence of irregularities (80% for the evaluated schools) makes their detailed evaluation essential. FEMA154 groups the irregularities in two categories and quantifies their effect estimating the worst possible scenario. This not only fails to capture each building's specific characteristics, but also leads to over-conservative results. NRC92 partly overcomes these shortcomings defining seven different types of irregularities.

Keywords: Seismic Parameters, Damage Indices, Seismic Ground Motion, Damage Potential, Reinforced Concrete.

Abstract. *This paper provides a methodology to quantify the interrelationship between the seismic intensity parameters and the structural damage. First, a computer-supported elaboration of the accelerograms provides several peak, spectral and energy seismic parameters. After that, nonlinear dynamic analyses are carried out to provide the structural response for a set of seismic excitations. Among the several response characteristics, the overall structure damage indices after Park/Ang and the maximum inter-story drift ratio are selected to represent the structural response. Correlation coefficients are evaluated to express the grade of interrelation between seismic acceleration parameters and the structural damage. The presented methodology is applied to a six-story reinforced concrete frame building. According to the first step of the methodology sixteen seismic parameters are evaluated: PGA, PGV, PGA/PGV, spectral acceleration (SA), spectral velocity (SV), spectral displacement (SD), central period (CP), absolute seismic input energy (E_{imp}), Arias intensity (I_A), strong motion duration after Trifunac/Brady (SMD_{TB}), seismic power ($P_{0.90}$), root mean square acceleration (RMS_a), intensity after Fajfar/Vidic/Fischinger (I_{FVF}), spectral intensities after Housner (SI_H), after Kappos (SI_K) and after Martinez (SI_M). The frame structure has been designed according to the rules of the recent Eurocodes. Then, a nonlinear dynamic analysis has been carried out for the evaluation of the seismic response. Among the several response parameters, the focus is on the overall structure damage indices. This is due to the fact, that this parameter summarizes statistically all the existing damages on columns and beams in a single value, which can be easily correlated to single value seismic parameters. As seismic input for the nonlinear dynamic analysis, a set of spectrum-compatible synthetic accelerograms has been used. To emphasize the grade of interrelation between seismic acceleration parameters and the overall structure damage indices, the correlation coefficient after Pearson and the rank correlation coefficient after Spearman have been calculated. As the numerical results have shown, the spectral and energy parameters provide strong correlation to the damage indices. On the opposite, the CP, SMD_{TB} and the term PGA/PGV delivered poor correlation with the damage indices. Due to this reason, spectral and energy related parameters are better qualified to be used for the characterization of the seismic damage potential.*

1 INTRODUCTION

It is well-known that seismic accelerograms are ground acceleration time-histories that cannot be described analytically. Several seismic parameters have been presented in the literature during the last decades. These can be used to express the intensity of the seismic excitations and to simplify its description. Post-seismic field observations and numerical investigations have indicated the interdependency between the seismic parameters and the damage status of buildings after earthquakes [1, 2]. The latter can be expressed by proper damage indices, while the interdependency between the considered quantities can be quantified numerically by appropriate correlation coefficients. Their values deliver the correlation grade (low, medium or high) between the examined quantities.

This paper provides a method for quantifying the interrelationship between the seismic parameters and global damage indices. First, a computer analysis of the accelerograms provided several peak ground motion, spectral and energy seismic parameters. After that, nonlinear dynamic analyses were carried out to provide the structural response for a set of seismic excitations and a given reinforced concrete frame structure. Keeping in mind that most of the seismic loading parameters are characterized by a single numerical value, single-value damage indicators have also been selected to represent the structural response. Thus, the overall structural damage index (OSDI) after Park/Ang ($DI_{G,PA}$) and the maximum inter-story drift ratio (MISDR) are selected to represent the structural response. Finally, correlation coefficients are evaluated to express the grade of interdependency between seismic acceleration parameters and the used damage indices. The presented methodology is applied to a six-story reinforced concrete frame building subjected to several artificial accelerograms.

2 SEISMIC INTENSITY PARAMETERS

In general, the intensity parameters can be classified with peak, spectral and energy parameters. In this work the following parameters have been selected to represent the seismic intensity: peak ground acceleration PGA, peak ground velocity PGV, the term PGA/PGV, spectral acceleration (SA), spectral velocity (SV), spectral displacement (SD), central period (CP), absolute seismic input energy (E_{inp}), Arias intensity (I_A), strong motion duration after Trifunac/Brady (SMD_{TB}), seismic power ($P_{0.90}$), root mean square acceleration (RMS_a), intensity after Fajfar/Vidic/Fischinger (I_{FVF}), spectral intensities after Housner (SI_H), after Kappos (SI_K) and after Martinez-Rueda (SI_{MR}). They have been chosen from all three of the seismic parameter categories. Table 1 provides an overview of the used parameters and their literature references, respectively. The definition of each parameter is presented in the mentioned literature.

No	Seismic parameters	Reference	No	Seismic parameters	Reference
1	PGA	[3]	9	I_A	[7]
2	PGV	[3]	10	SMD_{TB}	[8]
3	PGA/PGV	[3]	11	$P_{0.90}$	[9]
4	SA	[4]	12	RMS_a	[3]
5	SV	[4]	13	I_{FVF}	[10]
6	SD	[4]	14	SI_H	[11]
7	CP	[5]	15	SI_K	[12]
8	E_{inp}	[6]	16	SI_{MR}	[13]

Table 1: Seismic parameters.

3 SEISMIC ACCELERATION TIME HISTORIES

The seismic excitations used for the dynamic analyses in this study are based on artificial accelerograms created to be compatible with the design spectra of the current Greek antiseismic code (2004). The reason for choosing this approach rather than relying on natural accelerograms was dictated by the need to have a sufficiently large database for statistical reasons. For the creation of the aforementioned artificial accelerograms the program SIMQKE [14] has been utilized. As artificial accelerogram creation parameters the PGA, the total duration (TD) and the design spectra for all three Greek seismic regions (nominal PGA equal to 0.16g, 0.24g and 0.36g) have been used. All created for subsoil category B, as described in Eurocode 8 (EC8) [15] and the Greek Antiseismic Code [16]. This subsoil category belongs to deep deposits of medium dense sand or over-consolidated clay at least 70 m thick. In order to cover most types of Greek region seismic activity, an artificial accelerogram creation procedure has been devised comprising the creation of 5 random artificial accelerograms for each of the 15 preselected PGA values that were assigned for the three different Greek seismic regions. Thus, 75 different synthetic accelerograms have been compiled, which ensures that the overall structural damages of the examined structure will cover all the possible damage grades, from low to severe, in order to cover statistical demands as well.

4 GLOBAL DAMAGE INDICES

As explained previously, attention is focused on damage indicators that consolidate all member damage into one single value that can be easily and accurately be used for the statistical exploration of the interrelation with the also single-value seismic parameters in question. Thus, in the OSDI model after Park/Ang [17] the global damage is obtained as a weighted average of the local damage at the ends of each element. The local damage index is a linear combination of the damage caused by excessive deformation and that contributed by the repeated cyclic loading effect that occurs during seismic excitation. Thus, the local DI is given by the following relation:

$$DI_{L,PA} = \frac{\theta_m - \theta_r}{\theta_u - \theta_r} + \frac{\beta}{M_y \theta_u} E_T \quad (1)$$

where, $DI_{L,PA}$ is the local damage index, θ_m the maximum rotation attained during the load history, θ_u the ultimate rotation capacity of the section, θ_r the recoverable rotation at unloading, β a strength degrading parameter, M_y the yield moment of the section and E_T the dissipated hysteretic energy. The Park/Ang damage index is a linear combination of the maximum ductility and the hysteretic energy dissipation demand imposed by the earthquake on the structure.

The global damage index after Park/Ang [17] takes into account the local damages of all elements of the examined structure (e.g. beams and columns of a frame). Thus, it depends both, the distribution and the severity of the localized damage and is given by the following relation:

$$DI_{G,PA} = \frac{\sum_{i=1}^n DI_{L,PA} E_i}{\sum_{i=1}^n E_i} \quad (2)$$

where, $DI_{G,PA}$ is the global damage index, $DI_{L,PA}$ the local damage index after Park/Ang, E_i the energy dissipated at location i and n the number of locations at which the local damage is computed.

The MISDR [18, 19] is a simple OSDI that describes satisfactorily various forms of damages after an earthquake. The post-seismic damage degree can be classified according to this index. Equation (3) defines the maximum inter-storey drift ratio (MISDR) as the ratio of the maximum absolute inter-story drift $|u|_{\max}$ to the inter-storey height h :

$$\text{MISDR} = \frac{|u|_{\max}}{h} 100 [\%] \quad (3)$$

5 APPLICATION

The reinforced concrete frame structure shown in Figure 1 has been detailed in agreement with the rules of the recent Eurocodes for structural concrete and aseismic structures, EC2 and EC8 [20, 15]. According to the EC8 Eurocode, the structure shown in Figure 1, has been considered as an "importance class II, ductility class M"-structure with a subsoil category B. The cross-sections of the beams are considered as T-beams with 30 cm width, 20 cm slab thickness, 60 cm total beam height and 1.45 m effective slab width. The distances between each frame of the structure is equal to 6 m while the ground floor has a 4 m height and all subsequent floors 3 m. The subsoil was of type B (deep deposits of medium dense sand or over-consolidated clay at least 70 m thick). The eigenperiod of the frame was 1.0 s.

Figure 1: Reinforced concrete frame structure.

After the design procedure of the reinforced concrete frame structure, a nonlinear dynamic analysis evaluates the structural seismic response, using the computer program IDARC [21]. A three-parameter Park model specifies the hysteretic behavior of beams and columns at both ends of each member. This hysteretic model incorporates stiffness degradation, strength deterioration, slip-lock and a tri-linear monotonic envelope. Experimental results of cyclic force-deformation characteristics of typical components of the studied structure, specifies the parameter values of the above degrading parameters. This study uses the nominal parameter for stiffness degradation. Among the several response parameters, the focus is on the overall structural damage indices (OSDI) described in the previous section.

6 RESULTS

The first step was the creation of the aforementioned set of 75 synthetic accelerograms using the SIMQKE program. This program generates baseline corrected acceleration-time histories. The next step was a computer supported evaluation of 16 seismic parameters as presented in Table 1. Nonlinear dynamic analyses has been performed for the reinforced concrete frame building under question, including all artificial acceleration-time histories, in order to obtain the structural damage indices after Park/Ang and the MISDR. Statistical procedures provide the correlation coefficients after Pearson and Spearman [22], between all the evaluated seismic parameters and damage indices. The Pearson correlation shows how well the data fit a linear relationship, while the Spearman correlation shows how close the examined data are to monotone ranking. The latter coefficient is more important in the present study. Table 2 summarizes the results of the correlation study.

Seismic parameters	Pearson correlation		Spearman rank correlation	
	DI _{G,PA}	MISDR	DI _{G,PA}	MISDR
PGA	0.568	0.523	0.635	0.631
PGV	0.657	0.659	0.788	0.795
PGA/PGV	-0.355	-0.367	-0.393	-0.394
SA	0.711	0.678	0.803	0.806
SV	0.724	0.696	0.804	0.804
SD	0.738	0.706	0.849	0.845
CP	-0.342	-0.326	-0.351	-0.332
E _{inp}	0.668	0.667	0.812	0.821
I _A	0.682	0.659	0.824	0.821
SMD _{TB}	0.103	0.086	0.155	0.145
P _{0.90}	0.685	0.662	0.823	0.820
RMS _a	0.713	0.677	0.824	0.821
I _{FVF}	0.655	0.656	0.789	0.796
SI _H	0.703	0.664	0.796	0.795
SI _K	0.702	0.670	0.802	0.806
SI _{MR}	0.614	0.558	0.725	0.725

Table 2: Correlation coefficients between the seismic parameters and the OSDIs.

It is supposed that correlation coefficients up to 0.5 means low correlation, coefficients between 0.5 and 0.8 means medium correlations, while coefficients greater than 0.8 means strong correlation between the two variables. Table 2 presents the correlation coefficients after Pearson and the rank correlation coefficients after Spearman among all the examined seismic parameters presented and the examined the damage indices. Thus, the results show low Pearson and Spearman correlation between the term PGA/PGV, CP, SMD_{TB} and the examined damage indices. All the remaining seismic parameters provided medium Pearson correlation with the damage indices. On the other hand, high rank correlation is observed between SA, SV, SD, E_{inp}, I_A, P_{0.90}, RMS_a, SI_K and the damage indices. In addition, medium rank correlation is observed between PGA, PGV, I_{FVF}, SI_H, SI_{MR} and the damage indices.

Finally, the seismic parameters show the same correlation grade with DI_{G,PA} with MISDR in all the cases. All the seismic parameters show the same correlation grade for both, Pearson and Spearman correlation, with exception the cases with high rank correlation. There, the Pearson correlation grade is medium.

7 CONCLUSIONS

- In this paper a methodology for the value estimation of the interdependence between seismic acceleration intensity parameters and damage indices has been presented. Peak, spectral and energy parameters have been considered. The global damage index after Park/Ang and the MISDR represented the post-seismic structural damage status. The degree of the interrelationship between seismic parameters and damage indices has been expressed by the Pearson correlation coefficient and by the Spearman rank correlation coefficient.
- The results show low Pearson and Spearman correlation between the term PGA/PGV, CP, SMD_{TB} and the examined damage indices.
- Medium correlation is observed between PGA, PGV, I_{FVF} , SI_H , SI_{MR} and the damage indices, in all the cases.
- High rank correlation is observed between SA, SV, SD, E_{inp} , I_A , $P_{0.90}$, RMS_a , SI_K and the damage indices. In all these cases, the corresponding Pearson correlation grade was medium.
- The seismic parameters show the same correlation grade with $DI_{G,PA}$ with MISDR in all the cases
- All these results lead to conclude that the spectral and energy seismic parameters are reliable descriptors of the seismic damage potential and to recommend them as appropriate descriptors of the seismic damage potential.

Keywords: Dual Structures, Hysteretic Dampers, Cable Bracing, Energy Dissipation Systems.

Abstract. *Technological advances in the seismic design of energy dissipation systems raise the issue of the codes dominated capacity design of structures. Building code requirements that describe the dynamic behavior, modeling and analysis of structures with different types of energy dissipation systems are currently under review. A new seismic design approach, described in the current paper, adds to the current research activities of the authors on passively controlled systems with integrated hysteretic damper and cable bracings. The control system considers at first place the effect of added stiffness when conventional bracings are added to structural frames that are necessary for the integration of the damping devices. An increase in the systems stiffness may result to a reduction of the peak displacement, i.e. peak pseudo-acceleration, and thus to an increase of the shear forces. In addition, an increase in damping can significantly influence the response of elastic and inelastic systems. The new system proposed aims at both, energy dissipation and damage control. It consists of an energy dissipation device and a portal cable bracing mechanism with a kinetic closed loop, working only in tension. The closed bracing mechanism does not practically affect the initial stiffness of the system, i.e. the concept relies on two completely “separate” systems: a primary for the vertical- and wind loads and a secondary for the earthquake loads. Analysis model considerations for describing the physical behavior of the system in computational language are presented, by incorporating the SAP2000 program, revealing step by step the procedure followed for the resulting desired dynamic performance. Based on the energy balanced equation at each time-step, the hysteretic energy dissipation demand is reduced when the supplemental damping system is utilized. An Effective Toughness Index, in accordance to the time-dependence of the hysteretic energy dissipation is proposed to characterize the portions of the input energy dissipated by the control system. The predominant parameters that characterize the system’s seismic behavior are derived on the basis of a parametric analysis under selected international strong ground motions. Finally the systems behavior is verified in respect to the mechanical properties of the control elements under the action of ten selected earthquake excitations of the Greek-Mediterranean region. The parametric analyses of the system’s seismic behavior conclude with a proposed preliminary design methodology for the passively controlled SDOF models.*

1 INTRODUCTION

The design of frame structures with additional control members for earthquake resistance refers primarily to the need for the primary systems to exhibit essentially a linear behavior under seismic actions [1]. A reduction of the energy dissipation demand on primary structural systems was successfully aimed at by a number of researchers [2]. Passive metallic yielding, viscoelastic and viscous damping devices may be added to frame structures to dissipate input energy during an earthquake and to substantially reduce or eliminate damage to the gravity-load-resisting frames. ADAS and TADAS are well known examples, available for both, new seismic resisting designs and retrofit of frame buildings [3]. Some types of supplemental damping can substantially change the force-displacement response of the structure by adding strength and stiffness. Stiff bracings in such energy dissipation systems (EDS) reduce inter-story drifts, but they produce high accelerations; on the other hand more flexible slender bracings, such as cables or tension-only rods, attract smaller forces and tend to reduce floor accelerations. Additionally the effective added damping benefit of EDS is shadowed by the coupling effect of the primary- and control system, due to the unavoidable stiffness increase of the former [4-6].

The research inquiry of utilizing the performance of mild steel in terms of strength, flexibility and minimal weight, coupled with the need of a smooth, non-coupled operation under dynamic excitations has led to the development of Adaptable Dual Control Structures (ADCS) [7-10]. The basis of the design philosophy of the systems comprises the component deformation capacity that characterizes the performance and damage of the system. The cable bracing mechanism with closed loop and the integrated hysteretic damper that forms within moment resisting frames an ADCS enables the primary system to respond elastically under load combinations of static- (gravity and equivalent static wind) and dynamic (moderate, extremely irregular base excitations) actions. The design objective for the proposed systems is to “dual” the response performance between the primary frame and the added control members that practically do not affect the elastic response of the main structure, but concentrate all the damage to the replaceable damper. A number of critical configurations have been conceived by the authors [7, 8], of which one is presented in the current paper.

Following the construction design of ADCS, the design parameters have been defined through a parametric analysis that involves 342 combinations of both geometrical and mechanical system properties, subjected to three international strong earthquake motions: El Centro 1940, Kobe 1995 and Northridge 1994. The range of the design application is clearly stated in terms of both, the characteristic period and the limiting lateral displacements of the passively controlled system. The designer may target to a desirable performance by defining an effective energy deformation index (EEDI). Predominant design parameters for characterizing the ADCS's response are revealed through the parametric analysis, defined as a function of the non-linear link's elastic stiffness and yield force, the Damper Ratio (DR). ADCS's effective response behavior in terms of energy dissipation, minimal displacements and practically non-coupled performance between the frame and the added dissipaters is verified under ten selected earthquake records of the Greek-Mediterranean seismic zone.

2 BRACING CONFIGURATION

Prestressed tensile bracings are used as tension-only members in ADCS. In common applications, not only the low stiffness of cables, but also the nature of hinged frame construction, makes these elements vulnerable to lateral and vertical movements. Through respective modification of their geometry the elements initiate a static non-linear response to the induced strong ground movements at their base and adapt to this by activating a kinetic mechanism,

Figure 1. The displacement is transferred at the optimal joint where the hysteretic device is connected at its one end, while its other end is fixed at the primary beam and follows the lateral frame's movement in every cycle. Tuning of both, the mechanical and geometric characteristics of the composed members with the respective primary frame may lead to high portions of energy dissipation and therefore add damping to the system. The control system is also responsible for the system's relative displacements and the avoidance of any significant base shear increase. Due to the characteristic configuration, ideally the reactions from the added elements to the primary frame are neutralized. The optimization of the damper-bracing mechanism involves tuning between the stiffness, the yield force and the relative displacement that the hysteretic damper develops to the tension-only bracings and in extent, to the primary frame, so that the energy flow in terms of hysteresis for the damper and the elastic strain energy for the cable restraints and the primary frame are effective.

Figure 1: Frame Configuration for ADCS, S1.

2.1 Connection Design

The construction technique developed for ADCS aims at achieving among others the necessary stiffness on the flexible members, their prestressing and the stabilization of the system. When ADCS proposed systems are subjected to earthquake loads a kinematic mechanism is activated. This is made possible through eccentrically placed discs at the main joint region that rotate and drag along the horizontal bracing member that induces relative deformations between the damper's ends, defined as the Interdamper Drift, Figure 2. The damper is designed to yield in its inelastic region and dissipate energy. When the lateral translation on the frame changes to the opposite sense, the procedure is repeated. At the end of a complete cycle, all tension-only members are stretched to their maximum potential. ADCS utilize the previously established knowledge on the effectiveness of the yielding metallic dampers, ADAS and TADAS that have already been confirmed through ample tests and analytical studies [2, 3]. ADCS design introduces slightly modified shape sections of similar dampers. The damper's section is selected to result in uniform bending curvature over the section's height. The transverse force applied at the end of each plate causes uniformly bending curvature and all section lines reach their maximum yielding potential at the same time.

Figure 2: Connections' Design for ADCS, S1.

ADCS response for the desirable level of seismic protection depends primarily on two main factors:

1. The effective values of the relative stiffness of the primary frame, the bracing and the hysteretic device at the target displacement that leads to the selection of the design stiffness of the damper, k_d , given by the following equation:

$$k_d = \frac{n(2 + a/b)EI_b}{h^3} \quad (1)$$

where k_d is the initial elastic stiffness of the hysteretic damper, I_b , the second moment of area at the top of the steel plates used as hysteretic damper, h is the height, b is the upper width (fixed to the beam) and a is the lower width (connected to the bracing member), $E = 2.1 \times 10^4$ kN/cm², $\rho = 78.5$ kN/m³ for S235 mild steel material of the damper plates, as shown in parallel arrangement in Figure 2.

2. The load, at which the damper yields and dissipates energy through its inelastic yielding deformation, given by the following equation:

$$P_y = \frac{nf_ybt^3}{4h} \quad (2)$$

where f_y is the yield stress ($f_y = 24$ kN/cm² for S235), and t is the thickness of each plate.

3 PRELIMINARY INVESTIGATION

3.1 Frame Modeling

The finite element analysis of ADCS relies on a simplified model, whereas non-linearity is only addressed for the hysteretic damper, i.e. the non-linear link. The dynamic behavior of the simulated ADCS was examined using the FE program SAP2000. A typical geometry was assigned for the ideal model of the steel moment resisting frame: a 6.0 m long beam and 4.5 m high column members in a 2D representation model. The bracing members were modeled as tension-only elements and a suitable pretension stress was applied to each of them. The ADCS's tendons' geometry was carefully drawn for the software model to represent the configuration with high accuracy. The disc was modeled as a composition of three short frame members, assigned with large stiffness values to represent the real property of a shaft. The preliminary analysis was completed for a number of combinations of characteristic design variables. IPB1500 sections were assigned for the columns and IPB1550 for the beam. The dimensioning of the members was based on Eurocode 3, having assumed a static vertical load of 1200 kN and a static equivalent wind load of 15 kN. A range of diameters between $d_c = 15$ mm and $d_c = 40$ mm was tested in the investigation. The geometry of the steel plates varied in the parametric analysis, as follows: $h = 15, 20, 25, 30, 35, 40$ cm; $n = 6, 8, 10$; $b = 4, 5, 6$ cm; $t =$

8, 10, 11, 12, 13, 14, 15, 16, 18, 20 mm. The calculated initial stiffness for the damper varied between $450 \text{ kN/m} < k_d < 24200 \text{ kN/m}$ and the yield force, between $3.5 \text{ kN} < P_y < 43 \text{ kN}$.

3.2 Input Seismic Records

The system's displacement depends directly on the amplitude of the ground motion; although the damper's dynamic properties are defined by the designer. In order to identify the parameters that dominate the response of ADCS, the configuration presented in Figure 1, was analytically tested under the records of El Centro, Kobe and Northridge as described in Table 1.

Record	Mw	PGA (g)	Duration (s)	Scale factor
El Centro 1940	6.9	0.348	53.76	2.871
Kobe 1995	6.9	0.821	48.00	1.218
Northridge 1994	6.7	0.604	30.00	1.655

Table 1: International Seismic Input Records.

The predominant design parameters of ADCS are the stiffness of the damper k_d and the yield load P_y , as given by equations (1) and (2). Based on the analysis results, the Damper Ratio (DR) that describes the response of ADCS as a function of its stiffness and yield force is introduced, as follows:

$$DR = \frac{k_d}{P_y} \quad (3)$$

where k_d is the damper's stiffness and P_y is the yield load of the hysteretic device, measured in $1/\text{m}$ units. A range between $55 \text{ 1/m} < DR < 780 \text{ 1/m}$ values was examined to construct the parametric analysis results diagram.

3.3 Modeling of the Non-Linear Behavior

Hysteretic dampers may exhibit a bilinear or trilinear hysteresis, an elasto-plastic or rigid-plastic behavior, which can be captured with the structural analysis software SAP2000. The damper used in ADCS was modeled as a non-linear link element. The damper's force-deformation relationship for a respective degree of freedom, corresponding to shear, was modeled to follow the hysteretic model described as Wen plasticity property type of uniaxial deformation. Several hysteresis models were tested analytically to represent the damping feature of the composed damper. The Wen-Plasticity model was finally adopted and the results were calculated based on this characteristic hysteresis model, mathematically described as follows:

$$f = \text{ratio} \cdot k \cdot d + (1 - \text{ratio}) \cdot \text{yield} \cdot z \quad (4)$$

where f is the force and d , the induced displacement, k is the elastic spring constant, i.e. initial stiffness, "yield" is the yield force, "ratio" is the specified ratio of the post-yield stiffness to the elastic stiffness, i.e. secondary stiffness ratio, and z is an internal hysteretic variable that evolves according to the following differential equation:

$$\dot{z} = \frac{k}{\text{yield}} \left\{ \dot{d}(1 - |z|^{\text{exp}}) \text{ if } \dot{d}z > 0, \text{ or } \dot{d} \text{ otherwise} \right\} \quad (5)$$

where "exp" is an exponent greater than or equal to unity (practically about 20), z , a path dependency parameter. SAP2000 provides the analytical model shown in equation (4), which

represents the hysteretic behavior of the device. During the dynamic motion, inertia forces are activated by all concentrated masses; including the mass distributed on the rigid plates' section (m_d in SAP2000, assigned with a default value of 0.24 kg) for the inertia forces contributed by the damper. The related resistance is given as the integral of the “second moment” about an axis of all the elements of mass dm , which compose the body of the steel plate used for the added damping, known as “MMI”, Mass Moment of Inertia, RI in SAP2000 and assigned with a default value of $RI=0.175$.

3.4 Parametric Analysis

The parametric analysis conducted provides information that may be used to assess the adequacy of ADCS design for a range of SDOF systems representative for new or existing frame structures with a characteristic period between the values of $0.60 \text{ s} < T < 1.30 \text{ s}$. ADCS are tuned to specific predefined earthquake hazard protection levels as defined by the user in quantifiable energy measures of deformation. Hence the system is designed for a target building performance level. In the present study the performance index for structural safety has been defined as Effective Energy Deformation Index (EEDI) that physically represents the amount of the seismic input energy needed to be dissipated by the hysteretic device. A number of 342 combinations of assigned values to the damper's stiffness and yield force were used to construct the diagram, illustrating a measure of the effective deformation of energy, Figure 3. The presented area of the hysteretic energy by the input energy of the system was calculated for each combination of k_d and P_y and the ratio variation is marked at the y-axis, whereas at the x-axis the design parameter of the Damper Ratio DR is shown.

Figure 3: Parametric Analysis Results.

As Figure 3 illustrates, in all ADCS design parameters combinations the energy dissipation is more than 60 %. The investigation results refer to the systems' responses developed for the earthquake records, described in Table 1.

3.5 Preliminary Design

A simplified structural analysis and design procedure may be used to test the reliability of ADCS when under arbitrary seismic input records. The numerical application involves a selection of 10 real records in the Mediterranean earthquake prone zone for peak ground accelerations ranging between 0.10g and 0.50g, time durations, between 10 s and 50 s and different frequency contents, Table 2.

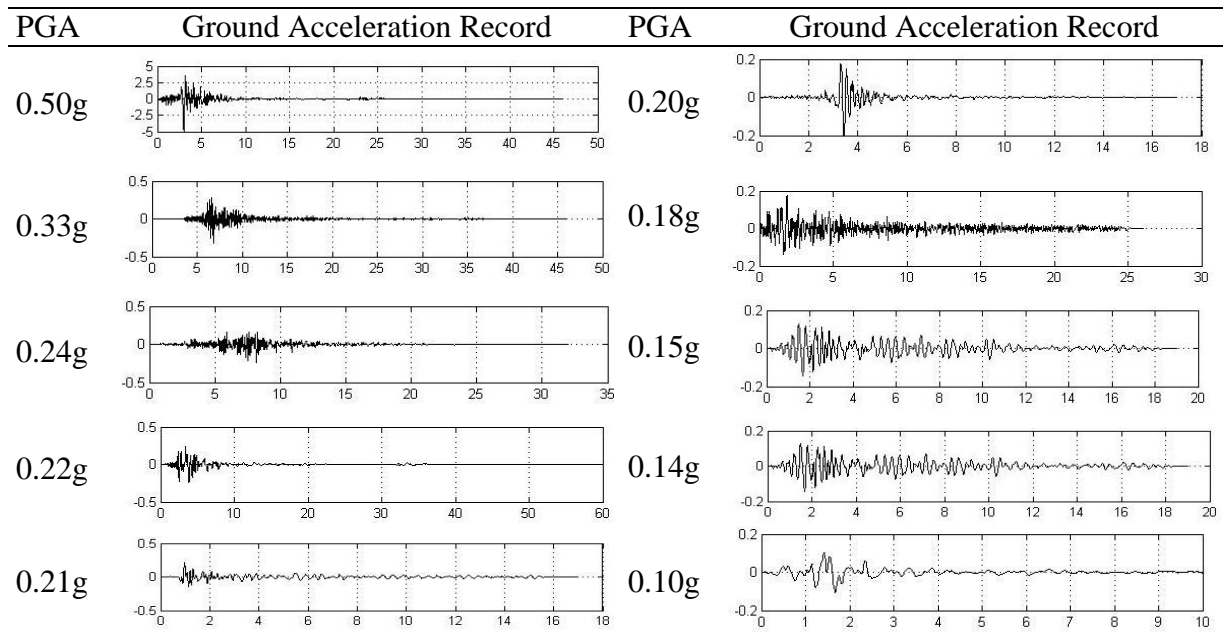

Table 2: Mediterranean Seismic Input Records.

The following steps are suggested for the design:

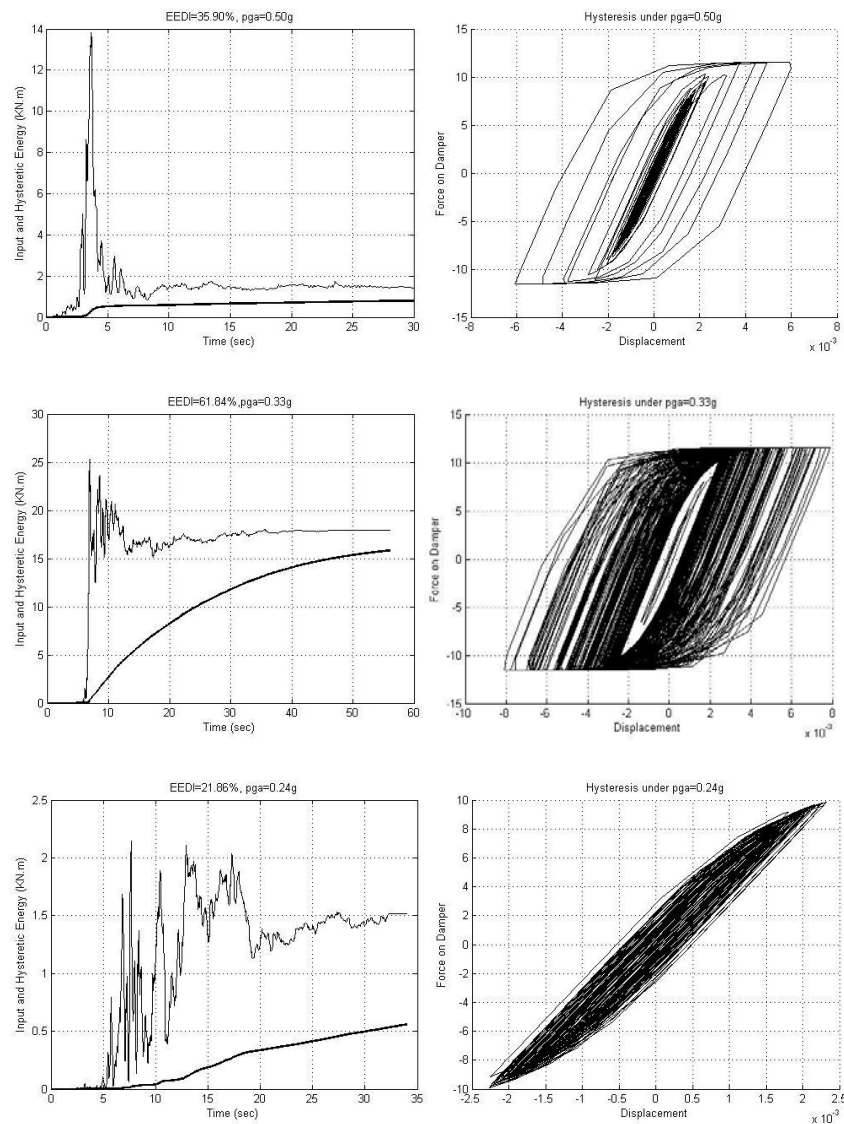

1. Select the design earthquake and assign a critical damping coefficient of 0 %.
2. Dimension the primary frame system to resist the gravity and wind load actions, (i.e. 1200 kN vertical and 15 kN lateral), combined with 25% of the static equivalent seismic load according to Eurocode 3.
3. Calculate for the dimensioned SDOF frame, the stiffness property in respect to both, the assigned mass (i.e. gravity load) and the initial estimation of the characteristic period. The period has to be within the suggested range of $0.60 \text{ s} < T < 1.30 \text{ s}$ for the indicated configuration.
4. Select the target allowable relative system's displacement as a percentage of its height and according to the displacement-based analysis (i.e. 1.5 % of the SDOF system's height). The procedure is based on previously established research results on ADCS response behavior for the estimation of the initial system's design parameters [7-11]. The proposed values are adopted for the next step of the design procedure.
5. Calculate the initial stiffness of the tension-only bracings by addressing the suggested factor of 1.65 to the inverse of the tendons stiffness, i.e. $1/k_b$, k_b : bracing's stiffness [11].
6. Determine the bracing's configuration under P-Delta load combinations so that it maintains its configuration without becoming slack after the structure is loaded. In the present application example, the cables are assigned with a diameter of $d_c = 20 \text{ mm}$, with $E = 1.6 \times 10^4 \text{ kN/cm}^2$ and $f_y = 79.5 \text{ kN/cm}^2$.

3.6 Effective Yielding

In order for the yielding of the non-linear link to be effective, the kinetic response of the cable-restraints should be verified to be tuned to the hysteretic performance of the damper for an arbitrary case of selected design parameters as shown in Figure 4. The diagrams present for each one of the seismic inputs the comparison of input and hysteretic energy and the respective hysteresis for the damper with characteristics of $h=15$ cm, $n=6$, $t=1.2$ cm, $b=5$ cm, $m=0.24$ kg, and a rotational inertia of $RI=0.175$.

The resulting hysteresis in the damper is assumed to be equal with the dot product of the damper's yield force P_y and the design Interdamper drift Δ_d , expressed as follows:

$$E_H = P_y \Delta_d \Rightarrow P_y = \frac{E_H}{\Delta_d} \quad (6)$$

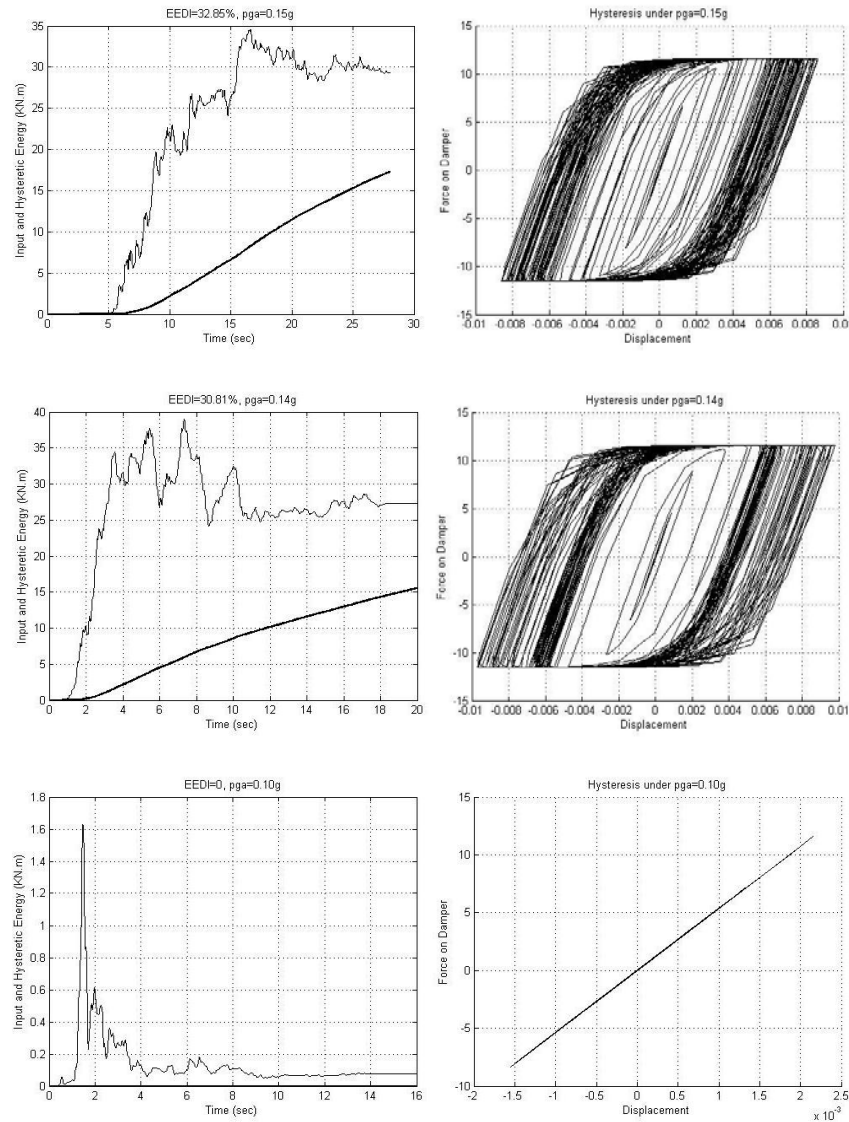

Figure 4: Effective Hysteresis of ADCS Damper.

A tuning of the damper-bracing mechanism follows the design steps 1-6:

7. Define the material and cable properties and assign compression limits for the tension-only cables (i.e. 5 kN prestressing) to make sure that the bracings will not carry compression.
8. Perform a static non-linear analysis to verify that displacements on the geometric non-linear configuration of the cables are kept under defined limits.
9. Calculate the initial elastic stiffness of the damper by addressing the suggested factor of 0.1062 for the damper to the frame stiffness according to [11].
10. Based on the initial estimations of the design parameters, (i.e. damper's stiffness and - yield force), calculate the Damper Ratio DR value according to equation (3).
11. Verify the respective performance indicator EEDI value according to Figure 3. When the demand coincides with the amount of energy dissipation, the EEDI value can be selected.
12. Calculate the damper's hysteretic energy according to equation (6), for the EEDI and select the design yield force, P_y , in relation to the allowable maximum inter-damper drift, Δ_d .

The final step of the design procedure involves the dimensioning of the damper according to the system's response, as this may be characterized through its initial elastic stiffness k_d and its yield force P_y :

13. According to the selected damper's yield force and stiffness, select the number and geometry of the damper's steel plates by using equations (1) and (2).

3.7 Base Shear

The design should verify that the base shear on ADCS is not increased after the addition of the damper-bracing mechanism. Otherwise, the input energy may also increase. In addition to the latter, an increase of the strength demand on the primary frame may become higher than the foundations can carry at the end of the flow of forces circle. As Table 3 shows, there is a decrease of the base shear of the controlled system in 80 % of the cases and an increase in 20 % of the cases that can be neglected because of its small magnitude. According to the numerical results of the parametric analysis, the increase of the base shear can be practically neglected. An example is shown in Table 3.

Record	Primary Frame (kN)		ADCS: S1 (kN)

3.8 Displacement Control

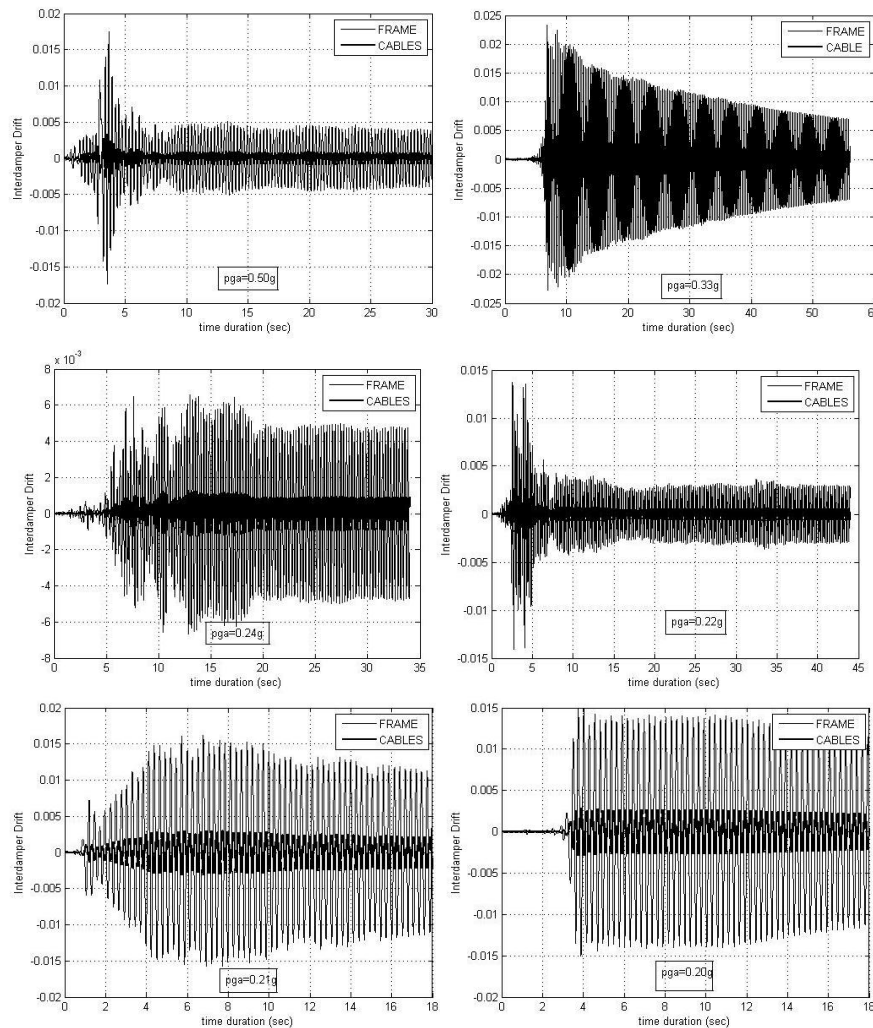

A range of defined allowable relative displacement limits should be followed for the frame to resist elastically, for the tension-only bracings to avoid compression and for the hysteretic damper to be energized. Table 4 shows the respective analysis results of the primary frame and for the arbitrary selection of ADCS assigned parameter values. A reduction of the response displacements is found in 80 % of the cases.

Record	Primary Frame (cm)		ADCS: S1 (cm)

Table 4: Relative Displacement Results.

3.9 Interdampner Drift

The effectiveness of the proposed ADCS is based on the relative displacements between its composed members, in particular, the damper's end points. The displacement is defined as Interdampner Drift, i.e. the relative displacement of the primary frame to the cable bracings. Some respective indicative results for the numerical example analyzed are plotted in Figure 5. The relation between the Interdampner Drift for a given seismic action load and the Effective Energy Dissipation is vital for the optimization procedure of ADCS design.

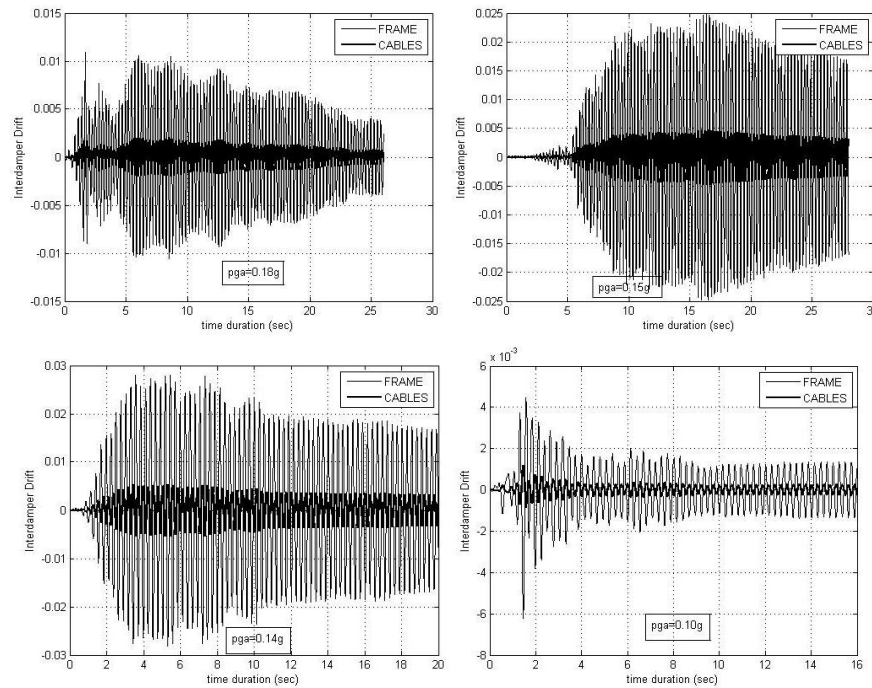

Figure 5: Interdampner Drift.

4 CONCLUSIONS

The application of Adaptable Dual Control Systems that may be designed to supply measurable added damping to frame structures through the yielding of an integrated hysteretic damper is proposed in the present paper. The concept refers to a kinetically developed damper-bracing mechanism. A configuration design of tension-only bracings with closed circuit and a hysteretic damper are investigated under strong earthquakes. In principle the optimization procedure for the best seismic control response of ADCS refers to a good trade-off between the desirable increase in energy dissipation and control of both, base shear and relative displacements, compared to the response of the primary frame without the control mechanism. The leading parameters of the design were traced through a parametric analysis that has been based on 342 combinations of design parameters. New design properties that seemed to govern the design were defined and calculated for each analytical test. The design parameters have been verified in the response behavior of ADCS under the earthquake records of the Greek-Mediterranean seismic zone, significantly different from each other and from the international ones, in their frequency content, time duration and peak ground acceleration characteristics. The benefit of high energy dissipation levels by ADCS has been proven for a broad range of the hysteretic damper's mechanical and geometrical properties. Additionally, the common concern in passively controlled frame structures, of stiffness increase, or induction of larger displacements, and the limitation of the maximum displacements of the damper-bracing mechanism's members proved to be managed satisfactorily in the designs. Ready made diagrams that may be used for further applications are given to assist the procedure for designing structures that may develop an adaptable seismic control response mainly due to the property of "duality" as it is valid for ADCS.

Keywords: Pushover analysis, Incremental dynamic analysis, Monte Carlo simulation, Vulnerability.

Abstract. *Capacity-spectrum-based-methods are also used for assessing the vulnerability and risk of existing buildings. Capacity curves are usually obtained by means of nonlinear static analysis. Incremental Dynamic Analysis is another powerful tool based on nonlinear dynamic analysis. This method is similar to the pushover analysis as the input is incrementally increased but it is different as it is based on dynamic analysis. Moreover, it is well known that the uncertainties associated to the structural response can be significant, because the uncertainties involved in the mechanical properties of the materials and the expected seismic actions are also highly uncertain. In this work selected mechanical properties are considered as random variables and the seismic hazard is considered in a probabilistic way. A number of accelerograms of actual European seismic events have been selected in such a way that their response spectra fitted well the response spectra provided by the seismic codes for the zone where the target building is constructed. In this work a fully probabilistic approach is tackled by means of Monte Carlo simulation and it is applied to a detailed study of the seismic response of a reinforced concrete building. The building is representative for office buildings in Spain but the methods used and the results obtained can be extended to other types of buildings. The main purposes of this work are 1) to analyze the differences when static and dynamic techniques are used and 2) to obtain a measure of the uncertainties involved in the assessment of the vulnerability of structures. The results show that static based procedures are somehow conservative and that uncertainties increase with the severity of the seismic actions and with the damage. Low damage state fragility curves have little uncertainty while high damage grades fragility curves show great scattering.*

1 INTRODUCTION

Aiming to prevent the seismic risk, it is necessary to assess the vulnerability of existing structures. To do that, several methods have been proposed, starting from different approaches. One is the vulnerability index method in which the action is defined from the EMS-98 by macroseismic intensities and structural behaviour through a vulnerability index [1, 2]. Another highly used method is based on the capacity spectrum. In this, the seismic action is defined by means of the elastic response spectra and the vulnerability or fragility of the building by means of the capacity curve; the latter is calculated from an incremental nonlinear static analysis, commonly known as "Pushover Analysis" [3, 4 5]. Another tool used to evaluate the performance of structures against seismic actions is the Incremental Dynamic Analysis (IDA) proposed by Vamvatsikos & Cornell [6]. The purpose of IDA is to obtain a measure of damage in the structure by increasing the intensity of the action record, in this case the peak ground acceleration. Vamvatsikos & Cornell make an interesting analogy between the PA and the IDA, because both procedures increases the load on the structure and measure the response of the system in terms of a control variable which may be the maximum displacement at the roof, the maximum inter storey drift, etc. This procedure allows obtaining the dynamic response of a structure when the seismic action is increased. On the other hand, the mechanical properties of the materials which constitute the structure and the seismic action are random variables and, therefore, the vulnerability of the building is also a random variable. To take into account the inherent randomness of the problem, it is appropriate to use the Monte Carlo method. Therefore, in this paper, a probabilistic comparison between the PA and the IDA is performed when calculating the vulnerability of an existing reinforced concrete building. The main conclusion from this comparison highlights the importance of measuring the vulnerability of structures taking into account that the variables involved are random. This approach, mixed with powerful tools to analyze the structure such as the PA and the IDA, provide valuable information that can hardly be obtained with other methodologies.

2 BUILDING DESCRIPTION

This paper analyzes a reinforced concrete structure, consisting of columns and waffle slabs, which is part of the North Campus of the Universidad Polit cnica de Catalu a. It has 7 levels and 4 spans, the height is 24.35 m and the width is 22.05 m (see Figure 1). The fundamental period of the building is 0.97 seconds. This value is higher when compared to that of conventional reinforced concrete buildings, because in the numerical model, the waffle slabs are approximated with beams of equivalent inertia and, therefore, are structural elements wide and flat leading to a reduction of the lateral stiffness of the structure. In the calculation model, the structural elements (equivalent beams and columns) follow an elastic-plastic constitutive law, which does not take into account either hardening or softening. Yielding surfaces are defined by the moment-axial load interaction diagram in columns and by the moment-angular deformation interaction diagram in beams.

Figure 1. Picture of the building omega located in the Universidad Polit cnica de Catalu a, Barcelona, Spain.

3 DAMAGE INDEX BASED ON PUSHOVER ANALYSIS

A tool often used to evaluate the behaviour of the structures against seismic loads, is the nonlinear static analysis, commonly called Pushover Analysis (PA). This numerical tool consists in apply a horizontal load to the structure, according to a certain pattern of forces, and in increasing its value until the structural collapse is reached. From this procedure one obtain a relationship between the displacement at the roof of the building and the base shear, called capacity curve. In this article, due to the probabilistic approach, the PA is performed repeatedly, therefore, it is appropriate to apply a procedure for obtaining automatically the horizontal load limit. For this, Satyarno [7] proposes the adaptive incremental nonlinear analysis that establishes the horizontal load limit as a function of the tangent fundamental frequency, i.e. the frequency associated with the first vibration mode, which is being calculated for each load increment. Therefore, in each step is calculated the first mode of vibration to determine the shape of the load in height. A detailed description of this procedure is found in the manuals of the program Ruaumoko [8] used for calculating the static and dynamic nonlinear structural response. As mentioned in the introduction, the mechanical properties of materials are considered as random variables. To do this, the values used in the structural design for concrete compressive strength f_c , and the tensile strength associated with steel yield strength f_y , are treated as random variables and using the inversion method of the cumulative probability distribution curve are generate 1000 random samples of these variables. In this paper, it is assumed that the generated random variables follow a Gaussian probability function whose mean and standard deviations are shown in Table 1.

	Mean Value (kPa)	Standard deviation (kPa)	Coefficient of variation
f_c	25000	2500	0.1
f_y	500000	50000	0.1

Table 1. Features of the Gaussian random variables considered.

For the generated samples, the PA is performed 1000 times and the capacity curve is obtained as the random variable shown in Figure 2.

Figure 2. Capacity curves obtained from the PA, taking into account the uncertainty in the mechanical properties of materials.

The capacity curves shown in Figure 2 are transformed into capacity spectra, which relate the spectral displacement to spectral acceleration by means of the following equations [9]:

$$sd_i = \frac{\delta_i}{PF_1} \quad (1)$$

$$sa_i = \frac{V_i}{W} \frac{1}{\alpha_i}$$

The subscript i in equations (1) is referred to the applied load increments on the structure during the PA; sd_i is the spectral displacement; δ_i is the displacement at the roof of the building; PF_1 is the modal participation factor of the first mode of vibration; sa_i is the spectral acceleration; V_i is the base shear; W is the weight of the building and α_i is the modal mass coefficient of the first mode of vibration. On the other hand, the capacity spectrum can be represented in a bilinear form, which is useful for defining damage states. Assumptions to build the bilinear capacity spectrum are: 1) The area under the bilinear curve must be equal to the area of the original curve. 2) The coordinates of the point of maximum displacement must be the same in both curves. 3) The slope of the initial branch should be equal in both curves. Figure 3 shows an example of the bilinear representation of the capacity spectrum. This can

be defined completely by the points (D_y, A_y) and (D_u, A_u) . These points are useful to define the states of damage, according to the procedure described in Lantada et al (2009).

Figure 3. Capacity spectrum and the bilinear representation.

Different studies have been proposed to calculate the damage of the structure from the definition of damage states (ds), which are a description of the damage in the structure for a given spectral displacement. For example, HAZUS 99 [10] and Risk EU [11], define 4 ds , namely slight, moderate, extensive and complete. Description of the damage states depends on the type of structure. For example, According to HAZUS, in the case of reinforced concrete structures, the ds slight is described as the beginning of cracking due to bending moment or shear in beams and columns. Collapse state considers that the structure reaches an imminent risk of collapse. Risk EU seeks to define the damage states in simplified form, starting from the capacity spectrum in a bilinear representation. Based on the values (D_y, A_y) and (D_u, A_u) , the spectral displacements for the four damage states threshold ds_i are obtained according to the following equations:

$$\begin{aligned}
 ds_1 &= 0.7 * D_y \\
 ds_2 &= D_y \\
 ds_3 &= D_y + 0.25 * (D_u - D_y) \\
 ds_4 &= D_u
 \end{aligned} \tag{2}$$

Therefore, after calculating the capacity spectrum in bilinear representation and applying equations 2, it is possible to obtain the damage states thresholds as random variables, as shown in Figure 4.

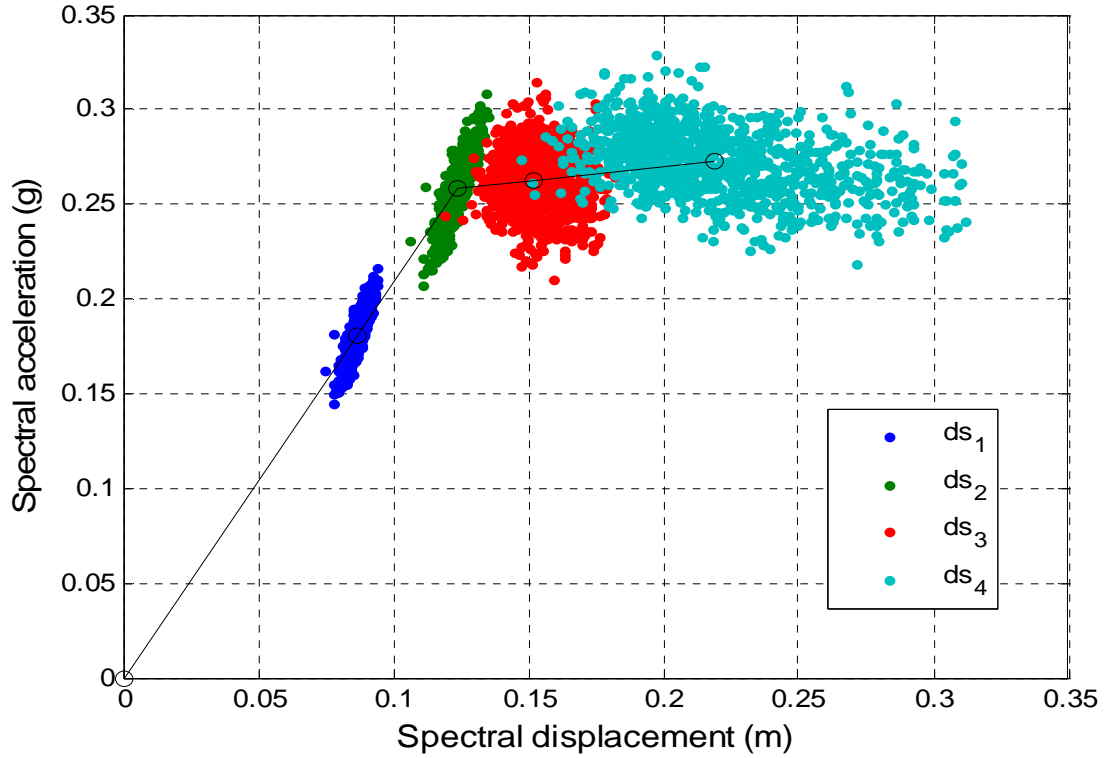

Figure 4. Damage states as random variables.

The mean, standard deviation and coefficient of variation of the damage states are shown in Table 2, in which it can be seen that the coefficient of variation of the damage state 4 is greater than that of the input variables. This is due to the fact that the problem is nonlinear and therefore it shows the importance of the probabilistic approach in this type of analysis.

	ds_1 (cm)	ds_2 (cm)	ds_3 (cm)	ds_4 (cm)
μ_{ds}	8.6	12.3	15.2	21.9
σ_{ds}	0.27	0.38	1.00	3.25
$c.v.$	0.03	0.03	0.06	0.15

Table 2. Mean value, standard deviation and coefficient of variation of the damage states.

After obtaining the damage states as random variables it is possible to calculate the fragility curves, which represent the probability of reaching or exceeding a damage state, in function of a parameter representing the seismic action. In this work, this parameter is the spectral displacement. To obtain the fragility curves the following assumptions must be considered: 1) The probability that the spectral displacements in each damage state threshold, ds_i , equals or

exceeds the damage state is 50%. 2) The fragility curves follow a lognormal cumulative probability function described by the following equation:

$$P[ds_i / sd] = \phi \left[\frac{1}{\beta_{ds_i}} \ln \left(\frac{sd}{ds_i} \right) \right] \quad (3)$$

where sd is the spectral displacement and β_{ds_i} is the standard deviation of natural logarithm of the variable ds_i . 3) The expected seismic damage in buildings follows a binomial probability distribution. Figure 5 shows all fragility curves calculated after applying the described procedure.

Figure 5. Fragility curves as random variables.

Since the probabilities of occurrence of each state of damage are easily obtained from the fragility curves, one can calculate the expected damage index, DI , which is the normalized mean damage state, which can be interpreted as a measure of the overall expected damage in the structure.

$$DI = \frac{1}{n} \sum_{i=0}^n i P(ED_i) \quad (4)$$

where n is the number of damage states considered, in this case 4 and $P(ds_i)$ is the probability of occurrence of ds_i . Figure 6 shows the ID calculated from the fragility curves of Figure 5. The curves of Figure 6 can be interpreted as random vulnerability curves.

Figure 6. Damage index obtained starting from the PA as random variable.

4 DAMAGE INDEX BASED ON THE INCREMENTAL DYNAMIC ANALYSIS

Incremental dynamic analysis allows obtaining the dynamic response of a structure to an earthquake action. This earthquake is scaled to various PGA. As mentioned above, the purpose of this article is to compare the results obtained with the methodology based on the capacity spectrum with the incremental dynamic analysis. According to the probabilistic approach it is necessary to obtain the seismic action as a random variable. To do that, 20 earthquakes have been selected from two databases, one from Spain and the other from Europe, whose elastic response spectra are compatible with elastic response spectrum taken from Eurocode 8. In this case, the elastic spectrum type 1 and soil D is selected. Figure 9 shows the spectra of the selected earthquakes, their average value, and the spectrum type 1 soil D, taken from Eurocode 8.

Figure 7. Selected spectra of the accelerograms that are compatible with spectrum type 1 soil D of Eurocode 8.

After selecting the accelerograms, the dynamic response of the structure is calculated, for different PGA until a maximum of 0.32 g, at intervals of 0.04 g. In each run of the nonlinear dynamic analysis, the damage index proposed by Park & Ang [12] is calculated and, also, the maximum displacement at the roof of the building, allowing to compare these results with those obtained previously from static procedure. Figure 8 shows the results obtained with both methods, and shows that the damage index obtained with the procedure based on the PA is conservative compared to the results obtained with the procedure based on IDA. However, when the damage index is close to 1, similar values are obtained with both procedures. On the other hand, it can be seen in the curves obtained with the PA procedure that the structural damage begins for a smaller spectral displacement than in the case of the IDA procedure and that, in both cases, slopes are similar. This means that the PA curves are shifted respecting the IDA curves what could be easily adjusted by changing the damage states coefficients. It is important to note the large scatter in both cases, showing the importance of assessing the vulnerability of structures from a probabilistic perspective, whichever procedure is used.

Figure 8. Damage index obtained with static and dynamic procedures.

5 CONCLUSIONS

In this work, the vulnerability of a real reinforced concrete structure, with columns and waffle slab has been assessed, taking into account that the input variables are random. Two approaches to evaluate the vulnerability of the building have been used. The first one is based on the pushover analysis and the second one is based on the incremental dynamic analysis. An important conclusion is that, despite working with advanced structural analysis, these procedures show significant uncertainties when taking into account the randomness of the variables associated with the problem. It should be emphasized that in this work relatively small coefficients of variation for input variables have been considered taking into account the uncertainties that may exist in older structures that did not have quality control and have not been designed according to the earthquake-resistant criteria. An important conclusion is that the results obtained with the procedure based on the capacity curve are conservative when compared with the results obtained with the incremental dynamic analysis. However, within the procedure based on the capacity curve, there are factors such as those given in equation 2, which can be modified to improve the correlation with the results based on dynamic calculation. The main conclusion of this paper is that whichever the procedure is used to evaluate the vulnerability of a structure, it is important to note that the input variables, such as the mechanical properties of materials and the seismic action, are random variables and these generate large uncertainties in the seismic response, which can lead to overestimate or to underestimate the real damage that can occur in a structure.

Keywords: Distributed Seismicity, Diffused Seismicity, Seismic Area Source Zone, Fixed Kernel Technique, Adaptive Kernel Technique, Kernel Bandwidth, Peak Ground Acceleration, Uniform Hazard Spectra.

Abstract. *Peninsular India is known for its complex intraplate seismicity and the southern part of it is characterized by diffused and distributed seismicity. In such cases the most commonly adopted seismic source is the area source zone. The formation of seismic area source zone is subjective for regions such as south India and hence zonefree techniques to probabilistic hazard analysis have been carried out in the past. The zonefree technique specifically the kernel technique is still new and has been applied to specific sites in south India such as Chennai and Kanchipuram. In this study the fixed and adaptive kernel techniques have been applied to the whole of south India to obtain the hazard value. The most influencing parameter affecting the kernel technique has been varied in two ways - the bandwidth parameters determined for the whole earthquake catalogue of south India and the other by determining the bandwidth parameters for the earthquakes lying in an influence area of 300 km radius around a particular site. It was observed that the adaptive kernel technique yielded slightly higher hazard values in regions of high seismic activity and lower values in regions of low seismic activity. However both the techniques yielded similar results in regions of spatial uniform seismicity. A significant difference was observed in the uniform hazard spectra obtained for specific sites in south India when the bandwidth parameters were estimated considering whole of south India (regional) and an influence area of 300 km radius (local).*

1 INTRODUCTION

Seismic Hazard Analysis (SHA) is carried out to provide ground shaking values in the form of acceleration, velocity or displacement to determine the seismic input to be considered in the design of buildings. SHA is carried out in two ways – probabilistic or deterministic. In probabilistic seismic hazard analysis (PSHA), uncertainties in the earthquake location, magnitude and path of travel are considered. In deterministic seismic hazard analysis (DSHA), the ground shaking value is determined considering the worst case for location, magnitude and path of travel of the earthquake. This form of analysis is usually carried out for very important structures e.g. nuclear power plant facilities. However PSHA is the most commonly used form of hazard analysis; and the most widely used technique is the Cornell-McGuire approach [1, 2]. The first step in the conventional PSHA is the identification and characterization of the seismic sources. These sources may be in the form of point, line or area seismic source zone. The low to moderate seismicity regions are often characterized by diffused and distributed seismicity and hence the most common form of seismic source adopted is the area source zone.

The Cornell-McGuire approach to PSHA has been found to have several drawbacks when applied to some specific site conditions. These drawbacks are as follows:

1. Insufficient data to fit the G-R recurrence relation for low seismicity regions [3].
2. Difficulty in satisfying the homogeneity condition (b value constant) within an area source zone [4].
3. Areal extent of applicability of G-R recurrence law not known [5, 6].
4. Sudden change of seismicity at the zonal boundaries [7].
5. Expert knowledge of geology, seismology and tectonics required to form source zones [8, 9].

Probability theory provides several latest techniques of estimating the probability density function (PDF) for a given set of data viz. kernels, splines and wavelets. Hence, it is important to adopt new and also the most appropriate techniques available in probability theory in determining the density. Such techniques need to be implemented in seismic hazard analysis to help overcome some of the drawbacks of the conventional methodology.

2 KERNELS

Density estimation techniques can be broadly classified as parametric and nonparametric techniques. In the nonparametric techniques no prior assumption regarding the distribution is made, but is derived from the data in hand. The simplest technique under this category is the histogram and some latest techniques such as kernels, splines and wavelets can be found. Among the newer techniques, the kernel density estimation technique is the simplest one which consists of placing standard curves such as uniform, triangular, normal or quartic on each of the data point and the density is determined as the normalized sum of each of these individual kernels (Fig. 1).

Kernel density estimation technique has been popular in many areas of earthquake engineering such as hazard analysis [10], seismic occurrence rate determination [11], determination of influence area of an earthquake [12] and source size characterization to name a few. The kernel technique to seismic hazard analysis has already been applied to a few sites in south India such as Chennai [13, 14] and Kanchipuram [15] where the results matched well with the Cornell-McGuire approach.

There are two variables to be considered in kernel density estimation – shape of the kernel to be used and the spread of the kernel also known as the bandwidth or window width. Figure

Figure 1: Kernel density estimation concept.

2 shows the various forms of kernels being placed on individual data points (say 7, 8, 9, 12 and 14) and the final form of the PDF obtained. It can be concluded that the shape of the kernel does not play an important role as the final PDF obtained is insensitive to the form of kernels used. However there are several works by previous researchers [16, 17, 18] stressing the importance of the bandwidth. The optimal bandwidth to be used for a data set can be fixed across the data or can be varied. The former is called the fixed kernel density estimation technique while the latter is called the variable or adaptive kernel density estimation technique.

Figure 2: Various forms of kernels [de SMITH et al.¹⁹]

2.1 Fixed kernel density estimation technique

In the fixed kernel density estimation technique, the bandwidth or spread of the kernel function placed on the data are same across all the data. Consider the probability distribution of a random variable X given as

$$P(a \leq X \leq b) = \int_a^b f(x) dx \quad (1)$$

where $f(x)$ is the PDF, a and b are the selected lower and upper bounds. A univariate PDF from the fixed kernel technique is given as

$$f(x) = \frac{1}{nh} \sum_{i=1}^n K\left(\frac{x-x_i}{h}\right) \quad (2)$$

where n is the number of data or observation, h is the fixed bandwidth which controls the variance of the symmetric function $K((x-x_i)/h)$, x is any point and x_i is the data. A multivariate PDF in d -dimensional space from the fixed kernel technique is given as

$$f(x) = \frac{1}{nh^d} \sum_{i=1}^n K\left\{\frac{1}{h}(\mathbf{x} - \mathbf{x}_i)\right\} \quad (3)$$

The kernel K considered must satisfy the following conditions

$$\int_{R^d} K(t)dt = 1, \int_{R^d} tK(t)dt = 0, \text{ and } \int_{R^d} t^2 K(t)dt = k_2 \neq 0$$

and the unknown density f has a continuous derivatives of all orders required and the constant k_2 is the variance of K .

There are several methods of determining the optimal bandwidth in the literature [16, 17, 18] and are summarized as the least-square cross validation, biased cross validation, plug-in bandwidth selection, smoothened cross validation, root-n bandwidth selection and the contrast methods [20].

2.2 Adaptive kernel density estimation technique

In adaptive kernel density estimation technique the bandwidth is varied depending on the spatial location of the data. It follows the principle that smaller bandwidth is more appropriate in regions of high density since a larger number of samples enable a more accurate estimation of density in these regions. From Fig. 3a it can be observed that larger bandwidth leads to over smoothing whereas smaller bandwidth leads to spiky PDF (Fig. 3b). A larger bandwidth is more appropriate in low density areas where a few sample points are available.

Figure 3a: Large bandwidth kernels

Figure 3b: Small bandwidth kernels

The PDF from the adaptive kernel technique is determined as

$$f(\mathbf{x}) = \frac{1}{n} \sum_{i=1}^n \frac{1}{[h(\mathbf{x}_i)]^d} K\left\{\frac{1}{h(\mathbf{x}_i)}(\mathbf{x} - \mathbf{x}_i)\right\} \quad (4)$$

There are several techniques of varying the bandwidth, however in the present study, a three step procedure has been adopted [16] and is given as

1. Find a pilot estimate of $f(\mathbf{x})$ that satisfies $f(\mathbf{x}_i) > 0$ for all i
2. Define local bandwidth factor λ_i by

$$\lambda_i = \{f(\mathbf{x}_i) / g\}^{-\alpha} \quad (5)$$

where g is the geometric mean of $f(\mathbf{x}_i)$ given as

$$\log g = n^{-1} \sum \log f(\mathbf{x}_i) \quad (6)$$

and α is the sensitivity parameter ($0 \leq \alpha \leq 1$).

3. Define the adaptive kernel estimate $f(\mathbf{x})$ by

$$f(\mathbf{x}) = n^{-1} \sum_{i=1}^n h^{-d} \lambda_i^{-d} K\{h^{-1} \lambda_i^{-1} (\mathbf{x} - \mathbf{x}_i)\} \quad (7)$$

where h is the global bandwidth.

When α is 0, the estimate reduces to fixed kernel and a value closer to 1 causes the estimate to become more sensitive to the variation in bandwidth from point to point. A value of $\alpha = 0.5$ has been proven to give good results [16, 21]. The above three step procedure has been used to arrive at the earthquake occurrence model by smoothing the annual activity for Australia and New Zealand [11].

2.3 Implementation of kernels in seismic hazard analysis

In PSHA, the mean annual rate of exceedance λ_{y^*} of the selected ground motion parameter Y (acceleration, velocity or displacement) exceeding a particular value y^* is given by

$$\lambda_{y^*} = \sum_{i=1}^{N_s} \sum_{j=1}^{N_M} \sum_{k=1}^{N_R} v_i P[Y > y^* | m_j, r_k] P[M = m_j] P[R = r_k] \quad (8)$$

where N_s is the number of sources, N_M is the range of magnitudes, N_R is all the possible range of distances from site to source, v_i is the seismicity rate for each source defined by the G-R recurrence law, $P[Y > y^* | m_j, r_k]$ is obtained from the attenuation relationship, $P[M = m_j]$ and $P[R = r_k]$ are obtained from the probability density function of magnitude and distance respectively. In kernel approach, the seismicity rate v_i is replaced by the spatial activity rate density function given as

$$v(M, x) = \sum_{i=1}^N \frac{K(M, x - x_i)}{T_i} \quad (9)$$

where N is the number of earthquake events, x is the observation/estimation point and T_i is the effective return period evaluated using the following expression:

$$T_i = \text{Timeperiod} \sum_i p_i \quad (10)$$

where p_i is the detection probability of the event in a particular time period and a numerical value is assigned to it based on the seismicity of the region.

An anisotropic kernel form used for earthquakes [22] is given as

$$K(M, r) = \frac{n-1}{\pi h^2(M)} \frac{1 + \delta \cos^2 \phi}{1 + (\delta/2)} \left(1 + \left(\frac{r}{h(M)} \right)^2 \right)^{-n} \quad (11)$$

where n is the exponent of the power law or fractal scaling index taking value between 1.5 and 2, h is the bandwidth and is a function of magnitude, r is the distance to the epicentre, the parameter ϕ is the angle subtended at r between the intersection of the fault plane with the

earth's surface and the epicentre location and δ is the degree of anisotropy taking value between 0 and 2. A value of zero indicates isotropy and higher value signifies anisotropy. Anisotropic kernel is useful when the activity rate associated with a fault needs to be determined. However in this study, isotropic kernel was used since most parts of south India are known for distributed seismicity.

The most important step in kernel technique is to arrive at an optimal bandwidth keeping in mind the earthquake phenomenon. For this the power law which takes into consideration the fractal behaviour of the earthquakes is used [10] and is given as

$$h(M) = ce^{(dM)} \quad (12)$$

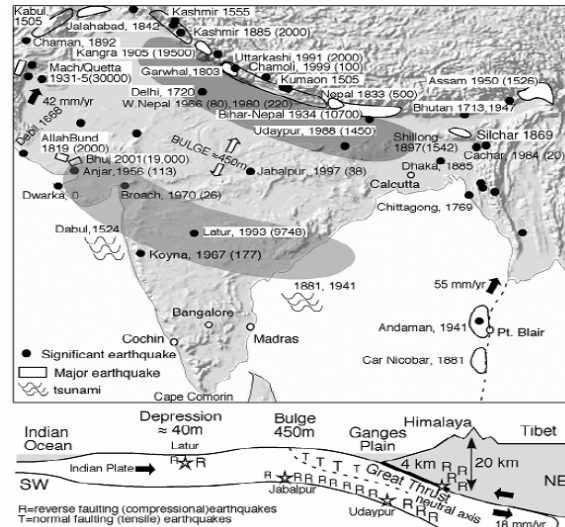

where parameters c and d depend on the spatial distribution of earthquake epicentres. These parameters are calculated by forming various magnitude bins and for each earthquake event within the bin, the distance to the nearest epicentre is determined. The mean nearest distance for each bin is obtained and through a least-square fit between the magnitude and bandwidth, the parameters c and d are obtained.

It has been observed by previous studies [23, 24] that the fixed kernel technique yields similar results for low to moderate seismicity regions and lower values in high seismicity regions when compared to the Cornell-McGuire approach. The adaptive kernel technique has been used to determine the seismic hazard for Chennai City [14]. It is concluded that the adaptive technique yielded similar results to the fixed kernel technique since Chennai city lies in low to moderate seismicity region and it needs to be tested for other regions. Hence in this study an attempt has been made to evaluate the suitability of the kernel techniques to the other regions of south India and on a much larger scale.

3 GEOLOGY, SEISMOLOGY AND TECTONIC SETTINGS OF SOUTH INDIA

South India mainly consists of four states – Andhra Pradesh, Karnataka, Kerala and Tamil Nadu lie on Deccan Trap which is a part of Peninsular India. The movement of the Indian plate northward from rest of the Gondwana over geologic hotspots caused the melting of the Indian craton underneath. The melting broke out on the surface of the craton creating the Deccan Trap. Hence the Deccan Trap was formed as a result of sub-aerial volcanic activity during the Mesozoic era. Peninsular India is one of the oldest land masses of the earth's crust and is the most stable Precambrian Shield subjected to tectonic and orogenic activities in its subsequent geological history. The region is bounded by Western Ghats (WG) along the coast line and similarly the Eastern Ghats (EG) on the eastern coast line.

Seismically south India has experienced less seismic activity and the earthquakes are due to intraplate seismicity and hence are very complex. Although several faults have been identified in the region [25, 26], there movement has not been recorded. Hence the seismicity is distributed in nature and also diffused. There are several anomalies regarding the seismicity of this region. Wang et al.²⁷ noted that there is no major deformation of the Peninsular region based on the velocity reading observed at two stations – one located in the northern Ganges plain and the other in Bengaluru located in Karnataka state and hence no major seismic activity. Bilham²⁸ on the other hand noted that the Indian plate has undergone sufficient flexure (Fig. 4) resulting in major earthquakes such as Koyna ($M_w = 6.3$, 1967), Latur ($M_w = 6.1$, 1993), Jabalpur ($M_w = 5.8$, 1997) and Bhuj ($M_w = 7.7$, 2001) in Peninsular India. However most of the earthquakes that have occurred in south India are mild and shallow-depth earthquakes. The average focal depths of the earthquakes in these regions are within the upper-crustal (0-12 km) layers complying with the depth of the Moho varying from 34 to 41 km beneath the region of southern India [27].

Figure 4: Schematic views of Indian tectonics [Bilham²⁸]

The India tectonic plate is currently penetrating into the Eurasian plate at a rate of approximately 45 mm/year along with an anticlockwise rotation in the Indian plate (Fig. 5).

Figure 5: Tectonic map of the northern Indian plate [Biswas and Majumdar³⁰]

South India's major tectonic features are seen in Fig. 6. A major compression zone lying over the transition zone running from Mulki in the west to Pulicat late located on the east has been observed [31]. It has been formed due to the continuous spreading of the sea floor in the Indian Ocean. This zone acts has a major block and hence numerous earthquakes of smaller magnitude are observed around this region. However major earthquakes are observed north of this zone (Latur, Jabalpur). The Southern Granulite Terrain (SGT) Craton has several lineaments and notable earthquakes have occurred in this region (Coimbatore and Pondicherry). The Caddapah Basin forms part of the extended stable continental region and consists of the Pampar lineament and the east-west trending Tiruttani swarms of lineaments.

Figure 7: Epicentre distribution and analysis area for south India.

Magnitude (M_w)	Bandwidth (H) in km
3.75	27.0575
4.25	43.4948
4.75	68.4529
5.25	117.5171
5.75	287.4365
6.25	501.6688

Table 1: Bandwidth for magnitude bins.

Figure 8 shows the bandwidth parameters obtained from the curve. The reference year was determined by assigning various probability of detection for each magnitude bin separately for onshore and offshore earthquakes.

Figure 8: Magnitude-bandwidth relation to estimate the parameter c and d.

As an example the probability of detection for magnitude bin 4.0 to 4.49 for both onshore and offshore earthquakes is given in Table 2. The reference year so obtained is summarized in Table 3.

Time period (D_i)	Onshore		Offshore	
	Probability (p_i)	Effective return period ($p_i D_i$)	Probability (p_i)	Effective return pe- riod ($p_i D_i$)
1000 - 1500	0.05	25	0.005	2.5
1500 - 1800	0.15	45.00	0.05	15.00
1800 - 1850	0.25	12.50	0.15	7.50
1850 - 1900	0.35	17.50	0.25	12.50
1900 - 1950	0.50	25.00	0.30	15.00
1950 - 1960	0.60	6.00	0.50	5.00
1960 - 1970	0.75	7.50	0.65	6.50
1970 - 1980	0.85	8.50	0.75	7.50
1980 - 1985	0.88	4.40	0.80	4.00
1985 - 1990	0.92	4.60	0.85	4.25

1995 - 2000	0.98	4.90	0.95	4.75
2000 - 2005	0.98	4.90	0.98	4.90
2005 - 2008	0.98	2.94	0.98	2.94

Table 2: Probability assignment for various time periods.

Magnitude bin (M_w)	Reference year	
	Onshore	Offshore
> 6.0	1639	1764
5.5 - 5.99	1687	1836
5.0 - 5.49	1736	1860
4.5 - 4.99	1785	1884
4.0 - 4.49	1835	1914
3.5 - 3.99	1882	1951

Table 3: Reference year for each magnitude bin.

4.2 Attenuation relationship

The ground motion parameter gets attenuated from source to site. The resulting ground motion at the site is determined using the attenuation relationship. These attenuation relationships are empirical equations which estimate the ground motion parameter as a function of independent parameters characterizing the earthquake and the site.

The attenuation relationship suggested by the Working Committee of Experts for micro-zonation of the Indian landmass formed by the National Disaster Management Authority (Iyengar et al.)³⁵ was used. The functional form of the attenuation relationship is

$$\ln\left(\frac{S_a}{g}\right) = C_1 + C_2 M + C_3 M^2 + C_4 r + C_5 \ln(r + C_6 e^{C_7 M}) + C_8 \log(r) f_0 \quad (13)$$

where S_a is the spectral acceleration, r is the hypocentral distance in kilometers, M is the earthquake moment magnitude and $f_0 = \max(\ln(r/100), 0)$. The attenuation relationship accounts for geometrical spreading, anelastic attenuation and magnitude saturation. The attenuation coefficients for different regions can be used to construct the mean and response spectrum on A-type rock in any part of India. It was developed from a simulated database of 80,000 samples by a two step stratified regression following Joyner and Boore³⁶ approach. However, in the present study, the coefficients calculated for south India were used.

5 RESULTS AND DISCUSSION

The hazard was estimated by forming a grid of $0.5^\circ \times 0.5^\circ$ over the study region (4.667°N to 17.889°N and 70.409°E to 85.687°E). At every grid point, an influence area of 300 km radius was considered and all earthquakes lying within this area were considered for analysis. The density was estimated at every 10 km. The minimum cut-off magnitude considered for hazard analysis was $M_w = 4.0$. Magnitude uncertainty of ± 0.49 was considered for every magnitude. The PGA obtained for 475 years return period from the fixed kernel technique considering bandwidth parameters calculated for the whole south Indian region is shown in Fig. 10a. Similarly the PGA obtained for 475 years return period from the adaptive kernel technique is shown in Fig 10b.

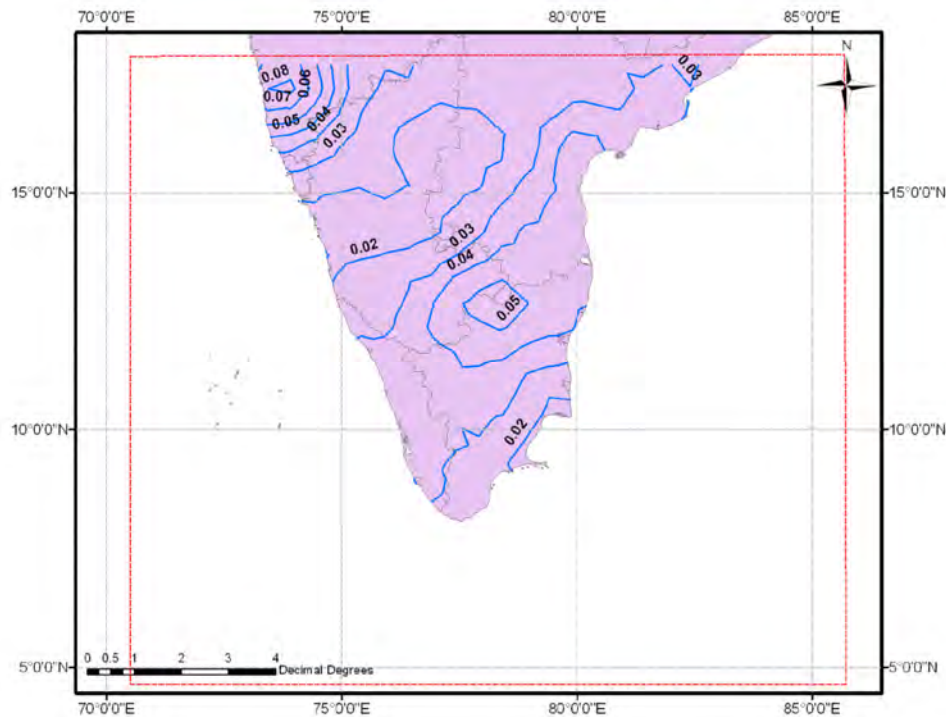

Figure 10a: PGA for 475 years return period by fixed kernel technique

It can be seen that the PGA values marginally differ among the two kernel techniques. Also the hazard value obtained for 475 years return period is quite low when compared to previous studies carried out for a few regions of the study area. Table 4 presents the PGA values for Chennai, Bengaluru, Koyna and Ongole for 475 years return period.

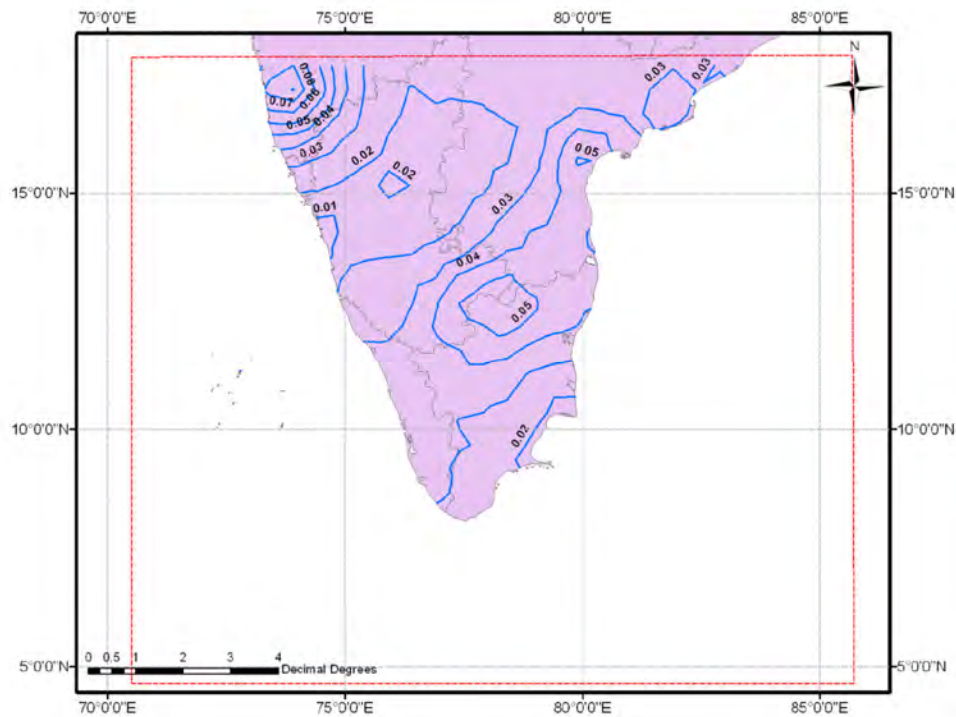

Figure 10b: PGA for 475 years return period by Adaptive kernel technique

Site	Studies	PGA (g)
Chennai	Iyengar et al. ³⁵	0.06
	Ramanna and Dodagoudar ^{13,14}	0.08
	Fixed kernel (present study)	0.04
	Adaptive kernel (present study)	0.04
	Jaiswal and Sinha ³⁹	0.03
	IS 1893:2002 ³⁷	0.08
Bengaluru	Iyengar et al. ³⁵	0.03
	Vipin et al. ³⁸	0.10
	Fixed kernel (present study)	0.05
	Adaptive kernel (present study)	0.05
Koyna	Iyengar et al. ³⁵	0.12
	Jaiswal and Sinha ³⁹	0.2
	Fixed kernel (present study)	0.07

Table 4: PGA for various regions in south India from previous studies

The UHS were determined for the selected regions by calculating the bandwidth parameters considering the earthquake epicentres lying within the influence area of 300 km radius

from the site. The bandwidth parameters so obtained for four different sites are summarized in Table 5.

Site	c	d
Site 1	0.4616	0.9678
Site 2	0.9441	0.8459
Site 3	0.3013	0.9227
Site 4	3.5285	0.4675

Table 5: Bandwidth parameters for various sites

The UHS for these sites are shown in Fig. 11a to 11d. It can be observed that there exist large differences in spectral values due to change in the way the bandwidth parameters were determined. For Site 1 a percentage difference in peak spectral value of 8% (percentage calculated with respect to fixed technique) is seen between the kernel techniques irrespective of whether the parameter was determined at local level or regional level. However a difference of 10% (percentage calculated with respect to local parameters) was observed in the peak spectral value for fixed technique when the bandwidth parameters were varied. For adaptive technique

Figure 11a: Impact on UHS for Site 1

Figure 11b: Impact on UHS for Site 2

Figure 11c: Impact on UHS for Site 3

Figure 11d: Impact on UHS for Site 4

a difference of 16.5% (percentage calculated with respect to local parameters) was observed in the peak spectral value when the parameters were varied. The % difference in the peak spectral values for all the four sites are summarized in Table 6.

Site	% Difference between fixed and adaptive kernel techniques		% Difference between local and regional parameters	
	Using local parameters	Using regional parameters	for fixed technique	for adaptive technique
Site 1	8	8	10	16.5
Site 2	17.5	10	18	23
Site 3	9	11.5	40	38
Site 4	15.4	7	40	45

Table 6: Impact on peak spectral acceleration

6 CONCLUSIONS

Seismic hazard analysis has been carried out for whole of south India using the fixed kernel and adaptive kernel technique. It was found that the hazard results varied among the kernel and adaptive kernel technique in regions of very high seismic activity and in regions of very low seismic activity. In regions of very high seismic activity, the adaptive kernel technique resulted in slightly higher results (Ongole and Koyna) and in regions of low seismicity, it yielded lower values (Northern Karnataka region) when compared to fixed kernel technique. Further the impact on the hazard value by varying the bandwidth parameter was analyzed. An important observation was made that there was significant difference in the hazard values when the bandwidth parameter was calculated for smaller region (regional seismicity) and larger region (south India catalogue). The difference was more noticeable for Site 3 and Site 4. Hence it is very important to carry out further study on the influence of the bandwidth parameter on the seismic hazard analysis. With regards to the technique, the adaptive kernel technique is more appropriate kernel technique since it takes into consideration the spatial clustering of the earthquake epicentres.

Keywords: equivalent SDOF model, saddle form cable net, nonlinear dynamic response, similarity relations.

Abstract. *The purpose of this paper is to estimate the geometrically nonlinear dynamic behavior of a saddle form cable net, using an equivalent single-degree-of-freedom model. First, a symmetric simple cable net is assumed, consisting of two crossing cables, considering the vertical displacement of the central node as the only degree of freedom. The equation of motion is found to be similar to the one of the Duffing oscillator with a hardening cubic term. Next, a MDOF symmetric cable net model is considered, with fixed cable ends, having a circular plan view and forming a surface of a hyperbolic paraboloid. Harmonic external loads act vertically on every node of the net, with the same amplitude and time variation. Modal analyses are conducted in order to calculate the linear eigenfrequencies and the corresponding eigenmodes of the network. The nonlinear dynamic response of the cable net is obtained by performing time history analysis. Detecting nonlinear phenomena, such as bending of the response curve, jump phenomena, different response amplitudes according to the initial conditions, superharmonic or subharmonic resonances, demands much computational effort for different load amplitudes and ratios of loading frequency. Based on a method of approximate analysis for prediction of the response of cable nets, the MDOF model is transformed to an equivalent SDOF one, using similarity relations. The analytical solution of the single-degree-of-freedom model can provide, with minimum computational time, the basic information needed for nonlinear dynamic response, i.e. secondary resonances, jump phenomena, dependence on the initial conditions and the exact loading frequency for which the maximum steady state oscillation amplitude is obtained. The comparison between the two models by means of the steady state amplitude of the central node, demonstrates that the behavior of the SDOF model describes satisfactorily the one of the MDOF model, predicting the dominant nonlinear phenomena.*

1 INTRODUCTION

Nonlinear phenomena, such as superharmonic or subharmonic resonances, bending of the response curve and jump phenomena, as well as response amplitudes dependent on the initial conditions, that occur in nonlinear systems [1], are very difficult to be detected in a multi-degree-of-freedom system. The only way to plot a response curve, which can show if the above phenomena take place, is by conducting a large number of nonlinear time history analyses, for different closely spaced load amplitudes and frequencies, but this is a time consuming procedure requiring much computation effort.

The idea of solving an equivalent SDOF system to estimate the dynamic response of a complex structure has been adopted by many researchers ([2]-[9]). This idea is based on equating the energy of the real structure to the one of the SDOF system. Ensuring equal displacements and velocities in both systems, the kinematic similarity is maintained. This approach has the advantage that the equation of motion for a SDOF oscillator can be solved analytically. Hence, it is possible to determine the range of the parameters that influence the dynamic response of the system. On the other hand, it is impossible to assess the overall response of the MDOF system, because the simulation is obtained only in the main direction of motion, neglecting the other two dimensions of the large structure.

Another method of reducing the dimensions of a large scale event, using a smaller one with similar characteristics, is a method based on the Buckingham Pi theorem [10]. This theorem states that if an equation involves a number of variables and k fundamental measurement units, then the equation can be expressed in terms of k fewer arguments that are non-dimensional ratios of the original variables. The concept is based on the notion that an equation must be dimensionally homogeneous, that is, its solution must be invariant to any change in the system of measurement units employed. This technique has been used to design small scale experiments in order to simulate with accuracy large scale phenomena.

Gero ([11], [12]), inspired by this theorem, presented a method to estimate the static behaviour of a large cable net, using charts that describe the behaviour of a smaller one, by means of the maximum deflection and cable tension. The transformation of the large structure to the smaller one was obtained by similarity relations. The proposed method was restricted to nets with fixed cable edges. The two networks should have similar geometries, with the same sag-to-span ratio, so that their corresponding quantities could also be similar.

This latter method was extended by the authors of the present paper to elastically supported cable network structures, by taking into account the characteristics of the edge ring, and more specifically its flexural stiffness $E_r I_r$ ([13] - [15]). Thus, the ring was no longer considered rigid, but elastically deformable, accounting for more realistic boundary conditions for the cables. Additional charts and similarity relations were provided for the preliminary design of the edge ring, including the sag-to-span ratio of the net as a variable in the transformation relations. This method was further developed for the case of dynamic response [16], providing additional similarity relations for the mass and the natural frequency of the system, for the case of fixed cable ends.

This preliminary design method is used in the present work to transform a MDOF cable net, called prototype, into an equivalent SDOF cable net, called model, in order to solve analytically the equation of motion, and thus have the possibility to detect nonlinear phenomena and estimate the nonlinear dynamic response of the large structure. The analytical solution, which plots the steady state amplitude of the equivalent SDOF model, is compared with the steady state response of the MDOF system, obtained numerically. The accuracy of the method is evaluated by means of a numerical example.

2 PROTOTYPE AND MODEL ASSUMPTIONS

The cable net used as prototype, has a diameter $L_p=100\text{m}$ and sag-to-span ratio equal to $f_p/L_p=1/35$ ($f_p=2.857\text{m}$), while the number of cables in each direction is $N_p=25$ (Figure 1). The Young modulus is assumed equal to $E_p=165\text{GPa}$. The unit weight of the cables is taken equal to $\rho_p=100\text{kN/m}^3$, which corresponds to a concentrated mass on every node equal to:

$$M_p = \frac{2A_p \rho_p L_p}{g(N_p + 1)} = 0.151 \text{ kN sec}^2 \text{ m}^{-1} \quad (1)$$

Uniform harmonic loads, expressed as $P_p(t)=(P_0)_p \cos \Omega_p t$, are assumed to be exerted vertically on every node of the net, having the same amplitude and time variation. The maximum permissible cable stress is assumed equal to the yield stress of the material. In this work the yield stress is assumed equal to 1570MPa considering one of the two most common categories of steel for cables $1570/1770\text{MPa}$. The oscillation of the central node of the net will be used to describe the response of the net. Raleigh damping [17] is also introduced taking into account damping ratio equal to $\zeta_p=2\%$, which is a common value for such structures [18]. The subscript p refers to the prototype.

Figure 1: Geometry of the prototype

The model utilized as the equivalent SDOF system consists of two crossing cables ($N_m=1$), with a concentrated mass at the central node M_m . In order to minimize the scaling error, the model has the same sag-to-span ratio f_m/L_m , cable span L_m , and Young modulus E_m with the prototype. A harmonic load, expressed as $P_m(t)=(P_0)_m \cos \Omega_m t$, is exerted vertically on the central node (Figure 2). The subscript m refers to the model.

Figure 2: Geometry of the model

3 SIMILARITY RELATIONS

The relations that are used in this work for the transformation of the large cable net (prototype), to the simple one (model), are based on the ones given in [16], for a cable net with fixed cable ends. Taking into account that the sag-to-span ratio, the cable span and the Young modulus are the same for both the prototype and the model, the similarity relations that will be used are the following:

$$(P_0)_m = (P_0)_p \left(\frac{N_p + 1}{N_m + 1} \right)^2 \quad : \text{nodal load amplitude} \quad (2)$$

$$D_m = D_p \sqrt{\left(\frac{N_p + 1}{N_m + 1} \right)} \quad : \text{cable diameter} \quad (3)$$

$$A_m = A_p \left(\frac{N_p + 1}{N_m + 1} \right) \quad : \text{cable cross-sectional area} \quad (4)$$

$$(EA)_m = (EA)_p \left(\frac{N_p + 1}{N_m + 1} \right) \quad : \text{cable axial stiffness} \quad (5)$$

$$(N_0)_m = (N_0)_p \left(\frac{N_p + 1}{N_m + 1} \right) \quad : \text{cable initial pretension} \quad (6)$$

$$M_m = M_p \left(\frac{N_p + 1}{N_m + 1} \right)^2 \quad : \text{nodal mass} \quad (7)$$

$$w_m = w_p \quad : \text{nodal deflection} \quad (8)$$

$$\omega_m = \omega_p \quad : \text{natural frequency} \quad (9)$$

where N is the number of cables per direction and E the elastic modulus of the cables, while the subscripts m and p refer to the model and the prototype, respectively. Two more relations are added, describing the loading frequency and the damping ratio:

$$\Omega_m = \Omega_p = \Omega \quad : \text{loading frequency} \quad (10)$$

$$\zeta_m = \zeta_p = \zeta \quad : \text{damping ratio} \quad (11)$$

4 ANALYTICAL SOLUTION FOR THE MODEL

4.1 Equation of motion

In this section, the analytical equation of motion of the simple cable net, which consists the model of the method, is derived. The initial pretension is introduced as initial elongation $\varepsilon_{0,m}$ to all cable segments, which, according to Hook's law, is equal to:

$$(N_0)_m = (EA)_m \varepsilon_{0,m} \quad (12)$$

S_N is the length of each segment at the equilibrium state under pretension, given as:

$$S_N = \sqrt{(L_m/2)^2 + f_m^2} \quad (13)$$

The initial length S_0 for all segments is equal to:

$$\frac{S_N - S_0}{S_0} = \varepsilon_{0,m} \Rightarrow S_0 = \frac{S_N}{1 + \varepsilon_{0,m}} = \frac{S_N}{1 + \frac{(N_0)_m}{(EA)_m}} \quad (14)$$

If the vertical displacement of the central node is defined as w_m , the deformed lengths of the cable segments are given as:

$$S_{1,2} = \sqrt{(L_m/2)^2 + (f_m + w_m)^2}, \quad S_{3,4} = \sqrt{(L_m/2)^2 + (f_m - w_m)^2} \quad (15)$$

The cable tension for each deformed segment is expressed as:

$$(N_i)_m = (EA) \left(\frac{S_i - S_0}{S_0} \right) = (N_0)_m + (EA)_m \left(\frac{S_i - S_N}{S_0} \right), \quad i=1,2,3,4 \quad (16)$$

Their components, referring to the global axes, are calculated as:

$$\begin{aligned} (N_{1,2x})_m &= (N_{1,2})_m \cdot (L_m/2) / (S_{1,2}), & (N_{1,2z})_m &= \pm (N_{1,2})_m \cdot (f_m + w_m) / (S_{1,2}) \\ (N_{3,4y})_m &= (N_{3,4})_m \cdot (L_m/2) / (S_{3,4}), & (N_{3,4z})_m &= \pm (N_{3,4})_m \cdot (w_m - f_m) / (S_{3,4}) \end{aligned} \quad (17)$$

The sum of forces at the central node, referring to the x, y, z global axes, are:

$$(N_x)_m = (N_y)_m = 0, \quad (N_z)_m = (N_{1z})_m - (N_{2z})_m + (N_{3z})_m - (N_{4z})_m \quad (18)$$

Differentiating Eq. (18) with respect to w_m , and considering zero displacement for the unforced and undeformed state, the stiffness coefficient at the prestressed equilibrium state is:

$$K_m = \frac{4(EA)_m}{L_m} \cdot \frac{\left(8 \frac{f_m^2}{L_m^2} + 2 \frac{(N_0)_m}{(EA)_m} + 8 \frac{(N_0)_m}{(EA)_m} \frac{f_m^2}{L_m^2} \right)}{\sqrt{\left(1 + 4 \frac{f_m^2}{L_m^2} \right)^3}} \quad (19)$$

In case a dynamic vertical load $P_m(t)$ is applied on the central node, the equation of motion of this node is expressed in the equilibrium state:

$$M_m \ddot{w}_m + C \dot{w}_m + (N_{1z})_m - (N_{2z})_m + (N_{3z})_m - (N_{4z})_m = P_m(t) \quad (20)$$

The damping C is a function of the damping ratio ζ , expressed as [17]:

$$C = \zeta \cdot C_{cr} = 2\zeta M_m \omega_m \quad (21)$$

where ω_m is the natural frequency of the system.

If the dynamic load is expressed as $P_m(t) = (P_0)_m \cos \Omega t$, substituting the expressions of the tension of the cables, given by Eq. (16) and the prestressed, initial and deformed lengths, given by Eqs. (13) - (15), into the vertical components of the cable tensions (Eq. (17)), the differential equation (20) becomes:

$$\begin{aligned} M_m \ddot{w}_m + C \dot{w}_m - \frac{4(EA)_m (f_m + w_m)}{L_m \sqrt{1 + 4 \frac{(f_m + w_m)^2}{L_m^2}}} + \\ + \frac{4(EA)_m (f_m - w_m)}{L_m \sqrt{1 + 4 \frac{(f_m - w_m)^2}{L_m^2}}} + \frac{4w_m ((EA)_m + (N_0)_m)}{L_m \sqrt{1 + 4 \frac{f_m^2}{L_m^2}}} = P_m(t) \end{aligned} \quad (22)$$

Taking into account that the sag-to-span ratio f/L is usually very small for actual cable nets, allowing thus to neglect its second, third or higher powers, Eq. (22), developed in Taylor series, reduces to:

$$\begin{aligned} M_m \ddot{w}_m + C \dot{w}_m + \frac{16(EA)_m w_m^3}{L_m^3} + \\ + \frac{4(EA)_m}{L_m} \cdot \left(8 \frac{f_m^2}{L_m^2} + 2 \frac{(N_0)_m}{(EA)_m} - 4 \frac{(N_0)_m}{(EA)_m} \frac{f_m^2}{L_m^2} \right) w_m = P_m(t) \end{aligned} \quad (23)$$

Expanding the expression of the stiffness K_m , given by Eq. (19), in Taylor series with respect to the term f/L and neglecting terms of $(f/L)^4$, leads to:

$$K_m = \frac{4(EA)_m}{L_m} \cdot \left(8 \frac{f_m^2}{L_m^2} + 2 \frac{(N_0)_m}{(EA)_m} - 4 \frac{(N_0)_m}{(EA)_m} \frac{f_m^2}{L_m^2} \right) \quad (24)$$

Thus, Eq. (23) can be rewritten as:

$$\ddot{w}_m + \frac{C}{M_m} \dot{w}_m + \frac{K_m}{M_m} w_m + \frac{16(EA)_m}{M_m L_m^3} w_m^3 = \frac{(P_0)_m}{M_m} \cos(\Omega t) \quad (25)$$

where a nonlinear cubic term appears with a coefficient depending on the modulus of elasticity of the cable material, the cable cross-section area and the span of the cables.

Nayfeh and Mook [19] thoroughly explored the equation:

$$\ddot{w} + 2\epsilon\mu\dot{w} + \omega_0^2 w + \epsilon\alpha w^3 = K \cos(\Omega t) \quad (26)$$

known as the equation of motion referring to a forced damped Duffing oscillator, with μ being positive, and the coefficient of the nonlinear term α being either positive (hard spring) or negative (soft spring). The equation of motion of the simple cable net, described by Eq. (25), can take the form of Eq. (26), with positive coefficient of the nonlinear term and become:

$$\ddot{w}_m + 2\epsilon\mu\dot{w}_m + \omega_m^2 w_m + \epsilon\alpha w_m^3 = p_m \cos(\Omega t) \quad (27)$$

where:

$$\epsilon\mu = \zeta\omega_m \quad (28)$$

$$\omega_m = \sqrt{\frac{4(EA)_m}{M_m L_m} \cdot \left(8 \frac{f_m^2}{L_m^2} + 2 \frac{(N_0)_m}{(EA)_m} - 4 \frac{(N_0)_m}{(EA)_m} \frac{f_m^2}{L_m^2} \right)} \quad (29)$$

$$\varepsilon\alpha = \frac{16(EA)_m}{M_m L_m^3} \quad (30)$$

$$p_m = \frac{(P_0)_m}{M_m} \quad (31)$$

The parameter ε is assumed to be small and dimensionless, with $\varepsilon < 1$, defining the small scale of the coefficients of the velocity and the cubic term in the equation of motion with respect to the one of the linear term. The exact value of this parameter is not important, because the solution of the problem is independent of ε . It depends only on the parameters $\varepsilon\mu$ and $\varepsilon\alpha$, as defined in Eqs. (28) and (30), respectively, meaning that the parameter ε never appears alone in the solution. In what follows the main features of the investigation of the Duffing oscillator are reported from [19].

4.2 Fundamental resonance

In case of fundamental resonance the excitation is assumed to be weak, in order to prove that a weak excitation produces large scale oscillations. The small amplitude of the load is expressed as:

$$\varepsilon p = \frac{(P_0)_m}{M_m} \quad (32)$$

For fundamental resonant conditions, the steady state response is given as:

$$w(t) = a \cos(\Omega t - \gamma) \quad (33)$$

where Ω is the loading frequency expressed as:

$$\Omega = \omega_m + \varepsilon\sigma \quad (34)$$

with $\varepsilon\sigma$ a frequency detuning, which, for a given amplitude of the response, is calculated by the following equation:

$$\sigma = \frac{3\alpha a^2}{8\omega_m} \pm \sqrt{\frac{p^2}{4\omega_m^2 a^2} - \mu^2} \Rightarrow \varepsilon\sigma = \frac{3\varepsilon\alpha a^2}{8\omega_m} \pm \sqrt{\frac{(\varepsilon p)^2}{4\omega_m^2 a^2} - (\varepsilon\mu)^2} \quad (35)$$

Taking into consideration Eqs. (28), (30) and (32), Eq. (35) can be rewritten as:

$$\varepsilon\sigma = \frac{6a^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} \pm \sqrt{\frac{(P_0)_m^2}{4M_m^2 \omega_m^2 a^2} - (\zeta\omega_m)^2} \quad (36)$$

4.3 Superharmonic resonance

For superharmonic resonant conditions, the steady state response is given as:

$$w(t) = a \cos(3\Omega t - \gamma) + \frac{(P_0)_m}{M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) \cos \Omega t \quad (37)$$

The loading frequency is expressed as:

$$3\Omega = \omega_m + \varepsilon\sigma \quad (38)$$

For a given amplitude of the free oscillation term a , the frequency detuning is calculated by:

$$\begin{aligned} \sigma &= \frac{3\alpha\Lambda^2}{\omega_m} + \frac{3\alpha a^2}{8\omega_m} \pm \sqrt{\frac{\alpha^2\Lambda^6}{\omega_m^2 a^2} - \mu^2} \Rightarrow \\ \Rightarrow \varepsilon\sigma &= \frac{48\Lambda^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} + \frac{6a^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} \pm \sqrt{\frac{\Lambda^6}{\omega_m^2 a^2} \cdot \left(\frac{16(EA)_m}{M_m L_m^3}\right)^2 - (\zeta\omega_m)^2} \end{aligned} \quad (39)$$

where

$$\Lambda = \frac{(P_0)_m}{2M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) \quad (40)$$

4.4 Subharmonic resonance

In case of subharmonic resonance, the loading frequency is expressed as:

$$\Omega = 3\omega_m + \varepsilon\sigma \quad (41)$$

For a given detuning $\varepsilon\sigma$, subharmonic solutions with non trivial amplitudes ($a \neq 0$) exist only if:

$$\begin{aligned} \frac{\sigma}{\mu} - \sqrt{\frac{\sigma^2}{\mu^2} - 63} &\leq \frac{63\alpha}{4\omega_{z0}\mu} \Lambda^2 \leq \frac{\sigma}{\mu} + \sqrt{\frac{\sigma^2}{\mu^2} - 63} \Rightarrow \\ \frac{\varepsilon\sigma}{\zeta\omega_m} - \sqrt{\frac{(\varepsilon\sigma)^2}{(\zeta\omega_m)^2} - 63} &\leq \frac{256\Lambda^2}{\zeta\omega_m^2} \cdot \frac{(EA)_m}{M_m L_m^3} \leq \frac{\varepsilon\sigma}{\zeta\omega_m} + \sqrt{\frac{(\varepsilon\sigma)^2}{(\zeta\omega_m)^2} - 63} \end{aligned} \quad (42)$$

where Λ is given by Eq. (40), while for a given Λ subharmonic solution with non trivial amplitudes ($a \neq 0$) exist if:

$$\sigma \geq \frac{63\alpha}{8\omega_m} \Lambda^2 + \frac{2\omega_m}{\alpha} \frac{\mu^2}{\Lambda^2} \Rightarrow \varepsilon\sigma \geq \frac{126\Lambda^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} + \frac{M_m L_m^3}{8(EA)_m} \frac{\zeta^2 \omega_m^3}{\Lambda^2} \quad (43)$$

with amplitude given by:

$$\begin{aligned} a^2 &= \left(\sigma \frac{8\omega_m}{9\alpha} - 6\Lambda^2 \right) \pm \sqrt{\left(\sigma \frac{8\omega_m}{9\alpha} - 6\Lambda^2 \right)^2 - \frac{64\omega_m^2}{81\alpha^2} \left[\left(\sigma - \frac{9\alpha\Lambda^2}{\omega_m} \right)^2 + 9\mu^2 \right]} \Rightarrow \\ \Rightarrow a^2 &= \left(\varepsilon\sigma \frac{\omega_m M_m L_m^3}{18(EA)_m} - 6\Lambda^2 \right) \pm \\ &\pm \sqrt{\left(\varepsilon\sigma \frac{\omega_m M_m L_m^3}{18(EA)_m} - 6\Lambda^2 \right)^2 - \frac{M_m^2 L_m^6 \omega_m^2}{324(EA)_m^2} \left[\left(\varepsilon\sigma - \frac{9\Lambda^2}{\omega_m} \cdot \frac{16(EA)_m}{M_m L_m^3} \right)^2 + 9(\zeta\omega_m)^2 \right]} \end{aligned} \quad (44)$$

In case no subharmonic resonant conditions exist, the steady-state response depends only on the external load:

$$w(t) = \frac{(P_0)_m}{M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) \cos \Omega t \quad (45)$$

while, for the non trivial stable solution of a ($a \neq 0$), the response of the nonlinear system at steady-state is:

$$w(t) = a \cos \left(\frac{\Omega t - \gamma_0}{3} \right) + \frac{(P_0)_m}{M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) \cos \Omega t \quad (46)$$

5 NUMERICAL EXAMPLE 1

A numerical example is used in order to explain the method. For this example, the cable diameter of the prototype is assumed equal to $D_p=50\text{mm}$, with a cross-sectional area $A_p=0.00196\text{m}^2$. Approximating realistic structures, the initial cable pretension is $(N_0)_p=600\text{kN}$, which corresponds to 19% of the yield stress, considering yield stress 1570MPa .

5.1 Transformation of the prototype to the model

Using the similarity relations, the equivalent SDOF model has the following characteristics:

$$D_m = D_p \sqrt{\left(\frac{N_p + 1}{N_m + 1} \right)} = 0.05 \sqrt{\left(\frac{26}{2} \right)} = 0.18\text{m} \quad (47)$$

$$A_m = A_p \left(\frac{N_p + 1}{N_m + 1} \right) = 0.00196 \cdot \frac{26}{2} = 0.0255\text{m}^2 \quad (48)$$

$$(EA)_m = (EA)_p \left(\frac{N_p + 1}{N_m + 1} \right) = 165000000 \cdot 0.0255 = 4211697.6\text{kN} \quad (49)$$

$$(N_0)_m = (N_0)_p \left(\frac{N_p + 1}{N_m + 1} \right) = 600 \frac{26}{2} = 7800\text{kN} \quad (50)$$

$$M_m = M_p \left(\frac{N_p + 1}{N_m + 1} \right)^2 = 0.151 \cdot \left(\frac{26}{2} \right)^2 = 25.52\text{kN sec}^2 \text{ m}^{-1} \quad (51)$$

5.2 Analytical solution for the SDOF model

5.2.1. Eigenfrequency of the model

The eigenfrequency of the SDOF model is calculated by Eq. (29):

$$\omega_m = 8.22 \text{ sec}^{-1} \quad (52)$$

5.2.2. Fundamental resonance

A load amplitude is chosen for the prototype equal to $(P_0)_p=1.30\text{kN}$, corresponding to a nodal load for the SDOF model, equal to:

$$(P_0)_m = (P_0)_p \left(\frac{N_p + 1}{N_m + 1} \right)^2 = 1.30 \cdot \left(\frac{26}{2} \right)^2 = 219.70 \text{ kN} \quad (53)$$

The load amplitude is chosen large enough to cause nonlinear phenomena, without cable tensile failure. The response curve is based on Eq. (36):

$$\varepsilon\sigma = \frac{6a^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} \pm \sqrt{\frac{(P_0)_m^2}{4M_m^2 \omega_m^2 a^2} - (\zeta\omega_m)^2} = \left(0.12a^2 \pm \sqrt{\frac{0.27}{a^2} - 0.027} \right) \text{ sec}^{-1} \quad (54)$$

while the frequency ratio is calculated as:

$$\frac{\Omega}{\omega_m} = \frac{\omega_m + \varepsilon\sigma}{\omega_m} \quad (55)$$

The amplitude of the steady state response, given by Eq. (54), with respect to the ratio of the loading frequency over the eigenfrequency, is plotted in Figure 3. The bending of the curve indicates the intense nonlinearity of the system. This bending means that jump phenomena are expected to characterize the response of the prototype, multiple response amplitudes dependent on the initial conditions, while the maximum steady state amplitude is predicted for frequency ratio larger than 1.

Figure 3: Fundamental resonance: response curve of the SDOF model for load amplitude $(P_0)_m=219.70\text{kN}$

5.2.3. Superharmonic resonance

A load amplitude is chosen for the prototype equal to $(P_0)_p=14\text{kN}$, corresponding to a nodal load for the SDOF model, equal to:

$$(P_0)_m = (P_0)_p \left(\frac{N_p + 1}{N_m + 1} \right)^2 = 14 \cdot \left(\frac{26}{2} \right)^2 = 2366 \text{ kN} \quad (56)$$

meaning:

$$\Lambda = \frac{(P_0)_m}{2 \cdot M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) = 0.772 \text{ m} \quad (57)$$

Again, the load amplitude is chosen large enough to cause nonlinear phenomena, without cable tensile failure. The diagram of the steady state response is defined by Eq. (39):

$$\varepsilon\sigma = \frac{48\Lambda^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} + \frac{6a^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} \pm \sqrt{\frac{\Lambda^6}{\omega_m^2 a^2} \cdot \left(\frac{16(EA)_m}{M_m L_m^3} \right)^2 - (\zeta\omega_m)^2} \Rightarrow$$

$$\varepsilon\sigma = 0.574 \text{ sec}^{-1} + 0.12a^2 (\text{sec}^{-1}) \pm \sqrt{\frac{0.022}{a^2} (\text{sec}^{-2}) - 0.027 (\text{sec}^{-2})}$$
(58)

and the frequency detuning is calculated for a given response amplitude. The total response amplitude is given as:

$$w_m = a + 2\Lambda$$
(59)

where Λ this time is calculated as:

$$\Lambda = \frac{(P_0)_m}{2 \cdot M_m} \left(\frac{1}{\omega_m^2 - \Omega^2} \right) = \frac{46.36 \text{ m/sec}^2}{(8.22 \text{ sec}^{-1})^2 - \Omega^2}$$
(60)

with

$$\Omega = \frac{\omega_m + \varepsilon\sigma}{3}$$
(61)

The response diagram, based on Eq. (58), is plotted in Figure 4.

Figure 4: Superharmonic resonance: response curve of the SDOF model for load amplitude $(P_0)_m=2366\text{kN}$

5.2.4. Subharmonic resonance

As explained in section 4.4, subharmonic solutions, with non trivial amplitudes of the free oscillation term a , exist for a given value of Λ only if:

$$\varepsilon\sigma \geq \frac{126\Lambda^2}{\omega_m} \cdot \frac{(EA)_m}{M_m L_m^3} + \frac{M_m L_m^3}{8(EA)_m} \cdot \frac{\zeta^2 \omega_m^3}{\Lambda^2} \Rightarrow \varepsilon\sigma \geq 2.53\Lambda^2 (\text{sec}^{-1}) + \frac{0.168}{\Lambda^2} (\text{sec}^{-1})$$
(62)

Based on Eq. (40) and assuming that:

$$\Omega = 3\omega_m + \varepsilon\sigma$$
(63)

the load amplitude is calculated:

$$(P_0)_m = 2M_m \Lambda (\omega_m^2 - \Omega^2)$$
(64)

for a frequency detuning satisfying inequality (62), while the amplitude of the oscillation is calculated by Eq. (44):

$$\begin{aligned}
 a^2 &= \varepsilon\sigma \frac{\omega_m M_m L_m^3}{18(EA)_m} - 6\Lambda^2 \pm \\
 &\pm \sqrt{\left(\varepsilon\sigma \frac{\omega_m M_m L_m^3}{18(EA)_m} - 6\Lambda^2 \right)^2 - \frac{M_m^2 L_m^6 \omega_m^2}{324(EA)_m^2} \left[\left(\varepsilon\sigma - \frac{9\Lambda^2}{\omega_m} \cdot \frac{16(EA)_m}{M_m L_m^3} \right)^2 + 9(\zeta\omega_m)^2 \right]} \Rightarrow \\
 a^2 &= c \pm \sqrt{c^2 - d \cdot e}
 \end{aligned} \tag{65}$$

where

$$c = (2.77\varepsilon\sigma - 6\Lambda^2)(m^2) \tag{66}$$

$$d = 7.66m^4 \text{ sec}^2 \tag{67}$$

$$e = [(\varepsilon\sigma - 2.89\Lambda^2)^2 + 0.24](\text{sec}^{-2}) \tag{68}$$

Thus, Eq. (65) becomes:

$$\begin{aligned}
 a^2 &= (2.77\varepsilon\sigma - 6\Lambda^2)(m^2) \pm \\
 &\pm \sqrt{[(2.77\varepsilon\sigma - 6\Lambda^2)(m^2)]^2 - 7.66 \cdot [(\varepsilon\sigma - 2.89\Lambda^2)^2 + 0.24](m^4)}
 \end{aligned} \tag{69}$$

Figure 5 illustrates the curve that defines the region of the subharmonic solutions, by means of Λ and $(P_0)_m$ with respect to the frequency ratio and to the response amplitude, given by Eq. (69). A detail of the same diagrams is given in Figure 6, for frequency ratio up to 4. In Figure 7 the response amplitude is plotted with respect to the frequency ratio and the loading amplitude. In Figure 8 the detail of the same diagrams is given for frequency ratio up to 4.

Figure 5: Subharmonic resonance of the SDOF model: a) Λ vs frequency ratio, b) $(P_0)_m$ vs frequency ratio

Figure 6: Subharmonic resonance of the SDOF model (detail): a) Λ vs frequency ratio, b) $(P_0)_m$ vs frequency ratio

Figure 7: Subharmonic resonance of the SDOF model: a) Response amplitude a vs frequency ratio, b) Load amplitude $(P_0)_m$ vs response amplitude a

Figure 8: Subharmonic resonance of the SDOF model (detail): a) Response amplitude a vs frequency ratio, b) Load amplitude $(P_0)_m$ vs response amplitude a

The frequency ratios that could cause subharmonic resonance are larger than 3.15 with load amplitude larger than 5239kN, which corresponds to 31kN for the MDOF prototype. A parametric analysis, changing the load amplitude, the frequency ratio and the initial deflection, keeping the initial velocity of the central node equal to 16m/sec, showed that as the load amplitude increases, the minimum initial deflection $w_{0,m}$ and the frequency ratio that can cause subharmonic resonance decrease (Figure 9).

Figure 9: Subharmonic resonant conditions for the SDOF model: a) $(P_0)_m$ vs frequency ratio, b) initial deflection vs frequency ratio

If, for example, the load amplitude is equal to $(P_0)_m = 9464$ kN, which corresponds to a load amplitude $(P_0)_p = 56$ kN for the MDOF prototype, the minimum initial deflection required in order to have a subharmonic resonance is 1.49m with a loading frequency equal to $\Omega = 3.32\omega_m$, taking into account an initial velocity equal to 16m/sec. The time history diagrams of the central node deflection, for these initial conditions and for null initial conditions, are shown in Figure 10, based on the results obtained by solving numerically the analytical equation of

motion, given by Eq. (25). For a load amplitude equal to $(P_0)_m=8619\text{kN}$, corresponding to 51kN for the MDOF prototype, an initial velocity 16m/sec, a minimum initial deflection 2.28m and a loading frequency $\Omega=3.44\omega_m$ constitute the conditions for subharmonic resonance. The time history diagrams of the central node deflection, for these initial conditions and for null initial conditions, are shown in Figure 11.

Figure 10: Time history diagrams of the central node deflection for $\Omega/\omega_m=3.32$ and $(P_0)_m=9464\text{kN}$: a) with null initial conditions, b) with initial displacement and velocity

Figure 11: Time history diagrams of the central node deflection for $\Omega/\omega_m=3.44$ and $(P_0)_m=8619\text{kN}$: a) with null initial conditions, b) with initial displacement and velocity

5.3 Numerical results for the MDOF prototype

In order to evaluate the accuracy of this method, numerical analyses are conducted to estimate the dynamic response of the MDOF cable net, being the prototype for this example.

5.3.1. Eigenfrequencies and eigenmodes of the prototype

A modal analysis is performed to calculate the vibration modes and the natural frequencies of the system. The first six vibration modes are shown in Figure 12. The first vibration mode is the first symmetric mode (denoted as 1S) having frequency $\omega_p=9.902\text{sec}^{-1}$.

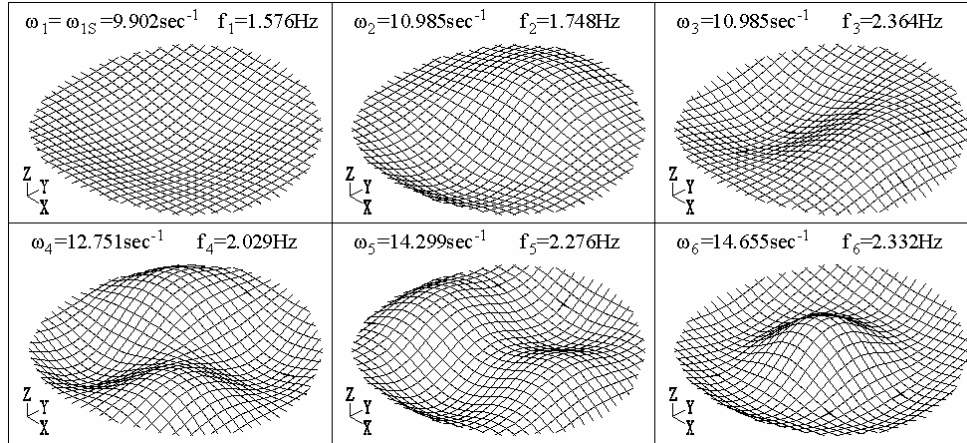

Figure 12: The first six vibration modes of the prototype

According to similarity relation (9) the natural frequency of the model, calculated as $\omega_m = 8.22 \text{ sec}^{-1}$, should be equal to the prototype's one. The natural frequency of mode 1S, obtained by the equivalent SDOF model, is 17% smaller than the one calculated by modal analysis of the MDOF system. The difference is rather large, because the difference between the model and the prototype, regarding the number of cables is also large. Nevertheless, this method is not used to calculate with accuracy the eigenfrequency, the maximum deflection or the cable tension of the prototype, but it is proposed to detect the occurrence of nonlinear phenomena.

5.3.2. Fundamental resonance

Accounting for fundamental resonant phenomena the load amplitude of the harmonic uniform load is chosen in section 5.2.2, equal to $(P_0)_p = 1.30 \text{ kN}$. The load frequency varies between $0.90\omega_p$ and $1.30\omega_p$. The damping ratio, according to similarity relation (11), is considered equal to $\zeta_p = \zeta_m = \zeta = 2\%$. The amplitude of the steady state response for the central node of the MDOF prototype with respect to the ratio of the loading frequency over the eigenfrequency, is plotted in Figure 13. In the same diagram the response of the SDOF model of Figure 3 is also illustrated for comparison reasons. According to similarity relation (8), the nodal dynamic deflection of the prototype should be equal to the one of the model. For frequency ratios between $\Omega/\omega_p = 0.90$ and $\Omega/\omega_p = 1.10$, the error of the calculation is not more than 10%, which is considered as satisfactory. After the peak amplitude and as the frequency ratio increases, the error increases too, arising at 45% for $\Omega/\omega_p = 1.30$. This occurs because the sixth mode of the MDOF system is another symmetric mode, having a natural frequency equal to $\omega_6 = 14.655 \text{ sec}^{-1} = 1.48\omega_1 = 1.48\omega_p$. Thus, as the loading frequency approaches the frequency of this mode, the amplitude increases, leading to a fundamental resonance for the sixth mode. Using the equivalent SDOF model, which has a unique frequency, is not possible to predict this second fundamental resonance.

Figure 13: Fundamental resonance: response curve of the MDOF prototype for load amplitude $(P_0)_p=1.30\text{kN}$

The bending of the response curve for the MDOF system is obvious from the diagram of Figure 13. If null initial conditions are assumed, by means of deformation and velocity on every node, when the frequency ratio is $\Omega/\omega_p=1.07$ the steady state amplitude is 2.52m, while for $\Omega/\omega_p=1.08$, the amplitude drops suddenly to 1.06m, verifying the jump phenomenon. However, if initial conditions are assumed, the amplitude of the steady state deflection for $\Omega/\omega_p=1.08$ is 2.62m, verifying that the dynamic response of the MDOF prototype depends on the initial conditions. The initial conditions are deformations and velocities with respect to the three global axes, applied on every node, taken from the response of the MDOF system for $\Omega/\omega_p=1.07$ (Figure 14).

Figure 14: Time history response of the central node for $\Omega/\omega_p=1.07$: a) deflection diagram and b) vertical velocity diagram

At time $t=49.58\text{sec}$, both vertical displacement and velocity are considerable (Figure 15), thus the deflection (Figure 16) and the velocity (Figure 17) at that time are chosen as initial conditions for the next frequency step. The time history diagrams for $\Omega/\omega_p=1.08$, for these two cases of initial conditions, are plotted in Figure 18, showing the different response amplitudes.

Figure 15: Time history response of the central node for $\Omega/\omega_p=1.07$ (detail): a) deflection diagram and b) vertical velocity diagram

Figure 16: Vertical initial deflection for $\Omega/\omega_p=1.08$

Figure 17: Vertical initial velocity for $\Omega/\omega_p=1.08$

Figure 18: Time history diagrams of the central node deflection for $\Omega/\omega_p=1.08$: a) with null initial conditions, b) with initial displacement and velocity

These phenomena, namely the maximum steady state amplitude occurring for frequency ratio larger than 1, leading to the bending of the curve, the jump and the multiple response amplitudes dependent on the initial conditions, also verified by the numerical simulation, confirm the intense nonlinearity of the MDOF cable net, which was predicted by the SDOF model.

5.3.3. Superharmonic resonance

In case of superharmonic resonance the load amplitude for the MDOF prototype is chosen in section 5.2.3, equal to $(P_0)_p=14\text{kN}$. The load frequency varies between $0.30\omega_p$ and $0.60\omega_p$. The amplitude of the steady state response for the central node of the MDOF prototype with respect to the frequency ratio, and the response of the equivalent SDOF model of Figure 4, are plotted together in Figure 19. The steady state amplitudes, estimated by the method of the SDOF model, are between 25% and 48% larger than the ones obtained by numerical analysis. This estimation cannot be considered as satisfactory. On the other hand, the peak amplitude for frequency ratio $\Omega/\omega_p=0.36$, predicted by the equivalent SDOF model, is verified for the prototype, confirming the occurrence of the 3:1 superharmonic resonance for the first symmetric mode.

Figure 19: Superharmonic resonance: response curve of the MDOF prototype for load amplitude $(P_0)_p=14\text{kN}$

In Figure 20 the response of the central node is depicted by means of time history diagram and response spectrum, verifying this nonlinear resonance. The steady state response, obtained after 20sec, is an oscillation of at least two different frequencies. This is also illustrated in the response spectrum, in which two peaks are noted for frequencies 0.56Hz (3.52sec^{-1}), which is almost equal to the loading frequency ($\Omega=0.36 \cdot 9.902\text{sec}^{-1}=3.56\text{sec}^{-1}$) and

1.68Hz (10.56sec⁻¹), which is almost equal to the eigenfrequency of the first symmetric mode ($\omega_1=\omega_{1S}=\omega_p=9.902\text{sec}^{-1}$).

Figure 20: Response diagrams of the central node deflection for $\Omega/\omega_p=0.36$: a) time history diagram, b) response spectrum

In Figure 19, a second peak of the amplitude is observed for frequency ratio $\Omega/\omega_p=0.53$ for the MDOF system, which corresponds to a 2:1 superharmonic resonance for the same mode. In this case, the loading frequency is $\Omega=0.53\cdot\omega_p=5.52\text{sec}^{-1}=0.36\omega_6$, where ω_6 is the eigenfrequency of the sixth mode equal to $\omega_6=14.655\text{sec}^{-1}$. Hence, this second peak indicates also a 3:1 superharmonic resonance for the sixth mode being the second symmetric mode of the system.

In Figure 21a, the time history diagram of the central node deflection is plotted. In Figure 21b, the response spectrum of the central node deflection illustrates that the oscillation of the central node is characterized by three frequencies: at 0.84Hz, corresponding to 5.28sec^{-1} , which is very close to the loading frequency ($\Omega=0.53\cdot\omega_p=5.25\text{sec}^{-1}$), at 1.72Hz (10.81sec^{-1}), being close to the eigenfrequency of the first symmetric mode ($\omega_1=\omega_{1S}=\omega_p=9.902\text{sec}^{-1}$) and at 2.52Hz (15.83sec^{-1}), which is close to the eigenfrequency of the second symmetric mode ($\omega_6=14.655\text{sec}^{-1}$). Thus, both modes are activated in this case and the occurrence of the 3:1 and 2:1 superharmonic resonance for the first and the second symmetric mode, respectively, is verified. With the equivalent SDOF model having only one frequency, it is not possible to predict this second superharmonic resonance for the mode of higher order. In addition, the SDOF model, having only a cubic nonlinear term, cannot detect 2:1 superharmonic resonances.

Figure 21: Response diagrams of the central node deflection for $\Omega/\omega_p=0.53$: a) time history diagram, b) response spectrum

5.3.4. Subharmonic resonance

Based on the parametric analysis of section 5.2.4, assuming a load amplitude on every node equal to $(P_0)_p=51\text{kN}$, with a load frequency equal to $\Omega=3.44\omega_p$, and an initial deflection and velocity on every node, so that the ones for the central node are 2.30m and 16m/sec, respectively, subharmonic resonance should be developed, but before the first cycle of the oscillation concludes, cable tensile failure occurs. The same also occurs for load amplitude $(P_0)_p=56\text{kN}$, loading frequency $\Omega=3.32\omega_p$ and initial conditions, corresponding to a deflection and velocity for the central node, 1.48m and 16m/sec, respectively (Figure 22). For smaller load amplitudes, a larger initial deflection is required, and for smaller initial deflection, a larger load amplitude can cause a subharmonic resonance. Both cases lead to cable tensile failure. Thus, for this cable net, it is impossible for the subharmonic resonance to evolve, because the large load amplitude and the large initial conditions required for such a resonance, cause cable tensile failure as soon as the vibration starts.

Figure 22: Time history response of the central node for: a) $(P_0)_p=51\text{kN}$ and $\Omega/\omega_p=3.44$
b) $(P_0)_p=56\text{kN}$ and $\Omega/\omega_p=3.32$

6 EVALUATION OF THE METHOD

The pros of the proposed method are the following:

- The computational time required to solve the equation of motion and have an assessment of the response of the MDOF system is minimal.
- The intensity of the geometrical nonlinearity of the MDOF system can be estimated very satisfactorily, by means of the bending of the response curve, the jump phenomena and the existence of double response amplitudes due to the initial conditions.
- The loading frequency detuning, for which nonlinear resonances for the first symmetric mode occur, can be estimated with good accuracy.

The cons of this method are the following:

- The equivalent SDOF model, having only one eigenfrequency and eigenmode, cannot detect resonances for higher modes for a MDOF cable net.
- The equivalent SDOF model, having only a cubic nonlinear term, cannot predict 2:1 superharmonic or 1:2 subharmonic resonances for the large system.
- The analytical solution of the SDOF cable net is given for the vertical load applied on the central node, causing a vertical vibration. Thus, only the oscillation amplitude of the central node of the MDOF system can be estimated.
- In addition, this vertical motion corresponds to the first symmetric mode of the cable net. Hence, the method of the equivalent SDOF model cannot be used to estimate the response

of the MDOF cable net for other modal shapes, or for other spatial loading distributions, such as anti-symmetric ones about one or two horizontal axes.

- The analytical solution of the SDOF cable net gives the steady state amplitude of the response but not the maximum transient response, for which a cable tensile failure is possible to occur, before the steady state response is reached.

7 SUMMARY AND CONCLUSIONS

A method of an equivalent single-degree-of-freedom cable net is introduced, in order to predict the nonlinear dynamic response of a multi-degree-of-freedom cable net. The geometrical and mechanical characteristics of the large cable net are transformed to the corresponding ones of the small cable net, using similarity relations. The analytical solution of the SDOF model is explored, in order to detect nonlinear phenomena, such as the bending of the response curve, the occurrence of superharmonic and subharmonic resonances, jump phenomena and the double response amplitudes with respect to the initial conditions. The results of the SDOF model, by means of the maximum load, the maximum deflection and the loading frequency, are transformed to the ones of the MDOF system, by using the inverse similarity relations. Conducting nonlinear dynamic analyses and numerical simulation of the MDOF cable net, the nonlinear phenomena are verified.

This investigation verifies that the saddle form cable nets have cubic nonlinearities, but also quadratic ones. Near resonances, although damping exists, a small change of the loading frequency may cause large difference in the oscillation amplitude. The initial conditions influence significantly the response of the cable net, as occurs in nonlinear systems. Jump phenomena and superharmonic resonances are also confirmed. Concerning the subharmonic resonances, it is very difficult to detect them for a MDOF system, because they require specific load amplitude, load frequency and initial conditions. It is impossible to know which load amplitude and frequency and which initial deflection and velocity can cause this kind of nonlinear resonance, because no analytical solutions are available. The investigation of the SDOF model showed that subharmonic resonances may occur under certain conditions, but for the MDOF they are difficult to exhibit, because the large initial conditions and the large load amplitude required for this phenomenon lead to cable tensile failure at the beginning of the vibration.

The numerical investigation of the overall nonlinear dynamic behaviour of a MDOF cable net system is a time consuming procedure. It requires much computational time and a large number of nonlinear time history analyses, for different load amplitudes and for very small time steps and frequency steps. This method, estimating the loading amplitudes and frequencies for which nonlinear phenomena take place, can be a very useful guideline for the design of such cable structures.

Keywords: Secondary System, Floor Response Spectra, Nonstructural Component.

Abstract. *Damage to nonstructural components may conduce heavy financial losses and injuries; therefore, it is a necessity for these components to be carefully designed for seismic loads. Meanwhile, even the most recent editions of the corresponding codes and instructions are still based on some assumptions that impair their accuracy and degree of conservatism. In this paper, it is intended to highlight the influential effect of some of these assumptions and the other related parameters that affect the floor acceleration response in buildings. For this reason, this paper constitutes the nonlinear dynamic time-history analysis of seven code-designed multi-story regular steel moment-resisting frames which have been subjected to selected strong ground motions (SGMs) for each individual building. Floor acceleration response spectra (FARS) have been calculated for the building floors. The spectra have been computed for the case of the components having dynamic interaction with the primary structure or not, so that the influence of the dynamic interaction is spotlighted. Besides, the FARS have been specified for different component mass ratios so as to account for the effect of the component weight. Another factor which is neglected in most of the instructions and studies is damping. Different damping coefficients have been utilized to investigate the effect of this parameter. The frame beams have the freedom to bend; therefore, the buildings are not consisted of simple shear frames. The effects of all mentioned parameters have been quantitatively illustrated and the results have been compared with each other for various cases. It is found that the mass ratio of the component, the degree of damping in primary or secondary systems, and the interaction between the primary and the secondary structure are crucial factors to be considered in seismic design of nonstructural components (NSCs), which regarding them helps improve the precision of studies. Moreover, results indicate that in contrary to the assumptions of current seismic codes, not always does the fundamental vibration mode of the primary structure produce the highest floor acceleration responses. Also, it can be inferred that if such factors are included in seismic design codes, their level of conservatism can become more rational and proposed methods can get closer to reality.*

1 INTRODUCTION

During past earthquakes, damage to nonstructural components has always shown to constitute a wide portion of economic losses. Thus, in recent decades, the seismic behavior of NSCs has become an area of research interest. Compared to structural components, our knowledge of nonstructural systems is relatively limited and research works and available codes and guidelines in this field are, for the most part, based on past experience, engineering judgment, and intuition, rather than on experimental and analytical results.

There are many different factors which affect the design force of secondary systems in buildings. In this study, the influence of the secondary system mass ratio, secondary and primary system damping ratios, and the primary-secondary system interaction on floor acceleration demand has been investigated. In past studies, these parameters have either been neglected or their effects have not been spotlighted quantitatively using precise time-history analyses. This study; however, quantifies the crucial effects of these parameters via comprehensive numerical analyses.

2 STRUCTURAL MODELS AND SELECTED GROUND MOTIONS

In this paper, seven multi-story building frames have been utilized for the dynamic time-history analysis. The frames have been pulled out of seven code-designed building structures such that their dynamic behavior is the same as that of the buildings. The studied buildings comprise a group of 4-, 6-, 8-, 12-, 16-, 20-, and 25-story special steel moment-resisting frames which bear a single-degree-of-freedom linear secondary system on one of their floors for each analysis. The secondary systems have been attached to the bottom, middle, or top floor of each building (equivalent frame) every time. Figure 1 shows a schematic of the 6-story building typical floor plan and interior frame with nonstructural components attached at its floors. The other six studied buildings have similar floor plans with frames which have been designed for each individual building.

Figure 1: 6-story building typical floor plan (left) and interior frame (right) with nonstructural components attached to its lower, middle or top floor.

Since this study aims to gain an understanding of the behaviour of nonstructural components mounted on nonlinear buildings, the ground motions used in the analysis are selected based on their ability to stimulate the nonlinear behaviour of the buildings. Thus, for each

building, the earthquake input for this study is defined in terms of eight strong ground motion (SGM) acceleration time histories recorded in different earthquake events and scaled to match the spectral ordinate at the fundamental period of the building. Table 1 shows the exclusively selected SGMs for the 6-story building from M6.5 scenario SGM data base proposed by Hatefi, Ashtiany and Ansari [4] using SGM selection method proposed by Ashtiany, Mousavi and Azarbakht [5].

3 INFLUENTIAL FACTORS TO AFFECT FLOOR ACCELERATION

In this section it is intended to spotlight some of the important and influential parameters that affect the floor acceleration values in buildings or other structures which are mostly neglected in code provisions or other studies. For this reason, the nonlinear acceleration floor response spectra (AFRS) have been calculated using the aforementioned structural models and ground motions for the bottom, middle, and top floors of the buildings. Since floor spectra can illustrate the frequency content of the responses, they have been taken advantage of in the study to show the effects of the secondary system mass ratio, the primary and the secondary system damping ratio, and the dynamic interaction between the primary and the secondary system. The spectra have been calculated for a range of secondary system periods from 0.01 to 5 seconds. These spectra have been obtained for every floor of the buildings but here, they are only shown for the 6-story building. The master values for the secondary system mass ratio, the primary system damping ratio and the secondary system damping ratio in this study have been chosen 0.01, 0.05 and 0.05, respectively, and all other cases are compared with these quantities. Besides, the master model in this study is the one in which the dynamic primary-secondary system interaction is considered.

3.1 Mass ratio

Secondary system mass ratio is defined as the ratio of the secondary system mass to the mass of the floor to which the NSC is attached. Here, the NSCs mass ratios have been se-

lected to be equal to 0.005, 0.01, 0.02, or 0.05. For each analysis, a secondary system with one of the four different mass ratios has been added to one of the three different building floors (top, middle, or bottom) of each building to investigate how the secondary system mass ratio may affect the floor acceleration response. For each building, the AFRS have been obtained using the corresponding selected eight ground motions and the mean AFRS have been used as one may see in the following figures. Since it is not possible to show all of the figures, the mean AFRS for only the 6-story building are presented here at the bottom, middle, and top floor for different secondary system mass ratios in figures 2, 3, and 4, respectively. Also shown on the figures are the building modal periods in vertical dashed lines.

Figure 2: 6-story building mean AFRS at the 2nd (bottom) floor for different secondary system mass ratios.

Figure 3: 6-story building mean AFRS at the 4th (middle) floor for different secondary system mass ratios.

Figure 4: 6-story building mean AFRS at the 6th (top) floor for different secondary system mass ratios.

It may be realized from the figures that, in the six-story building, an increase in the mass ratio from 0.005 to 0.05 may decrease the AFRS values slightly in all of the three locations along the building height. For the other six buildings, similar mean AFRS have been obtained and such an overall decrease has been observed. To quantify the differences in the response spectra due to mass ratio changes and see how this parameter can generally affect the floor acceleration demand along the building height in all of the seven investigated buildings, the root mean square deviation (RMSD) of the AFRS has been calculated out of the mean AFRS values for the top, middle, and bottom stories. Figure 5 quantifies these effects, compared to the master mass ratio value in this study (i.e. 0.01), on the AFRS values.

Figure 5: Root mean square deviation of the mean AFRS for different secondary system mass ratios.

As it may be seen in the figure, mass ratio has a relatively slight influence on floor acceleration response and the maximum deviation resulting from the two farthest mass ratio values, which are 0.005 and 0.05, reaches an average value of 0.04g. It may also be observed that going higher along the building height, the effect of mass ratio on floor acceleration demand increases.

3.2 Primary system damping ratio

Primary system damping ratio is another important factor whose effect has been investigated in this section. In this case, for each analysis, the secondary system is attached to one of the three different building locations (top, middle, or bottom floor) while the primary structure damping ratio equals one of three different values each time. The Primary system damping ratios which have been studied here are 0.02, 0.05, or 0.07. Note that, in this section, properties of the secondary system are those of the master model, i.e. a damping ratio of 0.05 and a mass ratio of 0.01. To investigate how the primary system damping ratio may affect the floor acceleration response, for each building, the AFRS have been obtained using the corresponding selected eight ground motions and the mean spectra have been used for the comparisons. Here, the mean AFRS are presented only for the 6-story building at the bottom, middle, and top floor for different primary system damping ratios as in figures 6, 7, and 8, respectively. The building modal periods have been also shown on the figures in vertical dashed lines.

Figure 6: 6-story building mean AFRS at the 2nd (bottom) floor for different primary system damping ratios.

Figure 7: 6-story building mean AFRS at the 4th (middle) floor for different primary system damping ratios.

Figure 8: 6-story building mean AFRS at the 6th (top) floor for different primary system damping ratios.

One may realize from the figures that, in the six-story building, when the primary system damping ratio increases from 0.02 to 0.07 the AFRS values decrease. For the other six buildings, similar mean AFRS have been obtained and such an overall decrease has been observed.

Considering the respective curves for other buildings, this acceleration response attenuation becomes lower for the secondary systems with fundamental periods higher than 1 second. So, it seems that for such NSCs the primary system damping ratio has no influence on the responses. However, for other secondary systems, especially for those with a fundamental period close to one of the modal periods of the primary building, this effect is notable. To quantify the differences in the AFRS curves due to primary system damping ratio changes in all of the seven investigated buildings, the root mean square deviation (RMSD) of the AFRS has been calculated using the mean spectral values for the top, middle, and bottom stories. Figure 9 illustrates these effects, compared to the master primary system damping ratio value (i.e. 0.05).

Figure 9: Root mean square deviation of the mean AFRS for different primary system damping ratios.

As seen in the figure above, the primary system damping ratio has a notable influence on floor acceleration response. The maximum deviation resulting from the two farthest damping ratios, which are 0.02 and 0.07, has an average value of 0.11g while this value in the top stories may reach an average of 0.15g. Again, it is observed that if the NSC is placed at higher locations along the building, the induced difference increases.

3.3 Secondary system damping ratio

In this section the effect of secondary system damping ratio has been investigated. Like the previous sections, NSCs with damping ratios of 0.05, 0.07, 0.10, or 0.20 are attached to one of the three different buildings floors. Other properties of the primary and secondary systems are those of the master model, i.e. a primary building damping ratio of 0.05 and a mass ratio of 0.01. The AFRS have been calculated using the corresponding selected eight ground motions for each building and the mean response spectra have been obtained. Again, only the 6-story building mean AFRS for different secondary system damping ratios are shown in figures 10, 11, and 12 with the building modal periods.

Figure 10: 6-story building mean AFRS at the 2nd (bottom) floor for different secondary system damping ratios.

Figure 11: 6-story building mean AFRS at the 4th (middle) floor for different secondary system damping ratios.

Figure 12: 6-story building mean AFRS at the 6th (top) floor for different secondary system damping ratios.

Figures 10 to 12 show that, in the six-story building, with an increase in the secondary system damping ratio from 0.05 to 0.20 the AFRS values in all of the three building height locations decrease. When the other buildings spectral values are taken into account, it may be inferred that the secondary system damping ratio is another factor which can affect the AFRS significantly. Also, one may notice that the spectral values are amplified when the secondary system is tuned with one of the building modal vibration periods. This amplification; however, lessens for more highly damped NSCs while the curves become smoother.

Figure 13 quantitatively illustrates the differences in the AFRS values caused by the secondary system damping ratio changes in all of the seven studied buildings. The RMSD of the mean AFRS has been calculated for the top, middle, and bottom stories and compared with the %5 master secondary system damping.

Figure 13: Root mean square deviation of the mean AFRS for different secondary system damping ratios.

Figure 13 shows that the secondary system damping ratio is another important parameter to affect the floor acceleration demand in buildings with an average induced deviation of 0.18g while comparing the %5 and %20 damped NSCs. The figure shows that the effect of secondary system damping ratio is almost the same along the building height and the component location seems to have no substantial influence on the responses.

3.4 Interaction

One of the most important factors which is, for the most part, neglected in different studies is the effect of the dynamic interaction between the primary and the secondary structures. In most of the studies the primary and the secondary systems are modeled and analyzed separately, i.e. at first the primary building response is calculated at the point of attachment of the NSC to the building and then this response is used as the input for the secondary system excitation. This way, the interaction is not taken into account.

In this section; however, it is intended to show how this interaction may affect the AFRS values. Thus, two groups of models have been developed: in the first group the interaction is neglected and the primary building has been separately modeled and its floor acceleration responses have been used as new inputs to calculate the secondary system responses; meanwhile, in the second group the effect of the interaction effect has been completely considered and in spite of the higher cost of the numerical analyses, the models have been set up such that the NSC is part of the whole model and the primary and secondary systems are in physical contact with each other (see Fig. 1 for example). Like the previous sections, three different building floor locations (top, middle, or bottom) of each building have been investigated and the mean AFRS have been obtained using the corresponding selected eight ground motions. The results for the 6-story building are as in figures 14 to 16. Other primary and secondary system properties are those of the master model.

Figure 14: 6-story building mean AFRS at the 2nd (bottom) floor considering or without considering interaction.

Figure 15: 6-story building mean AFRS at the 4th (middle) floor considering or without considering interaction.

Figure 16: 6-story building mean AFRS at the 6th (top) floor considering or without considering interaction.

The recent figures and the similar figures obtained from the other six buildings show that considering the effect of primary-secondary system interaction to calculate floor acceleration

demand in buildings has a very notable impact. As the figures indicate, for very flexible NSCs with higher fundamental periods, neglecting the interaction contributes to response underestimation. However, the response values can not be claimed to be higher or lower after consideration of the interaction, but, the induced difference or error is noteworthy and evident. In order to quantify this error in the response spectra and see how this parameter may generally affect the floor acceleration demand along the building height in all of the seven investigated buildings, the root mean square error (RMSE) of the AFRS has been calculated out of the mean AFRS values for the top, middle, and bottom stories as in figure 17.

Figure 17: Root mean square error of the mean AFRS considering or without considering interaction.

Figure 17 also shows that at the upper building floors, the error caused by missing the interaction effect reduces. However, on the whole, these errors in the three studied portions are almost equal with an average value of 0.14g.

4 CONCLUSIONS

Based on this study, it is found that the mass ratio of the component, the degree of damping in primary or secondary systems, and the interaction between the primary and the secondary structures are crucial factors to be considered in seismic design of nonstructural components, which regarding them helps improve the precision of studies. Moreover, as it was illustrated in the proposed figures and results, in contrary to the assumptions of some current seismic codes (e.g. the Eurocode8 seismic provisions), not always does the fundamental vibration mode of the primary structure produce the highest floor acceleration responses. Also, it can be inferred that if such factors are included in seismic design codes, their level of conservatism can become more rational and proposed methods can get closer to reality.

Keywords: Near-Fault Ground Motions, Near-Source Effect, Forward Directivity, Single-degree-of-freedom Oscillators, Inelastic Displacement Ratio.

Abstract. *The effect of rupture directivity at near-fault sites is investigated. The study compares the ratio of maximum inelastic to maximum elastic displacement demand, C_R , for a wide range of SDOF systems subjected to fault-normal, near-field ground motions. Oscillators with both bilinear and quadrilinear backbones are considered. The quadrilinear oscillators include an elastic, a hardening and a negative stiffness branch that terminates at a horizontal plateau, and therefore this modelling is more suitable for simulating the real-world buildings, which degrade. A sensitivity analysis of the parameters that describe the SDOF systems is performed in order to study their effect on C_R . It is demonstrated how the seismic response varies with respect to the backbone parameters, the period and the seismic demand. The results show that the bilinear approximation, which is the common, underestimates the ductility demand compared to the quadrilinear case, regardless of the seismic intensity and the backbone parameters.*

1. INTRODUCTION

Near-fault ground motions with forward directivity are characterized by strong, coherent, long period pulses and permanent ground displacements. These properties differentiate the response of structures subjected to “non pulse like” ground motions. The special characteristics of near-field, forward directivity ground motions are directly correlated to the magnitude, the source type, the direction of rupture propagation relative to the site and also to the residual ground displacement resulting from the slip of the fault. The frequency content of near-field motions, which differentiates them from near-field non forward directivity and far-field ground motions, is not evident in every record in a zone approximately 20-60 km around the location of fault rupture. The impulsive character is present mainly in the strike-normal direction, generating the forward directivity effect (Somerville *et al.* 1997, Baker, 2007). The effect of significant velocity pulses on the structural response was first highlighted by Bertero and Mahin (1978). Divergent views can be found in the literature, that either associate the directivity effects of near-fault ground motions to acceleration pulses (Makris and Black 2004, Sucuoglu *et al.* 1999) or to displacement pulses.

The conflicting opinions about the origin of directivity effects, which focus the influence of near-fault ground motions at different spectral regions and the elevated seismic demand they induce on structures, indicate the use of quadrilinear SDOF to simulate structural response far into the inelastic region. The deteriorating quadrilinear models can be used in order to obtain the response under high inelastic demand, where the system capacity is expected to degrade rather than steadily increase as in the case of bilinear systems. Furthermore, Ibarra *et al.* (2005) suggests that the backbone characteristics, and a parameter for cyclic deterioration may be sufficient to correspond to the structural response, regardless of the loading history.

The objective of this study is to investigate the effects of near-field ground motions on the inelastic behavior of single-degree-of-freedom (SDOF) systems with varying properties. Medians of the inelastic displacement ratio, C_R , of SDOF systems are shown for both bilinear and quadrilinear systems. The study emphasizes on the response of quadrilinear systems, since this is a more realistic description of the capacity of structures, while most contemporary literature refers to bilinear oscillators. The properties of a series of oscillators are varied, studying their effect on C_R , with respect to the ratio of the fundamental period over the pulse duration T_p .

2. INELASTIC DISPLACEMENT RATIO C_R

The inelastic displacement ratio, C , is defined as the maximum lateral inelastic displacement demand divided by the maximum elastic displacement demand, over the entire time history. Therefore, C is given by the expression (Chopra, 2007):

$$C = \frac{u_m}{u_y} = \frac{\mu}{R_y} \quad (1)$$

To compute C we adopt systems with given demand R_y , where R_y is the strength reduction factor equal to the ratio of acceleration demand S_a over the yield acceleration of the oscillator. The inelastic displacement ratio for given R_y , is denoted as C_R , being consistent with the notation in Miranda (2000). The assumption of given yield strength reduction factor R_y , has certain advantages over the constant-ductility

case. Producing systems with selected yield strength reduction factor R_y , requires only linear and mainly invertible functions, since only one value of yield strength corresponds to a selected R_y value, while in order to calculate the C for systems with given ductility μ , requires an iterative procedure.

Current seismic design provisions for the computation of inelastic deformations are based on the inelastic design spectrum of Newmark and Hall (1982), which uses the R_y - μ - T_I , relationships of Veletsos and Newmark (1960). This equation has been the basis for several approaches to obtain approximate R_y - C_R - T relationships for near-field ground motions, as discussed in the following paragraph. According to the Newmark-Hall approach, C_R for far-fault ground motion record can be calculated as:

$$C_R(T_1) = \begin{cases} \infty & T_1 < T_a \\ (R_y^2 + 1) / 2R_y & T_b < T_1 < T_{c^*} \\ 1 & T_1 > T_c \end{cases} \quad (2)$$

where

$$T_{c^*} = \frac{2R_y}{1 + R_y^2} T_c \quad (3)$$

T_a, T_b, T_c , are spectral periods which vary according to the soil type.

The computation of C_R for structures located in the near-fault zone has been addressed for many years by the research community and various approximate relationships for C_R have been proposed, referring almost exclusively to bilinear systems. However, the different pulse periods of pulse-type motions, its significant influence on the spectral shape and the local amplifications it causes on C_R , indicates that it is preferable to normalize the fundamental period with the pulse period. Moreover this practice substantially decreases the record-to-record variability and eliminates the influence of the parameters that characterize the near-fault excitation. While Báez and Miranda (2000) suggest that PGV is the most influential parameter on C_R , according to Ruiz-Garcia (2011), neither PGV nor the distance to the source significantly affect C_R once T_I is normalized with respect to the predominant period of the ground motion, T_p , where T_p is the period of vibration corresponding to the peak spectral velocity of a linear SDOF system having 5% damping ratio. Other studies, including Mavroeidis *et al.* (2004), discuss also the moderate influence of earthquake magnitude on structural response, focused on some distinct values of normalized periods ($T_I/T_p < 1$). Finally, Chopra and Chintanapakdee (2004), support that when the periods are normalized with the spectral value T_c , the produced C_R values for near-field and far-fault ground motions are very close.

3. MODELLING OF THE OSCILLATORS

The SDOF oscillators are modeled either as bilinear having an elastic and a hardening branch, or with quadrilinear backbones having pinching hysteresis and including an elastic, a hardening, and a negative stiffness branch, terminating at a residual plateau (Fig.1). These systems are described by the post-yield hardening ratio a_h , corresponding to the strain-hardening stiffness, the negative slope of the post-capping stiffness a_c , the pre-capping ductility μ_c defining the beginning of the softening branch, and finally, the coefficient r representing the residual strength capacity, as a fraction of the yield strength. The parameters are varied one at a time,

generating several plausible structural models, some of them being more brittle and other more ductile. Using an oscillator with properties $a_h = 5\%$, $\mu_c = 1.2$, $a_c = -50\%$,

Figure 1: The force-displacement relationship of the oscillator in normalized coordinates (Vamvatsikos and Fragiadakis, 2006).

T_p (sec): The period of the velocity pulse.

D_{5-95} (sec): Significant duration of the records. The duration is defined as the time needed to build up between 5 and 95 percent of the total Arias Intensity.

R_{rup} (km): Closest distance to rupture plane.

R: Reverse.

SS: Strike-Slip.

N: Normal.

RO: Reverse-Oblique.

$r = 5\%$, and a fixed damping ratio equal to 5%, we have formed a reference oscillator that is used as the basis for comparing all modified models.

4. EARTHQUAKE GROUND MOTIONS

A total of 33 ground motions have been used, recorded normal to the fault trace. The records and their properties are listed in Table 1. The classification of the records and their pulse period follows that of PEER NGA database [18]. In many records, the normal components show strong directivity effects (e.g. record #21, record #31), while the fault-parallel components are associated with weak directivity effects. In some cases, prominent directivity effects are evident in both components, as in Erzincan (record #23), where the pulse period is very close for both components.

5. PARAMETRIC INVESTIGATION

The influence of the type of the oscillator and its properties on the seismic demand are studied through plots of C_R versus the period of the systems.

Figure 2: Median inelastic displacement ratios of quadrilinear oscillators and bilinear oscillators subjected to the normal component of pulse type records.

5.1 Influence of oscillator type

Current research on the effects of near-fault ground motions has concentrated on the investigation of bilinear systems, while there are very few studies on degrading systems, which is the case of most real world buildings. Figure 2, presents the median inelastic deformation ratio C_R of quadrilinear against bilinear systems. The oscillators are subjected only to the fault-normal component of ground motions that contain a velocity pulse. The post-stiffness ratio of the bilinear oscillator is set equal to 0.05,

Figure 3: Influence of the slope of the hardening branch, a_h of the oscillators characterized by $\mu_c=1.2$ and $\mu_c=6$, on C_R .

while the quadrilinear system is the reference oscillator, described in section 2. The plots are obtained for four different intensity levels corresponding to R_y factor values equal to 2, 4, 6 and 8.

According to Fig. 2, the ductility developed by quadrilinear oscillators exceeds the levels of the corresponding bilinear for given C_R values. For $R_y=2$, the two curves converge for normalized periods larger than 0.85, having significant divergence only for small T_1/T_p values. For weaker systems, as R_y increases, the bilinear SDOF underestimates the C_R -demand over the entire period range. For every level of R_y , the two curves converge to $C_R=1$ as T_1/T_p increases, which takes place approximately at $T_1/T_p=4$, as opposed to $T_1/T_p=0.8$ for bilinear systems. From Fig. 2, it is evident that median C_R values are quite different when computed for bilinear and quadrilinear

systems, indicating that using a bilinear model to estimate the inelastic response, is conservative when the structure has a degrading backbone.

5.2 Influence of oscillator's properties

As shown in Fig.1, the oscillator can be fully described by four parameters. The four parameters are the non-negative slope of the hardening branch, a_h , the normalized displacement μ_c , which defines the beginning of the negative stiffness segment, the slope of the negative stiffness branch, a_c , and the height of the residual plateau, r , equal to the ratio of the residual strength over the yield strength. These backbone properties (a_h , a_c , μ_c , r) are set according to the reference oscillator and are varied one at a time to study their effect on C_R .

Figure 4: Hysteresis loops of quadrilinear oscillators characterized by $\mu_c=1.2$ and $\mu_c=6$ for the Chi-Chi Taiwan record and $T_I/T_p=0.45$.

Median inelastic displacement ratios for two quadrilinear oscillators characterized by $\mu_c=1.2$ and $\mu_c=6$ are presented in Fig. 3. The other backbone parameters are set according to the reference oscillator.

Compared to the oscillator having $\mu_c=1.2$, the bilinear system (solid black line) underestimates the C_R compared to the quadrilinear oscillators, especially as R_y increases. Regardless of the R_y -demand, for $T_I/T_p < 1$, the normal component of the near-field ground motions produce increased ductility demand compared to values

beyond this limit. Considering nearly elastic systems ($R_y=2$), this threshold is slightly decreased to 0.85 and approaches the response observed for bilinear systems. In this region of small periods, the inelastic displacements are significantly higher than the elastic and increase exponentially for shorter periods. The increased C_R values at short periods, already apparent from the Newmark-Hall relationship (Eq.2), starts for T_l/T_p larger than that of the bilinear case. This segment is affected by the residual capacity of the system and will be shown more clearly when we will study the effect of the r parameter. For $R_y>2$, three regions can be identified. The first is, as in the case of systems with $R_y=2$, the ductility demand significantly exceeds R_y . In the second region, between $T_l/T_p \approx 1 \div 2$, C_R is stabilized around 1.5. For $T_l/T_p > 2$, the values of C_R decrease linearly as T_l/T_p increases until a limiting value of T_l/T_p which depends on the level of R_y . This threshold also marks the beginning of the fourth, equal deformation region ($R_y \approx \mu$).

Figure 5: Influence of the negative slope, a_c of the negative stiffness segment on C_R .

On the other hand, if increasing μ_c of the reference oscillator from 1.2 to 6 the seismic response differentiates significantly and approaches that of the bilinear system. The effect of varying the slope a_h on C_R is increased mainly for fundamental periods less than $0.5.T_p$ and as the level of R_y increases. It can be noted that for $a_h=50\%$, the produced C_R values are smaller than the values of the bilinear system.

Regarding the reference oscillator ($\mu_c=1.2$), it can be observed that the sensitivity of C_R with respect to post-yield stiffness a_h , is rather small. The negligible differences when varying the slope a_h , are attributed to the hysteretic behavior of the system. To be more specific, the hysteresis loops of the reference oscillator and of the oscillator

characterized by $\mu_c=6$, for T_l/T_p equal to 0.45, subjected to the Chi-Chi Taiwan record (Table 1, #31), are shown in Fig.4, for $R_y=2,4$.

As can be seen from Fig.3, differences in the response of the reference oscillator are observed only for some T_l/T_p values e.g., Fig.3, $R_y=2$ and T_l/T_p between 0.2 and 0.5. In that region as shown in Fig.4, the hysteresis is performed in the pre-fracturing range ($\mu < \mu_c$), forming large loops. The energy is absorbed in a narrow, with respect to the displacement, region around the origin of the axes, while the strength reaches its peak values. For larger ratio T_l/T_p the loops follow the same pattern of hysteresis for every level of R_y . For $R_y > 2$ only a minor part of the hysteresis is performed in the initial range of the backbone, while the residual energy is absorbed through cycling beyond the negative drop. As R_y increases, the hysteresis of the backbone practically begins when the negative slope takes over, at a displacement over sixty times the corresponding yield displacement, while the level of strength is significantly reduced.

Figure 6: Influence of the normalized displacement, μ_c on the C_R

In the case of the oscillator characterized by $\mu_c=6$, the variance in a_h shifts the hysteresis loops increasing the sensitivity of the response. For $R_y=2$, the response is not significantly influenced by the increase of μ_c and the hysteresis shape approaches that of the reference oscillator ($\mu_c=1.2$). As R_y increases, the loops are formed again in the pre-fracturing region, while their shape is not affected. Respectively, the strength and displacement of the system under cyclic loading are not impressively varied with respect to the level of lateral strength, indicated by R_y . More pronounced variance in the shape of the loops can only be seen for large values of T_l/T_p and for highly ductile systems. Finally, it should be pointed out that with the exception of μ_c , neither the

slope of the negative segment a_c nor the height of the residual plateau r , significantly affect the hysteretic behavior of systems with regard to variations of a_h .

Contrary to the rather insignificant effect of a_h on the seismic response of the reference oscillator, the variation of the negative stiffness slope a_c , has a more pronounced affect as shown in Fig. 5. For systems with R_y equal to 2, $a_c=200\%$ results to remarkably higher values of C_R compared to systems with smaller a_c values. Moreover, for $a_c=200\%$, the spectral shape of C_R compared to other a_c values, is not affected by the increase in R_y . Inversely, a smaller slope value of 10% in the high-frequency and moderate-frequency region will give responses considerably smaller than those computed for oscillators having negative slope $a_c=-50\%$ or $a_c=-200\%$ and close to that of the bilinear system. This trend is amplified by the low value of the residual strength r and the relatively small value of μ_c of the reference system.

Figure 7: Influence of the height of the residual plateau, r , on the C_R .

It is remarked that increasing the value of μ_c is expected to affect mostly highly inelastic systems ($R_y=8$). Increasing the level of the residual strength (e.g., $r=20\%$), will eliminate the sensitivity of the response to variations of a_c , thus reducing its importance. However, it can be proved that there is no divergence in the response of systems for a_c varying between 10% and 25%.

The response of quadrilinear oscillators with varying μ_c is very close to the response observed for varying a_c concerning the spectral shape of the curves and the T_1/T_p values, where the spectral shape differs (Fig. 6). For high and moderate R_y levels only oscillators with low μ_c ($\mu_c=1.2$) have considerably divergent behavior. It should be pointed out that the influence of the normalized displacement on C_R is associated,

as discussed before, to the properties of the reference oscillator. For residual strength $r=20\%$, or larger, the effect of μ_c on C_R is smaller compared to the case of $r=5\%$.

The sensitivity of seismic response to the r parameter is shown in Fig.7. The C_R curves corresponding to different values of r , have a similar degrading pattern, while, the peak values of C_R for $T_I/T_p > 1$ and $R_y=4, 6, 8$ range around 1.5 and 2 and coincide with the formerly computed values. The trends observed in the previous plots are verified again. The different regions are clearly segregated, while the T_I/T_p thresholds coincide with the previously mentioned values. For $R_y=2$, the differences on C_R are clustered in the region of small periods ($T_I/T_p < 0.85$). The response seems very sensitive to r , while as R_y increases causes larger divergences in C_R values, compared to all other parameters investigated. The deviation in the calculated values can be observed for every value of the r , not only for the outliers, and is obvious for a wide range of periods, regardless of R_y .

6 CONCLUSIONS

The median of inelastic displacement ratios, C_R , of bilinear and quadrilinear oscillators with varying backbone parameters when subjected to fault-normal, near-fault ground motions are investigated. The conclusions of this study are briefly summarized:

- The relationship between the peak deformation of the inelastic and the corresponding linear SDOF systems is considerably affected by the properties of the oscillator. Oscillators with quadrilinear backbones produce C_R values remarkably higher than those of bilinear oscillators.
- The properties of the backbone affect significantly the seismic behavior. The C_R ratios are sensitive to all four backbone parameters. Among the four parameters considered, the normalized height of the residual plateau r , seems to be the most influential for almost all periods values, regardless of the level of R_y -demand. However, the response is also sensitive to the combination of the four parameters, especially that of μ_c and r .
- For nearly elastic systems the differences on C_R are clustered in the region $T_I/T_p < 0.85$, while after this threshold the equal deformation rule applies. For larger R_y values four regions can be identified, depending on the value of the T_I/T_p ratio. Initially increased ductility demand increases C_R for shorter periods. In the second region, $T_I/T_p \approx 1 \div 2$, C_R is stabilized around 1.5. For $T_I/T_p > 2$, C_R decreases linearly as T_I/T_p increases, until a limiting value, beyond which the equal-displacement rule applies.

Keywords: Seismic reliability, Incremental Dynamic Analysis (IDA), Secant Stiffness Degradation Index (SSDI), Cornell's Reliability Index.

Abstract. *Presented herein is a methodology that enables us to obtain in an efficient manner the seismic reliability of buildings for different levels of seismic intensity, taking into account the uncertainties associated with the properties of the structural system considered and with the seismic registers. This methodology is developed by means of Incremental Dynamic Analysis of the Secant Stiffness Degradation Index (IDA-SSDI), whose results enable evaluation of the intensity of system collapse in an easy and efficient manner in order to evaluate the reliability by means of Cornell's β index and a Z safety margin. The methodology is applied to a sample of eight 10-story buildings taken from Monte Carlo's simulation and 40 accelerograms registered in the Valley of Mexico City. The buildings simulated are modeled in the computer program DRAIN 2D for non-linear analysis.*

1 INTRODUCTION AND METHODOLOGY

The objective of this research is to collaborate in the mitigation of risks of a natural phenomenon that has been considered very important due to its effects and its ability to cause the end of the life cycle of a structure in a few seconds as in a seismic movement. The collapse of a structure brings with it the loss of human life and property which is associated with this type of natural disaster. The analysis of the probability of structural failure or of its complement, structural reliability, which has its beginnings in the 1960's, has served as a base in the development of structural engineering design methods that are presently being utilized as a guide in the creation of codes and manuals employed for the design and construction of secure structures by taking into account natural phenomena and uncertainties throughout the world.

Estimating of this structural reliability with reference to collapse occasioned by some seismic action is based on the capacity of lateral deformation in such a way that this collapse occurs when the maximum amplitude of the structural seismic response, or demand, surpasses the structural capacity. The deformation capacity concept as an indicator of the variable that determines the condition of collapse has severe limitations in its practical use when being used in quantitative terms.

These limitations range from sensitivity at the moment of impeding the collapse to certain variables, such as: the lateral deformation pattern of the system and the reductions of resistance and stiffness associated with the damage produced by previous response cycles corresponding to previous seismic occurrences, or by other causative agents of damage such as differential settlements. All these factors have inspired many new investigative endeavors to develop alternative criteria oriented to obtaining probabilistic estimations of seismic intensity values that lead to system collapse (Y_c).

One of the criteria utilized is the *Incremental Dynamic Analysis Method (IDAM)* proposed by Vamvatsikos and Cornell [1], which is based on the collapse intensity estimation (Y_c) with the help of an adequate scale factor that should be applied to the accelerogram. The possibilities of visualizing the evolution of the seismic response amplitudes in the manner in which the intensity grows and of observing the values reached by that intensity before the appearance of the seismic response amplitude outside of its limits, constitutes an important advantage of this method. For these reasons, in this article, the collapse intensity (Y_c) is obtained by using the *Incremental Dynamic Analysis Method* but applied for the first time to the *Secant Stiffness Degradation Index (IDAM-SSDI)*. This index is arrived at by the following equation [2]:

$$D(y) = 1 - \frac{K}{K_0} \quad (1)$$

Where (y) is the intensity of the seismic movement, K_0 is the value that K acquires when linear, and K is the value of the degraded secant stiffness adopted by the system at the moment when the lateral displacement in the roof reaches its maximum value. In this way, the collapse intensity (Y_c) is obtained when $D(Y_c)=1$.

On the other hand, the seismic reliability level is obtained by means of Cornell's [3] reliability index β , as follows:

$$\beta(y) = \frac{m_Z(y)}{\sigma_Z(y)} \quad (2)$$

Where $m_Z(y)$ is the median value of the building security margin Z before an earthquake with an intensity equal to (y), and $\sigma_Z(y)$ is the standard deviation of the said security margin. For the estimation of the index $\beta(y)$, for the present work, an alternative approach proposed by Díaz and Esteva, [4] was used, where the safety margin $Z(y)$ is defined as the natural loga-

rithm of the rate of (Y_c) and of the intensity of the ground movement (y) that act upon the system.

$$Z(y) = \ln \frac{Y_c}{y} = \ln Y_c - \ln y \quad (3)$$

Consequently, collapse occurs when $Z(y)=0$ for $D(y)=1$. The reliability index is defined as:

$$\beta(y) = \frac{E(\ln Y_c) - \ln(y)}{\sigma(\ln Y_c)} \quad (4)$$

Where $E(\ln Y_c)$, is the expected value of $\ln Y_c$.

2 ANALYZED STRUCTURES

The aforementioned methodology is applied to a sample of eight 10-story buildings from the Monte Carlo simulation taking into account the uncertainties associated with the concrete strength (f'_c), the steel yield (f_y), the live loads (W_{vmax}) and 40 accelerograms registered in the valley of Mexico City. The geometric properties of the original building are shown in Figure 1a. The building was designed in accord with the Mexico City Seismic Design Code [5,6] for office use. The fundamental period of the building is $T_o = 1.17s$ and has a yield strength coefficient of $C_y=0.4$, [7].

The simulated buildings are modeled in the DRAIN 2D program modified by Campos and Esteva [8], for its linear analysis. Each building contains an exterior and interior structural frame connected by a rigid floor diaphragm. The coupling between the frames was taken into account by means of a two-dimensional structural model connected by hinged links, see Figure 1b. The frames were constituted by flexural beams and columns. The moment-rotation ratio for each element was calculated assuming the model for confined concrete originally proposed by Kent and Park [9] and modified by Park et al [10]. The axial stress-strain ratios corresponding to the steel bars were represented by means of Mander model [11]. The hysteretic structural behavior was assumed to be bilinear with the ratio of the post-yielding to the initial stiffness equaling 3.0%.

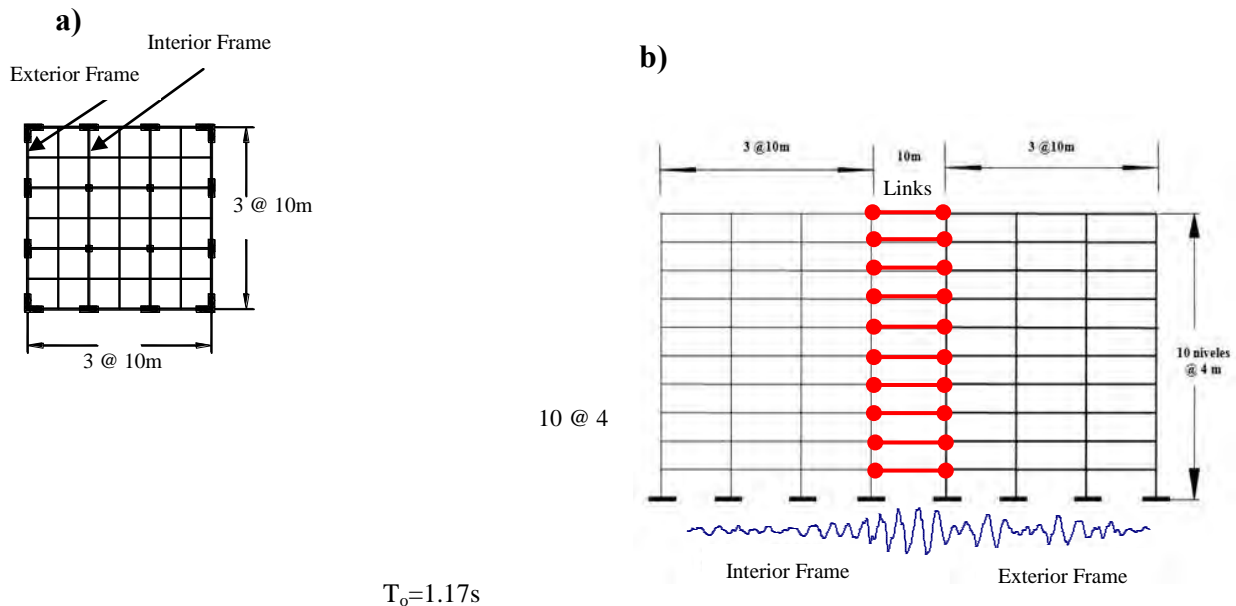

Figure 1. a) Original building plan and elevation and b) two-dimensional model used for non-linear analysis.

In Table 1 the eight models are shown that consider the uncertainties of the mechanical properties of the materials (f'_c and f_y) and in the maximum live loads applied ($W_{vm\acute{a}x}$). The nominal values (MM) and means (MN) are also shown. In this table the nomenclature ($M1$ - $M8$) is used to denote the models with uncertain values for mechanical properties of the materials and applied live loads. ($M9$) is used for the model with median values and ($M10$) is used for the model with nominal values. The uncertain values of each parameter (f'_c , f_y and $W_{vm\acute{a}x}$) are obtained through simulations [12].

<i>Frame</i>	f'_c (kg/cm^2)	f_y (kg/cm^2)	$W_{vm\acute{a}x}$ (kg/m^2)
<i>M1</i>	308	5090	78
<i>M2</i>	246	4445	134
<i>M3</i>	287	3970	40

3 SEISMIC MOVEMENTS USED FOR THE ANALYSIS

The analysis of seismic reliability requires the use of registers that can adequately reflect the dynamic characteristics and the energy content of the seismic movements expected to occur at the construction site. For this analysis, forty narrow-band earthquakes registered in the lake region of Mexico City were used. All the seismic movements were recorded during subduction events with epicenters located on the Pacific coast of Mexico, see Figure 2a, which present magnitudes (M_w) from 6.0 to 8.1 grades. The corresponding elastic strength spectra of pseudo-acceleration are shown in Figure 2b, for a critical damping percentage (ξ) of 5%. It can be seen that the seismic movement spectra present dominant periods of between 1.5 and 2.2s.

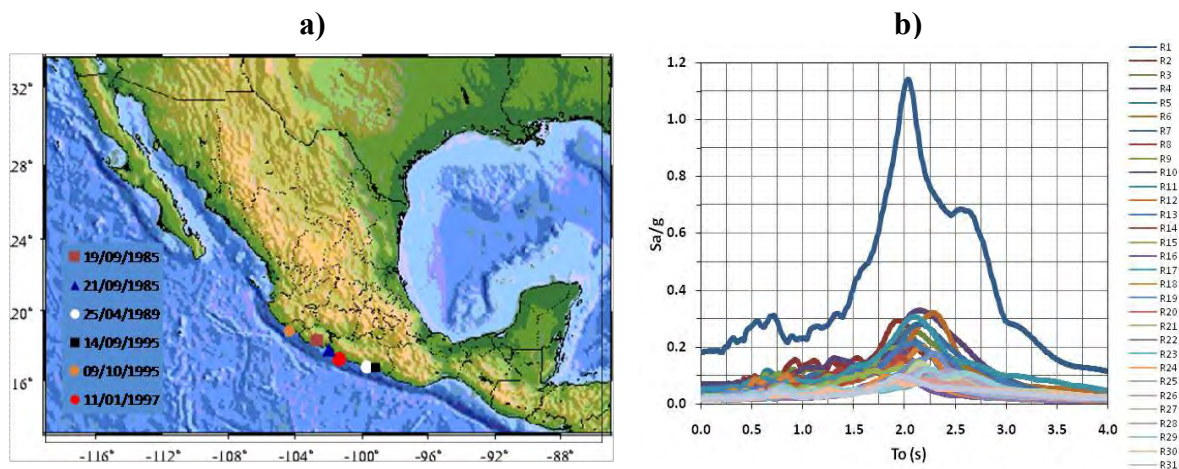

Figure 2. a) Subduction earthquake epicenters used for the analyses and, b) the pseudo-acceleration corresponding elastic spectra for 5% damping.

4 INCREMENTAL DYNAMIC ANALYSIS OF THE SECANT STIFFNESS DEGRADATION INDEX (*IDA-SSDI*).

The *Incremental Dynamic Analysis Method of the Secant Stiffness Degradation Index (IDAM-SSDI)* was used to obtain the probabilistic estimations of the seismic intensity values that lead to system collapse in order to evaluate the structural reliability. These results are shown in Figure 3 associated with the 40 earthquakes and eight 10-story frames used for the analysis, taking into account the uncertainties associated with the earthquakes and the mechanical properties of the building materials. In this figure, we graph the seismic intensity level measured by means of the pseudo-acceleration spectral corresponding to the fundamental period of the structure ($T_o=1.17s$) for a 5% critical damping (Sa/g) divided by the acceleration of gravity (g), which in turn has been affected by an adequate scaling factor in order to bring about the collapse of the structure.

In the horizontal axis the performance of the structure is graphed measured by the Secant Stiffness Degradation Index $D(y)$, which is an index proposed as an indicator of structural damage caused by an earthquake according to increase in intensity. The seismic effects decrease the capacity of the building leaving the structural system in a state of greater vulnerability and eventually leading to collapse.

Figure 3. Incremental Dynamic Analysis of the Secant Stiffness Degradation Index (*IDA-SSDI*) for 40 earthquakes and the eight 10-story buildings being studied. Yellow circles indicate the intensity approaching collapse (Y_{cc}) and red circles indicate the collapse intensity (Y_c).

The curve forms in Figure 3 vary depending on the earthquake, the frame and the grade of the non-linear structure. These curves are obtained by scaling the seismic intensity until a state of collapse occurs. This is indicated in the figure by means of red circles (Y_c), which occur when the secant stiffness degradation value adopted by the system at the moment when the lateral displacement in the roof reaches its maximum value, that is zero, ($K=0$). That is to say, when the Secant Stiffness Degradation Index is equal to the unit ($D(Y_c)=1$), which corresponds to a base shear in terms of very low or zero capacity. One moment before the state of collapse occurs, the seismic intensities nearing collapse are obtained, which are indicated in the figure with yellow circles (Y_{cc}), varying from $0.823 \leq D(y) < 1.0$. Using $D(y)$ as an index of collapse is very useful because it eliminates the difficulty of defining the collapse state from the maximum displacement of the roof. By means of *IDAM-SSDI* analysis, valuable information can be obtained regarding the behavior of the structural system ranging between $0.8 \leq d < 1.0$ associated with the limit state near collapse.

The statistical values of the parameters corresponding to the average and to the standard deviation of collapse and near collapse for the intensity and the damage index are shown in Table 2.

	Y_{Cc} Sa/g	Y_C Sa/g	$D(Y_{Cc})$	$D(Y_C)$
Average	0.8832	0.8898	0.9308	1.00
Standard deviation	0.2610	0.2620	0.0470	0.00

Table 2. Statistical parameters of the limit state near collapse and at collapse.

There are no significant differences between the intensities Y_{Cc} and Y_C needed in order to evaluate reliability, which is not the case for $D(Y_{Cc})$ and $D(Y_C)$, whose values vary depending on the structural sensitivity in the zone near collapse.

The Incremental Dynamic Analysis Method results attained for each frame and earthquake by means of the scale factors used from a state near collapse to a state of collapse intensity (Y_C) are presented in Figure 4. The curves with greater slope require a Scaling Factor (SF) greater than that required for curves with lesser slope. It can be observed that for some earthquakes, very low scale factors of 3 or 4 are needed; for other earthquakes, factors as high as 70 or 80 are needed, which means that these factors vary due to the uncertain nature of earthquakes and the variations in mechanical properties of the materials of the buildings under investigation.

Figure 4. Incremental Dynamic Analysis Method of the Secant Stiffness Degradation Index (*IDAM-SSDI*), depending on the scale factor (SF).

It can also be observed that the seismic collapse intensity values range from $0.594g$ as a minimum value in Figure 3 for the Frame $M8$ and the earthquake $R35$ with a 25.21 scaling factor SF in Figure 4, up to the maximum value of $1.52g$ found for Frame $M7$ for the seismic record $R39$ with a 60.17 SF .

Figures 5a, b, and c, show the effect of the scale factor (SF) has on the overall structural response and is represented by means of the base shear and maximum roof displacement hysteresis cycles. From this the secant stiffness (K) required to obtain the damage index $D(y)$ is obtained. This stiffness is obtained from the straight line slope that connects the origin with

the maximum roof displacement. The slope is obtained by dividing the base shear from the corresponding maximum roof displacement.

In Figure 5a, it can be observed that for a $SF=17.51$ for this earthquake and frame (R34, M5), there exists an almost linear behavior, such that the secant stiffness $K=7196.92 \text{ tons/m}$ is similar to the elastic stiffness: $K_0=9882.86 \text{ tons/m}$, so that the result for the damage index is low: $D(y)=0.272$. This is to say, a structure that is practically elastic.

In Figure 5b, for $SF=23$, the nonlinear behavior is significant, therefore the secant stiffness is low: $K=384.40 \text{ tons/m}$, resulting in a damage index close to one: $D(y)=0.9611$.

In Figure 5c, for an $SF=26.30$, as can be observed, the structure has collapsed, and displacements is considerable, giving a value of $K=0$; and therefore, a damage index of $D(y)=1$.

Of course, in the previous cases, there was intermediate SF s, which made possible the observation of the evolution of the damage index $D(y)$ as can be seen in Figures 3 and 4.

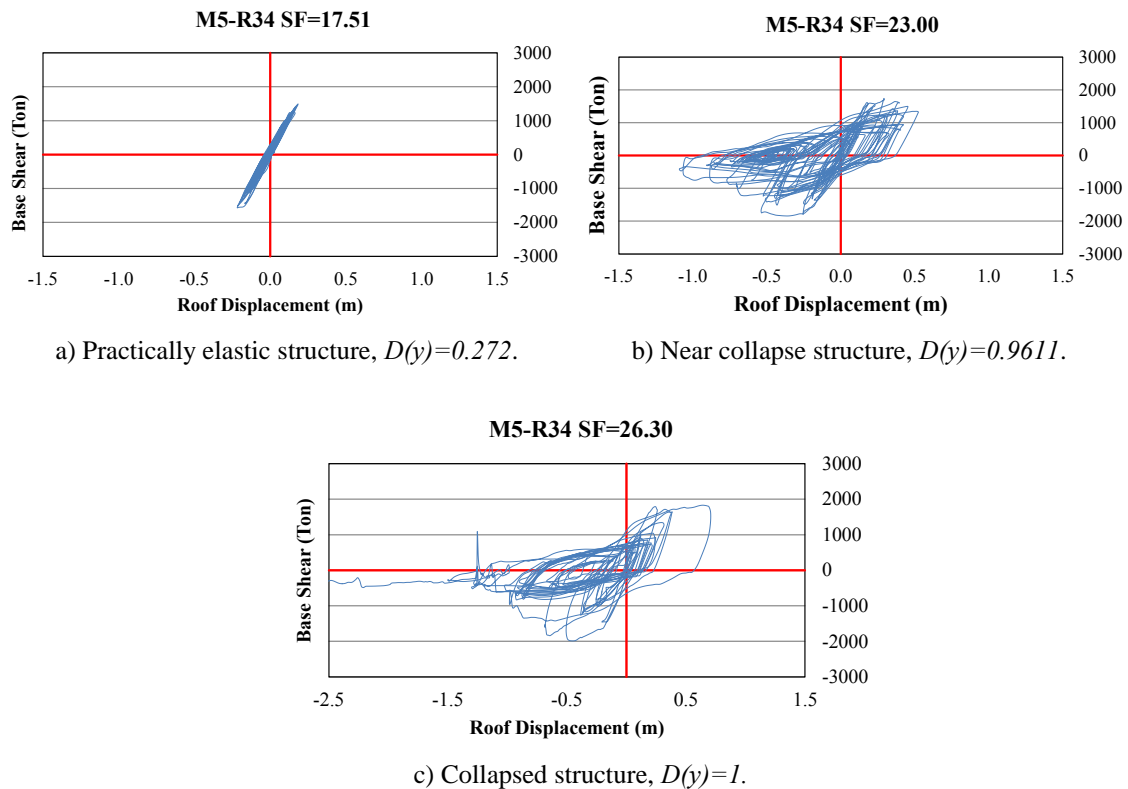

Figure 5. Global response hysteresis cycles for different Scale Factors (SF).

The elastic stiffnesses (K_0) of the simulated frames were obtained from the Pushover analyses, which are shown in Figure 6.

Figure 6. Pushover analyses for eight 10-story frames (M1-M8). The black line corresponds to the frame with mean mechanical proprieties (MPM).

5 RELATIONSHIP BETWEEN THE DAMAGE INDEX $D(y)$ AND THE SAFETY MARGIN $Z(y)$.

Another way of seeing how structures vary as they near to collapse, when $D(y)$ reaches its maximum value $D(y)=1$, is by means of the relationship between the damage index $D(y)$ and the safety margin $Z(y)$, which is a function of the collapse intensity (Y_C), and the earthquake intensity (y), in other words: $Z(y)=\ln(Y_C)-\ln(y)$, see Equation 3. The value pairs for these variables can be seen in Figure 7 for the different frames and earthquakes analyzed. It can be observed that as the safety margin decreases the structure approaches collapse when $D(y)=1$ and $Z(y)=0$. This tendency can be better seen by means of linear regression represented by the blue curve representing the expected value of the safety margin $E(Z)$. It can be noted that this curve begins in an area where the values represent a low structural vulnerability, values of $Z>0$ far from collapse and values for d close to zero with linear elastic structural behavior, to the collapse values when $(D=d=1, Z=z=0)$, or better, when $\ln D=0$ and $Z=0$. In the event that $Z(y)$ is negative, $Z(y)<0$ indicates that the structural collapse intensity (Y_C) was surpassed by the earthquake intensity (y), which is to say that it has already collapsed $D(y)=1$, as can be seen in Figure 7.

Figure 8 shows the deviation trend for the safety margin Z related to the damage index values $D(y)$ and its trend curve which is produced by linear regression. It may be noted that in general the values are low as the structure approaches collapse $D(y)\Rightarrow 1$, the variance $\sigma^2(Z)$ tends to zero.

Figure 7. Relationship between the damage index $D(y)$ and the safety margin $Z(y)$. Blue line: expected value of $E(Z)$.

Figure 8. Mean square error values used to estimate the variance of Z and its trend line in red.

6 OBTAINING SEISMIC STRUCTURAL RELIABILITY: $\beta(y)$ vs $Z(y)$.

With the collapse intensities (Y_C) obtained from the IDA 's, the seismic reliability of buildings in terms of the safety margin Z in Figure 9 is obtained. The straight lines of the figure are obtained using Cornell's index $\beta(y)$ (vertical axis) corresponding to the eight 10-story frames and 40 earthquakes used for the analyses and how they relate to the safety margin for $Z(y)$ (horizontal axis), from the state of system collapse when $Z(y=Y_C)=0$, to values of $Z(y < Y_C)=1$, when the intensity of the earthquake (y) is much lower than that of collapse (Y_C), when the structure is elastic. As can be seen, their relationship is linear, so a greater safety margin $Z(y)$ in the system corresponds to a higher reliability index $\beta(y)$ in the structure.

Figure 9. Cornell's Reliability Index $\beta(y)$ for different values of the Safety Margin $Z(y)$ for the eight 10-story frames of Monte Carlo simulated and 40 earthquakes used in the analyses.

With lower resistance in the frame and higher intensity of the earthquake, a straight line with a lower reliability index in Figure 9 is obtained. For the same $Z(y)$, different reliability levels are obtained depending on the level of uncertainties in the frame and the earthquake in question.

For purposes of design or evaluation, a suitable reliability index $\beta(y)$ must be positive, reaching values of up to 5 as shown in Figure 9 for a safety margin $Z(y)=1$, indicating a structure with a completely elastic behavior. A negative reliability index is an undesirable index, which indicates a high probability of collapse and this happens when the expected value of the natural logarithm of collapse intensity is reached and/or surpassed by the intensity of earthquake; in other words: $y_i \geq E(\ln Y_C)$. In this way, a safety margin $Z(y)$ would be recommended as long as it is high enough for a determined limit state for a positive reliability index. For example, for the straight lines in the lowest part of the figure, the minimum $Z(y)$ required should be greater than 0.6 to obtain a positive index. This happens to the frame of least resistance $M8$ and for an intense earthquake $R37$, and for $M7-R39$ and $M8-R36$.

The forty straight lines corresponding to each building and earthquake ($M-R$) in Figure 9 are all parallel to each other, consequently, they share the same slope m , showing the differences between each one of these straight lines in the corresponding values for $\beta(Y_C)$ when $Z(Y_C)=0$. Due to the linear relationship of the variables, in general terms, the lines in the figure can be expressed as follows:

$$\beta(y) = \beta_{Z=0}(Y_C) + m \cdot Z(y) \quad (5)$$

Where: $\beta_{Z=0}(Y_C)$ is the ordinate at $x=0$, which is to say that the value of $\beta(y)$ when collapse occurs: $Z(y)=0$.

Moreover, a particular expression can be found for obtaining the reliability index, or the safety margin that we wish to assign it to the structure in question considering that $\beta_{Z=0}(Y_C)$ is known or easily obtained from the results already obtained, in this case for the 10-story buildings:

$$\beta(y) = \beta_{Z=0}(Y_C) + 3.698 Z(y) \quad (6)$$

Where: $\beta_{Z=0}(Y_C)$ indicates the level of uncertainties associated with the earthquake, the mechanical properties and the live loads of the building considered in this study. For the par-

ticular case in which the ordinate is zero: $\beta_{Z=0}(Y_C)=0$, the index $\beta(y)$ will have a relationship of 3.7 times the safety margin $Z(y)$.

7 CORNELL'S RELIABILITY INDEX $\beta(y)$ RELATED TO THE SECANT STIFFNESS DEGRADATION INDEX $D(y)$.

Another way of relating Cornell's reliability index $\beta(y)$ is based on the damage index $D(y)$ for a given intensity (y), such as is shown in Figure 10. To the degree that the reliability level decreases according to the damage index comes closer to collapse, that is to say for $D(y)=1$. Just as in Figure 9, when $\beta(y)$ is negative indicating that the average collapse intensity of has been surpassed by the intensity of the earthquake. If collapse intensity coincides with that of the average of all frames and earthquakes, then a reliability index of zero would occur: $\beta(y)=0$, as takes place for the safety margin: $Z(y)=0$, when $D(y)=1$, but by definition $\beta(y)$ takes into account the average of all collapse intensities, see Eq. 4 and not the collapse intensity of each earthquake, as $Z(y)$, see Eq. 3. In relation to this, this leads us to observe that in Figure 10 for a $\beta(y)=0$ or negative, a structural collapse has not necessarily been brought about; this happens only when the earthquake collapse intensity is close to average. In such a way a collapse could be obtained a $D(y)=1$ for a positive reliability $\beta(y)$ or a non-collapse $D(y)<1$ when reliability $\beta(y)$ is negative. Therefore, this figure is not the most suitable for establishing the relationship between the reliability and the damage index, but rather, it does provide a general idea of their values and facilitates the understanding of the behavior of these variables.

Figure 10. Cornell's Reliability Index $\beta(y)$ in relation to the damage index $D(y)$ corresponding to the eight 10-story frames and 40 simulated earthquakes used in the analyses.

8 CONCLUSIONS

- A more efficient methodology based on the Incremental Dynamic Analysis of Secant Stiffness Degradation Index (*IDA-SSDI*) for evaluating the reliability of buildings by means of Cornell's index $\beta(y)$ and the safety margin $Z(y)$ was developed.
- An expression, see Equations 5 and 6 that allows us to directly and simply evaluate the reliability of a 10-story building from a determined safety margin, (e.g. for the evaluation and/or structural design associated with a determined limit state) was obtained.
- For the first time Incremental Dynamic Analyses applied to the Secant Stiffness Degradation Index (*IDA-SSDI*) were obtained. These results allow easy and efficient evaluation of the collapse intensity (Y_C) of the system needed in order to assess the reliability.

- From Figure 9 suitable limits can be established for structural design and/or evaluation purposes of $\beta(y)$ and $Z(y)$, from 0.0 to 5.0 and from 0.6 to 1.0, respectively, for a 10-story building and depending on the limit state that one wishes to evaluate. We recommend studying other multi-story buildings, as a second phase.

Abstract. *Confining wraps or jackets to rehabilitate and strengthen existing concrete columns has proven to be an efficient technique for seismic retrofit of structures. However, most of the compressive strength models of confined concrete only consider the increased strength and ductility provided by fiber reinforced polymers (FRPs), neglecting the contribution of the existing steel reinforcement inside the column’s section. Even if the existing steel stirrups in a reinforced concrete column are not sufficient to confine the concrete core, they must also contribute along with the FRP jacket in confining the section. Therefore, the FRP-confined concrete model proposal by fib has been enhanced to take into account the confining effect of the already existing steel reinforcement when retrofitting a reinforced concrete column with FRP jacketing. To this end, confining pressures contributed at each step of deformation by the case of existing transverse and longitudinal steel reinforcement have been evaluated considering the stress-strain law of the reinforcing steel. Moreover, compatibility of strain in the lateral direction between the jacketing system and the encased concrete is enforced. Finally, the bilinear stress-strain response of FRP-confined concrete is terminated by jacket rupture owing to hoop strains exceeding the strain capacity of the material or to interaction of the jacket with the buckled longitudinal bars. Correlation with three experimental studies gives promising results.*

1 MODELING OF CONCRETE CONFINED WITH STEEL&FRP

The behavior of confined circular sections under axial load is characterized by the radial lateral dilation, which causes radial confining forces or else axisymmetric passive confining pressure that increases with the amount of lateral expansion. Considering this scheme for the case of confinement by means of FRP jacketing, in order to define the confining pressure acting on the section, it is necessary to define the jacket strain, or circumferential strain, parallel to the fibers orientation. Relating the circumferential strain to the strain in the radial direction, the following simple relationship is obtained (Figure 1):

$$\varepsilon_c = \frac{\Delta C}{C} = \frac{2\pi R(1 + \varepsilon_r - 1)}{2\pi R} = \varepsilon_r \quad (1)$$

Owing to the axisymmetry of the problem, the outcome is that the circumferential strain and the strain in the radial direction are equal. This property has been extensively used to calculate directly the radial confining forces based on experimental data by strain gages attached parallel to the fibers orientation in order to obtain the circumferential strains. Along this line, it seems useful to try and extend the simple calculation above to the case where steel stirrups and external FRP jacketing are simultaneously present. The steel ties divide the section into two parts: the first is the concrete core and the second is the concrete cover.

$$\begin{aligned} \varepsilon_c &= \frac{\Delta C}{C} = \frac{2\pi \{ [R_{core}(1 + \varepsilon_{r,core}) + c(1 + \varepsilon_{r,cover})] - (R_{core} + c) \}}{2\pi(R_{core} + c)} \\ \varepsilon_c &= \frac{\Delta C}{C} = \frac{R_{core}(1 + \varepsilon_{r,core}) + c(1 + \varepsilon_{r,cover})}{(R_{core} + c)} - 1 \end{aligned} \quad (2)$$

However, for the concrete core the following assumption still holds:

$$\varepsilon_{c,core} = \varepsilon_{r,core} \quad (3)$$

As explicitly stated above, the equation of radial strains and jacket strains for the case of both FRP and steel confined concrete in circular sections is no longer valid. The circumferential strain of the external jacket is based on the radial strains of both concrete cover and concrete core, where in the latter the presence of the steel ties plays an important role.

Figure 1: Circular Concrete Section confined by steel stirrups and/or FRP Jackets

2 NUMERICAL MODEL

The mechanical properties of concrete (strength, ductility, energy dissipation) are substantially enhanced under a triaxial stress state. In practice, in order to develop a similar stress state, closed stirrups or spiral reinforcement are used, so that, together with the longitudinal reinforcement, the lateral expansion of concrete is limited. This kind of (passive) confinement affects the behavior of the material favorably after the initiation of internal cracking, which gives rise to the initiation of expansion.

For low strain values, the stress state in the transverse steel reinforcement is very small and the concrete is basically unconfined. In this range, steel and FRP jacketing behave similarly. That is, the inward pressure as a reaction to the expansion of concrete increases continuously. Therefore, speaking in terms of variable confining pressures corresponding to the axial strain level in the section and active triaxial models defining axial stress-strain curves for concrete subject to constant lateral pressure, it can be stated that the stress-strain curve describing the stress state of the section has to cross all active confinement curves up to the curve with lateral pressure equal to the one applied by the stirrups at yielding. Beyond yielding of stirrups, the lateral pressure is still increasing only due to the FRP jacketing, while the steel lateral pressure remains constant. The corresponding stress-strain curve of the section throughout this procedure converges to a confined-concrete axial stress-strain curve that is associated with a lateral pressure magnitude equal to the tensile strength of the FRP jacket plus the yielding strength of ties (excluding the strain hardening behavior of steel, since ultimate strains of steel are usually much higher than those of FRP jackets). In order to model this behavior, an existing FRP-confined concrete model (Spoelstra and Monti 1999) has been enhanced to include the steel ties contribution and thus model in a more consistent way circular columns with transverse reinforcement and retrofitted with FRP jacketing. The above model was based on an iteration procedure that needed to be modified as Figure 2 shows.

In the procedure below (Figure 2), after imposing an axial strain on the section, a pressure coming from the FRP jacket is assumed. Then, the Poisson's coefficient until yielding of steel stirrups and the pressure coming from the steel ties is calculated based on the BGL model (Braga et al 2006). Here, also the longitudinal bars' contribution and the arching action between two adjacent stirrups along the column are taken into account according to that model (see Table 1). The confining pressure in the concrete core is simply the summation of

the lateral pressures contributed by the two confining systems (FRP and Steel). The *fib*'s model proposal (Spoelstra and Monti 1999) beyond this point is basically used to define the remainder of the parameters declared above, applying that model for the two different regions already mentioned. The focal point of the procedure is in the last step where the confining pressure of the jacket is defined based on the circumferential strain of Equation. 2. Finally, at this point, cases where partial wrapping is applied have been included too (14th fib bulletin 2001, Table 1). Such an approach permits also in cases of repair and retrofit two different concrete strengths to be considered, one for the new layer of concrete applied externally and the other for the old concrete in the concrete core which may also be cracked due to former seismic loading.

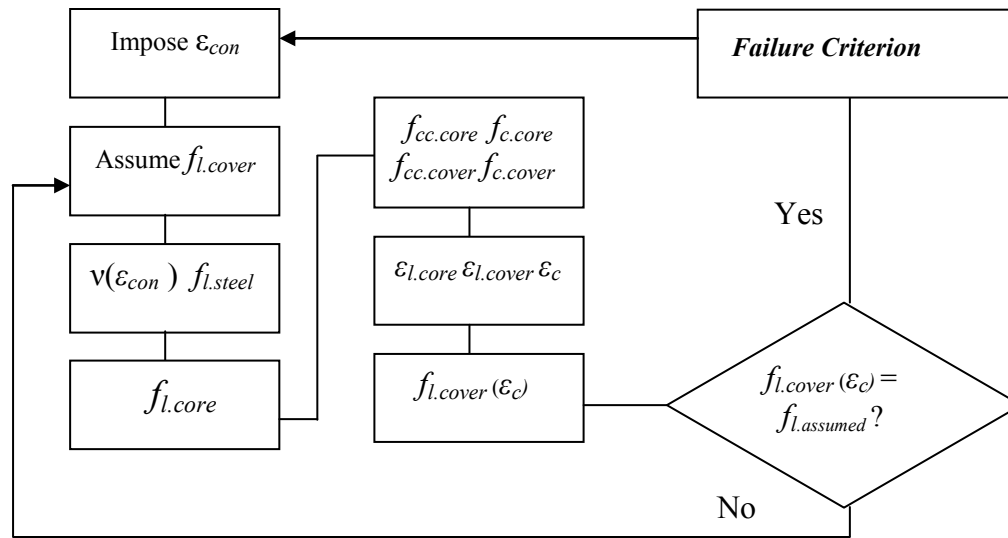

Figure 2. Iterative Procedure

3 FAILURE CRITERION

3.1 FRP Confined Circular RC Sections

It has been well established in recent studies that the rupture strains/strengths measured in tests on FRP confined cylindrical specimens fall substantially below those from flat coupon tensile tests. Several reasons have been suggested for the observed lower rupture strains in place, among which are [(Carey and Harries 2005), (Lam and Teng 2004), (Matthys et. al. 2005)]:

- Misalignment or damage to jacket fibers during handling and lay-up.
- The radius of curvature in FRP jackets on cylinders as opposed to flat tensile coupons.
- Near failure the concrete is internally cracked resulting in no homogeneous deformations. Due to this non-homogeneity of deformations and the high loads exerted on the cracked concrete, local stress concentrations may occur in the FRP reinforcement.
- The existence of a lap-splice zone in which the measured strains are much lower than strains measured elsewhere.

Accounting for these effects an ultimate tensile coupon FRP strain reduced by a k factor (ranging in literature between 50-80 %) is compared to the circumferential strain of concrete (Equation. 2) and the ultimate compressive axial strain of concrete is considered to be attained when:

$$\varepsilon_c \leq k \cdot \varepsilon_{j.rup.coup} \quad (4)$$

3.2 FRP&Steel Confined Circular RC Sections

In old-type circular columns with inadequate transversal reinforcing details (where FRP jacketing are a commonly used remedy), the unsupported length of longitudinal bars (between 2 successive stirrups) is often much greater than $6D_b$. Therefore, the risk for buckling of longitudinal bars under compressive loads soon after yielding is higher. A dire implication is reduced effectiveness of the FRP wraps due to interaction between buckled longitudinal bars and the jacket which may cause premature failure by rupture of the jacket (Sheikh S.A. & Yao G. 2002), (Tastani et al. 2006). This is an additional source of error contributing to overestimation of strength of FRP confined concrete in addition to that generated by the difference between nominal and in-situ strain capacity of the wraps as detailed above. It is the objective of the present paper to study the interaction between wraps and compression reinforcement in FRP-encased reinforced concrete columns, with particular emphasis on the occurrence of instability conditions and the dependable compressive strain of the column prior to actual buckling of the rebars.

In this model, the dilation of concrete core and concrete cover are described through the following equation (Equation. 5) of the model by Spoelstra and Monti (1999).

$$\varepsilon_r(\varepsilon_{con}, f_l) = \frac{E_{con}\varepsilon_{con} - f_c(\varepsilon_{con}, f_l)}{2\beta f_c(\varepsilon_{con}, f_l)} \quad (5)$$

$$\beta = \frac{5700}{\sqrt{|f_{co}|}} - 500$$

Thus, the lateral pressure of the FRP jacket confining the concrete cover has been taken into account and by relating the critical buckling conditions with the onset of significant strength loss of the concrete cover, the effect of the confining pressure exerted by the jacket in delaying the occurrence of buckling of the longitudinal bars can be evaluated. Therefore, the critical buckling conditions are delayed depending on how axially stiff is the jacket, which accordingly delays the failure of the concrete cover (that laterally supports the longitudinal bar). This onset of loss of resistance in concrete has been proved to be the point when the net volumetric strain of the material becomes equal to zero (Pantazopoulou and Mills 1995). In circular sections this occurs when:

$$\varepsilon_V = 0 \Rightarrow 2 \cdot \varepsilon_r = \varepsilon_{con} \Rightarrow \nu = 0.5 \quad (6)$$

However, another condition that should be valid for the attainment of critical instability conditions of the longitudinal bars in the high confining stress states under consideration is the occurrence of compression yielding of the longitudinal bar. Regarding this step, it is interesting to note with reference to Figure 3 for a given concrete strength, the point where the volumetric ratio becomes zero moves forward into higher axial compression strain values with increasing confining pressures. Thus, as shown by the two curves in Figure 3 corresponding to different confining pressures, the difference in the lateral behavior of the concrete cover (confined with the jacket's pressure) and the concrete core (confined by both the steel's and FRP's pressure) should also be considered.

Figure 3: Volumetric Strain versus Axial Compressive Strain (Pantazopoulou and Mills 1995)

As it is shown in previous studies (Monti and Nuti 1992), (Bae et al. 2005), the buckling length and the L_{buck}/D_b ratio are critical parameters for the post buckling behavior of longitudinal bars under compression. In cases of columns constructed with obsolete codes with the spacing of the stirrups ranging between 200-500 mm (buckling length) and bar diameters from 12-20 mm, the L_{buck}/D_b ratio is ranging between 10-42. However, apart from old type columns the assumption that the buckling length is equal to the spacing of the stirrups in a RC column does not hold true in all cases (Dhakal and Maekawa 2002) and it may extend over more than a single tie spacing. In order to take into account this behavior (cases of reinforcement repair and FRP retrofit) the following procedure is suggested.

The longitudinal bar is modeled as a pin-ended bar supported along its length by an elastic foundation as shown in Figure 4. The foundation modulus is k (N/mm²) and it is such that when the bar deflects by an amount u , a restoring force ku (N/mm) is exerted by the foundation normal to the bar.

Figure 4: A pin-ended bar on elastic foundation.

The governing homogeneous differential equation and the associated eigenvalue problem are:

$$EI v^{iv} + P v'' + k v = 0 \quad (7)$$

$$P_{cr} = \frac{\pi^2 EI_{red}}{L_{buck}^2} \left[m^2 + \frac{1}{m^2} \left(\frac{k L_{buck}^4}{\pi^4 EI_{red}} \right) \right]$$

Note that if $k = 0$ (which occurs upon yielding of the stirrups), the minimum value of P_{cr} becomes the classical Euler buckling load. In order to determine the critical load, the buckling mode m equal to 1 should be used. The stiffness k representing the supporting system of stirrups could be calculated as follows:

$$k = n \cdot \frac{E_s \cdot A_{sh}}{L_{buck} \cdot \pi \cdot D_{core}} \quad (8)$$

$$L_{buck} = (n + 1) \cdot S$$

$$EI_{red} = 0.5 \cdot E_s \cdot I_b \cdot \sqrt{\frac{f_{yl}}{400}} \quad (\text{Dhakar and Maekawa 2002})$$

Solution of the problem above is obtained by setting the critical load of the bar equal to its yield force; in this case the only unknown is the number n of the stirrups, n over the buckling length. Therefore, by solving Equation.7 for n , the buckling length is determined. The value of n may be rounded to the nearest integer owing to that the pin-ended bar segment engaged in buckling is assumed to span between successive inflection points of the real deformed shape. If convergence is not possible for $n > 1$, the buckling length is taken equal to the spacing of stirrups.

Summing up, after the critical conditions of a longitudinal compressive bar have been attained (this is assumed to coincide upon compression yielding of the bar and the Poisson's coefficient at the concrete cover exceeds the value of 0.5) the buckling length of the bar is determined. Then, based on the model by Bae et al. 2005 who have related the axial strain with the transversal displacement of the buckled longitudinal bar for a given L_{buck}/D_b ratio the transversal displacement of the bar is calculated (Table 1). Since, for a longitudinal bar embedded in a RC member axial shortening of the bar means the same amount of shortening for the surrounding concrete mass (Pantazopoulou 1998), the axial strain in the bar is taken as equal with the axial strain of concrete. Finally, the jacket's circumferential strain due to buckling is determined as follows:

$$\varepsilon_{c.buck} = \frac{2 \cdot \pi \cdot |w - c|}{\pi \cdot D} \leq \varepsilon_{j.rup.coup}, \text{ (Full wrapping)}$$

$$\varepsilon_{c.buck} = \frac{2 \cdot \pi \cdot \left|w - \frac{c}{2}\right|}{\pi \cdot D} \leq \varepsilon_{j.rup.coup}, \text{ (Partial wrapping)}$$
(9)

It follows from the above equation (Equation. 9) that a tolerance equal to the concrete cover for full wrapping and half of the concrete cover for partial wrapping is given before the initiation of jacket's strains due to buckling of longitudinal bars since the concrete cover should be severely cracked in case of full wrapping and some spalling could appear in case of partial wrapping. Since, the displacement of the buckled longitudinal bar could be high and the phenomenon affects locally the jacket where the FRP material behavior could be considered linear-elastic, the results are compared to the deformation capacity of tensile coupons (dilation strains and buckling strains are studied independently). In the proposed algorithm detailed above, the failure criterion is used in two steps. Firstly, the circumferential strain due to dilation of concrete under compression is compared to a reduced FRP tensile coupon strain and secondly the induced circumferential strains due to buckling which locally accelerate the jacket's rupture are compared to the deformation capacity of flat FRP tensile coupons. If one of these conditions are fulfilled the iteration procedure is terminated.

(Braga et al. 2006)	$f_{l.steel}(\varepsilon_{con}) = k_{sl} \frac{E_{con} E_s A_{sh} \nu(\varepsilon_{con})}{R_{core} E_{con} S + E_s A_{sh} [1 - \nu(\varepsilon_{con})] \cdot [\nu(\varepsilon_{con}) \cdot \varepsilon_{con} + 1]} \cdot \varepsilon_{con}, \varepsilon_{sh} \prec \varepsilon_{yh}$ $f_{l.steel}(\varepsilon_{con}) = k_{sl} 0.5 \rho_{sh} f_{yh}, \varepsilon_{shu} \geq \varepsilon_{sh} \geq \varepsilon_{yh}$ $\rho_{sh} = \frac{4 A_{sh}}{D_{core} S}, \varepsilon_{yh} = \frac{f_{yh}}{E_s}, \varepsilon_{sh} = \varepsilon_{c.core} = \varepsilon_{r.core} = \nu(\varepsilon_{con}) \cdot \varepsilon_{con}$ $\nu(\varepsilon_{con}) = \nu_0 \left[1 + 0.2 \left(\frac{\varepsilon_{con}}{\varepsilon_{c0}} \right) - \left(\frac{\varepsilon_{con}}{\varepsilon_{c0}} \right)^2 + 1.55 \left(\frac{\varepsilon_{con}}{\varepsilon_{c0}} \right)^3 \right], \nu_0 = 0.2, \varepsilon_{c0} = 0.002$ $k_{sl} = \frac{45 \xi_l^3}{45 \xi_l^3 + \beta \xi_{st}}, \xi_l = \frac{D_b}{S}, \beta = \frac{D_h}{D_b}, \xi_{st} = \frac{2 D_h}{\pi R_{core}}$
(Spoelstra and Monti 1999)	$f_c = \frac{f_{cc} \cdot x \cdot r}{r - 1 + x^r}, x = \frac{\varepsilon_{con}}{\varepsilon_{cc}}, \varepsilon_{cc} = \varepsilon_{co} \left[1 + 5 \left(\frac{f_{cc}}{f_{co}} - 1 \right) \right], r = \frac{E_{con}}{E_{con} - E_{sec}}$ $E_{sec} = \frac{f_{cc}}{\varepsilon_{cc}}, \frac{f_{cc}(f_l)}{f_{co}} = 2.254 \sqrt{1 + 7.94 \frac{f_l}{f_{co}}} - 2 \frac{f_l}{f_{co}} - 1.254,$ $\varepsilon_r(\varepsilon_{con}, f_l) = \frac{E_{con} \varepsilon_{con} - f_c(\varepsilon_{con}, f_l)}{2 \beta f_c(\varepsilon_{con}, f_l)}, \beta = \frac{5700}{\sqrt{ f_{co} }} - 500,$ $E_{con} = 5700 \cdot \sqrt{ f_{co} } (MPa)$

(14th fib Bulletin)	$k_j = \frac{\left(1 - \frac{S_j}{2D}\right)^2}{1 - \frac{A_b}{A_g}} \approx \left(1 - \frac{S_j}{2D}\right)^2 \text{ (Coefficient for Partial Wrapping)}$ $f_{l.cover} = \frac{1}{2} k_j \rho_j E_j \varepsilon_c, \rho_j = \frac{4t_j}{D}$
Iterative Procedure	$f_{l.core} = f_{l.cover} + f_{l.steel}, f_{c.av} = \frac{A_{core}}{A_{tot}} f_{c.core} + \frac{A_{cover}}{A_{tot}} f_{c.cover}$
(Bae et al. 2005)	$\varepsilon_{sl} = \max \left[\left(\frac{0.035 \cos \theta + \theta}{\cos \theta - 0.035 \theta} \right) \frac{w}{D_b}, \left(\frac{0.07 \cos \theta + \theta}{\cos \theta - 0.07 \theta} \right) \left(\frac{w}{D_b} - 0.035 \right) \right],$ $\theta = \frac{6.9}{(L_{buck} / D_b)^2} - 0.05, \varepsilon_{sl} = \varepsilon_{con}$

Table 1: Equations embodied in the iterative procedure.

4 CORRELATION WITH EXPERIMENTAL RESULTS

Three experimental studies have been included in this work for validation of the proposed iterative procedure. The first is one of the few extensive experimental studies on large scale FRP wrapped circular columns where different FRP configurations have been applied, for identical embedded steel reinforcement (Matthys et al. 2005). It includes 8 large-scale columns subjected to axial loading. The columns had a total length of 2 m, a longitudinal reinforcement ratio of 0.9% and 8 mm diameter stirrups spaced at 140 mm. All columns had circular cross section with 400 mm diameter. Different types of FRP reinforcement (CFRP, GFRP & HFRP) have been used to confine the columns. The comparison seems to be satisfactory (Figure 5, 6), although the solution has moderate success in resolving the problem of predicting the actual instance of jacket's failure in terms of axial and circumferential ultimate strains. Some clarifications are in order for the last graph (Figure 7) which illustrates the model's estimations of the circumferential strains in the FRP jacket owing to concrete dilation and to buckling of longitudinal bars at the ultimate axial strain reported in the tests for each specimen. These values are compared to the experimental rupture strain of the jacket (from strain gages) and to the deformation capacity of the flat tensile coupons which was reported, accordingly.

The second experimental study (Demers and Neale 1999) includes 16 reinforced concrete columns having a circular section 300 mm in diameter and 1200 mm high. These columns were confined by means of carbon-epoxy sheets and loaded concentrically in axial compression. The effects of various parameters on the structural behavior of the confined concrete columns are investigated. These parameters included the concrete strength, longitudinal steel reinforcement, steel stirrups, steel corrosion and concrete damage while the FRP configuration was kept constant. The comparison between model estimates and experimental results

depicted in Figure 8 and 9 also in this case could be characterized as satisfactory, moreover due to the fact that in this experimental study the lateral pressures from both confining materials (Steel and FRP) are provided based on circumferential strains obtained by strain gages applied on both FRP Jacket and Steel ties. (It should be underlined that the horizontal strain gages on the jacket were located midway between two successive stirrups). Among the 16 specimens in only one case (Specimen U40-4) the pressures coming from the ties were evidently higher than those of the FRP jacket and the model was able to detect that (Figure 10).

The third and the last experimental study (Gallardo-Zafra R. & K. Kawashima, (2009)) contains a series of cyclic loading tests that was conducted on six reinforced concrete column specimens 400 mm in diameter and 1.350 mm in effective height. The specimens were grouped into A and B series where each series consisted of three specimens each; one was as-built while the second and the third were wrapped laterally by CFRP with a single layer and with two layers, respectively. The tie reinforcement ratio was 0.256% (150 mm spacing) for the A-series and 0.128% (300 mm spacing) for the B-series. Figures 12, 13, 14 and 15 depict the comparison with the two groups of cyclic tests on bridge piers having different levels of confinement in terms of lateral steel reinforcement and FRP jacketing. The modeling of the bridge piers was the same as in the original paper and has been performed using the “MatLab Finite Elements for Design Evaluation and Analysis of Structures” (FEDEAS Lab) developed by Professor F.C.Filippou of the Department of Civil and Environmental Engineering of the University of California Berkeley. While in the original proposal the fiber section had to be divided in the concrete core and concrete cover and two different stress-strain relations were applied for the concrete core (confined by both FRP & Steel) and concrete cover (confined by only the FRP), in this work since the material response is already averaged based on the different responses of those two regions, the same stress strain law is applied for each fiber (FEM). This fact gives a clear advantage to the proposed model. In addition to the force-displacement response of the cantilever columns also the response in the level of the section is provided for each specimen in terms of material stress-strain hysteresis. It can be seen that the agreement is very close to the experimental one with some deviation concentrated on the parts of reloading after reversal of the imposed displacement. This difference in response in terms of modeling can be explained based on the way the cracks on the concrete surface are described in the level of the material model. Since the crack is described as two event phenomenon, which means or open or closed (while in reality it is not the case – imperfect crack closure) the contribution of concrete while the longitudinal steel reinforcement is in compression and the crack is closing gives this deviation in the response. The comparison with the originally proposed model of this experimental study is impressively the same. However, the proposed model describes rationally the procedure of the passive confinement based on the calculation of the lateral concrete expansion in terms of the different levels of lateral pressures coming from the two different materials (Steel and FRP). Moreover, the active (constant lateral pressure) confinement model proposed by Kawashima et al. (1999) is based on regression analysis of the experimental results of cylindrical specimens under compression and it is specifically calibrated for Carbon Fiber Composite material (CFRP). Finally, it doesn't consider the confinement effect of the longitudinal reinforcement and the effect of partial confinement due to the vertical arching action of the adjacent stirrups along the member but also cases of partial FRP wrapping of the column.

An important comment that should be made before concluding, is related to some studies (Gallardo-Zafra and Kawashima 2009, Khaloo et al. 2008) that have reported for FRP and Steel confined concrete in circular RC sections a different behavior (softening) in respect to

the already recognized bilinear one (Carey and Harries 2005). The authors attribute that to the small scale of the reinforced concrete specimens used while the most important explanation which could lead to those results is the influence of concrete strength. According to Mandal et. al. (2005) the FRP wraps provide a substantial increase in strength and ductility, for low-to-medium-strength concrete, which shows a bilinear stress strain response with strain hardening. For high-strength concrete, however, enhancement in strength is very limited, with hardly any improvement in ductility. The response in this case shows a steep post peak strain softening.

5 CONCLUSIONS

- *fib*'s FRP-confined concrete model proposal has been enhanced to take into account the confining effect of the already existing steel reinforcement when retrofitting a reinforced concrete column with FRP jacketing. To this end, the transverse steel reinforcement has been considered not as imposing a constant value of confining pressure, rather, following the steel stress-strain law at each deformation step according with the BGL model (Braga et al. 2006), while also considering the confining contribution of longitudinal reinforcement.
- Similar to BGL model an important aspect of the model is that the cross-section tangential stresses (shear), which are generally neglected, have an essential role in ensuring plane strain conditions.
- In addition, compatibility in the lateral direction, inwards for confining pressures and outwards for lateral strains, between the two confining materials (FRP and Steel) has been established. Through this approach the difference in the lateral behavior of the concrete cover (confined with the jacket's pressure) and the concrete core (confined by both the steel's and FRP's pressure) has been considered.
- This allows the application of the model also in cases of reinforcement repair and FRP retrofit where two different concrete strengths should be considered, one for the new layer of concrete applied externally and the other for the old concrete in the concrete core which may also be cracked due to former seismic loading.
- Moreover, in case of bridge column modeling with a fiber nonlinear beam-column element, apart from the immediate incorporation of shear deformations in the section level (in contrast to the standard fiber beam-column formulation), the averaged response of the two different regions -concrete core and concrete cover- gives an evolutionary advantage in terms of modeling since it allows the assignment of a unique stress-strain law for all the fibers/layers of the circular section (FEM).
- Finally, a two-condition failure criterion has been incorporated regarding dilation of concrete and buckling of longitudinal bars as independent events. Correlation with experimental results seems to be satisfactory, although the model has moderate success in predicting the actual instance of rupture of the FRP jacket.

ACKNOWLEDGEMENTS

This work has been carried out with the financial support of the program RELUIS (Dept of Civil protection) and with the collaboration of Valbruna, Mapei, Altomodulo s.r.l., etc. The first author would like sincerely to thank also Professor F.C.Filippou and his PhD student Veronique Le Corvec for their support for the third experimental correlation during his stay as Visiting Scholar at UC Berkeley.

Keywords: Reinforced Concrete, Jacket, Retrofit, Strengthening, Shear transfer mechanisms, Cyclic loading.

Abstract. *In the study presented herein, an analytical model for predicting the response of members with old-type detailing, rehabilitated with reinforced concrete (R/C) jacketing under reversed cyclic loading is developed. The analytical model considers that there is partial connection between the existing member (core of the retrofitted member) and its outer R/C shell, thus allowing relative slip of the two bodies. Slip takes place at the interface between the existing member and the jacket, mobilizing the shear resistance mechanisms, such as aggregate interlock, friction and dowel action. Constitutive models from the international literature are adopted to describe the mechanisms that resist relative sliding under cyclic shear reversals. Dual-section analysis is adopted to calculate the shear flow at the interface between the existing member and the jacket. An algorithm is developed to estimate the flexural response under cyclic loading taking into account slip at the interfaces. The proposed algorithm is utilized for the derivation of moment – curvature response histories of members tested in the laboratory, selected from a database compiled in the framework of the present study.*

1 INTRODUCTION

Reinforced concrete structures hold a significant percentage of the building stock in South Europe and especially in Greece. The vast majority of these structures built in the 70's do not comply with current seismic codes [1]. Due to lack of seismic detailing and capacity design, premature failure is foreseen. Rehabilitation measures are considered necessary and often a combination of both global and local intervention methods provides the most efficient retrofit solution [2]. Reinforced concrete jacketing is an intervention method used extensively in practice to accommodate deficiencies related to global response indices such as stiffness and strength. The use of this method allows uniform distribution of lateral load capacity throughout the structure, thereby avoiding concentrations of lateral load resistance.

Variations of the method are related to the means of connection (i.e. dowels, U-shaped links, etc.) between the 'old' cross section, which serves as the core of the jacketed member, and the jacket itself, along with the preparation of the surface of the existing member (i.e. roughening). All these measures aim to provide full composite action between the two bodies and reduce the effect of slip at the interface between the existing member and the jacket.

The usual practice adopted by intervention codes for proportioning of R/C jacketed members in order to simplify the design procedure is the use of monolithicity factors. These reduction factors are used to obtain the resistance and deformation indices of the jacketed members and are applied to the respective properties of monolithic members with identical geometry. In the case of Eurocode 8, Part 1.3 (§A.4.2, [3]) and under the assumptions of: (i) full composite action between old and new concrete, (ii) application of full axial load in the jacketed member, and (iii) application of the concrete properties of the jacket over the full section of the element, monolithicity factors are equal to $K_V=0.9$ for shear strength, $K_{My}=1.0$ for moment at yield, $K_{\theta u}=1.0$ for the rotation at ultimate, whereas for the rotation at yield, the value $K_{\theta y}=1.05$ applies in case that measures for roughening of the interface have been taken and the value $K_{\theta y}=1.20$ applies for the rest of the measures taken for the connection of the jacket to the existing member or when no particular measures are taken. The Hellenic code for retrofitting (§8.2.1 5 [4]) suggests monolithicity factors for shear strength $K_V=0.9$, for stiffness, $K_K=0.8$, and rotation at yield and ultimate $K_{\theta y}=1.25$ and $K_{\theta u}=0.80$, respectively.

The values adopted by the codes are empirical, mainly due to the limited understanding of the influence of shear resistance mechanisms mobilized at the interface due to slip. To this purpose an analytical model is developed for predicting the response of R/C jacketed members taking into account slip at the interface between the existing member and the jacket under cyclic loading conditions. The solution algorithm is based on previous research conducted by Thermou *et al.* [5, 6] for monotonic loading. In this paper, it is further modified and extended to account for cyclic shear reversals.

2 SHEAR TRANSFER MECHANISMS UNDER CYCLIC LOADING

Shear transfer along interfaces plays a crucial role in the response of composite members. Describing in detail the mechanisms mobilized along interfaces due to slip and their interaction is a rather complex mechanical issue, especially under cyclic loading conditions where degradation should also be accounted for. Although issues of connection between existing and newly cast concrete arise often in retrofitting of R/C structures, as in the case of the R/C jacketing technique, it remains an issue that has not been fully addressed by codes.

Mechanisms that resist sliding (slip) are: (i) aggregate interlock between contact surfaces, including any initial adhesion of the jacket concrete on the substrate; (ii) friction owing to clamping action of reinforcement normal to the interface; and (iii) dowel action of any prop-

erly anchored reinforcement crossing the sliding plane. The first two mechanisms refer to the contribution of concrete, since they are based on the friction resistance of the interfaces. The relationship that describes the contribution of the individual shear transfer mechanisms is:

$$\tau_{tot} = \tau_{agr} + \tau_f + \tau_D = \tau_{agr} + \mu\sigma_N + \tau_D \quad (1)$$

where $\sigma_N = \sigma_c + p\sigma_s = v f_c + \rho\sigma_s$

In the above equation, τ_{agr} represents the shear resistance of the aggregate interlock mechanism, μ is the interface shear friction coefficient, σ_N is the normal clamping stress acting on the interface and τ_D is the shear stress resisted by dowel action in cracked reinforced concrete. The clamping stress represents any normal pressure, p , externally applied on the interface, but also the clamping action of reinforcement crossing the contact plane as illustrated in Fig. 1 (σ_s is the axial stress of the bars crossing the interface, ρ is the corresponding reinforcement area ratio, $v = N/(A_c f_c) = \sigma_c / f_c$ is the dimensionless axial load at the interface of A_c area and f_c is the concrete compressive strength).

The first two terms in Eq. (1) collectively represent the *contribution of concrete* as they depend on the frictional resistance of the interface planes.

Figure 1: Slip at a concrete interface crossed by reinforcement.

Shear transfer along interfaces has been a subject of ongoing research for many years now. Analytical models and design expressions have been proposed by various researchers, the majority of which are either empirical or based on substantial simplifications. The models found in the literature are classified in two categories. To the first belong those models where all forces are transferred through reinforcement [7-12], whereas the second includes those models that apart from reinforcement contribution include a cohesion term [13-21].

For the needs of the present study, the model of Tassios & Vintzēleou [18], Vintzēleou & Tassios [19, 20] was used because it was the only model found in literature that describes the shear transfer mechanisms under cyclic loading. Furthermore, this model predicted with satisfactory precision the shear resistance developed at the interface between old and new concrete after cross-correlating with the experimental results of a parametric experimental investigation where twenty four (24) specimens of double interface were tested with parameters of study the diameter and the area of reinforcement bars crossing vertically the interface, as well as the degree of interface roughness [22]. The model estimates the combined dowel and shear friction resistances for a given slip value at the interface.

2.1 Friction resistance

The shear stress transferred through friction due to slip is described by the following set of equations [18-20]:

$$\frac{\tau(s)}{\tau_{f,u}} = 1.14 \left(\frac{s}{s_u} \right)^{1/3} \quad \text{for } \frac{s}{s_u} \leq 0.5 \quad (2a)$$

$$\frac{\tau(s)}{\tau_u} = 0.81 + 0.19 \left(\frac{s}{s_u} \right) \quad \text{for } \frac{s}{s_u} > 0.5 \quad (2b)$$

where s_u (≈ 2 mm) is the higher value of slip attained, whereas the higher value of friction resistance, τ_{fu} , is equal to:

$$\tau_{fu} = \mu (f_c^2 \sigma_N)^{1/3} \quad (3)$$

where μ is the friction coefficient, taken equal to 0.44 for $s_u=2$ mm.

According to Tassios and Vintzēleou [18], it is assumed that the bars pullout by $w/2$ from each side of the contact surface and that the separation w and lateral slip, s , are related by: $w=0.6 \cdot s^{2/3}$ (Fig. 1). To calculate the axial stress of the bars crossing the interface, σ_s , the separation w between contact surfaces as they slide overriding one another is considered (Fig. 1). Considering uniform bond stresses along the embedment length, the axial bar stress, σ_s , at the contact plane is estimated from:

$$\sigma_s = \left(\frac{0.3 s_f^{2/3} E_s f_c}{D_b} \right)^{1/2} \quad (4)$$

where E_s is the elastic modulus of steel and D_b is the diameter of the bars clamping the interface (here, the stirrup legs of the jacket).

In case of cyclic loading the frictional resistance is reduced at each cycle according to:

$$\tau_{f,n} = \tau_{f,1} \left\{ 1 - \left[0.002(n-1) \frac{f_c}{\sigma_N} \frac{s_f}{s_{f,u}} \right]^{1/3} \right\} \quad (5)$$

where $\tau_{f,1}$ is the higher frictional resistance value attained in the first cycle. The hysteretic model of frictional resistance is differentiated depending on the value of slip at which reversal takes place. Two cases are identified; in the first, unloading takes place at lower slip values compared to the higher value of slip, $s < s_u$ (Fig. 2(a), [21]), whereas in the second unloading takes place at the higher value of slip attained, s_u (Fig. 2(b), [18]).

2.2 Dowel resistance

In the model proposed by Vintzēleou & Tassios [19, 20], it is considered that the bar behaves as a horizontally loaded free-headed pile embedded in cohesive soil and that yielding of the dowel and crushing of concrete occur simultaneously. Dowel force, F_D , is given as a function of slip, s , by:

$$\frac{F_D(s)}{F_{D,u}} = 0.5 \frac{s}{s_{el}} \quad \text{for } s \leq s_{el} = 0.006 D_b \quad (6a)$$

$$\text{for } \frac{F_D(s)}{F_{D,u}} \geq 0.5 \Rightarrow s = 0.006D_b + 1.76s_u \left[\left(\frac{F_D(s)}{F_{D,u}} \right)^4 - 0.5 \left(\frac{F_D(s)}{F_{D,u}} \right)^3 \right] \quad (6b)$$

where s_{el} is the elastic slip value, s_u is the ultimate slip value, $F_{D,u}$ is the ultimate dowel force and D_b is the diameter of the dowels (i.e. the legs of the jacket transverse reinforcement). The ultimate dowel strength and associated interface slip are given by:

$$F_{D,u} = 1.3D_b^2 [f_{cd} f_{yd} (1 - \alpha^2)]^{1/2} = D_b^2 [f_c f_y (1 - \alpha^2)]^{1/2}; \quad s_{D,u} = 0.05D_b \quad (7)$$

where α is the bar axial stress normalized with respect to its yield value, $f_{yd}(=f_y/1.15)$ is the design yield strength of steel and $f_{cd}(=f_{ck}/1.5)$ is the design concrete compressive strength. The dowel resistance constitutive laws are depicted in Fig. 3.

Figure 2: Frictional resistance constitutive laws for (a) $s < s_u$ [21]; (b) $s = s_u$ [18].

Figure 3: Dowel resistance constitutive law [19, 20].

2.3 Interaction of friction and dowel resistance

In case that the bars are subjected simultaneously to tension (pullout due to frictional resistance) and shear (dowel action), then the dowel strength capacity at yield is consumed by both resistance mechanisms. In order to take into account the interaction of the two resistance mechanisms, the higher friction and dowel resistance capacity are determined by the following relationship [21]:

$$\left(\frac{\sigma_s - \sigma_{SN}}{f_{sy}} \right)^{3/2} + \left(\frac{F_D(s)}{F_{D,u}} \right)^{3/2} = 1; \quad \sigma_{SN} = \frac{\nu \cdot f_c}{\rho + E_c/E_s} \quad (8)$$

where σ_s is the pullout stress mobilized at slip, f_c is the concrete compressive strength, E_c , E_s , are the elastic modulus of concrete and steel, respectively, $\nu (=N/(A_c f_c))$ is the dimensionless axial load, and ρ is the percentage of reinforcement that crosses the interface.

The solution of Eq. (8) corresponds to a value for s_{crit} , for which the dowel and friction resistance cannot increase further. This assumption leads to a modification of the hysteretic diagram of dowel action in cyclic loading.

The total shear resistance of an interface with contact area A_{int} crossed by k dowels is:

$$F(s) = \tau_f(s) A_{int} + k F_D(s) \quad (9)$$

where $\tau_f(s)$ and $F_D(s)$ are calculated from Eqs. (2) and (6), respectively, for a given amount of interface slip.

3 ANALYTICAL MODEL OF R/C JACKETED MEMBERS SUBJECTED TO CYCLIC SHEAR REVERSALS

The analytical model for the flexural behaviour of brittle R/C members rehabilitated with concrete jacketing presented herein is based on previous research conducted by Thermou et al. [5, 6] but it is further extended to cyclic loading conditions after a series of adaptations and additions. The proposed analytical model introduces a degree of freedom allowing the relative slip at the interface between the existing member and the jacket. Slip along the member's length is attributed to the difference in normal strains at the contact interfaces (Fig. 4(a)). For flexural analysis, the cross section is divided into three layers which deform with the same curvature, φ (Fig. 4(a)). The two external layers represent the contribution of the jacket, whereas the internal one represents both the core (existing cross section) and the web of the jacket shell. Slip at the interface mobilizes the shear transfer mechanisms such as aggregate interlock, friction owing to clamping action and dowel action of the stirrup legs of the jacket (Fig. 4(b)). The friction and dowel resistance constitutive laws in cyclic loading proposed by Tassios & Vintzēleou [18], Vintzēleou & Tassios [19, 20] are adopted (see section 2) and further modified as described in section 4.2 for the needs of the current study.

Figure 4: (a) Strain profile of the jacketed cross section; (b) Shear transfer mechanisms at the interface between the jacket and the core.

According to the proposed analytical model of Thermou et al. [5, 6] for R/C jacketed members, shear transfer at the interface between the existing member and the jacket is carried out between half crack intervals along the length of the jacketed member as considered in bond analysis. At the initial stages of loading, cracks form only at the external layers (jacket) increasing in number with increasing load, up to crack stabilization. This occurs when the jacket steel stress at the crack, $f_{s,cr}$ exceeds the limit [23]:

$$f_{s,cr} > f_{ctm} \frac{1 + \eta \rho_{s,eff}}{\rho_{s,eff}} \quad (10)$$

where f_{ctm} is the tensile strength of concrete, $\eta (= E_s/E_{cm})$ is the modular ratio and $\rho_{s,eff}$ is the effective reinforcement ratio defined as the total steel area divided by the area of mobilized concrete in tension, usually taken as a circular domain with a radius of $2.5D_b$ around the bar [23]. Using the same considerations in the combined section it may be shown that a number of the external cracks penetrate the second layer (core) of the jacketed member (Fig. 5(a)). The distance between those cracks, taken as c , is a key element of the proposed methodology.

3.1 Crack spacing estimation

After crack stabilization and assuming that the neutral axis depth is about constant in adjacent cross sections, from the free body equilibrium in the tension zone of the core of the composite section (Fig. 5(b)), the crack spacing is defined as follows:

$$c = \frac{0.64 \cdot b_J l_c f_{ct,c}}{n_c D_{b,c} f_{b,c} + n_J D_{b,J} f_{b,J}} \quad (11)$$

where b_J is the width of the jacketed cross section, l_c is the height of the tension zone in the core component of the composite cross section, $f_{ct,c}$ is the tensile strength of concrete core, n_c , n_J are the number of bars in the tension steel layer of the core and the jacket, respectively, $D_{b,c}$, $D_{b,J}$ are the bar diameter of the core and jacket longitudinal reinforcement, respectively, and $f_{b,c}$, $f_{b,J}$ are the average bond stress of the core and the jacket reinforcement layer, respectively.

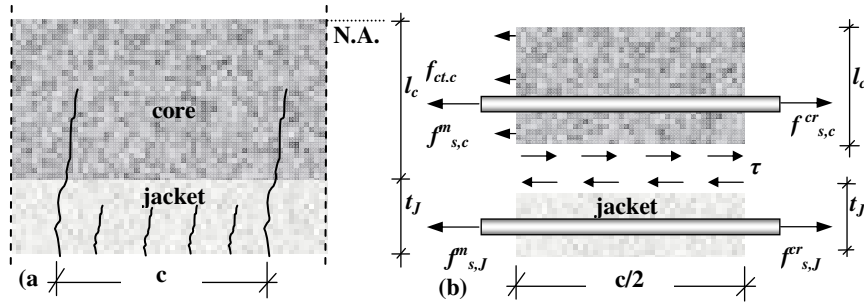

Figure 5: (a) Crack spacing, c ; (b) Free body equilibrium in the tension zone of the core of the composite section.

3.2 Shear stress demand at the interfaces

Shear stress demand at the interfaces, $\tau_{d,i}$, is determined by examining the cross section along the height and a member length equal to the distance between successive cracks (Figure 6(a)). The layer force resultant ΣF_i (sum of concrete and steel forces at each layer), for the externally applied axial load, N_{ext} (considered to be applied to the jacketed section), is used to calculate the vertical shear stress demand of the member, $\tau_{d,i}$. With the assumption that the shear flow, q , reversal takes place at length equal to $c/2$ (Figure 6(b), where c is the crack spacing), the average stress demand $\tau_{d,i}$ is equal to:

$$\tau_{d,i} = \frac{\Sigma F_i}{0.5 c b_j} \quad (12)$$

where ΣF_i is the layer force resultant, b_j is the width of the jacketed cross section, and c is the crack spacing length.

Figure 6: (a) R/C jacketed column; (b) Section equilibrium between adjacent cracks; (c) Assumption for the estimation of shear flow, q .

4 ALGORITHM FOR MOMENT – CURVATURE ANALYSIS

The calculation algorithm aims at the derivation of moment – curvature histories of R/C members retrofitted with R/C jackets taking into account slip at the interfaces between the existing member (core) and the jacket under cyclic loading conditions. Thus, given a curvature loading history (Fig. 7), at each loading step the objective is twofold: (i) equilibrium establishment between the shear stress capacity and demand at the interfaces for relative slip, s ,

and (ii) establishment simultaneously of force equilibrium at the cross section. Equilibrium is established though an iterative procedure until convergence is achieved.

Figure 7: Loading history considered in the calculation algorithm.

In the first step of the analysis (very low curvature value) slip is taken equal to zero at both interfaces. In the next steps, as curvature increases, the inclination of the strain profile is modified (allowing continuously increasing difference of strain at the interfaces) in order to establish cross section equilibrium.

The proposed calculation algorithm comprises the following steps:

For each loading cycle ℓ :

- 1) Set sectional curvature equal to $\varphi^n(+)$. Problem unknowns are, the normal strain at the top fiber of the jacketed cross section, $\varepsilon_{J1}^{n,m}$, the interface slip at the upper, $s_1^{n,r}$, and bottom interfaces, $s_2^{n,r}$.
- 2) Estimate the normal strain at the top fiber of the cross section, $\varepsilon_{J1}^{n,m}$ (Fig. 4(a)).
- 3) Estimate the interface slip at the upper and bottom interfaces, $s_1^{n,r}$ and $s_2^{n,r}$. Slip at the interface is related to the difference of strains at the upper and lower interface, $\Delta\varepsilon_1^{n,r}$ and $\Delta\varepsilon_2^{n,r}$, as follows:

$$s_1^{n,r} = \Delta\varepsilon_1^{n,r} c = (\varepsilon_{c1}^{n,r} - \varepsilon_{j2}^{n,r}) c, \quad s_2^{n,r} = \Delta\varepsilon_2^{n,r} c = (\varepsilon_{j3}^{n,r} - \varepsilon_{c2}^{n,r}) c \quad (13)$$

where variables $\varepsilon_{c1}^{n,r}$, $\varepsilon_{j2}^{n,r}$ and $\varepsilon_{j3}^{n,r}$, and $\varepsilon_{c2}^{n,r}$ are normal strains in the section layers above and below the contact surfaces (Fig. 4(a)), and c is the average crack spacing (Eq. (11), Fig. 5(a)).

- 4) Check equilibrium at the interfaces - Shear strength capacity of the top and bottom interface, $\tau_1^{n,r}$ and $\tau_2^{n,r}$, are estimated from the respective slip values, $s_1^{n,r}$ and $s_2^{n,r}$, according to the constitutive laws that describe the behaviour of the interface under cyclic loading (Eqs. 2-9). Shear strength demand at the upper and bottom interface, $\tau_{d,1}^{n,r}$ and $\tau_{d,2}^{n,r}$, are also estimated according to Eq. (12). Check if $\tau_1^{n,r} = \tau_{d,1}^{n,r}$ and $\tau_2^{n,r} = \tau_{d,2}^{n,r}$. If this is valid, then equilibrium is established and the next step follows, otherwise return to step 3 and set $s_1^{n,r+1} = s_1^{n,r} + ds_1$, $s_2^{n,r+1} = s_2^{n,r} + ds_2$, where ds_i is the selected increment in the slip value. Revise slip values at the top and bottom interface till convergence.
- 5) Check cross section equilibrium: The force resultant, ΣF_i (Fig. 6(a)) is calculated at each layer. In case that equilibrium is not established, $\Sigma \Sigma F_i - N_{ext} \geq \text{tolerance}$, then the normal strain profile is revised by returning to step 2 and setting $\varepsilon_{J1}^{n,m+1} = \varepsilon_{J1}^{n,m} + d\varepsilon_J$, where $d\varepsilon_J$ is the step increment in the top strain of the jacketed cross section.
- 6) Store the convergent values for which equilibrium at both interface and cross section level was established ($\varepsilon_{J1}^n = \varepsilon_{J1}^{n,m}$, $s_1^n = s_1^{n,r}$, $s_2^n = s_2^{n,r}$).
- 7) Estimate the moment resultant, M^n .
- 8) Unloading
- 9) Repeat steps 1-7 for $\varphi^n(-)$

- 10) Unloading
- 11) Repeat steps 1-10 for $\ell=\ell+1$. Calculations stop when the shear capacity of the interface is exhausted.

An original program was developed based on the proposed solution algorithm as described in the flowchart of Fig. 8. Fiber analysis was considered. The behaviour of concrete and steel was described by adopting uniaxial constitutive laws under cyclic loading from the literature (details are provided in section 4.1). The constitutive laws for the description of the shear transfer mechanisms mobilized due to slip at the interface are based on the models of Tassios & Vintzēleou [18], Vintzēleou & Tassios [19, 20], further enhanced to account for arbitrary loading history (load cycles of unequal amplitude).

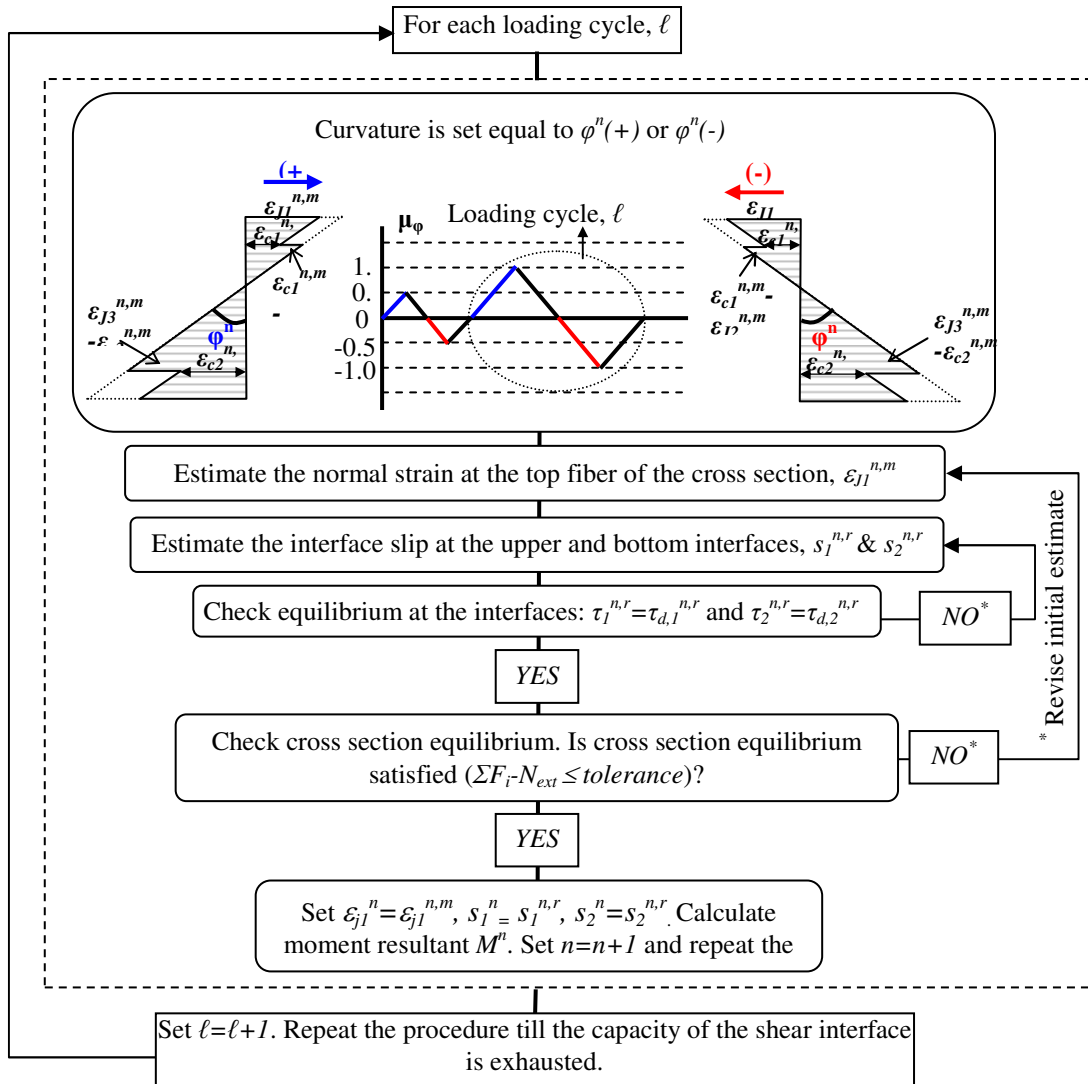

Figure 8: Flowchart of the proposed algorithm.

4.1 Material constitutive laws

Concrete: The constitutive law for concrete adopted is based on the model of Mander et al. [24] as far as the relationship between stresses-strains is concerned and on the hysteresis rules of Martinez-Rueda & Elnashai [25]. Confinement due to transverse reinforcement (taken into

account by factor K) is considered constant during loading and follows the relationships proposed by Mander et al. [24]. This law is adequate for modelling R/C elements, especially those subjected to random cyclic loading (e.g. seismic loading). The general shape of the response curve is presented in Fig. 9(a).

Steel: The constitutive law for steel utilized in the proposed algorithm is based on the stress-strain relationship developed by Menegotto-Pinto [26] in combination with the rules of isotropic hardening proposed by Fillippou et al. [27]. It is suitable for modelling reinforced concrete elements subjected to cyclic loading as in seismic conditions. The response curve in its general form is presented in Fig. 9(b).

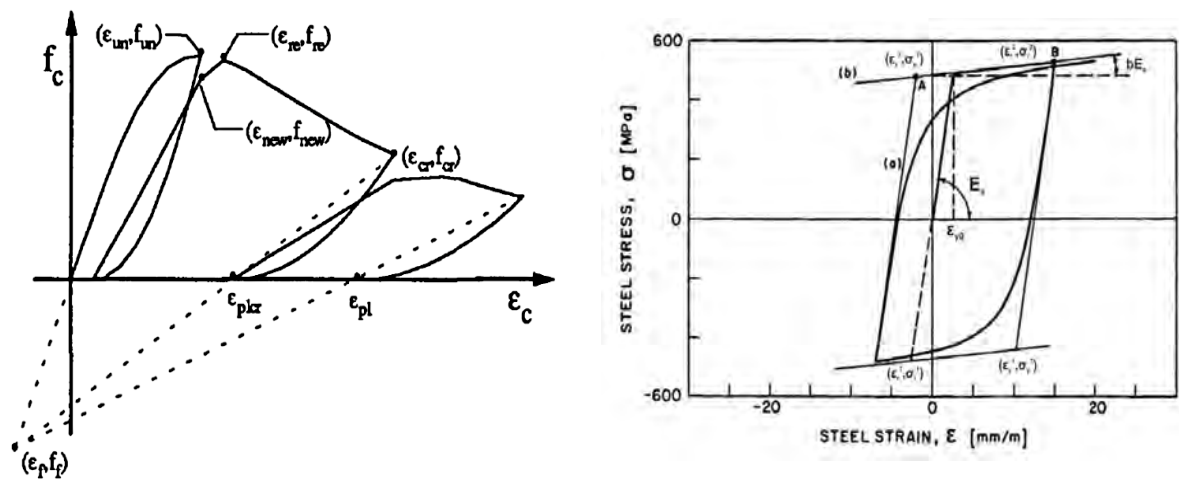

Figure 9: (a) Concrete [25]; (b) Steel constitutive laws [27].

4.2 Interface shear resistance constitutive law

The friction and dowel resistance models as proposed by Tassios & Vintzēleou [18], Vintzēleou and Tassios [19, 20] were further modified to account for the case of non-symmetric reversed cyclic loading. In Fig. 10, for a given random loading history that depends on slip magnitude, s , the extracted dowel resistance hysteretic curve and the total resistance curve according to Eq. (9) are shown.

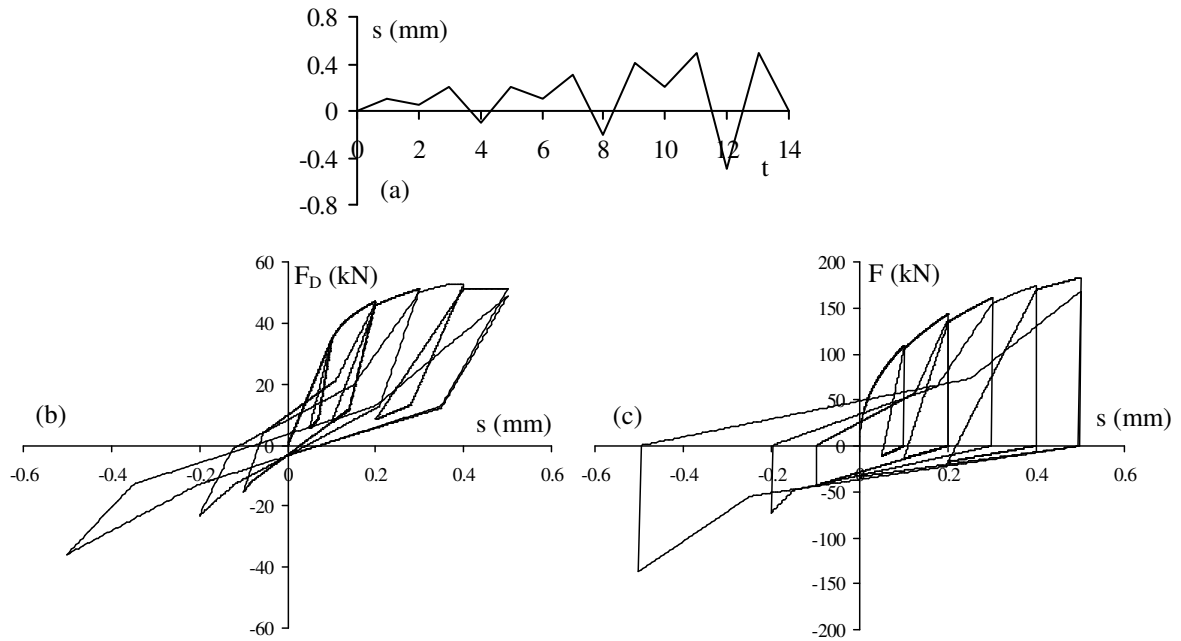

Figure 10: (a) Non-symmetric loading history; (b) Dowel resistance hysteretic curve; (c) Total interface resistance hysteretic curve.

5 RESULTS OF THE ANALYSIS

In this section the proposed analytical model is used for estimating the flexural response of R/C jacketed members for the case that slip at the interface between the jacket and the existing member is neglected. The case-studies selected to be presented herein were taken from the experimental database which was created for the needs of this ongoing study.

5.1 Presentation of the experimental database

An experimental database was created which includes forty four (44) specimens from eleven (11) experimental studies. The database includes specimens where various connection measures were taken between the existing member and the jacket, whereas the jacket construction was done using shotcrete or cast-in-place concrete. The range of database parameters is shown in Table 1. The database along with the symbols used are presented in detail in Tables A1 and A2 of the Appendix.

The specimens selected to be analyzed with the proposed algorithm are specimens R2R [29] and Q-RCR [36]. Details on the geometrical and material characteristics are presented in Tables A1 and A2 of the Appendix.

Existing cross section		Jacket	
b_c (mm)	200~350	b_J (mm)	260~550
h_c (mm)	200~500	h_J (mm)	260~650
$D_{b,c}$ (mm)	10~20	$D_{b,J}$ (mm)	10~20
ρ_{lc} (%)	0.81~2.05	ρ_{lJ} (%)	0.75~1.64
$D_{bs,c}$ (mm)	6~8	$D_{bs,J}$ (mm)	6~10
s_c (mm)	50~265	s_J (mm)	50~100
ρ_{wc} (%)	0.16~0.66	ρ_{wJ} (%)	0.22~0.94
f_c (MPa)	22.9~58.2	f_c (MPa)	7~68.7
f_y (MPa)	313~550	f_y (MPa)	400~520
f_{yw} (MPa)	350~520	f_{yw} (MPa)	330~599

		v (%)	0~26

Table 1: Range of database parameters.

5.2 Results of the case studies considered

Specimens P2R [29] and Q-RCR [36] are subjected to the applied curvature ductility history presented in Fig. 11. Each loading cycle increases by $\frac{1}{4}$ of φ_y . The curvature at yield, φ_y , was estimated by the following simplified expression [4]:

$$\varphi_y = 1.77 \frac{f_y}{E_s h_J} \quad (1)$$

where f_y is the yield strength of steel of the reinforcement bars of the jacket, h_J the height of the jacketed member and E_s the modulus of elasticity of steel. For specimen P2R curvature at yield is $\varphi_y=1.6 \times 10^{-2}$ (rad/m), displacement at yield is $\Delta_y=5.5$ mm and drift at yield is $\theta_y=0.54\%$, whereas for specimen Q-RCR curvature at yield is $\varphi_y=1.08 \times 10^{-2}$ (rad/m), displacement at yield $\Delta_y=9.2$ mm and drift at yield $\theta_y=0.57\%$. The hysteretic response of the two test specimens is depicted in Figures 12 and 13.

Figure 11: Curvature loading history subjected to specimens P2R [29] and Q-RCR [36].

Figure 12: Response of specimen P2R [29] to cyclic loading conditions for the case that slip is neglected.

Figure 13: Response of specimen Q-RCR [36] to cyclic loading conditions for the case that slip is neglected.

6 CONCLUSIONS

An analytical model for predicting the response of old-type columns rehabilitated with concrete jacketing under reversed cyclic loading was developed. The composite cross section is divided into three layers which develop the same curvature. The proposed analytical model allows slip at the interface between the existing member and the jacket. Shear transfer mecha-

nisms are mobilized due to sliding at the interface between existing and new concrete. The shear capacity is described by constitutive models for cyclic loading conditions and is given as a function of slip. The shear demand at the interface is controlled by the flexural stresses on the cross section and by the spacing of cracks in the longitudinal direction. Equilibrium at the interfaces is established when shear capacity and demand are equalized. An algorithm was developed for determining the moment – curvature histories of R/C jacketed members with partial connection between the existing member (core) and the jacket. The response of test specimens selected from a database compiled within the framework of this work was studied by utilizing the proposed solution algorithm for null slip at the interface.

ACKNOWLEDGEMENTS

The research conducted in this paper was funded by the Hellenic Earthquake Planning and Protection Organization (E.P.P.O.); the authors gratefully acknowledge this support.

APPENDIX

Symbols used in the database:

b_c ; b_j : width of the existing and the jacketed cross section;
 $D_{b,c}$; $D_{b,j}$: bar diameter of the core and the jacket longitudinal reinforcement, respectively;
 $D_{bs,c}$; $D_{bs,j}$: bar diameter of the stirrups of the core and the jacket, respectively;
 d_c ; d_j : depth of the existing and the jacketed cross section, respectively;
 $f_{c,c}$; $f_{c,j}$: core and jacket concrete cylinder uniaxial compressive strength, respectively;
 $f_{y,c}$; $f_{y,j}$: yield strength of the longitudinal reinforcement of the core and jacket, respectively;
 $f_{yw,c}$; $f_{yw,j}$: yield strength of the transverse reinforcement of the core and jacket, respectively;
 h_c ; h_j : height of the existing and the jacketed cross section, respectively;
 L_s : shear span length;
 $n_{c,mid}$; $n_{j,mid}$: total number of web longitudinal reinforcement bars of the core and the jacket, respectively;
 n_c ; n_j : total number of top and bottom longitudinal reinforcement bars of the core and the jacket, respectively;

s_c ; s_J : stirrup distance in the existing and jacketed cross section respectively;

Greek symbols:

v : dimensionless axial load % estimated based on the compressive strength of the jacket concrete quality.

ρ_{lc} : longitudinal reinforcement ratio of the existing cross section defined as $A_{sc,tot}/(b_c h_c)$, where $A_{sc,tot}=(n_c+n_{c,mid})D_{b,c}^2/4$

ρ_{lJ} : longitudinal reinforcement ratio of the jacketed cross section defined as $A_{sJ,tot}/(b_J h_J - b_c h_c)$, where $A_{sJ,tot}=(n_J+n_{J,mid})D_{b,J}^2/4$

ρ_{wc} ; ρ_{wJ} : volumetric ratio of stirrups of the existing and the jacketed cross section, respectively.

Keywords: FRP-Confined Concrete, Force-Deformation, Strengthening

Abstract. *In this study, the FRP-confined concrete models for prismatic members given in the ACI440.2R-08 and Turkish Earthquake Code (TEC2007) are compared with the experimental data taken from the literature. It is found that TEC2007 assumes only hardening behavior for concrete strengthened with FRP. Although ACI440.2R-08 assumes a hardening and softening behavior depending on the confinement-effectiveness, the limit separating the hardening and softening must be improved to predict the behavior well. The assumptions in these codes cannot predict the post-peak region of force-deformation curves because of the high factor of safeties. It is essential to understand the degree of confinement, confinement effectiveness and the resulting stress-strain relationship of a concrete strengthened with FRP.*

1 INTRODUCTION

Reinforced concrete structures should have enough capacity to resist lateral forces. Most buildings in high seismic zones in Turkey do not have the desired capacity and their situations are getting worse by the environmental effects, such as temperature variations, humidity, corrosion etc. It is obvious that vulnerable structures should be strengthened against the potential high magnitude earthquakes. Since the number of deficient buildings is high, strengthening method should be easy to apply in a short period, i.e. occupant friendly techniques must be preferred.

Fiber reinforced polymer (FRP) can be one of the optimal choice because of its unique properties. It has high strength and modulus. It is durable when compared to steel and concrete. It is easy to apply which enables to strengthen more buildings in a shorter period. Moreover, strengthening can be done without disturbing the residents via evacuation.

Considering the abovementioned advantages, codes start to recommend the use of FRP as one of the alternative strengthening technique. However, because of some uncertainties related to either material behavior or strengthening application, codes define equations that are more conservative. Since the material and application result in a high initial investment, the equations in the codes make it difficult to utilize.

In this study, the force-deformation characteristics of square columns are searched via analytical study.

2 MATERIAL MODELS

To generate a force-deformation curve, material models should be defined first. For FRP-confined concrete, the models available in the ACI440.2R-08 and Turkish Earthquake Code (TEC2007) are used. For steel model, a simple model is proposed and used.

2.1 FRP-Confined Concrete Model

2.1.1. TEC2007 Model

In TEC2007-Section 7E, evaluation of strength and ductility enhancement using FRP-confined concrete columns, equations related to the strength, strain and shear calculations are introduced.

Strength Enhancement:

In this section, it is stated that in order to increase the axial load capacity of a column using FRP material, the ratio of long side to short side of the column should not be greater than 2.0. If corners of rectangular sections rounded and the section turns to be an elliptical section, than the ratio can be 3.0. Dimensions of each section are given in Figure 1. f_{cc} can be calculated as follows:

$$f_{cc} = f'_{co} \left[1 + 2.4 \left(\frac{f_l}{f'_{co}} \right) \right] \geq 1.2 f'_{co} \quad (1)$$

$$f_l = \frac{1}{2} \kappa_a \rho_f \varepsilon_f E_f \quad (2)$$

$$\varepsilon_f \leq \begin{cases} 0.004 \\ 0.5 \varepsilon_{fu} \end{cases} \quad (3)$$

$$\kappa_a = \begin{cases} 1 & \text{Cylindrical sections} \\ \left(\frac{b}{h}\right) & \text{Ellipsoid sections} \\ 1 - \frac{(b - 2r_c)^2 + (h - 2r_c)^2}{3bh} & \text{Rectangular sections} \end{cases} \quad (4)$$

where κ_a is section effectiveness factor, ρ_f is the volumetric ratio of FRP, ε_{fu} is the ultimate strain capacity of FRP, ε_f is the effective strain capacity of FRP, E_f is the modulus of elasticity of FRP, b is the short dimension of prism and h is the long dimension of the prism.

Figure 1. Sectional properties

Ductility Enhancement:

Ultimate strain capacity can be calculated as follows:

$$\varepsilon_{cc} = 0.002 \left[1 + 15 \left(\frac{f_l}{f'_{co}} \right)^{0.75} \right] \quad (5)$$

2.1.2. ACI440.2R-08 Model

In ACI440.2R-08-Chapter 12, strengthening of members subjected to axial force or combined axial and bending forces, equations related to strength and strain are introduced. It is stated that “The provisions are not recommended for members having noncircular section featuring side aspect ratios h/b greater than 2.0, or face dimensions b or h exceeding 900 mm unless testing demonstrates their effectiveness”.

In pure axial compression section, the maximum confined concrete compressive strength (f_{cc}) and the maximum confinement pressure (f_l) are calculated using Lam and Teng's equation [9] with an additional reduction factor $\psi = 0.95$.

For ultimate strain, the code limits the strain value to prevent excessive cracking and resulting loss of concrete integrity.

$$f_{cc} = f'_{co} + \psi 3.3 \kappa_a f_l \quad (6)$$

$$f_l = \frac{2E_f n t_f \varepsilon_{fe}}{D} \quad (7)$$

$$\varepsilon_{fe} = \begin{cases} \kappa_e \varepsilon_{fu} & \text{axial compression } (\kappa_e = 0.55) \\ 0.004 \leq \kappa_e \varepsilon_{fu} & \text{combined axial compression and bending} \end{cases} \quad (8)$$

$$D = \sqrt{b^2 + h^2} \quad (9)$$

$$\varepsilon_{cc} = \varepsilon_{co} \left(1.5 + 12\kappa_b \frac{f_l}{f'_{co}} \left(\frac{\varepsilon_{fe}}{\varepsilon_{co}} \right)^{0.45} \right) \leq 0.01 \quad (10)$$

$$\kappa_a = \frac{A_e}{A_c} \left(\frac{b}{h} \right)^2 \quad (11)$$

$$\kappa_b = \frac{A_e}{A_c} \left(\frac{h}{b} \right)^{0.5} \quad (12)$$

$$\frac{A_e}{A_c} = \frac{1 - \left[\left(\frac{b}{h} \right) (h - 2r_c)^2 + \left(\frac{h}{b} \right) (b - 2r_c)^2 \right]}{3A_g} - \rho_g \quad (13)$$

In these equations, κ_a , κ_b are the efficiency factor (for strength and strain, respectively) which takes the shape of the section into account, ε_{fe} is the effective strain level in FRP, κ_e , is the FRP strain efficiency factor, $\frac{A_e}{A_c}$, is the effective confinement area ratio, ρ_g is the longitudinal steel ratio, n is the number of FRP layers and t_f is the thickness of the FRP material.

2.1.3. Comparison of the models

It is found out that FRP usage does not result in a hardening behavior all the time. Depending on some parameters such as, unconfined concrete strength, number of FRP layers and corner radius in prismatic members, a softening behavior is possible if the FRP effectiveness is not adequate.

Mirmiran et. al. [6] proposed “Modified Confinement Ratio (MCR)” to determine if a section shows hardening or softening behavior. The equation for MCR is given in Eqn. 14. It is seen that parameters affecting MCR are confinement effectiveness and sectional properties. It is stated by Mirmiran et. al. that if MCR is greater than 0.15 then it is possible to see a hardening behavior. To validate whether this limit is well-defined or not, 132 experimental data (76 tests having hardening behavior and 56 having softening behavior) are collected from the literature and their MCR factors are calculated. MCR values are compared with the experimental data as seen in Table 1 and it is realized that MCR factor can be used to predict the behavior.

$$MCR = \frac{2.r.f_l}{D.f'_{co}} \quad (14)$$

$$f_l = \frac{2.t_{FRP}.f_{FRP}}{D} \quad (15)$$

ACI440.2R-08 also takes the degree of confinement into account and states that for minimum confinement ratio $\frac{f_l}{f'_{co}} \geq 0.08$ should be used. As it is seen from Table 1 the limit can predict if a section shows hardening or softening behavior but it is not as successful as the MCR factor.

Table 1. Verification of the hardening limits

Number of Experimental Data	MCR Prediction		ACI440.2R-08 Prediction	
	# of data	Accuracy, %	# of data	Accuracy, %
76 Hardening	62 Hardening 14 Softening	82	73 Hardening 3 Softening	96
56 Softening	52 Softening 4 Hardening	93	17 Softening 39 Hardening	30
Total 132 data	86 % of the data is accurately predicted		68 % of the data is accurately predicted	

In Figure 2, typical behaviors of low strength square concrete specimens confined with FRP are given together with the analytical predictions. As seen in the figures, ACI440.2R-08 and TEC2007 models assume lower strain and strength values, which yields higher factor of safety (Figure 2a). If the confinement is inadequate as shown in Figure 2b both procedures give higher strength and low strains. From the figures, it can be seen that TEC2007 assumes hardening behavior in both cases, but ACI440.2R-08 can predict the change in the behavior.

Figure 2: FRP-confined concrete a) Adequate confinement [3] b) Inadequate confinement [8]

2.2 Steel Model

For steel model, it is assumed that steel does not behave similar in both tension and compression. It is assumed that, in tension steel shows a trilinear behavior, i.e., steel yields and then shows strain hardening behavior. However, in compression it is assumed that steel shows softening behavior after yielding (Figure 3).

In Figure 3, at the tension zone, yield strength is denoted by f_y and yield strain by ϵ_y , ϵ_{sh} ($=10\epsilon_y$) represents strain at the point where the hardening starts, f_u is the ultimate strength of the steel (and can be taken as $1.25f_y$) whereas ϵ_u ($=50\epsilon_y$) is the ultimate strain at f_u . In the compression zone, since there exists no hardening, f_u stands for the stress at $0.2f_y$ and ϵ_u is taken as $50\epsilon_y$.

Figure 3. Model for the reinforcing steel

3 FORCE-DEFORMATION RELATIONSHIP

Moment-curvature relationship based on the FRP-confined concrete models and the reinforcing steel model is used to evaluate the force-deformation characteristic of a column. The assumptions made in the moment curvature analysis are as follows:

- 1) Plane sections remain plane
- 2) Concrete does not take any tension force. Tension forces are only carried by steel reinforcement.
- 3) FRP is only active in compression part.

Deformation consists of two parts: first part is calculated from the fixed-end rotation caused by the bar slip and second part is calculated from the curvature.

$$\Delta = \Delta_{bar\ slip} + \Delta_{curvature} \quad (16)$$

Deformation due to the fixed end rotation caused by bar slip can be found using the equations proposed by Ozcan et. al [5] as follows.

$$u = 0.4 \sqrt{f'_{co}} \quad (17)$$

$$s = \begin{cases} \frac{\varepsilon_s f_s d_b}{8u}, & \varepsilon_s \leq \varepsilon_y \\ \frac{d_b}{8u} [\varepsilon_s f_s + 2(\varepsilon_s + \varepsilon_y)(f_s - f_y)], & \varepsilon_s > \varepsilon_y \end{cases} \quad (18)$$

$$\Delta_{bar\ slip} = \frac{s}{d - d'} L \quad (19)$$

In these equations, ε_s is the steel strain, f_s is the corresponding steel stress, d_b is the bar diameter, u is the maximum bond stress, ε_y is the yield strain for steel, f_y is the yield stress for steel, d is the effective depth of the section and s is the bar slip.

Deformation due to curvature is found as follows:

- 1) The column is divided into a number of segments
- 2) For each segment, two moment values are calculated. First moment is for the base of the segment and the second one is for the top of the segment (Figure 4)
- 3) Curvatures for each segment corresponding to the moments are found

- 4) The area surrounded by curvatures are calculated
- 5) The area is then multiplied by the distance to find the corresponding deformation
- 6) Total deformation due to curvature is evaluated by summing each deformations found for each segment:

$$\Delta_{curvature} = \sum K_i x_i d_i \quad (20)$$

- 7) After reaching the maximum moment at the base, because of the FRP rupture it is assumed that a plastic hinge develops.
- 8) Plastic hinge length is calculated as follows [4].

$$\frac{l_p}{h} = \left[0.3 \left(\frac{N}{N_o} \right) + 3 \left(\frac{A_s}{A_g} \right) - 0.1 \right] \left(\frac{L}{h} \right) + 0.25 \geq 0.25 \quad (21)$$

where N is the axial load on the column, N_o is the axial load carrying capacity of the column, A_s is the total longitudinal steel area and A_g is the gross area of the column.

- 9) For the plastic hinge region, it is assumed that curvature values are the same for the entire region (Figure 4b).

Figure 4. Deformation calculation from curvature

After establishing the procedure for force-deformation relationship, the models are compared with the experimental data taken from Ozcan et al [6].

Ozcan et. al. tested 4 reinforced concrete columns strengthened with CFRP material. Columns were square in cross-section with 350x350 mm and they were 2000 mm tall. Sections were rounded to 30 mm in order to increase the FRP effectiveness. Although target strength was 15 MPa, concrete strength was found to be between 11 MPa and 19.4 MPa.

They used 1 or 2 layers of CFRP to understand the effect of CFRP thickness. Longitudinal reinforcement was of eight 18 mm diameter plain bars, which correspond to a reinforcement ratio of 1.66%. 10 mm diameter plain bars were used as lateral reinforcements and they were spaced at every 200 mm. Lateral reinforcements had 90° hooks to simulate the deficient case in Turkey.

From Figures 5 and 6, analytical curves are compared with the experimental data. It can be seen from the figures that neither ACI440.2R-08 nor TEC2007 captures the post peak behavior because of limiting the strain capacity of FRP-confined concrete. The arrows in the figures point the end of each curve. Since TEC2007 assumes that FRP application results in a hardening behavior depending on the degree of confinement, it results in a hardening behavior in the force-deformation relationship also. However, it is well known that hardening may be observed when the concrete member is adequately confined, that is, when the MCR value is above a certain limit as discussed above.

4 DISCUSSIONS

In this study, the axial stress-strain estimations and models given in ACI440.2R-08 and TEC2007 are compared with the experimental data to investigate the differences and the estimates that codes make. It is found that TEC2007 assumes only hardening behavior for concrete strengthened with FRP. Although ACI440.2R-08 assumes a hardening and softening behavior depending on the confinement-effectiveness, the limit defining the behavior as hardening or softening is not good to predict the behavior because in that equation no corner radius for rectangular sections is taken into account. The assumptions in these codes result in a more conservative prediction at the post-peak region of the force-deformation curves. It is

essential to understand the degree of confinement, effectiveness of the confinement and the resulting stress-strain relationship of a concrete strengthened with FRP. Assuming a hardening behavior in all the case is not reasonable.

Since the material and application result in a high initial investment, the equations in the codes make it difficult to utilize. Codes may decrease the factor of safety used in FRP-confined concrete members because the reliability of the material is verified and it is still being studied. This will make the material easy to reach and easy to apply in strengthening applications.

Abstract. *The use of steel bracing systems for the strengthening of existing reinforced concrete (RC) frames may lead to increase of both strength and stiffness. However, in most of the cases the main target is the increase of the energy dissipation capacity. This paper studies, both experimentally and numerically, the efficiency of a specific strengthening type which utilizes a small steel link element having an I-shaped cross-section connected to the RC frame through bracing elements. The energy is dissipated through the plastification of the steel link element. The case studied in this paper is a typical one bay, single storey RC frame constructed according to older code provisions, which is strengthened through two different types of steel link elements. The behaviour of the strengthened frames is studied with respect to the one of the original bare frame. The experimental study is supported by complete numerical simulations of the performed tests. To this end, detailed numerical models are formulated, which are able to follow the highly non-linear nature of the problem, involving the plastification of the steel rebars, the cracking and plastification of concrete and the plastic deformation and hysteretic response of the dissipative link elements.*

1 INTRODUCTION

The strengthening of existing reinforced concrete (RC) buildings with pilotis (soft ground floor) is a current necessity in seismic prone areas. It is well known that the majority of these buildings were designed and built according to older codes. Moreover, they lack sufficient longitudinal and transverse reinforcement and their structural materials are of low quality or exhibit degradation of their mechanical properties. As a result, these structures present weaknesses concerning their strength, ductility and stiffness. Strengthening this type of structures is essential in order to avoid damages or even loss of life from earthquakes.

One of the more popular methods for the strengthening of RC frames is the use of steel braces. A specific category in this strengthening type concerns the additional use of dissipative devices which exhibit extensive plastification under the design earthquake. During the last decades significant research effort has been dedicated in this direction. For example, RC frames strengthened with such system were tested by Kunisue et al [1]. Failure was observed at the elastoplastic energy dampers. The test results showed that the strength and the energy dissipation capacity can be significantly improved by the use of these dampers. A calculation method was also suggested for the estimation of the strength increase in strengthened RC frames and satisfactory approximation between experimental and analytical results was observed. In tests performed by Perera et al [2] the strengthening of masonry infilled RC frames was examined. In some frames the masonry was replaced by a system of two steel braces and significant improvement of the energy dissipation was observed. Tests on two full scale, four storey RC frames were executed by Pinto et al [3]. For the frame with no strengthening interventions high vulnerability to seismic loads was observed. It was found that through the use of steel braces, the seismic response of the strengthened frame and the energy dissipation capacity are significantly improved. A full scale, 3D, two storey, RC frame was tested by Antonucci et al [4]. Viscous dampers were used at the connection point of the top of the bracing system to the middle of the RC beam. It was found that viscous dampers can dissipate up to 95% of the induced seismic energy. The storey drift was also significantly reduced. Three tests were performed by D'Aniello [5] on an existing RC building that was strengthened against seismic actions by the use of the same system of two steel braces. It was concluded from the tests that shear elements can be easily connected at the concrete and the steel elements and can also be easily replaced after an important seismic event. A simplified simulation method was also used and a satisfactory approximation resulted between analytical and experimental results. It is concluded from the literature review that the use of a system of two steel braces with a purposely designed steel link element at the top with shear and/or flexural type of failure, could increase the shear strength and the energy dissipation capacity of existing RC frames under seismic actions.

In the present work the efficiency of a specific type of strengthening device, which consists of two steel braces connected to the RC frame through two different types of dissipative steel link elements, is investigated. Six specimens were tested under horizontal cyclic loading, three of them (one bare RC frame and two similar strengthened RC frames) without additional vertical loads at the columns and another identical group of three specimens with vertical loads.

The experimental investigation is complemented by a numerical study. All the tested RC frames are simulated numerically through detailed finite element (F.E.) models, which are able to follow the highly non-linear nature of the problem [6, 7, 8]. The numerical results are then compared with the respective experimental ones. After the verification of the simulation models according to the experimental results, it will be possible to perform reliable “numeri-

cal tests” in order to investigate the effects of several parameters, reducing the required number of experiments [9].

2 TYPES OF RC FRAMES STUDIED

2.1 Geometry and configurations

The specimens studied in this paper represent a single storey one bay frame rigidly based on a strong foundation and are manufactured to a scale of 1:3. The RC part is exactly the same in all the tested specimens. The geometry and the reinforcement arrangement of the specimens are shown in Fig. 1.

The frames are assumed to be constructed according to older regulations and thus, smooth steel rebars and sparsely spaced stirrups were used, even at the critical regions of the possible plastic hinges. Moreover, the anchorage length of the steel bars was small and does not meet the modern requirements.

Figure 1: Geometry and reinforcement arrangement of the specimens (m).

The presented frame is strengthened by means of a steel link which is connected to the beam of the RC frame and to strong steel bracing members. As shown in Fig. 2, the bracing system is composed by two steel elements that are connected to each other at their top. At this point there is a steel plate on which the link element is welded. The top of the link element is connected to the midpoint of the beam through a steel U shaped collar which is placed around the beam. The collar element is connected to the top beam by means of six bolts which pass through the width of the cross-section of the beam. The diagonal elements of the bracing system were connected at the lower ends of the columns and on the base beam by external threaded rods. The elements of the bracing system, the collar and the connections to the beams and the columns were not considered as parameters under investigation in the present study. Therefore, they were oversized in order to avoid local failures at these elements. Consequently, the inelastic deformations of the strengthened specimens are expected to be concentrated mainly at the link element. This type of link elements is expected to significantly increase the strength and stiffness of the strengthened frame. However, the most important

advantage of these systems is the high energy dissipation capacity and, consequently, the reduction of the seismic strength demands.

Figure 2: Specimens F2 and F3 strengthened by steel bracing system and a steel link element at the top.

Three different types of specimens were tested. Specimen type F1 is the bare frame, which is used as a reference for the evaluation of the strengthening types. In order to allow the direct comparison, the bracing system was also installed in this frame (as in the other specimens) but without the link element. This layout was selected in order to ensure the same geometrical conditions for all the specimens concerning the free height of the columns.

In the other two types of specimens (types F2 and F3) the bracing system was connected in the middle of the top beam by a steel link element. The links used in each type are presented in Fig. 3. The first link, used in the type F2 specimens, is a steel element that has a symmetrical I cross-section with total section height $d = 60$ mm, flange width $b = 30$ mm, flange and web thickness $t = 6$ mm and length $l = 100$ mm. The second link, used in the type F3 specimens, has also a symmetrical I cross-section with total section height $d = 80$ mm, flange width $b = 40$ mm, flange and web thickness $t = 6$ mm and length $l = 200$ mm.

Figure 3: The dissipative steel link elements of the strengthened frames F2 and F3, respectively.

The above three types of specimens (F1, F2 and F3) were tested with and without additional vertical loading placed at the columns. Therefore, the total number of specimens and tests was six. The three specimen types in which the vertical loading was present at the columns during the testing are referenced as F1,N, F2,N and F3,N respectively. The tests are presented schematically in Figs 4 - 6.

Figure 4: Specimen F1 and F1,N with the bracing system of the strengthened frames but without a link element

Figure 5: Specimens F2 and F2,N strengthened by steel bracing system and a steel link element at the top.

Figure 6: Specimens F3 and F3,N strengthened by steel bracing system and a steel link element at the top.

2.2 Materials

As the RC specimens were assumed to be constructed according to older regulations, a low strength concrete was used with a compressive strength of 16 MPa and a tensile strength of 2.1 MPa. The smooth steel rebars of the longitudinal reinforcement had a yield stress of 450 MPa and an ultimate stress of 540 MPa (it was not possible to find lower strength smooth steel rebars with a diameter of 6 mm), while the transverse reinforcement had a yield stress of 265 MPa and an ultimate stress of 390 MPa. Finally, the yield stress of the steel link elements was equal to 300 MPa and the ultimate stress equal to 375 MPa.

2.3 Experimental test setup

For the tests, the facilities of the Laboratory of Concrete and Masonry Structures of the Aristotle University of Thessaloniki, were used (Fig. 7). The reaction frame consists of steel beams and columns connected to each other by prestressed threaded rods. One double acting actuator is connected at the top beam of the specimens applying horizontal displacement reversals. Another actuator can also be connected to the system to apply vertical axial loads on the columns through a top steel beam in a load control mode.

Figure 7: Test setup

The reaction frame is connected to the strong floor of the laboratory by the use of steel stoppers in combination with vertical prestressed threaded rods. The test specimens were also connected to the floor by the same technique. It is worth mentioning that during the tests no slip was recorded between the specimens and the laboratory floor. The horizontal actuator was connected at the top of the specimens by a system of two stiff steel plates at the vertical outer sides of the beam - column joints, connected to each other by four long threaded rods. In order to allow free rotation at the connection points, beyond the 3D rotational hinges of the actuator at the ends of its length, two more rotational hinges were provided between the steel plates and the two top beam - column joints of each specimen.

2.4 Loading procedures

The horizontal loads were imposed in a displacement control mode. The displacement history was composed by 16 levels of displacement. For each displacement level, two full cycles were imposed. The loading increment had the value of 1mm until a total displacement of 3mm and the value of 3mm till the maximum displacement (42mm). For the specimens with the axial loading (F1,N – F2,N – F3,N), apart from the horizontal displacement, a constant axial load of 80kN was applied at each column. Figure 8 shows the horizontal loading history.

Figure 8: Horizontal loading history

The specimens were instrumented by the use of seven LVDTs. The layout of these instruments is shown in Fig. 9. LVDTs 1, 5, 2, 6 were used for the measurement of the shortening and the elongation of the outer fibres at the ends of the left column. LVDT 8 was used for the measurement of the top horizontal displacement of the specimen and was compared with the measurements of the internal LVDT of the horizontal actuator. LVDTs 4 and 7 were used for the measurement of the net horizontal displacement at the top and bottom ends of the steel link element. The measurements of the external and internal LVDTs together with the measurements given by the load shell of the horizontal actuator were recorded through a digital controller. In the present work, only a small part of the experimental measurements and the post-processed data are presented due to limited available space.

Figure 9: LVDT arrangement on the specimens

3 THE PRINCIPLES OF NUMERICAL SIMULATION

The numerical simulation of the tested frames presented several difficulties due to the complexity of the problem and the existence of various nonlinearities, such as cracking in concrete and the plastification of the steel link elements. Moreover, while a three-dimensional model is expected to be more realistic and reliable due to the nature of its elements, it has the disadvantage of a high computational cost. Therefore, simpler two-dimensional models were formulated, which were able to capture in a rather accurate manner the overall behaviour of the studied problem [10]. The attempt to simulate a 3D problem through a 2D finite element model resulted in several simulation problems, which had to be solved efficiently.

3.1 Geometric and material properties

The 2D simulation models of the RC frames consist of different F.E. meshes, which overlap, connected at the same grid of nodes. Especially for the models of the strengthened F2 and F3 frames, another F.E. mesh was added to the F.E. mesh of the RC frame, simulating the link element. Plane-stress and truss elements were used for the formulation of the 2D numerical models. Figure 10 shows the numerical model of the F2 strengthened frame together with a detail of the link element, after the discretization. The plane-stress elements were used for the simulation of the concrete and of the steel link elements. The truss elements were used for the simulation of the longitudinal and transverse reinforcement. The properties of the problem in the third direction (perpendicular to the modelling plane) were taken into account by assigning different thickness values to the respective finite elements.

Figure 10: The 2D F.E. model of the strengthened RC frame and detail of the steel link element.

The plane-stress elements representing the concrete beam and columns were assigned a thickness equal to the width of the corresponding cross-section, that is 100 mm and 150 mm thickness for the beam and the columns, respectively. The cross-sectional area of the two-node, constant cross-section truss elements that represent the longitudinal and transverse reinforcement was taken equal to the total area of the corresponding reinforcing bars. That is, for the line of elements representing the top and the bottom steel reinforcement the cross-sectional area was $3 \times 28.26 = 84.78 \text{ mm}^2$ ($3\text{Ø}6$) and for those representing the middle longitudinal reinforcement, the cross-sectional area was $2 \times 28.26 = 56.52 \text{ mm}^2$ ($2\text{Ø}6$). For the lines of elements representing the stirrups of the beam and columns, the cross-sectional area was $2 \times 4.91 = 9.81 \text{ mm}^2$ in order to account for the two vertical legs of the $\text{Ø}2.5$ stirrup. For the steel links, the plane-stress elements representing the flanges and those representing the web were assigned different thickness values. More specifically, for the first link (F2) the elements representing its web were assigned a thickness of 6 mm and those representing the flanges were assigned a thickness of 30 mm, whereas for the second link (F3), the elements representing the web had thickness equal to 6 mm and those representing the flanges had thickness equal to 40 mm.

It must be noted that the links were simulated through a much denser finite element mesh, as already shown in Fig. 10. This dense discretization of the links was considered necessary in order to simulate as accurately as possible their behaviour, which dominates the strengthened systems. The two different F.E. meshes (the one corresponding to the RC frame and the one representing the link element) were connected through kinematical relationships, due to the fact that their nodes, at their common boundary, do not coincide.

Figure 11 presents the stress-strain relationship considered for concrete, steel reinforcement and the steel links. The elements representing concrete were equipped with the stress-strain relationship of Fig 11a, which exhibits an elasto-plastic behaviour for compressive loading and a cracking behaviour for tensile loading. The loss of tensile strength after cracking was modelled through a softening branch with a slope $k_s = 10^8 \text{ MPa}$. The elasticity modulus was taken equal to 28.4 GPa and the Poisson's ratio $\nu = 0.16$. The longitudinal and transverse reinforcement bars were assumed to behave elastoplastically with hardening. A modulus of elasticity of 200 GPa and a Poisson's ratio $\nu = 0.20$ were given. The stress-strain diagram for

the steel rebars is depicted in Fig. 11b. Finally, the F.E. simulating the steel links were also equipped with the stress-strain relationship given in Fig.11b, which exhibits elastoplastic behaviour with hardening. The elasticity modulus for these elements was taken equal to 210 GPa and the Poisson's ratio $\nu = 0.30$.

Figure 11: Stress-strain relationships considered for a) concrete and b) all the steel elements of the model.

3.2 Boundary conditions – loading procedure

All the specimens (F1, F2 and F3) were subjected to horizontal cyclic loading, with and without additional vertical load at the columns. The cyclic load was applied incrementally in the form of induced displacement, whereas the constant vertical load was applied as a point load. The simulation of the load application procedure introduced several difficulties, which required a special numerical treatment. In general, it was not possible to apply the load directly to a nodal point of the F.E. mesh, due to the elastic-plastic and cracking properties of concrete. When the applied load caused the formation of a compressive stress zone in the neighbourhood of the load application node, stress concentrations and non-realistic stress fields occurred, creating excessive plastification of the elements representing concrete. In order to avoid this phenomenon, a steel plate was placed on each load application position, through which the respective load was applied.

On the other hand, during the load reversal, the applied load produced a tensile stress zone in the region of the applied load. Even for moderate load values, stress concentration appeared locally, near the node at which the load was applied and therefore, non-realistic conditions for cracking were created, destroying the adjacent elements and leading to the premature termination of the numerical process. To overcome this obstacle, a system of two plates was adopted, one on the upper left and one on the upper right side of the frame. Unilateral contact conditions were assumed between the plates and the frame. The two plates were connected by kinematical constraints in order to achieve the load application in both directions and so that only compressive forces are imposed through the respective contact surfaces of the specimen. The above described loading procedures resulted in rather realistic stress and strain fields in the load application areas.

Finally, clamped supports were assumed at the positions where the steel rigid braces are connected to the frame and to the steel link.

3.3 Numerical solution procedure

The solution to the described numerical problem was obtained by using the software code MSC-MARC. A Newton-Raphson iterative procedure was applied to handle the nonlinearities of the problem. The cyclic load was applied in the form of an induced displacement δ and the resulting force P at the points of the incrementally applied displacement was monitored. A relative convergence criterion was adopted, based on the residual forces. The relative force tolerance was set to 0.01.

4 EXPERIMENTAL AND NUMERICAL RESULTS

4.1 Overall behavior of the specimens

Figures 12-14 present the load – displacement curves of the tested specimens. Also, in Fig. 15, the envelop curves that result from the aforementioned diagrams (consideration of first cycles only) are compared. In Fig. 16 the dissipated energy with respect to the imposed displacement for each specimen is presented. The observations on the response of the specimens during the tests and the obtained results are given below.

Specimen F1: During the first cycles, flexural cracks were formed, initially at the base and later at the top of the columns. The cracks at the base of the columns were formed just over the point where the Λ -shaped steel bracing system connects at the columns (Fig. 17). At these cracks the reinforcement was elongated inelastically and thus, flexural plastic hinges were formed. The inelastic deformations were all developed at these plastic hinges. Although the stirrups were sparsely spaced, the strength of the specimen appeared a slight increase, even for drifts of the order of 3% (Fig. 12). For higher levels of the imposed displacement, strength reduction was observed.

Specimen F1,N: It can be noticed, even from the first cycles of the imposed load, that the stiffness of this specimen is higher than the stiffness of the corresponding specimen without the axial force (F1). Moreover, the hysteresis loops of the F1,N specimen are richer than those obtained from the F1 frame. Initially, cracks appeared at the columns and at the two ends of the top beam. As the values of the imposed cyclic displacement increased, the inelastic deformations were mainly developed at the plastic hinges which were formed at the ends of the columns. Due to the existence of the axial loads at the columns, the strength of the specimen and the dissipated energy were increased by 50% and 100% respectively, in comparison with specimen F1 (Figs 15 and 16).

Specimen F2: In this case, due to the activation of the steel link, there was a significant increase of the strength, the stiffness and the energy dissipation capacity of the specimen, in comparison with the bare frames (Figs 13, 15 and 16). More specifically, the strength of the F2 specimen was four times higher than that of the F1 specimen. Also, the hysteresis loops were very rich and no pinching occurred. The link started to fail by fracture at the tensioned regions of the link, for a drift of 1.8%. As the loading was cyclic, the fracture appeared at both ends of the link (Fig. 18). The welds did not show signs of failure. After the failure of the link element, the overall behaviour of the F2 frame, in terms of strength and energy dissipation capacity, appeared to be similar to the behaviour of the F1 frame. The final failure mode was similar as in the case of the specimen F1, since the plastic hinges were formed at the same locations.

By the use of the U-shaped steel jacket, the force undertaken by the link element was transferred at the middle of the beam. Due to this reason, many cracks appeared at the middle of the top beam, as well as, loss of concrete cover (Fig. 19). However, the crack pattern at the

ends of the columns and at the ends of the beam didn't differ from those that appeared in specimen F1. Moreover, after the failure of the link element the response of the two specimens was very similar.

Specimen F2,N: Due to the existence of the axial load, the strength and stiffness of this specimen were increased, in comparison with the specimen F2 (Figs 13 and 15). Moreover, this specimen appears to have an increased strength and dissipation capacity of the order of 40% and 50% respectively with respect to that of the specimen F2 (Figs 15 and 16). The failure mode of the link element was the same as in the previous case. The link failed again for a drift of 1.8%. After the failure of the link element, the recorded response of the specimen F2,N was similar with the response of the specimen F1,N.

Specimen F3: This specimen was strengthened with a link element of different type (Fig. 3). The dimensions of the cross-section of the present link in combination with its longer length resulted in lower stiffness compared to the link of the specimen F2. However, the ultimate strength for this specimen is slightly higher than that of specimen F2. The main improvement for the present specimen is that the strength was sustained without reduction until a drift of 2.7%, thus, improving the ductility of the strengthened frame (Figs 14 and 15). The failure of the link element started at a drift of 2.7% and completed at a drift of 3.6%. After that point the specimen had the response of the unstrengthened specimen F1. This high ductility of the specimen is attributed to the higher rotational capacity of the link element. Due to the higher forces and the significant inelastic deformations that were developed, the U-shaped jacket at the middle of the top beam caused local damage. Moreover, the bending moment that develops at the mid-span of the beam due to the eccentricity of the horizontal force undertaken by the link, led to the development of high shear forces along the two parts of the beam. Characteristic is the development of bidiagonal shear cracks at the left and right parts of the top beam (Fig. 20). Also, plastic hinges were formed at both ends of the columns.

Specimen F3,N: Due to the existence of the axial loads at the columns, the strength of the specimen and the dissipated energy were increased by 35% and 40% respectively, in comparison with specimen F3 (Figs 15 and 16). For an imposed displacement of 3mm, the resisted force was 90kN. Due to the high stiffness, the first cracks appeared at the top beam, at the left and right of the U-shaped jacket. Also, due to the existence of axial loads, the cracks at the columns were significantly reduced. For this reason, the inelastic deformation was developed mostly at the middle of the top beam through the rotation of the U-shaped jacket. The ultimate strength was achieved for an imposed displacement of 21mm. Due to the extended damage that developed at the top beam, the test was terminated at that displacement value, for safety reasons. The link element did not fail.

4.2 Overall behaviour of the specimens

Before displaying the numerically obtained results, it should be mentioned that, for most of the cases treated here, it was not possible to simulate the performed experiments beyond a displacement of about 12 mm, due to numerical instabilities in the models which led to the termination of the applied Newton – Raphson iterative procedure. The reason for the aforementioned problem was the significant damage of concrete that occurred for displacement values higher than 12 mm. For the same reason it was decided to simulate numerically only one load cycle for each displacement level instead of two similar cycles that were applied in the experiments. Therefore, the experimental $P-\delta$ curves used in this section for the comparison of the numerical with the experimental results are actually, part of the complete response diagrams of each experiment (Figs. 12-14).

The comparison between the numerical and experimental $P-\delta$ curves of the bare frame without axial force (F1) and with axial force (F1,N) is presented in Fig. 21. It can be noticed that the numerical model cannot approximate adequately the unloading branch of the experimental $P-\delta$ diagram, leading to narrower hysteresis loops. It seems that the smeared crack approach used for the modelling of cracking cannot simulate accurately enough the closure of cracks and therefore, the behaviour of the specimen during the load reversal procedure. This deficiency of the numerical model is more obvious in the case of F1,N, where, except from the narrower hysteresis loops, one can notice differences between the load values P obtained

for the negative cycles by the analysis and the experiment. Figure 22 presents the comparison of the P - δ envelopes obtained by the experiment and the analysis of the F1 and the F1,N frames. In these diagrams, only positive values are given for each applied displacement level, that correspond to the mean of the absolute values of the respective positive and negative cycles. The aforementioned discrepancies that appear in the P - δ diagrams of the F1,N case concerning the experimental and numerical load values of the negative cycles, are reflected in the respective P - δ envelope curves. Figure 23 gives the comparison of the dissipated energy in each load cycle. It can be observed that for the case of F1 the differences between the experimental and numerical values of dissipated energy are rather small and result from the narrower numerical hysteresis loops. However, for the case of the F1,N frame, the corresponding discrepancy is much wider, due to the additional differences in the negative load values.

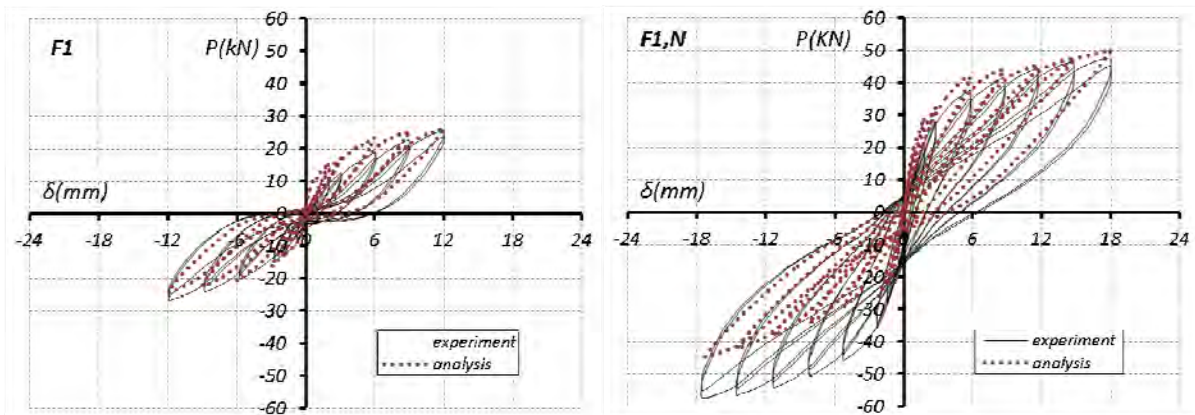

Figure 21: Comparison of the numerical and experimental results of the frames F1 and F1,N.

Figure 22: Comparison of the P - δ envelope results obtained by the experiment and the analysis of the frames F1 and F1,N.

Figure 23: Comparison of the experimental and the numerical results for the dissipated energy in the frames F1 and F1,N.

Contrary to the bare frame F1, the overall behaviour of the frames strengthened by the steel link elements, F2 and F3, is significantly improved after the immediate activation of the link elements. Figure 24 shows the P - δ curves for the F2 strengthened frame (without axial load) and the F2,N strengthened frame (with axial load), obtained by the 2D numerical model together with the experimental results. Figure 25 displays the corresponding envelopes of the P - δ curves. It is noticed that, especially for the case of the F2 frame, there is a good agreement between the numerical and the experimental results, as far as the load values, the quality of the hysteresis loops and therefore, the overall behaviour of the specimen, is concerned. The small differences that arise in the obtained values can be considered acceptable, taking into account the highly nonlinear nature of the studied problem. However, once again, in the case where the axial load is imposed at the columns, greater differences can be noticed between the numerical and the experimental results, mainly in terms of the obtained load values, whereas the quality of the hysteresis loops is similar. In Fig. 26 the numerical and experimental results for the dissipated energy of the F2 and F2,N frames are presented. As expected, there is a very good agreement between the results for the F2 frame, whereas some differences arise for the F2,N strengthened frame, due to the above mentioned differences in the obtained values of the P - δ curves.

The same conclusions can be drawn from the comparison of the numerical and experimental results presented in Figs 27, 28 and 29, which concern the F3 strengthened frame (without axial load) and the F3,N strengthened frame (with axial load). For the F3 case, the numerical and experimental results are in a rather good agreement, in terms of obtained load values, quality of the hysteresis loops and dissipated energy. For the F3,N case, although the numerical P - δ curves, the P - δ envelope curves and the dissipated energy present some differences with respect to the experimentally obtained ones, they can be considered acceptable, taking into account the nonlinear phenomena that are present in the physical model.

It can be concluded that the good agreement between the numerical and experimental results of the strengthened frames is derived from the fact that in these cases the behaviour of the steel link element is dominant. In this case, the numerical model has the ability to simulate efficiently the isotropic and homogenous behaviour of the steel link element, as well as its stable elasto-plastic deformation.

Finally, Figs 30 and 31 show the plastic strain fields of the link elements F2, F2,N and F3, F3,N, respectively for a displacement of about 12 mm. Both types of links present a combined shear and bending behaviour. However, their failure is mainly of bending type, as greater stresses appear in the flanges at the top and bottom ends of the elements, rather than the web, especially in the case of the F3 and F3,N links. The failure modes match well with the failure type of the link elements that was noticed in the corresponding experiments.

5 CONCLUSIONS

After comparing the behaviour of the specimens under study, it can be concluded that the use of the steel link elements can increase considerably the strength, the stiffness, but mainly the energy dissipation capacity of the frame. Moreover, the use of the F3 type of link element results to slightly lower overall stiffness, but to increased ultimate strength, with respect to the F2 type of link element. However, the significant improvement for the F3 strengthened frame is its increased ductility; the high load carrying capacity is maintained without reduction for much higher values of imposed displacements. Also, it is evident that the existence of axial loads at the columns resulted to an increase of the strength, stiffness and dissipated energy for all the frames studied. It must be noted, however, that attention should be paid to the connection of the link element to the midpoint of the beam, through the U-shaped steel jacket, as local damage appeared at that specific area of the beam of the strengthened frames. By a careful selection of the geometry of the steel link and appropriate detailing of its connection with the frame, this local failure at the middle of the top beam can be prevented, so that it does not affect or alter the failure mode of the frame.

Finally, after the comparison of the numerical with the experimental results, some differences are observed in the case of the bare frames (F1 and F1,N) which are attributed to the inability of the used type of finite elements to simulate adequately the unloading behaviour of concrete. On the other hand, the results obtained from the numerical models of the strengthened frames can be considered satisfactory in terms of the stiffness, load carrying capacity, quality of the hysteresis loops and dissipated energy, with respect to the experimental results, given the complexity of the studied problem.

ACKNOWLEDGEMENTS

The work presented here is part of a broader program, partially sponsored by the Greek Earthquake Planning and Protection Organization, the contribution of which is gratefully acknowledged.

Abstract. *This paper deals with an application of wavelet analysis for damage detection of frame structure subjected to earthquake excitation. Non linear dynamic analysis has been performed and response data at each story are obtained which are used as simulation data. Damage in the frame is introducing by the non linear behaviour of columns and beams. In order the structural members go beyond the elastic limit and start yielding the earthquake excitation was scaled up with appropriate scale factor. Discrete wavelet analysis was performing in order to analyze the simulation response data for each floor because the dynamic behaviour of inelastic structures subjected to an earthquake is a non-stationary process.*

It was shown that structural damage, due to non linear behaviour of structural elements and the time when this damage occurred, can be clearly detected by spikes in the wavelet details.

The effect of noise is taken into account by adding a white Gaussian noise to the simulation response data and discrete wavelet analysis was performing again. It was observed that if the level of details and the order of wavelets are increased, spikes can be detected again and damage would be recognized. Results show the great promise of the wavelet approach for damage detection and structural health monitoring.

1 INTRODUCTION

Damage in the buildings is often observed during their service life. Damage may be caused due to excessive earthquake excitation, severe environmental condition, degradation of the materials properties, fatigue, cumulative crack growth, etc. Usually the existence and the location of the damage can be determined through visual inspection. However, in some cases visual inspection may not be feasible. To ensure structural safety and low maintenance cost, structural health monitoring, SHM, is an efficient strategy to monitor the system performance and make a corresponding maintenance decisions.

Damage detection is a part of damage identification which includes the estimation of the severity of damage, determination of the location of damage and prediction of the remaining service life. One main group of methods for damage detection is, modal analysis methods, which are based on the fact that the change in structural properties causes a variation in the modal parameters; natural frequencies, damping ratios and mode shapes. Many analytical and experimental studies have been conducted to establish analytical correlations between damage severity and modal parameters. Kirmser, [1], investigated the relationship between natural frequencies and the introduction of a crack in an iron beam. A literature review on methods of damage detection using vibration signals for structural and mechanical systems was provided by Doeblin et al. [2] and Carden and Fanning, [3]. Other works based on change in modal parameters is the work of Humar et al. [4] and Khoo et al., [5].

Structural health monitoring techniques based on changes in dynamic characteristics have success when the damage is substantial. Improved research directions for damage detection including the use of innovative signal processing, new sensors, are described in the work of Chang et al., [6]. Neural network approaches can be used for damage detection. Wu et al., [7], trained a neural network to recognize the behaviour of the undamaged structure as well as the behaviour of the structure with various possible damage states. When the trained network is subjected to the measurements of the structural response, it is able to detect any existing damage. Tsou, and Shen, [8], applied neural network to discrete structural systems. Masri et al., [9], train a neural network with measurements from healthy structure and this trained network was fed comparable vibration measurements from the same structure under different episodes of response in order to monitor the health of structure. Vanik and Beck, [10], Chandrashekhar and Ganguli, [11], used fuzzy logic for determination of damage location. Friswell and Mottershead, [12], use a combination of sensors and analytical model of structure for damage detection. Parameters of the model that are related to damage are updated so that the dynamic characteristics of the model correspond to the measurements sensors, Papadimitriou and Ntotsios, [13]. Reigh and Park, [14], utilised methods of localized flexibility in order to determining the damage and its location in a structure. Panetsos et al, [15], describe the Egnatia Odos Bridge Management system (EOBMS) which used for deterioration prediction and maintenance, repair cost.

Engelhardt et al., [16], were investigated the Crack and flaw identification in elastodynamics using Kalman filter techniques. Soyoz and Feng, [17], used an extended Kalman filtering (EKF) method in order to instantaneously identify elemental stiffness values of a structure during damaging seismic events based on vibration measurement. This method is capable of dealing with nonlinear as well as linear structural responses. Sakelariou and Fasois, [18], introduced a stochastic output error for damage detection and assessment (location and quantification) in structures under earthquake excitation. De Roeck and Reynders, [19], present a number of recent innovations to extend the borders of what is realistically feasible with the current system identification and damage detection methods.

Medda and DeBrunner, [20], proposed a novel technique that employs the use of compactly supported sub-band space-frequency and time-frequency analysis using local vibration characteristics.

Another tool for damage detection is wavelet-based damage detection which has been considered by several researchers over the last decade, Staszewski, [21]. Newland, [22], have used wavelets to vibration analysis. He applied a wavelet analysis to study the vibration of buildings caused by underground trains, road traffic and earthquake excitations. Taha et al., [23], presents a view of wavelet transform and its technologies. They discuss specific needs of health monitoring addressed by wavelet transform. Masuda et al, [24], use orthonormal discrete wavelets transform to detect the degradation of stiffness due to fatigue. They applied the method to the laboratory-scale experiments to detect the sudden changes in the structural parameters. Kim and Melhem, [26], provide a review of the research that has been conducted on damage detection by wavelet analysis. Hou et al., [27], proposed a wavelet-based approach for structural damage detection. Their model consists of multiple breakable springs which is may suffer either for irreversible damage when the response exceeds a limit value nor the number of cycles of motion is accumulated beyond their fatigue life. In any case, occurrence of damage and the time when it occurs can be clearly determined in the details of the wavelet decomposition of these data. Hera and Hou, [28], applied wavelet analysis for detection and locating damage for a four-story prototype benchmark building provided by ASCE Task Group on Health Monitoring, Johnson et al., [29]. They were found that structural damage due to sudden breakage of structural elements and the time when it occurred can be clearly detected by spikes in the wavelet details. In the work of Khatam et al., [30], wavelet analysis is used for damage identification in beams subjected in harmonic loading. The damaged region can be determined by the spatial distribution pattern of the observed spikes. Yaghin and Hesari, [31], use Wavelet Analysis in crack detection at the arch concrete dam. Noh et al., [32], use the Wavelet Coefficient Energies in order to perform structural damage diagnosis for non stationary response signals. Nair and Kiremidjian, [33], have shown that the energies of the wavelet coefficients at appropriate scales can be used as damage sensitive features. A wavelet based, distortion energy approach is presented by Bukkapatnam et al., [34], as a method, for quantifying and locating the damage to structural systems. Another application of the wavelet transform for damage detection based on optical measurements is presented in the work of Patsias and Staszewski, [35].

In this paper the method of spikes in the wavelet details, from discrete wavelet analysis, is used in order to detect the damage in the frame structure. Damage in the structure was introduced by the non linear behaviour of the members. In order the members go slightly beyond the yielding point, and small damage occurred, the earthquake excitation was scaled up with appropriate factor. The analyzing data were obtained by non linear dynamic analysis of plane frame. Since the dynamic behaviour of inelastic structures during an earthquake is a non-stationary process wavelet analysis is more appropriate tool than conventional Fourier analysis.

2 BACKGROUND OF WAVELET ANALYSIS

Wavelet analysis provides a powerful tool to characterize local features of a signal. Unlike the Fourier transform, where the function used as the basis of decomposition is always a sinusoidal wave, other basis functions can be selected for wavelet shape according to the features of the signal. The basis function in wavelet analysis is defined by two parameters: scale and translation. This property leads to a multi-resolution representation for non-stationary signals.

The continuous wavelet transform of a signal $f(t)$ is defined as:

$$f(a, b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} f(t) \bar{\Psi}\left(\frac{t-b}{a}\right) dt \quad (1)$$

where a, b are the scale and translation parameters respectively and $\bar{\Psi}$ denotes the complex conjugate of Ψ . The functions $\Psi(t, a, b)$ are called wavelets. They are dilated and translated versions of the mother wavelet $\Psi(t)$.

By discretizing the parameters a and b , a discrete version of the wavelet transform (DWT) is obtained. The procedure becomes more efficient if dyadic values of a and b are used, i.e.

$$a = 2^j \quad b = 2^j k \quad j, k \in \mathbb{Z} \quad (2)$$

where \mathbb{Z} is a set of positive integers. The corresponding discretized wavelets $\psi_{j,k}$ defined as:

$$\Psi_{j,k}(t) = 2^{-j/2} \Psi(2^{-j}t - k) \quad (3)$$

$\psi_{j,k}$ forms an orthonormal base. In the discrete wavelet analysis, a signal can be represented by its approximations and details. The signal is passed through a series of highpass filters, which relates to details, to analyze the high frequencies, and through a series of low-pass filters, which relates to approximations, to analyze the low frequencies. The detail at level j is defined as:

$$D_j = \sum_{k \in \mathbb{Z}} a_{j,k} \Psi_{j,k}(t) \quad (4)$$

where $a_{j,k}$ is defined as :

$$a_{j,k} = \int_{-\infty}^{\infty} f(t) \bar{\Psi}_{j,k}(t) dt \quad (5)$$

and the approximation at level J is defined as:

$$A_J = \sum_{j > J} D_j \quad (6)$$

Finally, the signal $f(t)$ can be represented by:

$$f(t) = A_J + \sum_{j \leq J} D_j \quad (7)$$

The DWT can be very useful for on-line health monitoring of structures, since it can efficiently detect the time of a frequency change caused by stiffness degradation.

3 DETECTION OF DAMAGE USING WAVELETS

When the structure subjected to the earthquake excitation the envelop of the hysteretic behavior of base shear versus the roof displacement is similar to figure 1. If the excitation is strong enough and push the structure in region c or b then damage in structures is obvious since large displacements and rotations can be observed with visual inspection, and no damage detection technique is needed to verify it. If the excitation is not too small, structure behaves elastic and no permanent displacement are observed or no damage occurs. In between the two extreme above cases, the structure can be go slightly non linear, region a, and small damage that is difficult to observe by visual inspection, can be occurred.

Figure 1. Global behavior envelop curve of a structure.

The above global behaviour of structure is a result of the behaviour of each element that consist the structure. The frame element has its own nonlinear characteristics based on section and material. A generalized force-displacement characteristic of frame element (or hinge properties) is shown in figure 2. Region AB, corresponds to a linear behaviour and point B represents yielding of the element. The ordinate at C corresponds to nominal strength and abscissa at C corresponds to the deformation at which significant strength degradation begins. The drop from C to D represents the initial failure of the element and resistance to lateral loads beyond point C is usually unreliable. The residual resistance from D to E allows the frame elements to sustain gravity loads. Beyond point E, the maximum deformation capacity and gravity load can no longer be sustained. This formulation is according to FEMA 356 for force deformation behaviour of structural element subjected to monotonic loading. This nonlinear behaviour can be used during nonlinear direct integration time history analysis.

Figure 2. Generalized Force-Displacement Characteristic of a Degrading Frame Element.

As the structural elements reach the region DE or the end of the region BC the damage is clear by visual inspection since large displacement and rotation is occurred. If the element is in a linear elastic branch AB no damage is occurred. Finally if the element goes slightly beyond the yielding point, B, then small damage occurs and is difficult to be observed by visual inspection. Visual detection of damage becomes more difficult considering that structural elements are covered by other material or is difficult to access them.

Once the plastic hinge is occurred during the excitation, the frequency of the system is also change. This change in frequency has as a result the change in frequency in the response sig-

nal. From the other hand if a signal which changes its frequency is analyzed by discrete wavelet transform spikes will be observed in the details. This is clearly indicated in figure 3.

Figure 3. Spike in the detail of a signal which consists of two different frequencies.

Combining the above two characteristics (plastic hinge-chance of frequency, chance of frequency-spikes in details) the strategy that used in order to detect the damage in frame structures is as follow: The response signal is analyzed by discrete wavelet analysis and the details of the signal are obtained according to equation (4). If spikes will be observed in the details of the response signal this means that the structural element goes beyond the yielding point and damage is occurred. The time moment that the spikes appear in the details, represent the time were a plastic hinge is created. If no spikes would be observed in the detail of the response signal the structure would remain elastic and no damage would be happen. The above cases are shown schematically in figure 4.

When any structural element yields, this phenomenon is imprinted as spikes in the details of wavelet analysis of the acceleration response signal. This can be used in opposite direction, suppose that is not easy to see the situation of the structural element and the only measured data that is available is the acceleration response signal of the structure. If spikes are observed in the wavelet analysis of the signal, then yielding (damage) has been occurred.

4 NUMERICAL EXAMPLES

The above damage detection strategy has been applied to one single, one two and one eight story frame structure with the properties shown in figure 5. The frames were subjected to earthquake excitations. The nonlinear dynamic analysis and the response of the frames have been done using the software programme SAP2000nl, [36]. The wavelet analysis of the response signal has been done by the MATLAB software, [37], using the wavelet toolbox. Four order Daubechies wavelets and five levels of the details have been used for the wavelet analysis of response signal.

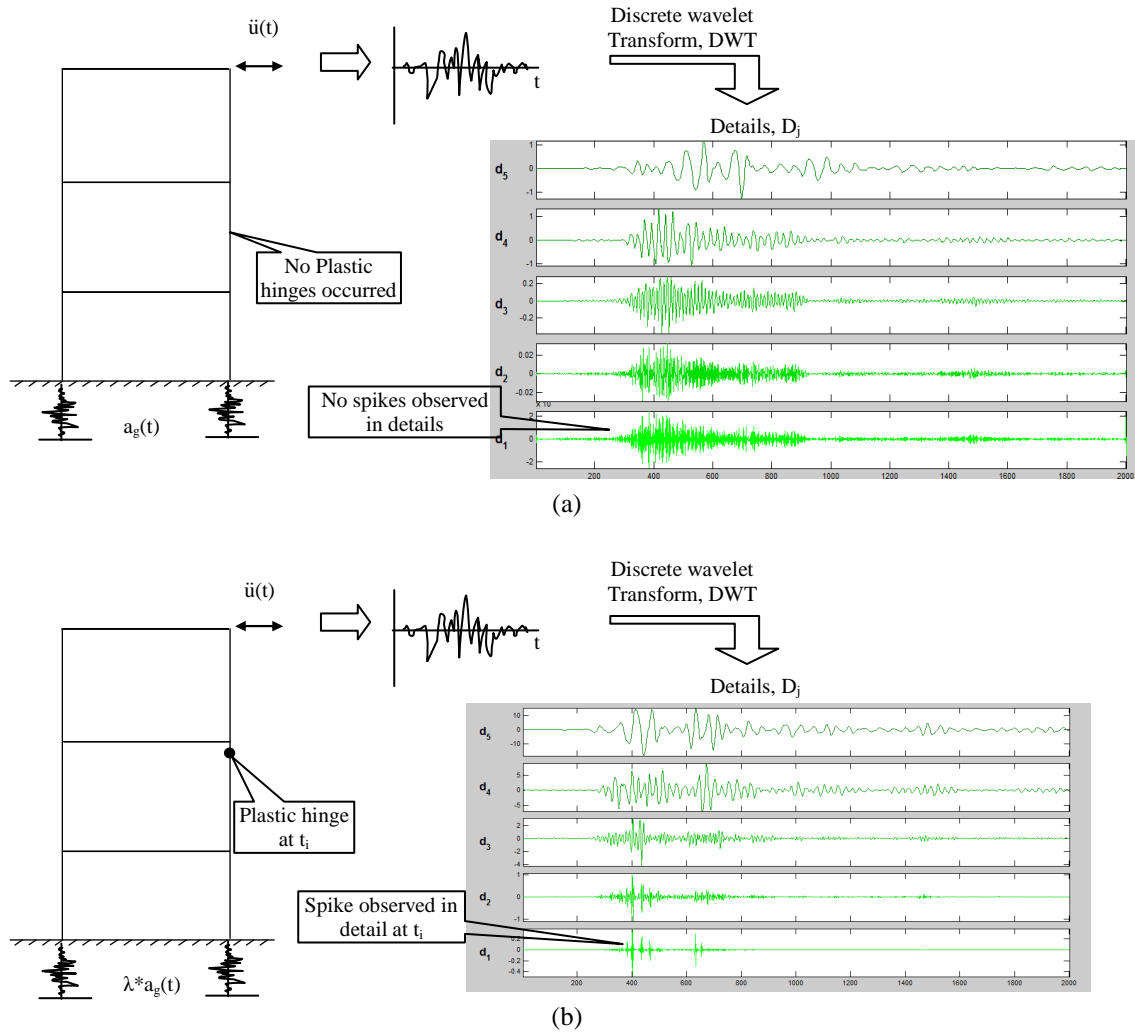

Figure 4. Procedure for detection the existence of plastic hinges in the structure. (a) no plastic hinges occurred no spices are observed, (b) plastic hinges occurred at time t_i spices are observed at t_i .

The single story frame subjected to Athens earthquake signal and no hinges has occurred. The response acceleration on the top of the frame were analyzed by wavelet analysis and the results of the approximations and details of the signal are shown in figure 6(a). It is clear, in the details of signal, d_1 , no spikes are observed and consequently no damage occurred. This is verified by the nonlinear dynamic analysis where no plastic hinges occurred during the Athens earthquake excitation. The earthquake signal is scaling up gradually and dynamic non linear analysis is performing again until plastic hinges will be observed. When the factor λ becomes equal to 4 the first plastic hinges were created. For this case, the response signal at the top of the frame is analyzed again, by discrete wavelet analysis and the details are shown in figure 6(b). From the result of the wavelet analysis it is seems that spikes are observed in the details of signal. This indicates that damage has been occurred in frame. This is verified by the results of the dynamic nonlinear analysis of the frame where a plastic hinges, damage, occurred to the frame when subjected to Athens earthquake record scaled up four times. It is also remarkable, that the time ($t=4.05$ s) when the first plastic hinges occurred, at the base of frame, is the same when the first spike is observed in the details of the signal. After a while at time ($t=4.07$ s) the plastic hinges at the beam of the frame occurred and spike at time ($t_i=4.07$ s) was also observed. The moment-rotation diagram of plastic hinge at the base of the frame is

shown in figure 7. Nevertheless the rotation of the element is too small, after yielding, this nonlinearity, or small damage, can be captured by the detail of the response signal.

Figure 5. The examined frames, their load, geometrical and sections properties.

The two story frame subjected to the same earthquake signal and the results are shown in figure 8(a). No plastic hinge has occurred in the frame and no spikes were observed in the details of the response signal at the second floor. The earthquake is scaling up with the factor λ equal to 4 and the results are shown in figure 8(b). For this case the results from the non linear analysis show that plastic hinges at the beam of the first floor have occurred at the time $t=3.91$ s, while, the plastic hinge at the column have occurred at time $t=4.22$ s. At the same times, the first two spikes have been observed in the details of the response signal as it is shown in figure 8(b).

(a)

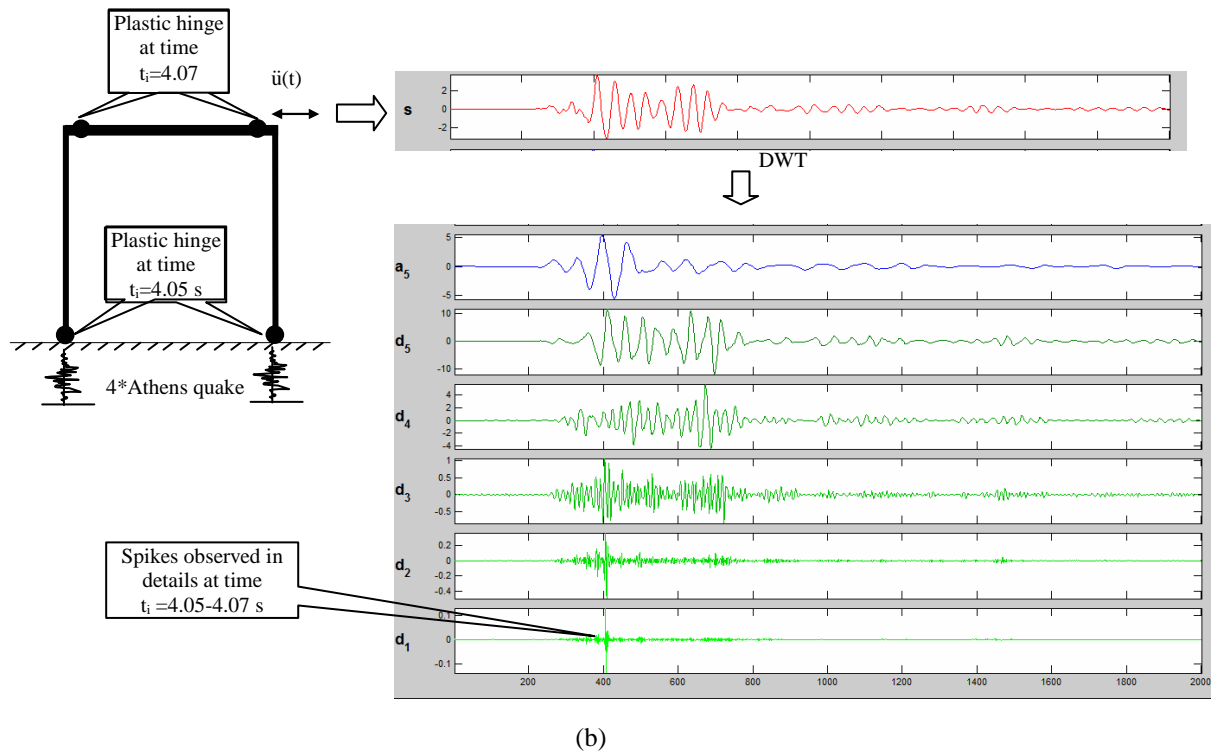

Figure 6. The approximation a_5 , and the details d_1 - d_5 of the response acceleration signal, s , at the top of the frame subjected to (a) Athens earthquake signal and (b) four times scale up Athens earthquake signal.

Figure 7. Moment-rotation hysteretic curve for base column of the single frame subjected to four time scale Athens earthquake record.

In the details of response signal it is also observed spikes at the times, $t = 4.60$ s and $t = 6.15$ s. These spikes correspond to the times when the hinges at the beam reach the yielding point for the third and fourth time as can be seen in figure 9. In this figure it is seems that the hinge starts from zero and have an elastic behavior until 3.91 s where reach, for first time, the yield point. It remains in the post yield region until 3.98 s and then rebounds, because of the change in direction of earthquake, and reaches again the yield point, for the second time, at 4.22 s and remains in the post yield region until 4.30 s. Then rebounds and reach, for the third time, the yielding point at time 4.60 s, and remains in post yield region until 4.66 s, then rebounds again and behaves elastically. Finally the hinge reach, for forth time, the yield point at time 6.15 s, remains to the post yield region until the 6.22 s and then rebounds and behave elastically until the end of the earthquake. All the times, where the plastic hinge reach the yielding point, ($t = 3.91$ s, $t = 4.22$ s, $t = 4.60$ s, $t = 6.15$ s), are observed as spikes in the wavelet analysis of the acceleration response signal in figure 8(b).

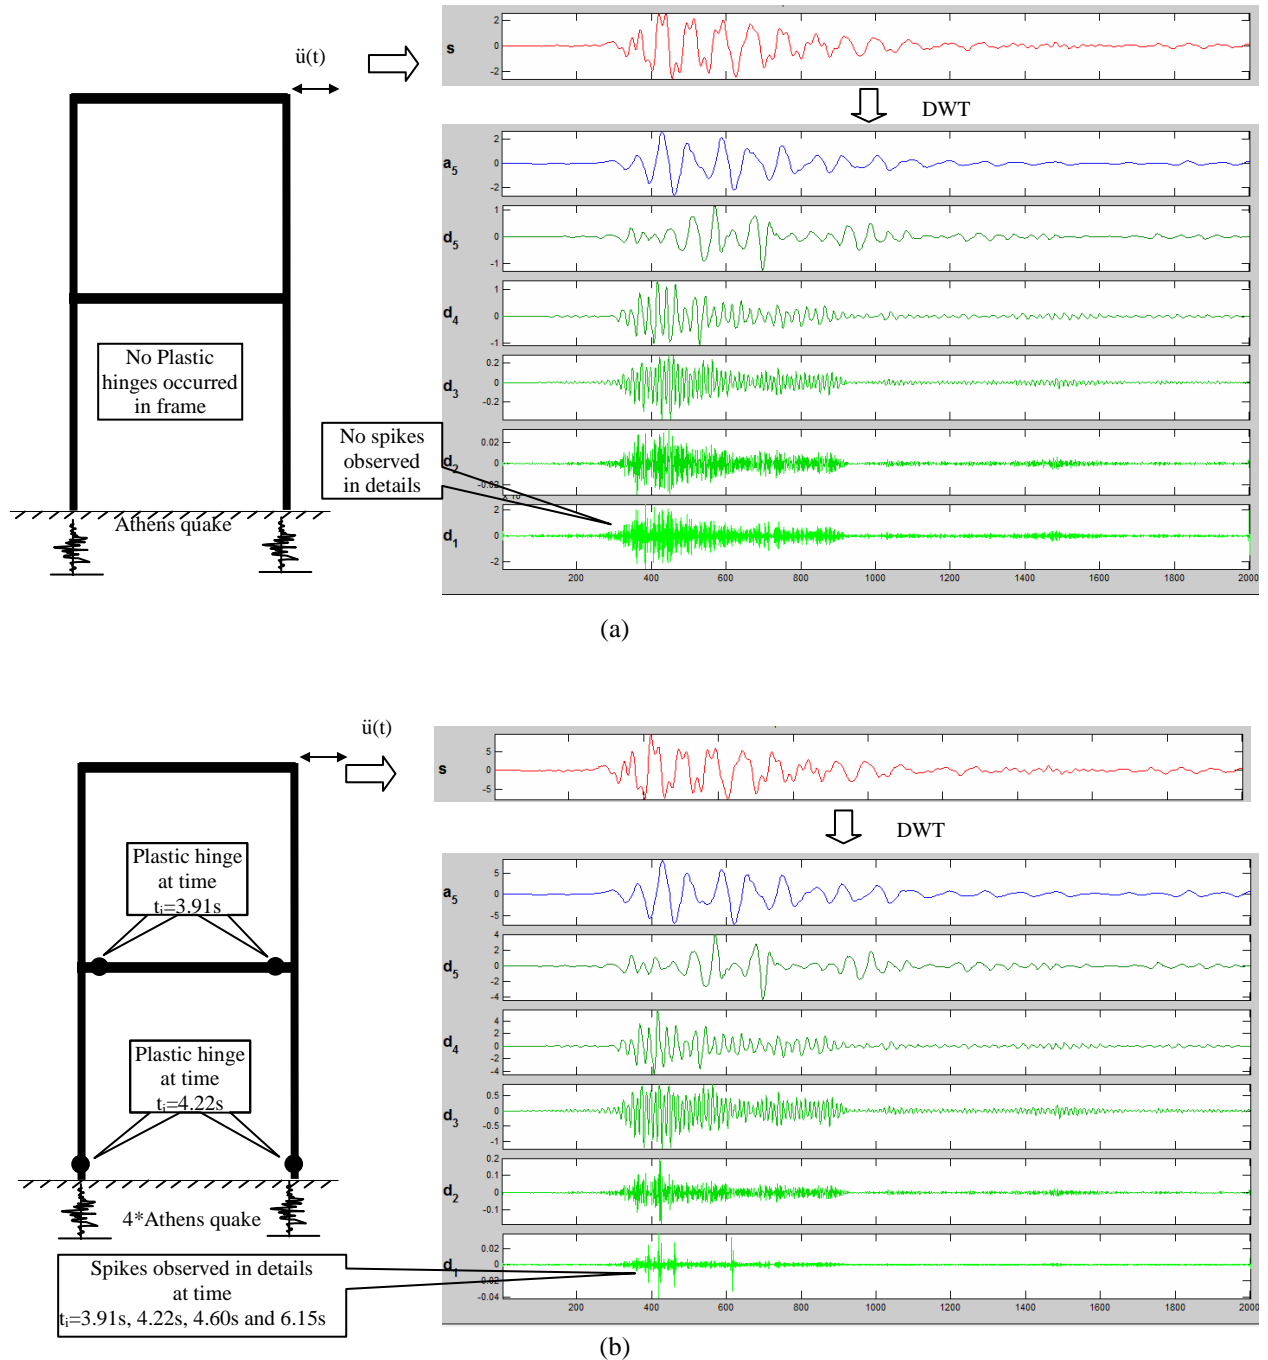

Figure 8. The approximation a_5 , and the details d_1 - d_5 of the response acceleration signal, s , at the top of the frame subjected to (a) Athens earthquake signal and (b) four times, scale up, Athens earthquake signal.

The moment curvature curve for the base column is shown in figure 10. In this figure seems that the hinge reach the yield point at time 4.22s, which is the same time when the beam yields for second time. It is observed that when any structural element starts yielding for first time or rebounds and yields again for the subsequence times this phenomenon is imprinted as spikes in the wavelet analysis of the acceleration response of the signal.

Figure 9. Moment-rotation hysteretic curve for first floor beam of the two story frame subjected to four time scale Athens earthquake record.

Figure 10. Moment-rotation hysteretic curve for base column of the two story frame subjected to four time scale Athens earthquake record.

Similar results are obtained in eight story building. In figure 11 are shown the locations of plastic hinges, (damage), the wavelet analysis of the response acceleration of the eighth floor of the frame subjected to Athens earthquake signal scaled with the factors 1 and 8 respectively. When the building subjected to the Athens earthquake signal no plastic hinges have appeared and no spikes in the details of the response signal were observed. When the earthquake was scaled up by a factor of 8, then plastic hinges, (damage), were created at the beams, between the time period 3.80s-4.11s. Plastic hinges were also created at the base columns at time 3.84s. In the details of the wavelet analysis of the response signal spikes are observed at the same period of the hinges creation.

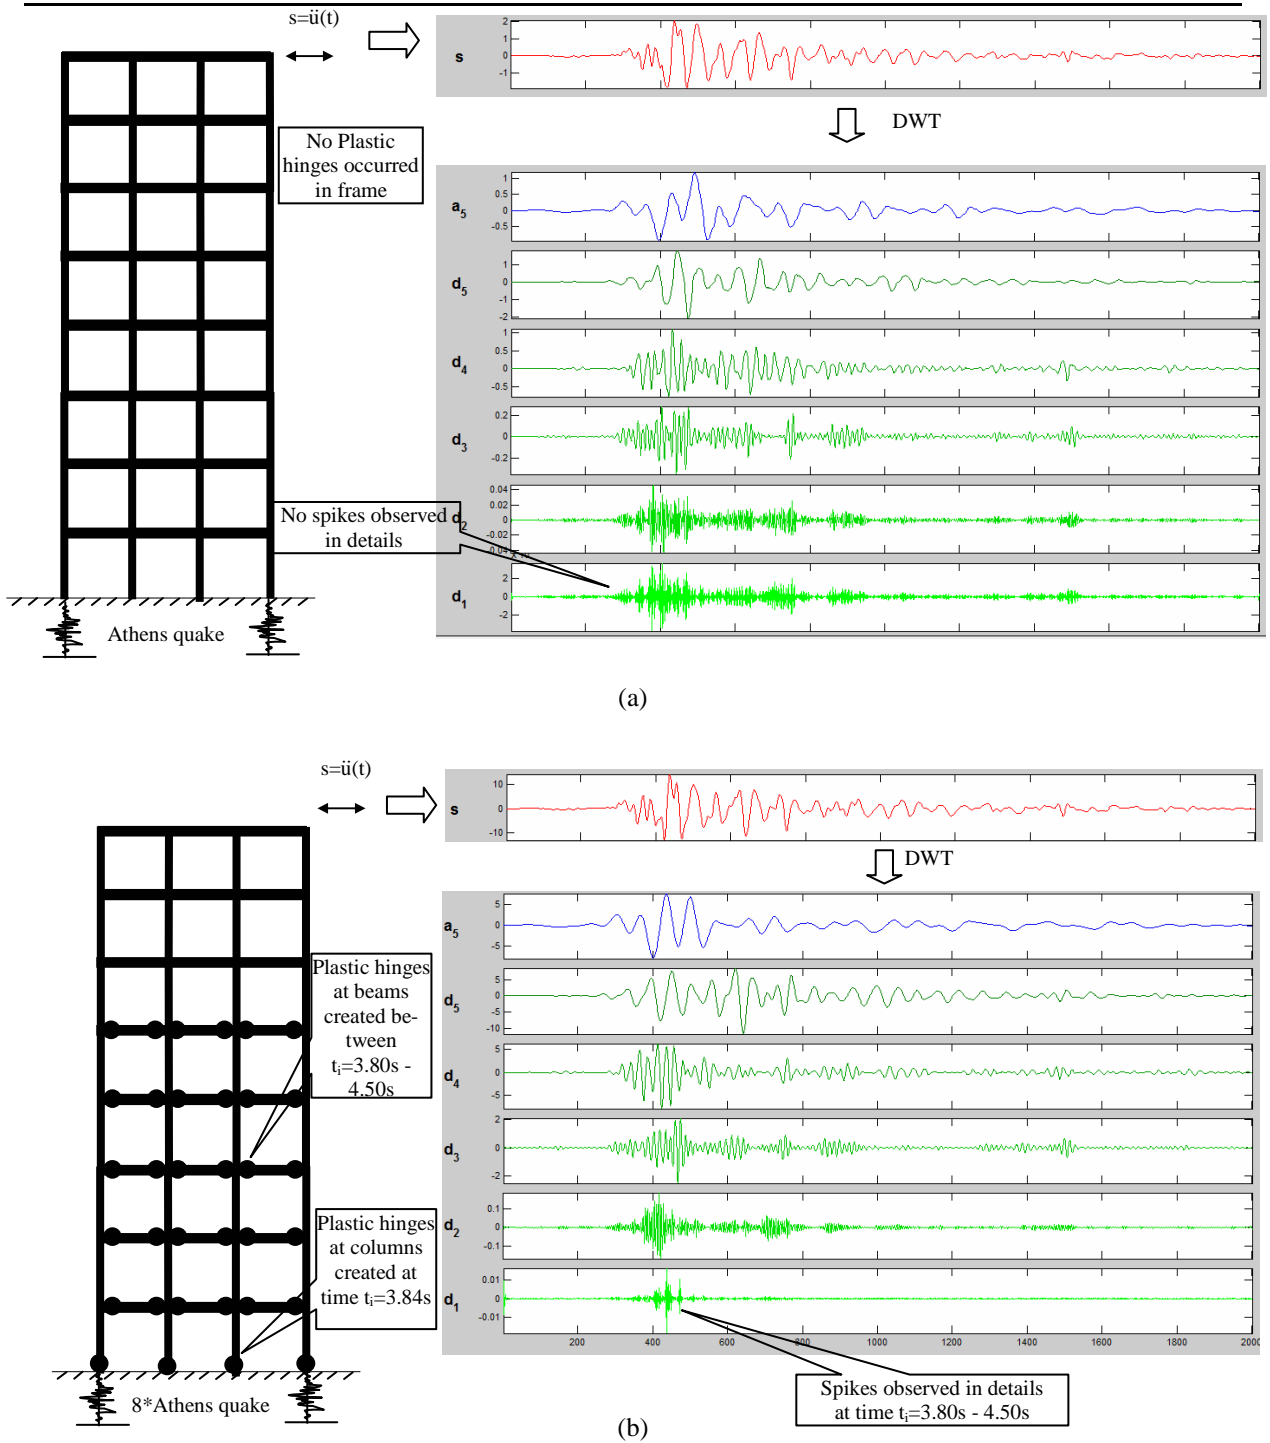

Figure 11. The approximation a_5 , and the details d_1 - d_5 of the response acceleration signal, s , at the top of the frame subjected to (a) Athens earthquake signal and (b) eight times scale up Athens earthquake signal.

5 NOISE INFLUENCE

In the previous examples, the response data were obtained by the computer program without contain noise. In practice the presence of noise in measurement signals is unavoidable. In the work of Hera and Hou (2004) is shown the effect of noise to the wavelet approach. The effectiveness of the wavelet approach for structural health monitoring depends on the measurement noise level and the damage severity. The lower the level of noise is, the easier to detect the damage. As far as the damage level concerns, the higher the damage severity is, the easier to detect the damage by wavelet analysis. In this study the measurement noise was

modelled as a Gaussian process with signal to noise ratio equal to 15%. A measurement noise was added to the acceleration response signal and then wavelet analysis was performed again. In order to detect spikes in the details of noise signal, the level of details and the order of the wavelet were increased. In this case, the level of details decomposition in the wavelet analysis was increased to twelve, (12), instead of five, (5), which was in the examples for signals without noise. The order of the wavelet which is used is also increased. For the noise signal the Daubechies wavelet of twelve order was used instead of fourth order which was used for the signals without noise.

Another factor that plays important role in the analysis of the noise signal is the sampling rate. The higher the sampling the better it is. In the numerical example the response signal without noise was obtained by non linear dynamic analysis where the sampling interval was 0.01 s. While, for the noise response signal was obtained by non linear dynamic analysis where, the sampling interval was decreased to 0.0001 s.

The wavelet analysis of the noise response acceleration signal, of the single story building is shown in figure 12. In this figure, are shown the approximation and the details of the response acceleration signal, s , contaminated with noise. In the detail level 9, a spike it is observed for time period between 4.00 to 4.10 s which is in agreement for the case of single story frame without noise.

Figure 12. The approximation a_{12} , and the details d_1 - d_{12} of the response acceleration signal, s , contaminated with noise, at the top of the single story frame subjected at four times scale up the Athens earthquake signal.

6 CONCLUSIONS

A discrete wavelet analysis for damage detection of frame structure subjected to earthquake excitation has been done. Wavelet analysis is a good tool to analyze the non-stationary dynamic behaviour of inelastic structures. It was shown that structural damage, which was introduced by non linear behaviour of structural elements, and the time that this occurred can be clearly detected by spikes in the details of discrete wavelet analysis of the response signal.

These spikes can also be observed in the case where the response signal contaminates noise. In order to detect the spikes of the noise signal the level of details and the order of the wavelet must be increased. The numerical results show the great promise of the wavelet approach for damage detection in structures subjected to earthquake excitation.

Abstract. *Integration algorithms are typically utilized to solve temporally discretized equations of motion in structural dynamics. Stability is an important property to be considered when selecting the proper integration algorithm for analysis of structures with a large number of degrees of freedom. The recent development of real-time structural testing brings more challenges to the integration algorithm. An explicit integration algorithm is more favorable in real-time structural testing because of its computational efficiency. However, the presence of numerical errors will lead to the spurious growth of high-frequency response in the dynamic analysis and the presence of inevitable experimental errors will aggravate this effect during real-time structural testing. It is therefore advantageous for an explicit integration algorithm to possess numerical damping to suppress any spurious participation of the high-frequency response while the lower modes are accurately integrated. This paper presents the development of a family of explicit direct integration algorithms with controllable numerical damping. Discrete control theory is utilized to assign proper stable poles to the discrete transfer function of the integrations algorithms to achieve unconditional stability and numerical damping. The properties of the proposed algorithm are investigated and compared with other well established algorithms such as the Newmark family of integration algorithms and the CR integration algorithm.*

1 INTRODUCTION

Integration algorithms are usually utilized to solve the equations of motion of structures subjected to external excitations. Various integration algorithms have been developed and applied in structural dynamics such as the Newmark Family of integration algorithms [1] and the Hilber-Hughes-Taylor α -method [2]. Various methods have been used to develop integration algorithms, including Taylor series expansions, weighted residual methods, Hamilton's principle, and least-squares methods [3]. Currently available integration algorithms can usually be classified as either explicit or implicit. An integration algorithm is explicit if the displacements for the next time step can be determined from the accelerations, velocities and displacements at the current and previous time step, otherwise it is implicit. The implicit integration algorithms are usually unconditionally stable such as the Newmark method with constant average acceleration and the HHT α -method, while the explicit integration algorithms are often conditionally stable, including the Newmark explicit method and the central difference method. In many structural dynamics applications, where iterations are not concerned in the analysis, the implicit integration algorithms with unconditional stability are generally preferred over conditionally stable explicit integration algorithms.

In addition to the structural dynamic analysis, integration algorithms are also applied in on-line structural experiments, where they are utilized to solve the dynamics of a prototype structure to sequentially determine the displacement response of an experimental structure in the laboratory. This application was first investigated by Takanashi *et al.* [4] and then by Mahin and Shing [5], and can be categorized as quasi-static pseudodynamic testing or quasi-static substructure testing. It is believed that by having the structural components (usually difficult to model numerically) tested in the laboratory and keeping the remainder of the structural system modeled analytically, the response of the entire structure under a selected ground motion can be replicated in an economic and efficient manner. Both explicit and implicit integration algorithms have been utilized in quasi-static pseudodynamic and substructure testing [5, 6]. Since the experiments are conducted in an extended time scale (i.e., quasi-statically), the required iterations for implicit integration algorithms are not critical and the implicit integration algorithms therefore are often used because of their unconditional stability.

Recent earthquake engineering research have advanced the quasi-static pseudodynamic and substructures testing methods to real-time pseudodynamic testing [7] and real-time hybrid simulation [8] to accommodate rate-dependent behavior in the experimental specimens. These two structural testing methods will be referred to as real-time testing hereafter. Unlike the conventional experimental methods, real-time testing requires that the command displacements from the integration algorithm be applied accurately to the experimental substructures in a real-time manner. Integration algorithms therefore are required to solve the equations of motion and compute the command displacements in a timely manner so as not to introduce any time delay in the real-time test. This poses a great challenge to the integration algorithm when the real-time test involves a complex structure with a large number of degrees of freedom. Explicit integration algorithms thus present more attractive solution for real-time testing than implicit integration algorithms since no iterations are necessary.

More recently, several unconditionally stable explicit integration algorithms were developed by researchers to enable real-time structural tests [9, 10]. Unlike other available integration algorithms, integration parameters of these algorithms are defined as functions of the linear elastic properties of the structure to be analyzed. By carefully selecting the integration parameters, these algorithms possess both explicitness and unconditional stability. When applied for nonlinear structural behavior, Chen and Ricles [11, 12] showed that these algorithms maintain the stability when the structure has softening behavior. The explicitness and uncon-

ditional stability of these integration algorithm present great potential for real-time structural testing. Chen *et al.* [13] implemented the unconditional explicit CR integration algorithm for real-time hybrid simulation of structures with an elastomeric damper. The experiment results were compared with those using the existing HHT α -method with a fixed number of substep iteration [14]. Good agreement was observed, indicating that the unconditional explicit CR algorithm is applicable for real-time testing. Chen *et al.* [15] further extended the application of the CR algorithm for the real-time hybrid simulation of a moment resisting frame (MRF) with magneto-rheological (MR) dampers in passive mode. The prototype MRF had a total of 122 degrees of freedom and 71 elements. The experimental results was later compared with pure numerical simulation by Chen *et al.* [16]. Good agreement further validated the effectiveness of the CR algorithm for real-time testing. However, it was observed that the experimental results, especially the restoring forces in the experimental substructures (i.e., the MR dampers), had high frequency noise. Small oscillation was also observed in the structural displacement response. These high frequency mode responses are attributed to the spatially discretized equations of motion and do not necessarily represent the true behavior of the prototype structure under earthquakes. In addition, the presence of numerical errors will lead to the spurious growth of high-frequency response and the inevitable experimental errors will aggravate this effect in real-time tests. Therefore, it is advantageous for an algorithm to possess numerical damping to suppress any spurious participation of the high-frequency response and minimize the effect of numerical and experimental errors, while the lower modes can be integrated accurately. However, the current unconditionally stable explicit CR integration algorithm has zero or only little numerical damping properties. It is thus desirable to introduce controllable numerical damping into the algorithm while maintaining its explicitness and unconditional stability. This paper presents the development of a family of unconditionally stable explicit integration algorithm using the discrete control theory.

2 INTEGRATION ALGORITHM AND DISCRETE TRANSFER FUNCTION FOR SDOF STRUCTURE

Consider a single-degree-of-freedom (SDOF) linear elastic structure represented by the following differential equation of motion under external excitation $F(t)$:

$$m \cdot \ddot{x}(t) + c \cdot \dot{x}(t) + k \cdot x(t) = F(t) \quad (1a)$$

where m , c and k are the mass, viscous damping and linear elastic stiffness of the SDOF structure, respectively; and $x(t)$, $\dot{x}(t)$, $\ddot{x}(t)$ are the displacement, velocity and acceleration of the SDOF structure, respectively. Integration algorithms in structural dynamics are usually applied to solve the temporally discretized equation of motion of Eq. (1a) for structural response, which can be written as:

$$m \cdot \ddot{x}_{i+1} + c \cdot \dot{x}_{i+1} + k \cdot x_{i+1} = F_{i+1} \quad (1b)$$

where x_{i+1} , \dot{x}_{i+1} , \ddot{x}_{i+1} are the displacement, velocity and acceleration of the SDOF structure at the $(i+1)^{\text{th}}$ time step, respectively; and F_{i+1} is the value of excitation $F(t)$ at the $(i+1)^{\text{th}}$ time step.

To obtain an explicit integration algorithm, the variation of the displacement and velocity over the time step can be defined as

$$\dot{x}_{i+1} = \dot{x}_i + \alpha_1 \cdot \Delta t \cdot \ddot{x}_i \quad (2a)$$

$$x_{i+1} = x_i + \Delta t \cdot \dot{x}_i + \alpha_2 \cdot \Delta t^2 \cdot \ddot{x}_i \quad (2b)$$

where α_1 and α_2 are integration parameters and will be determined later; x_i , \dot{x}_i , \ddot{x}_i are the displacement, velocity and acceleration of the SDOF structure at the i^{th} time step, respectively; and Δt is the time step for the dynamic analysis.

It can be observed that both the displacement x_{i+1} and velocity \dot{x}_{i+1} in Eqs. (2a) and 2(b) are explicit since they are only dependent on the structural response of the previous time step. This explicitness will lead to significant computational efficiency when the algorithm is used in dynamic analysis structures subjected to earthquakes. Eqs. (2a) and (2b) were also used by Chen and Ricles [10] to develop the unconditionally stable CR explicit integration algorithm. The discrete transfer function $G(z)$ for the integration algorithms can be derived by substituting Eqs. (2a) and (2b) into Eq. (1b), whereby it can be written in the following general form

$$G(z) = \frac{X(z)}{F(z)} = \frac{n_2 z^2 + n_1 z + n_0}{d_2 z^2 + d_1 z + d_0} \quad (3)$$

where $G(z)$ is a discrete transfer function relating the displacement response of the structure and the external excitation; $X(z)$ and $F(z)$ are discrete z-transforms of the displacement response x_{i+1} and excitation force F_{i+1} , respectively; z is the complex variable in the discrete z-domain; n_2 , n_1 , n_0 , d_2 , d_1 and d_0 are coefficients of the numerator and denominator of the discrete transfer function $G(z)$, respectively. The coefficients of the discrete transfer function are tabulated in Table 1 for the new algorithms. It can be observed that the coefficients in Table 1 are dependent on the structure properties (m , c , and k) and the integration time step Δt as well as the two integration parameters (α_1 and α_2).

Numerator		Denominator	
n_2	0	d_2	m
n_1	$\alpha_2 \cdot \Delta t^2$	d_1	$\alpha_2 \cdot k \cdot \Delta t^2 + \alpha_1 \cdot c \cdot \Delta t - 2m$
n_0	$(\alpha_1 - \alpha_2) \cdot \Delta t^2$	d_0	$(\alpha_1 - \alpha_2) \cdot k \cdot \Delta t^2 - \alpha_1 \cdot c \cdot \Delta t + m$

Table 1. Coefficients of $G(z)$ for the new integration algorithm

Chen and Ricles [10] indicated that the poles of the discrete transfer function $G(z)$ in Eq. (3) determine the properties of the corresponding integration algorithm including the stability and accuracy. The complex poles of $G(z)$ in Eq. (3) can be written in the following form

$$p_{1,2} = \sigma \pm \varepsilon \cdot i = \exp[\bar{\Omega} \cdot (-\zeta_{eq} \pm i\sqrt{1 - \zeta_{eq}^2})] \quad (4)$$

where σ and ε are the real components, and i is the imaginary unit defined as $i = \sqrt{-1}$; the apparent frequency $\bar{\Omega}$ and the equivalent damping ratio ζ_{eq} are defined as

$$\bar{\Omega} = \tan^{-1}(\varepsilon / \sigma) / (\sqrt{1 - \zeta_{eq}^2}) \quad (5a)$$

$$\zeta_{eq} = -\ln(\sigma^2 + \varepsilon^2) / 2\bar{\Omega} \quad (5b)$$

The integration algorithm will be unconditionally stable if the poles in Eq. (4) are always located inside or on the unit circle of the discrete z-domain as shown in Figure 1. Otherwise, the algorithm is conditionally stable. Compared with the conventional stability criterion [17], the magnitude of the complex poles in Eq. (4) represent the spectral radius, while Eqs. (5a) and (5b) determine the period elongation and numerical damping of the integration algorithm.

To achieve unconditional stability, Chen and Ricles [10] used the Tustin transform [18] to discretize the continuous poles and assigned the resulting discrete poles to the discrete transfer function in Eq. (3), which leads to the integration parameters α_1 and α_2 for the unconditionally stable explicit CR algorithm.

Figure 1: Schematic of Stable and Unstable Poles in Complex z -domain.

3 INTEGRATION PARAMETER DERIVATION FOR INTEGRATION ALGORITHMS WITH NUMERICAL DAMPING

Chen and Ricles [11, 12] demonstrated that an integration algorithm can schematically be represented by a open-loop block diagram in Figure 2(a), or by a closed-loop block diagram in Figure 2(b). The inputs and the outputs in Figures 1(a) and 1(b) are the external excitation $F(t)$ and the structural response $x(t)$, respectively. The block $G(z)$ in Figure 1(a) represents the discrete transfer function in Eq. (3) for the integration algorithm, while the block k in Figure 1(b) is the linear elastic stiffness of the SDOF structure and $G'(z)$ is referred to as the open-loop transfer function for the integration algorithm.

Figure 2: Block diagram representation of: (a) open loop system; and (b) closed loop system.

The relationship between the discrete transfer functions $G(z)$ and $G'(z)$ can be expressed as

$$G(z) = \frac{G'(z)}{1 + k \cdot G'(z)} \quad (6)$$

To determine the parameters for the integration algorithms defined by Eqs. (2a) and (2b), the open-loop transfer function $G'(z)$ for the Newmark method with constant average accelera-

tion is utilized in this paper, where its coefficients are tabulated in Table 2 and the discrete transfer function of $G'(z)$ can be written as

$$G'(z) = \frac{(z^2 + 2z + 1) \cdot \Delta t^2}{(4m + 2c \cdot \Delta t) \cdot z^2 - 8m \cdot z + (4m - 2c \cdot \Delta t)} \quad (7a)$$

Numerator		Denominator	
n_2	Δt^2	d_2	$4m + 2c \cdot \Delta t$
n_1	$2\Delta t^2$	d_2	$-8m$
n_0	Δt^2	d_0	$4m - 2c \cdot \Delta t$

Table 2. Coefficients of $G'(z)$ for the Newmark method with constant average acceleration.

It can be observed that the discrete transfer function $G'(z)$ has duplicate zeros at $z = -1$. To develop an integration algorithm with numerical damping, the transfer function $G'(z)$ in Eq. (7a) is assigned to have two duplicate zeros at $z = -\lambda$, which can then be written as

$$G'(z) = \frac{(z + \lambda)^2 \cdot \Delta t^2}{(4m + 2c \cdot \Delta t) \cdot z^2 - 8m \cdot z + (4m - 2c \cdot \Delta t)} \quad (7b)$$

where λ is a positive real number and has a value between zero and one. If Eq. (7b) is used for the open-loop transfer function, the corresponding closed-loop transfer function can be derived using Eq. (6) as

$$G(z) = \frac{X(z)}{F(z)} = \frac{(z + \lambda)^2 \cdot \Delta t^2}{(4m + 2c \cdot \Delta t + k \cdot \Delta t^2) \cdot z^2 + (-8m + 2\lambda \cdot k \cdot \Delta t^2) \cdot z + (4m - 2c \cdot \Delta t + k \cdot \Delta t^2)} \quad (8a)$$

The poles of the discrete transfer function in Eq. (8a) can be derived by setting the denominator equal to zero and solving for the values of z :

$$(4m + 2c \cdot \Delta t + k \cdot \Delta t^2) \cdot z^2 + (-8m + 2\lambda \cdot k \cdot \Delta t^2) \cdot z + (4m - 2c \cdot \Delta t + k \cdot \Delta t^2) = 0 \quad (8b)$$

Assigning the poles of the closed-loop transfer function of Eq. (8b) to the transfer function $G(z)$ for the integration algorithms defined by Eqs. (2a) and (2b), and solving for α_1 and α_2 leads to

$$\alpha_1 = \frac{2m \cdot (\lambda^2 + 2\lambda + 1)}{(2\lambda^2 + 4\lambda + 2) \cdot m + (3 + 2\lambda - \lambda^2) \cdot c \cdot \Delta t + 2k \cdot \Delta t^2} \quad (9a)$$

$$\alpha_2 = \frac{4m \cdot (\lambda + 1)}{(2\lambda^2 + 4\lambda + 2) \cdot m + (3 + 2\lambda - \lambda^2) \cdot c \cdot \Delta t + 2k \cdot \Delta t^2} \quad (9b)$$

For different values of the parameter λ , Eqs. (9a) and (9b) lead to different sets of integration parameters α_1 and α_2 , and a family of explicit integration algorithms, which will be referred to the new algorithm. It can also be derived that for the case of λ equal to 1.0, Eqs. (9a) and (9b) reduce to

$$\alpha_1 = \alpha_2 = \frac{4m}{4m + 2c \cdot \Delta t + k \cdot \Delta t^2} \quad (10)$$

Eq. (10) gives the integration parameters for the unconditionally stable explicit CR integration algorithm [10]. This indicates that the CR algorithm can be considered as a special case of the new integration algorithms.

4 STABILITY AND ACCURACY ANALYSIS

With the integration parameters defined in Eqs. (9a) and 9(b), the discrete transfer function for the new family of integration algorithms can be derived and written in the general form of Eq. (3). The coefficients are tabulated in Table 3. The stability and accuracy of the family of algorithms are then investigated using Eqs. (4) through (5b).

Numerator		Denominator	
n_2	0	d_2	$2 \cdot k \cdot \Delta t^2 - (\lambda + 1) \cdot (\lambda - 3) \cdot c \cdot \Delta t + 2(\lambda + 1)^2 \cdot m$
n_1	$4(\lambda + 1) \cdot \Delta t^2$	d_1	$4\lambda \cdot k \cdot \Delta t^2 + 4(\lambda^2 - 1) \cdot c \cdot \Delta t - 4(\lambda + 1)^2 \cdot m$
n_0	$2(\lambda^2 - 1) \cdot \Delta t^2$	d_0	$2\lambda^2 \cdot k \cdot \Delta t^2 - (\lambda + 1) \cdot (3\lambda - 1) \cdot c \cdot \Delta t + 2(\lambda + 1)^2 \cdot m$

Table 3. Coefficients of $G(z)$ for the new algorithms.

4.1 Stability analysis for linear elastic SDOF structures

Figure 3 shows the spectral radius of the new family of integration algorithms for a linear elastic SDOF structure, where ω_n is the natural frequency of the SDOF structure. Zero viscous damping (i.e., $c=0$) is assumed to represent the most critical case for stability. Different values are used for the parameter λ , including $\lambda=1.0$, 0.75 and 0.5. Also presented in Figure 3 is the Newmark method with constant average acceleration. It can be observed that for selected values of λ in Figure 3, the new algorithm is stable for $\omega_n \Delta t$ up to 6.0. It can be further shown that the new algorithm is unconditional stable with λ between zero and one for any value of $\omega_n \Delta t$. Figure 3 also shows that for λ equal to 1.0, the new algorithm has the same spectral radius as the CR algorithm. This further proves that the CR algorithm is a special case of the new family of integration algorithms.

Figure 3: Spectral radius for the new family of integration algorithms.

4.2 Accuracy analysis for linear elastic SDOF structures

The accuracy of the family of new integration algorithms is analyzed using numerical damping (ND) and period elongation (PE). The SDOF structure is assumed to have zero inherent viscous damping. The equivalent damping computed from Eq. (5b) therefore represents the numerical damping introduced by the new algorithms. Cases with the values of λ equal to 1.0, 0.75 and 0.5 are considered. Figure 4 shows the numerical damping of the new algorithms, where it is compared with the Newmark method with constant average acceleration integration algorithm. The new algorithm with $\lambda=1.0$ and the Newmark method with constant average acceleration have almost zero numerical damping. When λ takes values of 0.75 and 0.5, the new algorithm is shown to introduce significant numerical damping, approaching 25% and 10% for values of $\omega_n \Delta t$ greater than 3.0, respectively. This numerical damping will help to minimize the effects of unrealistic higher mode response and the experimental errors during the structural experiments. However, Figure 4 also shows that the new algorithm introduces numerical damping for small values of $\omega_n \Delta t$ smaller than 3.0.

Figure 4. Numerical damping of the new algorithm.

Figure 5. Period elongation of the new algorithm.

The period elongation presented in Figure 5 is observed to be almost same for the new algorithms for the various values of λ . The new algorithm with $\lambda=1.0$ is observed to be identical as that of the Newmark method with constant average acceleration. The new algorithm is shown to introduce period elongation for all three values of λ equal to 1.0, 0.75 and 0.5, but nearly identical as that of the Newmark method with constant acceleration for all cases.

4.3 Stability analysis for nonlinear SDOF structure

The above analysis indicates that the new family of explicit integration algorithms have comparable stability and accuracy properties as the Newmark method with constant average acceleration. Application of an integration algorithm for structural dynamic analysis often involves nonlinear structural behavior. Chen and Ricles [11, 12] proposed to use the discrete transfer function to analyze the stability limits of direct integration algorithms for nonlinear structural behavior. For a SDOF nonlinear structure, the equation of motion in Eq. (2) can be revised as

$$m \cdot \ddot{x}_{i+1} + c \cdot \dot{x}_{i+1} + r_{i+1} = F_{i+1} \quad (11a)$$

In Eq. (11a), r_{i+1} is the restoring force of the nonlinear SDOF structure at the $(i+1)^{\text{th}}$ time step. Eq. (11a) can be written in an incremental form as

$$m \cdot \Delta \ddot{x}_i + c \cdot \Delta \dot{x}_i + \Delta r_i = \Delta F_i \quad (11b)$$

The increments of acceleration $\Delta \ddot{x}_i$, velocity $\Delta \dot{x}_i$ and restoring force Δr_i are defined as $\Delta \ddot{x}_i = \ddot{x}_{i+1} - \ddot{x}_i$, $\Delta \dot{x}_i = \dot{x}_{i+1} - \dot{x}_i$ and $\Delta r_i = r_{i+1} - r_i$. For small values of Δt , the increment of restoring force can be approximated as $\Delta r_i = r_{i+1} - r_i = k_t \cdot \Delta x_i$ [17], where k_t is the tangent stiffness of the nonlinear SDOF structure. Using the open loop block diagram in Figure 2(b), the new integration algorithms can be represented by an open-loop transfer function $G'(z)$ with the restoring force expressed by a varying feedback gain representing the varying stiffness [11]. The open-loop discrete transfer function can again be written in the general form in Eq. (3) and its coefficients are tabulated in Table 4.

Numerator		Denominator	
n_2	0	d_2	$2 \cdot k \cdot \Delta t^2 - (\lambda + 1) \cdot (\lambda - 3) \cdot c \cdot \Delta t + 2(\lambda + 1)^2 \cdot m$
n_1	$4(\lambda + 1) \cdot \Delta t^2$	d_1	$-4k \cdot \Delta t^2 + 4(\lambda^2 - 1) \cdot c \cdot \Delta t - 4(\lambda + 1)^2 \cdot m$
n_0	$2(\lambda^2 - 1) \cdot \Delta t^2$	d_0	$2k \cdot \Delta t^2 - (\lambda + 1) \cdot (3\lambda - 1) \cdot c \cdot \Delta t + 2(\lambda + 1)^2 \cdot m$

Table 4: Coefficients of $G'(z)$ for the new algorithms.

The root locus approach is then used to determine the stability limit of the new family of explicit integration algorithms. Figure 6 shows a typical root locus for the open-loop transfer function with λ equal to 1.0. It can be observed that one branch of the root loci falls outside the unit circle. Therefore the new algorithm with is only stable for a finite range of stiffness values. The root locus plot crosses the unit circle at $z = -1$, and the stability limit for the improved CR algorithm can therefore be solved by substituting $z = -1$ into the denominator of the closed-loop transfer function derived from $G'(z)$, whereby

$$\begin{aligned} & [2 \cdot k \cdot \Delta t^2 - (\lambda + 1) \cdot (\lambda - 3) \cdot c \cdot \Delta t + 2(\lambda + 1)^2 \cdot m] \cdot z^2 - [4(k - k_t(1 + \lambda) \cdot \Delta t^2 \\ & - 4(\lambda^2 - 1) \cdot c \cdot \Delta t + 4(\lambda + 1)^2 \cdot m) \cdot z + [2(k - k_t + \lambda^2 k_t) \cdot \Delta t^2 - (\lambda + 1) \cdot (3\lambda - 1) \cdot c \cdot \Delta t \\ & + 2(\lambda + 1)^2 \cdot m]]_{z=-1} = 0 \end{aligned} \quad (12)$$

Solving Eq. (12) for k_t leads to

$$k_t \leq \frac{4[-k \cdot \Delta t^2 + (\lambda^2 - 1) \cdot c \cdot \Delta t - m \cdot (\lambda + 1)^2]}{(\lambda - 3) \cdot (\lambda + 1) \Delta t^2} \quad (13a)$$

Eq. (13a) gives the stability limit for the new algorithms when applied to nonlinear SDOF structures. The stability limit in Eq. (13a) is observed to be dependent on the parameter λ as well as the structure properties (m , c , and k) and the integration time step Δt .

Figure 6: Typical root locus of the open loop transfer function $G'(z)$ for the new integration algorithm ($\lambda=1.0$).

Eq. (13a) can be revised and expressed as

$$\left(\frac{k_t}{m}\right) \cdot \Delta t^2 \leq \frac{4[-\omega_n^2 \Delta t^2 + (\lambda^2 - 1) \cdot 2\zeta \cdot \omega_n \Delta t - (\lambda + 1)^2]}{(\lambda - 3) \cdot (\lambda + 1)} \quad (13b)$$

where ζ is the inherent viscous damping ratio of the SDOF structure. Figure 7 shows the variation of the stability limit in Eq. (13b) with respect to the value of λ for the case of $\zeta=0.0$. It can be observed that larger values of λ would lead to a larger stability limit.

Figure 7: Stability limits for the new algorithms applied to nonlinear SDOF structure.

For the case of λ equal to one, the stability limit in Eq. (13) reduces to

$$k_t \leq \frac{k \cdot \Delta t^2 + 4m}{\Delta t^2} \quad (14a)$$

Eq. (14a) is same as the stability limit for the CR algorithm applied to a nonlinear structure [11]. When the algorithm is applied to a linear elastic structure, i.e., $k_t = k$, the stability limit in Eq. (13) reduces to

$$k\Delta t^2 \leq \frac{4[(\lambda^2 - 1) \cdot c \cdot \Delta t - m \cdot (\lambda + 1)^2]}{(\lambda - 3) \cdot (\lambda + 1) + 4} \quad (14b)$$

For the case of λ equal to one, the stability limit in Eq. (14b) can be further simplified as $k\Delta t^2 \leq \infty$, which implies that the algorithm is stable for all values of ω_n and Δt .

5 SUMMARY AND CONCLUSIONS

This paper presents the development of a new family of unconditionally stable explicit integration algorithms with controllable numerical damping using the discrete control theory. A parameter λ is utilized to introduce and control the numerical damping for the new algorithms. Using different values of λ between zero and one results in different properties of the new algorithms. The stability of the algorithm is investigated for both linear and nonlinear structures. The new algorithms are demonstrated to be unconditionally stable for a linear elastic structure and conditionally stable for a nonlinear structure. The accuracy of the new algorithms is investigated for linear elastic structures in terms of numerical damping and period elongation. For the range of the parameter λ investigated in the present study, the new algorithm is shown to introduce small period elongation and significant numerical damping for high frequencies. This makes this new algorithms especially appealing for real-time structural testing.

Abstract. *For noise and vibration attenuation, various approaches can be employed depending on the frequency range to attenuate. Generally, active or passive piezoelectric techniques are effective in the low frequency range, while dissipative materials, such as viscoelastic or porous treatments, are efficient for higher frequency domain. In this work, a reduced order model is developed for the resolution of a fully coupled electro-mechanical-acoustic system using modal projection techniques. The problem consists of an elastic structure with surface-mounted piezoelectric patches coupled with an inviscid and compressible fluid. The piezoelectric elements, connected with a resistive or resonant shunt circuit, are used for the vibration damping of the coupled system. Numerical examples are presented in order to illustrate the accuracy and the versatility of the proposed reduced order models, notably in terms of prediction of attenuation..*

1 INTRODUCTION

For noise and vibration reduction, various approaches can be employed depending on the frequency range to attenuate. Generally, active or passive piezoelectric techniques are effective in the low frequency range, while dissipative materials (such as viscoelastic treatments or porous insulations) are efficient for higher frequency domain. In this work, we propose a reduced order model to describe a fully coupled electro-mechanical-acoustic problem in the low frequency range. The system consists of an elastic structure with surface-mounted piezoelectric patches coupled with an inviscid, compressible and barotropic fluid, gravity effects being neglected. The piezoelectric elements, connected with a resonant shunt circuit, are used for the vibration damping of the coupled system.

First, a non-symmetric finite element formulation of the coupled system is derived from a variational principle involving structural displacement, electrical voltage of piezoelectric elements, and acoustic pressure inside the fluid cavity. This formulation, with only one couple of electric variables per patch, is well adapted to practical applications since realistic electrical boundary conditions, such that equipotentiality on the electrodes and prescribed global electric charges, naturally appear. The global charge/voltage variables are intrinsically adapted to include any external electrical circuit into the electromechanical problem and to simulate the effect of resistive or resonant shunt damping techniques.

The second part of this work is devoted to the introduction of a reduced-order model of the coupled problem. The proposed methodology, based on a normal mode expansion, requires the computation of the eigenmodes of the structure with short-circuited piezoelectric patches, and the rigid acoustic cavity. It is shown that the projection of the full-order coupled finite element model on the uncoupled bases, leads to a reduced order model in which the main parameters are the classical fluid-structure and electromechanical modal coupling factors. Despite its reduced size, this model is proved to be very efficient for simulations of steady-state and transient analyses of the coupled structural-acoustic system with shunt damping.

In the last part of the paper, a three-dimensional numerical example is investigated. The problem consists of an elastic plate equipped with piezoelectric elements and coupled with an acoustic cavity. This example is analyzed in order to show that the reduced order model is capable of capturing the main characteristics of the system dynamic behavior, notably in terms of attenuation.

2 FINITE ELEMENT FORMULATION OF THE STRUCTURAL ACOUSTIC PROBLEM WITH PIEZOELECTRIC PATCHES

We briefly recall in this section the variational formulation of a fluid/piezoelectric-structure interaction problem in terms of structural mechanical displacement \mathbf{u} , electric potential in the structure ψ and fluid pressure p of the inviscid acoustic fluid (for more details, we refer the reader to [1, 2]). Secondly, this coupled formulation is adapted to the general case of an elastic structure equipped with P piezoelectric patches (see Fig. 1) as done for structural vibrations in [3]. This modified formulation allows taking into account realistic electrical boundary conditions such as equipotentiality on patches electrodes and prescribed global charges. Finally, the resulting finite element formulation is applied to a structural acoustic problem with one piezoelectric patch connected to a RL series shunt circuit.

Figure 1: Fluid/piezoelectric-structure coupled system.

It should be noted that standard indicial notations are adopted throughout the paper: subscripts i, j, k and l denote the three-dimensional vectors and tensor components and repeated subscripts imply summation. In addition, a comma indicates a partial derivative.

2.1 Variational formulation of the fluid/structure/piezo-patches coupled system

We consider a piezoelectric structure occupying the domain Ω_S filled with an inviscid linear acoustic fluid occupying the domain Ω_F . We denote by Σ the fluid-structure interface and by n_i^S and n_i^F the unit normal external to Ω_S and Ω_F , respectively.

The structure is clamped on a part Γ_u and subjected (i) to a given surface force density F_i^d on the complementary part Γ_σ of its external boundary and (ii) to a pressure field p due to the presence of the fluid on its internal boundary Σ . The electric boundary conditions are defined by a prescribed electric potential ψ^d on Γ_ψ and a surface density of electric charge q^d on the remaining part Γ_D . Thus, the total structure boundary, denoted $\partial\Omega_S$, is such that $\partial\Omega_S = \Gamma_u \cup \Gamma_\sigma \cup \Sigma = \Gamma_D \cup \Gamma_\psi$ with $\Gamma_u \cap \Gamma_\sigma \cap \Sigma = \Gamma_\psi \cap \Gamma_D = \emptyset$.

The linearized deformation tensor is $\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i})$ and the stress tensor is denoted by σ_{ij} . Concerning the electric field variables, D_i is the electric displacement verifying the electric charge equation for a dielectric medium $D_{i,i} = 0$ in Ω_S and the electric boundary conditions $D_i n_i^S = -q^d$ on Γ_D ; E_i denotes the electric field vector such that $E_i = -\psi_{,i}$.

The linear piezoelectric constitutive equations write:

$$\sigma_{ij}(u, \psi) = c_{ijkl} \varepsilon_{kl}(u) - e_{kij} E_k(\psi) \quad (1)$$

$$D_i(u, \psi) = e_{ikl} \varepsilon_{kl}(u) + \epsilon_{ik} E_k(\psi) \quad (2)$$

where c_{ijkl} denotes the elastic moduli at constant electric field, e_{kij} the piezoelectric constants and ϵ_{ik} the dielectric permittivity at constant strain. Moreover, we denote by ρ_S the mass density of the structure.

Let us introduce the admissible spaces C_u and C_ψ of regular functions u_i and ψ defined in Ω_S . We then consider the subspaces $C_u^* = \{u_i \in C_u \mid u_i = 0 \text{ on } \Gamma_u\}$, $C_\psi^d = \{\psi \in C_\psi \mid \psi = \psi^d \text{ on } \Gamma_\psi\}$ and $C_\psi^* = \{\psi \in C_\psi \mid \psi = 0 \text{ on } \Gamma_\psi\}$.

The variational formulation, corresponding to the response of the piezoelectric structure subjected to the prescribed boundary conditions and to the pressure field p on the interface Σ writes:

Find $u_i \in C_u^*$ and $\psi \in C_\psi^d$ such that:

$\forall \delta u_i \in C_u^*$:

$$\int_{\Omega_S} c_{ijkl} \varepsilon_{kl} \delta \varepsilon_{ij} dv - \int_{\Omega_S} e_{kij} E_k \delta \varepsilon_{ij} dv + \rho_S \int_{\Omega_S} \frac{\partial^2 u_i}{\partial t^2} \delta u_i dv = \int_{\Gamma_\sigma} F_i^d \delta u_i ds + \int_{\Sigma} p n_i^F \delta u_i ds \quad (3)$$

where $\delta \varepsilon_{ij} = \frac{1}{2}(\delta u_{i,j} + \delta u_{j,i})$, ε_{kl} and E_k being functions of u_i and ψ , and

$\forall \delta \psi \in C_\psi^*$:

$$\int_{\Omega_S} e_{ikl} \varepsilon_{kl} \delta E_i dv + \int_{\Omega_S} \epsilon_{ik} E_k \delta E_i dv = \int_{\Gamma_D} q^d \delta \psi ds \quad (4)$$

where $\delta E_i = -\delta \psi_{,i}$, ε_{kl} and E_k being functions of u_i and ψ .

This formulation must be completed by appropriate initial conditions.

We consider now the special case of an elastic structure (domain Ω_E) equipped with P piezo-electric patches and completely filled with an internal fluid (domain Ω_F). Each piezo-electric patch has the shape of a plate with its upper and lower surfaces covered with a very thin layer of conducting material to obtain electrodes. The p -th patch, $p \in \{1, \dots, P\}$, occupies a domain $\Omega^{(p)}$ such that $(\Omega_E, \Omega^{(1)}, \dots, \Omega^{(P)})$ is a partition of the all structure domain Ω_S . A set of hypotheses, which can be applied to a wide spectrum of practical applications, are now formulated:

- The piezoelectric patches are thin, with a constant thickness $h^{(p)}$ for the p -th patch;
- The thickness of the electrodes is much smaller than $h^{(p)}$ and is thus neglected;
- The piezoelectric patches are polarized in their transverse direction (i.e. the direction normal to the electrodes).
- The electric field vector, of components E_k , is normal to the electrodes and uniform in the piezoelectric patch, so that for all $p \in \{1, \dots, P\}$:

$$E_k = -\frac{V^{(p)}}{h^{(p)}} n_k \quad \text{in } \Omega^{(p)} \quad (5)$$

where $V^{(p)} = \psi_+^{(p)} - \psi_-^{(p)}$ is the potential difference between the upper and the lower electrode surfaces of the p -th patch which is constant over $\Omega^{(p)}$ and n_k is the k -th component of the normal unit vector to the surface of the electrodes.

Under those assumptions and by considering successively each of the $P+2$ subdomains $(\Omega_F, \Omega_E, \Omega^{(1)}, \dots, \Omega^{(P)})$, the variational formulation of the fluid/structure/piezoelectric-patches coupled system can be written in terms of the structural mechanical displacement u_i , the electric potential difference $V^{(p)}$ constant in each piezoelectric patch, and the fluid pressure p :

- *Mechanical equation* : $\forall \delta u_i \in C_u^*$,

$$\int_{\Omega_s} c_{ijkl} \varepsilon_{kl} \delta \varepsilon_{ij} dv + \sum_{p=1}^P \frac{V^{(p)}}{h^{(p)}} \int_{\Omega^{(p)}} e_{kij} n_k \delta \varepsilon_{ij} d\Omega - \int_{\Sigma} p n_i^F \delta u_i ds + \rho_s \int_{\Omega_s} \frac{\partial^2 u_i}{\partial t^2} \delta u_i dv = \int_{\Gamma_\sigma} F_i^d \delta u_i ds \quad (6)$$

- *Electrical equation* : $\forall \delta V^{(p)} \in R$,

$$\sum_{p=1}^P \delta V^{(p)} C^{(p)} V^{(p)} - \sum_{p=1}^P \frac{\delta V^{(p)}}{h^{(p)}} \int_{\Omega^{(p)}} e_{ikl} \varepsilon_{kl} n_i d\Omega = \sum_{p=1}^P \delta V^{(p)} Q^{(p)} \quad (7)$$

where $C^{(p)} = \epsilon_{33} S^{(p)} / h^{(p)}$ defines the capacitance of the p -th piezoelectric patch ($S^{(p)}$ being the area of the patch and $\epsilon_{33} = \epsilon_{ik} n_i n_k$ the piezoelectric material permittivity in the direction normal to the electrodes) and $Q^{(p)}$ is the global charge in one of the electrodes (see [3]).

- *Acoustic equation* : $\forall \delta p \in C_p$,

$$\frac{1}{\rho_F} \int_{\Omega_F} p_{,i} \delta p_{,i} dv + \frac{1}{\rho_F c_F^2} \int_{\Omega_F} \frac{\partial^2 p}{\partial t^2} \delta p dv + \int_{\Sigma} \frac{\partial^2 u_i}{\partial t^2} n_i^F \delta p ds = 0 \quad (8)$$

The first two equations are directly derived from Eqs. (3) and (4) using the procedure described in [3]. The last equation corresponds to the variational formulation of the Helmholtz equation in the acoustic cavity $p_{,ii} = \ddot{p} / c_F^2$ in Ω_F together with the boundary condition $p_{,i} n_i^F = -\rho_F \ddot{u}_i n_i^F$ on Σ . This relation expresses the continuity of the normal displacements of the fluid and the structure on Σ . c_F is the constant speed of sound in the fluid and ρ_F the mass density of the fluid. C_p is the admissible space of regular functions p defined in Ω_F .

Thus, the variational formulation of the fluid/structure/piezo-patches coupled problem writes as follows: given (F^d, ψ^d, q^d) , find $(u_i \in C_u^*, \psi \in C_\psi^d, p \in C_p)$ such that Eqs. (6) to (8) are satisfied. The formulation must be completed by appropriate initial conditions.

This formulation, with only a couple of electric variables per patches, is well adapted to practical applications since (i) realistic electrical boundary conditions such that equipotentiality on the electrodes and prescribed global charges naturally appear, (ii) the global charge/voltage variables are intrinsically adapted to include any external electrical circuit into the electromechanical problem and to simulate shunted piezoelectric patches.

2.2 Finite element formulation of the fluid/structure/piezo-patches coupled system

Let us introduce \mathbf{U} (of length N_s) and \mathbf{P} (of length N_f) corresponding to the vectors of nodal values of u_i and p respectively, and $\mathbf{Q} = (Q^{(1)} Q^{(2)} \dots Q^{(P)})^T$ and $\mathbf{V} = (V^{(1)} V^{(2)} \dots V^{(P)})^T$ the column vectors of electric charges and potential differences. The submatrices corresponding to the various linear and bilinear forms involved in Eqs. (6) to (8) are defined by

$$\begin{aligned}
 \int_{\Omega_S} c_{ijkl} \varepsilon_{kl} \delta \varepsilon_{ij} dv &\Rightarrow \delta \mathbf{U}^T \mathbf{K}_u \mathbf{U} & \sum_{p=1}^P \frac{V^{(p)}}{h^{(p)}} \int_{\Omega^{(p)}} e_{kij} n_k \delta \varepsilon_{ij} d\Omega &\Rightarrow \delta \mathbf{U}^T \mathbf{C}_{uV} \mathbf{V} \\
 \int_{\Omega_S} \rho_S u_i \delta u_i dv &\Rightarrow \delta \mathbf{U}^T \mathbf{M}_u \mathbf{U} & \sum_{p=1}^P \frac{\delta V^{(p)}}{h^{(p)}} \int_{\Omega^{(p)}} e_{ikl} \varepsilon_{kl} n_i d\Omega &\Rightarrow \delta \mathbf{V}^T \mathbf{C}_{uV}^T \mathbf{U} \\
 \frac{1}{\rho_F} \int_{\Omega_F} p_{,i} \delta p_{,i} dv &\Rightarrow \delta \mathbf{P}^T \mathbf{K}_p \mathbf{P} & \int_{\Sigma} p n_i^F \delta u_i ds &\Rightarrow \delta \mathbf{U}^T \mathbf{C}_{up} \mathbf{P} \\
 \frac{1}{\rho_F c_F^2} \int_{\Omega_F} p \delta p dv &\Rightarrow \delta \mathbf{P}^T \mathbf{M}_p \mathbf{P} & \int_{\Sigma} u_i n_i^F \delta p ds &\Rightarrow \delta \mathbf{P}^T \mathbf{C}_{up}^T \mathbf{U} \\
 \sum_{p=1}^P \delta V^{(p)} C^{(p)} V^{(p)} &\Rightarrow \delta \mathbf{V}^T \mathbf{K}_V \mathbf{V} & \sum_{p=1}^P \delta V^{(p)} Q^{(p)} &\Rightarrow \delta \mathbf{V}^T \mathbf{Q} \\
 & & \int_{\Gamma_\sigma} F_i^d \delta u_i ds &\Rightarrow \delta \mathbf{U}^T \mathbf{F}
 \end{aligned} \tag{9}$$

where \mathbf{M}_u and \mathbf{K}_u are the mass and stiffness matrices of the structure; \mathbf{C}_{uV} is the electric mechanical coupled stiffness matrix; $\mathbf{K}_V = \text{diag}(C^{(1)} C^{(2)} \dots C^{(P)})$ is a diagonal matrix filled with the P capacitances of the piezoelectric patches; \mathbf{M}_p and \mathbf{K}_p are the mass and stiffness matrices of the fluid; \mathbf{C}_{up} is the fluid-structure coupled matrix; \mathbf{F} is the applied mechanical force vector.

Thus, the variational equations (6) to (8) for the fluid/structure/piezo-patches coupled problem can be written, in discretized form, as the following unsymmetrical matrix system:

$$\begin{bmatrix} \mathbf{M}_u & 0 & 0 \\ 0 & 0 & 0 \\ \mathbf{C}_{up}^T & 0 & \mathbf{M}_p \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{U}} \\ \ddot{\mathbf{V}} \\ \ddot{\mathbf{P}} \end{bmatrix} + \begin{bmatrix} \mathbf{K}_u & \mathbf{C}_{uV} & -\mathbf{C}_{up} \\ -\mathbf{C}_{uV}^T & \mathbf{K}_V & 0 \\ 0 & 0 & \mathbf{K}_p \end{bmatrix} \begin{bmatrix} \mathbf{U} \\ \mathbf{V} \\ \mathbf{P} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ \mathbf{Q} \\ 0 \end{bmatrix} \tag{10}$$

with appropriate initial conditions.

2.3 Structural acoustic problem with piezo patches connected to RL shunt circuit

The above discretized formulation (Eq. (10)) can be used for a wide range of applications of mechanicals structure coupled with acoustic domain and associated with piezoelectric patches. It is particularly adapted to the case where the piezoelectric patches are shunted, i.e. connected to a passive electrical network [3]. In this case, neither \mathbf{V} nor \mathbf{Q} are prescribed by the electrical network but the latter imposes only a relation between them. In the case of a resonant shunt connected to the p -th patch and composed of a resistance $R^{(p)}$ and an inductance $L^{(p)}$ in series (Fig. 1), we have the following relation between electrical potential difference $V^{(p)}$ and the electric charge $Q^{(p)}$:

$$\mathbf{L} \ddot{\mathbf{Q}} + \mathbf{R} \dot{\mathbf{Q}} + \mathbf{V} = 0 \tag{11}$$

where $\mathbf{R} = \text{diag}(R^{(1)} \dots R^{(P)})$ and $\mathbf{L} = \text{diag}(L^{(1)} \dots L^{(P)})$ are diagonal matrices filled with the P resistances and inductances of the shunt circuits.

Figure 2: Piezoelectric patch connected to RL shunt circuit.

Due to the direct piezoelectric effect, the piezoelectric patch converts a fraction of the mechanical energy of the vibrating structure into electrical energy which can be dissipated through the resistive components of the RL circuit. It is well known that the damping effect due to this circuit is maximal when the resonance circular frequency $1/\sqrt{LC}$ of the shunt circuit is tuned on the circular frequency of the structural-acoustic eigenmode to be controlled. The resistance R and the inductance L can be adjusted and properly chosen so as to maximize the damping effect. Therefore, the optimal resistance and inductance for a series resonant shunt can be calculated by [4, 5]

$$R^{\text{opt}} = \frac{\sqrt{2k_{\text{eff},i}^2}}{C\omega_i(1+k_{\text{eff},i}^2)} \quad (12)$$

$$L^{\text{opt}} = \frac{1}{C\omega_i^2(1+k_{\text{eff},i}^2)} \quad (13)$$

where ω_i is the short circuit natural frequency of the i -th mode and $k_{\text{eff},i}$ is the effective electromechanical coupling coefficient [3].

Using the second row of Eq. (10), the degrees-of-freedom associated with the electrical potential difference \mathbf{V} can be expressed in terms of structural displacements \mathbf{U} and electric charge \mathbf{Q} as

$$\mathbf{V} = \mathbf{K}_V^{-1} \mathbf{C}_{uV}^T \mathbf{U} + \mathbf{K}_V^{-1} \mathbf{Q} \quad (14)$$

Thus, after substitution of \mathbf{V} into Eq. (11) and using Eq. (10), we get the following electro-mechanical-acoustic system:

$$\begin{bmatrix} \mathbf{M}_u & 0 & 0 \\ 0 & \mathbf{L} & 0 \\ \mathbf{C}_{up}^T & 0 & \mathbf{M}_p \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{U}} \\ \ddot{\mathbf{Q}} \\ \ddot{\mathbf{P}} \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & \mathbf{R} & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \dot{\mathbf{U}} \\ \dot{\mathbf{Q}} \\ \dot{\mathbf{P}} \end{bmatrix} + \begin{bmatrix} \mathbf{K}_u + \mathbf{C}_{uV} \mathbf{K}_V^{-1} \mathbf{C}_{uV}^T & \mathbf{C}_{uV} \mathbf{K}_V^{-1} & -\mathbf{C}_{up} \\ \mathbf{K}_V^{-1} \mathbf{C}_{uV}^T & \mathbf{K}_V^{-1} & 0 \\ 0 & 0 & \mathbf{K}_p \end{bmatrix} \begin{bmatrix} \mathbf{U} \\ \mathbf{Q} \\ \mathbf{P} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ 0 \\ 0 \end{bmatrix} \quad (15)$$

Note that this $(\mathbf{U}, \mathbf{Q}, \mathbf{P})$ formulation is well suited for switch shunting applications.

3 REDUCED ORDER MODEL

In this section, we introduce a reduced-order formulation of the discretized problem obtained in the previous section. This formulation, based on a modal superposition method, consists in expanding (i) the structural displacement over the *in vacuo* structure modes in short circuited configuration, (ii) the acoustic pressure over the acoustic modes of the fluid in rigid cavity. This approach is widely used and effective for structural acoustic systems with weak coupling. It can be noted that the acoustic basis is enriched by a static mode ([6]) and that the main motivation of choosing the structural modes with short-circuited patches is that they can be computed using a classical elastic formulation.

3.1 Eigenmodes of the structure in vacuo with short-circuited patches

In a first phase, the first M_s eigenmodes of the structure *in vacuo* with all patches short-circuited are obtained from the following equation

$$(\mathbf{K}_u - \omega_{si}^2 \mathbf{M}_u) \Phi_{si} = 0 \quad \text{for } i \in \{1, \dots, M_s\} \quad (16)$$

where (ω_{si}, Φ_{si}) are the natural frequency and eigenvector for the i -th structural mode. These modes verify the following orthogonality properties

$$\Phi_{si}^T \mathbf{M}_u \Phi_{sj} = \delta_{ij} \quad \text{and} \quad \Phi_{si}^T \mathbf{K}_u \Phi_{sj} = \omega_{si}^2 \delta_{ij} \quad (17)$$

where Φ_{si} have been normalized with respect to the structure mass matrix.

3.2 Eigenmodes of the internal acoustic cavity with rigid walls

In this second phase, the first M_f eigenmodes of the acoustic cavity with rigid boundary conditions are obtained from the following equation

$$(\mathbf{K}_p - \omega_{fi}^2 \mathbf{M}_p) \Phi_{fi} = 0 \quad \text{for } i \in \{1, \dots, N_f\} \quad (18)$$

where (ω_{fi}, Φ_{fi}) are the natural frequency and eigenvector for the i -th acoustic mode. These modes verify the following orthogonality properties

$$\Phi_{fi}^T \mathbf{M}_p \Phi_{fj} = \delta_{ij} \quad \text{and} \quad \Phi_{fi}^T \mathbf{K}_p \Phi_{fj} = \omega_{fi}^2 \delta_{ij} \quad (19)$$

where Φ_{fi} have been normalized with respect to the fluid mass matrix.

3.3 Modal expansion of the general problem

By introducing the matrices $\Phi_s = [\Phi_{s1} \dots \Phi_{sN_s}]$ of size $N_s \times M_s$ and $\Phi_f = [\Phi_{f1} \dots \Phi_{fN_f}]$ of size $N_f \times M_f$ corresponding to the uncoupled bases, the displacement and pressure are sought as

$$\mathbf{U} = \Phi_s \mathbf{q}_s(t) \quad \text{and} \quad \mathbf{P} = \Phi_f \mathbf{q}_f(t) \quad (20)$$

where the vectors $\mathbf{q}_s = [q_{s1} \dots q_{sN_s}]^T$ and $\mathbf{q}_f = [q_{f1} \dots q_{fN_f}]^T$ are the modal amplitudes of the structure displacement and the fluid pressure respectively.

Substituting these relations into Equations (15) and pre-multiplying the first row by Φ_s^T and the third one by Φ_f^T , we obtain the equation

$$\begin{bmatrix} \Phi_s^T (\mathbf{K}_u + \mathbf{C}_{uv} \mathbf{K}_V^{-1} \mathbf{C}_{uv}^T) \Phi_s & \Phi_s^T \mathbf{C}_{uv} \mathbf{K}_V^{-1} & -\Phi_s^T \mathbf{C}_{up} \Phi_f \\ \mathbf{K}_V^{-1} \mathbf{C}_{uv}^T \Phi_s & \mathbf{K}_V^{-1} & 0 \\ 0 & 0 & \Phi_f^T \mathbf{K}_p \Phi_f \end{bmatrix} \begin{bmatrix} \mathbf{q}_s \\ \mathbf{Q} \\ \mathbf{q}_f \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & \mathbf{R} & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \dot{\mathbf{q}}_s \\ \dot{\mathbf{Q}} \\ \dot{\mathbf{q}}_f \end{bmatrix} + \begin{bmatrix} \Phi_s^T \mathbf{M}_u \Phi_s & 0 & 0 \\ 0 & \mathbf{L} & 0 \\ \Phi_f^T \mathbf{M}_p \Phi_f & 0 & \Phi_f^T \mathbf{M}_p \Phi_f \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{q}}_s \\ \ddot{\mathbf{Q}} \\ \ddot{\mathbf{q}}_f \end{bmatrix} = \begin{bmatrix} \Phi_s^T \mathbf{F} \\ 0 \\ 0 \end{bmatrix} \quad (21)$$

This matrix equation represents the reduced order model of the structural acoustic problem with piezoelectric shunt damping treatments. If only few modes are kept for the projection, the size of this reduced order model ($M_s \times P \times M_f$) is much smaller than the initial one ($N_s \times P \times N_f$) (see examples below).

Equation (21) can be also written in the following form of coupled differential equations

- N_s mechanical oscillators

$$\ddot{q}_{si} + 2\xi_i \omega_{si} \dot{q}_{si} + \omega_{si}^2 q_{si} + \sum_{p=1}^P \sum_{k=1}^{N_s} \frac{\gamma_i^{(p)} \gamma_k^{(p)}}{C^{(p)}} q_{sk} + \sum_{p=1}^P \frac{\gamma_i^{(p)}}{C^{(p)}} Q^{(p)} - \sum_{j=1}^{N_f} \beta_{ij} q_{fj} = F_i \quad (22)$$

- N_f acoustic equations

$$\ddot{q}_{fi} + \omega_{fi}^2 q_{fi} + \sum_{j=1}^{N_s} \beta_{ij} q_{sj} = 0 \quad (23)$$

- P electric equations

$$L^{(p)} \ddot{Q}^{(p)} + R^{(p)} \dot{Q}^{(p)} + \frac{Q^{(p)}}{C^{(p)}} + \sum_{i=1}^{N_s} \frac{\gamma_i}{C^{(p)}} q_{si} = 0 \quad (24)$$

where $F_i(t) = \Phi_{si}^T \mathbf{F}$ is the mechanical excitation of the i -th mode; $\beta_{ij} = \Phi_{si}^T \mathbf{C}_{up} \Phi_{fj}$ are the fluid structure coupling coefficients and $\gamma_i = \Phi_{si}^T \mathbf{C}_{uv}$ the electromechanical coupling factors.

We can note that modal damping coefficients ξ_i have been added in Equation (22) in order to take into account the structural damping which can be measured experimentally.

The initial finite element formulation previously introduced has been replaced by the modal formulation of Equations (22), (23), (24) whose unknowns are the N_s structure modal coordinates q_{si} , the N_f fluid modal coordinates q_{fi} and the P charges $Q^{(p)}$ associated with the piezoelectric patch. Its major interest, and especially the choice of the short-circuit eigenmodes as the expansion basis, is that the above computations of the parameters necessitate only a modal analysis of an elastic problem. This operation can thus be done by any standard finite elements code.

4 NUMERICTLA EXAMPLES

We consider a 3D acoustic cavity completely filled with air (density = 1.2 kg/m³; speed of sound = 340 m/s). The cavity walls are rigid except the top one which is a flexible aluminium plate of thickness 1 mm clamped at its four edges. The density of the plate is 2700 kg/m³ the Young modulus 72 GPa and the Poisson ratio 0.34. On the top surface of the plate, two identical piezoelectric patches of thickness 0.5 mm are bounded. For the mechanical characteristics of the piezoelectric material PIC151, the reader can be referred to [7]. The geometrical data and mesh are presented in Fig. 3.

Figure 3: Acoustic/structure/piezo-patches coupled system: (a) geometrical data (in m) and (b) mesh.

Concerning the finite element discretization, we have used, for the structural part, 200 four-node plate elements based on Mindlin theory with five degrees-of-freedom per node ($N_s=1155$). The portions of the plate covered by the PZT patches have been modelled according to the first-order shear deformation laminated theory [8]. As discussed in the previous sections, only one electrical degree of freedom is used to represent the electrical charge Q in each patch. The acoustic cavity is discretized using 2600 hexahedric elements with one degree-of-freedom per node corresponding to the acoustic pressure ($N_f=3234$). Note that the structural and acoustic meshes are compatible at the interface.

4.1 Modal analysis of the acoustic/structure/piezo-patches coupled problem

Table 1 presents the eigenfrequencies in three following cases: (i) the 3D rigid acoustic cavity; (ii) the clamped plate with the two patches short circuited; and (iii) the plate/acoustic-cavity coupled system in the short circuit case. All coupled frequencies, except the sixth, are associated with the first vibration modes of the structure (lower than 450 Hz), and the sixth coupled frequency corresponds to the first acoustic mode in rigid cavity. It can be confirmed by comparing the mode shapes in case (iii) with those obtained in cases (i) or (ii) which are not shown here for sake of brevity. Moreover, as expected, the natural frequencies of the coupled modes (structure dominated) are lower than those for the structure in vacuum (except for the first mode) due to the "added-mass effect" of the fluid.

Fluid in rigid cavity	Structure without fluid	Coupled problem	Type of coupled mode S: Structure / F: Fluid
297.94	77.93	85.40	S
561.56	123.64	122.53	S
569.00	194.29	192.79	S
614.82	212.29	211.94	S
642.29	237.12	236.14	S
681.94	316.11	298.31	F
799.44	346.32	315.59	S
837.71	383.89	346.24	S
875.22	434.73	382.23	S
881.62	451.03	433.61	S

Table 1: Computed frequencies (in Hz) of the structural-acoustic coupled system.

For illustration purpose, Fig. 4 shows the deformed plate and the pressure field for the first ten vibration modes in the coupled case.

Figure 4: First 4 fluid-structure coupled modes: pressure level in the cavity and plate displacement.

4.2 Transient analysis of the acoustic/structure/piezoelectric-patch coupled problem

In this part, a multiple-mode shunt system with two piezoelectric patches as shown in Fig.5 is used in order to get an optimal multi-modal damping of the coupled system. The patches are tuned simultaneously on the second and the fourth modes of the plate. For each mode, the optimal values of the shunt electrical parameters are computed using Equations (27) and (28) (with $R_1 = 632.73 \Omega$ $L_1 = 9.47$ H for the second mode and $R_2 = 735.56 \Omega$ and $L_2 = 3.17$ H for the fourth mode). The plate is excited by a mechanical force of intensity 1 N located at $(x = 0.14$ m, $y = 0.06$ m, $z = 0.3$ m). The system vibratory response is obtained with the modal reduction approach defined by Equation (36) with a truncation on the first $M_s = 10$ structural modes and the first $M_f = 10$ acoustic modes.

Figure 5: Vibration plate coupled with an acoustic cavity and connected to RL shunt circuit.

Figures 6 and 7 present the frequency response of the system with and without shunt. The mechanical transverse displacement in the plate at the point of coordinates ($x = 0.14$ m, $y = 0.06$ m, $z = 0.3$ m) is presented in Fig. 6 and the sound pressure level in the acoustic cavity at the point of coordinates ($x = 0.15$ m, $y = 0.09$ m, $z = 0.1$ m) in Fig. 7. These Figures show that the modal resonant magnitude for each considered mode have been significantly reduced simultaneously. In fact, the strain energy present in the piezoelectric material is converted into electrical energy and hence dissipated into heat using the *RL* shunt device.

Figure 6: Frequency response function: transverse displacement amplitude in dB at the excited point.

Figure 7: Frequency response function: pressure level in dB at $x = 0.15$ m, $y = 0.09$ m, $z = 0.1$ m.

5 CONCLUSIONS

In this work, an original finite element formulation of structural acoustic problems with piezoelectric patches is presented. This formulation, involving only a couple of electric variables by patch, allows take into account naturally realistic electric boundary conditions. A reduced-order model, based on a normal mode expansion, is then developed. The proposed methodology requires the computation of the eigenmodes of the structure with short-circuited piezoelectric patches, and the rigid acoustic cavity. It is shown that the projection of the full-order coupled finite element model on the uncoupled bases, leads to a reduced order model in which the main parameters are the classical fluid-structure and electromechanical modal coupling factors. Despite its reduced size, this model is proved to be very efficient for simulations of steady-state analyses of structural-acoustic coupled systems with shunt damping.

Keywords: penalty functions, critical time step, explicit dynamics, time integration.

Abstract. *Penalty functions are a popular tool to add constraints to a system of equations, such as for instance Dirichlet boundary conditions or setting a relation between different degrees of freedom. Although implementation of the penalty method is simple, the commonly used stiffness-type penalties have a drawback in dynamics in that they increase the speed of sound locally. Thus, in conditionally stable time integration schemes the critical time step is lowered (often by orders of magnitude) if stiffness penalties are used. As an alternative, one may use inertia penalties that lower the speed of sound and therefore increase the critical time step, but in this paper we suggest the simultaneous use of stiffness and inertia penalties, which is called the bi-penalty method. In the bi-penalty method the relative magnitudes of stiffness penalty and inertia penalty can be tuned so that the net effect on the critical time step is neutral, thereby removing a major disadvantage of stiffness-type penalty methods.*

1 INTRODUCTION

Penalty functions are a popular technique to impose constraints in computational mechanics. Penalties can be used to enforce support conditions, tyings, interface conditions and/or contact. In mechanics, penalty functions are usually based on adding stiff springs to the system of equations. The accuracy of the constraint imposition depends on the magnitude of the penalty parameter, that is the stiffness of the added springs — the larger the penalty parameter, the more accurate the constraint is realised [1].

However, the penalty parameters cannot be chosen arbitrarily large: the condition number of the system matrix is affected adversely by increased penalty parameter, which deteriorates numerical accuracy. Furthermore, in dynamics an additional disadvantage is that stiffness-type penalties increase the speed of sound (at least locally where the penalty is applied). This becomes particularly significant in case a time domain analysis is performed with a conditionally stable time integration scheme; such schemes have a so-called *critical time step* which acts as an upper bound on the time step that can be used — larger time steps may (and usually do) lead to numerical instabilities. The critical time step is inversely proportional to the (local) speed of sound. Since the speed of sound increases with increased stiffness, applying stiffness penalties leads to increased speed of sound and decreased critical time steps [2].

As an alternative to stiffness-type penalties, it has more recently been suggested to use inertia-type penalties [3, 4]. Whereas stiffness-type penalties can be considered as stiff springs that prohibit displacement of the associated degree of freedom, inertia-type penalties act like heavy masses that prohibit acceleration of the corresponding degree of freedom. Although inertia penalties are not as accurate as stiffness penalties of equal magnitude, the beneficial effect of inertia penalties in dynamics is that they decrease the speed of sound and therefore increase the critical time step [4, 5].

To combine the benefits of stiffness penalties and inertia penalties, we suggest the simultaneous use of stiffness-type penalties and inertia-type penalties — a concept which is denoted as the bi-penalty method [5]. As explained above, stiffness penalties and inertia penalties have opposite effects on the critical time step; thus, critical ratios between the two penalty parameters can be derived such that their combined effect on the critical time step is neutral. The simultaneous use of inertia penalties and stiffness penalties has been suggested in the mid 1980s by Asano [6, 7, 8] for reasons of computational accuracy (and in fact penalties were also added to the damping matrix in these works), and more recently in [9] where the main focus was on frequency domain analysis.

In this paper, expressions will be given to compute the critical penalty ratio (CPR) described above. We will review the method to compute the CPR given in [5] and also present an alternative, much simpler method that has been developed recently. It will also be demonstrated that the critical time step remains unaffected if the penalty ratio is chosen not larger than the critical penalty ratio, whereas instabilities may occur otherwise. The bounds between stable and unstable simulations turn out to be very crisp, which is evidence for accuracy and relevance of the derived expressions for the critical penalty ratio.

2 BI-PENALISED EQUATIONS OF MOTION

We consider a linear elastic structure with stiffness matrix \mathbf{K} , mass matrix \mathbf{M} , external force vector \mathbf{f} and degree of freedom (DOF) vector \mathbf{u} . A constraint $u_n - \bar{u} = 0$ is applied to the n^{th} DOF where \bar{u} is the user-prescribed value of u_n . The constraint is enforced using stiffness and inertia penalty functions. For the former, the constraint in its usual form is added to the potential

energy \mathcal{U} . For the latter, the rate format of the constraint is taken and added to the kinetic energy \mathcal{T} . The penalised potential and kinetic energy functionals thus read

$$\mathcal{U} = \frac{1}{2} \mathbf{u}^T \mathbf{K} \mathbf{u} - \mathbf{u}^T \mathbf{f} + \frac{1}{2} \alpha_s (u_n - \bar{u})^2 \quad (1)$$

and

$$\mathcal{T} = \frac{1}{2} \dot{\mathbf{u}}^T \mathbf{M} \dot{\mathbf{u}} + \frac{1}{2} \alpha_m (\dot{u}_n - \dot{\bar{u}})^2 \quad (2)$$

where α_s and α_m are penalty parameters of the stiffness type (dimension N/m) and inertia type (dimension Ns^2/m), respectively. The equations of motion of the structure follow from

$$\frac{d}{dt} \frac{\partial \mathcal{T}}{\partial \dot{\mathbf{u}}^T} + \frac{\partial \mathcal{U}}{\partial \mathbf{u}^T} = [\mathbf{M} + \mathbf{M}^P] \ddot{\mathbf{u}} + [\mathbf{K} + \mathbf{K}^P] \mathbf{u} - (\mathbf{f} + \mathbf{f}^P) = \mathbf{0} \quad (3)$$

The components of \mathbf{M}^P and \mathbf{K}^P are all zero except for the diagonal entries $M_{nn}^P = \alpha_m$ and $K_{nn}^P = \alpha_s$. Similarly, $f_n^P = \alpha_m \ddot{\bar{u}} + \alpha_s \bar{u}$ with all other components of \mathbf{f}^P equal to zero.

3 COMPUTING THE CPR FROM THE BI-PENALISED SYSTEM

The critical time step Δt_{crit} of explicit time integration schemes, such as the central difference method, follows from

$$\Delta t_{\text{crit}} = \frac{2}{\omega_{\text{max}}} \quad (4)$$

where ω_{max} is the maximum eigenfrequency of the structure, which can be approximated (and is in fact bounded [10]) by the maximum eigenfrequency of the smallest element.

We require the critical time step to remain unaffected by the use of the bi-penalty method; thus, we require the maximum eigenfrequency of the bi-penalised system $\omega_{\text{max}}^{\text{BP}}$ to be not larger than the maximum eigenfrequency of the unpenalised system $\omega_{\text{max}}^{\text{UP}}$. We define the critical penalty ratio (CPR) as the ratio α_s/α_m for which the maximum eigenfrequency of the bi-penalised system is identical to the maximum eigenfrequency of the unpenalised system. To find expressions for the CPR we proceed as follows:

1. Find $\omega_{\text{max}}^{\text{UP}}$ as the largest root from the unpenalised eigenvalue problem

$$\det \left(\mathbf{K} - (\omega^{\text{UP}})^2 \mathbf{M} \right) = 0 \quad (5)$$

2. Substitute $\omega_{\text{max}}^{\text{UP}}$ into the bi-penalised eigenvalue problem:

$$\det \left([\mathbf{K} + \mathbf{K}^P] - (\omega_{\text{max}}^{\text{UP}})^2 [\mathbf{M} + \mathbf{M}^P] \right) = 0 \quad (6)$$

The free parameters of the latter expression are the two penalty parameters α_s and α_m .

3. Define the CPR as $\text{CPR} = \alpha_s/\alpha_m$ and find an expression for the CPR from Equation (6).

This is the approach that was used in [5] to compute the CPR for linear bar elements, beam elements and two-dimensional four-noded square elements. Whilst valid results can be obtained with this approach, it is nevertheless somewhat cumbersome in that the eigenvalue problem of the bi-penalised system must be solved. The complexity of the expressions increases rapidly when more than one DOF is penalised. Thus, it is of interest to explore alternative methods to compute the CPR.

4 COMPUTING THE CPR FROM THE UNPENALISED SYSTEM

As it turns out, it is possible to compute the CPR without the need to consider the bi-penalised eigenvalue problem. Here, we will present some basic principles of the proofs — the full proofs are quite elaborate and will be published in detail elsewhere. The bi-penalised eigenvalue problem is written as

$$\left[(\mathbf{K} + \mathbf{K}^P) - (\omega^{\text{BP}})^2 (\mathbf{M} + \mathbf{M}^P) \right] \mathbf{v} = \mathbf{0} \quad (7)$$

where \mathbf{v} is an eigenvector of the bi-penalised system. The eigenvectors can be scaled such that they are \mathbf{K} -orthogonal and \mathbf{M} -orthonormal [1], that is

$$\mathbf{v}_I^T (\mathbf{K} + \mathbf{K}^P) \mathbf{v}_J = (\omega_I^{\text{BP}})^2 \delta_{IJ} \quad (\text{no summation over } I) \quad (8)$$

$$\mathbf{v}_I^T (\mathbf{M} + \mathbf{M}^P) \mathbf{v}_J = \delta_{IJ} \quad (9)$$

Taking $I = J$, we obtain for large values of α_s and α_m that $\alpha_s v_n^2 = (\omega_I^{\text{BP}})^2$ and $\alpha_m v_n^2 = 1$, where v_n is the penalised component of the I^{th} eigenvector \mathbf{v}_I . Elimination of v_n^2 then yields

$$\sqrt{\frac{\alpha_s}{\alpha_m}} = \omega_I^{\text{BP}} \quad (10)$$

that is, for large values of the penalty parameters the square-root of the penalty ratio $\sqrt{\alpha_s/\alpha_m}$ is an eigenvalue of the bi-penalised system. It will be proven elsewhere that if $\sqrt{\alpha_s/\alpha_m}$ is chosen equal to the largest eigenvalue of the unpenalised system, then it is also equal to the largest eigenvalue of the bi-penalised problem, so that the overall conclusion is that by taking $\alpha_s = (\omega_{\text{max}}^{\text{UP}})^2 \alpha_m$ the maximum eigenfrequencies of the bi-penalised system and the unpenalised system are identical. Thus, the critical penalty ratio is

$$\text{CPR} = (\omega_{\text{max}}^{\text{UP}})^2 \quad (11)$$

This result is also valid for an arbitrary number of penalised DOF.

5 EXAMPLE

For illustration, we will consider the well-known case of one-dimensional linear bar elements. The lumped mass matrix and stiffness matrix are given as

$$\mathbf{M} = \frac{\rho A h}{2} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad \mathbf{K} = \frac{EA}{h} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \quad (12)$$

where A is the cross-sectional area, h is the element length, E is Young's modulus and ρ is the mass density. The unpenalised eigenvalue problem can be expanded as

$$\det \left(\mathbf{K} - (\omega^{\text{UP}})^2 \mathbf{M} \right) = (\omega^{\text{UP}})^2 \left((\omega^{\text{UP}})^2 - \frac{4E}{\rho h^2} \right) = 0 \quad (13)$$

so that $\omega_{\text{max}}^{\text{UP}} = 2c_e/h$ where $c_e = \sqrt{E/\rho}$ is the one-dimensional speed of sound. The CPR is then found as $\text{CPR} = 4c_e^2/h^2$, which corresponds with the dimensionless CPR found earlier in [5]. For the consistent mass matrix, a similar procedure leads to $\text{CPR} = 12c_e^2/h^2$.

As a numerical example, we consider a bar of length $L = 100$ m and cross-sectional area $A = 1$ m². A force $F = 1$ N is applied at the left end from time $t = 0$ s onwards. Stiffness

Figure 1: Wave propagation in a bar — strain profiles across the bar at time $t = 150$ s with critical penalty ratio (top) and super-critical penalty ratio (bottom)

and inertia penalties are applied at the right end of the bar to simulate fixed-end conditions. The material parameters are taken as $E = 1 \text{ N/m}^2$ and $\rho = 1 \text{ kg/m}^3$. The used finite element mesh consists of 100 two-noded bar elements. We apply a time step $\Delta t = \Delta t_{\text{crit}} = 1$ s, which means that the simulation should be numerically stable in the interior of the domain; if instabilities occur, they will occur due to the penalisation at the right end of the bar. The inertia penalty parameter $\alpha_m = 50$. Figure 1 shows the strain profiles across the bar at time $t = 150$ s for two values of the stiffness penalty: one whereby $\alpha_s/\alpha_m = \text{CPR}$ and one whereby $\alpha_s/\alpha_m = 1.002 \cdot \text{CPR}$. It is clear that selecting a penalty ratio equal to the CPR leads to a simulation that is numerically stable. It can also be seen that if the penalty ratio is taken slightly larger than critical, instabilities are initiated at the penalised end of the bar.

6 CONCLUDING REMARKS

The bi-penalty method, in which inertia penalties are used simultaneously with the usual stiffness penalties, can be used in explicit dynamics to control the critical time step. The effects of stiffness penalties and inertia penalties on the critical time step are opposite, therefore their relative magnitudes can be tuned to obtain a zero net effect on the critical time step. We have also outlined procedures to compute so-called *critical penalty ratios* (CPRs) that set the stability

limit for numerical simulations. An earlier method required that the bi-penalised eigenvalue problem was solved, but a new method has been formulated by which the CPR can be computed directly from the unpenalised eigenvalue problem.

In this paper, we have presented the computation of the CPR for simple one-dimensional bar elements. More sophisticated results for beam elements and two-dimensional square elements, obtained using the earlier method to compute the CPR, have been reported in [5], whereas the eigenfrequencies for unpenalised square elements (using plane various integration schemes) have also been given in [11].

Abstract. *This paper presents experimental and nonlinear Finite Element (FE) simulation of shear deficient reinforced concrete (RC) cantilever beams strengthened with Near Surface Mounted (NSM) Glass Fiber Reinforced polymer (GFRP) rods and subjected to cyclic loading. Two RC beam specimens were casted; the first beam is used to serve as a control specimen while the second was strengthened with GFRP NSM bars reinforcement. The two beams were tested under cyclic loading up to failure of the specimens. Then, a 3D Finite Element (FE) model that integrate different nonlinear constitutive material modeling laws and techniques such as concrete cracking, steel yielding, and imperfect bonding was developed using the finite element code ANSYS. The imperfect bonding captures the bond slip behavior between the NSM reinforcement and concrete surfaces. In addition, the developed FE models were validated against the experimental tests via a comparison of the load-deflection response envelopes and hysteresis loops. A Good matching between the experimental results and FE simulation were observed. Further experimental testing and numerical validation will be carried out in a future extensive research study to further investigate the performance of such systems when subjected to cyclic loading as in a seismic event.*

1 INTRODUCTION

In the last decade, strengthening reinforced concrete (RC) structures using externally bonded fiber reinforced polymer (FRP) materials have become a preferred technique to engineers and designers. Extensive research has been carried out to evaluate the contribution of FRP to different structural elements i.e. columns, beams, slabs etc. [1-3]. Although theoretically it is possible to achieve full capacity of strengthened elements, performed tests showed that achieving full capacity of FRP is unattainable due to debonding of the FRP sheets from the concrete surfaces [3-5]. A new strengthening technique known as near surface mounted (NSM) system seemed to be more efficient than the conventional externally bonded system. The NSM practice uses embedded FRP bars or strips into predefined grooves cuts in the concrete cover, thus achieving better bonding and protection from environmental exposures.

Extensive research has been performed on the performance of RC beams strengthened with carbon fiber reinforced polymer (CFRP) bars or strips [6-8]. Limited studies have been conducted on the use of glass fiber reinforced polymers (GFRP) bars as possible strengthening materials in shear. The aim of this study is to investigate experimentally and numerically the performance of RC beams strengthened in shear with NSM GFRP rods when subjected to cyclic loading. Two RC beams were casted and tested under cyclic loading up to failure of the specimens. In addition, a finite element (FE) model is developed to capture the response and behavior of such strengthening system. The developed model was validated by comparing the load-deflection response envelopes and load-displacement hysteresis loops with that of the obtained experimental data.

2 EXPERIMENTAL PROGRAM

Two RC cantilever beams deficient in shear are casted. The first beam "SPEC-1" was kept unstrengthened to serve as a control specimen. The detailing of the control beam is shown in Figure 1. The beams were 200mm wide, 350mm high and 1700mm long as shown in Figs. 1 and 2. Four 20mm diameter bars in the compression zone and four 20mm diameter bars in the tension zone are used as longitudinal reinforcements. A concrete clear cover of 30mm was used to avoid any embedding problems.

Figure 1: Reinforcement Details of Specimen Beams

The second RC beam specimen "SPEC-2" is strengthened in shear with GFRP NSM bars as shown in Fig. 2. The center-to-center spacing between the NSM GFRP bars was 160 mm.

Figure 2: Strengthening scheme used for SPEC-2

3 MATERIALS

The maximum aggregate size in the concrete mix used was 20mm. Four concrete cylinders were casted and tested after 28 days to determine their compressive strengths. The average compressive strengths of concrete was 25MPa. Deformed mild steel reinforcement is used and tested in tension to obtain their mechanical properties. The measured elastic modulus and yield strength was 205 GPa and 414 MPa for the longitudinal steel bars and 192 GPa and 275 MPa for the steel shear reinforcement (stirrups), respectively. In addition, coupon tensile tests for the GFRP bars reinforcements were carried out in a serco-controlled test machine. The stress-strain relationships obtained was linear up to failure. The tensile strength and elastic modulus of the GFRP bars were 550MPa and 40.8GPa, respectively. The adhesive (Sikadur®-330) used to bond the GFRP bars was composed of two parts, base and hardener. The direct tensile strength and secant elastic modulus of the epoxy Sikadur®-330 was 30MPa and 3.8GPa, respectively.

4 BONDING PROCEDURE

The sizes of the groove cuts were equal to $1.5d_f$ where d_f is the diameter of the FRP bar. The height of each groove was equal to the height of the beam's cross section. The strengthening procedure starts by filling half the grooves were with epoxy resin. Then, the GFRP bar was subsequently inserted and gently pressed to ensure that the epoxy flowed around the bar and fill any pores between the rod and sides of the groove. Finally, the beam was left to cure at room temperature for a period of two weeks prior to testing.

5 EXPERIMENTAL SETUP

A loading column was designed as shown in Figs. 1 and 2 to connect to the beam's free end in order to perform cyclic loading. The loading column contained two hinges, a load cell and a hydraulic jack. The capacities of the hydraulic jack and the load cell were 500 kN and 400kN, respectively. The two specimens were tested under increasingly cyclic loading up to failure. The loads were applied in cycles of loading and unloading and the applied loading history is shown in Fig. 3.

Figure 3: Applied cyclic loading history

6 FINITE ELEMENT MODEL

The developed Finite Element (FE) model has the same geometry, dimensions, material properties, and boundary conditions of the tested beams. The FE model was developed and simulated using the commercial finite element software, ANSYS [9]. Only one half of the tested beam was modeled, due to the symmetry in the transverse direction. Such decision would reduce the overall computational time while maintain the same accuracy. The developed finite element model is shown in Fig. 4.

Figure 4: The developed FE model

Both the concrete and epoxy materials were simulated using ANSYS SOLID65 [9] elements. SOLID65 is defined by 8-nodes, each node of has three translational degrees of freedom in the x, y, and z directions and the element is capable of modeling the nonlinear behavior of materials and cracking in tension. The steel and GFRP bars were modeled using LINK8 [9] element. LINK8 is defined by two nodes with three translational degrees of freedom at each node. The element is capable of elastic-plastic deformation, stress stiffening, and large deflection. The rigid concrete column support used in the experimental program didn't observe any cracking during testing and thus was modeled as an elastic material using

SOLID45 [9] elements. Perfect bond assumption is used herein between the longitudinal steel bars and concrete, GFRP bars and epoxy, and epoxy and concrete surfaces.

Table 1 lists the mechanical material properties used in the FE simulation. The nonlinear plastic behavior of concrete in compression is defined using the Hognestad (parabola) model [10]. The William and Warnke [11] model implemented in the concrete constitutive material model in ANSYS [9] is used. The model requires values for the open and closed shear coefficients which typically ranges from 0.0 and 1.0. In this study a value of 0.2 is used for both coefficients. In addition, the constitutive material model for concrete in tension assumes a linear elastic behavior up to the tensile strength of concrete listed in Table 1. The nonlinear response of the steel reinforcement bars is assumed to be linear elastic-perfectly plastic. The Von-Mises failure criterion is used to define yielding of the steel reinforcement. The GFRP reinforcement was modeled as a linear elastic material up to failure. Failure in the FE simulation is defined once divergence in the solution occurs.

Table 1 Material Properties used in the FE simulation

	Compressive strength (MPa)	Yield strength (MPa)	Tensile strength (MPa)	Elastic Modulus (GPa)	Poisson ratio
Concrete	25	-	3.1*	24**	0.20
Steel	-	414	-	200	0.30
GFRP***	-	-	550	40.8	0.28
Epoxy	-	-	30	3.8	0.29

* $f_t = 0.62\sqrt{f'_c}$ in MPa

** $E_x = 4800\sqrt{f'_c}$ in MPa

7 RESULTS AND DISCUSSIONS

The Control specimen “SPEC-1” failed in shear due to a critical shear crack that was developed at a load level of 61.90kN that corresponds to a maximum deflection of 11.69mm. The first crack appeared as a flexural crack for both specimens. The developed flexure cracks propagated through the sides of the beam specimens and caused shear crack propagations. In addition, shear cracks were developed at the unstrengthened part of the strengthened specimen “SPEC-2” between the GFRP bars. As the applied load increased, the shear cracks were propagated until reaching the edges of adjacent epoxy-filled grooves on both sides of the crack. Additional loads caused the development of a major crack that resulted in failure of the specimens. The strengthened specimen failed at a load 92.68kN with a maximum deflection of 22.68mm. Thus, the use of NSM GFRP bars as strengthening materials in shear increased the load carrying capacity of the RC beam by 94% over the control beam.

The measured and predicted load-deflection response envelopes of SPEC-1 and SPEC-2 are shown in Fig. 5. In addition, Fig. 6 shows a comparison between the predicted and measured load-deflection hysteresis loops. Table 2 draws a comparison between the tested and simulated specimens according to their ultimate load and maximum deflection. It is clear from Figs. 5 and 6 and Table 2 that there is a good agreement between the tested and simulated FE numerical results with a maximum deviation less than 5%.

Figure 5: Comparison of the response hysteresis

Figure 6: Comparison of the load-deflection envelopes

Table 2 Comparison between the FE predicted and experimental results

Specimen	FE Model	Failure Load (KN)		Percentage Difference $1-(\text{Exp.}/\text{FE})$	Maximum Deflection (mm)		Percentage Difference $1-(\text{Exp.}/\text{FE})$
		Exp.	FE		Exp.	FE	
SPEC-1	FE SPEC-1	-61.90	-62.1	0.3%	-11.69	-12.2	4.2%
SPEC-2	FE SPEC-2	92.68	95.05	2.5%	22.68	23.6	3.9%

7. Summary and Conclusions

This paper presented an experimental and numerical simulation of two shear deficient rectangular RC beams subjected to cyclic loading. The first beam was unstrengthened to serve as a control specimen, while the second beam was strengthened by means of NSM GFRP bars. The following conclusions can be drawn from the results of this study:

- The use of NSM GFRP bars can enhance the load-carrying capacity of shear deficient RC beams.
- The ultimate obtained load for the strengthened beam was greater than that of the unstrengthened specimen by 94%.

- The developed FE models are in close agreement with the measured experimental data at all stages of loading up to failure.
- The developed and verified finite element model in this study could be used as a valid tool for further investigation of NSM GFRP strengthened RC beams under cyclic loading and as a supplement or alternative to expensive and time consuming experimental testing.

The authors will conduct further experimental testing and numerical validation a future extensive research study to further investigate the performance of such shear deficient RC beams strengthened with NSM reinforcement and subjected to cyclic loading.

EXPLICIT CALIBRATION AND SIMULATION OF STOCHASTIC FIELDS BY LOW-ORDER ARMA PROCESSES

Keywords: ARMA simulation, Stochastic fields, Wind field simulation.

Abstract. *A simple framework for autoregressive simulation of stochastic fields is presented. The autoregressive format leads to a simple exponential correlation structure in the time-dimension. In the case of scalar processes a more detailed correlation structure can be obtained by adding memory to the process via an extension to autoregressive moving average (ARMA) processes. The ARMA format incorporates a more detailed correlation structure by including previous values of the simulated process. Alternatively, a more detailed correlation structure can be obtained by including additional 'state-space' variables in the simulation. For a scalar process this would imply an increase of the dimension of the process to be simulated. In the case of a stochastic field the correlation in the time-dimension is represented, although indirectly, in the simultaneous spatial correlation.*

The model with the shortest memory – the single-step autoregressive model – is analyzed in detail, and an efficient multi-step calibration procedure is developed. The calibration makes direct use of conditional correlations and means, expressed explicitly in terms of the zero and k -step correlation matrices of the stochastic field. The correlation structure of an isotropic turbulent wind field is developed from the generalized von Kàrmàn spectrum in terms of the Airy function, and the simulation procedure is illustrated for turbulent wind with Airy or exponential function representation of the correlation structure. In spite of the basic simplicity of the simulation algorithm, the details of the transverse correlation, that should satisfy an integral condition for consistency, is represented well.

1 INTRODUCTION

Stochastic fields play an important role in several technical contexts, notably as models for loads from wind, waves and earthquakes, and for representation of spatial properties e.g. of materials. In the first class of applications there is a time dimension, as well as one or more spatial dimensions, and this makes it appealing to consider the field as a development of a spatial field in time. Stochastic fields are characterized by their correlation, and for stationary fields a Fourier transformation relates the correlation function to a spectral density representation. For physical processes such as waves and wind there is often a background theory, that is most easily expressed in terms of spectral properties, and this suggests simulation based on spectral densities via a Fourier representation of the field. However, a Fourier representation is typically based on a finite time interval, to be selected as basis for the representation before the simulation, and furthermore computational efficiency suggests the use of a number 2^N of equal intervals in order to enable the use of the FFT formalism.

For stochastic fields with a time dimension there would be clear advantages in the use of sequential simulation techniques based on recurrence relations in time as expressed in the autoregressive moving average (ARMA) format. For scalar processes the details of the correlation structure is represented via a ‘memory’ that accounts for recent history. In principle the memory effect could be represented by including a number of auxiliary ‘state-space’ variables. For scalar processes this would imply an undesirable computational overhead, and the ARMA format is mostly retained. However, in the case of a stochastic field information of the correlation of the field may already be present in the correlation between simultaneous observations, and thus it may be possible to obtain a representation of the correlation structure, also in the time direction, via the additional information contained in a simultaneous observation of the field. This suggests the possibility of using ARMA models with rather short memory, corresponding to models with only a few coefficient matrices. The present paper deals with the shortest memory model – the single-step AR model – for stochastic fields, and develops a direct k -step calibration procedure that overcomes the problem of lack of robustness associated with single-step calibration. The model is illustrated for simulation of a turbulent wind field, where the along-wind correlation is implicitly contained in the instantaneous spatial correlation.

2 LOW-ORDER ARMA MODELS

The family of autoregressive (AR) processes with or without moving average (MA) terms generates a series \mathbf{u}_n of scalar or vector valued variables from a corresponding series of uncorrelated independent variables $\boldsymbol{\xi}_n$. In the context of stochastic fields the variables are vectors of dimension m ,

$$\mathbf{u}_n = [u_1, u_2, \dots, u_m]^T, \quad \boldsymbol{\xi}_n = [\xi_1, \xi_2, \dots, \xi_m]^T. \quad (1)$$

These variables are typically associated with individual points in space, and the vectors refer to a section through the field, while the sequence $\dots, n-1, n$ moves the section across the field as illustrated in Fig. 1.

The general format of the combined autoregressive moving average process is

$$\begin{aligned} \mathbf{u}_n = & \mathbf{A}_1 \mathbf{u}_{n-1} + \mathbf{A}_2 \mathbf{u}_{n-2} + \dots + \mathbf{A}_j \mathbf{u}_{n-j} \\ & + \mathbf{B}_1 \boldsymbol{\xi}_{n-1} + \mathbf{B}_2 \boldsymbol{\xi}_{n-2} + \dots + \mathbf{B}_k \boldsymbol{\xi}_{n-k}, \quad n = 1, 2, \dots \end{aligned} \quad (2)$$

where j denotes the number of regression terms, and k similarly the number of averaging terms. Typically, calibration of the process matrices makes use of direct matching to the covariance

Figure 1: Discretized stochastic field as sequence of sections $\dots, \mathbf{u}_{n-1}, \mathbf{u}_n$.

properties of the field to be simulated via the Yule-Walker equations, or use is made of discrete spectral properties involving the a discrete Fourier transformation, [1].

2.1 First-Order Autoregressive Format

The present simulation algorithm will concentrate on the first order autoregressive format. In this format the current vector \mathbf{u}_n is given as a linear combination of the previous vector \mathbf{u}_{n-1} and a random vector $\boldsymbol{\xi}_{n-1}$,

$$\mathbf{u}_n = \mathbf{A}\mathbf{u}_{n-1} + \mathbf{B}\boldsymbol{\xi}_{n-1}, \quad n = 1, 2, \dots \quad (3)$$

The random vectors $\boldsymbol{\xi}_n$ are here taken in the form of uncorrelated normalized normal components, whereby

$$\mathbb{E}[\boldsymbol{\xi}_i \boldsymbol{\xi}_j^T] = \delta_{ij} \mathbf{I}. \quad (4)$$

Hereby the role of the matrix \mathbf{B} is to generate the correlation between the components of the input in the AR equation (4).

The matrices \mathbf{A} and \mathbf{B} determine the properties of the series, and are determined to reproduce desired properties of an underlying stochastic field. The AR format (3) corresponds to a field with zero expectation of all vectors \mathbf{u}_n . The properties of the stochastic field are given in terms of the covariance matrices

$$\mathbf{C}_k = \mathbb{E}[\mathbf{u}_n \mathbf{u}_{n-k}^T]. \quad (5)$$

The stochastic field is assumed to homogeneous, and thus the covariance matrix is independent of the subscript n , identifying the section. Furthermore the present algorithm relates to the first order single-step format (3). This corresponds to fields with one-step memory, the so-called Markov property. The covariance structure of this type of field can be generated from the single-step covariance properties, contained in the two matrices

$$\mathbf{C}_0 = \mathbb{E}[\mathbf{u}_n \mathbf{u}_n^T], \quad \mathbf{C}_1 = \mathbb{E}[\mathbf{u}_n \mathbf{u}_{n-1}^T]. \quad (6)$$

These two covariance matrices determine the AR coefficient matrices \mathbf{A} and \mathbf{B} .

2.2 Coefficient matrices and conditional field properties

The matrices \mathbf{A} and \mathbf{B} can be determined from basic operations involving pre-multiplication of the AR equation (4). However, it is illuminating to derive the expressions directly from the corresponding conditional expectation and covariance of the underlying field. When using the AR equation (3), the vector \mathbf{u}_n is formed as the sum of a deterministic part $\mathbf{A}\mathbf{u}_{n-1}$, determined by the previous step, and a stochastic zero-mean component $\mathbf{B}\boldsymbol{\xi}_{n-1}$. Both coefficient matrices \mathbf{A} and \mathbf{B} are determined by rewriting the recurrence relation (3) in the form

$$\mathbf{u}_n - \mathbf{A}\mathbf{u}_{n-1} = \mathbf{B}\boldsymbol{\xi}_{n-1}. \quad (7)$$

By definition the stochastic variable ξ_{n-1} is independent of \mathbf{u}_{n-1} and has the expectation zero. The relation (7) then identifies the conditional expectation of \mathbf{u}_n as in the full sequence, when the previous vector \mathbf{u}_{n-1} is known, i.e.

$$E[\mathbf{u}_n | \mathbf{u}_{n-1}] = \mathbf{A} \mathbf{u}_{n-1}. \quad (8)$$

In the special case of zero-mean variables the conditional variance of \mathbf{u}_n for given \mathbf{u}_{n-1} is, see e.g. [2],

$$E[\mathbf{u}_n | \mathbf{u}_{n-1}] = \mathbf{C}_1 \mathbf{C}_0^{-1} \mathbf{u}_{n-1}. \quad (9)$$

Thus, the regression matrix \mathbf{A} is identified as the matrix in the conditional mean formula, whereby

$$\mathbf{A} = \mathbf{C}_1 \mathbf{C}_0^{-1}. \quad (10)$$

This equation gives the regression matrix \mathbf{A} explicitly in terms of the covariance matrices \mathbf{C}_0 and \mathbf{C}_1 of the stochastic field.

The matrix \mathbf{B} is also determined directly from the relation (7). Both sides represent a vector variable with zero mean. The vector \mathbf{u}_{n-1} is known, and thus the covariance matrix of the right hand side must correspond to the conditional covariance of \mathbf{u}_n ,

$$\text{Cov}[\mathbf{u}_n \mathbf{u}_n^T | \mathbf{u}_{n-1}] = \mathbf{B} E[\xi_{n-1} \xi_{n-1}^T] \mathbf{B}^T. \quad (11)$$

The conditional covariance matrix of two sets of variables of which one is known is given by, see e.g. [2],

$$\text{Cov}[\mathbf{u}_n \mathbf{u}_n^T | \mathbf{u}_{n-1}] = \mathbf{C}_{0|1} = \mathbf{C}_0 - \mathbf{C}_1 \mathbf{C}_0^{-1} \mathbf{C}_1^T. \quad (12)$$

The vector ξ_{n-1} has independent normalized components according to (4), and thus the expectation on the right hand side of (11) gives the unit matrix. Comparison of the two expressions for the conditional covariance $\mathbf{C}_{0|1}$ then gives the following equation of the matrix \mathbf{B} ,

$$\mathbf{B} \mathbf{B}^T = \mathbf{C}_{0|1} = \mathbf{C}_0 - \mathbf{C}_1 \mathbf{C}_0^{-1} \mathbf{C}_1^T. \quad (13)$$

This equation determines the product $\mathbf{B} \mathbf{B}^T$.

The role of the matrix \mathbf{B} in the autoregressive relation (7) is to generate correlated input from the uncorrelated components of the random vectors ξ_n . This leaves a certain indeterminacy of the matrix \mathbf{B} as only the product $\mathbf{B} \mathbf{B}^T$ contributes to the mutual correlation correlation of the components in the equation. A simple and direct solution consists in assuming that the coefficient matrix \mathbf{B} is in the form of a lower triangular matrix. The equation (13) then immediately identifies \mathbf{B} via the Cholesky factorization of the conditional covariance matrix $\mathbf{C}_{0|1}$ of the stochastic field. Alternatively, the matrix \mathbf{B} may be expressed in symmetric form in terms of the eigenvalues Λ and eigenvectors \mathbf{U} of the conditional covariance matrix $\mathbf{C}_{0|1}$, defined by

$$\mathbf{C}_{0|1} \mathbf{U} = \mathbf{U} \Lambda. \quad (14)$$

It then follows from the orthogonality relations of the eigenvectors \mathbf{U} that the coefficient matrix \mathbf{B} can be expressed as

$$\mathbf{B} = \mathbf{U} \Lambda^{1/2} \mathbf{U}^T. \quad (15)$$

This completes the single-step calibration procedure.

3 MULTI-STEP MODEL CALIBRATION

It is observed that the two parameter matrices of the AR filter are determined by the conditional expectation and the conditional covariance with the previous variable \mathbf{u}_{n-1} known. Direct use of these relations is justified, when the correlation properties of the stochastic field are captured well by the relation between two neighboring vectors \mathbf{u}_{n-1} and \mathbf{u}_n . However, the use of closely spaced vectors may introduce undesirable sensitivity in the calibration, and a more robust procedure can be obtained by calibrating the model via the properties of vectors with larger separation. A simple direct procedure using the vectors \mathbf{u}_{n-k} and \mathbf{u}_n , separated by k steps, is described in the following.

3.1 Recurrence matrix \mathbf{A}

The single-step recurrence relation may be extended by substituting \mathbf{u}_n from the previous relation and so forth. This leads to the k -step relation

$$\mathbf{u}_n = \mathbf{A}^k \mathbf{u}_{n-k} + (\mathbf{A}^{k-1} \mathbf{B} \boldsymbol{\xi}_{n-k} + \cdots + \mathbf{A} \mathbf{B} \boldsymbol{\xi}_{n-2} + \mathbf{B} \boldsymbol{\xi}_{n-1}). \quad (16)$$

In the previous section the matrix \mathbf{A} was determined via the conditional expectation of \mathbf{u}_n for known \mathbf{u}_{n-1} , i.e. for one-step separation. This formula is now generalized to k -step separation. First the term containing \mathbf{u}_{n-k} is moved to the left side of the equation,

$$\mathbf{u}_n - \mathbf{A}^k \mathbf{u}_{n-k} = (\mathbf{A}^{k-1} \mathbf{B} \boldsymbol{\xi}_{n-k} + \cdots + \mathbf{A} \mathbf{B} \boldsymbol{\xi}_{n-2} + \mathbf{B} \boldsymbol{\xi}_{n-1}). \quad (17)$$

The terms on the right are statistically independent with mean zero, and thus the conditional expectation of \mathbf{u}_n for known \mathbf{u}_{n-k} is

$$\mathbb{E}[\mathbf{u}_n | \mathbf{u}_{n-k}] = \mathbf{A}^k \mathbf{u}_{n-k}. \quad (18)$$

The conditional expectation also follows directly from the unconditional covariance between \mathbf{u}_n and \mathbf{u}_{n-k} as

$$\mathbb{E}[\mathbf{u}_n | \mathbf{u}_{n-k}] = \mathbf{C}_k \mathbf{C}_0^{-1} \mathbf{u}_{n-k}. \quad (19)$$

Comparison of these two expressions for the k -step conditional expectation gives the following expression for the k -power of the recurrence matrix,

$$\mathbf{A}^k = \mathbf{C}_k \mathbf{C}_0^{-1}. \quad (20)$$

This relation identifies the recurrence matrix \mathbf{A} from the covariance properties at a separation of k steps.

In order to extract the matrix \mathbf{A} from (20) an eigenvalue decomposition is used. To this end the notation

$$\mathbf{A}_k = \mathbf{C}_k \mathbf{C}_0^{-1} \quad (21)$$

is introduced. This matrix is non-symmetric and the eigenvalue decomposition takes the form

$$\mathbf{A}_k \mathbf{P} = \mathbf{P} \boldsymbol{\Gamma}^k, \quad \mathbf{A}_k^T \mathbf{Q} = \mathbf{Q} \boldsymbol{\Gamma}^k, \quad (22)$$

where \mathbf{P} and \mathbf{Q} are the right and the left eigenvector matrices of \mathbf{A}_k , respectively. The eigenvalues are contained in the diagonal matrix $\boldsymbol{\Gamma}^k = [\gamma_1^k, \gamma_2^k, \cdots, \gamma_m^k]$. The eigenvector matrices are normalized to satisfy the bi-orthogonality relations

$$\mathbf{Q}^T \mathbf{P} = \mathbf{P}^T \mathbf{Q} = \mathbf{I}. \quad (23)$$

Pre-multiplication of the eigenvalue equation (22a) with \mathbf{Q}^T and use of orthogonality gives the representation

$$\mathbf{Q}^T \mathbf{A}_k \mathbf{P} = \mathbf{\Gamma}^k. \quad (24)$$

Now, introducing $\mathbf{A}^k = \mathbf{A}_k$ and using the orthogonality relations (23) this relation takes the form

$$(\mathbf{Q}^T \mathbf{A} \mathbf{P})^k = \mathbf{\Gamma}^k. \quad (25)$$

From this relation and the orthogonality relations (23) it follows that

$$\mathbf{A} = \mathbf{P} \mathbf{\Gamma} \mathbf{Q}^T. \quad (26)$$

This formula determines the recurrence matrix \mathbf{A} from its k -step properties and generalizes the single-step procedure from Section 2.2. Clearly, the single-step result is recovered for $k = 1$, and it is seen that the eigenvalue decomposition becomes superfluous in that case.

3.2 Input matrix B

The input matrix \mathbf{B} is determined from the conditional variance by generalizing the single-step procedure from Section 2.2. In the relation (17) both sides represent a random vector with zero mean. When \mathbf{u}_{n-k} is known the covariance of the left side is seen to constitute the conditional covariance of \mathbf{u}_n for given \mathbf{u}_{n-k} , i.e.

$$\text{Cov}[\mathbf{u}_n \mathbf{u}_n^T | \mathbf{u}_{n-k}] = \mathbf{E}[(\mathbf{A}^{k-1} \mathbf{B} \boldsymbol{\xi}_{n-k} + \cdots + \mathbf{B} \boldsymbol{\xi}_{n-1})(\mathbf{A}^{k-1} \mathbf{B} \boldsymbol{\xi}_{n-k} + \cdots + \mathbf{B} \boldsymbol{\xi}_{n-1})^T]. \quad (27)$$

In this case the conditional variance of the stochastic field is given by

$$\text{Cov}[\mathbf{u}_n \mathbf{u}_n^T | \mathbf{u}_{n-k}] = \mathbf{C}_{0|k} = \mathbf{C}_0 - \mathbf{C}_k \mathbf{C}_0^{-1} \mathbf{C}_k^T. \quad (28)$$

The expression in terms of the matrices \mathbf{A} and \mathbf{B} of the model follow from evaluating the expectation on the right side of (27),

$$\text{Cov}[\mathbf{u}_n \mathbf{u}_n^T | \mathbf{u}_{n-k}] = \mathbf{A}^{k-1} \mathbf{B} \mathbf{B}^T (\mathbf{A}^{k-1})^T + \cdots + \mathbf{A} \mathbf{B} \mathbf{B}^T \mathbf{A}^T + \mathbf{B} \mathbf{B}^T. \quad (29)$$

The two expressions (28) and (29) for the conditional variance establish an equation between the conditional variance $\mathbf{C}_{0|k}$ of the stochastic field, and a series expansion in terms of powers of the matrix \mathbf{A} .

It follows from the l -factor product of the eigenvalue representation (26) that the l 'th power of \mathbf{A} can be expressed as

$$\mathbf{A}^l = \mathbf{P} \mathbf{\Gamma} \mathbf{Q}^T \cdots \mathbf{P} \mathbf{\Gamma} \mathbf{Q}^T = \mathbf{P} \mathbf{\Gamma}^l \mathbf{Q}^T, \quad (30)$$

where the orthogonality relation (23) has been used to cancel the inner matrix products. Substitution of this representation into the expression (29) for the conditional covariance matrix leads to the equation

$$\mathbf{C}_{0|k} = \mathbf{P} \mathbf{\Gamma}^{k-1} \mathbf{Q}^T \mathbf{B} \mathbf{B}^T \mathbf{Q} \mathbf{\Gamma}^{k-1} \mathbf{P}^T + \cdots + \mathbf{P} \mathbf{\Gamma} \mathbf{Q}^T \mathbf{B} \mathbf{B}^T \mathbf{Q} \mathbf{\Gamma} \mathbf{P}^T + \mathbf{B} \mathbf{B}^T. \quad (31)$$

The factors \mathbf{P} and \mathbf{P}^T are now eliminated by pre-multiplication with \mathbf{Q}^T and post-multiplication with \mathbf{Q} . This gives the relation

$$\mathbf{Q}^T \mathbf{C}_{0|k} \mathbf{Q} = \sum_{l=0}^{k-1} \mathbf{\Gamma}^l [\mathbf{Q}^T \mathbf{B} \mathbf{B}^T \mathbf{Q}] \mathbf{\Gamma}^l. \quad (32)$$

It is seen that the right side of the equation is a summation in which the components of the symmetric matrix

$$\mathbf{D} = \mathbf{Q}^T \mathbf{B} \mathbf{B}^T \mathbf{Q}. \quad (33)$$

are multiplied by powers of the eigenvalues $\gamma_1, \gamma_2, \dots, \gamma_m$. The summation is conveniently carried out by using the sum of a k -term series with geometric progression. In component form

$$[\mathbf{Q}^T \mathbf{C}_{0|k} \mathbf{Q}]_{ij} = \sum_{l=0}^{k-1} [(\gamma_i \gamma_j)^l D_{ij}] = \frac{1 - (\gamma_i \gamma_j)^k}{1 - (\gamma_i \gamma_j)} D_{ij}. \quad (34)$$

This equation gives the components of the matrix \mathbf{D} as

$$D_{ij} = \frac{1 - (\gamma_i \gamma_j)}{1 - (\gamma_i \gamma_j)^k} [\mathbf{Q}^T \mathbf{C}_{0|k} \mathbf{Q}]_{ij}. \quad (35)$$

When the components of \mathbf{D} have been computed from this relation, the input matrix \mathbf{B} is determined from (33). Pre-multiplication with \mathbf{P} and post-multiplication with \mathbf{P}^T gives the equation

$$\mathbf{B} \mathbf{B}^T = \mathbf{P} \mathbf{D} \mathbf{P}^T. \quad (36)$$

This is an equation of the same form as (13) for the single-step procedure.

It is noted that in the case $k = 1$ the first factor in (35) is unity, and eigenvalue decomposition becomes superfluous, as the matrix on the left side of (36) is simply equal to the conditional covariance matrix $\mathbf{C}_{0|1}$ in that case. In the multi-step case the input over k steps has components occurring at different times, and the memory effect is accounted for by the dependence on the eigenvalues Γ as illustrated in (35).

4 WIND FIELD SIMULATION

An application area of considerable current interest is that of a turbulent wind field. Specific applications range from structures like towers, high-rise buildings and long bridges to wind turbines. Traditionally, the level of ambition regarding the representation of the turbulent wind load in these applications has been very different, with structural applications often making use of simple analytical approximations for the resulting load, while wind turbine design typically makes use of rather detailed wind field simulation, often based on FFT techniques, see e.g. [3].

4.1 Isotropic wind field correlation

The turbulent wind field used in the present paper is represented in the form of isotropic incompressible turbulence as described by Batchelor [4]. It follows from invariance to coordinate transformations that the general form of the covariance between the turbulent velocity components at two points separated by the spatial vector \mathbf{r} as shown in Fig. 2 is of the form

$$\mathbf{R}(\mathbf{r}) = \mathbf{E}[\mathbf{v}(\mathbf{r}_0 + \mathbf{r}) \mathbf{v}(\mathbf{r}_0)^T] = \sigma_v^2 \left([f(r) - g(r)] \frac{\mathbf{r} \mathbf{r}^T}{\mathbf{r}^T \mathbf{r}} + g(r) \mathbf{I} \right), \quad (37)$$

where $r = |\mathbf{r}|$ is the distance between the two points, and σ_v^2 is the variance of a single component at a point. The functions $f(r)$ and $g(r)$ describe the lengthwise and transverse correlation, respectively.

Figure 2: Two-point correlation of isotropic wind field.

At the typical wind speeds in the natural wind the flow can be assumed to be incompressible. It then follows from the incompressibility condition $\nabla_{\mathbf{r}}^T \mathbf{v}$ that the correlation functions are related by

$$g(r) = f(r) + \frac{r}{2} \frac{d}{dr} f(r). \quad (38)$$

Thus, the isotropic incompressible stochastic field is described entirely in terms of a single scalar correlation function, e.g. the lengthwise correlation function $f(r)$. The lengthwise correlation function $f(r)$ is often represented in terms of its spectral density function $F(k)$, where k is the wavenumber,

$$\sigma_v^2 f(r) = \int_{-\infty}^{\infty} F(k) e^{ikr} dk. \quad (39)$$

Analytically tractable results are obtained, when using the generalized form of the von Kàrmàn spectral density, [5, 6],

$$\sigma_v^2 F(k) = \frac{1}{\sqrt{\pi}} \frac{\Gamma(\gamma)}{\Gamma(\gamma - \frac{1}{2})} \frac{\sigma_u^2 \ell}{[1 + (k\ell)^2]^\gamma}. \quad (40)$$

Here ℓ is a length-scale of the turbulence, and the Kolmogorov cascade theory implies that the exponent is $\gamma = 5/6$. The analytical details of this case has been investigated by Kristensen and Jensen [7], and it was demonstrated that coherence and correlation functions can be expressed in terms of modified Bessel functions of the second kind with fractional index. In the present context it is convenient to use an alternative representation of the correlation functions in terms of Airy functions [8]. This formulation makes use of a non-dimensional transformed variable z to represent the distance,

$$z = \left(\frac{3r}{2\ell} \right)^{2/3}, \quad (41)$$

whereby

$$f(r) = \frac{\text{Ai}(z)}{\text{Ai}(0)}, \quad g(r) = f(r) + \frac{z}{3} \frac{\text{Ai}'(z)}{\text{Ai}(0)}. \quad (42)$$

Here $\text{Ai}(z)$ is the Airy function and $\text{Ai}'(z)$ its derivative.

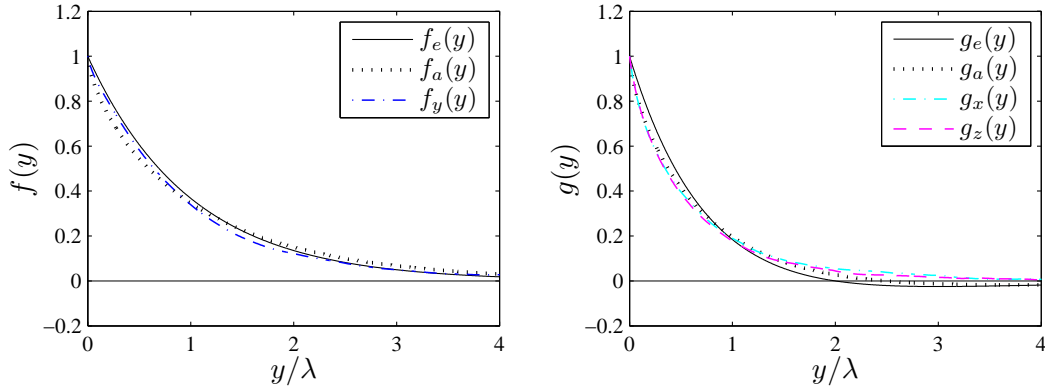

A simpler approximate formulation can be obtained by using the exponent $\gamma = 1$, whereby

$$f(r) = e^{-r/\lambda}, \quad g(r) = \left(1 - \frac{1}{2} \frac{r}{\lambda} \right) e^{-r/\lambda}. \quad (43)$$

Here the parameter λ is the integral spatial length-scale of the turbulence, defined by

$$\lambda = \int_0^\infty f(r) dr. \quad (44)$$

When substituting the representation (42) of the correlation functions in terms of the Airy function in the definition of the integral length-scale, it is found that $\ell = 1.339\lambda$.

 Figure 3: Correlation functions $f(r)$ and $g(r)$: Airy (dots), Exponential (full).

The lengthwise and the transverse correlation functions are illustrated in Figs. 3a and 3b, respectively. The exponential representation (43) is shown in full line, while the Airy function representation is shown by a dotted curve. It is seen that the curves from the two representations cross at $r \simeq \lambda$. The AR simulation format is closely related to exponential attenuation, and the curves suggest the distance $r \simeq \lambda$ may be appropriate for calibration of the AR model.

4.2 Simulated wind field

The AR field simulation is based on selecting a number of points in a plane, e.g. the xz -plane. The coordinates of these points are arranged in a global vector

$$\mathbf{x}_n^T = [\mathbf{r}_1^T, \mathbf{r}_2^T, \dots, \mathbf{r}_m^T]_n. \quad (45)$$

and the corresponding velocities are similarly arranged in the global vector

$$\mathbf{u}_n^T = [\mathbf{v}_1^T, \mathbf{v}_2^T, \dots, \mathbf{v}_m^T]_n. \quad (46)$$

The global covariance matrix is then given by

$$\mathbf{C}_k = \mathbb{E}[\mathbf{u}_n \mathbf{u}_{n-k}^T] = \begin{bmatrix} \vdots & \vdots & \vdots \\ \vdots & \mathbb{E}[\mathbf{v}_{i,n} \mathbf{v}_{j,n-k}^T] & \vdots \\ \vdots & \vdots & \vdots \end{bmatrix} = \begin{bmatrix} \vdots & \vdots & \vdots \\ \vdots & \mathbf{R}(\mathbf{r}_{i,n} - \mathbf{r}_{j,n-k}) & \vdots \\ \vdots & \vdots & \vdots \end{bmatrix}. \quad (47)$$

where the final form consists of the 3×3 block matrices representing the covariance between the point \mathbf{r}_i in layer n and the point \mathbf{r}_j in layer $n-k$. The simulation procedure consists of a k -step calibration of the matrices \mathbf{A} and \mathbf{B} , based on the covariance matrices \mathbf{C}_0 and \mathbf{C}_k as described in Section 3, followed by sequential use of the single-step recurrence (7).

Simulation of a turbulent wind field by the present procedure was used in [9] for wind turbine response analysis. The field is represented by 24 radial lines of length 43 m with 8 points in each. In the example the integral length-scale is $\lambda = 120$ m. The simulation is based on sections separated by $\Delta y = 0.5$ m, and the calibration distance is taken to be the integral length-scale λ , corresponding to $k = 240$. The model is calibrated by use of the exponential representation of the wind field correlation. Lengthwise and transverse correlation for points with axial separation y are shown in Fig. 3. It is seen that the lengthwise correlation represented by $f(y)$ retains much of the exponential form, while the simulated transverse correlation represented by $g(y)$ closely follows the theoretical Airy-function representation from the von Kàrmàn spectrum.

5 CONCLUSIONS

A simple framework for autoregressive simulation of stochastic fields has been presented. The autoregressive format leads to a simple exponential correlation structure in the time-dimension. In the case of scalar processes a more elaborate correlation structure can be obtained by adding memory to the process via an extension to autoregressive moving average (ARMA) processes. The ARMA format incorporates a more detailed correlation structure by including previous values of the simulated process. Alternatively, a more detailed correlation structure can be obtained by including additional ‘state-space’ variables in the simulation. For a scalar process this would imply an increase of the dimension of the process to be simulated. In the case of a stochastic field the correlation in the time-dimension is represented indirectly in the simultaneous spatial correlation.

The model with the shortest memory – the single-step autoregressive model – has been analyzed, and an efficient multi-step calibration procedure has been developed. The calibration makes direct use of conditional correlations and means, expressed explicitly in terms of the zero and k -step correlation matrices of the stochastic field. The correlation structure of an isotropic turbulent wind field is developed from the generalized von Kàrmàn spectrum in terms of the Airy function, and the simulation procedure is illustrated for turbulent wind with Airy or exponential function representation of the correlation structure. In spite of the basic simplicity of the simulation algorithm, the details of the transverse correlation, that should satisfy an integral condition for consistency, is represented well.

Keywords: Eccentrically braced frames, overstrength factor, incremental dynamic analysis

Abstract: *Among the resisting steel types suitable for the design of high ductility structures, Eurocode 8 proposes MRFs and EBFs. Also if the formers are generally considered a more efficient structural solution for high-ductility design, they suffers a strong weakness in the lateral stiffness creating, during the design process, cumbersome procedures to avoid excessive lateral displacements maintaining quite high ductile behaviour under design seismic actions. In many cases, the design process produces not optimized structural members, oversized respect to the minimum seismic requirements due to lateral deformation limitations. On the contrary, EBF combines high lateral stiffness furnished by bracing elements and high dissipative capacities furnished by plastic hinges developed in links. Eurocode 8 proposes a design procedure for realizing high ductility EBF in which iterative checks are required to properly design the links assigning to every link a defined level resistance dependant on all other links resistance. The present paper investigates the seismic behaviour of EBFs using the Incremental Dynamic Analysis technique in order to explore their mechanical response under increasing seismic action levels. A set of steel structures is designed according to Eurocode 8. The numerical simulations are executed considering the variability of both steel mechanical properties and seismic input, aiming to a complete probabilistic characterization of mechanical response of the system and deeply analyzing the effective level of structural safety and the ability to internally redistribute plasticizations during the earthquake. Structural safety conditions will be defined according to a multi-level performance approach. The paper presents also some final suggestions for possible improvements/simplifications in EBF design.*

1 INTRODUCTION

In the last seventies the use of eccentrically braced frames (EBFs) as earthquake resistant structures in medium and high seismicity regions greatly increased; this was mainly due to the fact that, respect to other traditional structural typologies, EBFs are able to join good dissipative performances to high elastic stiffness [1], combining the plastic dissipative behaviour of moment resisting frames (MRFs) with the high lateral stiffness of concentrically braced frames (CBFs) [2].

The dissipative behaviour of EBFs is related to particular beam elements called “links”: during an earthquake the link, designed to plasticize while all the other elements remain in the elastic range, develops high plastic deformations and consequently dissipates seismic energy.

The behaviour of link elements, and afterwards the way they dissipate energy, is related to their length (e): short links (i.e. characterized by a ratio between the plastic shear and the plastic moment smaller than 1.6 times the link length) generally develop high shear deformations, while long links (i.e. characterized by a ratio between the plastic shear and the plastic moment higher than 2.5 times the link length) mainly dissipate energy trough the formation of flexural deformations.

The ability of EBFs in dissipating energy strictly depends on the criteria adopted in the design: the plastic deformations are essentially located on link elements, dimensioned for yielding before beams, braces and columns that, otherwise, are proportioned using the forces generated by the yielded and hardened links [3] in order to remain in the elastic field, according with the principles of capacity design. The overstrength of non dissipative elements is consequently related to the mechanical and geometrical characteristics of the links; the overstrength behaviour of elastic elements is expressed trough the factor Ω , defined as the ratio between the plastic design resistance and the effective action on the dissipative elements (shear for short links and bending for long links). According to actual standards, such as Eurocode 8, the distribution of the overstrength factor Ω should be quite uniform, not varying more than 25% respect to its minimum value: this is necessary for guaranteeing a uniform distribution of link plasticization on all the floors and the global dissipation of seismic energy.

Otherwise, recent studies [4] evidenced that frequently, especially in presence of a high number of storeys, EBFs underwent undesired collapse mechanisms, despite the presence of small plasticization of the links of some floor and the respect of the design criteria. This fact can be partially caused by the difference between the nominal design value and the real effective value of the mechanical properties of steel [1, 5]: this difference, generally taken into account trough the introduction of the material overstrength coefficient γ_{ov} , can lead to the alteration of the failure modes supposed in the design, causing premature local collapse phenomena of the structure and consequently avoiding the global dissipation of seismic energy. The present work aims at the investigation of the influence of variability material properties on the dissipative behaviour of EBFs and was developed in the framework of a European Research Project funded by the Research Found for Coal and Steel (OPUS – Optimizing the seismic Performance of steel and steel-composite concrete strUctures by Standardizing material quality control). To this purpose, different steel buildings were firstly designed according to actual European standards and then analyzed trough the execution of non linear incremental dynamic analyses (IDA), considering the variability of both mechanical properties of materials and seismic input, in order to achieve a complete probabilistic characterization of the mechanical response of the system. The results obtained using the nominal and the real values of mechanical material properties, provided by the European steel producers partners of the project, were compared in terms of activation of

collapse criteria, analyzing the effective level of structural safety and the ability of the structure to redistribute the plastic demand imposed by the earthquake.

2 PROPOSED METHODOLOGY

Probabilistic techniques were adopted in order to assess structural response of case studies as function of seismic input and mechanical properties variability.

Indeed, even if in general seismic actions are time-variant variables (processes) and therefore reliability problems in earthquake engineering are time-variant reliability problems, for OPUS purposes, the problem was transformed in a time-invariant problem (i.e. looking only at extreme values) and a Monte Carlo simulation technique was applied in an efficient way; moreover, a probabilistic procedure able to furnish a good estimation of failure probability for all identified design points was also defined.

According to these final considerations, the research project adopted the following general approach devoted to the effective evaluation of seismic reliability for all structural case studies designed during the research:

- **step 1. Deep knowledge of structural systems.** The knowledge about the structural behaviour of the case studies was completed and determined thorough several numerical simulations, adopting non-linear static and dynamic analyses.
- **step 2. Nonlinear modelling and collapse modalities assessment.** Each structural system was described by accurate nonlinear models individuating the relevant collapse criteria.
- **step 3. Characterization of seismic hazard.** Seismic actions were modelled adopting parameters and hazard proposed by EN1998-1-1; in particular, hazard function (i.e. annual exceedance probability) for European seismicity is taken from EN1998-1-1 and calibrated according to design parameters associated to ultimate limit state verification. Seven seismic inputs to be adopted in the numerical simulations were artificially generated from response spectra adopted in the design.
- **step 4. Probabilistic model of mechanical variables.** Scattering of steel products was represented by a multi-variable model where yielding stress – $R_{e,H}(f_y)$ –, tensile strength – $R_m(f_t)$ – and elongation at fracture – $A(\epsilon_u)$ – were considered with their probabilistic interdependencies.
- **step 5. Execution of nonlinear analyses and optimal planning of numerical simulations.** The correlation between the seismic demand and the structural response of case studies was defined employing non-linear dynamic analyses; peak ground acceleration (PGA) of selected seismic inputs was varied according to appropriate levels chosen in order to activate collapse modes. In such a way, the number of simulations characterized by failures according to different modes was increased.
- **step 6. Probabilistic procedure for P_{fail} estimation.** Numerical results coming from dynamic analyses were analyzed employing a statistical procedure that furnishes fragility curves and yearly threshold exceedance probability of the relevant collapse modes for each case study.

The numerical simulations were executed using Incremental Dynamic Analysis techniques, suitable for the analysis of structural response at different PGA levels.

3 DESCRIPTION OF CASE STUDY

In the widest framework of OPUS project, fifteen different buildings in steel and steel – composite concrete structure were designed, in order to cover the most common geometrical

and functional structural typologies in Europe: MRFs, CBFs and EBFs for offices, industrial buildings and car parks were analyzed.

The present paper deals with the seismic behaviour of EBF steel structures; three different buildings, so on called building 3, 4 and 16, were designed according to the criteria imposed by Eurocode 8. External EBFs were designed to resist the total seismic horizontal forces: stating the symmetry of geometrical properties and mass distribution, the design of the buildings was calibrated on single eccentrically braced frames referring to the two main directions of the structure. The consistency of the design was verified comparing the results so obtained with the ones coming from dynamic modal analyses of 3D global models of the buildings.

Building 3 and 4 are office buildings, while building 16 is a car park; buildings 3 and 16 are located in high seismicity region and present short shear links, while building 4, located in medium-low seismicity area, presents long bending links. Buildings 3 and 4 have a similar geometry, characterized by 5 storeys with an interstorey height of 3.50 m and a span length varying between 6 and 7 m; building 16 is characterized by a span length between 8 and 10.5 m and presents only two storeys with interstorey height equal to 4.0 m. The link disposition and length vary in relation to the typology (shear or bending) and to floor position.

A duplication of secondary beams was applied in buildings 3 and 4 in order to avoid the amount of vertical loads and connection of elements in correspondence of the dissipative zone of links (see Figure 1c). Pinned connections were used at the ends of non dissipative elements, such as braces and columns, and between beams and columns for K-brace frames (frame 3xz, 16xz and 16yz); welded connection were adopted for the beam to column joints in D-brace frames. The general geometrical properties of EBF buildings are presented in Table 1.

For all described buildings a floor type characterized by a concrete slab on prefabricated trussed slab for a global thickness of 23 cm was used; in the design of buildings 3 and 4 steel grade S355 (nominal yielding strength equal to 355 MPa) was used; building 16, on the other hand, was designed considering steel grade S275 (nominal yielding strength equal to 275 MPa). As regards seismic action, in buildings 3 and 16 a PGA equal to 0.25 g and a soil of category B were considered, while building 4 was dimensioned for a PGA equal to 0.10 g and a soft soil of type C; the response spectra adopted in the design are compatible with both Eurocode 8 [6] and actual Italian Standards for constructions NTC2008 [7]. Table 2 summarizes vertical and horizontal loads adopted in the design.

The general geometry of buildings is represented in Figures 1-4.

Building number	Height	Steel Quality	X direction		Y direction	
			Resisting system	Span [n° x L]	Resisting system	Span [n° x L]
3	5x3.5 m	S355	EBF shear	3x7m	EBF shear	4x6m
4	5x3.5 m	S355	EBF bending	3x7m	EBF bending	4x6m
16	2x4.0 m	S275	EBF shear	5x8m + 2x10m	EBF shear	6x10.5m

Table 1: Summary of geometric properties of EBF buildings.

According to Eurocode 8 and in relation to the location of the buildings, design factors respectively equal to 6 and 4 were adopted for high ductility class (HDC) buildings (3 and 16) and for low ductility class (LDC, building 4). All the EBF buildings so far described were designed to resist to vertical and horizontal forces provided by actual standards, both for seismic and static combination, without encountering global or local collapses. The design was optimized in order to have a uniform plasticization of links in all the floors: an accurate

distribution of the overstrength factors Ω_i was pursued, obtaining variation smaller than 25% among the floors. The obtained values for overstrength factors are summarized in Table 3.

	Roof 5	1.86	2.24
4	Storey 1	1.68	1.99
	Storey 2	1.87	1.74
	Storey 3	1.63	1.78
	Storey 4	1.66	1.76
	Roof 5	1.51	1.61
16	Storey 1	1.53	1.57
	Roof 2	1.88	1.91

Table 3: Overstrength factors for each building.

The sizing of the links with actions coming from the linear analysis was the base for the proportioning of the other overstrengthening elements such as beams, braces and columns, according to the principles of capacity design; buckling phenomena of elements in compression and interstorey drift limits, i.e. lateral stiffness requirements, were also conditioning for the definition of brace and columns profiles.

Typically, HEB sections were used for columns and braces in all the buildings; otherwise, HEB or IPE sections were adopted for links: HDC buildings with short shear links present HEB section for dissipative elements (e varies between 250 and 700 mm), while LDC

building employs IPE section for long bending links (e equal to 1000 mm), as presented in Table 4.

Building	Storey	X direction		Y direction	
		Link profile	Link length (mm)	Link profile	Link length (mm)
3	Storey 1	HEB200	700	HEB200	600

4 DESCRIPTION OF NON LINEAR MODELS

4.1 Numerical Non linear models

In order to evaluate the influence of the variability of material properties on the effective seismic behaviour of EBF structures, non linear Incremental Dynamic Analyses (IDA) were executed on plane frame models of the buildings previously described.

As many past works evidenced [8, 9] the modelling of link elements should be very accurate for obtaining numerical outcomes consistent with the EBF response prediction; both short and long links, despite the different mechanism they use for dissipating seismic energy, develop flexural forces combined with shear ones: the model of link should consequently be able to reproduce both the two effects.

Many numerical models were proposed in literature to represent the behaviour of link elements, for example one component models with concentrated plastic hinges at the ends of the element [10] or two component models constituted by beams working in parallel [8]; nevertheless, only more recent models are able to encounter the shear behaviour of the dissipative link element [8].

In the present work, bi-dimensional models of the main frames of the buildings were realized using the numerical software OpenSees [11]. The dissipative behaviour of link elements and the combined effect of shear forces and bending moments were directly taken into account modelling all the elements as “fiber section elements” (Figure 5a). The calibration of the software was executed comparing the outcomes from cyclic loading histories on single components (for example the braces) with literature results [12].

Inelastic fiber elements were used for representing columns, beams without links and short shear links; on the other hand, two elements were used for modelling each long bending link and four elements were employed for each brace. Buckling phenomena of braces were directly taken into account giving an initial imperfection equal to 1/500 of the brace length to the middle point of the brace, as represented in Figure 5b; a similar imperfection was also

assigned to the top of columns in order to include in the analysis P- Δ effect (Figure 5b). The value adopted for the imperfection was evaluated from the calibration with literature results.

Figure 5: a) General scheme of fiber elements and b) model of imperfections of braces and columns.

For modelling the flexural behaviour of steel members – beams, braces and columns –, the Menegotto-Pinto law [13], characterized by bilinear elastic-plastic stress-strain curve with kinematic hardening, accurately calibrated in order to agree with literature results, was used (Figure 6a); moreover, as regards the force-distortion law used for representing the shear behaviour of elements, a bilinear elastic-plastic law with kinematic hardening was used for links (Figure 6b).

Figure 6: Constitutive law adopted for a) flexural behaviour, b) shear behaviour of dissipative elements.

4.2 Definition of collapse criteria for EBFs

For evaluating the global ductile behaviour of the structures under seismic action all the possible collapse mechanism for EBFs were analyzed, referring to what prescribed by actual standards, such as EN 1993-1 [15] and FEMA [16]; the collapse limits individuate the point at which IDA simulation should be stopped, since for higher levels of PGA it's not important to consider the behaviour of the structure. The collapse limitations adopted are strictly related to different limit states, assessing the structural performances both at ultimate and serviceability limit state. One of the most conditioning collapse criteria for eccentrically braced frames is obviously the failure of link elements, in which plastic deformation are concentrated according to the design principles. The plastic rotation is calculated as the ratio between the relative vertical displacement (δ) and the link length (e), see expression (1): for shear short link δ is evaluated as the relative vertical displacement between the two ends of the link (Figure 7a), for long bending links δ refers to the mid length of the element (Figure 7b). The limits assumed according to the standards are presented in Table 5.

Figure 7: Evaluation of link plastic rotation a) for short shear links, b) for long bending links.

$$\frac{v_1 - v_2}{e} = \frac{\delta}{e} = \gamma_{LINK} \quad (1)$$

The limit axial load for the buckling of steel members in compression (columns and braces) is evaluated according to Eurocode 3 [15] with expression (2), and is consequently strongly influenced by the mechanical properties of materials (yielding strength f_y):

$$N_{b,Rd} = \frac{\chi \cdot A \cdot f_y}{\gamma_{M1}} \quad (2)$$

The limitation imposed to interstorey drift should be assessed; the respect of the lateral stiffness requirements strongly influenced the sizing of steel members such as braces, especially in building 4, designed for low-ductility class. For EBFs, the collapse criteria to be taken into account are summarized in Table 5.

Collapse Criteria	Reference code	Limit value
Ultimate plastic rotation	EC8, FEMA 356	110 mrad (shear), 20 mrad (bending)
Global buckling	EN 1993-1	-
Interstorey drift ratio	EN 1998-1	1.5% x Interstorey height

Table 5: Summarizing table of collapse criteria for EBFs.

5 SEISMIC HAZARD vs. SEISMIC INPUT

5.1 Seismic hazard

Seismic hazard of a particular site expresses its natural exposure to severity of possible earthquake. Seismic hazard analysis characterize the maximal amplitude of ground shaking during the earthquake by chosen design ground motion parameter in the specified level of probability and time of occurrence of the event.

According to EN1998-1 guidelines, it is possible to assume that the annual rate of exceedance of the reference peak ground acceleration a_{gR} may be taken to vary with a_{gR} as:

$$H(a_{gR}) = k_0 \cdot a_{gR}^{-k} \quad (3)$$

Moreover, EN1998-1 suggests that exponent k , depending on seismicity, can be generally taken equal to 3. The value of k_0 was fixed according to basic performance requirements imposed by EN1998-1: the design seismic action should have a exceeding probability of 10% (P_{NCR} , probability of non collapse requirement) in 50 years (T_L , exposition period of the structure) for the non-collapse requirements. The return period of seismic action, T_R , is correlated with P_{NCR} and T_L by the following formula

$$T_R = \frac{-T_L}{\ln(1 - P_{NCR})} \quad (4)$$

that gives a return period of 475 years for the design PGA. According to PGA levels assumed during seismic design, 475 years of return period corresponded, respectively, to 0.25g in high seismicity areas and 0.10g in low seismicity areas and fixed k_0 parameter in eqn. (3) equal to 3.29×10^{-5} for high seismicity areas and 2.10×10^{-6} . Resulting hazard functions for high and low seismicity are presented in Figure 8.

Figure 8: Hazard function according to EN1998-1 prescriptions: (a) high seismic hazard; (b) low seismic hazard.

5.2 Definition of accelerograms

According to EN1998-1-1 prescription, seven earthquake time-histories of natural earthquakes or artificially generated time histories can be used. To obtain results representative for any seismic area in Europe, it is reasonable to use artificial accelerograms, which meet the elastic response spectra in EN 1998-1 and are so consistent with chosen hazard model. In order to generate artificial earthquake time histories, the program SIMQKE [14], developed by Gasparini and Vanmarcke (1976), was used.

Two types of seismic intensities were considered: for high seismicity the PGA level was 0.25 g, while the type 1 spectrum for soil type B was used; for low seismicity the PGA was fixed 0.10 g, while the type 2 spectrum for soil type C was applied, Figure 9a. The filter function was defined by a trapezoidal shape, where the time intervals for the initial and ending ramp were 5 s and the strong motion duration was 10 s for high and 5 s for low seismicity, Figure 9b. The relevant Eigen-periods were assumed to be in a range between 0.1 s and 3.0 s. The chosen sampling interval of $\Delta t = 0.01$ s allowed a sufficient accurate calculation for Eigen-frequencies up to 20Hz (5 points for each period).

The verification of the accelerograms by determining the velocity and displacement time histories showed that the displacements were running out (Figure 10). Hence, a baseline correction was applied to obtain a sufficient small displacement at the end of the record. The adequacy of the accelerograms was checked by determination of their elastic response spectra, Figure 11. For periods lower than T_B the spectrum value S_a was slightly too high, Figure 12; however, the target spectrum is sufficiently met and the requirements defined in EN1998-1 were met.

Figure 9: Target spectra (a) and filter function (b) for the generation of artificial time histories

Seismicity	p.g.a.	Spectrum	Soil	Total duration	Strong motion duration
Low	0.10 g	Type 2	Type C	15 s	5 s
High	0.25 g	Type 1	Type B	20 s	10 s

Table 6: Parameters of target spectra and filter function for low and high seismicity

Figure 10: Baseline correction for an artificial accelerogram (high seismicity)

The COV of the spectral values for the 7 accelerograms is between 0.04 and 0.12, Figure 13. It should be noted, that the energy density of artificial accelerograms is much higher than of natural accelerograms, as all frequencies of interest are included.

Figure 11: Target spectrum and elastic response spectra of 7 artificial accelerograms: low seismicity (a) and high seismicity (b).

Figure 12: Target spectrum and mean value of the elastic response spectra of 7 artificial accelerograms: low seismicity (a) and high seismicity (b).

Figure 13: COV of the elastic response spectra of 7 artificial accelerograms: low seismicity (a) and high seismicity (b).

5.3 Seismic input for nonlinear analyses

IDA simulations were executed scaling generated seismic inputs at different PGA levels; PGA levels, considered as significant for the probabilistic assessment of seismic response of designed structure, were previously determined studying structural response of case studies. In particular, for each plain structure (see Figures 2, 3 and 4), different excitation levels were individuated according to the collapse modes that can be activated increasing PGA, see table 7. It is worth noting that collapse of columns was a mode that cannot be activated for PGA levels lower than 1.50g; hence, PGA levels corresponding to column collapse were not considered; concerning 3EBFX also collapse mode associated to braces was not activated. This high level of PGA for these two collapse modes was correlated to the frame design: columns are sized through column verification under full vertical static actions at Ultimate Limit State; braces for 3EBFX were over-sized due to the extreme sensitivity of structural configuration to second order effects.

6 EXECUTION OF NONLINEAR ANALYSES

For each case study, collapse criteria were analysed for each considered PGA level, executing incremental dynamic analyses adopting alternatively the 7 artificially generated accelerograms.

Monte Carlo Method was applied to each analysis generating 500 samples of mechanical variables and running IDA for each of them. In particular, to be adherent to the real assembling of steel structures, all beams and braces members were considered as probabilistically not dependant (generating independent sets of mechanical variables) while columns of two subsequent floors were considered as characterized by the same probabilistic variables, see generation scheme in Figure 14c.

In order to generate samples of mechanical properties, a log-normal model was assumed for each of them – yield strength $R_{e,H}$, ultimate strength R_m and elongation A – so that their distribution resulted multivariate in which the three variable were inter-correlated.

The correlation matrix of the adopted model was determined from statistical parameters derived from industrial steel production [15], summarized in Table 8.

The generation procedure was based on the adoption of an equivalent multi-normal probabilistic distribution [17] obtained from the original multivariate log-normal model.

In such a way, for each case study 3500 numerical simulations were carried out (i.e. 7 quakes \times 500 material samples) for each considered PGA level and each considered collapse criterion.

Defining, for each collapse criterion, the damage measure (DM) for the relevant engineering demand parameter (EDP) stated in the Table 5, nonlinear analyses explored structural responses using a strip method as depicted in Figures 14a and 14b (Figure 14a

includes seismic input and material variability, 3500 results for each PGA level; Figure 14b only shows material variability, 500 results for each PGA level).

Moreover each set of 500 nonlinear analyses, results (related to a single collapse criterion, a PGA level and accelerogram) were suitably standardised referring to the values $Y_i = 100 \cdot DM_i / DM_u$ being, for the specified collapse criterion, DM_i the damage measure assumed by the EDP in the i -th analysis and DM_u its limit value corresponding to collapse.

The so obtained new set of data was statistically analysed evaluating the basic parameters (maximum, minimum and mean values and standard deviation) and executing the χ^2 test to check the hypothesis of Normal or Log-Normal distributions. When the χ^2 test was not negative a Normal or Log-Normal distribution was assumed; alternatively the statistical cumulative density function was built, completed in correspondence of tails by suitable exponential functions [18].

The probability of failure related to each set of 500 data (related to a single collapse criterion, a PGA level and accelerogram) was so simply evaluated using its cumulative density function, being $P_f = P[Y > 100]$. Clearly, for each collapse criterion and each PGA level, 7 values of P_f , and so 7 fragility curves, were obtained, one for each accelerogram. The averaged of 7 fragility curves was assumed as the fragility curve related to that specific collapse criterion (see Figure 15).

Fragility of case studies referred to a collapse mode, was finally integrated with European Seismic Hazard function, as described in [6], furnishing annual probability of failure for relevant collapse criteria of all case studies, shortly presented in Tables from 9a to 9f.

7 ANALYSIS OF RESULTS

The statistical procedure defined for a comprehensive analysis of IDA outputs was extensively applied to most part of structural members; in particular, all collapse modes presented in Table 5 were analyzed. The results in terms of annual seismic risk are reported in Tables 9a and 9b for frame 3, in Tables 9c and 9d for frame 4 and in Tables 9e and 9f for frame 16.

Comparing failure probability of braces in frame 3, it is clear which checks had conditioned the design: risk associated to braces in X direction is 5 times less than risk associated to Y frame, confirming the over-sizing required during the design for braces in X direction. The accurate design followed during the sizing of links in order to reduce as much as possible Ω factor and its differences between dissipative members it is confirmed by comparable failure probabilities for all links. The comparison of Ω factor derived from the elastic design, see Table 3, with link failure probability confirms that higher Ω are related to lower failure probability.

Failure probability associated to columns are really low, confirming that for such kind of structural systems, static combinations with complete factorized set of vertical loads represents for the column the most demanding check in many cases. The annual exceedance probability is often zero or 10^{-5} , largely lower than accepted threshold fixed between 10^{-3} and 10^{-4} for this type of structure accurately designed [19] and belonging to a standard (common)

use category. It is worth noting that this trend is confirmed also for the columns in the frame 16: columns have a (annual) failure probability lower than 10^{-5} also if in such a case vertical loads are not relevant. This effect is related to the capacity design and, in particular, to the contribution of Ω factor: this coefficient is equal to 1.5 in the most optimized design and higher in the common practice, increasing of 50% seismic solicitation without material over-strength factor.

Table 9d: Annual exceedance probability (Seismic risk) associated to 4EBFY collapse modes.

Seismic links contained in the frame 3 and 16 were shear links designed for high seismicity zones and their annual failure probability are fixed about 10^{-4} , while for bending links – frame 4 – failure probability is set about 10^{-5} , giving in such a case a more conservative design respect those executed in high seismic zones and with higher behaviour factor. This could suggest that EN1998 design procedure cannot allow the designers to optimize structural solutions designed for low seismic loads or with low behaviour factors.

It is also important to underline that all case studies furnished annual failure probability in-line with the limit proposed by Melcher of 10^{-4} for such structures subjected to exceptional loading conditions [19]. This confirms that control measures considered inside capacity design approach, as material over-strength factor – γ_{OV} – and structural over-strength – Ω , can guarantee an adequate protection level to braces and columns. It seems, moreover, that this protection is too pronounced in the columns and so probably capacity design rules could be relaxed for this structural member.

7.1 Upper limitation on yielding stress: influence on IDA results

The probabilistic procedure was newly applied imposing a preconditioning of material input variables: the f_y of dissipative members was limited imposing a fictitious upper limit equal to 1.375, 1.35, 1.30 and 1.25 time the nominal yielding of the steel quality; in such a way, all results coming from simulations characterized by seismic link yielding higher than fixed limits were not considered. These limits were equivalent to impose a fictitious quality control for the seismic qualification, according to [6] or more severe limits, of steel profiles produced according to EN10025 [20]. Upper yielding definition reduced the number of useful material samples (variables) employable in the failure probability estimation; this reduction was more marked, as expected, for S275 quality being a steel quality less controlled than S355. In the Figure 16 it has been reported the effect of imposing an upper limit of 1.375 times the nominal yielding on link 1 properties for frame 3X and 16X: the upper yielding limit has no effect on generated samples while the effect is stronger for S275.

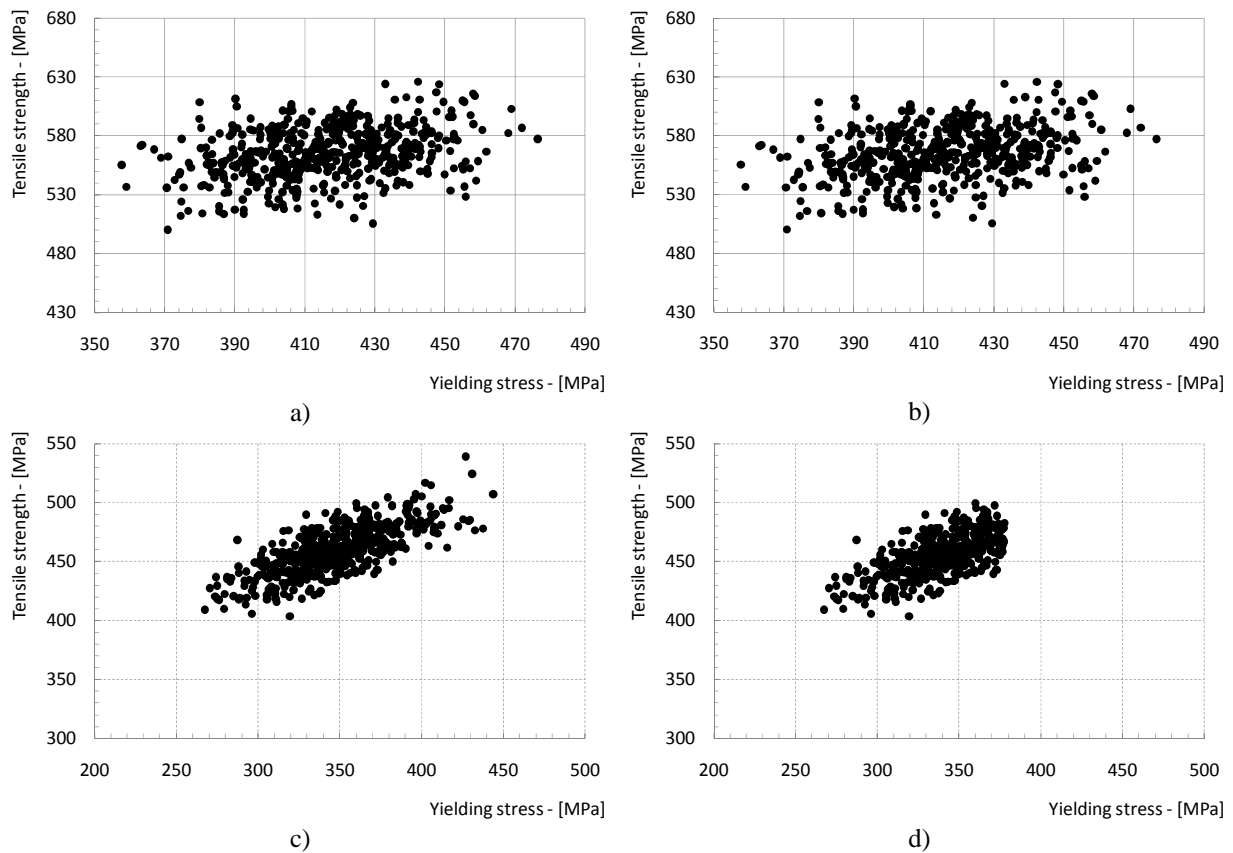

Figure 16: a) S355 without upper limit on f_y ; b) S355 with upper limit on f_y equal to 1.375; c) S275 without upper limit on f_y ; d) S275 with upper limit on f_y equal to 1.375.

Results in terms of annual failure probabilities (risk) calculated with the previous procedure are presented in Figures 17a and 17b.

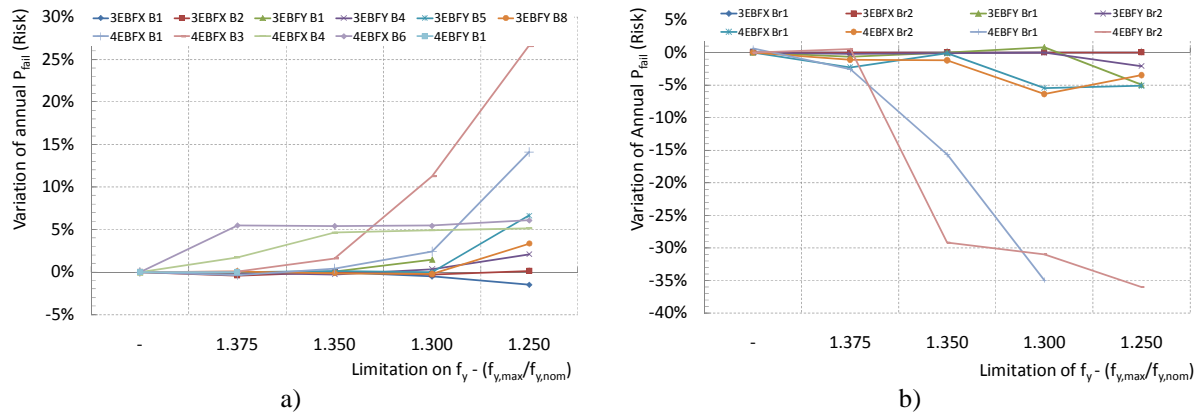

Figure 17: a) variation of risk associated to ultimate plastic rotation of links; b) variation of risk associated to buckling of first storey braces.

The assignation of upper f_y limits produced, as expected, a variation in the risk associated to link rotation and brace buckling; in particular, the annual probability of the link failure increased from 2% to 25% also while probability associated to braces failure decreased from 1% to 35%. According to these results it is clear that the definition of upper f_y limits must be accurately evaluated in order to do not unbalance too much the design in the exploitation of link plastic resources over its failure. At the same time it is also clear that the big decreasing of risk associated to brace failure is related to 4EBFY only, in which braces were really optimized (i.e. Capacity Design=Buckling Strength); in the other cases, more adherent to day-to-day practice, a little over-sizing (i.e. C.D.=0.92B.S.) furnished maximum variations of risk about -6%, mitigating strongly the effects of upper f_y limit. It is worth noting that the benefits and the safety increment associated to additional controls for the seismic qualification of steel profiles must be carefully evaluated because structural safety herein estimated, considering both seismic input and material variability – Tables 9a-9f, is in-line with nominal values proposed by experts for the structural cases – 3EBFX, 3EBFY, 4EBFX, 4EBFY, 16EBFX and 16EBFY – under exceptional loading situation as earthquake.

AKCNOWLEDGEMENT

The results presented in this work were obtained in the framework of the OPUS research project, Optimizing the seismic Performance of steel and steel-composite concrete strUctures by Standardizing material quality control, funded by European Commission through Research Fund for Coal and Steel, contract RFCR-CT-2007-00039. Authors would like to thank dr. Max Guendel from RWTH for his support in the artificial earthquakes generation. Nevertheless opinions expressed in this paper are those of the writers and do not necessarily reflect those of the sponsors.

Abstract. *For the purpose of energy dissipation steel structures exposed to seismic loading intentionally experience inelastic material behavior. Experiments of mild construction steel have shown that the behavior of structural steel is highly sensitive to loading velocity. Under cyclic loading, the Bauschinger effect decreases the yield stress. In addition, the steel suffers from material damage if the material is subjected to inelastic deformations.*

Therefore, to evaluate the structural safety of steel structures in case of earthquakes, a more detailed description of the material behavior is inevitable. The proposed material model describes the evolution and distribution of inelastic strains and damage in steel structures under seismic excitation by means of a set of internal variables. The model takes into account viscoplastic material behavior, isotropic and kinematic hardening, ductile damage, and a nonlocal extension in the form of an implicit gradient formulation to overcome the phenomenon of strain localization. To determine the material model parameters, numerical results are compared with experiments under static and dynamic loading. In order to indicate the influence of the description of the material behavior on the response of 3D structures subjected to seismic excitation different approaches for the material are used.

1 INTRODUCTION

Earthquakes are unpredictable disasters which can damage structures severely and therefore endanger human safety. Thus, building codes in periled regions have to include methods to verify this special loading. The European code EC 8 uses the linear response spectrum method to specify static forces which act on the structure. The response spectrum is determined for elastic material behavior and the verification does not differ from static load cases. Material-dependent energy dissipation is taken into account by decreasing the response spectrum, and therefore the load, by a factor. This is a simple practical approach which considers the material behavior in a very general way depending on the method of construction.

Moreover the EC 8 also permits nonlinear time-history computations, but demands precise material modelling to capture the energy dissipation. In order to predict the structural response to seismic loading the inelastic material behavior, that accounts for the dissipation of energy, needs to be described in detail. Along with inelastic deformations a deterioration of the material can be observed, which is referred to as damage. It evolves from voids in the microstructure and this microstructural damage, which is not visually detectable from the outside, can increase over time and finally lead to macrocracks and failure [1, 2]. This paper focuses on a method to predict even small damage with a high precision. For that purpose, a continuum damage model is developed in the framework of thermodynamics taking into account the evolution of the material behavior including phenomena like hardening, softening, and damage. Since softening and damage are always accompanied by localization of deformation in small process zones of undefined width, local damage models suffer from a dependency on the fineness of finite-element discretization. As a remedy an implicit gradient enhanced formulation for a non-local damage variable is introduced which includes an additional material-dependent parameter to affect the size of the process zone.

Applying the proposed model to a FE analysis of a structure provides the distribution of damage across the structure. Therefore, highly stressed regions can be identified, but it is not possible to evaluate the damage state of the structure in general which encourages the formulation of a scalar global damage index.

2 MATERIAL MODEL

For the designing of steel constructions linear elastic material behavior is generally considered. To increase the degree of utilization plastic material behavior can be taken into account through a plain linear elastic ideal plastic stress-strain relationship.

For static loads these assumptions are conservative. To compute the response of a structure excited by earthquakes this simplified description of the material behavior is insufficient.

2.1 Material behavior of mild construction steel

To reveal the material behavior of mild construction steel subjected to seismic loading, experiments have been conducted at the Technische Universität Braunschweig [3]. Figure 1 depicts the measured stress of a uniaxial bar loaded by a strain record deduced from the north-south component of the 1995 Kobe earthquake. The characteristic yield stress occurs only for the first load path. Beginning with the first reverse loading hysteresees develop which exhibit a continuous transition between the linear elastic and the nonlinear inelastic range. The hysteresis shape shows that the initiation of plastic deformations occurs earlier after load reversals. This phenomenon called Bauschinger effect can be taken into account by kinematic hardening. Repeated cyclic straining with strain amplitudes $> 6\%$ leads to cyclic increase of the yield

stress which can be described by isotropic hardening. Moreover, experiments have shown that the cyclic deformation behavior of mild steel is closely related to the inelastic strain amplitude history [4, 5]. In order to consider this fact, a strain memory surface is integrated into the model.

Figure 1: Hysteresis curves and development of stress of the Kobe earthquake obtained experimentally [3]

At the level of atoms inelastic deformations decrease the number of bonds which leads to material deterioration with an impairment of the elementary area of resistance. This damage is, in general, strongly anisotropic and can be observed as growing microvoids which eventually results in macroscopic cracks. For a low alloy steel Figure 2 shows the microscopic debonding of a notched specimen after cyclic loading. The cross section is deteriorated although a macro-crack cannot be located yet. The existence of damage in mild steel is investigated for example in [7, 8].

Figure 2: Metallographic section of a notched specimen after cyclic loading according to [6]

For the description of damage evolution a model is proposed which bases on the isotropic ductile damage model for monotonic loading presented in [9]. Modifications adjust the model to micromechanical observations under cyclic straining. The initiation of ductile damage is difficult to specify. Experiments have shown that nucleation of cavities does not occur below a certain amount of plastic strain. However, it is hard to determine this threshold so that a large variety of different proposals is available in literature. This work uses a threshold based on the equivalent plastic strain in order to capture the characteristics of mild construction steel. Since mild construction steel S 355 does not show pronounced damage in the form of a continuous reduction of the modulus of elasticity for cyclic loading with small strain amplitudes [10], the

model prohibits damage evolution below a certain amount of plastic strain. But ductile damage due to irregular large cyclic straining is captured. The chosen criterion enables ductile damage evolution under large strains and thus provides a precise method in order to describe damage evolution under seismic loading.

2.2 Material equations

The mathematical description of the material behavior is achieved by a set of ordinary differential equations of first order with respect to time. The current state of the material is described by internal variables and related evolution equations, which can be derived from thermodynamics. The material equations contain isotropic nonlocal damage \bar{D} .

Assuming small strains, the total strain rate can be split up additively in an elastic and an inelastic part

$$\dot{\epsilon} = \dot{\epsilon}^{el} + \dot{\epsilon}^{in}. \quad (1)$$

The elastic strain rate is based on Hooke's law and contains an isotropic degradation of the modulus of elasticity by the damage variable \bar{D} following the principle of energy equivalence [11]. Considering the influence of damage on stiffness under alternating tension and compression, it is assumed according to Lemaitre [12] that some but not every crack closes under compression so that the stiffness of the material under compression lies between the undamaged and the damaged stiffness. In order to define the compressive stiffness of damaged material a crack closure parameter h is introduced. Thus, effective stress and strain are defined differently for tension (+) and compression (-):

$$\tilde{\sigma}^+ = \frac{1}{1-D} \cdot \sigma^+ \quad , \quad \tilde{\epsilon}^+ = (1-D) \cdot \epsilon^+ \quad (2)$$

I .t
the)
use c
load

Figure 3: Stiffness under tension and compression

The inelastic viscoplastic deformations are obtained following the approach by Chaboche and Rousselier [1, 2]. The over-stress σ_{ex} , that determines the onset of viscoplastic deformation,

corresponds to the yield function and results from a modified criterion based on Gurson [13] and Tvergaard and Needleman [14] with the first ($J_1(\boldsymbol{\sigma}_{eff}) = \frac{1}{3}tr(\boldsymbol{\sigma} - \mathbf{X})$) and the second ($J_2(\boldsymbol{\sigma}_{eff}^d) = \frac{1}{2}tr((\boldsymbol{\sigma} - \mathbf{X})^d \cdot (\boldsymbol{\sigma} - \mathbf{X})^d)$) invariant of the effective stress tensor $\boldsymbol{\sigma}_{eff} = \boldsymbol{\sigma} - \mathbf{X}$ and the effective stress deviator $\boldsymbol{\sigma}_{eff}^d = (\boldsymbol{\sigma} - \mathbf{X})^d$, respectively

$$\sigma_{ex} = \sigma_{eq} - \sigma_F - K = \frac{1}{1 - \bar{D}} \sqrt{3J_2(\boldsymbol{\sigma}_{eff}^d) + \bar{D}J_1(\boldsymbol{\sigma}_{eff})^2} - \sigma_F - K. \quad (4)$$

The yield function considers isotropic hardening K and kinematic hardening \mathbf{X} which appropriately describe inelastic behavior according to Chaboche and Rousselier in case of undamaged material by the v. Mises yield criterion.

Figure 4: Yield surface

Figure 4 depicts the v. Mises yield cylinder for undamaged material and the contraction of the yield surface combined with a formation of caps at the ends of the yield cylinder due to damage. In case of damage, the yield function employs volumetric inelastic deformations and permits coupling of viscoplasticity and damage.

The initiation of damage is determined by a damage threshold surface which is defined via the equivalent positive plastic strain

$$\varepsilon_{eq}^{in} = \sqrt{\frac{2}{3} (\langle \varepsilon_{11}^{in} \rangle^2 + \langle \varepsilon_{22}^{in} \rangle^2 + \langle \varepsilon_{33}^{in} \rangle^2 + 2\langle \varepsilon_{12}^{in} \rangle^2 + 2\langle \varepsilon_{13}^{in} \rangle^2 + 2\langle \varepsilon_{23}^{in} \rangle^2)} \quad (5)$$

where the McAuley brackets omit negative strains and thus prohibit damage evolution under compression. The equivalent strain has to exceed the scalar damage threshold strain parameter ε_D^{in} for damage evolution

$$\begin{aligned} \varepsilon_{eq}^{in} - \varepsilon_D^{in} \leq 0 &\longrightarrow \dot{D} = 0 \\ > 0 &\longrightarrow \dot{D} \end{aligned} \quad (6)$$

While Pirondi and Bonora [15] propose that the damage threshold strain decreases under compression due to the presence of broken inclusions, the damage threshold strain here is assumed

to be constant.

In order to consider different damage evolution under tension and compression, the evolution of local ductile damage

$$\dot{D} = (c_1 + c_2 e^{-c_3 \frac{1}{(1-\bar{D})} p^+}) \frac{1}{(1-\bar{D})} \dot{p}^+ + c_4 (c_5 - \bar{D}) \left\langle \text{tr} \left(\frac{\partial \sigma_{ex}}{\partial \boldsymbol{\sigma}} \dot{p}^+ \right) \right\rangle \quad (7)$$

depends on a newly defined variable p^+ called active accumulated plastic strain based on [15]:

$$\dot{p}^+ = \dot{p} \left\langle \frac{J_1}{|J_1|} \right\rangle = \dot{\epsilon}_0 \left\langle \frac{\sigma_{ex}}{\sigma_p} \right\rangle^n \left\langle \frac{J_1}{|J_1|} \right\rangle. \quad (8)$$

Thus, the evolution of ductile damage is enabled only if the first invariant of the stress tensor is positive. The two terms of the damage evolution equation (7) consider transient and saturation behavior in damage evolution as well as damage due to volumetric yielding and depend on the damage parameters $c_1 - c_5$.

The memory of the strain loading history is considered by a strain memory surface M , which depends on two variables β and q where β describes the displacement of the surface and q specifies its amplitude. Within this work, a maximum strain amplitude memory [4] is defined in the three-dimensional space as

$$M = \frac{2}{3} (\boldsymbol{\epsilon}^{in} - \boldsymbol{\beta}) (\boldsymbol{\epsilon}^{in} - \boldsymbol{\beta}) - q^2 \leq 0 \quad (9)$$

with

$$\dot{\boldsymbol{\beta}} = 0.5 H(M) \dot{\boldsymbol{\epsilon}}^{in}, \quad (10)$$

$$\dot{q} = 0.5 H(M) \mathbf{n}_F \mathbf{n}_M \dot{p}, \quad (11)$$

where $H(M)$ is the Heaviside function with $H(M) = 1$ if $M \geq 0$ and $H(M) = 0$ if $M < 0$, \mathbf{n}_F is the normal to the yield surface, and \mathbf{n}_M is the normal to the strain memory surface. A plastic strain state outside the current strain memory surface leads to the growth and adjustment of the variables β and q , while β and q remain constant for plastic strain states inside the memory surface. Thus, the inelastic strain amplitude variable q will not decrease and always remembers the maximum strain reached so far during loading.

Considering the influence of the strain memory surface on isotropic hardening, the saturation value of isotropic hardening Q becomes a function of the amplitude of the strain memory surface q . Within this work, the evolution rule of the saturation value of isotropic hardening Q is assumed to be linear.

As shown in Figure 5 the numerical results according to the proposed model match the measured stress, comparing Figure 1, very well. Solely the observed yield plateau cannot be described with the given model.

2.3 Non-local extension

The dissipation of energy concentrates on small areas of the structure called process zones. With the grave decrease of stiffness when reaching inelastic material behavior this causes high strain gradients. If the size of the process zone is not defined in a finite element computation the results of local damage models depend on the fineness of discretization. Reducing the element

Figure 5: Hysteresis curves and development of stress of the Kobe earthquake obtained by numerical simulation

size leads to a decreasing process zone and less energy dissipated. It is obvious that for an evanescent volume and therefore inelastic material behavior without dissipation the description is physically incorrect and an extension to provide accurate results is needed. Mathematically, the problem becomes ill-posed since the differential equations lose their elliptic form and the acoustic tensor of the tangential stiffness tensor becomes singular [12, 16].

In order to determine the size of the process zone and to regularize the solution, the models need to be extended by a material-dependent internal length scale. An overview of the state of the art for different non-local extensions may be found in [17, 18]. Peerlings et al. [19] and Engelen et al. [20] show the derivation of models with gradients of internal variables from nonlocal integral models and differentiate between explicit and implicit gradient models.

This work examines the use of non-local implicit gradient models in 3D-FE structural analysis. By means of an additional gradient equation, non-local substitutes of the local variables can be obtained. Following the derivation of Engelen [20] and using gradients of the damage variables, the non-local damage variable \bar{D} can be determined by the gradient equation

$$\bar{D} - l_c^2 \nabla^2 \bar{D} = D \quad (12)$$

with the local damage variable D for which its evolution equation is given with Eq. 7, the material-specific internal length l_c and the boundary condition $\nabla \bar{D} = 0$.

3 STRUCTURAL ANALYSIS

The structural response to seismic excitation is described by equation of motion

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{B}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{M}\ddot{\mathbf{u}}_g \quad (13)$$

with the measured ground acceleration vector $\ddot{\mathbf{u}}_g$. Damping is considered through a numerical approach using the velocity-dependent term $\mathbf{B}\dot{\mathbf{u}}$ as well as energy dissipation through inelastic straining and damage evolution. The stiffness of the structure, represented by \mathbf{K} , depends on the development of hardening, softening and damage.

3.1 Discretization

Stress-deformation analysis of structures implies the solution of the underlying initial boundary value problem of the body Ω . With the principle of virtual work the weak form of the

equation of motion can be obtained

$$\begin{aligned} \int_{\Omega} \delta \mathbf{u} \cdot \rho \ddot{\mathbf{u}} d\Omega + \int_{\Omega} \delta \mathbf{u} \cdot \mathbf{f} d\Omega + \int_{\Omega} \delta \boldsymbol{\varepsilon} : \boldsymbol{\sigma} d\Omega = \\ \int_{\Omega} \delta \mathbf{u} \cdot \mathbf{p} d\Omega + \int_{\partial\Omega} \delta \mathbf{u} \cdot \bar{\mathbf{t}} d\partial\Omega + \int_{\Omega} \delta \mathbf{u} \cdot \rho \ddot{\mathbf{u}}_g d\Omega \end{aligned} \quad (14)$$

with virtual displacement vector $\delta \mathbf{u}$ and virtual Almansi strain tensor $\delta \boldsymbol{\varepsilon}$, density ρ , acceleration vector $\ddot{\mathbf{u}}$, damping force \mathbf{f} , Cauchy stress tensor $\boldsymbol{\sigma}$, volume load vector \mathbf{p} , surface load vector $\bar{\mathbf{t}}$. Assuming linear kinematics $\boldsymbol{\varepsilon} = \nabla \mathbf{u}$ and Rayleigh damping $\mathbf{f}_c = \mathbf{c} \dot{\mathbf{u}}$, Equation (14) is discretized in space with the finite-element method, while the Newmark method is used for the discretization in time.

The material behavior is connected to the equation of motion via Cauchy stresses $\boldsymbol{\sigma}$ which are coupled with Almansi strains $\boldsymbol{\varepsilon}$ and internal variables \mathbf{V}

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}(\boldsymbol{\varepsilon}, \mathbf{V}) = \boldsymbol{\sigma}(\boldsymbol{\varepsilon}, r, \boldsymbol{\alpha}, D) \quad (15)$$

where the latter characterize the state of the material (hardening, softening, damage). The material equations, see Section 2.2, are discretized in time using the implicit Euler approach.

Equation (12) can be assumed to be time-independent since the spatial propagation of the nonlocal damage variable \bar{D} is very fast compared to the evolution of the other variables. The weak form of the additional partial differential equation for the non-local damage field \bar{D} results from weighted residua

$$\int_{\Omega} (\delta \bar{Y} (\bar{D} - D) - \nabla \delta \bar{Y} l_c^2 \nabla \bar{D}) d\Omega - l_c^2 \int_{\partial\Omega} \delta \bar{Y} \bar{t}_{\bar{D}} d\partial\Omega = 0 \quad (16)$$

with the virtual nonlocal energy release rate $\delta \bar{Y}$ and Neumann boundary condition $\bar{t}_{\bar{D}} - \mathbf{n} \nabla \bar{D} = 0$, which prohibits a damage flux through the boundary of the domain. Here, $\bar{t}_{\bar{D}}$ is forced to zero. The gradient equation is discretized in space by the finite-element method.

Structural analysis is performed using triquadratic twentyseven-node brick elements for the spatial discretization of the field of displacement and the field of damage. The discretization in time uses linear approximations for the material variables while the approximations for the unknowns of the equation of motion depend on the choice of the Newmark integration parameters α and β (see for example [21]). Here, the Newmark integration parameters are set to $\alpha = \frac{1}{2}$ and $\beta = \frac{1}{4}$ which leads to the approach of constant mean acceleration. If damping is considered via Rayleigh damping the parameters $c_{\alpha} = 0.01$ and $c_{\beta} = 0.001$ are employed.

3.2 Global damage index

In order to characterize the damage state of the whole structure a global damage index has to be defined. There exists a large variety of different damage indices from literature and they all agree in having a range between 0 and 1, where 0 corresponds to the undamaged state and 1 to the state of failure [22]. Global damage indices for steel structures are for example proposed by [23, 24, 25], but not all rest on the transformation of damage variables into one global index. Colombo [26], for example, develops an index that takes into account the maximum attained deformation and the energy dissipation in ductile and brittle elements. Ghobarah et al. [27] propose an index which depends on the initial and final stiffness of the structure before and

after the earthquake obtained by push-over analysis. However, if the global damage measure is calculated directly, the local damage distribution remains unknown. In this contribution the indicator for global damage, in the following abbreviated as *GDI*, is based on the eigenvalue decomposition

$$[\mathbf{K}_t - \lambda_{t,i}^2 \mathbf{K}_0] \mathbf{v}_{t,i} = \mathbf{0} \quad (17)$$

where $\lambda_{t,i}$ are the eigenvalues, $\mathbf{v}_{t,i}$ are the eigenvectors, \mathbf{K}_0 is the initial stiffness matrix and \mathbf{K}_t is the current stiffness matrix due to hardening, softening and damage. Further information concerning this index can be found in [28].

3.3 Seismic excitation of cantilever

In the following the influence on results of structural analysis of different levels of precision concerning the material model is presented for a cantilever consisting of an IPE 80 profile. Moreover the global damage index is evaluated for this structure.

With a height of 5 m and an additional mass of 380 kg assigned to the top the investigated cantilever has an eigenfrequency of 0.55 Hz. The structure is subjected to the north-south component of the Kobe earthquake from 1995 acting in the direction of the strong profile axis, see Figure 6.

Figure 6: Cantilever and acceleration record of the north-south component of the Kobe earthquake (1995)

In a first analysis elastic material behavior is assumed and damping is neglected. Figure 7(a) depicts the displacement at the top of the cantilever over time. The maximum value of displacement is 69 cm. It is obvious that the vibration mainly consists of the first eigenfrequency. The missing of any damping leads to an increasing displacement even when the amplitudes of the ground acceleration decrease.

For a more detailed simulation the material model is extended by viscoplastic material behavior including isotropic and kinematic hardening. The earthquake causes inelastic cyclic straining in the bottom part of the cantilever. The hystereses in the material behavior lead to dissipation of energy and the top displacement is reduced compared to the elastic behavior. The maximum deflection is 42 cm. Considering the frequencies involved in the vibrations, depicted in the frequency spectra in Figure 7(b), it can be noticed that the amplitude decreases. Furthermore no shift of the involved frequencies can be observed although damping is included by the material model.

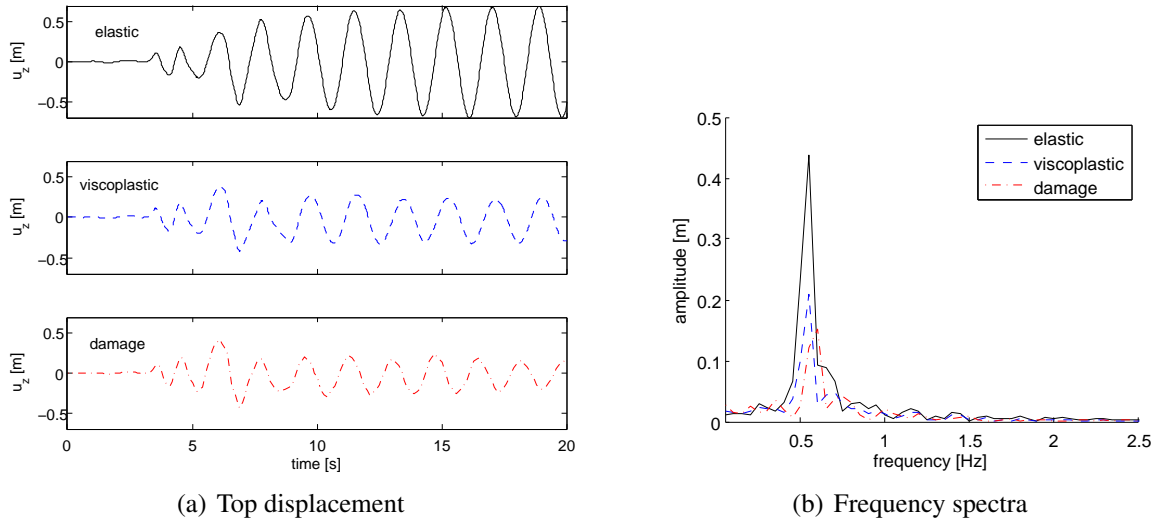

Figure 7: Displacement of the cantilever top and frequency spectra for elastic, viscoplastic and damaged material

Finally the complete proposed model is applied to compute the response of the cantilever, also considering Rayleigh damping. With about 44 cm the displacement is slightly larger than for the viscoplastic material which is caused by the softening. Because of large inelastic strain material damage evolves at the base of the cantilever. As an example Figure 8(b) shows the distribution of damage throughout the base of a strongly damaged HEA 180 cantilever. It can be seen that damage occurs in the flanges which are subjected to high alternating tension and compression. Evidently the shear bands accumulate damage and weaken the structure. To evaluate the damage state of the cantilever the global damage index is computed for every timestep, see Figure 8(a). The highest rise of the index corresponds to the largest displacement. With falling intensity of the ground acceleration the damage only increases slightly due to the inelastic deformations remaining below a threshold or only occurring in small exposed regions. The decreasing top displacement is mainly caused by the included numerical damping. The structure shows a slight permanent deformation of 3 cm, since the free vibration does not occur around its zero position.

The deteriorated material at the cantilever base reduces the stiffness of the structure and leads to a shift of the eigenfrequencies which can be seen in the frequency spectrum, see Figure 7(b).

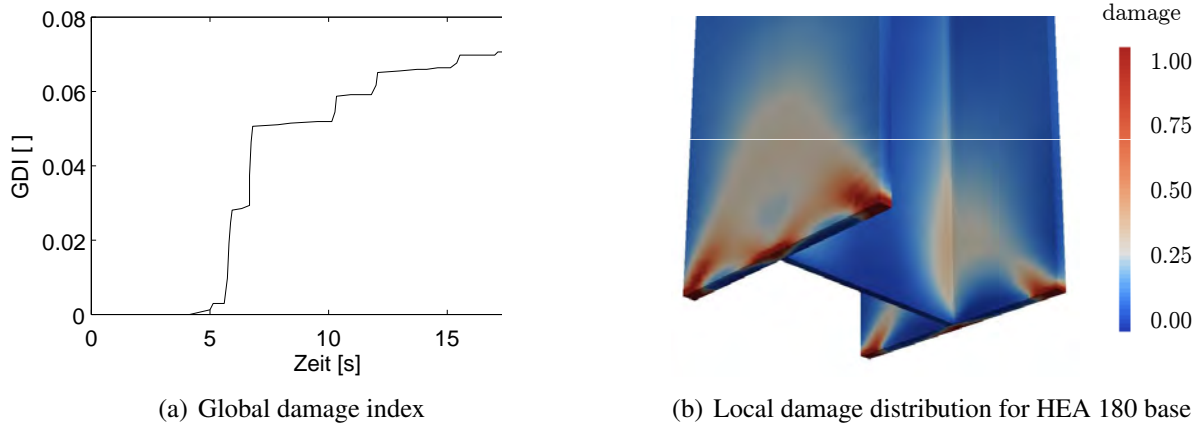

Figure 8: Damage evolution of the cantilever

4 CONCLUSIONS

Nonlinear time-history computations of structures subjected to earthquakes are possible if material models are used which are able to describe the viscoplastic material behavior. Furthermore the material deterioration has to be taken into account since the softening of the material leads to a shift of the eigenfrequencies and therefore to a different response to the stochastic acceleration.

Keywords: Optimum Design, Steel Structures, Particle Swarm Optimization, EC3

Abstract. *A number of optimization algorithms have been used in structural design optimization in the past, ranging from gradient-based mathematical algorithms to probabilistic-based search algorithms, for addressing global non-convex optimization problems. Many probabilistic-based algorithms have been inspired by natural phenomena, such as Evolutionary Programming (EP), Genetic Algorithms (GA), Evolution Strategies (ES), among others. Recently, a family of optimization methods has been developed based on the simulation of social interactions among members of a specific species.*

One of these methods is the Particle Swarm Optimization (PSO) method that is based on the behavior reflected in flocks of birds, bees and fish that adjust their physical movements to avoid predators and seek for food. In PSO, as in GA, a population of potential solutions is considered and utilized to search within the design space. However, its members do not reproduce but rather communicate with each other their knowledge of solutions in order to reach the optimum. Each “particle”, “flies” through the multi-dimensional design space, with a certain velocity vector for each iteration.

In this study, a discrete PSO algorithm is employed for the optimization of 2D and 3D steel frames and the results are compared to the ones obtained with a discrete GA. Both methods are applied in single-objective, discrete, constrained structural engineering optimization problems where the aim is to minimize the weight of the steel structure under various constraints on displacements and forces (biaxial bending with axial force and shear force) which are based on Eurocode 3.

The constraints are checked by performing a Finite Element analysis for every candidate optimum design. A new linear analysis software tool for three-dimensional frames has been developed, featuring some distinct characteristics. The applied loads can be nodal or elemental (uniform, triangular or trapezoidal in any direction within an element), while any release (translational or rotational) can be implemented at an end of any element, in any of the 6 Degrees Of Freedom (DOFs). The output of the analysis program includes the constraint reactions, nodal displacements, forces at the ends of the elements, plus the displacements of the released DOFs of all elements with releases, and any displacement or any force at any given point within an element. The accuracy of the analysis results is verified by a direct comparison to the corresponding results of a reliable commercial finite element software program.

For each method, the performance, functionality and effect of different setting parameters are studied. After a fine tuning of the parameters, the results are compared to each other. The comparison is done with regard to the speed of convergence, in terms of number of objective function evaluations, and accuracy of the solution. Various 2D and 3D steel structures are considered as test examples.

1 DESIGN OPTIMIZATION

1.1 Formulation of a single-objective optimization problem

The formulation of a generic single-objective optimization problem can be written as follows:

$$\begin{aligned}
 & \min_{\mathbf{x} \in \mathbb{R}^n} f(\mathbf{x}), \quad \mathbf{x} = [x_1, \dots, x_n]^T, \quad f \in \mathbb{R} \\
 & \text{Subject to} \\
 & \mathbf{g}(\mathbf{x}) \leq 0, \quad \mathbf{g} \in \mathbb{R}^p \\
 & \mathbf{h}(\mathbf{x}) = 0, \quad \mathbf{h} \in \mathbb{R}^q \\
 & x_i \in X_i \quad \text{for } i = 1, \dots, n
 \end{aligned} \tag{1}$$

where:

- $\mathbf{x} = [x_1, \dots, x_n]^T$ is a vector of length n containing the design variables.
- X_i is the set of x_i , which may be continuous, discrete or integer. The whole design space for the n design variables can be denoted as X .
- $f(\mathbf{x}): \mathbb{R}^n \rightarrow \mathbb{R}$ is the objective function, which returns a scalar value to be minimized.
- $\mathbf{g}(\mathbf{x})^T = [g_1(\mathbf{x}), \dots, g_p(\mathbf{x})]$ is the vector function of p inequality constraints.
- $\mathbf{h}(\mathbf{x})^T = [h_1(\mathbf{x}), \dots, h_q(\mathbf{x})]$ is the vector function of q equality constraints.

In structural design optimization, inequality constraints are mainly used, since equality constraints are not applicable for real-world problems. If the objective function is the weight of the structure, it is given by

$$f(\mathbf{x}) = \rho \cdot \sum_{i=1}^{N_e} A_i \cdot L_i \tag{2}$$

where ρ is the material density, N_e is the number of elements of the model and A_i, L_i are the cross sectional area and the length of each element, respectively.

1.2 Discrete and continuous formulations

In structural design optimization, due to manufacturing limitations, the design variables are not described by continuous functions but are discrete variables [1] since cross-sections have usually to belong to a certain predefined set provided by the manufacturers. There are also cases where the design variables are mixed, continuous and discrete, e.g. in a topology-sizing optimization problem where the design variables include nodal coordinates (continuous) as well as beam cross-sectional sizes (discrete).

With the general formulation of Eq. (1), the design variables may have continuous, discrete or integer values, or a combination of them, with the restriction

$$x_i \in X_i \quad \text{for } i = 1, \dots, n \tag{3}$$

where X_i is the set of the design variable x_i , which may be continuous or discrete. When discrete design variables are only used, then the available set of values is clearly defined. When continuous design variables are considered, then the above restriction is usually written as

$$\mathbf{x}^L \leq \mathbf{x} \leq \mathbf{x}^U \quad (4)$$

where \mathbf{x}^L and \mathbf{x}^U are two vectors of length n containing the lower and upper bounds of the design variables, respectively.

Various methods have been proposed for dealing with mixed problems, with continuous and discrete design variables [2]. Usually discrete variables are handled as equivalent continuous variables, and at the end of the optimization process the design variables are given the appropriate discrete values, as close as possible to the optimal continuous values [3]. In case of a discrete problem where the design space can be univocally arranged for all the characteristics of the cross sections, the above method can give a good approximation of the discrete optimum solution. Nevertheless, in realistic engineering problems this may not be the case. Most of the methods that have been proposed convert the mixed problem to a series of continuous problems that are solved consecutively [4-6].

In the present study, a discrete optimization problem is studied, where the design variables are the cross sections of the elements of the steel structure, which belong to predefined sets given by the manufacturers, as described in detail in the numerical examples section.

1.3 Particle Swarm Optimization (PSO)

Many probabilistic-based search algorithms have been inspired by natural phenomena, such as Evolutionary Programming, Genetic Algorithms, Evolution Strategies, among others. Recently, a family of optimization methods has been developed based on the simulation of social interactions among members of a specific species looking for food or resources in general. One of these methods is the *Particle Swarm Optimization* (PSO) method that is based on the behavior reflected in flocks of birds, bees and fish that adjust their physical movements to avoid predators and seek for food. The method has been given considerable attention in recent years among the optimization research community.

A swarm of birds or insects or a school of fish searches for food, resources or protection in a very typical manner. If a member of the swarm discovers a desirable path to go, the rest of the swarm will follow quickly. Every member searches for the best in its locality, learns from its own experience as well as from the others, typically from the best performer among them. Even human beings show a tendency to behave in this way as they learn from their own experience, their immediate neighbors and the ideal performers in the society. The PSO method mimics the behavior described above. The algorithm was first proposed by Kennedy and Eberhart [7]. It is a population-based optimization method built on the premise that social sharing of information among the individuals can provide an evolutionary advantage.

PSO has been found to be highly competitive for solving a wide variety of optimization problems [8-14]. A number of advantages over other algorithms make PSO a prospective candidate to be used also in structural optimization problems. It can handle non-linear, non-convex design spaces with discontinuities. Compared to other non-deterministic optimization methods it is considered efficient in terms of number of function evaluations as well as robust since it usually leads to better or the same quality of results. Its easiness of implementation makes it more attractive as it does not require specific domain knowledge information, while being a population-based algorithm, it can be straight forward implemented in parallel computing environments leading to a significant reduction of the total computational cost.

Compared to GA, PSO is easier to implement and there are only a few parameters to adjust. PSO has been successfully applied to many fields, such as mathematical function optimization, artificial neural network training and fuzzy system control. Promising results have been presented in the areas of structural shape optimization [15, 16] as well as topology optimization [17]. Perez and Behdinan [13, 18] implemented the PSO algorithm for constrained structural optimization of plane and space truss structures while Li et al. [19] tried a heuristic PSO scheme for the optimization of truss structures.

The general concept of the PSO method involves a swarm, modeled as a number of individual particles, moving through the search space in search of the global optimum. The particles communicate with their neighbors the progress made so far and adjust their moving velocity according to that information. In the beginning, a population of candidate solutions is created randomly, each of which is considered to be a particle moving through the multi-dimensional design space in search of the position of the global optimum. The particle can be characterized by its physical position in the space and its velocity vector, while it has the ability to remember two things. The first is the best position it has “seen” so far (local best or LBest) and the second is the best position that any particle of the swarm has “seen” so far (global best or GBest). The latter is possible because each particle has the ability to communicate with a number of neighboring particles, which are defined by a predetermined network topology. The fitness of each particle shows the quality of each solution and is evaluated by a fitness function. In every iteration, the velocity of the particle is adjusted stochastically in combination with those two quantities that the particle remembers and its new position is determined by the old one and the new velocity vector. The update equations for the speed and position of a particle are:

$$\mathbf{v}^j(t+1) = w\mathbf{v}^j(t) + c_1\mathbf{r}_1 \circ (\mathbf{x}^{\text{Pbj}} - \mathbf{x}^j(t)) + c_2\mathbf{r}_2 \circ (\mathbf{x}^{\text{Gb}} - \mathbf{x}^j(t)) \quad (5)$$

$$\mathbf{x}^j(t+1) = \mathbf{x}^j(t) + \mathbf{v}^j(t+1) \quad (6)$$

where w is the inertia weight, $\mathbf{v}^j(t)$ denotes the velocity vector of particle j at time t , $\mathbf{x}^j(t)$ represents the position vector of particle j at time t , vector \mathbf{x}^{Pbj} is the memory of particle j at current iteration (the personal best ever position of the particle, corresponding to the objective function value $Pbest_j$), and vector \mathbf{x}^{Gb} is the global best location found by the entire swarm up to the current iteration (corresponding to the objective function value $Gbest$, the same for all particles). The acceleration coefficients c_1 and c_2 represent “trust” settings which indicate the degree of confidence in the best solution found by the individual particle (c_1 - cognitive parameter) and by the whole swarm (c_2 - social parameter), respectively, while \mathbf{r}_1 and \mathbf{r}_2 are two vectors containing random numbers with uniform distribution in the interval $[0, 1]$.

The symbol “ \circ ” denotes the Hadamard product (entry-wise vector or matrix multiplication). For instance, for two matrices A and B with size 2×2 the Hadamard product is the following:

$$A \circ B = \begin{bmatrix} a_{11}b_{11} & a_{12}b_{12} \\ a_{21}b_{21} & a_{22}b_{22} \end{bmatrix} \quad (7)$$

The basic parameters of the PSO algorithm and their common values are presented in Table 1.

Symbol	Description	Details
NP	Number of particles	A typical range is 10-40. For most problems 10 particles is sufficient enough to get acceptable results. For some difficult or special problems the number can be increased to 50-100.
n	Dimension of particles	It is determined by the optimization problem.
w	Inertia weight	Usually is set to a value less than 1. It can also be updated during iterations. A linear, decreasing variation is common.
$\mathbf{x}^L, \mathbf{x}^U$	Vectors containing the lower and upper bounds of the n design variables, respectively	They are determined by the problem to be optimized. Different ranges for different dimensions of particles can be applied in general.
\mathbf{v}_{max}	Vector containing the maximum allowable velocity for each dimension during one iteration	Usually is set as half the length of the allowable interval for the given dimension. Different values for different dimensions of particles can be applied in general. $\left(v^{\max} = \frac{x^U - x^L}{2} \right)$
c_1, c_2	Cognitive and social parameters	They represent "trust" settings which indicate the degree of confidence in the best solution found by the individual particle (c_1 - cognitive parameter) and by the whole swarm (c_2 - social parameter). Usually $c_1 = c_2 = 2$ but other values can also be used, provided that $0 < c_1 + c_2 < 4$ [18]

Table 1: Main PSO parameters.

Figure 1 depicts a particle's movement, in a two-dimensional design space, according to Eqs. (5) and (6). The particle's current position $\mathbf{x}^j(t)$ at time t is represented by the dotted circle at the lower left of the drawing, while the new position $\mathbf{x}^j(t+1)$ at time $t+1$ is represented by the dotted bold circle at the upper right-hand corner of the drawing. It can be seen how the particle's movement is affected by: (i) its velocity $\mathbf{v}^j(t)$; (ii) the personal best ever position of the particle, $\mathbf{x}^{pb,j}$, at the right of the figure; and (iii) the global best location found by the entire swarm, \mathbf{x}^{Gb} , at the upper left of the figure.

In the above formulation, the global best location found by the entire swarm up to the current iteration (\mathbf{x}^{Gb}) is used. This is called a fully connected topology (fully informed PSO), as all particles share information with each other about the best performer of the swarm. Other topologies have also been used in the past where instead of the global best location found by

the entire swarm, a local best location of each particle's neighbourhood is used. Thus, information is shared only among members of the same neighbourhood.

Figure 1: Visualization of the particle's movement in a two-dimensional design space.

1.4 Discrete PSO

In this study a discrete version of the PSO algorithm is applied in order to solve structural optimization problems for steel structures. First, a mapping is performed; every member of a predefined set for the design variables is mapped to an integer number, starting from one. This way, the discrete optimization problem is transformed into an integer optimization problem. It should be noted that not all members should belong to the same discrete predefined set. For example, in a steel frame, the beams can belong to the IPE section group of the Eurocode, while the columns can belong to the HEA or HEB group. There is no limitation in the groups that will be taken into account for the optimization problem.

The discrete PSO algorithm is basically the same as the continuous one with the modification that eq. (5) for the particle's velocity is rounded to their nearest integer value. Using a round function which rounds a number to its nearest integer, the equation for velocity takes the following format:

$$\mathbf{v}^j(t+1) = \text{round} \left[w\mathbf{v}^j(t) + c_1 r_1 \circ (\mathbf{x}^{\text{Pbj}} - \mathbf{x}^j(t)) + c_2 r_2 \circ (\mathbf{x}^{\text{Gb}} - \mathbf{x}^j(t)) \right] \quad (8)$$

For an integer optimization problem of steel structures, where the design variables belong to groups of the Eurocode (IPE, HEA, HEB and others), it was found that the maximum allowable velocity (v_{\max}) should be set equal to 1 (or 2 as a maximum), so that the particles will move around small areas of the discrete design space in each iteration and as a result the probability of approaching the optimum solution will be higher. Of course, this conclusion is not general, as it depends on the size of the section group. For larger sets, the maximum velocity should be set higher, in order to achieve faster convergence.

1.5 Genetic Algorithm

The Genetic Algorithm (GA) method is the most widely used type of Evolutionary Algorithm. In a genetic algorithm, a population of strings (called chromosomes or genotype), which encode candidate solutions (called individuals or phenotypes) of the optimization problem, evolves toward better solutions. Traditionally, solutions are represented in binary form as strings of 0s and 1s, but other encodings are also possible. The evolution usually starts from a population of randomly generated individuals and takes place in generations. In each generation, the fitness of every individual in the population is evaluated, multiple individuals are stochastically selected from the current population based on their fitness, and modified to form a new population. The new population is then used in the next iteration of the algorithm and this procedure goes on until the optimum solution is found or a convergence criterion has been satisfied. Commonly, the algorithm terminates when either a maximum number of generations has been reached, or a satisfactory fitness value has been achieved for a member of the population. The GA method consists of the following processes:

- a) *Encoding* of the information carried by the chromosomes using fixed-length binary strings.
- b) *Fitness evaluation*, where the objective function value is calculated.
- c) *Selection* of members who will become parents and will produce the next generation (Tournament selection, Ranking selection, Roulette Wheel).
- d) *Crossover* operator (Scattered crossover, One-point crossover, Two-point crossover, Uniform crossover, Arithmetic crossover, Heuristic crossover).
- e) *Mutation* operator, which is an operator that inserts a small probability that a single binary bit in a given chromosome will be changed from its initial value. The main purpose of the mutation operator is to maintain diversity within the population and inhibit premature convergence.
- f) *Termination* of the algorithm, when convergence has been achieved.

In a structural constrained optimization problem the steps of the Genetic Algorithm are briefly shown in the following figure

1. *Initialization*: Selection of parent vectors of the design variables, usually randomly.
2. *Analysis and Evaluation*: Evaluation of the parents by the fitness function.
3. *Feasibility Check*: If not all parents are feasible, modification of infeasible parents and back to step 2.
4. *Genetic Operators*: Mutation of all members and crossover of parents to produce offspring.
5. *Analysis and Evaluation*: Evaluation of the offspring by the fitness function.
6. *Feasibility Check*: If not all offspring are feasible, discard infeasible offspring and back to step 4.
7. *Genetic Operators*: Selection, mutation and crossover of the next generation parents.
8. *Termination Criterion*: If any one of the termination criteria is reached then stop, else go back to step 4.

Figure 2: GA steps in constrained optimization problems.

1.6 Constraint Handling Technique for PSO

The structural optimization problems are subjected to a number of inequality constraints. These constraints impose limitations to the values that the design variables can take and limit the available search space in which the optimum solution can be searched and found. In general, different optimization methods handle constraints in different ways. In this study a penalty method will be used to handle the constraints of the PSO problem and in particular the penalty method proposed by Plevris [20] which is proven to be a simple and effective method which in the case of a typical constraint has the following form:

$$g_k(\mathbf{x}) = |q_k(\mathbf{x})| - q_{allow,k} \leq 0 \quad (9)$$

where $q_k(\mathbf{x})$ is a response measure (usually displacement, stress or strain) for design vector \mathbf{x} and $q_{allow,k}$ its maximum allowable absolute value.

In this case the penalty function $\Phi_k(\mathbf{x})$ for the typical constraint is the following:

$$\Phi_k(\mathbf{x}) = \begin{cases} 1 & \text{if } \frac{|q_k(\mathbf{x})|}{q_{allow,k}} \leq 1 \\ \frac{|q_k(\mathbf{x})|}{q_{allow,k}} & \text{if } \frac{|q_k(\mathbf{x})|}{q_{allow,k}} > 1 \end{cases} \quad (10)$$

Having calculated the penalty function for all violated constraints, the penalized fitness value of a design \mathbf{x} is obtained by multiplying the objective function to be minimized (structural weight) by the maximum penalty factor among all constraints:

$$f_p(\mathbf{x}) = f(\mathbf{x}) \max \{\Phi_k(\mathbf{x})\} \quad (11)$$

where $f_p(\mathbf{x})$ is the new penalized objective function and $\max \{\Phi_k(\mathbf{x})\}$ the maximum value of the penalty function among all active constraints of the optimization problem.

Using the previous method, there is a case where the penalized objective function can obtain a better value compared to the optimum solution found at the iteration n of the algorithm, $GBest_n$. This undesirable case resets the best solution into the infeasible areas of the design space. To avoid this problem, the penalty is imposed on the optimum solution instead of the new objective function, as shown in the following equations:

$$\left\{ \begin{array}{ll} f_p(\mathbf{x}) = f(\mathbf{x}) \max \{\Phi_k(\mathbf{x})\} & \text{if } \max \{\Phi_k(\mathbf{x})\} > 1 \text{ and } f(\mathbf{x}) \geq Gbest_n \\ f_p(\mathbf{x}) = Gbest_n \max \{\Phi_k(\mathbf{x})\} & \text{if } \max \{\Phi_k(\mathbf{x})\} > 1 \text{ and } f(\mathbf{x}) < Gbest_n \end{array} \right\} \quad (12)$$

2 LINEAR STATIC ANALYSIS TOOL

A new software tool for the linear static analysis of three-dimensional frames has been developed, featuring some distinct characteristics. The applied loads can be nodal or elemental (uniform, triangular or trapezoidal in any direction - x, y, z - within an element), while any release (translational or rotational) can be implemented at an end of any element, in any of the 6 Degrees Of Freedom (DOFs), either translational or rotational. The input file of the program contains the information that is shown in Table 1.

Material Properties	Modulus of Elasticity E, Poisson ratio ν , Steel density d
Section Properties	Section area A, Moment of inertia y-axis (I_y), Moment of inertia z-axis (I_z), Torsion constant K
Nodes	Coordinates x, y, z
Elements	Start node, End node, Material number, Section number, Orientation vector coordinates x, y, z
Element Releases	Translational and rotational releases in any degree of freedom of the start and end node of any element.
Constraints	Translation and rotation constraints for any degree of freedom of any node.
Elastic Constraints	Stiffness value of translational and rotational springs for any degree of freedom of any node.
Concentrated Loads	Forces and moments for any degree of freedom of any node.
Distributed Loads	Trapezoidal forces in any global direction x, y, z. Values are given for the start and end node of the element, assuming linear variation within the element.

Table 2: Input file format of the linear analysis software tool.

The output of the analysis program includes the constraint reactions, nodal displacements, forces at the ends of the elements, plus the displacements of the released DOFs of all elements with releases, and also any displacement or any force at any given point within an element. The distinct characteristics of the specific analysis tool are mainly: (i) In the input of the model, that any release in any DOF of any element can be implemented and many releases can coexist in an element provided that the element can carry the defined loads (not be a mechanism). This is very important for steel structures where elemental releases (hinges or others) are common practice in construction. (ii) In the output of the program, that any displacement (or rotation) or any force (or moment) can be calculated and given in the output, for any point within an element. In most cases, finite element analysis programs provide their results only at the nodal points (two ends of an element), but in the analysis and design of steel structures it is important to have results also within the elements, for example in order to check the maximum (mid-span) deflection of a beam member. Usually, this is done by adding nodes to the model which makes the model more complex and will have a negative effect on the optimization process where the model has to be analyzed many times. In our case, no extra nodes are added, as the program provides the displacements and forces at any given point within an element, even for the case of elements with releases.

The accuracy of the analysis results is verified by a direct comparison to the corresponding results of a reliable commercial finite element software program (NX Nastran) while a self-comparison is also done, using the same analysis tool but with a different model.

3 CONSTRAINTS BASED ON EC3

The constraints of the structural optimization problems examined in the present study are based on Eurocode 3, including various checks of the values of displacements and forces, as described in detail in the following paragraphs.

3.1 Ultimate Limit State (ULS)

Biaxial bending with axial force

$$\text{value1} = \frac{|N_{sd}|}{A f_y / \gamma_{M0}} + \frac{|M_{y, sd}|}{W_{pl, y} f_y / \gamma_{M0}} + \frac{|M_{z, sd}|}{W_{pl, z} f_y / \gamma_{M0}} \leq 1.00 \quad (13)$$

Shear force (Y-axis)

$$\text{value2}_y = \frac{|V_{y,sd}|}{A_{v,y} f_y / (\sqrt{3} \gamma_{M0})} \leq 1.00 \quad (14)$$

Shear force (Z-axis)

$$\text{value2}_z = \frac{|V_{z,sd}|}{A_{v,z} f_y / (\sqrt{3} \gamma_{M0})} \leq 1.00 \quad (15)$$

where:

N_{sd} , $M_{y,sd}$, $M_{z,sd}$: Axial force, bending moment around y - axis and bending moment around z - axis, respectively

$V_{y,sd}$, $V_{z,sd}$: y - shear force and z - shear force, respectively

$W_{pl,y}$, $W_{pl,z}$: Plastic section modulus around y and z - axis, respectively

A : Section area

f_y : Yield stress of steel

γ_{M0} : The partial safety factor ($\gamma_{M0} = 1.00$ according to EC3)

$A_{v,y}$, $A_{v,z}$: Shear area for y - axis and z - axis, respectively

The above ULS constraints are checked for the following load combinations:

- a) $1.35G + 1.50Q + 0.60W$
- b) $1.35G + 1.50W + 0.60Q$
- c) $1.00G + 0.30Q + E$

Where G are the dead loads, Q are the live loads, W are the wind loads and E are the earthquake loads on the structure which are imposed using the equivalent static method of the Greek Seismic Code (EAK2000), which is similar to the lateral force method of the Eurocode 8.

3.2 Serviceability Limit State (SLS)

Serviceability check for full loading:

$$\text{value3} = \frac{250|v_z|}{L} \leq 1.00 \quad (16)$$

for the following load combinations:

a) $1.00G + 1.00Q + 0.60W$

b) $1.00G + 1.00W + 0.70Q$

Serviceability check for live loading only (without dead loads):

$$\text{value4} = \frac{300|v_z|}{L} \leq 1.00 \quad (17)$$

for the following load combinations:

a) $1.00Q + 0.60W$

b) $1.00W + 0.70Q$

where v_z is the vertical displacement at the middle of a beam element.

The constraint values are calculated for every element of the steel frame, in various positions within the element ($L/10$, $2L/10$, etc). The objective function of the structural optimization problem is the weight of the structure, to be minimized, which is described in Eq. (2).

4 NUMERICAL EXAMPLES

4.1 Verification of the linear static analysis tool

A Finite Element analysis of a three-dimensional frame is performed. The model (A) is depicted in Figure 3.

Figure 3: Three-dimensional analysis model A for verification purposes.

Various types of loads, releases and springs are applied, as shown in the tables below.

Node	Node Coordinates (m)			Constraints		
	x	y	z	Translations	Rotations	Description
1	0	0	0	XXX	OOO	Hinge
2	10	0	0	XOX	XXX	Y-Translation allowed
3	0	8	0	XXX	XXX	Fixed
4	10	8	0	XXX	XXO	Z-Rotation allowed
5	0	2	10	-	-	-
6	10	0	7	-	-	-
7	0	8	5	-	-	-
8	10	8	5	-	-	-

Table 3: Nodal data of the analysis model A (X denotes restriction of the DOF, O denotes free DOF).

Element	Start Node	End Node	Coordinates of Orientation Vector (R)		
			x^R	y^R	z^R
1	1	5	0	8	5
2	2	6	10	8	5
3	3	7	0	2	10
4	4	8	10	0	7
5	5	6	0	8	5
6	6	8	0	2	10
7	5	7	10	8	5
8	7	8	10	0	7

Table 4: Elemental data of the analysis model A.

Element	Start Node		End Node		Release Description
	Translations	Rotations	Translations	Rotations	
4	000	000	100	001	X-translation and Z-rotation at the end node of the element
5	000	000	001	010	Z-translation and Y-rotation at the end node of the element

Table 5: Elemental releases of the analysis model A.

Node	Degree Of Freedom	Stiffness value	Description
6	1	5000	Translational Spring (X-axis)
8	4,5,6	2000	Rotational Springs (X,Y,Z axes)

Table 6: Spring data of the analysis model A.

Node	F_x (kN)	F_y (kN)	F_z (kN)	M_x (kNm)	M_y (kNm)	M_z (kNm)
5	10	-25	-20	0	25	50
6	10	-20	-10	50	0	0
7	10	-10	10	0	-50	30
8	-20	10	30	0	0	0

Table 7: Nodal loads of the analysis model A (global system).

Element	F_x^i (kN/m)	F_x^j (kN/m)	F_y^i (kN/m)	F_y^j (kN/m)	F_z^i (kN/m)	F_z^j (kN/m)
5	-20	35	15	-30	0	0
7	10	-10	-25	15	0	0

Table 8: Elemental loads of the analysis model A.

Material properties: $E = 2.1 \cdot 10^8 \text{ kN/m}^2$, $\nu = 0.3$

Section properties: $A = 5 \cdot 10^{-3} \text{ m}^2$, $I_y = 8 \cdot 10^{-5} \text{ m}^4$, $I_z = 6 \cdot 10^{-6} \text{ m}^4$, $K = 2 \cdot 10^{-7} \text{ m}^4$

Results

The analysis tool calculates the displacements, forces and moments at any given intermediate point of any element. Having calculated the displacements at any given point of the element, the software provides a figure of the deformed shape of the analysis model, which for model A is shown in Figure 4.

SFrameMatlab elements displacements: model.dat

Figure 4: Deformed shape of the analysis model A.

The discontinuities observed at nodes 6 and 8 are due to the existence of translational and rotational releases at the ends of the corresponding elements of the model, as shown in Table 5. Selected groups of the analysis results are presented in the following tables. All the results of nodal points are presented (displacements and forces), while only the intermediate displacements in the X-axis and intermediate axial forces are presented in the tables.

Table 15: NX Nastran results – Element forces (local system)..

A full coincidence of the analysis results of the two programs can be observed. This proves that the nodal displacements and the element forces at the element ends are calculated with accuracy with the analysis tool.

Results verification: 2. Self-comparison

NX Nastran provides us the values of displacements and forces at the nodal points, but it cannot calculate the displacements and forces at any given point within an element. In order to verify these results also, a self-comparison is done, as described in detail in the following paragraphs.

We create a new model (model B) where each element has been divided into two elements with the addition of a new node within each element. The new node is not positioned always in the middle of the element, but rather at various points ($L/10$, $2L/10$, etc) within the element, as shown in the figure of model B below.

Figure 5: Analysis model B with the addition of new intermediate nodes.

By adjusting the loads, releases, etc, model B has been made equivalent to the first model A. By performing the new analysis, the corresponding results at the nodal points are found to coincide. Also, the intermediate results of the model A at various positions within the elements can now be checked, as in model B there are nodes at these points. By performing the analysis, and doing the corresponding comparisons, it is proven that the results coincide again, as the displacements and forces at the intermediate points within each element are the same as the nodal results of the corresponding new nodes of model B.

4.2 Structural Optimization Problems

One plane and one space steel frame are examined. The optimization results of the discrete PSO method are compared to the ones obtained with a discrete GA. In the discrete structural optimization problems that are examined, three steel section groups have been taken into account, namely the IPE, HEA, HEB section groups of the Eurocode, while it is easy to add other section groups also. In all test examples, the earthquake loading has been taken into account with the equivalent static load method of the Greek Seismic Code (EAK2000), where a peak ground acceleration of 0.36g has been taken into consideration.

The parameters of the GA and PSO algorithms, used in this study, are presented in the following tables.

Population size	20
Generations	100
Crossover function	Scattered

Table 16: GA parameter values.

Swarm size	20
Iterations	100
v_{\max}	1
w_{\max}	0.95
w_{\min}	0.8
c_1, c_2	2

Table 17: PSO parameter values.

Optimization example 1

The first optimization test example is a plane frame that is depicted in Figure 6. The details of the model are given in the tables below.

Element	Dead distributed loads (kN/m)		Live distributed loads (kN/m)		Wind distributed loads (kN/m)	
	G_z^i	G_z^j	Q_z^i	Q_z^j	W_x^i	W_x^j
1-5	-	-	-	-	3	3
21-35	-2	-2	-0.5	-0.5	-	-

2	Beams 23-25, 28-30, 33-35	IPE
3	Columns 1-2, 6-7, 11-12, 16-17	HEA
4	Columns 3-5, 8-10, 13-15, 18-20	HEB

Table 19: Design variables of model 1.

Figure 6: Model 1 geometry.

The results of the optimization process with GA and PSO are given in the Table 21. It is observed that both algorithms converge to the same optimum design. The constraint values for the optimum design are given in Table 21. The convergence histories for both methods are given in Figure 7. The PSO method appears to be faster in locating the solution at around 400 objective function evaluations, whereas the GA method needs 650 objective function evaluations to reach the optimum.

5 CONCLUSIONS

The linear static analysis tool that has been developed proved to be a very useful and accurate tool for the analysis of three-dimensional frames. The advantage of the software tool is its generality, as it can handle nodal or elemental loads (uniform, triangular or trapezoidal in any direction within an element), any release (translational or rotational) can be implemented at an end of any element, in any of the 6 Degrees Of Freedom (DOFs), while the output of the analysis program includes the displacements of the released DOFs of all elements with releases, and any displacement or any force at any given point within an element. The accuracy of the analysis results is verified by a direct comparison to the corresponding results of a reliable commercial finite element software program as well as by performing a self-comparison using an enhanced model with additional nodes.

Both PSO and GA methods proved to be accurate in finding the optimum design almost every single time. GA has a larger computational cost than PSO which exhibited in general better performance in terms of convergence speed. This fact is due to the more complex and time consuming procedures of GA as part of the genetic operators of the algorithm (selection, crossover, mutation). Also the quantity of random numbers generated for each iteration of the algorithm is larger in GA, which makes it slower for a single iteration.

The accuracy of the discrete version of PSO used in this study was quite satisfactory, although in a small percentage of the tests that were performed, the algorithm was trapped in local optima. Further investigation may be needed for the fine-tuning of the discrete PSO parameters for the optimization problem at hand.

The constraints used in the present study were based on Eurocode 3, but in fact not all Eurocode 3 constraints for steel structures have been implemented in the test examples. Most importantly, additional buckling constraints need to be taken into account, as they are many times critical in real world steel structures design. The implementation of these constraints is straight forward given the analysis and optimization frameworks that have been developed, and will be a subject for future research.

Keywords: beam-to-column joints, rigidity of joints, steel frames, detailed finite element modeling, $M-\phi$ curves, direct-integration nonlinear dynamic analysis, seismic response

Abstract. *The objective of this paper is to study the influence of the rigidity of joints on the nonlinear dynamic response of steel structures under seismic excitation. We consider bolted beam-to-column joints with extended end-plates. A detailed finite element simulation of the joints is performed using structural (beam and shell) and three-dimensional continuum (eight-node hexahedral solid) elements. Material as well as geometric nonlinearities with contact between the appropriate components of the connections are taken into account. The moment-rotation ($M-\phi$) response of characteristic joints, subjected to static loads, is calculated and compared with experimental results and EC3 predictions for the validation of the corresponding numerical models. The dynamic response of steel frames is examined, with detailed modeling of their joints via structural elements according to the above study, capturing all types of nonlinearities. Frame members are modeled either with shell (full simulation) or with beam elements combined with proper compatibility constraints at the interfaces with the joints (hybrid simulation) accounting for the excessive computational effort required to perform nonlinear dynamic analyses with detailed finite element models. Implicit direct-integration is implemented in order to study the nonlinear seismic response of the above frame models, while El Centro earthquake horizontal accelerogram is considered for the seismic excitation. In order to study the influence of the joints end-plate and bolts, parametric analyses are performed demonstrating the effect of each component on the overall dynamic behavior of steel structures. Time history curves of nodal displacements are displayed for the appropriate comparisons. The detailed finite element discretization of the joint and frame models is produced automatically from the corresponding geometric models.*

1 INTRODUCTION

Bolted beam-to-column joints with extended end-plates are used widely in steel structures. They form moment-resistant connections between steel members, but their behavior can be either rigid or semi-rigid depending on the stiffness and strength of their components. The consideration of semi-rigid connections corresponds to a more realistic simulation of the joints behavior leading to more reliable solutions. However, the large number of variables related to connection geometry makes the task of incorporating semi-rigid behavior of the connections into the frame design a complicated process. Additionally, structural joints may exhibit nonlinear behavior such as localized elastoplastic deformations, unilateral contact and slip phenomena. The behavior of steel joints has been the subject of both experimental [12-17] and numerical [5-11] studies by a number of researchers.

This paper first presents a finite element study of semi-rigid joints subjected to static loading. Stiffness, moment resistance and rotation capacity derived from the calculation of moment-rotation ($M-\varphi$) curves are compared with experimental results by Coelho et al. [12] and Eurocode 3 suggestions [2]. Then, multi-storey steel frames with detailed modeling of their connections according to the above study are subjected to seismic excitation in order to examine the influence of the rigidity of joints on the dynamic response of moment-resistant steel structures [16-17]. Parametric studies are performed demonstrating how variations of geometric characteristics of joint components can change the connection behavior and consequently the seismic response of steel frames. Moreover, various finite element simulations are investigated in order to find hybrid models of detailed finite element simulation of joints combined with beam simulation for the structural elements in an effort to combine accuracy and low computational cost. The finite element discretization of joints and structural elements is produced automatically from their geometric description. ABAQUS/Standard software is used for the static and dynamic numerical analyses of this paper [1].

2 FINITE ELEMENT MODELING OF STEEL JOINTS

2.1 Simulation with shell elements

Two different element types are used for modeling the end-plate bolted beam-to-column joint (Fig. 1). Plane components of the joint (beam/column flanges and web, end-plate, transverse web stiffeners) are modeled with the S4 quadrilateral shell element of appropriate thickness, while the bolts are modeled with beam elements of circular section. The interaction between the column flange and the end-plate is considered through surface-based contact simulation with element-based surface definition, which enables contact between independent meshes without node compatibility.

2.2 Simulation with continuum elements

Three-dimensional eight-node hexahedral solid elements are used for the detailed simulation of the extended end-plate bolted beam-to-column joint (Figs. 2, 3). Apart from the finite element discretization difficulties using three-dimensional solid elements, there are many complexities related to the contacts between the different components of a beam-to-column bolted joint. Particularly, there are five interactions that should be considered: (a) column flange with end-plate; (b) column flange with bolt head; (c) end-plate with bolt nut; (d) column flange hole with bolt shank; and (e) end-plate hole with bolt shank. All of them are modeled by using surface-based contacts with element-based surface definition that enables connection of independent meshes. Surfaces are defined through the appropriate faces of the hexahedral solids. More specifically, for cases (a), (d) and (e) small sliding contact formulation is considered

with a softened contact relationship. The slope of the linear pressure-overclosure curve is taken equal to 10^5 . The tangential behavior of the interfaces is modeled through the basic isotropic Coulomb friction model with a constant coefficient μ equal to 0.30. For the other cases tied contact simulation is considered, where each node on the slave surface has the same displacement with the corresponding contact point on the master surface.

Figure 2: Joint simulation with continuum (8-node hexahedral solid) finite elements

Figure 3: Bolt simulation with continuum (8-node hexahedral solid) finite elements

2.3 Experimental data

An experimental investigation of eight statically loaded extended end-plate moment connections was undertaken at the Delft University of Technology by Coelho et al. [12] to provide insight into the behavior of this type of joint up to collapse. The specimens were designed to confine failure to the end-plate and/or bolts without development of the full plastic moment capacity of the beam. The parameters investigated were the end-plate thickness and steel grade. Details of the test specimens are given in Table 1.

Test ID	Number	Column		Beam		End-plate	
		Profile	Steel grade	Profile	Steel grade	t_p (mm)	Steel grade
FS1	2	HEM340	S355	IPE300	S235	10	S355
FS2	2	HEM340	S355	IPE300	S235	15	S355
FS3	2	HEM340	S355	IPE300	S235	20	S355
FS4	2	HEM340	S355	IPE300	S235	10	S690

Table 1: Details of the test specimens [12]

2.4 Numerical results

The detailed geometry of the connections is considered in the numerical analyses performed. Hand tightened full-threaded M20 grade 8.8 bolts were used, which are modeled via an equivalent diameter of 18.80 mm that derives from the average of the gross diameter 20.00 mm and the effective diameter of the bolt shank (effective cross-section corresponding to the threaded part of the shank $A_s=245 \text{ mm}^2$, for M20). Boundary conditions and loading procedures are the same as in the experiments. Particularly, each node of the back column flange has been constrained and a vertical load is applied on the transverse web stiffener of the beam. The finite element analysis procedure is based on incremental Newton-Raphson technique, while material and geometric nonlinearities are taken into account via the von Mises isotropic plasticity model and large displacement consideration.

The moment-rotation ($M-\phi$) curves for the several connections are obtained from the beam vertical displacements and the applied load. The bending moment, M , acting on the connection corresponds to the applied load, L , multiplied by the distance, d , between the load application point and the face of the end-plate.

$$M = L \times d \quad (1)$$

The rotational deformation of the joint is the sum of the shear deformation of the column web panel zone and the connection rotational deformation. In these tests, the column hardly deforms as it behaves as a rigid element. Thus, the connection rotation ϕ is taken into account,

which is defined as the change in angle between the centerlines of beam and column and is approximately given by:

$$\varphi = \arctan \frac{\delta}{d} - \theta_{b,el} \quad (2)$$

where δ : vertical displacement of the beam at the load application point, and $\theta_{b,el}$: beam elastic rotation (neglected in this study).

EC3-1-8 states that a bolted end-plate joint may be assumed to have sufficient rotation capacity for plastic analysis, provided that both conditions are satisfied: (i) the moment resistance of the joint is governed by the resistance of either the column flange in bending or the end-plate in bending; and (ii) the thickness, t , of either the column flange or the end-plate (not necessarily the same basic component as in (i)) satisfies:

$$t \leq 0.36\varphi_b \sqrt{\frac{f_{u,b}}{f_y}} \quad (3)$$

where φ_b : bolt diameter, $f_{u,b}$: tensile strength of the bolt, and f_y : yield strength of the relevant basic component. EC3-1-8 prediction for stiffness S_j is given by the relationship:

$$S_j = S_{j,ini}/\eta \quad (4)$$

where $S_{j,ini}$: initial stiffness evaluated according to the component method, and η : stiffness modification factor which in the context of an elastic-plastic global structural analysis is taken as 2.0 for bolted end-plate beam-to-column joints.

Moment-rotation (M - φ) curves of the above test specimens are presented next and compared with the experimental results by Coelho et al. [12] and Eurocode 3 suggestions [2]. Moreover, for each test, horizontal deformation of the end-plate is observed. The first three models are plotted in stress scale 0-35.5 kN/cm² and the last in 0-69.0 kN/cm² according to each end-plate yield stress. Four models are examined, one with shell elements and three with continuum elements. All of them predict accurately the elastic stiffness of the joints and generally are reliable in linear elastic static analysis. Bending of end-plates is the main reason for differences between these simulations in the elastoplastic region. For thin end-plates, which are dominated by bending (FS1, FS4), the use of continuum elements with reduced integration performs better. This simulation predicts almost exactly the three main joint behavioral characteristics, which are stiffness, resistance and rotation capacity. The normal brick element overestimates the elastic behavior of the joint, while the enhanced with incompatible modes gives more accurate results but remains stiff for this type of problems underestimating their high rotation capacity. Joint modeling with shell elements has a drawback. Bolt forces are applied locally to the nodes that connect the column flange with the end-plate and as a result there is local concentration of stresses, especially for very thin end-plates and/or column flanges. As the thickness of end-plate increases (FS2, FS3) the simulations tend to coincide. Brick elements with reduced integration remain the more flexible, while bricks with incompatible modes give also reliable results. Simulation with shell elements behaves very satisfactory and can be used for such type of problems.

3 FINITE ELEMENT MODELING OF STEEL FRAMES

3.1 Numerical Modeling

Three different finite element simulations are examined: (i) *Type 1*: Simulation with beam elements for the members, while the joints are regarded as rigid; (ii) *Type 2*: Full simulation with shell elements for the members and detailed modeling of the joints according to 2.1 with shell and beam elements; and (iii) *Type 3*: Hybrid simulation with beam elements for the members and detailed modeling of the joints according to 2.1 with shell and beam elements. For this type of modeling proper compatibility constraints are assumed at the nodes of the interfaces. The length of the detailed joint part (beam/column) is taken as 0.10 of the corresponding total member length. The joints of this frame type are stiffened in two steps. In the first step (*Type 3 – stiff-a*), transverse web stiffeners are added to the columns at the height of the beam flanges ($t_s = t_{fb}$), and in the second (*Type 3 – stiff-b*), apart from these stiffeners, supplementary web plates are added to the column webs ($t'_{wc} = 2t_{wc}$). It should be mentioned that the simulation with three-dimensional solid elements requires excessive computational time to perform an implicit direct-integration dynamic analysis that takes into account material and geometric nonlinearities including contacts. The simulation with structural elements is practically and computationally more efficient, even though there are some drawbacks in the modeling.

The hysteretic stress-strain model that has been adopted for the steel subjected to dynamic loading is displayed in Fig. 8. The steel grade specified for every component of each model, except for the bolts, is S235 with the following characteristics: modulus of elasticity, $E = 21000 \text{ kN/cm}^2$, yield stress, $f_y = 23.5 \text{ kN/cm}^2$, ultimate stress, $f_u = 36.0 \text{ kN/cm}^2$, and ultimate strain, $\varepsilon_u = 0.25$. The grade of bolts is 8.8 which means that $f_{y,b} = 64.0 \text{ kN/cm}^2$ and $f_{u,b} = 80.0 \text{ kN/cm}^2$, while their strain hardening modulus, $E_t = 210 \text{ kN/cm}^2$.

Figure 8: Hysteretic stress-strain (σ - ε) steel model

The general direct-integration method with the Hilber-Hughes-Taylor operator is used for the dynamic numerical analyses of this paper. It is an extension of the trapezoidal rule and is implicit, while a set of simultaneous nonlinear dynamic equilibrium equations must be solved at each time increment. The solution is done iteratively using Newton's method with material and geometric nonlinearities being included. A constant time step of 0.01 sec is used in the dynamic analyses.

Two kinds of damping are taken into account. The first is the artificial damping, through the numerical damping control parameter α . A value of $\alpha = -0.05$ is used, which provides

slight numerical damping. The second is the material-Rayleigh damping, which introduces a damping matrix $[\underline{C}]$, defined as:

$$[\underline{C}] = \alpha_0 [\underline{M}] + \alpha_1 [\underline{K}] \quad (5)$$

where $[\underline{M}]$: the mass matrix, and $[\underline{K}]$: the stiffness matrix of the model. Factors α_0 and α_1 can be derived from the solution of the following equations [4]:

$$\frac{1}{2} \begin{bmatrix} 1/\omega_i & \omega_i \\ 1/\omega_j & \omega_j \end{bmatrix} \begin{Bmatrix} \alpha_0 \\ \alpha_1 \end{Bmatrix} = \begin{Bmatrix} \zeta_i \\ \zeta_j \end{Bmatrix} \quad (6)$$

where $\omega_{i,j}$: natural frequencies of interest, and $\zeta_{i,j}$: damping coefficients for the corresponding natural frequencies of interest. For steel structures with bolted joints ζ can be taken conservatively as 6% = 0.06. In the analyses of this paper, only α_1 is used with $\alpha_1 = 0.0020$ for the first frame test example and $\alpha_1 = 0.0025$ for the second.

The frames are subjected to the 1940 Imperial Valley (El Centro) S00E horizontal component acceleration record. The 10 seconds acceleration history is shown in Fig. 9, while Fig. 10 depicts the response spectra for 2% and 6% damping. Peak ground acceleration (PGA) of 0.60g is chosen for the numerical analyses of the frames that follow.

3.2 Frame No1

A steel frame of one opening (6 m) and two storeys (5 m each) is examined. Columns have a section profile HEB280 and beams IPE400. Details of the beam-to-column connections are shown in Fig. 11. Parametric studies on extended end-plate thickness, t , and bolts diameter, D , are performed. Each beam is assumed to have 20 times higher density than the density of steel (7850 kg/m^3) to account for the floor mass, while each column carries its own weight. The natural frequencies and periods are demonstrated in Table 2.

Figure 12: Frame 1, First and second mode

The results of various response analyses are presented in the next graphs. The parametric analyses (Figs. 13, 14) show that connection geometric characteristics do not affect the overall behavior of the frame with regard to the absolute maximum values. The tests performed showed that hybrid simulation is reliable and can be used instead of the full simulation, assuming that member beam elements do not exceed the yield stress, f_y , in order to account for the excessive computational effort required to perform nonlinear dynamic analyses with detailed finite element models. The comparisons between the different simulations are presented in Figs. 15-17.

3.3 Frame No2

A steel frame of two openings (6 m each) and three storeys (4 m each) is examined. There are also double-sided joints apart from single-sided of Frame No1. Columns have a section profile HEB280 and beams IPE400. Beam-to-column connections are shown in Fig. 11. Each beam is assumed to have 20 times higher density than the density of steel (7850 kg/m^3) to account for the floor mass, while each column carries its own weight. The natural frequencies and periods are demonstrated in Table 4.

Table 4: Frame 2, Dynamic characteristics

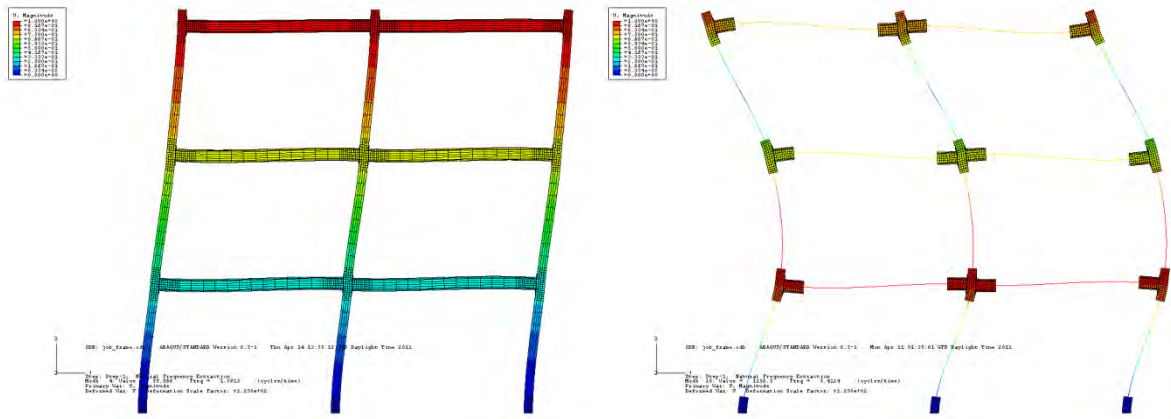

Figure 18: Frame 2, First and second mode

The results of the dynamic response of this test frame are presented in the next graphs. Parametric analyses (Figs. 19, 20) show that the geometric characteristics of the connections do not affect the overall behavior of the frame. As in the previous example, hybrid simulation is reliable and can be used instead of the full simulation, assuming that member beam elements do not exceed the yield stress, f_y . As the size of the problem increases, the computational effort required to perform nonlinear dynamic analysis with a detailed finite element model increases and the adoption of hybrid models becomes very useful and effective. For example, the time needed for a full simulation with shell elements of this frame is ~ 1.5 times greater than the time needed for a hybrid simulation. The comparisons between the different simulations are presented in Figs. 21-24.

4 CONCLUSIONS

- Detailed finite element modeling considering material and geometric nonlinearities including appropriate contacts of bolted extended end-plate beam-to-column joints is performed, which can capture all local phenomena that affect the behavior of the joints under static or dynamic loads.
- Experimental results can be reproduced accurately using detailed joint models of hexahedral eight-node solid continuum finite elements with either reduced integration or incompatible modes depending on the plate thickness.
- Simulation with shell elements can be used for the modeling of steel joints with high level of accuracy in realistic problems, instead of continuum elements, which are computationally very demanding.
- Hybrid models, where the joints are modeled with shell elements and the connecting structural elements with beam elements, with appropriate kinematic constraints at the interfaces, give reliable results at reduced computational times.
- Modeling of frames with beam elements considering rigid joints fails to predict the semi-rigidity and the various types of failure of the joint structural components that may affect considerably the joint behavior.
- Parametric studies on extended end-plate thickness and bolts diameter of semi-rigid joints show that the connection geometric characteristics do not have a substantial effect on the seismic response of the overall structure.

Abstract. *This paper gives a review of our recently proposed dual mortar approach combined with a consistently linearized semi-smooth Newton method for 3D finite deformation contact analysis. The mortar finite element method, which is applied as discretization scheme, initially yields a mixed formulation with the nodal Lagrange multiplier degrees of freedom as additional primary unknowns. However, by using so-called dual shape functions for Lagrange multiplier interpolation, the global linear system of equations to be solved within each Newton step can be condensed and thus contains only displacement degrees of freedom. All possible types of nonlinearities, including finite deformations, nonlinear material behavior and contact itself (active set search) are handled within one single iterative solution scheme based on a consistently linearized semi-smooth Newton method. The extension of the proposed framework towards additional model complexities such as Coulomb friction and self contact is addressed shortly. Moreover, an outlook towards multiphysics and multiscale simulations, coupling contact analysis with other physical fields and taking into account effects on different length scales is provided by exemplarily discussing the integration of mortar contact into a fixed-grid fluid-structure interaction (FSI) framework based on the extended finite element method (XFEM). Several numerical examples are presented to show the high quality of results obtained with the proposed methods.*

1 INTRODUCTION

Computational contact dynamics in general, and mortar-based discretization for finite deformations in particular, have seen a great thrust of research over the last decade. We discuss here the most important features of the recently proposed dual mortar finite element method combined with a consistently linearized semi-smooth Newton scheme for contact constraint enforcement. The present contribution is thus a shortened version of our articles [1, 2, 3, 4] to which we refer for full technical details, more profound discussion of the methods presented and further numerical examples.

Many newly proposed contact discretizations are based on the mortar method which was originally introduced in the context of domain decomposition [5]. Mortar contact formulations have successfully been applied to the solution of finite deformation contact problems in [6, 7, 8]. However, the mentioned formulations all apply a regularization of contact constraints based on the penalty method or an augmented Lagrangian type approach using the Uzawa algorithm. A recent application based on direct Lagrange multiplier techniques with standard multiplier spaces can be found in [9]. Yet, the dual Lagrange multiplier spaces proposed in [10, 11] seem to have the highest potential for efficient algorithms as they allow for a static condensation of the discrete Lagrange multiplier degrees of freedom. Thus, an undesirable increase in global system size, usually typical of direct Lagrange multiplier techniques, is avoided. Mortar methods with dual Lagrange multipliers have first been developed in the context of small deformation contact problems [12], where also the idea of interpreting the active set search as a semi-smooth Newton method (see e.g. [13, 14]) has been adapted. Some first steps towards a finite deformation implementation have been made in [15, 16], however still with an incomplete linearization of contact forces and constraints. In the authors' previous work [1, 2, 3], the ideas of dual Lagrange multipliers and a semi-smooth Newton approach for the active set search have been consistently extended to fully nonlinear 3D frictional contact problems.

Advantageous properties of the devised algorithms comprise superior robustness as compared with a traditional node-to-segment approach, the absence of any user-defined parameter (e.g. penalty parameter), the integration of all types of nonlinearities (including finite deformations, nonlinear material behavior and active set search) into one single iteration loop and the possibility to condense the discrete Lagrange multipliers from the global system of equations, to name only a few. First-order and second-order finite element interpolation, frictional sliding based on Coulomb's law as well as self contact are considered for both 2D and 3D. Some very challenging numerical examples are presented to illustrate the high quality of results obtained with the proposed approach. The design of our algorithms is based on overlapping domain decomposition, involving parallel contact search based on hierarchic binary tree structures and a novel dynamic load balancing strategy specifically developed for mortar coupling. This assures full parallel scalability of all algorithmic components when solving large contact dynamics problems with up to some million degrees of freedom.

Recently, the focus of our research in the field of computational contact dynamics has been extended towards multiphysics and multiscale simulations, coupling contact analysis with several other physical fields and taking into account effects on different length scales. Exemplarily, the integration of dual mortar contact into a fixed-grid fluid-structure interaction (FSI) framework based on the extended finite element method (XFEM) will be shortly addressed here. This approach allows for computing macroscopic contact of arbitrarily deforming structures embedded in a surrounding fluid. Again, we refer to a recent article [4] for the derivation and a more profound discussion of the proposed fluid-structure-contact interaction method.

Figure 1: Notation for the two body finite deformation contact problem in 3D.

The remainder of this contribution is organized as follows: Section 2 provides a rough overview of the general continuum mechanics problem setup for 3D finite deformation contact. The dual mortar finite element approach is described in Section 3. In Section 4, the semi-smooth Newton type active set strategy and the resulting solution algorithm are outlined. Section 5 highlights some recent model extensions, including friction and fluid-structure-contact interaction. Following this interlude, Section 6 demonstrates with several numerical examples the validity of the proposed approach. Finally, we conclude the findings.

2 PROBLEM FORMULATION OF FINITE DEFORMATION CONTACT

The basic problem definition has been described in detail in [2]. Figure 1 shows the reference and current configurations of two elastic bodies undergoing a finite deformation process and introduces some notation. The surfaces $\partial\Omega_t^{(i)}$, $i = 1, 2$ are divided into three disjoint boundary sets, namely the common Dirichlet and Neumann boundaries $\gamma_u^{(i)}$ and $\gamma_\sigma^{(i)}$ as well as the potential contact surfaces $\gamma_c^{(i)}$. Although a mortar discretization will be applied later, we still retain the customary nomenclature of slave and master contact surfaces.

Displacement vectors $\mathbf{u}^{(i)} = \mathbf{x}^{(i)} - \mathbf{X}^{(i)}$ describe the motion of the deformable bodies from reference configuration $\mathbf{X}^{(i)}$ to current configuration $\mathbf{x}^{(i)}$. Material nonlinearity is taken into account by assuming a compressible Neo-Hookean material behavior based on the second Piola-Kirchhoff stress tensor \mathbf{S} and the Green-Lagrange strain tensor $\mathbf{E} = \frac{1}{2}(\mathbf{F}^T \mathbf{F} - \mathbf{I})$, where \mathbf{F} is the deformation gradient. Based on these definitions, the well-known initial boundary value problem (IBVP) of finite deformation elastodynamics can be formulated. This paper focuses on contact interaction itself, which is typically described by a gap function $g(\mathbf{X}, t)$ in the current configuration. The classical Karush-Kuhn-Tucker (KKT) conditions of normal contact and the

frictionless sliding conditions then read as follows:

$$g(\mathbf{X}, t) \geq 0, \quad p_n \leq 0, \quad p_n g(\mathbf{X}, t) = 0, \quad (1)$$

$$t_\tau^\xi = t_\tau^\eta = 0, \quad (2)$$

where the normal and tangential components of the slave contact traction $\mathbf{t}_c^{(1)}$ are denoted as p_n , t_τ^ξ and t_τ^η . A corresponding formulation of Coulomb's law for frictional contact is omitted here, but can be found in our recent work [3]. For deriving a weak formulation the solution space $\mathcal{U}^{(i)}$ and the weighting space $\mathcal{V}^{(i)}$ are defined by employing the usual Sobolev spaces $H^1(\Omega^{(i)})$ and by taking into account Dirichlet boundary conditions. The method of weighted residuals then yields: Find $u_j^{(i)} \in \mathcal{U}^{(i)}$ such that

$$\begin{aligned} \delta \Pi(\mathbf{u}, \delta \mathbf{u}, \boldsymbol{\lambda}) &= \delta \Pi_{int, ext}(\mathbf{u}, \delta \mathbf{u}) + \int_{\gamma_c^{(1)}} \boldsymbol{\lambda} \cdot (\delta \mathbf{u}^{(1)} - \delta \hat{\mathbf{u}}^{(2)}) d\gamma = 0 \\ \forall \delta u_j^{(i)} &\in \mathcal{V}^{(i)}, \quad j = 1, 2, 3, \end{aligned} \quad (3)$$

where the negative contact traction on the slave side of the interface has been replaced by a Lagrange multiplier vector $\boldsymbol{\lambda} = -\mathbf{t}_c^{(1)}$. By arbitrary choice, the Lagrange multipliers $\lambda_j \in \mathcal{M}$, $j = 1, 2, 3$, have been introduced on the slave side, where \mathcal{M} is defined as dual space of the trace space $\mathcal{W}^{(1)}$ of $\mathcal{U}^{(1)}$ restricted to $\Gamma_c^{(1)}$. Corresponding test functions $\delta \lambda_j$ serve as weighting functions for the non-penetration constraint in (1):

$$\int_{\gamma_c^{(1)}} \delta \lambda_n g(\mathbf{X}, t) d\gamma \geq 0 \quad \forall \delta \lambda_n \in \mathcal{M}. \quad (4)$$

The remaining contact conditions in (1) and (2) are then rewritten as

$$\lambda_n \geq 0, \quad \lambda_n g(\mathbf{X}, t) = 0, \quad \lambda_\tau^\xi = \lambda_\tau^\eta = 0. \quad (5)$$

Altogether, equations (3)–(5) establish a mixed variational formulation with the solution $u_j^{(i)} \in \mathcal{U}^{(i)}$ and $\lambda_j \in \mathcal{M}$. An overview of mortar finite element discretization using dual Lagrange multipliers follows in the upcoming paragraph. Some of the contact constraints are still formulated as inequality conditions, which necessitates the application of a suitable active set strategy. The primal-dual active set strategy (PDASS) and our reformulation as a semi-smooth Newton scheme including consistent linearization will be addressed in Section 4.

3 DUAL MORTAR FINITE ELEMENT DISCRETIZATION

Spatial discretization of the contact terms requires a discretization of slave and master surface, which is directly connected to the underlying structural discretization based on their trace space relationship. We consider both first-order and second-order Lagrangian finite elements in 2D and 3D. A general definition of slave and master displacements then reads as follows:

$$\mathbf{d}^{(1)h}|_{\Gamma_c^{(1)h}} = \sum_{k=1}^{n_{sl}} N_k^{(1)}(\boldsymbol{\xi}^{(1)}) \mathbf{d}_k^{(1)}, \quad \mathbf{d}^{(2)h}|_{\Gamma_c^{(2)h}} = \sum_{l=1}^{n_m} N_l^{(2)}(\boldsymbol{\xi}^{(2)}) \mathbf{d}_l^{(2)}. \quad (6)$$

Spatially discretized quantities are labeled with a superscript h and the total number of slave and master nodes is n_{sl} and n_m , respectively. Nodal displacements are given by $\mathbf{d}_k^{(1)}$, $\mathbf{d}_l^{(2)}$ and

shape functions $N_k^{(1)}, N_l^{(2)}$ are defined with respect to the usual finite element parameter spaces $\xi^{(i)}$. Lagrange multiplier interpolation is based on dual shape functions Φ_j , as pioneered by Wohlmuth [10]:

$$\lambda^h = \sum_{j=1}^{n_{sl}} \Phi_j(\xi^{(1)}) \mathbf{z}_j, \quad (7)$$

with discrete nodal Lagrange multipliers \mathbf{z}_j . The construction of dual shape functions is based on a biorthogonality relation as introduced in [10, 11, 12]:

$$\int_{\gamma_c^{(1)h}} \Phi_j(\xi^{(1)}) N_k^{(1)}(\xi^{(1)}) d\gamma = \delta_{jk} \int_{\gamma_c^{(1)h}} N_k^{(1)}(\xi^{(1)}) d\gamma, \quad (8)$$

where δ_{jk} is the Kronecker delta. This approach will later allow for static condensation of the discrete multipliers \mathbf{z}_j . Note, that in the context of finite deformations dual shape functions become deformation-dependent themselves. For an overview and exemplary local calculations of element-specific dual shape functions in 2D and 3D contact analysis we refer to [1, 2, 15]. Nodal blocks of the two mortar integral matrices $\mathbf{D} \in \mathbb{R}^{3n_{sl} \times 3n_{sl}}$ and $\mathbf{M} \in \mathbb{R}^{3n_{sl} \times 3n_m}$ are then defined as

$$\mathbf{D}[j, k] = D_{jk} \mathbf{I}_3 = \delta_{jk} \int_{\gamma_c^{(1)h}} N_k^{(1)} d\gamma \mathbf{I}_3, \quad (9)$$

$$\mathbf{M}[j, l] = M_{jl} \mathbf{I}_3 = \int_{\gamma_c^{(1)h}} \Phi_j N_l^{(2)} d\gamma \mathbf{I}_3, \quad (10)$$

with $j, k = 1, \dots, n_{sl}$, $l = 1, \dots, n_m$ and with the identity $\mathbf{I}_3 \in \mathbb{R}^{3 \times 3}$. Owing to the biorthogonality relation (8), \mathbf{D} reduces to a diagonal matrix. This yields as algebraic notation of the discretized contact virtual work

$$\delta \Pi_c^h = \left(\delta \mathbf{d}^{(1)} \right)^T \mathbf{D}^T \mathbf{z} - \left(\delta \mathbf{d}^{(2)} \right)^T \mathbf{M}^T \mathbf{z}, \quad (11)$$

where all discrete nodal values of Lagrange multipliers and nodal test function values are assembled into global vectors \mathbf{z} , $\delta \mathbf{d}^{(1)}$ and $\delta \mathbf{d}^{(2)}$, respectively. For the ease of notation, the set of all finite element nodes is now split into three subsets: a subset \mathcal{S} containing all n_{sl} potential slave side contact nodes, a subset \mathcal{M} of all n_m potential master side contact nodes and the set of all remaining nodes \mathcal{N} . The global displacement vector can be sorted accordingly, yielding $\mathbf{d} = (\mathbf{d}_{\mathcal{N}}, \mathbf{d}_{\mathcal{M}}, \mathbf{d}_{\mathcal{S}})^T$. Then, the vector of discrete contact forces is

$$\mathbf{f}_c = [\mathbf{0} \quad -\mathbf{M} \quad \mathbf{D}]^T \mathbf{z}. \quad (12)$$

The contact forces extend the fully discretized force residual resulting from standard finite element discretization of internal and external virtual work in (3). This yields the total nonlinear force residual

$$\mathbf{r} := \mathbf{f}_{int}(\mathbf{d}) - \mathbf{f}_{ext} + \mathbf{f}_c(\mathbf{d}, \mathbf{z}) = \mathbf{0}. \quad (13)$$

A discrete version of the weak non-penetration condition is obtained by inserting the Lagrange multiplier interpolation (7) into (4)

$$\int_{\gamma_c^{(1)}} \delta \lambda_n g d\gamma \approx \sum_{j=1}^{n_{sl}} (\delta z_n)_j \int_{\gamma_c^{(1)h}} \Phi_j \hat{g} d\gamma := \sum_{j=1}^{n_{sl}} (\delta z_n)_j \tilde{g}_j \geq 0. \quad (14)$$

Here, \hat{g} is the discrete version of the gap function, and for each slave node $j \in \mathcal{S}$ a discrete normal weighted gap \tilde{g}_j has been introduced. Discretization of the remaining contact conditions yields as discrete formulation of the KKT conditions and the frictionless sliding conditions:

$$\tilde{g}_j \geq 0, (z_n)_j \geq 0, (z_n)_j \tilde{g}_j = 0, \quad (15)$$

$$(z_\tau^\xi)_j = (z_\tau^\eta)_j = 0. \quad (16)$$

It is worth mentioning that although a mortar discretization has been employed, the weighted constraints at discrete nodal points are enforced independently.

4 SOLUTION ALGORITHM

In our recent papers [1, 2, 3] the active set search has been successfully applied as a semi-smooth Newton method to both 2D and 3D finite deformation contact analysis. The main advantage of this new approach is the fact that all sources of nonlinearities, i.e. finite deformations, nonlinear material behavior and contact itself, can be efficiently treated within one single iterative scheme. The basic idea is a simple reformulation of the discrete KKT conditions in (15) within a so-called nonlinear complementarity function C_j for each slave node $j \in \mathcal{S}$:

$$C_j(\mathbf{z}_j, \mathbf{d}) = (z_n)_j - \max(0, (z_n)_j - c_n \tilde{g}_j) = 0, \quad c_n > 0. \quad (17)$$

It can be easily shown that (17) is equivalent to the set of KKT conditions and that this equivalence holds for arbitrary positive values of the purely algorithmic complementarity parameter c_n . While C_j is a continuous function, it is non-smooth and has no uniquely defined derivative at positions $(z_n)_j - c_n \tilde{g}_j = 0$. Yet, it is well-known from mathematical literature on constrained optimization [14] and from applications in small deformation contact analysis [12] that the *max*-function is semi-smooth and therefore a Newton method can still be applied. Deriving a consistent Newton method for the iterative solution of the nonlinear contact problem under consideration relies on the full linearization of all deformation-dependent quantities, such as nodal normal and tangential vectors or mortar integral matrices. This linearization process has been presented in great detail for both 2D and 3D case in [1, 2]. The resulting algorithm to be solved within one time increment is summarized next. All types of nonlinearities including the search for the correct active set are resolved within one Newton iteration, with the active and inactive sets \mathcal{A} and \mathcal{S} being updated after each semi-smooth Newton step:

Algorithm 1

1. Set $i = 0$ and initialize the solution $(\mathbf{d}_0, \mathbf{z}_0)$.
2. Initialization: $\mathcal{A}_0 \cup \mathcal{S}_0 = \mathcal{S}$ and $\mathcal{A}_0 \cap \mathcal{S}_0 = \emptyset$.
3. Find the primal-dual pair $(\Delta \mathbf{d}_i, \mathbf{z}_{i+1})$ by solving

$$\Delta \mathbf{r}|_i = -\mathbf{r}|_i, \quad (18)$$

$$\mathbf{z}_j|_{i+1} = 0 \quad \forall j \in \mathcal{S}_i, \quad (19)$$

$$\Delta \tilde{g}_j|_i = -\tilde{g}_j|_i \quad \forall j \in \mathcal{A}_i, \quad (20)$$

$$\Delta \boldsymbol{\tau}_j^{\xi/\eta} \cdot \mathbf{z}_j|_i + \boldsymbol{\tau}_j^{\xi/\eta} \cdot \mathbf{z}_j|_{i+1} = 0 \quad \forall j \in \mathcal{A}_i. \quad (21)$$

4. Update $\mathbf{d}_{i+1} = \mathbf{d}_i + \Delta \mathbf{d}_i$.

5. Set \mathcal{A}_{i+1} and \mathcal{J}_{i+1} to

$$\begin{aligned}\mathcal{A}_{i+1} &:= \{j \in \mathcal{J} \mid (z_n)_j|_{i+1} - c_n \tilde{g}_j|_{i+1} > 0\} , \\ \mathcal{J}_{i+1} &:= \{j \in \mathcal{J} \mid (z_n)_j|_{i+1} - c_n \tilde{g}_j|_{i+1} \leq 0\} .\end{aligned}\tag{22}$$

6. If $\mathcal{A}_{i+1} = \mathcal{A}_i$, $\mathcal{J}_{i+1} = \mathcal{J}_i$ and $\|\mathbf{r}_{tot}\| \leq \varepsilon_r$, then stop,
else set $i := i + 1$ and go to step (3).

Here, ε_r represents an absolute Newton convergence tolerance for the L2-norm of the total residual vector \mathbf{r}_{tot} , which comprises the force residual \mathbf{r} and the residual of the contact constraints (19)–(21). Numerous tests reveal that even for large step sizes and fine contacting meshes the correct active set is found after a few Newton steps. Once the sets remain constant, quadratic convergence is obtained due to the underlying consistent linearization. Owing to the dual Lagrange multiplier shape functions, the mortar matrix \mathbf{D} becomes diagonal, which makes its inversion trivial. Thus, the discrete multiplier values are eliminated by condensation and the resulting linear system of equations is not of saddle point type anymore but contains only displacement degrees of freedom. Here, we restrict the presentation to a schematic form

$$\mathbf{L}_{dd}|_i \Delta \mathbf{d}_i = -\tilde{\mathbf{r}}_{tot}|_i ,\tag{23}$$

which illustrates the modified residual vector $\tilde{\mathbf{r}}_{tot}$ emanating from \mathbf{r}_{tot} by condensation of the discrete Lagrange multiplier degrees of freedom. Similarly, we obtain a modified effective tangent stiffness matrix \mathbf{L}_{dd} including contact stiffness and condensed constraint terms.

5 RECENT EXTENSIONS OF THE PROPOSED METHODS

In this section, some recent extensions of the methods described above are outlined. This includes efficient parallel implementation, the treatment of self contact and Coulomb friction as well as the consistent integration of mortar contact into an XFEM based fixed-grid fluid-structure interaction framework.

5.1 Efficient parallel implementation and self contact

The solution of finite deformation contact problems is difficult to be managed due to the strong nonlinearities involved. A brute force approach for contact search may add another very time-consuming part, which is why efficient parallel search algorithms are needed. Here, we employ a recently developed approach [17] based on so-called discretized-orientation-polytopes (k-DOPs) as bounding volumes. Compared to the common axis-aligned bounding boxes, the k-DOPs allow for a much tighter and thus more efficient geometrical representation of the contact surfaces. Slave and master contact surface are organized within hierarchical binary tree structures so that very fast search and tree update procedures can be applied. The approach given in [17] for the single-processor case has been extended to fit into a parallel finite element simulation framework based on overlapping domain decomposition. An extension to self contact is presented in [18] and has also been included into our simulation framework. The search algorithm again is based on a bounding volume hierarchy organized as a binary tree. It is however crucial for self contact simulations to set up the bounding volume hierarchy in a *bottom-up* way based on mesh connectivity (e.g. using a dual graph). Moreover, a curvature criterion may be used to accelerate the searching procedure. Finally, dynamic assignment of slave and master sub-surfaces, which are unknown *a priori* for self contact problems, becomes necessary.

In addition, we make use of a novel strategy for dynamic load balancing specifically developed for mortar-based interface coupling. Within each time step the evaluation of contact integrals is adaptively distributed among all processors, so that an optimal balance of processor workload is obtained. Parallel (self) contact search and dynamic load balancing together assure the parallel scalability of all presented algorithmic components even when solving large contact dynamics problems with up to some million degrees of freedom.

5.2 Treatment of friction

An extension of the described mortar contact algorithms to the 2D frictional case has recently been proposed [3]. All steps outlined in Sections 2-4 remain conceptually unchanged. Only the frictionless sliding conditions introduced in (2) are replaced by frictional sliding conditions, e.g. using Coulomb's law. Based on an objective formulation of friction kinematic variables [8] the additional constraints again are recast into non-smooth nonlinear complementarity functions, as presented for the non-penetration constraint in (17). By applying full linearization, the frictional constraints are consistently integrated into the semi-smooth Newton scheme. All nonlinearities, now additionally including friction (i.e. search for the current stick and slip regions), are again treated within one single iterative scheme. For further details and numerical examples, the interested reader is referred to [3].

5.3 Fluid-structure-contact interaction

Finite deformation contact of flexible solids embedded in fluid flows occurs in a wide range of engineering scenarios. We recently proposed a novel three-dimensional finite element approach in order to tackle this problem class [4]. The method consists of the dual mortar contact formulation presented above, which is algorithmically integrated into an extended finite element method (XFEM) fluid-structure interaction approach [19, 20]. The combined fluid-structure-contact interaction method (FSCI) allows to compute contact of arbitrarily moving and deforming structures embedded in an arbitrary flow field. In [4], the fluid is described by stationary incompressible Navier-Stokes equations. An interface handling algorithm [21] is applied to obtain an exact fluid-structure interface representation, which permits to capture flow patterns around contacting structures very accurately as well as to simulate dry contact between structures. No restrictions arise for the structural and the contact formulation. A linearized monolithic system of equations can be derived, which contains the fluid formulation, the structural formulation, the contact formulation as well as the coupling conditions at the fluid-structure interface. This linearized system may then be solved either by partitioned or by monolithic fluid-structure coupling algorithms.

6 NUMERICAL EXAMPLES

We present three numerical examples to illustrate the capabilities of the proposed approach. All simulations are based on a parallel implementation of the contact and FSCI algorithms described above in our in-house multiphysics research code BACI [22]. A compressible Neo-Hookean constitutive law determined by Young's modulus E and Poisson's ratio ν is employed for all structures. Convergence of a Newton iterative scheme is measured in terms of the total residual norm with a relative convergence tolerance of 10^{-12} . The complementarity parameter described in Section 4 is set to $c_n = 1$, which guarantees for all problem setups considered that the correct active set is found within only a few semi-smooth Newton steps.

Figure 2: Two torus impact – displacement magnitude at characteristic stages of deformation: (a) $t = 3$; (b) $t = 5$; (c) $t = 7$; (d) $t = 7.5$; (e) $t = 8$; (f) $t = 10$.

6.1 Two torus impact

In this example, a finite deformation impact problem of two toruses ($E = 2250$, $\nu = 0.3$) is investigated. Both geometry and loading conditions are based on a quite similar analysis presented in [17] to evaluate contact search strategies. The finite element mesh consists of 1600 8-node hexahedral elements in total. The major and minor radius of the two hollow toruses is 76 and 24, respectively and the wall thickness is 4.5. The upper torus is rotated around the vertical axis by 45 degrees. We apply transient structural dynamics here using a Generalized- α time integration scheme [23] with the density of the contacting bodies chosen as $\rho = 0.1$.

During a total of 200 time steps (step size $\Delta t = 0.05$) the lower torus is first accelerated towards the upper torus and then a very general oblique impact situation with large structural deformations occurs. In addition to that, the proposed method needs to resolve continuous changes of the active contact set due to the large amount of (frictionless) sliding. Figure 2 shows six characteristic deformed configurations associated with the simulation stages described above.

Table 1 illustrates convergence of the presented fully linearized semi-smooth Newton scheme in terms of the total residual norm for two representative time steps both including large defor-

Newton step	(a) $t = 4.5$	(b) $t = 5.5$
1	1.09e+06 (*)	1.04e+06 (*)
2	2.16e+04 (*)	3.60e+04 (*)
3	4.05e+00	1.38e+01 (*)
4	1.53e-04	2.11e-03
5	2.46e-08	2.77e-08

(*) = change in active contact set

Table 1: Convergence behavior of the proposed semi-smooth Newton scheme in terms of the total residual norm for two representative time steps $\Delta t = 0.05$ starting from (a) $t = 4.5$ and (b) $t = 5.5$.

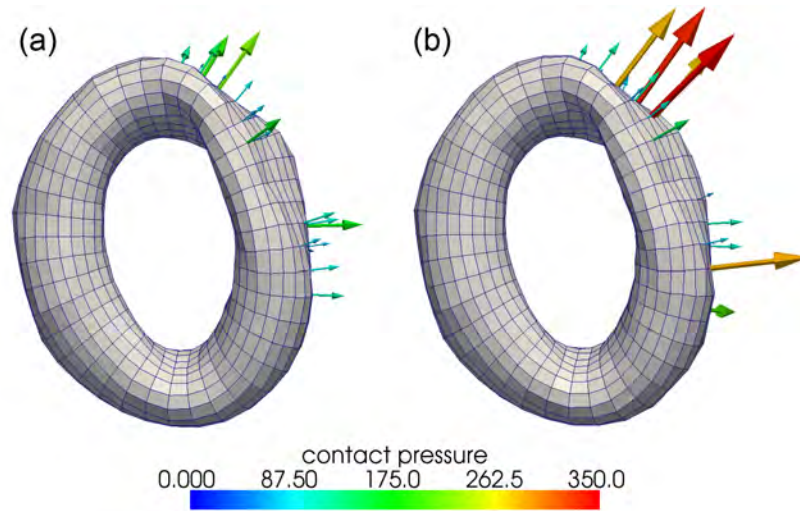

Figure 3: Two torus impact – exemplary visualization of the deformed lower torus and of the computed contact traction results at (a) $t = 5.5$ and (b) $t = 5.55$.

mations and considerable changes of the active contact set. The results demonstrate that the semi-smooth Newton method features excellent convergence in this example. The integration of all types of nonlinearities into a semi-smooth Newton scheme avoids tremendous computational cost as compared with a fixed-point type approach for the active set (see e.g. [9, 16]). Moreover, it is obvious that consistent linearization of all nonlinear quantities, including contact forces, normal and tangential vectors, is crucial to avoid deterioration of convergence.

To illustrate the strong nonlinearities involved in this problem setup even more clearly, Figure 3 shows the deformed lower torus at the beginning and at the end of the time step analyzed in column (b) of Table 1 (i.e. at $t = 5.5$ and at $t = 5.55$). The normal contact traction distribution, represented by the nodal Lagrange multiplier solution, is visualized with arrows and confirms that despite significant changes of the contact region, all nonlinearities are resolved efficiently and without deterioration of convergence within one single semi-smooth Newton iteration.

6.2 Hollow sphere pushed through elastic tube

In this example, a hollow sphere ($E = 500$, $\nu = 0.3$) is pushed through a tube ($E = 1000$, $\nu = 0.3$). Geometrical setup and finite element mesh based on 8-node hexahedral elements are depicted in Figure 4. Due to the application of a load-controlled scheme in combination with the frictionless sliding case considered, the deformation cannot be resolved by a quasistatic simulation. Thus, again transient structural dynamics is applied using Generalized- α time inte-

Figure 4: Sphere pushed through tube – geometry and finite element mesh.

Step	(a) during inflation	(b) during pushing

5	5.04e−11	4.87e−11

(*) = change in active contact set

Table 2: Convergence behavior of the proposed semi-smooth Newton scheme in terms of the total residual norm for two representative time steps during (a) inflation (steps 1–20) and (b) pushing (steps 21–40).

gration with the density of the contacting bodies chosen as $\rho = 7.8 \cdot 10^{-6}$. During a total of 40 time steps, we first inflate the hollow sphere by internal pressure (steps 1–20) and then push it along the axial direction of the tube (steps 21–40). Figure 5 shows two deformed configurations associated with the two stages described above.

Table 2 illustrates convergence in terms of the total residual norm for two representative time steps during inflation of the hollow sphere and during pushing. Again, for this transient contact simulation of two elastic bodies, the presented algorithm is capable of efficiently solving all types of nonlinearities including active set search within one semi-smooth Newton scheme.

Figure 5: Sphere pushed through tube – characteristic stages of deformation.

Figure 6: 3D torus contacting a stiff wall – (a) finite element mesh, (b) stream lines through the inner hole of the torus before contact (c)–(e) fluid velocity and structural movement are visualized for several time steps of the dynamic fluid-structure-contact interaction process.

6.3 Fluid-structure-contact interaction: elastic torus

The third test case illustrates a three-dimensional fluid-structure-contact interaction example. An elastic torus ($E = 4000$, $\nu = 0.4$) rotated around a horizontal axis by an angle of 65 degrees is placed in a 3D channel as depicted in Figure 6. A parabolic inflow profile is imposed at the top boundary of the channel and zero traction Neumann boundaries allow outflow on the left and right side near the bottom. All other channel boundaries are no-slip boundaries. Both the structural and the fluid mesh consist of 8-node hexahedral elements, with state-of-the-art stabilization techniques being used in the fluid elements. The velocity field around the moving torus is depicted in Figure 6. Stream lines illustrate the 3D fluid flow through the inner hole of the torus before contacting with the wall. At first, the torus is moving towards the wall due to the interaction with the fluid stresses. The exact interface representation allows to resolve flow patterns around the torus very close to contact and to simulate dry contact. After some time, the torus touches the wall and its further movement and deformation is influenced by the fluid at the fluid-structure interface and by contact forces at the contact interface.

7 CONCLUSIONS

The dual mortar method recently proposed by the authors for 3D finite deformation contact analysis has been reviewed and some important extensions have been highlighted. Consistent linearization of contact forces and constraints together with an interpretation of the active set search as a semi-smooth Newton scheme yields a very efficient solution algorithm. The accuracy of the presented method and its superior numerical robustness and efficiency have been demonstrated with several examples including finite deformations.

The integration of dual mortar contact into a fixed-grid fluid-structure interaction (FSI) framework based on the extended finite element method (XFEM) has been addressed shortly. This can be seen as a first step towards multiphysics and multiscale simulations, which couple contact analysis with several other physical fields and take into account effects on different length scales. Future work in this field will also focus on modeling finite deformation contact between slender beams and coupled thermomechanical contact, with applications ranging from Brownian dynamics of polymers in fiber networks to heat conduction and mechanical dissipation due to frictional sliding in turbine blade-to-disc joints.

Keywords: soft computing, evolutionary algorithm, artificial immune system, particle swarm optimizer, optimization, finite element method, boundary element method, dynamics

Abstract. *The paper is devoted to new computational techniques in structural dynamics where one tries to study, model, analyze and optimize very complex phenomena, for which more precise scientific tools of the past were incapable of giving low cost and complete solution. Soft computing methods differ from conventional (hard) computing in that, unlike hard computing, they are tolerant of imprecision, uncertainty, partial truth, and approximation. The paper deals with an application of the bio-inspired methods, like the evolutionary algorithms (EA), the artificial immune systems (AIS) and the particle swarm optimizers (PSO) to optimization problems. Structures considered in this work are analyzed by the finite element method (FEM) and the boundary element method (BEM). The bio-inspired methods are applied to optimize shape, topology and material properties of 3D structures modeled by the FEM and to optimize location of stiffeners in 2D reinforced plates modeled by the coupled BEM/FEM. The structures are optimized using the criteria depend on frequency, displacements or stresses. Numerical examples demonstrate that the methods based on the soft computation are effective for solving computer aided optimal design problems.*

1 INTRODUCTION

Structures are frequently subjected to dynamic loads and it is very important to analyze their transient dynamic response. Important properties of vibrating structures are eigenfrequencies. The dynamic response or natural frequencies of structures can be established by changing shape, topology and material properties of structures. Another possibility of the response improvement is applying stiffeners. The choice of their number, properties and location in a structure decides about the effectiveness of reinforcement. Reinforced structures are often used in practice because they are resistant, stiff and stable. A typical area of application of such structures is an aircraft industry, where light, stiff and highly resistant structures are required. Many aircraft elements are made as thin panels reinforced by stiffeners.

Dynamic response of structures with an arbitrary geometry, material properties and boundary conditions can be obtained by carrying out laboratory tests but they are usually very expensive and time consuming. In order to reduce costs and time, computer simulations are performed instead of experimental investigations. As a result, dynamic quantities of interest like displacements, velocities, accelerations, forces, stresses, i.e. can be determined. The most versatile methods of analysis of structures subjected to arbitrary static and time dependent boundary conditions are the finite element method (FEM) and the boundary element method (BEM). The coupling of these methods is very desirable in order to exploit their advantages. Optimal properties of dynamically loaded structures can be searched using the computer aided optimization tools.

In the present paper, coupling FEM and BEM with the bio-inspired methods in optimization of dynamically loaded structures is presented. The evolutionary algorithms (EA), the artificial immune systems (AIS) and the particle swarm optimizers (PSO) are used to optimize shape, topology and material properties of 3D freely vibrating structures and 2D dynamically loaded stiffened plates. The former are analyzed by the FEM and the latter by the coupled BEM/FEM.

2 SOFT COMPUTING METHODS

Soft computing techniques resemble human reasoning more closely than traditional techniques, which are largely based on conventional logical systems or rely heavily on the mathematical capabilities of a computer. These computing techniques are often used to complement each other in applications. It should be pointed out that simplicity and complexity of systems are relative, and certainly, most successful mathematical modeling of the past have also been challenging and very significant.

Unlike hard computing schemes, which strive for exactness and for full truth, soft computing techniques exploit the given tolerance of imprecision, partial truth, and uncertainty for a particular problem. Another common contrast comes from the observation that inductive reasoning plays a larger role in soft computing than in hard computing.

Three important areas of soft computing methods, namely:

- Evolutionary Computation (EC),
 - Artificial Immune Systems (AIS),
 - Particle Swarm Methods (PSM),
- are presented in the paper as soft computing methods.

2.1 Evolutionary Computation (EC)

Evolutionary algorithms [1, 10] are algorithms searching the space of solutions and they are based on the analogy to the biological evolution of species. Like in biology, the term of an individual is used, and it represents a single solution. Evolutionary algorithms operate on

populations of individuals, so while the algorithm works, all the time we deal with a set of problem solutions. An individual consists of chromosomes. Usually it is assumed that an individual has one chromosome. Chromosomes consist of genes which are equivalents of design variables in optimization problems. The adaptation is computed using a fitness function. All genes of an individual decide about the fitness function value. A flowchart of an evolutionary algorithm is presented in Fig. 1.

In the first step, an initial population of individuals is created. Usually, the values of the genes of particular individuals are randomly generated. In the next step, the fitness function value for each individuals is computed. Then, evolutionary operators change genes of the parent population individuals, they are then selected for the offspring population, which becomes a parent population and the algorithm is continuing iteratively till the end of the computation. The termination condition of the computation can be formulated as the maximum number of iterations.

In evolutionary algorithms the floating-point representation is applied, which means that genes included in chromosomes are floating-point numbers. Usually the variation of the gene value is limited.

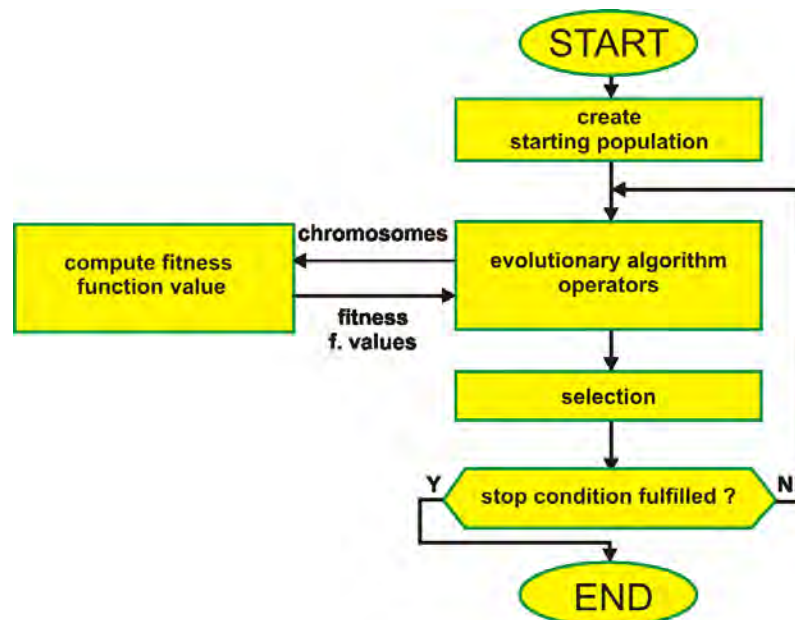

Figure 1: A flowchart of an evolutionary algorithm.

A single-chromosome individual (called a chromosome) ch_i , $i=1,2,\dots,N$, where N is the population size, may be presented by means of a column or line matrix, whose elements are represented by genes g_{ij} , $j=1,2,\dots,n$, where n is the number of genes in a chromosome. The sample chromosome is presented in Fig. 2.

$$ch_i = \begin{bmatrix} g_{i1} \\ g_{i2} \\ \vdots \\ g_{in} \end{bmatrix}$$

Figure 2: Structure of an individual.

Evolutionary operators change gene values like the biological mechanisms of mutation and crossover. Different kinds of operators are presented in publications, and the basic ones are:

- uniform mutation,
- mutation with Gaussian distribution,
- boundary mutation,
- simple crossover,
- arithmetical crossover.

A uniform mutation changes the values of randomly chosen genes in randomly selected individual. The new values of the genes are drawn in such a way that they could fulfill constraints imposed on the variation of the gene values. The diagram of how an operator works is presented in Fig. 3.

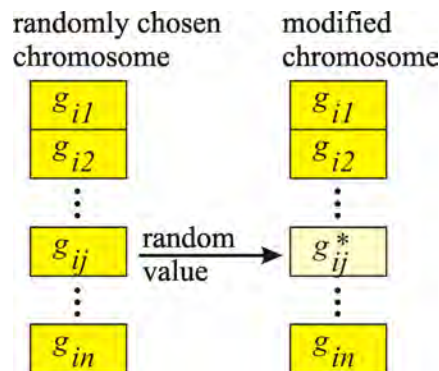

Figure 3: A diagram of an uniform mutation.

A mutation with Gaussian distribution is an operator changing the values of an individual's genes randomly, similarly to uniform mutation. New values of the genes are created by means of random numbers with Gaussian distribution. The operator searches the individual's surrounding.

A boundary mutation (Fig. 4) operates similarly to a uniform mutation, however, new values of the genes are equal to the left or right value from the gene variation range (left or right constraint on gene values).

Figure 4: A diagram of boundary mutation

A simple crossover is an operator creating an offspring on the basis of two parent individuals. A cutting position is drawn (Fig. 5), and a new individual consists of the genes coming partly from the first and partly from the second individual.

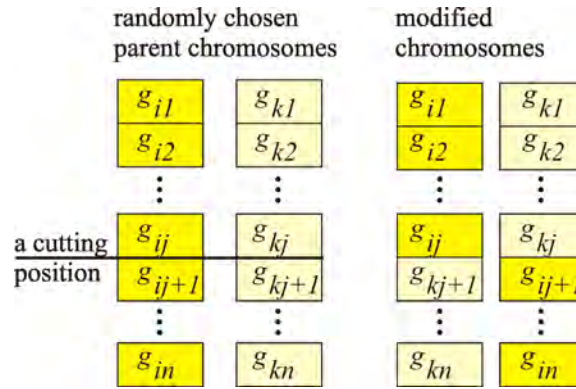

Figure 5: A diagram of a simple crossover

An arithmetical crossover has no biological counterpart. A new individual is formed similarly to a simple crossover, on the basis of two parent individuals, however, the values of the individual's genes are defined as the average value of the parent individuals' genes (Fig. 6).

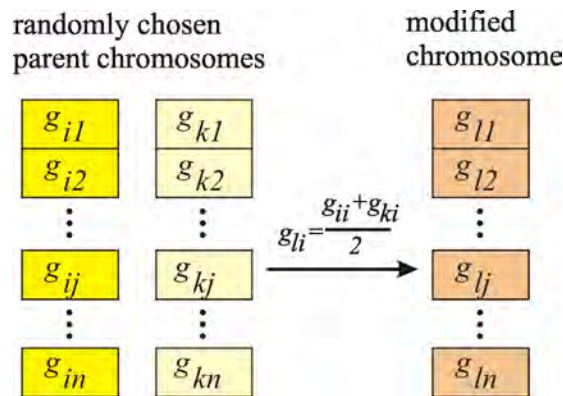

Figure 6: A diagram of an arithmetical crossover

An important element of an evolutionary algorithm is the mechanism of selection. The probability of the individual's survival depends on the value of the fitness function. Ranking selection is performed in a few steps. First, the individuals are classified according to the value of the fitness function, then a rank value is attributed to each individual. It depends on the individual's number and the rank function. The best individuals obtain the highest rank value, the worst obtain the lowest one. In the final step individuals for the offspring generation are drawn, but the probability of drawing particular individuals is closely related to their rank value.

2.2 Artificial Immune Systems (AIS)

The artificial immune systems (AIS) are developed on the basis of a mechanism discovered in biological immune systems [11]. An immune system is a complex system which contains distributed groups of specialized cells and organs. The main purpose of the immune system is to recognize and destroy pathogens - fungi, viruses, bacteria and improper functioning cells. The lymphocytes cells play a very important role in the immune system. The lymphocytes are divided into several groups of cells. There are two main groups B and T cells, both contains some subgroups (like B-T dependent or B-T independent). The B cells contain antibodies, which could neutralize pathogens and are also used to recognize pathogens. There is a big diversity between antibodies of the B cells, allowing recognition and neu-

tralization of many different pathogens. The B cells are produced in the bone marrow in long bones. A B cell undergoes a mutation process to achieve big diversity of antibodies. The T cells mature in thymus, only T cells recognizing non self cells are released to the lymphatic and the blood systems. There are also other cells like macrophages with presenting properties, the pathogens are processed by a cell and presented by using MHC (Major Histocompatibility Complex) proteins. The recognition of a pathogen is performed in a few steps (Fig. 7). First, the B cells or macrophages present the pathogen to a T cell using MHC (Fig. 7b), the T cell decides if the presented antigen is a pathogen. The T cell gives a chemical signal to B cells to release antibodies. A part of stimulated B cells goes to a lymph node and proliferate (clone) (Fig. 7c). A part of the B cells changes into memory cells, the rest of them secrete antibodies into blood. The secondary response of the immunology system in the presence of known pathogens is faster because of memory cells. The memory cells created during primary response, proliferate and the antibodies are secreted to blood (Fig. 7d). The antibodies bind to pathogens and neutralize them. Other cells like macrophages destroy pathogens (Fig. 7e). The number of lymphocytes in the organism changes, while the presence of pathogens increases, but after attacks a part of the lymphocytes is removed from the organism.

Figure 7: An immune system, a) a B cell and pathogen, b) the recognition of pathogen using B and T cells, c) the proliferation of activated B cells, d) the proliferation of a memory cell – secondary response, e) pathogen absorption by a macrophage.

The artificial immune systems [2], [3], [4] take only a few elements from the biological immune systems. The most frequently used are the mutation of the B cells, proliferation, memory cells, and recognition by using the B and T cells. The artificial immune systems have been used to optimization problems in [5], classification and also computer viruses recognition in [2]. The cloning algorithm presented by von Zuben and de Castro [4], [5] uses some mechanisms similar to biological immune systems to global optimization problems. The unknown global optimum is the searched pathogen. The memory cells contain design variables and proliferate during the optimization process. The B cells created from memory cells undergo mutation. The B cells evaluate and better ones exchange memory cells. In Wierzchoń [13] version of Clonalg the crowding mechanism is used - the diverse between memory cells is forced. A new memory cell is randomly created and substitutes the old one, if two memory cells have similar design variables. The crowding mechanism allows finding not only the global optimum but also other local ones. The presented approach is based on the Wierzchoń [13] algorithm, but the mutation operator is changed. The Gaussian mutation is used instead of the nonuniform mutation in the presented approach.

A flowchart of an artificial immune system is presented in Fig. 8. The memory cells are created randomly. They proliferate and mutate creating B cells. The number of clones created by each memory cell is determined by the memory cells objective function value. The objective functions for B cells are evaluated. The selection process exchanges some memory cells for better B cells. The selection is performed on the basis of the geometrical distance between each memory cell and B cells (measured by using design variables). The crowding mechanism removes similar memory cells. The similarity is also determined as the geometrical distance between memory cells. The process is iteratively repeated until the stop condition is fulfilled. The stop condition can be expressed as the maximum number of iterations.

Figure 8: An artificial immune system.

2.3 Particle Swarm Methods (PSM)

The particle swarm algorithms [12], similarly to the evolutionary and immune algorithms, are developed on the basis of the mechanisms discovered in the nature. The swarm algorithms are based on the models of the animals social behaviours: moving and living in the groups. The animals relocate in the three-dimensional space in order to change their stay place, the feeding ground, to find the good place for reproduction or to evading predators. We can distinguish many species of the insects living in swarms, fishes swimming in the shoals, birds flying in flocks or animals living in herds (Fig. 9).

Figure 9: Particles swarms: a) fish shoal (<http://www.sxc.hu/photo/1187373>), b) bird flock (<http://www.sxc.hu/photo/1095384>).

A simulation of the bird flocking was published in [12]. They assumed that this kind of the coordinated motion is possible only when three basic rules are fulfilled: collision avoidance, velocity matching of the neighbours and flock centring. The computer implementation of these three rules showed very realistic flocking behaviour flying in the three dimensional space, splitting before obstacle and rejoining again after missing it. The similar observations concerned the fish shoals. Further observations and simulations of the birds and fishes behaviour gave in effect more accurate and more precise formulated conclusions [9]. The results of this biological examination were used by Kennedy and Eberhart [7], who proposed Particle Swarm Optimiser – PSO. This algorithm realizes directed motion of the particles in n-dimensional space to search for solution for n-variable optimisation problem. PSO works in an iterative way. The location of one individual (particle) is determined on the basis of its earlier experience and experience of whole group (swarm). Moreover, the ability to memorize and, in consequence, returning to the areas with convenient properties, known earlier, enables adaptation of the particles to the life environment. The optimisation process using PSO is based on finding the better and better locations in the search-space (in the natural environment that are for example hatching or feeding grounds).

The algorithm with continuous representation of design variables and constant constriction coefficient (constricted continuous PSO) has been used in presented research. In this approach each particle oscillates in the search space between its previous best position and the best position of its neighbours, with expectation to find new best locations on its trajectory. When the swarm is rather small (swarm consists of several or tens particles) it can be assumed that all the particles stay in neighbourhood with currently considered one. In this case we can assume the global neighbourhood version and the best location found by swarm so far is taken into account – current position of the swarm leader (Fig. 10).

Figure 10: The idea of the particle swarm.

The position of the i -th particle is changed by stochastic velocity v_i , which is dependent on the particle distance from its earlier best position and position of the swarm leader. This approach is given by the following equations:

$$v_{ij}(k+1) = wv_{ij}(k) + \phi_{1j}(k)[q_{ij}(k) - d_{ij}(k)] + \phi_{2j}(k)[\hat{q}_{ij}(k) - d_{ij}(k)] \quad (1)$$

$$d_{ij}(k+1) = d_{ij}(k) + v_{ij}(k+1), \quad i = 1, 2, \dots, m; j = 1, 2, \dots, n \quad (2)$$

where:

$$\phi_{1j}(k) = c_1 r_{1j}(k); \quad \phi_{2j}(k) = c_2 r_{2j}(k),$$

m – number of the particles,

n – number of design variables (problem dimension),

w – inertia weight,

c_1, c_2 – acceleration coefficients,

r_1, r_2 – random numbers with uniform distribution $[0,1]$,

$d_i(k)$ – position of the i -th particle in k -th iteration step,

$v_i(k)$ – velocity of the i -th particle in k -th iteration step,

$q_i(k)$ – the best found position of the i -th particle found so far,

$\hat{q}_i(k)$ – the best position found so far by swarm – the position of the swarm leader,

k – iteration step.

The velocity of i -th particle is determined by three components of the sum in Equation (1). The first component $wv_i(k)$ plays the role of the constraint to avoid excessive oscillation in the search space. The inertia weight w controls the influence of particle velocity from the previous step on the current one. In this way this factor controls the exploration and exploitation. Higher value of inertia weight facilitates the global searching, and lower – the local searching. The inertia weight plays the role of the constraint applied for the velocities to avoid particles dispersion and guaranteeing convergence of the optimisation process. The second component $\phi_1(k)[q_i(k) - d_i(k)]$ realizes the cognitive aspect. This component represents the particle distance from its best position found earlier. It is related to the natural inclination of the individuals (particles) to the environments where they had the best experiences (the best value of the fitness function). The third component $\phi_2(k)[\hat{q}_i(k) - d_i(k)]$ represents the particle distance from the position of the swarm leader. It refers to the natural inclination of the individuals to follow the other which achieved a success.

The flowchart of the particle swarm optimiser is presented in Fig. 11. At the beginning of the algorithm the particle swarm of assumed size is created randomly. Starting positions and velocities of the particles are created randomly. The objective function values are evaluated for each particle. In the next step the best positions of the particles are updated and the swarm leader is chosen. Then the particles velocities are modified by means of the Equation (1) and particles positions are modified according to the Equation (2). The process is iteratively repeated until the stop condition is fulfilled. The stop condition is typically expressed as the maximum number of iterations.

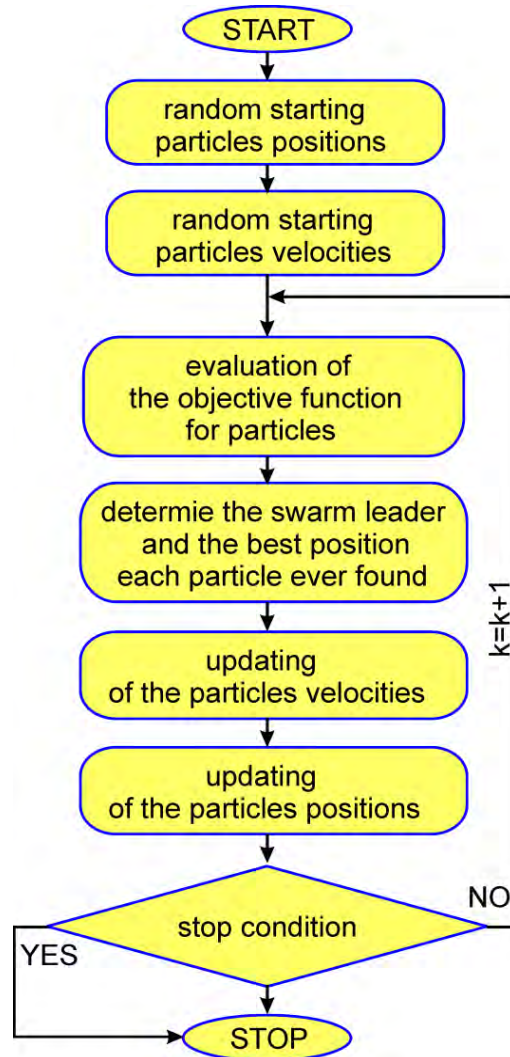

Figure 11: Particle swarm optimiser – block diagram.

The general effect is that each particle oscillates in the search space between its previous best position (position with the best fitness function value) and the best position of its best neighbour (relatively swarm leader), hopefully finding new best positions (solutions) on its trajectory, what in whole swarm sense leads to the optimal solution.

3 SOFT COMPUTING IN OPTIMIZATION OF DYNAMICALLY LOADED STRUCTURES

3.1 Evolutionary generalized optimization of structures modeled by the FEM

Consider a structure which, at the beginning of an evolutionary process, occupies a domain Ω_0 (in E^3), bounded by a boundary Γ_0 . The domain Ω_0 is filled by a elastic homogeneous and isotropic material of a Young's modulus E_0 and a Poisson ratio ν . The 3-D structures are considered in the framework of the linear theory of elasticity. During the evolutionary process the domain Ω_t , its boundary Γ_t and the field of Young's modulus $E(x, y, z) = E_t, (x, y, z) \in \Omega_t$ can change for each generation t (for $t=0$, $E_0=\text{const}$). The evolutionary process proceeds in an environment in which the structure fitness is describing by

maximization of the objective functions:

a) maximization of the first eigenfrequency

$$\max(\omega_1) \quad (3)$$

with a constraint imposed on the volume of the structure

$$\begin{aligned} V &\equiv |\Omega| \\ V &\leq V^{\max} \end{aligned} \quad (4)$$

b) maximization of the difference between first, second and third eigenfrequency

$$\max[(\omega_2 - \omega_1) + (\omega_3 - \omega_2)] \quad (5)$$

with a constraint imposed on the volume of the structure (4)

c) maximization of the difference between first, second, third eigenfrequency and forced vibration frequency ω_{forced}

$$\max\left[|\omega_1 - \omega_{forced}| + |\omega_2 - \omega_{forced}| + |\omega_3 - \omega_{forced}|\right] \quad (6)$$

with a constraint imposed on the volume of the structure (4).

The distribution of Young's modulus $E(x, y, z)$, $(x, y, z) \in \Omega_t$ in the structure is described by a hyper surface $W(x, y, z)$, $(x, y, z) \in H^3$. The hyper surface $W(x, y, z)$ is stretched under $H^3 \subset E^3$ and the domain Ω_t is included in H^3 , i.e. $(\Omega_t \subseteq H^3)$.

The shape of the hyper surface $W(x, y, z)$ is controlled by genes d_j , $j=1, 2, \dots, N$, which create a chromosome

$$ch = \langle d_1, d_2, \dots, d_j, \dots, d_N \rangle \quad (7)$$

Gene values are described by the function $W(x, y, z)$ in interpolation nodes (control points) $(x, y, z)_j$, i.e. $d_j = W[(x, y, z)_j]$, $j=1, 2, \dots, N$.

The following constraints are imposed on genes

$$d_j^{\min} \leq d_j \leq d_j^{\max} \quad (8)$$

where d_j^{\min} - the minimum value of the gene and d_j^{\max} - the maximum value of the gene.

The assignation of Young's moduli to each finite element Ω_e , $e=1, 2, \dots, R$ is performed by the mapping:

$$E_e = W[(x, y, z)_e], (x, y, z)_e \in \Omega_e, e=1, 2, \dots, R \quad (9)$$

It means that each finite element can have different material.

When the value of Young's modulus for the e -th finite element is included in the interval $0 \leq E_e < E_{\min}$, the finite element is eliminated and the void is created, the interval $E_{\min} \leq E_e < E_{\max}$, the finite element remains having the value of the Young's modulus from this material. As a result, shape, topology and material properties of the structure are changing simultaneously and this procedure is called *evolutionary generalized optimization*.

Example 1 – maximization of the first eigenfrequency of a 3D bracket

A structure like a 3D bracket (Fig. 12a) is optimized. The criterion of optimization is the maximization of the first eigenfrequency. The best solution obtained after 88 generations is presented in Fig. 12b. The Table 1 contains input data.

Minimal Young's module	Maximal volume
$0.4 \times 2 \cdot 10^5$ MPa	4000 mm^3
Numbers of chromosomes	
100	

Table 1: Input data.

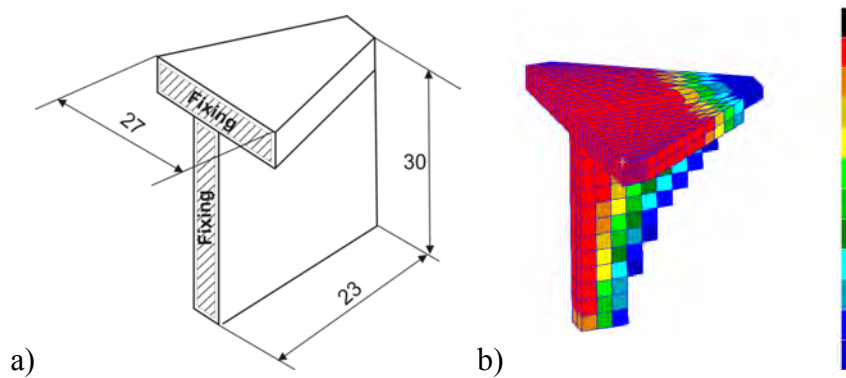

Figure 12: A 3-D bracket: a) geometrical dimensions b) distribution of Young's moduli

Example 2 – maximization of the difference between first, second and third eigenfrequency of a rectangular prism

A 3D structure in the form of a rectangular prism (Fig. 13a) is optimized. The criterion of optimization is the maximization of the difference between first, second and third eigenfrequencies. The best solution in the form of a distribution of Young's moduli obtained after 169 generations is performed in Fig. 13b. Input data are included in Table 2.

Minimal Young's module	Maximal volume
$0.4 \times 2 \cdot 10^5$ MPa	$4.8 \text{e}4 \text{ mm}^3$
Numbers of chromosomes	Dimensions of cuboid
100	$200 \times 80 \times 12 \text{ mm}$

Table 2: Input data.

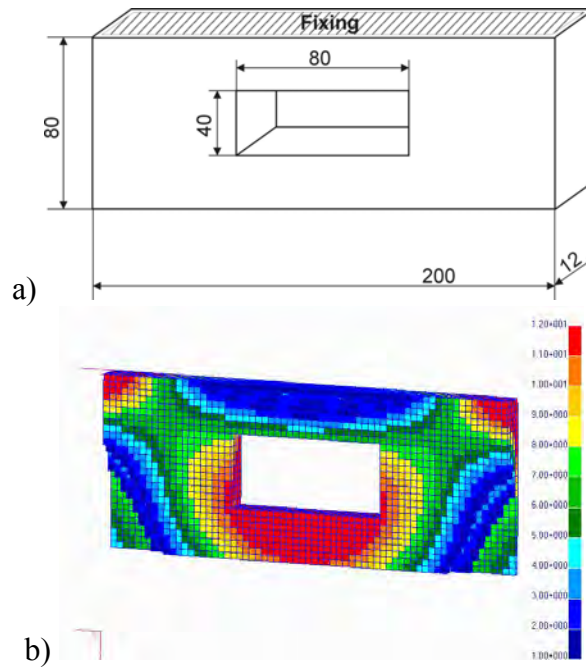

Figure 13: A rectangular prism: a) dimensions, b) distribution of Young's moduli.

Example 3 - maximization of the difference between first, second and third eigenfrequency and forced vibration frequency of a rectangular prism

The last example concerns optimization of a 3D structure from the previous example (Fig. 13a). The criterion of optimization is the maximization of the difference between first, second and third eigenfrequencies and forced vibration frequency. The best solution is obtained after 134 generations is presented in Fig. 14. Input data are included in Table 3.

Minimal Young's module	Maximal volume
$0.4 \times 2 \cdot 10^5$ MPa	80000 mm ³
Numbers of chromosomes	Dimensions of cubicoid
100	200 x 80 x 12 mm

Table 3. Input data

Figure 14: Distribution of Young's moduli for a rectangular prism obtained for the resonance criterion.

3.2 Bio-inspired optimization of structures modeled by the coupled BEM/FEM

A two-dimensional, homogenous, isotropic and linear elastic deformable body with boundary Γ_1 and occupying domain Ω_1 , is considered. The body is modeled as a plate in plane stress or strain and it is reinforced by the stiffener occupying domain Ω_2 . The body is supported (displacements $u(x, \tau)$ are known at a part of the outer boundary) and subjected to dynamic tractions $t(x, \tau)$ (where τ is time), applied at the outer boundary, as shown in Fig.15.

Figure 15: Reinforced plate subjected to dynamic loads.

The plate is modeled by the boundary element method (BEM) [6] and the stiffener by the finite element method (FEM) using beam finite elements, attached along the Γ_{12} boundary (the interface). A perfect bonding between the plate and the stiffener is assumed. The whole structure is analyzed by the coupled BEM/FEM and the subregion method [8]. The method allows modeling of bodies with many plate subdomains and stiffeners of different properties. The numerical equations, which are written for each plate and beam subdomain separately, are coupled using displacement compatibility conditions and traction equilibrium conditions at all nodes along the common boundaries.

A set of algebraic equations for the plate in Fig.15 has the following form:

$$\begin{bmatrix} \mathbf{M}^1 & \mathbf{M}^{12} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{u}}^1 \\ \ddot{\mathbf{u}}^{12} \end{Bmatrix} + \begin{bmatrix} \mathbf{H}^1 & \mathbf{H}^{12} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^1 \\ \mathbf{u}^{12} \end{Bmatrix} = \begin{bmatrix} \mathbf{G}^1 & \mathbf{G}^{12} \end{bmatrix} \begin{Bmatrix} \mathbf{t}^1 \\ \mathbf{t}^{12} \end{Bmatrix} \quad (10)$$

where: \mathbf{M} is the mass matrix, \mathbf{H} and \mathbf{G} are the BEM coefficient matrices, \mathbf{u} and $\ddot{\mathbf{u}}$ are displacement and acceleration vectors, respectively, \mathbf{t} is a vector of tractions applied at the outer boundary or the interface. The superscripts denote the matrices, which correspond to the outer boundary or the interface.

The equation of motion for the stiffener in Fig.15 in a matrix form is:

$$\mathbf{M}^{21} \ddot{\mathbf{u}}^{21} + \mathbf{K}^{21} \mathbf{u}^{21} = \mathbf{T}^{21} \mathbf{t}^{21} \quad (11)$$

where: \mathbf{K} is the FEM stiffness matrix, \mathbf{T} is the matrix, which expresses the relationship between the FE nodal forces and the BE tractions. The latter matrix allows treatment the finite element region as an equivalent boundary element region.

If the structure is subjected to time dependent boundary conditions, the dynamic interaction forces between the plate and the stiffener act along the interface. These tractions are treated as body forces distributed along the attachment line and they are unknowns of the problem. The displacement compatibility conditions and the traction equilibrium conditions at the nodes along the interface are:

$$\mathbf{u}^{12} = \mathbf{u}^{21} ; \quad \mathbf{t}^{12} = -\mathbf{t}^{21} \quad (12)$$

If the above conditions are taken into account in equations for the plate (10) and stiffener (11), the following system of equations for the whole structure is obtained:

$$\begin{bmatrix} \mathbf{M}^1 & \mathbf{M}^{12} \\ 0 & \mathbf{M}^{21} \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{u}}^1 \\ \ddot{\mathbf{u}}^{12} \end{Bmatrix} + \begin{bmatrix} \mathbf{H}^1 & \mathbf{H}^{12} & -\mathbf{G}^{12} \\ 0 & \mathbf{K}^{21} & \mathbf{T}^{21} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^1 \\ \mathbf{u}^{12} \\ \mathbf{t}^{12} \end{Bmatrix} = \mathbf{G}^1 \mathbf{t}^1 \quad (13)$$

The unknowns are displacements and tractions on the external boundary and at the interface in each time step.

Example 4 – Reinforced rectangular plate

Optimization of a reinforced rectangular plate (Fig.16) is performed by means of AIS, PSO and EA. The plate is dynamically loaded and it is reinforced by the frame-like structure composed of straight beams. The plate and the stiffeners are modeled by the boundary elements and frame finite elements, respectively. Different kinds of load and support are considered. The structure before optimization (the reference plate) is shown in Fig. 16.

Figure 16: Reinforced rectangular plate.

The length and the height of the plate is $L=10$ cm and $H=5$ cm, respectively. The thickness of the plate is $g=0.25$ cm, the dimensions of beams cross-section are $2a=0.5$ cm and $b=0.5$ cm.

The material of the plate and frame is aluminum and the mechanical properties are: modulus of elasticity $E=70$ GPa, Poisson's ratio $\nu=0.34$ and density $\rho=2700$ kg/m³. The material is homogeneous, isotropic and linear elastic and the plane stress is assumed.

The uniformly distributed load is applied at the upper edge of the plate. Two kinds of time dependent loads are considered (see Fig.17): a) the sinusoidal load $p(\tau)=p_0 \sin(2\pi\tau/T)$ with the period of time $T=20\pi$ μs, and b) the Heaviside load $p(\tau)=p_0 H(\tau)$. The value of the load in both cases is $p_0=10$ MPa. The time of analysis is 600 μs and the time step $\Delta t=2$ μs.

Figure 17: Dynamic loadings: a) sinusoidal, b) Heaviside.

Three different supports are considered (see Fig.18):

- support A – the plate is fixed on the left and right edge,
- support B – the plate is supported at two segments, each of 0.5 cm long,
- support C – the plate is fixed at the bottom edge.

Figure 18: Types of supports: a) support A, b) support B, c) support C.

The optimal positions of stiffeners are searched in order to maximize stiffness of the plate. The maximal dynamic vertical displacement on the loaded edge is minimized. Because of symmetry of the structure and boundary conditions, only a half of the structure is considered. The number of design variables defining the position of the frame is 4: $X1$, $X2$, $Y1$ and $Y2$ (see Fig.19). The longer beams are parallel to the x axis. The end points of beams can move along the edges of the plate within the constraints, as shown in Fig.19. The constraints on design variables are imposed: $X1$ and $X2$ variables are within the range from 0.5 to 4.75 cm, $Y1$ from 0.5 to 2.25 cm and $Y2$ from 2.75 to 4.5 cm. The parameters of AIS are: the number of memory cells and the clones is 6, the crowding factor and the Gaussian mutation is 0.5. The parameters of EA are: the number of chromosomes is 20, the probability of the Gaussian mutation is 0.5, the probability of a simple and arithmetic crossover is 0.05. The parameters of PSO are: numbers of particles is 20, inertia weight is 0.73 and two acceleration coefficients are 1.47.

Figure 19: Design variables and constraints.

The total number of boundary and finite elements in the BEM/FEM analysis is 120 and 120, respectively (each horizontal and vertical beam is discretized into 40 and 20 finite elements, respectively). The number of boundary and finite elements during the optimization is constant.

The values of design variables obtained by AIS, PSO and EA for the plate subjected to the sinusoidal load, the Heaviside load and for three kinds of supports, are presented in Table 3. The results obtained by three different methods are almost the same. The values of J_0 and J (where: J_0 and J is the objective function for the reference and the optimal plate, respectively) and the reduction $R=(J_0-J)/J_0 \cdot 100\%$, are also presented.

A significant reduction R , resulting in the improvement of dynamic response of the optimal plates in comparison with the initial designs, can be observed. The optimal structures for different kinds of supports and for the sinusoidal and the Heaviside loads are shown in Fig.20a and Fig.20b, respectively. It can be seen that in the present example most of constraints are active.

Load	Support	Design variables [cm]				J _o [10 ⁻⁴ cm]	J [10 ⁻⁴ cm]	R [%]
		X1	X2	Y1	Y2			
AIS, PSO and EA								
Sinusoidal	A	4.75	2.86	0.88	2.75	89	76	15
	B	4.75	1.81	0.57	2.75	92	73	21
	C	1.20	1.82	0.50	2.75	82	62	24
Heaviside	A	0.50	4.75	0.50	4.50	112	91	19
	B	4.75	1.41	0.50	4.50	211	149	29
	C	0.50	2.20	1.70	2.80	49	42	14

Table 4: Values of design variables, J and R .

Figure 20: Optimal plates subjected to dynamic loads: a) sinusoidal, b) Heaviside.

The number of fitness function evaluations by three different bio-inspired algorithms used in this example is presented in Table 5. It can be observed that the number of fitness function evaluations for obtaining the final design variables and the corresponding fitness functions presented in Table 5 is different and depends on the applied load and support. Generally, the efficiency of the AIS and the PSO is similar and much better for this particular example, than the efficiency of the EA.

Load	Support	EA	AIS	PSO
		fitness function evaluations		
Sinusoidal	A	2515	336	360
	B	3705	408	440
	C	1952	432	520
Heaviside	A	303	276	60
	B	1526	252	120
	C	2797	528	580

Table 5: Efficiency of bio-inspired methods.

Example 5 – Reinforced plate with a hole

Optimization of a rectangular reinforced plate with a hole (Fig. 21) is performed by means of PSO with the same parameters like in the example 4. The plate is dynamically loaded and it is reinforced by 8 symmetrically distributed rods of circular cross-section. The plate and the reinforcing rods are modeled by the boundary elements and beam finite elements, respectively. The structure before optimization (the reference plate) is shown in Fig. 21.

Figure 21. Reinforced plate with a hole.

The plate is stretched by a uniformly distributed load applied at its left and right edge. The dynamical load is defined by the Heaviside impulse $p(t)=p_oH(t)$, the value of the load is $p_o=10$ MPa. The time of analysis is $T=300 \mu s$ and the time step $\Delta t=3 \mu s$.

The length and the height of the plate and the hole radius is $L=10$ cm, $H=5$ cm and $R=1$ cm, respectively. The thickness of the plate is $g=1$ cm and the diameter of each rod is $d=0.3$ cm. Distance between the rod axes for the reference plate is 1 cm, the length of the shorter and longer rods is 3 cm and 4 cm, respectively. Distance between the end points of the rods to the left or right edge of the plate is 0.5 cm.

The plane stress is assumed. The materials of the plate (p) and stiffeners (s) are epoxy and steel, respectively. They are homogeneous, isotropic and linear elastic. The values of mechanical properties are: modulus of elasticity $E_p=4.5$ GPa and $E_s=210$ GPa, Poisson's ratio $\nu_p=0.37$ and $\nu_s=0.3$, density $\rho_p=1160$ kg/m³ and $\rho_s=7860$ kg/m³.

The optimal location of reinforcement in the interior of the plate is searched and the following objective function J is minimized:

$$J = \int_0^T \frac{|\sigma_x^A(t)|^2}{\sigma_o} dt \quad (14)$$

where $\sigma_x^A(t)$ is the x-component of stress at the point A (see Fig. 21), σ_o is a nominal stress at the weakened cross-section, defined as the ratio of the applied load to the area of this cross-section, T is a time of analysis.

The objective function (14) is minimized with respect to design variables ($X_{ij}, Y_{ij}, i, j=1,2$), defining the coordinates of the j -th end point of the i -th rod. It is assumed that during optimization the reinforcement is symmetrical with respect to two symmetry axes. Thus only a quarter of the plate with two rods is modeled (the appropriate boundary conditions at the symmetry axes are assumed) and the number of design variables is 8.

The constraints on design variables are imposed. The distance between the rods and the outer boundary (of the quarter of the plate) cannot be lower than 0.5 cm. The intersection of rods is not allowed.

The total number of boundary and finite elements in the BEM/FEM analysis is 92 and 64, respectively (each rod is discretized into 32 finite elements).

For this example five tests were performed and similar results were obtained. The values of design variables for the optimal solutions, rounded off to two decimal places, are: $X11=0.97$ cm, $Y11=1.03$ cm, $X12=4.50$ cm, $Y12=1.50$ cm, $X21=1.57$ cm, $Y21=2.00$ cm, $X22=4.50$ cm and $Y22=2.00$ cm. The optimal structure is shown in Fig. 22.

Figure 22. Optimal location of rods in the plate.

Example 6 – Reinforced cantilever plate

Optimization of a reinforced cantilever plate (Fig. 23) is performed by means of PSO with the same parameters like in the example 4. The dynamically loaded plate is reinforced at the whole non-fixed outer boundary and between two holes (at the interface between two BE regions). The reinforcement has rectangular cross-section. The plate and the reinforcement are modeled by the boundary elements and frame finite elements, respectively. The structure before optimization (the reference plate) is shown in Fig. 23.

Figure 23. Reinforced cantilever plate.

The uniformly distributed load is applied at the upper edge. The plate is subjected to the sinusoidal load $p(t)=p_o\sin(2\pi t/T)$. The amplitude of the load is $p_o=1\text{ MPa}$ and the period of time is $T=5\text{ ms}$. The time of analysis is 12 ms and the time step $\Delta t=0.02\text{ ms}$.

The length and the height of the plate is $L=50\text{ cm}$ and $H=40\text{ cm}$, respectively. The other dimensions are: $a=5\text{ cm}$, $b=1\text{ cm}$, $c=5\text{ cm}$ and $g=1\text{ cm}$. The $L1$, $L2$ and $H1$, $H2$ defining the shape of the cantilever, are design variables of the problem and they are within the range from 15 to 35 cm and 0 to 25 cm , respectively.

The plane stress is assumed. The cantilever is linear elastic, isotropic and homogeneous and its material is steel. The values of mechanical properties are: modulus of elasticity $E=210\text{ GPa}$, Poisson's ratio $\nu=0.3$ and density $\rho=7860\text{ kg/m}^3$.

The optimal shape of the cantilever is searched and the following objective function J is minimized:

$$J = \int_0^T \frac{|u_y^A(t)|^2}{u_o} dt \quad (15)$$

where $u_y^A(t)$ is a vertical displacement at the point A (see Fig. 23), u_o is an admissible displacement, T is a time of analysis.

The objective function (15) is minimized with respect to design variables (L_i , H_i $i,j=1,2$), defining dimensions of the structure.

The total number of boundary and finite elements in the BEM/FEM analysis is 84 and 72, respectively. The quadratic elements (with 2 degrees of freedom per node) are employed for the BEM mesh. The frame elements (with 3 degrees of freedom per node) are used for the FEM mesh. During optimization the number of boundary and finite elements is constant.

Figure 24. Optimal shape of the cantilever.

For this example five tests were performed and similar results were obtained. The values of design variables for the optimal solutions are (rounded off to two decimal places): $L1=30.62\text{ cm}$, $L2=35.00\text{ cm}$, $H1=25.00\text{ cm}$ and $H2=25.00\text{ cm}$. The optimal structure is shown in Fig. 24.

4 CONCLUSIONS

In the paper, the formulation and application of the finite element method, the boundary element method and the bio-inspired methods to optimization of shape, topology and material properties of dynamically loaded structures for different criteria of optimization is presented. The bio-inspired methods can be simply implemented because they need only the values of objective functions. An important feature of these approaches is a strong probability of finding the global optimal solutions. The described approaches are free from limitations of classic gradient optimization methods.

In the presented approach, shape, topology and material optimization is performed simultaneously for 3D freely vibrating structures analyzed by the finite element method. The optimal location of reinforcement is searched in order to increase a stiffness or strength of dynamically loaded reinforced plates analyzed by the coupled boundary/finite element method. As a result of optimization, a significant improvement of dynamic response is obtained, in comparison with initial designs.

Coupling of finite or boundary element method and the bio-inspired algorithms give an effective and efficient alternative optimization tool, which enables solving a large class of the optimization problems of mechanical structures. Numerical examples confirm the efficiency of the proposed optimization method and demonstrate that the methods based on soft computing are effective techniques for solving computer aided optimal design problems. Generally, for the considered numerical examples, the efficiency of the artificial immune systems and the particle swarm optimizers is better than the evolutionary algorithms.

Abstract. *The present paper investigates the optimum way of reinforcing existing composite steel-concrete structures that violate the criteria suggested in Eurocode 4. The motivation to conduct the specific research is the need for existing structures to conform to new regulations without extensive operations.*

Composite steel-concrete systems are an attractive construction method, since they have been found to be cost-effective, especially for multi-storey buildings, and also successfully take advantage of the high stiffness of steel without its vulnerability to fire. These structural systems are not new and have been used since the beginning of the 20th century, so there is a number of existing structures which have been designed with previous versions of structural codes and have to conform to the modern regulations. It is obvious that each new set of design codes takes into account new dangers that might occur and updates the design methods already used. On the other hand, the economic considerations which have to be taken into account and the high market competition force the engineers to seek solutions that are at the same time easily and rapidly constructed, but also yield the required performance with the minimum cost.

The present work presents two retrofit methods for composite steel-concrete frames, which are evaluated in the context of structural optimization. The frames considered fail to satisfy the provisions of Eurocode 4 and are therefore retrofitted with the two aforementioned methods in a way minimizing the total cost of steel and concrete required for the retrofit. This way, the frames are upgraded with minimal cost.

1 INTRODUCTION

The present paper investigates the optimum way of reinforcing existing composite steel-concrete structures that violate the criteria suggested in Eurocode 4. The motivation to conduct the specific research is the need for existing structures to conform to new regulations without extensive operations.

Composite steel-concrete systems are an attractive construction method, since they have been found to be cost-effective, especially for multi-storey buildings, and also successfully take advantage of the high stiffness of steel without its vulnerability to fire. These structural systems are not new and have been used since the beginning of the 20th century, so there is a number of existing structures which have been designed with previous versions of structural codes and have to conform to the modern regulations. It is obvious that each new set of design codes takes into account new dangers that might occur and updates the design methods already used. On the other hand, the economic considerations which have to be taken into account and the high market competition force the engineers to seek solutions that are at the same time easily and rapidly constructed, but also yield the required performance with the minimum cost.

The present work presents two retrofit methods for composite steel-concrete frames, which are evaluated in the context of structural optimization. The frames considered fail to satisfy the provisions of Eurocode 4 and are therefore retrofitted with the two aforementioned methods in a way minimizing the total cost of steel and concrete required for the retrofit. This way, the frames are upgraded with minimal cost. Both retrofit methods presented were selected so that they can be easily designed by the engineer and their application does not require too specialized knowledge.

2 RETROFIT METHODS

The retrofit philosophy used is the same for both methods presented in this work: the creation of an external layer of concrete with a metal cage that enhances the initial section's capacity and also confines the additional concrete. The difference between the two methods is in the type of reinforcement used. In the first method emphasis is given to steel, while the second method focuses on the use of concrete.

2.1 Method 1: Plates Method

This retrofit consists vertically of three plates per side; one rectangular and two of Γ -shape and horizontally of a number of rectangular plates that can be determined by the shear resistance criterion. The horizontal plates can be welded on the vertical ones or be added externally. The second option might seem easier to construct, but results in thicker concrete cover. Obviously, since there are only the cover concrete layer and a few patches between the plates, the concrete's contribution to the section's capacity might be ignored. However, in the present research, it has been taken into account.

The installation procedure is quite simple. The external smear is removed and steel plates are placed in touch with the existing concrete, as shown in Fig. 1. Depending on the construction method used, the whole cage might be in two parts, which are welded together on site, or independent horizontal and vertical plates that are welded one by one, as mentioned before (the horizontal ones at the outer side). Thus, a steel cage of the form shown in Fig. 2 is constructed. Then, the gaps between the plates and the desired concrete cover are filled with concrete.

Figure 1: Cross-section of the retrofitted column (plates method).

Figure 2: View of the cage on the column (plates method).

2.2 Method 2: Bars Method

In this method, the concrete is not only on the cover of the retrofit, but also in its core. The design of the new section is done with the typical philosophy of retrofitting a reinforced concrete column; there is longitudinal and transverse reinforcement surrounding the concrete, which contribute to the section's bending moment and shear capacity. The longitudinal reinforcement consists of 3 to 5 bars per side, depending on the dimensions of the existing column. The transverse reinforcement consists of rectangular stirrups that travel around the column. The location of the longitudinal bars is shown in Fig. 3, while the cage formed is illustrated in Fig. 4. The external smear has to be removed here too, in order to install the retrofit set-up. Contrary to the plates method, a rough surface of the existing concrete would increase the adhesion of it with the new concrete.

3 THE OPTIMIZATION PROBLEM

The objective function that has to be minimized is the total cost of retrofit that is calculated as:

$$P_{ref} = P_C \cdot V_C + P_S \cdot V_S \quad (1)$$

where P_{ref} : the total retrofit cost calculated in local currency
 P_C : the total cost for the concrete in local currency per m^3
 P_S : the total cost for the steel in local currency per m^3
 V_C : the total volume of concrete (m^3)
 V_S : the total volume of steel (m^3)

Figure 3: Cross-section of the retrofitted column (bars method).

Figure 4: View of the cage on the column (bars method).

It is obvious that since the total volume of each material is its total area on the floor plan multiplied by the total height of the column (ground to top), it can be appropriately replaced in the abovementioned function. Also, the data used provide the retrofit cost in units of currency, so each time the price changes the whole problem would have to change. Therefore, the price ratio of concrete cost to steel cost was used instead. Applying these changes, the retrofit cost is finally calculated as:

$$P_{ref} = CR \cdot A_C + A_S \quad (2)$$

where P_{ref} : the total retrofit cost calculated in equal steel area (m^2)
 CR : the cost ratio of the concrete cost to the steel cost ($CR = P_C/P_S$)
 A_C : the total area of concrete on the storey (m^2)
 A_S : the total area of steel on the storey (m^2)

The buildings' dimensions and the mechanical properties of the materials both on the existing section and the retrofit are not altered during the optimization procedure. All section dimensions including the beams, the columns and the retrofit are subject to change, depending on the problem solved (see next section). The data from which the optimizer chooses design variable values are provided in Table 1. The proportion dimension of each plate's height and breadth to the existing section's respective values is symbolized as β . Since there are three plates per side, the value of β cannot exceed the limit of $33,3\% \cdot (h + 2 \cdot t_{cg}) / h \cong 33,3\%$.

Table 1: Database used to define the section dimensions.

The constraints of the optimization problem include the member checks defined in Eurocode 4, which are evaluated with the help of linear analyses for each candidate optimum retrofit design. Additionally, performance constraints are imposed, which are evaluated using pushover analysis results.

The discrete optimization algorithm implemented is based on the evolution strategies method. The analysis platform employed for linear and pushover analyses is the software system Opensees.

4 NUMERICAL RESULTS

In order to determine the effect of the building's height to the optimum retrofit design, two buildings were simulated; a two-storey and a four-storey, which have the same floor plan (Figs. 5-6). The beams' span is 5.50m in both directions and the columns' height is 3.50m.

Because of the problem's complexity and the significant demand for computational effort, translated into several computer hours for each optimization, four sets of runs were conducted, where the succeeding one would benefit from the results of the previous one and also conclusions would be extracted at each stage. It is noticeable that each step requires much more analyses than the previous one.

Four groups of design variables are defined for both buildings. Group 1 includes all design variables associated with corner columns. Groups 2 and 3 refer to all side columns in *x*-direction and *y*-direction, respectively. Finally, Group 4 involves all internal columns of the 3D frame.

The aim of the first set was to determine the optimum design for both buildings, in order not to require retrofit (Eurocode 4 provisions satisfied). So, during this set, the retrofit parameters were set to zero and the initial sections of the columns and beams were chosen from databases of standard I-sections: HEB sections were used for the columns and IPE sections for the beams. The algorithm was allowed to choose the steel section for the columns, but the concrete cover layer was the same for all columns (5cm per side). Previous tests had shown that the contribution of the cover concrete is minimal, so this parameter could be ignored for the purposes of this research. The optimum design obtained for the two-storey building was HE400B for all column sections and IPE450 for the beams (Table 2). The respective results for the four-storey building are given in Table 3.

The second set of tests was similar to the first one. Its purpose was to examine whether the Eurocode 4 criteria were those that determined the optimum design or it is also influenced by the building's performance constraints. So, in this scenario, the Eurocode 4 criteria were deactivated and the algorithm was allowed to determine the optimum design choosing from a variety of initial sections including the combinations that had been rejected in the previous set, because the Eurocode 4 criteria were not fulfilled. According to the results of these runs, even smaller sections seem to be adequate for the beams, some of which would not even be able to bear the dead loads of the slabs. On the other hand, the selection of column sections was mostly determined by the structure's performance, especially for the four-storey building. The designs provided by the algorithm are presented in Table 4.

One can see in Table 4 that the use of a large section in one group and small sections for the other three seems to be much more efficient than the use of the same section in all four groups of columns. It is probably because such a selection increases the total stiffness without respective increase of the cost. However, this is only a mathematical optimum, since in both buildings the three out of four sections do not pass the Eurocode 4 criteria when tested independently.

Table 5: Optimum design for the four-storey building without Eurocode 4 constraints.

Comparison of the storeys' stiffness shows that they are of similar philosophy with the ones provided for the two-storey building, so one could conclude that the Eurocode 4 criteria do not determine the optimum design, but lead the algorithm to a more appropriate result.

The third set of tests aimed to determine the effect of the cost ratio (concrete price to steel price), since it was used in order to convert the concrete area to corresponding steel area. Two values of cost ratio were used: 40% and 10%. The initial sections were all the same for the four groups, but the retrofit dimensions could be different for each group. Only designs rejected at the first series of tests were used, including one per building that should not require retrofit as a control section. The results obtained are given in Tables 6-8.

Comparing the optimum design independently for each method of retrofit, it is evident that the cost ratio severely influences the most cost-effective solution, but not dramatically, since the total storey stiffness is almost the same in both cases. As was expected, the retrofit solutions with more concrete (bars method) are preferable when the cost ratio is low. On the other hand, higher cost ratios make the design with plates a more attractive solution. It should be noticed that, for initial steel sections HE260B, HE280B and HE300B, the optimum retrofit method is different for the two cost ratios considered.

Table 8: Comparison of the optimum retrofit method.

The final and most demanding set of optimization runs intended to determine the exact value of the cost ratio, for which both retrofit methods would have the same cost, calculated in equal steel area. Since this is a continuous parameter that does not take specific (discrete) values, as applies to section dimensions, the number of optimization runs needed would be infinite. In order to reduce the computational cost, there were targeted optimization runs using various values of the cost ratio until a converged results was obtained. The results are presented in Figs. 7-9.

Figure 7: Balance cost ratio for the retrofitted sections for the two-storey building.

Figure 8: Balance cost ratio for the retrofitted sections for the four-storey building.

Figure 9: General diagram of the balance cost ratio for the retrofitted sections for both buildings.

5 CONCLUSIONS

- Both methods of retrofit improve the structure's response.
- The variable that has the most significant effect on the selection of the optimum retrofit method seems to be the ratio of the concrete price to steel price.
- Low cost ratios make the bars method a more attractive choice, but this is reversed for higher ratio values.
- Another important factor is the initial steel section, since for sections that are not far below the optimum design, the plates method is dominant even for low cost ratios.
- Finally, the building height seems to move the balance cost ratio versus initial steel section height diagram to the right, increasing this way the bars method area. Note that the comparison is made within the feasible solutions region of the design space for each building.
