The proposed framework permits us to choose a couple of ground-motion parameters that are well correlated to the dynamic response of the studied building and, in the same time, are less inter-correlated. The obtained uncorrelated intensity-measures are then used to build unbiased two-variables fragility functions, based on the couple of parameters (PGD and PGA). A comparison between the one-parameter fragility curve and "slices" of the fragility surface shows that the use of a second ground-motion parameter delivers a clearer definition of the vulnerability: the different "slices" can be seen as confidence intervals that can be of great help to public planners, especially in the case of very low probabilities for instance (i.e., extreme events).

1 INTRODUCTION

Current methods of physical vulnerability assessment usually result in fragility curves (probability of a given damage level with respect to an intensity-measure parameter), mostly based on parameters such as Peak Ground Acceleration (PGA) or macroseismic intensity. However, it has been recently showed that other ground-motion parameters could be more accurate descriptors of the building fragility. Besides, usual fragility curves neglect the uncertainty introduced by the use of only one parameter to represent the seismic action. Actually, due to the complexity of the seismic loading, accounting for only one parameter may neglect other important characteristics of a seismic time-history, such as the frequency or energy content of the signal.

In the scope of the seismic risk assessment at an urban or regional scale, it is crucial to use accurate information on the vulnerability of common buildings, in order to reduce the scatter in the final results. To this end, the introduction of fragility surfaces (damage probability expressed with respect to two parameters, [1]) instead of single-parameter curves could offer a better knowledge of the vulnerability of a given typology of buildings and provide the public decision-makers with more elaborate data.

Consequently, this study aims at developing a methodology to build analytical fragility surfaces for unreinforced masonry structures: this approach is tested on a two-story brick masonry building. The choice of relevant ground-motion parameters to build the surfaces requires many time-history simulations (unlike a capacity curve approach): thus, the choice of the TREMURI code ([3]) for the structural models has been guided by the use of macrocomponents of masonry panels, which enables faster dynamic calculations than more detailed modeling softwares.

2 STRUCTURAL MODEL WITH TREMURI

2.1 A brief description of TREMURI code

Several post-earthquake observations have shown that unreinforced masonry (URM) panels are composed of rigid undamaged zones, as opposed to vertical or horizontal elements (located between wall openings) that are subjected to shear forces or bending moments. This behavior has led to the development of a masonry macromodel by [4], and later improved by [5] and [6]: this macroelement has been implemented in the TREMURI code and enables to accurately reproduce the behaviour of a masonry panel, while reducing computation times with respect to more detailed finite-element models. This equivalent-frame approach enables to discretize a masonry wall into several components (vertical elements, named "piers", horizontal ones, named "spandrels", and rigid undamageable zones), represented in Figure 1.

The nonlinear macrocomponent used here takes into account the common in-plane damage mechanisms of a masonry panel (see Figure 2), namely: shear failure (sliding or diagonal) and bending failure.

Damage by shear mechanism is achieved when the shear force of the macroelement reaches the ultimate shear strength, defined by the following criteria ([3]):

- Mohr-Coulomb criteria (for shear sliding):

$$V_u = l' t f_{v0} + \mu N \quad (1)$$

- Turnsek-Cacovic criteria (for diagonal cracking):

$$V_u = l t \frac{1.5 \tau_0}{b} \sqrt{1 + \frac{N}{1.5 l t \tau_0}} \quad (2)$$

Figure 1: Example of a masonry wall and its openings, modelled into an equivalent-frame. Blue and red elements are respectively the deformable spandrels and piers, whereas the rigid zones are represented in green.

Figure 2: Various damage mechanisms considered for a masonry pier (source - [7])

Where t is the thickness of the macroelement, l its width (l' denoting the actual width of the panel that is subjected to compression), and b a shape factor (height-on-width ratio). The parameter f_{v0} is the shear strength without any compression, and τ_0 the shear strength when the tensile strength is reached (first diagonal cracks appearing). Finally, μ is the Mohr-Coulomb friction coefficient and N denotes the axial force that generates compression on the panel.

The ultimate bending moment, representing flexural failure, is defined by:

$$M_u = \frac{l^2 t \sigma_0}{2} \left(1 - \frac{\sigma_0}{0.85 f_m}\right) = \frac{N l}{2} \left(1 - \frac{N}{N_u}\right) \quad (3)$$

The ultimate moment depends also on axial compression N , while σ_0 denotes current compression stress and f_m is the compression limit of the masonry.

In the case of 3D modelling, the walls are considered as bearing elements, whereas floors act as horizontal stiffening elements (flexible diaphragms governing the load distribution between the walls). One important assumption in TREMURI is that out-of-plane behavior is not taken into account: it is admitted that such a behavior is negligible due the floor diaphragms and the sound connections between horizontal and vertical components (global box-type behaviour). Thus, in-plane responses of the longitudinal walls (e.g. the ones along the direction of the seis-

mic loading) govern most of the building behaviour: those can take various forms, depending on the type of mechanism (shear or rocking) that is predominant (see Figure 3).

Figure 3: shear (left) and rocking (right) behavior of a single masonry macrocomponent, subject to monotonic (solid line) and cyclic (dotted line) loadings

2.2 Modeling of a two-story URM building

Using the TREMURI macroelement, a building was modeled, based on the results of an experiment in University of Pavia ([2]) on a real scale two-story URM building. The model uses the exact geometry of the real building, while the properties displayed in Table 1 were selected, based on experimental data and common features of brick masonry.

Figure 4: View of the Pavia experiment ([2]) and the corresponding TREMURI model

The structure is around 6m high, with plan dimensions of 6 by 4.4m. As axial forces are a crucial factor in the strength of the masonry, concrete blocks were added on each floor in order to account for live loads: this is traduced into the model with a vertical load of around 250 kN on each floor.

The modal analysis of the 3D model gives the first mode along the length of the building (referred to as the X -direction), for a period $T = 0.149s$ (almost 90% of the building mass is concentrated in the first mode along X). The next step is to perform a pushover analysis in

	Parameter	Value
E	Young modulus	3600 MPa
G	Shear modulus	600 MPa
ρ	Density	1800 kg/m ³
f_m	Compressive strength	6.2 MPa
f_{sh}	Shear strength	0.23 MPa
D_{sh}	Shear ultimate drift ratio	0.6%
D_{fl}	Rocking ultimate drift ratio	0.8%
μ	Friction coefficient	0.2

Table 1: Mechanical properties of the building model

order to obtain the building global strength and the ultimate top displacement: a progressive lateral force is applied along the X -direction, while the forces are distributed at each floor according to the first mode shape. Based on some previous studies ([8], [9]), it is admitted that the ultimate displacement is reached when the shear force falls down to 80% of its maximum value: using the equal-energy criterion, an idealized bilinear curve is then generated, yielding the elastic-limit point.

Figure 5: Pushover curve of the building model (solid line), along with the bilinear curve (dotted line). Limit-displacement values $d_y = 5.6\text{mm}$ and $d_u = 18.8\text{mm}$ can be identified.

The evaluation of the damage state at the building level is not trivial, as the criteria used to define the local damage level of a macrocomponent cannot be simply extrapolated to a global level. Among the numerous damage indicators available in the literature (index based on hysteretic energy dissipation [10], determinant of the stiffness matrix, maximum strain values at various locations, ...), it is chosen here to use the transient interstory drift ratio (ISDR) or floor displacements because their computation is rather straightforward and many correlations between floor displacement and damage states have been developed. The Risk-UE project ([11]) proposes some relations to link displacements d_y and d_u to the EMS-98 ([12]) damage scale

(see Table 2).

Damage state	Displacement-limit	Value (mm)
Slight	$d = 0.7d_y$	3.94
Moderate	$d = 0.7d_y + 0.05(0.9d_u - 0.7d_y)$	4.59
Extensive	$d = 0.7d_y + 0.2(0.9d_u - 0.7d_y)$	6.54
Very heavy	$d = 0.7d_y + 0.5(0.9d_u - 0.7d_y)$	10.43
Collapse	$d = 0.9d_u$	16.92

Table 2: Correlation between EMS-98 damage states and the transient top displacement, for unreinforced masonry buildings, according to [11]

The recommendations from the FEMA-356 [13] document for unreinforced masonry give some values of transient ISDR corresponding to different levels of safety: 0.1% for S-1 (Immediate Occupancy) and 0.5% for S-3 (Life Safety). The results of the static analysis on the studied building give a top displacement $d = 5.8\text{mm}$ for S-1 level, and $d = 20.8\text{ mm}$ for S-3. Even if both damage scales are not to be compared, it appears that the FEMA criteria tend to be much less conservative than the Risk-UE values for this specific building. FEMA criteria are fixed drift ratios that are the same for a generic typology of buildings, whereas the Risk-UE values are based on the strength and the ductility of each model and may be more accurate for specific cases. Thus, the boundaries in Table 2 will be used for the rest of the study.

2.3 Development of variant models

Once the first building model is developed and validated, the uncertainties on the mechanical properties of the brick masonry can be taken into account by deriving a set of variants with respect to the basic model. Those variants are developed by sampling material properties, which are assumed to have a normal distribution. The associated coefficients of variation can be taken from various past studies ([14], [15]) and the distributions of the varying parameters are represented in Table 3.

Parameter	Mean	C.O.V.	St.-Dev. s	Lower bound	Upper bound
E (MPa)	3600	20%	720	2160	5040
G (MPa)	600	20%	120	360	840
f_m (MPa)	6.2	20%	1.24	3.72	8.68
f_{sh} (MPa)	0.23	15%	0.0345	0.161	0.299
D_{sh} (%)	0.6	10%	0.06	0.48	0.72
D_{ft} (%)	0.8	10%	0.08	0.64	0.96

Table 3: Proposed variations of some basic mechanical parameters for the masonry model

For each parameter, some bounds (set at $+/- 2s$) prevent from sampling irrelevant values. We choose to generate 20 variant models out of the parametric distribution: a Latin hypercube sampling scheme is used in order to optimize the possible combinations with a reduced number of models. Thus, with 20 models, intervals of 5% can be defined and, for each parameter, an aleatory interval has been picked to sample the value for a given model. This procedure results in a total of 21 structures (one basic model plus 20 variants): for each of them, a pushover analysis is performed in order to identify the boundaries of the EMS-98 damage states.

3 NON-LINEAR DYNAMIC ANALYSES

3.1 Selection of the accelerogram dataset

The dynamic analyses on the models require a large set of seismic time-histories, in order to build consistent fragility functions. First, a sample of 120 records has been selected from the European Strong-Motion Database ([16]): these accelerograms were generated by earthquakes of magnitude (M_w) between 5.3 and 6.3, at a focal depth lower than 30km. These criteria correspond approximately to the kind of earthquakes that are to be expected in Southern France. In order to increase the size of the dataset, another series of signals has been generated, using the non-stationary stochastic procedure proposed by [17], an extension of [18]. This signal generation spans a magnitude range from 4.5 to 6.5, with the epicentral distance comprised between 10 and 100km. Also, for each magnitude-distance combination, the signal is derived for the five Eurocode-8 soil classes, in order to account for the variability in site conditions. Finally, these stochastic simulations have output 657 synthetic accelerograms, resulting in a total of 777 time-histories.

The consistency between real records and synthetic accelerograms has been checked for a wide selection of ground-motion parameters: the overall distribution of the two datasets (mean and standard-deviation) shows good agreement, except for duration-related parameters, which have a tendency to be underestimated in the synthetic signals used here ([17]).

3.2 Simulation scheme and results

The selected accelerograms are now applied at the basis of the structure, along the X -direction. The number of simulations has been optimized and the dataset of 777 accelerograms has been divided into 37 groups of 21 records each. Thus, within each group, it is possible to randomly assign each accelerogram with one of the 21 models. It is worth noting that the 37 groups were selected by ranking all accelerograms with respect to PGA (ground-motion parameter selected a priori to represent the "nocivity" of the signal): this ensures that each group contains homogeneous signals, and as a result all 21 models are subjected to accelerograms with similar intensity levels.

Then, all non-linear dynamic analyses are carried out and the maximum transient displacement at the top of the building is used to identify the different damage states, based on Table 2. The results of the analyses are summed up in Table 4, in terms of relative percentage of the 777 simulation runs. It appears that more than the half of the simulations have not induced any damage to the structure. About 17% of them induce the collapse, while intermediate levels (e.g. slight to very heavy damage) are clearly underrepresented.

Damage state (EMS-98)	Percentage of runs
None	62.8%
Slight	1.8%
Moderate	5.5%
Extensive	6.1%
Very heavy	6.4%
Collapse	17.4%

Table 4: Distribution of the number of simulations that have reached the different damage states

Using these raw results, fragility curves based on a single intensity-measure parameter (for

instance, PGA, as it is a widely known and usual parameter) can be built. These curves are fitted to a lognormal cumulative distribution function, as shown below:

$$P_k(PGA) = P(\text{damage} \geq D_k | PGA) = \phi\left[\frac{\ln(\frac{PGA}{\mu})}{\sigma}\right] = \frac{1}{2}\left[1 + \operatorname{erf}\left(\frac{\ln PGA - \ln \mu}{\sigma\sqrt{2}}\right)\right] \quad (4)$$

The median μ and the standard deviation σ can be defined using the maximum likelihood method, as proposed by [19]. After an optimisation procedure using the simplex method, the variables for each damage state are displayed in Table 5. The corresponding fragility curves are plotted on Figure 6.

Parameter	Slight	Moderate	Extensive	Very heavy	Collapse
μ	1.1108	1.2466	1.5724	2.1728	2.9359
σ	0.2928	0.3047	0.4146	0.4973	0.4966

Figure 6: Analytical fragility curves for the studied low-rise URM building, with respect to PGA

4 SELECTION OF GROUND-MOTION PARAMETERS

This section is devoted to the selection of proper ground-motion parameters that could make an adequate couple of IM variables for the fragility surfaces.

4.1 Clustering of ground-motion parameters

From each of the accelerograms used in the simulations, 46 ground-motion parameters have been estimated, ranging from PGA to cyclic and duration parameters or spectral values. The first step is to rank these parameters according to their cross-correlation: The VARCLUS procedure is used to this end. It consists in a succession of principal component analyses and the merging of the parameters with strong correlation into distinct class-variables, or "clusters". This procedure is very helpful to reduce the high number of parameters to only 3 or 4 variables that are representative of the distribution of the studied ground-motion parameters (see Table 6).

Cluster 1	Cluster 2	Cluster 3
PGA	PGV	Duration bracketed rel.
Arias intensity	PGD	Duration uniform rel.
A95	Duration bracketed abs.	Duration significant rel.
SLOPE75	Duration uniform abs.	Nb of effective cycles
SLOPE95	Duration significant abs.	
ARMS	Sd ($T = 0.05s$ to $T = 1.25s$)	
ASI	Sa ($T = 0.05s$ to $T = 1.25s$)	
Cyclic damage parameters		
Sd ($T = 1.5s$ to $T = 5s$)		
Sa ($T = 1.5s$ to $T = 5s$)		

Table 6: Generated clusters from the accelerogram dataset and corresponding ground-motion parameters

Some of the ground-motion parameters studied above are not usual ones, and we propose here a very brief description of some of them:

- A95: the level of acceleration which contains up to 95% of the Arias intensity.
- SLOPE75 and SLOPE95: the slope of the Husid plot (e.g. cumulative Arias intensity over time) between 5% and 75% (or 95%) of the total Arias intensity.
- ARMS (Root-mean-square acceleration): the square-root of the integral of squared acceleration over time.
- ASI (Acceleration spectral intensity): the integration of the spectral acceleration between two periods (here, 0.1s and 0.5s).

More details on the way to estimate these IM parameters are given in [20]: various definitions of the duration parameters are provided, along with the different ways to count cycles.

As a result, with only 3 variables remaining, it is more straightforward to study the correlation of the ground-motion parameters with the simulation results. In Table 7, the correlation coefficients between the transient drift and the 3 class-variables are represented.

This first analysis shows that relevant ground-parameters are to be selected from both clusters 1 and 2, whereas cluster 3 is almost uncorrelated to the drift and thus has very little impact on the behavior of the structure.

	Drift	Cluster 1	Cluster 2	Cluster 3
Drift	1	0.7715	0.9043	-0.1054
Cluster 1	-	1	0.8194	-0.0794
Cluster 2	-	-	1	-0.1712
Cluster 3	-	-	-	1

Table 7: Correlation coefficients between the drift obtained from simulations and the class-variables representative of ground-motion parameters

4.2 Selection of the adequate couple of ground-motion parameters

In order to build relevant fragility surfaces, the adequate IM parameters should be both well correlated with the response of the structure (e.g. the drift) and also as uncorrelated as possible between each other. As a result, based on the cluster analysis above, one IM parameter should be selected from cluster 1 and the other one from cluster 2. To this end, we represent in Table 8 all parameters from cluster 1 and 2 that have a correlation coefficient with the drift greater than $R = 0.75$. Also, parameters like cyclic damage, signal duration or SLOPE, are discarded because their computation through usual ground-motion prediction equations is not feasible right now: thus, in the scope of a seismic risk scenario, such IM parameters would be rather useless.

	A95	PGA	Arias Int.	ARMS	Sd1.5s	Sa1.5s	Drift
PGV	0.8657	0.8657	0.8034	0.8280	0.8450	0.8446	0.9107

PGD	0.6092	0.6132	0.6601	0.6144	0.6095	0.0.6092	0.7739
Drift	0.7902	0.7841	0.7784	0.7582	0.7504	0.7498	1

Table 8: Correlation coefficients between parameters from clusters 1 and 2, and also with the drift

An obvious move would be to choose Peak Ground Velocity (PGV) as the first IM parameter, because of its good correlation with the drift: yet, this parameter is also strongly correlated with all secondary parameters from the other cluster (coefficients R above 0.8) and this would add

no extra information on the seismic vulnerability of the structure. On the other hand, the PGA is quite well correlated with the drift ($R = 0.7841$) and shows also poor correlation (see Figure 7) with the Peak Ground Displacement (PGD) ($R = 0.6132$): as a result, the couple of variables (PGA, PGD) can be considered as good candidates upon which to build the fragility surfaces. One could argue that A95 and PGD would constitute a slightly better couple of parameters: yet, the parameter A95 cannot be easily obtained from ground-motion equations and its use is by far not as common as the PGA. Anyway, in a more physical sense, this means that the vulnerability of this low-rise masonry building can be well represented by both acceleration and displacement-based parameters.

Figure 7: Distribution of the PGA and PGD values for all the accelerograms used in the simulations

5 DEVELOPMENT OF FRAGILITY SURFACES

5.1 Mathematical formulation

While fragility curves are usually represented by well-known and readily parameterizable probability distributions like the lognormal one ([21], [19]), the problem gets more complex for surfaces, where bivariate distributions must be computed. One solution is to use the kernel density estimation procedure (or Parzen-Rosenblatt method), which allows a non-parametric definition of the probability density and is thus applicable to higher-dimension problems ([22]).

Let us consider the data (PGA_i, PGD_i) corresponding to the $n = 777$ accelerograms used in the simulations. Then it is possible to write a two-dimensional non-parametric estimator using the kernel density method:

$$f_h(PGA, PGD) = \frac{1}{n \cdot h_{PGA,n} \cdot h_{PGD,n}} \sum_{i=1}^n K\left(\frac{PGA_i - PGA}{h_{PGA,n}}\right) K\left(\frac{PGD_i - PGD}{h_{PGD,n}}\right) \quad (5)$$

The function K is the kernel and h is the "window", a parameter similar to the standard-deviation that controls the degree of smoothing of the estimation. K usually takes the functional form of a standard normal distribution:

$$K(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}} \quad (6)$$

The window h is estimated through optimisation functions that seek to minimize the error (Mean Integrated Squared Error is used as the metric), depending on the size n of the sample and whether it is homogeneously distributed or not.

According to Table 4, intermediate damage states seem not well represented and the resulting fragility surfaces might suffer from a too large scatter. Therefore it is decided to develop only the surfaces for the damage states "slight" and "collapse". If we want to build the fragility surface corresponding to the slight damage level, we have to define first the estimator $f_{h,all}$ for the whole data (the 777 points), as well as the estimator $f_{h,slight}$ that gives the density of the records reaching or exceeding the slight damage state (e.g. 289 points). Then, the probability of the structure reaching this damage state is given by:

$$P1(PGA, PGD) = \frac{289 f_{h,slight}}{777 f_{h,all}} = \frac{h_{PGA,777} \cdot h_{PGD,777}}{h_{PGA,289} \cdot h_{PGD,289}} \cdot \frac{\sum_{i=1}^{289} K\left(\frac{PGA_i - PGA}{h_{PGA,289}}\right) K\left(\frac{PGD_i - PGD}{h_{PGD,289}}\right)}{\sum_{i=1}^{777} K\left(\frac{PGA_i - PGA}{h_{PGA,777}}\right) K\left(\frac{PGD_i - PGD}{h_{PGD,777}}\right)} \quad (7)$$

The estimators are normalized by the size of the sample in order to get a proper cumulative distribution function, comprised between 0 and 1. In order to compare two estimators, both windows h should be the same so that densities are kept homogeneous. A high value of h denotes a small size sample or with strong disparities. Therefore the highest value of h is chosen, the limiting factor being the lowest quality estimator. We can then define:

$$\begin{aligned} h_{PGA} &= \max[h_{PGA,777}; h_{PGA,289}] \\ h_{PGD} &= \max[h_{PGD,777}; h_{PGD,289}] \end{aligned} \quad (8)$$

As a result, the probability of damage can finally be written as:

$$P1(PGA, PGD) = \frac{\sum_{i=1}^{289} K\left(\frac{PGA_i - PGA}{h_{PGA}}\right) K\left(\frac{PGD_i - PGD}{h_{PGD}}\right)}{\sum_{i=1}^{777} K\left(\frac{PGA_i - PGA}{h_{PGA}}\right) K\left(\frac{PGD_i - PGD}{h_{PGD}}\right)} \quad (9)$$

It is then possible to plot this bivariate probability function and represent it as a fragility surface (see Figure 8).

5.2 Interpretation of the results

The main motivation for developing fragility surfaces lies in a better definition of the level of seismic aggression, hence maybe a reduction of the uncertainty related to the hazard level description (usually represented by a single parameter like PGA). In order to confront both approaches, we transpose a fragility surface into 2D curves by isolating "slices" that represent the probability with respect to one IM parameter, while keeping the second one constant. An example is displayed in Figure 9, for the "slight" damage level.

Figure 8: Fragility surfaces of the studied structure, for levels of damage "slight" and "collapse"

Firstly, it can be noticed that the use of a second parameter (e.g. PGD, an easily accessible variable through ground-motion prediction equations) induces a steady increase of the damage probability. For instance, in the case of small accelerations (PGA lower than $0.5m/s^2$), the single-parameter curve shows almost zero probability of damage: however, the fragility surfaces indicates that if this ground-motion is generated along with important ground deformation (e.g. $PGD = 0.1m$ or $0.2m$), then there is actually a non negligible probability of damage (between 10% and 20%).

The single-parameter curve does not account for the different possible values of PGD, therefore there is a tendency to neglect physical damaging phenomena related to ground displacements: the black line in Figure 9 hides indeed the epistemic uncertainty due to the absence of the second IM parameter. On the contrary, this epistemic uncertainty is well quantified by the fragility surface, which "slices" can be seen as confidence intervals on the damage probability. According to [23], most decision makers in the field of natural risks are likely to deal with confidence intervals rather than averaged probabilities, especially in the case of rare or extreme events (on the extremities of the distribution). Let us take the example of strong accelerations (e.g. $PGA = 2.5m/s^2$): the single-parameter curve yields a damage probability of 99%. Let us assume that for this level of acceleration, it is possible to determine the PGD value with a confidence interval between 0.1m and 0.3m: thus, the fragility surface can show that the damage probability will be comprised between 95% and 100%, linking directly the uncertainty on a ground-parameter to the epistemic uncertainty on the fragility.

Figure 9: Single-parameter fragility curve (black line) compared to slices of the fragility surface

6 CONCLUSIONS

Starting from the use of the TREMURI code and its masonry macroelements, this study has proposed a procedure to derive analytical fragility surfaces through non-linear dynamic simulations, in the specific case of a low-rise URM building. The first steps of this procedure – such as the structural modelling, the static analyses to identify displacement boundaries for damage states, the selection of an accelerogram dataset and the time-history simulations – are the ones usually performed to develop single-parameter fragility curves.

Yet, in the case of fragility surfaces, the IM parameters are to be chosen carefully: both parameters should be well correlated with the response of the structure (e.g. top displacement or drift) in order to provide an efficient representation of the damage probability. However, there is also no point in choosing two IM parameters that are well correlated with each other, as such a surface would show nothing more than a single-parameter curve. To this end, a procedure of parameter selection has been proposed: it is based on the analysis of various ground-motion parameters and their ranking into clusters of variables. Then, a final judgement is made on the basis of correlation coefficients, in order to select the adequate couple of IM parameters.

Fragility surfaces, or in other words bivariate probability functions, have been built using a non-parametric probability density, through the use of kernel density estimators. The results have shown that these fragility surfaces can be useful in the sense that they provide a more complete description of the seismic aggression: as a result, the probability values obtained through

the surfaces add another layer of information (the epistemic uncertainty related to the second IM parameter) and allow the definition of confidence intervals for the damage probabilities, which may be more interesting for decision makers than averaged probability values.

ACKNOWLEDGEMENTS

The work presented in this article has been supported by BRGM funds and by French Research National Agency (ANR) through PGCU-2007 program (project EVSIM, A mechanical approach to Evaluate Seismic Vulnerability of Masonry structures). We thank the providers of the strong-motion and the structural data used. In addition, we thank Dr Guillaume Pousse for sending us his computer program to simulate strong-motion records using his method. Abstract. *Damage spectra for reinforced concrete buildings in Greece are presented in this paper based on a series of time-history nonlinear dynamic analyses for single-degree-of-freedom systems (Clough hysteresis model) with different deformation ductility and yielding capacities. The damage spectra are calculated for hundreds of horizontal ground motions recorded on rock-stiff soil in Greece since 1970's. Those damage spectra can be used in the seismic vulnerability assessment of existing reinforced concrete buildings in the country. To this end, the proposed damage spectra are evaluated via the damages observed in Athens as a result of the September 7, 1999 earthquake. The damage spectra confirm that low- to mid-rise RC buildings with lower ductility capacity experience heavy damage or collapse, as seen in the 1999 earthquake. The developed damage spectra can be also used for design purposes in the area. To this end, it is shown that the damage spectra can be used to determine what level of ductility capacity and yield strength is required to limit the expected damages to a certain accepted level according to the code provisions.*

1 INTRODUCTION

Quantification of damage potential of earthquakes can be a useful tool for those interested in seismic risk mitigation plans. A reliable estimation for such damage potential can have a wide range of application in the seismic vulnerability evaluation of existing buildings. One important application of this estimation is in scenario studies where the effects of a single earthquake, often historically significant ones, on present-day portfolios in a region are evaluated [1].

One way for quantifying the damage potential is using a damage index (DI) which has a value close to zero if the structure remains elastic, D1 damage grade of EMS-98 [2], and close to 1.0 when the structure reaches complete damage or collapse, D4 or D5 damage grade of EMS-98. Such index is known to be a function of earthquake parameters and structural properties as shown in Equation 1.

$$DI = f(M, R, \mu, T, F_y) \quad (1)$$

In Equation 1, M and R are the magnitude and source-to-site distance of the earthquake, respectively, μ is the global ductility of the structure, T is the period of vibration, and F_y is the yield strength. Several formulas are proposed in the literature to calculate the damage index ([3, 4, 5]). A very frequently-used relationship in different research works is the one proposed by Park and Ang [6] as shown in Equation 2.

$$DI_1 = (u_{max}/u_{mon}) + \beta \cdot E_H / F_y \cdot u_{mon} \quad (2)$$

In this equation, u_{max} and u_{mon} are the maximum deformations under earthquake loads and monotonically increasing lateral loads, respectively. Moreover, E_H is the non-recoverable dissipated hysteretic energy, and β is a positive constant, which depends on structural characteristics and history of inelastic response. An advantage of the Equation 2 is that it has been calibrated with experimental data. However, in some cases, when the system remains in the elastic mode ($E_H=0$), the equation gives DI values way bigger than zero which can be misleading towards the behavior evaluation of the building. To overcome this problem, a modified version of the DI_1 [7] defined as follows is used here in this paper.

$$DI_2 = \left((u_{max} - u_y) / (u_{mon} - u_y) \right) + \beta \cdot E_H / F_y \cdot u_{mon} \quad (3)$$

The variation of damage indices over a range of structural periods for a series of single-degree-of-freedom (SDOF) systems with different ductility and yield strength values forms “damage spectra” for a region [4]. The main objective of this paper is to present damage spectra for the existing reinforced concrete buildings in Greece based on the possible different structural characteristics of that building class. To this end, a range of period, ductility and normalized yielding strength (F_y/W) is considered to develop the DI values from Equation 3 based on series of nonlinear dynamic analyses of a SDOF system using the ground motion records of earthquakes that have happened in Greece since 1970. Those DI values are later used to develop damage spectra for the studied building class and used to assess their damage potential in future events. Finally, the accuracy of the developed damage spectra is evaluated using the damages that happened in RC buildings during the 1999 earthquake in Athens.

2 APPLIED METHODOLOGY

2.1 Ground motion records and structural properties

The ground motion records used to develop the damage indices for the RC buildings are selected from the European Strong-Motion Data [8]. To this end, earthquakes with a magnitude (M_s) equal or bigger than 5 which occurred in Greece since 1970 are used in this paper (Table 1).

Date	Epicentre	M_s

Table 1: List of earthquakes used in the nonlinear dynamic analysis

Consequently, 110 ground motion records recorded at various stations, located on rock or stiff soil, are chosen to perform the nonlinear dynamic analyses for a series of SDOF systems. The distribution of magnitude with source-to-site distance for those ground motion records are shown in Figure 1.

Figure 1: Distribution of the magnitude and source-to-site distance of the considered ground motion records

2.2 Structural properties of the SDOF

Taking into account that the damage spectra in this paper are being developed for RC buildings, Clough hysteresis model [9] is considered in the nonlinear dynamic analyses of the SDOF systems, performed with the computer program IDARC [10]. The structural properties of the SDOF systems are shown in Table 2.

Ductility	Period	Fy/W
2-5	0.3-1.0	0.05-0.10

Table 2: Range of the structural properties used for the RC buildings

2.3 Development of the damage spectra

As stated earlier, a damage spectrum consists of the variation of damage index values for a series of SDOF systems with various structural vibration periods. Using Equation 3, a damage index is developed from each of the 110 ground motion records shown in Figure 1 over the range of structural properties shown in Table 2. Such nonlinear dynamic analyses leads to approximately 7040 damage index values which are functions of various parameters as shown in Equation 1. An attenuation relationship is then defined (Equation 4) to estimate the variation of damage spectra with earthquake magnitude and source-to-site distance, for each ductility, yield strength, and period value.

$$\log(DI_2) = C_1 + C_2 \cdot M_s + C_3 \cdot \log(R) \quad (4)$$

C_1 , C_2 , and C_3 are regression parameters which are calculated from the regression analyses of the 7040 damage indices for different M_s and R values.

3 RESULTS

Table 3 to 6 show the values for the three coefficients C_1 , C_2 , and C_3 for the range of the structural properties considered in this study (Table 2).

Table 6: Values of coefficients C1, C2, and C3 for RC buildings with a ductility value of 5

Using the coefficient values in Tables 3 to 6 for Equation 4, the attenuation of the damage spectra with R is demonstrated in Figures 1 and 2, for the lower and upper bound values of earthquake magnitude and structural properties considered in this paper.

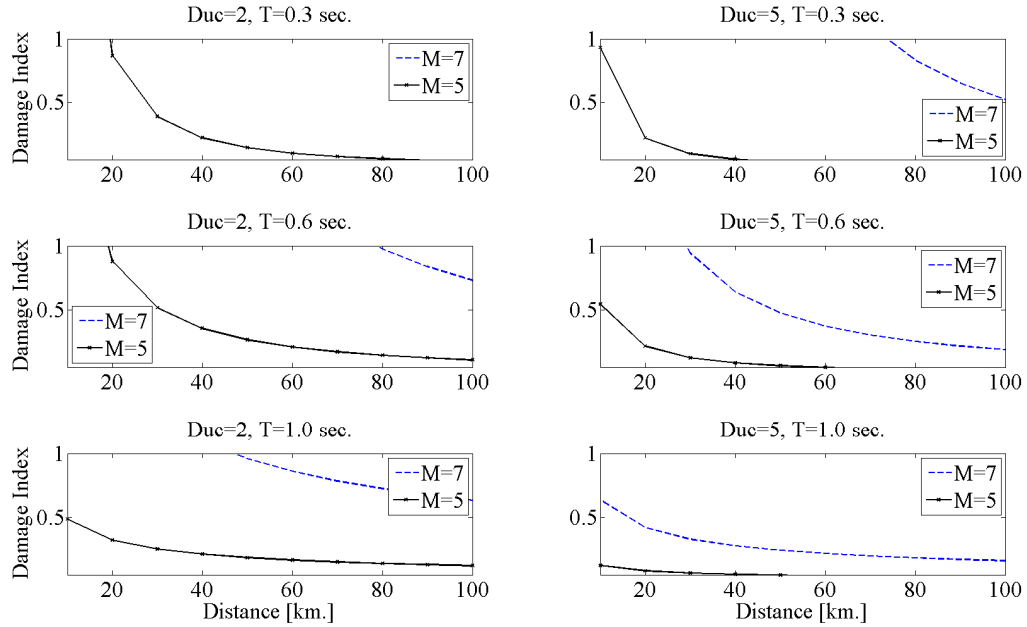

Figure 2: Attenuation of the damage spectra with source-to-site distance for structures with $F_y/W=0.05$

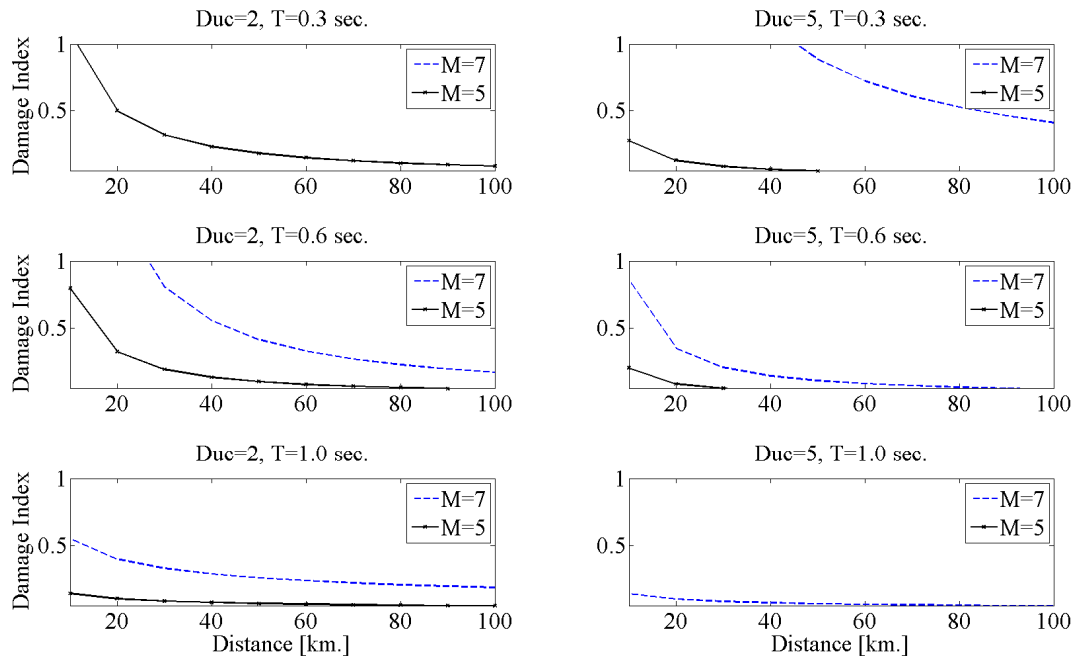

Figure 3: Attenuation of the damage spectra with source-to-site distance for structures with $F_y/W=0.1$

As seen in both Figures 2 and 3, low-rise RC buildings with 3 to 4 storeys ($T_1=0.3$ sec.) are completely vulnerable ($DI>0.6$) to big earthquakes ($M>6$) even at far distances. The increase of ductility, as expected, somewhat reduces such vulnerability. However, for different values

of ductility, those short buildings would experience complete damage ($DI > 1.0$) for near-to-source events and moderate damage ($DI > 0.5$) for far-to-source ones. Mid-rise RC buildings ($T_1 = 0.6$ sec.) especially those with higher yield strength ($F_y/W = 0.1$) and higher ductility show better behaviour as they experience slight damage ($DI < 0.5$) even for a near-to-source event. Finally, high-rise buildings ($T_1 = 1.0$ sec) only suffer moderate to extensive damage in lower ductilities and lower yield strength. It should be noted that such conclusions are applicable to regular buildings which have high enough mass participation factor for their first mode of vibration.

4 DISCUSSION OF RESULTS

To evaluate the damage spectra developed in this paper, the damage spectra for the 1999 earthquake in Athens is compared with the observed damages from that event which happened on September 7, 1999 at 14:56 local time (11:56 GMT) with a magnitude $M_w = 5.9$, close to the city of Athens in Greece.

Figure 4: Attenuation of the 1999 Earthquake damage spectra with source-to-site distance for structures with $F_y/W = 0.05$

Figure 5: Attenuation of the 1999 Earthquake damage spectra with source-to-site distance for structures with $F_y/W = 0.1$

It is reported that two- to five-storey RC buildings with low ductility capacity experienced the highest damage in the meizoseismal area at an epicentral distance between 10 to 20 km [11, 12]. Those were the buildings built according to the 1959 code [13], without ductility provisions, or illegally built ones with poor construction which would not fulfill the minimum requirements of the 1959 code.

Figures 4 and 5 show the attenuation of the damage spectra for the 1999 Earthquake for two different ductility values and two levels of yield strength. As seen in both figures, low- and mid-rise RC buildings ($T=0.3$ sec and 0.6 sec.) with low ductility capacity have DI values greater than 1.0 at epicentral distances lower than 20km. Both figures indicate that the structural damages rapidly decrease with the distance from the source.

According to the reports, no major damage was stated for bridges [11]: this is the fact seen in both Figures 4 and 5, as structures with higher periods ($T=1.0$ sec and bigger) have low DI values even at a close distance to the source.

The 1999 earthquake in Greece occurred at an epicentral distance of about 18 km from the historical center of Athens. The damage spectra for such a source-to-site distance are shown in Figure 6 for different ductility values. It is assumed here that the period of vibration is directly in proportion with the number of storeys ($T=0.1N$). In case of a similar scenario as the one in 1999, low- to mid-rise structures with low ductility capacity will experience near to collapse or complete damage. Figure 6 can also be helpful in the design of new RC buildings in the area as it clearly states the required ductility and yield strength values for a defined accepted level of damage. For example, a 6-storey building needs to have a minimum ductility value equal to 3 ($F_y/W=0.1$) or 6 ($F_y/W=0.05$) to experience DI's lower than 0.5. Similar to the case for the 1999 Earthquake, damage spectra can be calculated for any code's design earthquake with a specific return period (magnitude), for any site (source-to-site distance) in Greece.

Figure 6: Damage spectra for 1999 Greece earthquake at a source-to-site distance of 18 km

5 CONCLUSIONS

- An attenuation relationship of damage spectra for RC buildings in Greece is presented in this article based on a series of nonlinear dynamic analyses using 110 ground motions records from various earthquakes which happened in the country since 1970.

- Various damage spectra can be developed from the attenuation relationship based on desired structural properties such as ductility capacity, yield strength, and the vibration period of the RC buildings.
- The calculated damage spectra show good correlation with the observed damage of the 1999 Earthquake in Greece.
- Low-rise RC buildings show high vulnerability to big earthquakes ($M_s > 6$) even at far distances. In such situations, high ductility values ($\mu > 5$) are required to keep the DI lower than 0.5.
- Structures with longer period of vibration (e.g., bridges) show very low damage index values in a scenario similar to the 1999 earthquake. This is in accordance with the field observation from that earthquake.
- The developed damage spectra here can be also used in the seismic design of new RC buildings in Greece: to determine the required ductility capacity and yield strength for the credible earthquake in a region based on code requirements.

Keywords: Vertical oscillations, P-Delta and Secondary Effects, Structural response, Seismic Amplification, Structural Damage,

Abstract. *From a thorough observation of the images taken after major seismic events arises the conclusion that structures collapse vertically due to their lack of stability under vertical load amplification. Overturn of buildings due to earthquake effects happens in case of weak foundations or liquefaction effects (see Niigata, Japan 1964).*

Majority of collapses occurred due to structural instability as P-Delta effects under combined horizontal and vertical loads. Worse, there must be a dynamic effect due to vertical seismic oscillations that leads to amplification of the vertical loads. Vertical effects and P-Delta phenomena are mentioned in each seismic code but the effect is dealt statically for analysis and design purposes.

It is indicated that dynamic analysis should be performed by means of step by step nonlinear analysis.

The present work is intended to initiate a methodology to use the spectral capacity demand analysis to deal with the P-Delta effects compared with the results calculated by means of step by step analysis. The nonlinear effects develop at the bar ends (beams and columns) as plastic hinges with gradual plasticization due to the lateral displacements. Bending moments and shear effects in the structural elements are monitored during the simulations performed by means of the SAP2000 – Nonlinear Software.

1 INTRODUCTION

In his paper, written in 1994, John Lawson, Vice President Kramer & Associates Structural Engineers, Inc. Tustin, California stressed that "...new provisions addressing the effects of vertical seismic acceleration should not be incorporated into the Uniform Building Code without careful consideration." Since then a lot of new research were accomplished most of them based on actual severe seismic events. Nonlinear behavior has been introduced into the methodology of the analysis of structural behavior under seismic events.

Most of the existing codes still use the conventional methodology to check or design the behavior of structures under seismic loads. Horizontal effects solely are taken into account for the seismic loads. Vertical effects are taken into account for specific elements like cantilevers, long prestressed beams or beams that support columns. The secondary effects of earthquakes are taken into account by static methods (due to the weight of each story).

The instability of structures under vertical amplification effects is evident for a lot of collapses that occurred as consequence of seismic movements. Among these effects, the damages of soft floors when the structure lost its first floor are relevant. Figure 1 visualizes some residential buildings at Loma Prieta , California which due to the collapse of their columns of the open floor destroyed the garages underneath the residences.

Figure 1. Loma Prieta, soft story collapse.

The collapse was the consequence of the P-Delta effect combined with the amplification of the vertical oscillation. Similar effects occurred during the 6.8 Richter magnitude event of the Northridge earthquake damaging multistory residential units, parking garages and freeway overpasses. Figure 2 shows the one of the damaged multistory buildings after the 24 October, 1999, 7.6 Richter Magnitude, Taipei earthquake. The structure collapsed due to the plastic hinge developed at the first storey of the building due to the P-Delta effect.

Figure 2 Taipei Structure overturning.

One of the arguments of the author of the upper mentioned paper was the example of the spectacular collapse of the California State University Northridge Parking Structure. A paper in a local newspaper attributed the collapse to the vertical ground acceleration. According to John Lawson the load factors consider the downward vertical acceleration. His reasoning is based upon the dead load of the structure of about 5.75kPa and live load of at least 2.39kPa would lead to consider an ultimate design strength of:

$(1.4 \times 5.75) + (1.7 \times 2.39) = 12.113 \text{ kPa}$ Since the parking structure was empty at the time of the earthquake, this ultimate strength would have been reached at $(12.113 / 5.75 - 1) = 1.1g$ of effective vertical acceleration. If we compare this effective vertical acceleration with the current UBC's 0.4g effective horizontal peak ground acceleration for Seismic Zone 4 we see that the code's load factors do provide significant reserve strength for upward vertical accelerations compared to horizontal accelerations. The main idea of the paper states "that the additional consideration must be taken on the effects of the vertical acceleration on the P-Delta effects. This situation may create a governing load condition if very large horizontal and vertical accelerations occur simultaneously". To complete this statement is the resonant state which may provide severe damage due to the loss of structural stability in any direction (horizontally or vertically).

Figure 3 Static and dynamic stability for $mg \ll P_{cr} = P_E$

2. STRUCTURAL DYNAMIC INSTABILITY

The phenomenon of loss of stability occurs as consequence of an essential, sudden modification of the parameters defining the stationary state of the physical system. In case of a mechanical system there may be remarked two stationary states. 1) static equilibrium relative to an inertial system of coordinates, or 2) a movement mainly defined by the generalized coordinates q, \dot{q} according to the minimal action defined by Hamilton.

In the first case the equilibrium loss is a static phenomenon (a sudden increase of the deformations under the critical static loads); in the second case the mechanical system has a perturbation of the main movement through an unlimited increase of the velocity and acceleration of the system. For both cases the instability phenomenon takes place through the development of great accelerations and a gradual modification of the geometric configuration of the mechanical system and through the modification of the energetic equilibrium by the delivery of kinetical energy (the sudden feature of the loss of stability).

The dynamic systems have been classified as: autonomous systems and non-autonomous ones.

The first category comprises the systems with equation of movement according the following equation:

$$M\ddot{x} + F(P, x, \dot{x}) = 0 \quad \text{Eq. 1}$$

Where

M is the mass matrix of the system,

x, \dot{x}, \ddot{x} are the vectors for the displacements, velocities and the accelerations of the system,

P is the vector of the external action on the system.

Function F may be linear or non-linear according to x and \dot{x} for the mechanical system.

Actions which are based upon a potential (gravitation e.g.) are conservative and imply autonomous behavior.

In case of a linear elastic structure with viscous amortization the free oscillation has the following equation of movement:

$$M\ddot{x} + C\dot{x} + Kx = 0 \quad \text{Eq. 2}$$

Where

C is the damping matrix.

K is the rigidity matrix of the structure.

For positive coefficients in the damping matrix the free vibrations decay with time and the dissipated energy of the system may be expressed by a quadratic form:

$$E_d = \frac{1}{2} \dot{x}^T C \dot{x} \quad \text{Eq. 3}$$

The instability of the shape ($x \rightarrow \infty$) and the instability of the oscillations ($\omega \rightarrow 0$) is attained only when the rigidity matrix K becomes singular. If we complete Eq. 2 by means of the axial force participation such as:

$$-N \left(x, \frac{\partial x}{\partial z} \right) \quad \text{we define the rigidity diminution due to the axial force and thus}$$

the loss of stability may be sensed through the Equation 4.

$$\det[K - \lambda N] = 0 \quad \text{Eq. 4}$$

The increasing series of the λ values which are the roots of the equation 4 are the Eigen values for the external load.

Figure 4 Column under axial load combined with oscillatory perturbation θ

An example of a non-linear system is the pendulum with an elastic wire which suffers a change of its parameters during the oscillation process. This kind of pendulum is a non-autonomous system visualized by means of the Hill type equation:

$$\ddot{\theta} + \omega(t)\theta = 0 \quad \text{Eq. 5}$$

For a non-autonomous linear system the following Equation 6 is the dynamic equilibrium :

$$M\ddot{x} + C(t)\dot{x} + K(t)x = F(t) \quad \text{Eq. 6}$$

and gives the systems movement.

3 SECOND ORDER ANALYSIS OF THE STRUCTURAL RESPONSE

The P-Delta structural response leads to the collapse of the structure by increasing the moments and shear acting at the ends of the bars both columns and beams under seismic effects. All the codes for the seismic analysis deal in a way or in other with the structural behavior due to augmenting the static loads.

The Israeli Design Provisions for earthquake resistance of structures SI 413 takes into account the P –Delta effect by computing a coefficient that shows the ability to stand the drift the structure is going to get as result of the horizontal seismic load:

$$\theta_i = \frac{W\Delta_{el,i}K}{V_i h_i} \quad \text{Eq. 7}$$

Where:

$\Delta_{el,i}$ - the drift at the story “i” according to the elastic analysis.

V_i - the horizontal shear force at story i.

θ_i - the coefficient for the deformation at story i.

W – the total load over the floor i

K – the decrease coefficient of the loads acting on the structure.

h_i - the height for the story i.

According to SI 413 if the θ_i coefficient is less than 0.1 the structure is stable and no further analysis must be accomplished. If $0.10 < \theta_i \leq 0.20$ a second order analysis must be done.

As concerns the vertical seismic oscillations certain elements must be loaded by vertical loads.

The structural stability is a function of the axial force which develops in the columns due to the amplification in vertical direction. According to Nakamura (2000) the vertical component of the tremor retains the characteristics of the horizontal tremor at the bedrock.

Based on this assumption the Eurocode 8 defines the vertical spectrum in correlation with the horizontal spectrum (Fig. 5)

Figure 5 Shape of the elastic response spectrum

The vertical component of the seismic action shall be represented by an elastic response spectrum, $S_{ve}(T)$ derived by using the following expressions:

$$0 \leq T \leq T_B : S_{ve}(T) = a_{vg} \left[1 + \frac{T}{T_B} (\eta \bullet 3.0 - 1) \right] \quad (3.8)$$

$$T_B \leq T \leq T_C : S_{ve}(T) = a_{vg} \eta 3.0 \quad (3.9)$$

$$T_C \leq T \leq T_D : S_{ve}(T) = a_{vg} \eta 3.0 \left[\frac{T_C}{T} \right] \quad (3.10)$$

$$T_D \leq T \leq 4s : S_{ve}(T) = a_{vg} \eta 3.0 \left[\frac{T_C T_D}{T^2} \right] \quad (3.11)$$

The values to be ascribed to T_B, T_C, T_D and a_{vg} for each type (shape) of vertical spectrum may be found in its National Annex.

Table 1 Recommended values of parameters describing the vertical elastic response spectra

Spectrum	a_{vg} / a_g	$T_B(s)$	$T_C(s)$	$T_D(s)$
Type 1	0.90	0.05	0.15	1.0
Type 2	0.45	0.05	0.15	1.0

Where:

$S_e(T)$ is the elastic response spectrum; T is the vibration period of a linear single-degree-of-freedom system; a_g is the design ground acceleration on type A ground ($a_g = \gamma_I a_{gR}$) T_B is the lower limit of the period of the constant spectral acceleration branch;

T_C is the upper limit of the period of the constant spectral acceleration branch;

T_D is the value defining the beginning of the constant displacement response range of the spectrum;

S is the soil factor;

η is the damping correction factor with reference value of $\eta = 1$ for 5% viscous damping.

According ASCE/SEI 41-06 $P - \Delta$ effects shall be included in linear and nonlinear analysis procedures. For nonlinear procedures, static $P - \Delta$ effects shall be incorporated in the analysis by including in the mathematical model the nonlinear force-deformation relationship of all components subjected to axial forces.

Dynamic $P - \Delta$ effects are caused by a negative post-yield stiffness that increases story drift and the target displacement. The degree by which dynamic $P - \Delta$ effects increase displacements depends on the following:

1. The ratio of the negative post-yield stiffness to the effective elastic stiffness;
2. The fundamental period of the building;
3. The strength ratio, R ;
4. The hysteretic load-deformation relations for each story;
5. The frequency characteristic of the ground motion;
6. The duration of the strong ground motion.

Because of the number of parameters involved, it is difficult to capture dynamic $P - \Delta$ effects in linear and nonlinear static analysis procedures. For the nonlinear static procedure, dynamic instability is measured by the strength ratio R . For the nonlinear dynamic procedure $P - \Delta$ effects are captured explicitly in the analysis.

The strength ratio R shall be calculated in accordance with Eq. 3-15:

$$R = \frac{S_a}{V_y / W} C_m \quad (Eq.3 - 15)$$

Where

S_a is the response spectrum acceleration, at the effective fundamental period and damping ratio of the building in the direction under consideration;

V_y is the yield strength calculated using results of the nonlinear static procedure for the idealized nonlinear force-displacement curve developed for the building;

W is the seismic weight;

C_m is the effective mass factor. Alternatively, C_m is taken as the effective modal mass participation factor calculated for the fundamental mode using an Eigenvalue analysis.

C_m shall be taken as 1.0 if the fundamental period, T , is greater than 1.0 sec.

4 USE OF SAP2000 SOFTWARE

Building affected by seismic load both horizontally and vertically can be analyzed by means of SAP2000 software statically and dynamically. The static nonlinear methodology leads to the performance point which is placed at the intersection of the demand and capacity curves. If the capacity is determined by taking into account the $P - \Delta$ effect the capacity level is adjusted accordingly. The performance point indicates the influence of the vertical oscillations.

SAP2000 can be used for direct integration of the structural movement leading thus to the ability of the structure to withstand the seismic load till certain limit signaling the limit state of the structure.

Figure 6 Static behavior under seismic load – performance point determination

5 CONCLUSIONS

Structural instability plays an important role in structural collapse. Since earthquakes are dynamic phenomena dynamic instability occurs during seismic excitations.

A thorough observation of the oscillations which occur during seismic excitations lead to the remark that both horizontal and vertical oscillations take place together.

$P - \Delta$ effects affect the stability of structures.

More, these effects are amplified during the oscillations leading to what is considered the dynamic instability due to the environmental factors and the structural abilities.

This work will be followed by further research and software for

Keywords: Ports, Seismic Risk Assessment, Fragility Analysis, Nonlinear Dynamic Analysis

Abstract. *Container wharves are one of the main components in port systems which are susceptible to structural damage during seismic events. Since regional economies depend largely on the operation of port systems, assessment of the vulnerability of these systems to seismic events is crucial. Seismic risk analysis provides a framework to estimate potential economic losses by incorporating the available information on structure details, soil conditions, repair cost for different components, etc. This paper studies the fragility of wharf structures for a typical pile-supported wharf as part of the NEES-GC project, Seismic Risk Mitigation of Strategic Ports. For this purpose, a two dimensional detailed model is developed for a typical pile-supported wharf structure on the west coast of the United States. The modeled structure contains a pile-deck connection model calibrated to experimental results, pile elements with spread plasticity capability and fiber sections, and soil-structure interaction elements capable of liquefaction modeling. Based on experts opinion and experimental results, a set of limit states are considered for a number of critical components of the wharf structure whose damage induce a disruption in the normal operation of ports. Using the nonlinear model and the limit states, a set of fragility curves are developed for 63 ground deformations generated for this study. The outcome of this research will help port owners to indicate the most vulnerable components of port infrastructures and invest the limited retrofit resources for risk mitigation of ports.*

1 INTRODUCTION

Seaports are intermodal transfer points in transportation networks which have a major role in the regional economy. The physical activities of ports i.e. loading and unloading of cargo, raw materials, etc are concentrated in a small geographic area and therefore, any disruption in the normal performance of structural and geotechnical components of ports may lead to partial or even full disruption of the commercial activities of the port. Historical cases of seaport damage have shown that any disruption in the activities of port infrastructures may lead to significant direct and secondary losses. Particularly poignant examples were the 1995 Kobe earthquake and 2010 Haiti earthquake in which liquefaction and lateral spreading of embankments imposed severe damage to both structural and non-structural components of ports [1,2]. Seismic risk analysis as a key component in risk mitigation efforts provides a framework to estimate potential economic losses by incorporating the available information on structure details, soil conditions, repair cost for different components, etc. In general, seismic risk of a system can be decomposed into a number of components among which is the fragility of the system. The fragility of a wharf model defines the probability of occurrence of various damage states as a function of the firm-site ground motion.

Despite the importance of ports and their vulnerability to seismic damage, a limited number of researches studied the fragility of wharves to seismic events [3,4]. The present study focuses on developing fragility curves for a typical pile supported wharf with batter piles in the west coast of the United States. This is accomplished by incorporating realistic representations of the nonlinear behavior of pile elements, nonlinear force-deformation characteristics of pile-deck connections, and nonlinear dynamic pile-soil interactions in liquefaction susceptible soils. Based on experts' opinion and experimental results, a set of limit states are considered for a number of components of the wharf structure which their damage induces a disruption in the normal operation of ports. Using the nonlinear model and the limit states, a set of fragility curves are developed for 63 ground deformations of the soil embankment and pore water pressure generated for this study through free-field analysis.

2 NUMERICAL MODELING OF A TYPICAL PILE-SUPPORTED WHARF

2.1 Structural Elements

A typical pile supported wharf in the west coast of the United States is modeled in this study. The Finite Element (FE) model of the wharf is developed in OpenSees, an object-oriented FE analysis framework [5]. The transverse section of the wharf is shown in Figure 1. Directions parallel and normal to the landside-seaside direction in the plane of the wharf deck are defined as transverse and longitudinal directions, respectively. In the longitudinal direction, wharves consist of repeating segments, referred to as strips, which are used to represent the wharf in two dimensions. The deck of the wharf and the landside crane rail are supported by pre-stressed vertical and batter piles (Figure 1). The pre-stressed piles are modeled by force-based nonlinear beam-column elements [6,7] with fiber cross-sections. The piles and the deck are connected by T-headed dowel bars which is a common connection for wharf structures. In the FE model of the wharf, these connections are modeled by a link element at the top of pre-stress piles. In order to capture the nonlinear force-deformation characteristics of pile-deck connections, the implemented procedure is calibrated with the result of a full scale test conducted by Lehman et al. [8].

Figure 1. Configuration of the wharf and landside crane rail

2.2 Geotechnical Considerations

The profile of the soil at the location of the wharf is shown in Figure 1 which consists of three layers: a layer of loose sand in the top 18.3 m underlain by a layer of dense sand with a thickness of 2.6 m on top of a layer of clay. The water level is 4.6 m from the soil surface on the landside. Soil properties of the three layers including mass density, shear modulus, Poisson's ratio, friction angle, and undrained shear strength are presented in Table 1.

Pile-soil interaction in the horizontal direction is modeled by a series of nonlinear soil springs including macroelements [9] and conventional p-y springs [10] in sand and clay layers respectively. In the vertical direction, t-z and q-z springs are implemented to model the resistance in the face and end of the piles respectively. Soil springs are assigned at every 1 m in depth from the soil surface and their associated material properties are found for the corresponding soil layer.

Soil layer	γ (gr/cm ³)	G (MPa)	ν	ϕ (deg)	c_u (kPa)
Loose Sand	1.85	80	0.2	34	-
Dense sand	2.05	120	0.2	38	-
Clay	1.75	100	0.4	-	48

Table 1. Soil layers properties.

3 GROUND MOTIONS

Generating PSDMs for critical response measures of the wharf requires selection of representative ground motions as the inputs for nonlinear time-history analysis. A total of 63 empirical (i.e., observed) and simulated ground motions have been selected to represent a broad range of possible earthquake magnitudes and distances. The soil condition for these ground motions is typical of firm soils in coastal California. Among 63 ground motions, fifty six ground motion time-histories are empirical which are selected from the database used to de-

velop the Next Generation Attenuation of Ground Motions (NGA) project [11]. This suite of ground motions is selected randomly from the database such that all of the earthquakes have minimum moment magnitude (M_w) of 5.5 and closest distance to the rupture (R) of 0 to 60 km. All of the selected ground motions are earthquakes within the United States except for the 1995 Kobe, Japan and 1999 Chi - Chi, Taiwan earthquakes. Furthermore, seven simulated ground motions are added to the bin to represent large magnitude California earthquakes which are not present in the NGA database. The resulting bin of empirical and simulated ground motions covers a broad range of earthquake scenarios in terms of minimum moment magnitude and the closest distance to rupture. Figure (2) presents M_w versus R for the suit of sixty three earthquakes considered in this study.

Figure 2. Moment magnitude vs. the closest distance to rupture.

The selected ground motions are used as input for numerical models of the soil embankments supporting the wharf-foundation. The nonlinear coupled ground deformation and transient pore pressure response of the wharf embankment to input ground shakings are numerically evaluated by Vytiniotis et al. [12]. The analysis uses the advanced elasto-plastic effective stress soil model proposed by Dafalias and Manzari [13]. This model is able to realistically capture the stress-strain behavior of sand during cyclic mobility events. More details about the model and assumptions together with numerical results can be found in Vytiniotis et al. [12]. Soil deformations and excess pore water pressure ratios in sand layers in the horizontal direction are applied to the far-field end of the macroelement, while for other soil springs only soil deformations are input to the model. The dynamic response of the foundation-wharf-crane system is found for time-histories of ground deformation and pore pressures within the surrounding soil medium.

4 FRAGILITY ANALYSIS FRAMEWORK

A key component in predicting the damage of a structural system when subjected to an earthquake with expected characteristics is the fragility of the system. A fragility curve describes the probability that the structure fails to satisfy a prescribed performance criterion

conditioned on a seismic intensity measure (IM) representative of the seismic loading. In structural engineering community, it is common to define the event of a structure failing to meet a performance requirement called damage state by simply the case where demand (D) exceeds capacity (C); i.e. $C < D$. Assuming that both capacity and demand can be described by lognormal distributions, the probability of the structure exceeding a particular damage state for a given IM in closed form is

$$P(C < D | IM) = 1 - \Phi\left(\frac{\ln(m_C) - \ln(m_D)}{\sqrt{\beta_C^2 + \beta_D^2}}\right) \quad (1)$$

in which $\Phi(\cdot)$ is the standard normal distribution and m and β are the median and logarithmic standard deviation respectively.

According to Equation (1), evaluation of the seismic fragilities of structures requires developing models for demand on the structural components using nonlinear time-history analysis of the wharf-foundation system as well as capacity model for the critical components.

4.1 Probabilistic seismic demand models

One of the constitutive components of the conditional probability of failure in Equation (1) is the demand model for which a probabilistic analysis is required to determine the parameters m_D and β_D . Cornell et al. [14] showed that seismic median drift demands can be represented well as a power function of IM .

$$m_D = a(IM)^b \quad (2)$$

where a and b are constants determined by a simple linear regression analysis of the seismic demand in the transformed logarithmic space in the following form.

$$\ln(m_D) = \ln(a) + b \ln(IM) \quad (3)$$

The assumption of demand following a lognormal distribution with respect to the IM is applied to all demand measures associated with critical wharf components including the curvature of piles and pile-deck connections and the relative displacement of the structurally separated landside crane rail with respect to the wharf. Assuming that the dispersion of seismic demand parameters is independent from the IM in the logarithmic scale, the uncertainties in the seismic demand parameters β_D in Equation (1) is determined as the logarithmic standard deviation of errors in fitting the demand models as follows.

$$\beta_D = \sqrt{\frac{\sum_{i=1}^n (\ln(D_i) - \ln(aIM^b))^2}{n-2}} \quad (4)$$

Subjecting the wharf-foundation to time-histories of ground deformation and pore water pressures of the embankment soil, the dynamic response of the wharf is found using nonlinear time-history analysis and the maximum response in critical response measures are recorded. This study uses peak ground acceleration (PGA) as the IM which is a widely used IM in earthquake engineering community.

Figure (3) shows the seismic demand of the piles and pile-deck connections in terms of curvature and the relative displacement of the landside crane rail and wharf in the horizontal direction as a function of PGA. It is observed that the assumption of independence of the demand from intensity measure in the logarithmic scale is almost valid for all demand param-

ters. Furthermore all of the demand parameters are seen to be reasonably well described by a linear regression in the log scale which validates the assumption of demand be lognormally distributed.

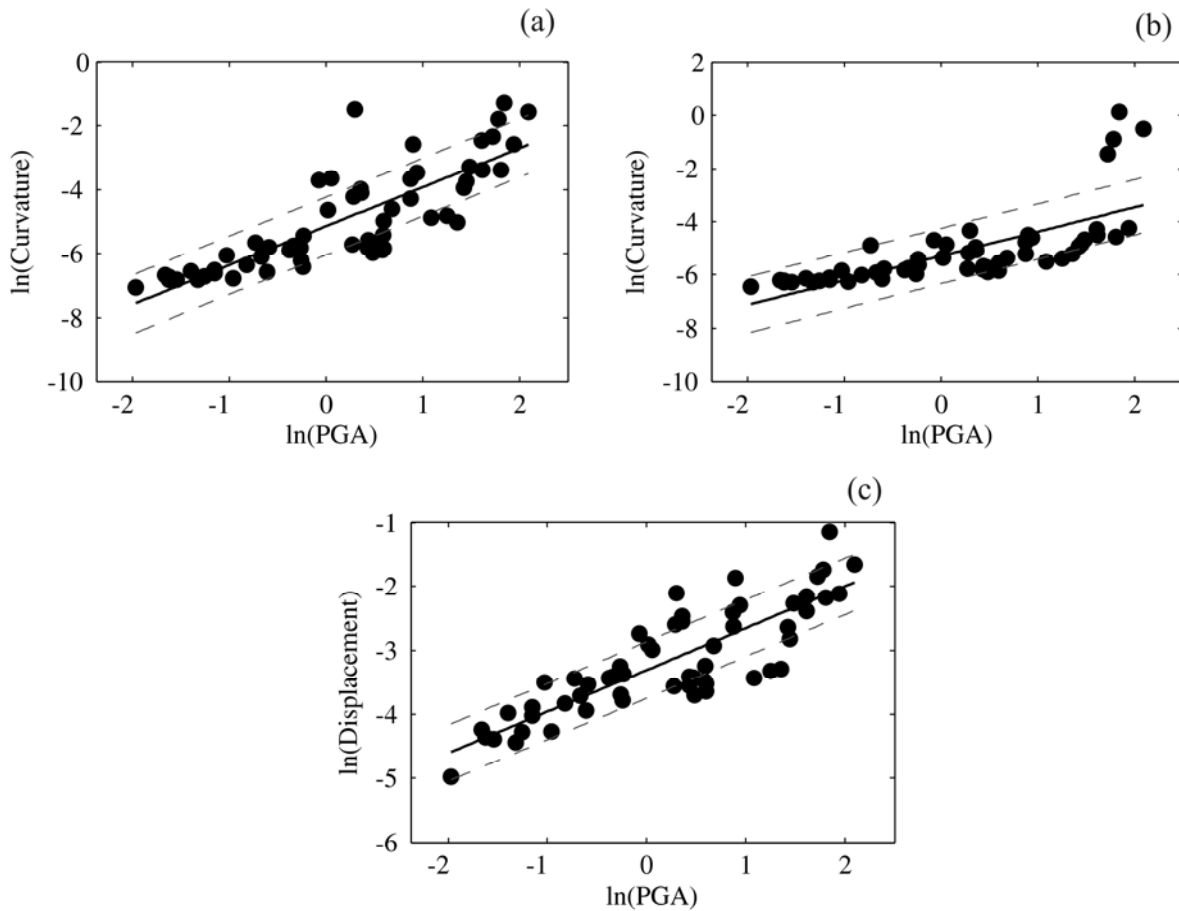

Figure 3. Probabilistic seismic demand models for (a) pile-deck connections, (b) pile sections, and (c) relative movement of the wharf with respect to the landside crane rail.

4.2 Component limit states

The study uses three damage states: slight, moderate, and extensive in which the first two states are adopted from PIANC [15]. The slight damage state has a high probability of occurrence during the life time of the wharf in which no structural damage is permitted. The moderate damage has a lower probability of occurrence compared to the slight damage state in which only reparable damages and limited residual deformations are allowed. Because of the mutual exclusiveness property of the damage states, all other damages that are more severe and consequently less probable than the ones associated with the moderate damage state falls into the extensive damage state category.

A number of response measures of the wharf that are critical in the overall structural response of the wharf and the performance of associated components such as cranes are considered in this study. As mentioned before, these critical response measures are the curvature of piles and pile-deck connections and the relative displacement of the wharf with respect to the landside rail. The limit states associated with these responses are assumed to be lognormally distributed.

The median m_C of the capacity limit state for the pile-deck connections is obtained from the experimental test conducted by Lehman et al. [8] in which the provided drift limits are converted to curvature limits at the connection using numerical simulation of the test specimen.

The curvature limit states for different pile sections are found using moment-curvature analyses. Typically the cross-section of a pile contains all or a number of the following discretized sub-regions, the cover layer of unconfined concrete, the inner core region of confined concrete, the circular layer of longitudinal reinforcing steel, and the circular layer of prestressing strands. In order to determine the median deformation capacity of the piles, the strain limits of the constitutive section materials provided by PIANC [15] are used to determine the corresponding section curvature. The strain limits, for each of the constitutive materials are presented in Table (2).

Material Response	Limit State		
	Slight	Moderate	Severe
Concrete extreme fiber compression strain	0.004	0.008	–
Core concrete extreme fiber compression strain	–	–	$2/3 \epsilon_{cu}$
Reinforcing Steel tension strain	0.01	0.01	$2/3 \epsilon_{su}$
Prestressing strand incremental strain	0.005	0.015	$2/3 \epsilon_{pu}$

Table 2. Strain limits associated with defined limit states for constitutive materials of pre-stress pile sections

Performing moment-curvature analyses for different sections of the pre-stressed piles in the wharf configuration, the curvature limits are determined as the minimum of the curvatures corresponding to the strain limits of different constitutive section materials for each limit state. The derived curvature limits for all sections in the wharf are presented in Figure (4). The median of the curvature limit of different pile sections in each limit state is considered as the median m_C of the capacity limit state.

Figure 4. Moment curvature curves of different sections of the piles and the median limit states.

The median of the limit states m_C for the relative movement of the landside crane rail with respect to the wharf is provided by Werner and Cook [16] based on expert opinion. The sum-

mary of deformation limits of different wharf components associated with three limit states chosen for this study are presented in Table (3).

Component	Limit State		
	Slight	Moderate	Severe
Pile-deck connection rotation (1/m)	0.007	0.035	0.08
Pile section curvature (1/m)	0.017	0.041	0.102
Relative displacement of the landside rail with respect to wharf deck (cm)	0.3	2.5	15.2

Table 3. The deformation limits of critical wharf components corresponding to the chosen limit states.

4.3 Component fragility curves

After developing the probabilistic seismic demand models and determining the corresponding limit states of the wharf damage for the critical components, the component fragilities are constructed using the closed form given in Equation (1). Following Ellingwood [17], the dispersion in the capacity is assumed 0.2 while the dispersion in the demand is found from Equation (4).

The resulting fragility curves for pile sections, pile-deck connections and the relative displacement of the landside crane rail with respect to the wharf are shown in Figure (5)

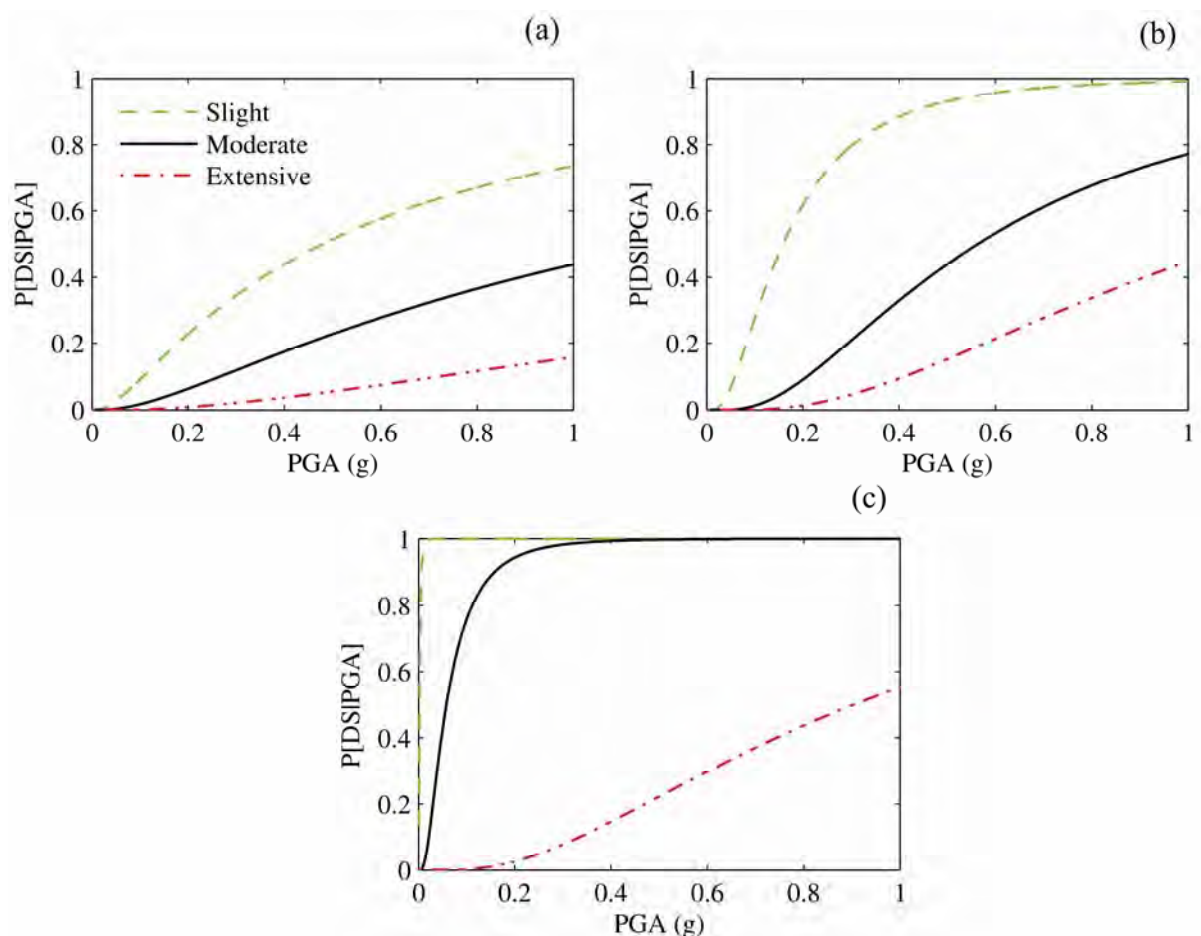

Figure 5 Seismic fragility curves for (a) pile-deck connections, (b) pile sections, and (c) relative movement of the wharf with respect to the landside crane rail.

respectively. It is observed that pile-deck connections are less susceptible to damage compared to pile sections for the same intensity measure i.e. PGA. This is in large due to the considerable relative deformation of the loose and dense sand layers (Figure 1) as a result of liquefaction of the embankment. This consequently imposes large curvature demands on pile sections close to the interface of soil layers. Furthermore, the wharf damage as a result of excessive relative displacement of the wharf with respect to the structurally separated landside crane rail is seen to be highly probable. This response measure of the wharf has a large impact on the operation of the container cranes, and therefore requires more attention. A possible retrofit measure for the excessive relative displacement of the wharf can be connecting the separate landside rail and wharf using reinforced concrete.

5 CONCLUSIONS

This study presents the analytical fragility analysis of a typical pile supported wharf in the west coast of the United States. The two dimensional numerical model of the wharf used for developing fragility curves includes realistic representation of the critical wharf components including piles, pile-deck connections, and soil springs for liquefiable soils. The ground motions for time-history analysis represent a broad range of earthquake scenarios in terms of moment magnitude and the closest distance to rupture. The study presents the results of the nonlinear time-history analysis of the wharf-foundation system and the associated probabilistic seismic demand models for the ground deformations and pore water pressures of the surrounding soil medium for various seismic hazard scenarios. Using the analytical relations for the conditional probability of exceeding defined damage states, a set of fragility curves are developed for critical wharf components including piles, pile-deck connections, and the relative displacement of the landside crane rail and the wharf. It was found that the relative displacement of the wharf with respect to the structurally separated landside crane rail is the most vulnerable component in the wharf response. Furthermore, pile sections were found to be more susceptible to damage compared to pile-deck connections.

Keywords: Structural Health Monitoring, Naïve Bayes, Bio-inspired.

Abstract. A bio-inspired two-mode structural health monitoring (SHM) system based on the Naïve Bayes (NB) classification method is discussed in this paper. For the micro-vibration mode, a two-tier auto-regression with exogenous (AR-ARX) process is used to extract the expression array from the recorded structural time history while an ARX process is applied for the analysis of the earthquake mode. The health condition of the structure is then determined using the NB classification method. To verify the performance and reliability of the SHM algorithm, a downscaled eight-storey steel building was used as the benchmark structure. The structural response from different damage levels and locations was collected and incorporated in the database to aid the structural health monitoring process. Preliminary verification has demonstrated that the structure health condition can be precisely detected by the proposed algorithm. To implement the developed SHM system in a practical application, a SHM prototype was developed, which consists of three separate modules namely, the input sensing module, the transmission module, and the SHM platform. The vibration data is first measured by the deployed sensor, and subsequently the SHM mode corresponding to the desired excitation is chosen automatically to quickly evaluate the health condition of the structure. Test results from the ambient vibration and shaking table test showed that the condition and location of the benchmark structure damage can be successfully detected by the proposed SHM prototype system, and the information is instantaneously transmitted to a remote server to facilitate real-time monitoring. Implementing the bio-inspired two-mode SHM practically has been successfully demonstrated.

1 INTRODUCTION

Recently, an increasing number of infrastructures and buildings all over the world have been unexpectedly damaged or have collapsed due to aging and long-term material degradation. Even though most of these structures have been periodically examined or monitored using modern techniques, these catastrophic failures continue to happen. Due to the existence of a large number of aging buildings, structural health monitoring (SHM) has become an important issue in civil engineering and must go hand in hand with the current research to improve the capacity of structures and to develop a safer design method.

The multidisciplinary research field of SHM was first proposed in the area of aerospace engineering. Accompanied by the development of advanced sensors, SHM was then subsequently developed for applications such as aerospace engineering, mechanical engineering, and civil engineering. However, contrary to the other two fields, civil engineering has faced specific challenges with respect to SHM development. For example, large-scale monitoring applications in civil engineering often using customized monitoring equipment make monitoring a difficult task. Unlike the mass production frequently seen in the field of mechanical engineering where a specific SHM module can be applied to all products to save time and cost, SHM devices used in a structure are commonly customized to cater to the demand and functionality of that particular structure. In addition, the unique requirements of the exterior of structural elements such as fire proofing or indoor appearance requirements, hinder the installation of a SHM system.

The first SHM systems consisted of simple instrumentation. With development in sensor and signal processor technology, SHM systems based on these techniques were capable of detecting the structural health of aircrafts and with the help of a preventive maintenance system greatly extended the lifetime of aircrafts [Hickman et al. 1991]. In 1998, a coordination was achieved between universities, government agencies, and industry, and an innovative SHM assessment method for the overall structural condition of structures was proposed by incorporating the basic concept of system identification [Aktan et al. 1998].

To reduce both the high cost and time required for the on-site cable installation of a traditional SHM system, wireless technology was introduced in the field of SHM. For example, a new method combining the advantages of an advanced sensor and the wireless technique was proposed by Pines et al., to remotely monitor the condition of various infrastructures in 1998. Data collected by the sensors from a structure can be remotely and wirelessly transmitted back to the server and processed by the SHM system on a computer giving an indication of both the damage location and the level of damage [Pines et al. 1998]. Other SHM systems integrating sensors, micro processors, and a wireless transmitter have also been developed, and targets like high speed, accuracy, and low-cost are gradually being accomplished [Tanner 2003, Wang et al. 2007].

In subsequent years, a tiny laser scanner has been developed which can be installed in different locations of the structure for scanning cracks and monitoring fatigue. Based on its specific characteristics, the device can be incorporated in aircrafts, railways, and civil structures [Buckner et al. 2008]. Due to extensive research and subsequent achievements over the past decade, the original SHM concept for structures is being used extensively today to monitor specific structure characteristics under both ambient and forced vibrations. A study conducted by Zimmerman et al. has also proved that data can be collected reliably and processed by a pure wireless

SHM system [Zimmerman et al. 2008]. A SHM system based on a hybrid wireless network has also been verified for its feasibility in the laboratory, and several structural response parameters have been effectively monitored on site for a rapid assessment of the conditions [Mascarenas et al. 2010].

In addition to the development of the SHM system, algorithms focusing on certain specific applications have also been proposed. Contrary to the original concept wherein sensors were installed on the structure to identify the location of the damage, researchers have started to employ customized SHM software to enable a more accurate diagnosis. SHM software development was initiated in the field of aerospace engineering in the year 2000 to reduce the heavy operating and maintenance fees and to further extend the aircraft lifetime [Boller 2000]. Around the same time, various SHM algorithms for infrastructures were developed in the field of civil engineering to offer more precise detection results using certain physical SHM techniques. For example, Johnson et al. utilized local vibration signals in combination with an intelligent diagnosis algorithm to demonstrate the feasibility of a distributed SHM system for damage location and monitoring [Johnson et al. 2004]. Another algorithm based on wavelet analysis to detect the location and the level of damage for the four-story benchmark structure proposed by the American Society of Civil Engineers (ASCE) was also developed. The efficacy of this SHM system was demonstrated by drawing a comparison with an established finite element model for wind loading [Hera and Hou 2004].

Studies on the selection of proper structural parameters for the SHM have been widely conducted over the past decade. Unlike the traditional identification method, parameters selected by the genetic algorithm (GA) have shown certain unique advantages of the SHM [Udwadia and Proskurowski 1998]. The monitoring of large-scale structures is a constant challenge faced by engineers especially when the measured data contains high-frequency noise. Thus, to overcome the above problems, a new statistical SHM system based on the Support Vector Machine (SVM) was proposed. This system was found to be highly reliable under different types and different levels of noise intensity [Zhang et al. 2006]. Furthermore, a new method integrating the Autoregressive Moving Average (ARMA) models and statistical theory was used to analyze the structural response in the time domain [Carden and Brownjohn 2008]. However, as mentioned above, researchers are still faced with the problem of selecting the proper parameters for the SHM algorithm.

As the bio-inspired concept was introduced in the field of engineering, researchers began to seek for possible solution inspired from the nature. The concept of gene expression monitoring was first proposed and implemented by Golub [Golub et al. 1999]. This method offered a new way to classify cancer cells and gave rise to further research in detecting diseases from a gene expression array. The results from the research ignited a new research field, and subsequent research by Slonim et al. also demonstrated the feasibility of combining the NB algorithm and the DNA array data for multi-class cancer diagnosis [Slonim et al. 2000]. In order to obtain high accuracy and overcome obstacles such as high manpower and high equipment costs for monitoring structures, a new two-mode SHM system based on bioinformatics has been proposed in this paper. The proposed system is composed of two main parts: the SHM software and SHM hardware. The basic theory of the SHM algorithm has been described in section 2. The preliminary verification of the proposed system has then been carried out on an eight-storey downscaled benchmark at NCREE in section 3. The proposed SHM system has then been implemented on a mobile SHM prototype in

section 4. Section 5 discusses the practical verification of the integrated SHM system, and based on the results, a summary and conclusion have been included.

2 THE PROPOSED SHM ALGORITHM

As the bio-inspired concept for engineering is a broadly discussed topic, a novel SHM algorithm employing array expression data as the Deoxyribonucleic acid (DNA) of the structures is proposed in this research. Based on the type of vibration which can either be strong ground excitation or ambient vibration, the recorded time history is converted using an auto-regression-auto-regression with exogenous (AR-ARX) process for micro-vibration and an ARX process for earthquake excitation. The AR regression model has proven to be effective in the illustration of the structure model under pure ambient vibration while the ARX model is suitable for significant external excitation conditions [Ljung, 1986]. A series of research conducted by Sohn et al. has also demonstrated the advantage of using the chosen AR-ARX model for unknown excitation between pure ambient and strong ground excitation [Sohn et al. 2000][Sohn and Farrar, 2001]. The obtained array is then compared using the Naïve Bayes (NB) classification method which is the core of the SHM algorithm to detect the damage condition and location as shown in Figure 1. The basic description of each part is briefly summarized as follows:

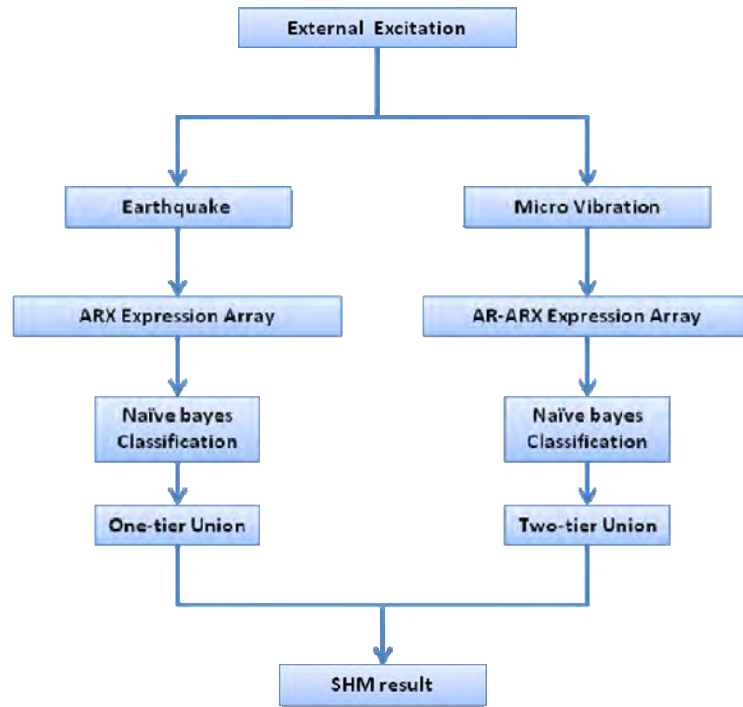

Figure 1: Flowchart of the SHM Algorithm

2.1 THE ARX EXPRESSION ARRAY

The array expression data for earthquake excitation is first extracted using the established ARX model. The measured acceleration response is used in the regression model to precisely describe the behavior of the structure.

For a single-input-single-output (SISO) system, the relationship between the input and output can be expressed as a linear differential equation, given by:

$$y(t) + a_1 y(t-1) + \dots + a_{n_a} y(t-n_a) = b_1 u(t-1) + \dots + b_{n_b} u(t-n_b) + e(t) \quad (1)$$

Where n_a and n_b represent the output and input steps used for regression, respectively.

As $e(t)$ is commonly treated as a random white-noise error in the differential equation, the model is termed the equation error model, and the adjustable parameters can be shown as:

$$\theta = [a_1 \quad a_2 \cdots a_{n_a} \quad b_1 \cdots b_{n_b}]^T \quad (2)$$

By assuming

$$A(q) = 1 + a_1 q^{-1} + \cdots + a_{n_a} q^{-n_a} \quad (3)$$

$$B(q) = b_1 q^{-1} + \cdots + b_{n_b} q^{-n_b} \quad (4)$$

The equation can be rewritten as:

$$A(q)y(t) = B(q)u(t) + e(t) \quad (5)$$

The regression model described in equation 5 is a typical example of the ARX model shown in Figure 2 where the AR part is denoted by $A(q)y(t)$, and X is the external input expressed as $B(q)u(t)$. The model becomes a typical AR model if the external excitation X is excluded as depicted in Figure 3, and will be used as a part of the AR-ARX model later on.

Figure 2: The ARX Model

Figure 3: The AR Model

2.2 THE AR-ARX EXPRESSION ARRAY

The array expression data for the micro-vibration mode of the two-mode SHM system is extracted using the two-tier AR-ARX model. As the velocity response of the structure is more sensitive compared to the acceleration under conditions of micro-vibration, it is employed in the regression model. The AR-ARX model is explained briefly below.

The velocity response $x(t)$ is first input to an AR regression model with p terms

$$x(t) = \sum_{j=1}^p \phi_{xj} x(t-j) + e_x(t) \quad (6)$$

Where $e_x(t)$ is the white-noise input signal defined as the external excitation of the AR model.

By assuming that the error generated from the model depicted in Figure 2 is the input of equation 7, the model combining these two parts represents the proposed AR-ARX model illustrated in Figure 4. The corresponding equation can be expressed as

$$x(t) = \sum_{i=1}^{n_a} a_i x(t-i) + \sum_{j=1}^{n_b} b_j e_x(t-j) + \varepsilon_x(t) \quad (7)$$

Where $e_x(t)$ is the error generated by the first AR model; n_a and n_b are the order for the input and output, respectively. The coefficients calculated from the AR-ARX model are then used in the micro-vibration mode of the SHM system.

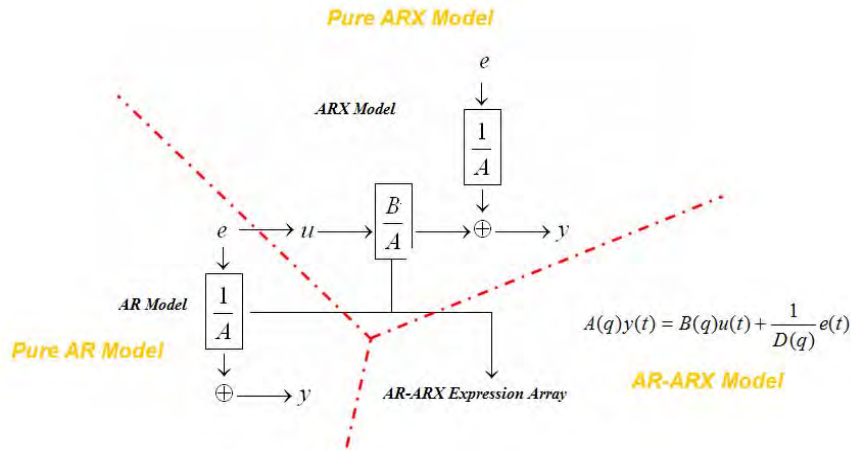

Figure 4: The AR-ARX Model

2.3 THE NAÏVE BAYES (NB) ALGORITHM

The NB algorithm which forms the core of the SHM software is a classification method established on the basics of probability theory. The a posteriori probability is estimated from the prior probability and can be expressed as a conditional probability. The test sample is inputted to the NB algorithm with a Bayes probability distribution defined by two parameters, namely, the mean value and standard deviation to determine the final probability.

The proposed methodology attempts to investigate every coefficient as the DNA of the monitoring structure as opposed to the traditional SHM method, where the health condition is usually determined by only comparing the prediction error of each pre-established regression model. The probability of a specific coefficient of the array expression data is calculated based on the presumed Gaussian distribution for an individual coefficient, which was proven to be easily satisfied. The final damage type is then determined by combining the total probability of the array expression data with the maximum a posteriori probability.

The NB algorithm can be simplified as:

$$Class(x) = \arg \max_i \left\{ \sum_{coefficient} \left[\log(\sigma_i^g) + 0.5 \left(\frac{x_i^g - \mu_i^g}{\sigma_i^g} \right)^2 \right] \right\} \quad (8)$$

Where i is the array number of the test sample; μ_i^g is the mean value of class i and gth coefficient; σ_i^g is the standard deviation of class i and gth coefficient, and x_i^g is the gth coefficient value of the test sample.

3 PRELIMINARY VERIFICATION

To verify the feasibility of the proposed SHM system in a practical structure, a series of experiments were conducted on the eight-storey downscale specimen at the National Center for Research on Earthquake Engineering (NCREE). As shown in Figure 5, eight high-sensitivity velocity meters and eight accelerometers were deployed on the specimen to measure the floor response under micro and earthquake vibration conditions, with the sampling rate set at 200 Hz.

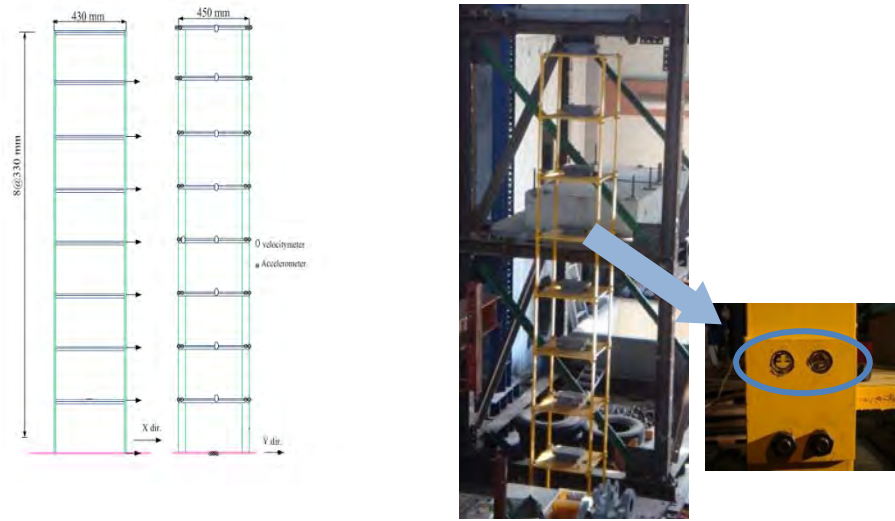

Figure 5: the eight-story SHM Benchmark at NCREE

Signals measured from the ambient vibration in the daily life are first used by the proposed system to enhance its practicability. The structural damages were classified into five major groups for 19 different damage conditions and were simulated by loosening four of the 16 bolts in each floor (1/4 of the beam-column connections). The dataset for the experiment was collected at night to avoid or substantially suppress the unwanted noise arising from machine operation or human activity in the laboratory which aimed to improve the reliability of the structural feature arrays. The 19 damage conditions are listed in Table 1, and 90 time histories each subjected to every damage condition for 20 seconds were recorded. The 19 damage conditions were achieved by switching the location of the loosened fasteners.

Concurrently, the structural response of the benchmark under earthquake excitation conditions was recorded by conducting the shaking table test at NCREE to verify the operation of the earthquake mode of the system. A list of the 11 damage conditions achieved by switching the location of the loosened fasteners is listed in Table 2, and 30 time histories including the 1940 El Centro, 1995 Kobe, TCU 072 and TCU 129 station record of the Chi-Chi earthquake were recorded for different peak ground acceleration (PGA) values for every damage condition.

8		5 & 6F
9	Severe	1 & 2 & 3F
10		4 & 5 & 6F
11	Ultimate	1 & 2 & 3 & 4F

The micro-vibration mode of the SHM algorithm was first verified. Three fundamental parameters (p , a , and b) of the basic AR-ARX model described in equations 6 and 7, were designed to be 10-8-4 based on the rule of thumb for system identification proposed by Ljung [Ljung, 1986]. The ratio of the coefficients a and b is set to 2, and the optimal value of p is then determined. Ljung suggests that better identification results can be obtained when the sum of a and b is smaller than p . However, better structural behavior can be achieved by adjusting the value of p from 12 to 10 using an optimization process.

The advantage of utilizing array expression data for SHM was also evaluated using three different array orders, namely, 30-24-12, 40-32-16, and 50-40-20 based on the format specified above to decipher the optimal array for the system while no significant difference of computation overhead was observed. To enable independent testing of the SHM system, 10 patterns selected from the database were used to verify the system performance. Figure 6 depicts the results of all 19 damage conditions which were obtained from the velocity meter located on the sixth floor (V6). The AR-ARX order increased from 30-24-12 in the top subplot to the final 50-40-20 in the bottom subplot. The 19 damage conditions are indicated in the longitudinal axis as UN, S1, S2, S3, S4, S5, S6, S7, S8, M12, M34, M56, M78, S123, S456, S678, E1234, E5678, and U12345678, where UN represents undamaged; S represents slight damage; M represents moderate damage; S indicates severe damage; E indicates extreme damage and U indicates ultimate damage. The detected damage condition is reflected in the latitudinal bar. The individual bars for each damage condition express all ten testing patterns. The numbers in the longitudinal axis represents the 19 damage conditions, and the diagnosis result is indicated in the latitudinal axis which should correspond to the same value in the X-axis. As demonstrated in Figure 6, the classification success rate can reach 100% by the proposed system for the 50-40-20 form which can be chosen as the optimal array for micro-vibration except damage conditions 3, 6, and 8 where the success rates are 80%, 90%, and 80%, respectively.

The optimal ARX configuration for earthquake excitation conditions was determined using the collected database. Similarly, the two fundamental parameters (a and b) of the basic ARX model described earlier were designed to have a form 8-4. The advantage of utilizing array expression data for SHM was again evaluated using three different array orders, namely, 48-24, 56-28, and 64-32 based on the 8-4 form. Five patterns recorded from the established database were used to verify the system performance. The ARX order was increased from 48-24 in the top subplot, to the final 64-32 form in the bottom subplot. The individual bars, as show in Figure 7, expressed all five testing patterns. The 11 damage conditions are included in the longitudinal axis as UN, S1, S2, S3, S5, S7, M12, M56, S123, S456, and U1234, where UN represents undamaged; S represents slight damage; M indicates moderate damage; S indicates severe damage, and U indicates ultimate damage. Similarly, the latitudinal bar reflects the detected damage condition while the actual damage condition is marked along the longitudinal axis. Structural damage was again correctly predicted by the system for the 64-32 form. The success rates are approximately 60% for damage conditions 8 and 9 and 80% for damage conditions 1, 2, 3, 4, and 7. This array was then chosen to represent the optimal array for earthquake excitation.

Figure 6:Verification under Micro Vibration

Figure 7:Verification under Earthquake Excitation

The union concept of multi-events or sensors has been introduced to achieve further improvement in the accuracy and reliability of the SHM system. The final SHM result can be determined by choosing the condition with the highest accumulated probability. Since earthquake excitations are infrequent in occurrence, only the union concept with three sensors was applied for earthquake excitation. Simultaneously, the micro-vibration mode was tested using three sensors on their respective floors (6F, 7F, and 8F) in the first union, and the results of these three different events were then combined to obtain a more accurate result. The verification of the two-mode system is summarized as follows: Table 3 shows the results obtained for earthquake excitation, and Table 4 depicts the outcome of the micro-vibration tests.

As shown in Table 3, the diagnosis result for three separate classes of earthquakes indicates almost the same damage condition and only a slight variation was observed for damage conditions 1, 3, 8, and 9. However, the approximate damage condition and location can still be rapidly and correctly determined after the occurrence of an earthquake. In addition, a more precise result can be achieved especially in the micro-vibration detection mode. Only a slight error was observed following the application of the first union of the three sensors, and the second-layer union guaranteed a reliable result. In short, the reliability of the two-mode SHM system has been demonstrated by the preliminary verification tests, indicating that the health condition of the structure under both earthquake excitation and micro-vibration conditions can be accurately detected by the proposed system.

Table 3: SHM result with the Union Concept under Earthquake Excitation Mode

Damage Condition Number	Event 1	Event 2	Event 3
1	1	1	2
2	2	2	2

18	18 (18/18/18)	18 (18/18/18)	18 (18/18/18)	18
19	19 (19/19/19)	19 (19/19/19)	19 (19/19/19)	19

As mentioned above, the performance of the proposed SHM system has been successfully demonstrated in dealing with damage conditions included in the system repository. However, it is impossible to include all possible damage conditions and structure locations into the SHM database. To verify the robustness of the proposed SHM algorithm, the system was examined by utilizing several damage conditions excluded from the original database. It is expected that the approximate damage condition and location can be detected.

Three damage conditions from both the micro-vibration and earthquake excitation modes were considered, and the rest damage conditions in Tables 1 and 2 were renumbered. For the micro-vibration mode, conditions selected included slight damage on the 5th floor, moderate damage on the 3rd and 4th floors, and severe damage on the 4th& 5th& 6th floors. For the earthquake excitation mode, slight damage on the 7th floor, moderate damage on the 5th and 6th floors, and severe damage on the 4th, 5th, and 6th floors were chosen as the test conditions. The array expression data was input to the SHM algorithm to determine the corresponding damage condition. As shown in Figure 8, the detected damage conditions are indicated by conditions 5, 9 and 12 which reflect the damage condition closest to the actual damage condition with an accuracy of 100%, 70%, and 60%, respectively. Meanwhile, the damage conditions for the earthquake excitation mode shown in Figure 9 were found to be condition 5, 6, and 7 with an accuracy of 80%, 70%, and 70%, respectively. These results strongly support the reliability of the proposed SHM algorithm for use in practical applications wherein the most likely damage condition can be approximated by utilizing the inherent interpolation or extrapolation capability.

4 MOBILE SHM PROTOTYPE

In order to implement the bio-inspired SHM system practically, a mobile SHM prototype was developed. As shown in Figure 10, the SHM prototype is composed of three fundamental parts including the sensing input module, the SHM platform for instrumentation and data processing, and the general packet radio service (GPRS) transmission module for conveying the final results to the remote server. To further enhance the mobility of the SHM prototype, a customized silver module depicted in Figure 10 is used for voltage stabilization and power regulation of the sensing unit and data processing center. The vibration data is first measured by the deployed sensor and is subsequently transmitted through the input module to the built-in microprocessor. The acceleration and velocity of the structure are both measured simultaneously to evaluate its structural health condition. In addition, by connecting multiple SHM prototypes, the system can be extended to form a SHM network.

Figure 10: The SHM Prototype

The details of the customized sliver module are shown in Figure 11. A total of seven connectors are mounted in the box. Both the velocity meter and the accelerometer can be connected to the two sensor connectors located in the rightmost column for different applications. For the micro-vibration mode, two measurement resolutions can be selected by using the built-in 10 V / Kine or 1 V / Kine converters. Up to 16 sensors can be powered simultaneously by the customized unit. In addition, two optional modules, a GPS module, and a memory card module for depositing the collected raw data can be installed adjacent to the input module. These two modules enable an easy extension of the functionality and mobility of the platform.

Figure 11: the SHM Monitoring Platform

In order to correctly execute the proposed algorithm in the prototype, the SHM algorithm is incorporated in the firmware of the mobile module. The corresponding software can be divided into two parts: the onsite program in the SHM platform and the demonstration program in the remote server where all the structure damage information is collected and displayed. As shown in Figure 12, the on-site program is subdivided into four parts: Data Pre-Processing, Coefficient Extraction, Health Condition Diagnosis, and GPRS & Wireless Module.

Figure 12: the On-Site Program

4.1 DATA PRE-PROCESSING

The Pre-Processing program performs three main functions: input data collection, digital filter design, and data size adjustment/setting for SHM processing. The use of the Pre-Processing program helps to eliminate the undesired noise successfully from the ambient environment to ensure clarity in the input data. In this study, the data sample rate was selected as 200 Hz, and a band-pass filter was chosen to filter out the unwanted high and low frequency sets of 90 Hz and 0.1 Hz. This also helped to eliminate errors arising from the voltage conversion between the analog and digital signals to enable accurate collection of desired data.

4.2 COEFFICIENT EXTRACTION MODULE

The Coefficient Extraction module was designed based on the two proposed SHM algorithms. In this study, the ARX and AR-ARX models are first established and then implemented with the desired order of settings. The Coefficient Extraction module assists in transforming the time history of the structural responses into array form quickly, and the damage condition of the structure can subsequently be evaluated in the next stage by making a comparison between the damage data and the collected database.

4.3 HEALTH CONDITION DIAGNOSIS

The condition and location of the structural damage are determined by the embedded NB-based SHM algorithm. By making a comparison between the arrays calculated from the previous block and the stored database, the probability of occurrence of all damage conditions for either earthquake excitation or micro-vibration modes is estimated by a designated loop, which subsequently enables the detection of the location and condition of the structural damage.

4.4 GPRS & WIRELESS MODULE

In order to achieve the goal of real-time monitoring following the analysis and classification of the damage, the GPRS Module is used to transfer the data back to the monitoring server. To ensure the security of the data being transmitted, it is encrypted. In this study, a technique to safely encrypt and decrypt the data by adding an initial AA string at the beginning of data transmission chain was developed. Only data with are equipped with this characteristic will then be received.

The mobile SHM prototype can be applied to real life structures by combining the software and hardware described above. The mobile SHM prototype has been designed to classify the structural damage condition within a span of one minute.

5 PRACTICAL VERIFICATION

The performance of the SHM prototype was tested using experimental verification. The eight-storey downscaled benchmark mounted on the shaking table at NCREE was used as the practical test structure. Structural damage testing was simulated by loosening four bolts on the third floor which represented damage condition 4. The response under both ambient and earthquake vibration modes was measured using the top three sensors (6F, 7F, and 8F) deployed on the structure.

By comparing the AR-ARX and ARX array obtained from the vibration data with the database deposited in the on-site SHM prototype, the structural health condition can be immediately evaluated. In addition, to demonstrate the feasibility of remote monitoring, the server was chosen at the headquarters of the National Science Council (NSC), and the health condition of the structure was immediately transmitted by the GPRS service, since the proposed SHM system only requires a small bandwidth. The locations of the benchmark and the monitoring server are shown in Figure 13.

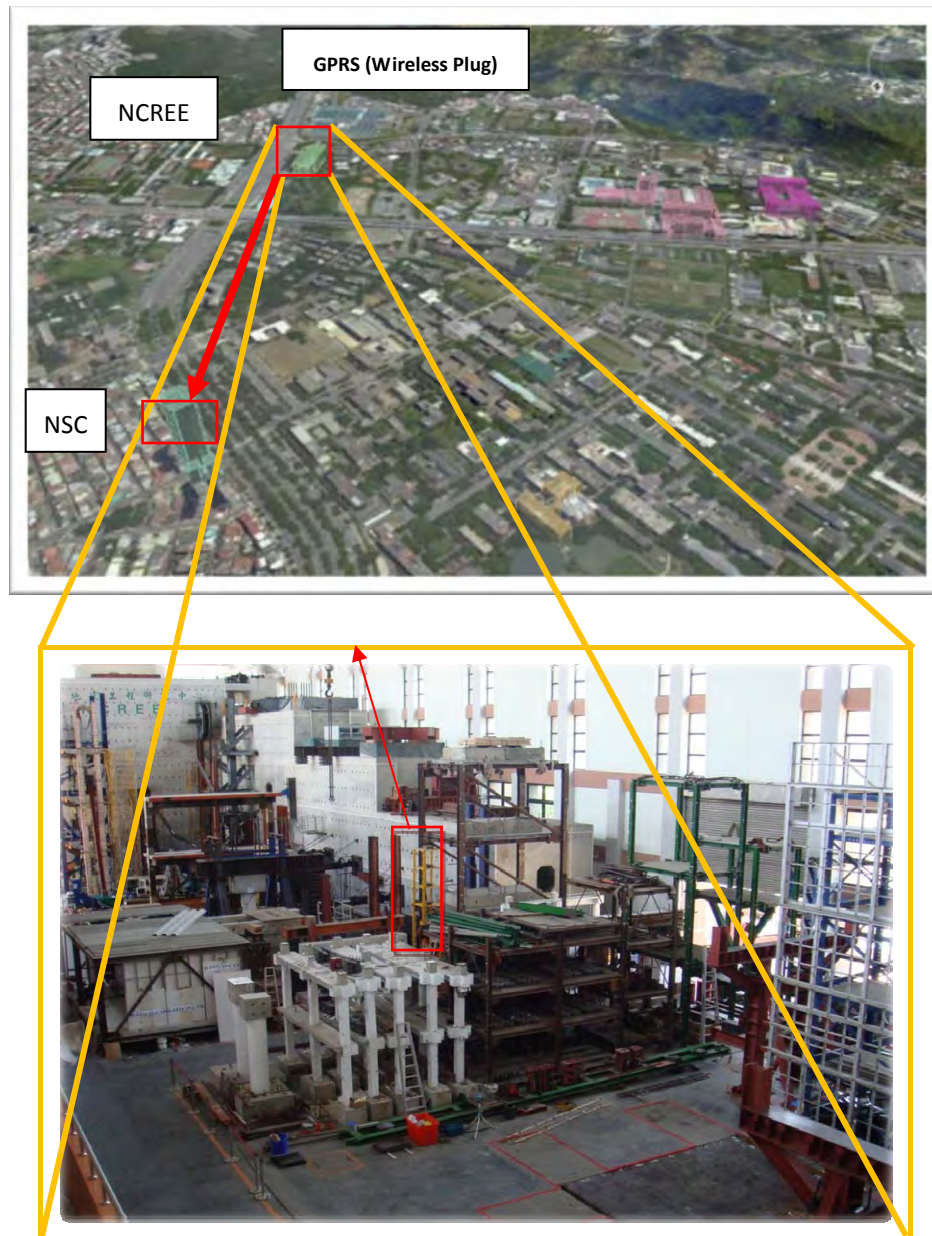

Figure 13: location of the benchmark and the monitoring server

The result from real-time monitoring is shown in Figure 14. It shows that SHM results can be determined by either the earthquake mode or the micro-vibration mode. The switching criterion between these two modes is set to enable an acceleration of 5 gal. If the largest measured acceleration is less than 5 gal, the structural response is measured and processed every 20 seconds, and the results are displayed sequentially in the top left-hand portion of the figure. The numbers shown in the panel represent

the classification result. As mentioned in the previous section, to avoid false alarms in practical applications, the SHM algorithm operates three times a minute with the two-layer union concept to determine the condition and location of the structure damage as depicted in Figure 14. The damage level of the structure is either none, slight, moderate, severe, extreme, or ultimate, and is shown in the middle of the figure. The detected damage location is highlighted on the structure. In addition, the SHM system was also tested by shaking the benchmark structure under earthquakes. The earthquake mode was launched once the detected acceleration value became greater than 5 gal. The union result from the three different sensors is shown in the bottom-left hand corner of Figure 14. The experiment result clearly demonstrated that both the damage condition, which was slight, and the location, i.e. the third floor, could be detected with precision by the two-mode SHM system.

In addition, not only can real-time structural damage be monitored by the mobile SHM prototype, the embedded parameters can also be remotely controlled. This flexible monitoring design can make the SHM system an optimal system for facilitating varied conditions and permit the immediate evaluation of any structural damage. Characteristics like high mobility and prompts on-site processing of the proposed mobile SHM system have finally been implemented.

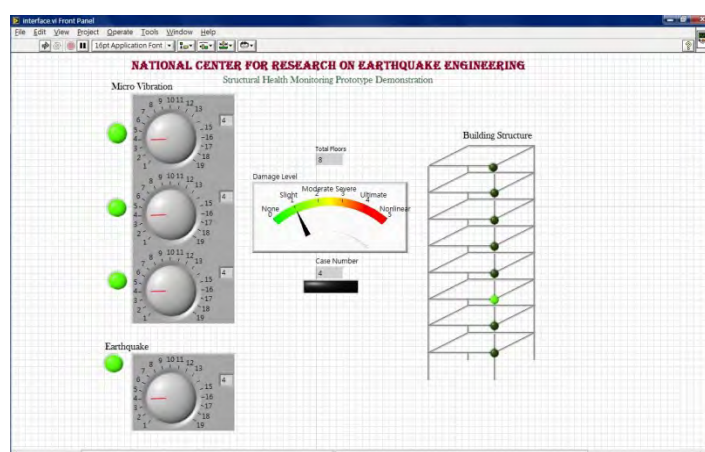

Figure 14: the Real-Time Monitoring Interface

6 SUMMARY AND CONCLUSION

A bio-inspired two-mode structural health monitoring (SHM) system based on the Naïve Bayes (NB) classification method was presented in this paper. Since research focus on the bio-inspired concept for engineering has only recently evolved, a novel SHM algorithm utilizing the array expression data of the Deoxyribonucleic acid (DNA) of the structures was developed. Based on the vibration mode, the proposed SHM algorithm can switch between a two-tier AR-ARX process for micro-vibration and an ARX process for earthquake excitation. The health condition of the structure is then determined by classifying the obtained array expression data using the NB method. Moreover, the union concept in probability was introduced to improve the accuracy of the system.

To verify the performance and reliability of the SHM algorithm, a downscaled eight-storey steel building located at the shaking table of NCREC was used as the

benchmark structure. The structural damage was simulated by loosening four of the 16 bolts in each floor (1/4 of the beam-column connection). The structural response was then determined for different damage levels and locations for inclusion in the structural health monitoring database. Experimental results have demonstrated that the approximate condition and location of the damage can be quickly determined immediately after the occurrence of an earthquake. A more precise result can be achieved in the micro-vibration detection mode.

To implement the proposed SHM system in a practical application, a SHM prototype consisting of three individual modules namely, the input sensing module, the transmission module, and the SHM platform was developed. The employed sensor first measures the structural response, and subsequently, the SHM mode corresponding to the excitation is chosen automatically by the system to rapidly evaluate the health condition of the structure using a preset criterion. Test results from the ambient vibration and shaking table test have shown that the condition and location of the benchmark structure damage can be successfully monitored by the SHM prototype system and can be instantly transmitted to a remote server to facilitate real-time monitoring.

Implementing the bio-inspired two-mode SHM practically has been demonstrated in this paper. The bio-inspired concept is made possible by the successful integration of software and hardware. With its unique mobility and powerful processing capacity, it is expected that the proposed SHM system can be applied to SHM networks in practical applications in the near future.

Keywords: Spectrum Intensity, Inelastic Velocity Response Spectrum, Combination Rules.

Abstract. *Seismic regulations and guidelines for buildings and bridges prescribe simplified combination rules to obtain the maximum structural response under multi-directional earthquake effects. An unfavorable internal force usually develops under the combined effects of an earthquake motion. This study uses the spectrum intensity concept to investigate the tri-directional effects of earthquakes on structures. For this purpose, a set of recent and past thirteen earthquakes ($M > 6$) are selected to predict tri-directional effects. Inelastic velocity response spectra for these earthquakes are numerically obtained and plotted for damping ratios of $\xi = 0.05$ and 0.20 , representing a wide range of damped and heavily damped (e.g. base isolated) structures. Spectrum intensities for both orthogonal and vertical directions and for the resultant direction are calculated using a computer program developed for this purpose. Unfavorable response is then calculated by equating the resultant spectrum intensity to principle direction's intensity plus the other direction's contribution as a percentage of the principle component, or equating the resultant spectrum intensity to principle direction's intensity plus a percentage of the other direction's contribution, or vice versa. The results obtained are strongly earthquake-dependent. Based on the proposed analysis way, well-known building regulations are reviewed and evaluated by emphasizing the prescribed combination rules. Numerical results show that coefficients for the tri-directional contribution varies largely in the range between $0.01 \sim 0.68$ for the selected force reduction factors of $\mu = 2$ and 8 , revealing that in some cases the code defined combination values may yield unconservative seismic designs.*

1 INTRODUCTION

Since analysis of structures under all possible angles of earthquake excitations is complex and time consuming, simplified combination rules have been developed for practical design purposes. Elastic forces and displacements are calculated based on the combination coefficients proposed by existing building codes. A structural design without considering the orthogonal earthquake effects may generally result in insufficient member dimensions, as an unfavorable internal force distribution in the structural elements would usually develop under the combined effects (bi-directional or tri-directional) of an earthquake strong ground motion.

As a common approach, the square-root-of-sum-of-squares (SRSS) procedure is based on the assumption that the actions on an element affected by earthquake excitations in two and three directions are combined. With the help of elastic velocity response spectra, Sesigür, Celik, and Cili [1,2] proposed a way of analysis for the bi-directional and tri-directional effects of earthquakes using the characteristics of the selected earthquakes. The 30% and 40% rules are simplified approximations to the SRSS and the CQC methods. Many current design codes [3 to 7] for buildings and bridges require that members should be designed for 100 percent of the seismic forces in one direction plus 30 percent of the seismic forces in the perpendicular direction (the 30% rule). ATC-32 [6] requires the 40 percent rule to be used in the design of bridges under bi-directional effects. In order to investigate the bi-directional effects of inelastic response of single degree of freedom (SDOF) structures, Sesigür, Celik, and Cili [8] presented some design recommendations.

For yielding/inelastic structures, the present study essentially aims to extend the bi-directional analysis way developed in [8] to tri-directional earthquake effects. As before, inelastic velocity response spectrum and the spectrum intensity concept (SI_H) corresponding to inelastic velocity response spectrum is used. Finally, numerical values for the combination coefficients are proposed and compared with code-defined values.

2 METHOD OF ANALYSIS

Since the velocity response spectrum is a powerful tool for estimating the damage potential of structures in the medium and long period range, the analysis method called as the spectrum intensity concept as proposed in [8] will be followed here for inelastic structures. The inelastic velocity response spectrum is obtained following the standard procedure given by Newmark [9]. The average acceleration method is used for nonlinear response analysis of SDOF system, taking $\gamma=1/2$ and $\beta=1/4$. The time step Δt is chosen as 0.02 to detect accurately the transitions from unloading to loading branches or around sharp corners of the force-deformation curves. Force-deformation relation is considered as a cyclic ideal elasto-plastic curve. Inelastic analysis is carried out by the force reduction factors of $\mu=2$ and 8, representing significantly rigid (e.g. masonry) and ductile structures (e.g. steel or RC).

Housner introduced a measure of ground motion intensity which defines the integral of the velocity response spectrum over a period range from T_1 to T_2 as the spectrum intensity (1) where SI , ξ , T , and S_v are intensity, damping ratio, fundamental period of the structure and the ordinate of the velocity spectrum respectively. T_1 and T_2 are proposed as 0.10~0.50sec and 2.50~5.00sec. This integral can be evaluated for any desired damping ratio (note that Housner recommended using $\xi=0.20$); however, to clarify the impact of damping ratio on the evaluation of this integral, damping ratios of $\xi=0.05$ and 0.20 are chosen.

$$SI = \int_{T_1}^{T_2} S_v(\xi, T, t) dT \quad (1)$$

For near-fault ground motions ($L \leq 15$ km, T_0 (fundamental period of soil) ≈ 0.20 sec, near the epicenter, stiff soil conditions and minimum focal depth is $H=30$ km), one component of the spectrum intensity might be negligible, and the other could be significant, (e.g. the 10.18.1989 Loma Prieta and the 01.17.1994 Northridge earthquakes). For the far-field motions ($L=40\sim 50$ km, stiff soil conditions, $T_0 \approx 0.05\sim 0.50$ sec and $2.50\sim 6.00$ sec), if the horizontal components of the intensities are close to each other then both components must be taken into account, (e.g. the 05.18.1940 El-Centro earthquake). For the earthquakes with a long period, the unfavorable conditions occur in the resultant direction, (e.g. the 07.06.1964 Mexico-City earthquake). Table 1 presents the data of thirteen recorded accelerograms used in the present study. Three earthquakes that greatly affected populated areas in Turkey are also chosen.

Table 1. Characteristics of the selected earthquakes

In some cases, the third component (i.e. the vertical component) of an earthquake could be of great importance. For example, large span cantilevered or other structures or structures having beams or cantilevers that support heavy vertical (gravity) column loading, and structures with irregularities in elevation might be critical under the effect of vertical component of an earthquake.

As explained in [8], under tri-directional earthquake excitations and under elastic conditions, the unfavorable response of a structure could be calculated in two alternative ways: The first way is to equate the resultant spectrum intensity to principle direction's intensity plus the other direction's (i.e. the other horizontal and vertical directions) equal contributions (α) as a percentage of the principle component. The second way would be to equate the resultant spectrum intensity to principle direction's intensity plus other components' unequal contributions (i.e. λ_1 for the other horizontal component and λ_2 for the vertical component) as a percentage of the principle direction's intensity. α , λ_1 , and λ_2 have numerically been calculated for each of the selected earthquake data. These coefficients can then be implemented in the combination rules to obtain the maximum response parameters. Apparently, numerical values are expected to be earthquake-dependent.

This analysis procedure will be generalized here for both tri-directional earthquake excitations and yielding/inelastic structures. A single degree of freedom (SDOF) system subjected to tri-directional strong ground motions and the evaluation of velocity spectrum intensities are illustrated in Figure 1.

Figure 1. Single degree of freedom system under tri-directional earthquake excitation and spectrum intensities for each component and resultant

Here, x indicates the earthquake direction that produces maximum internal forces in the system. Spectrum intensities for both orthogonal and vertical directions as well as for the resultant (i.e. the unfavorable) direction are defined as SI^x , SI^y , SI^z and SI^{xyz} , respectively. Depending on these numerically obtained values, the above mentioned coefficients can then be calculated using the following equations:

$$\alpha = 0.5(SI^{xyz}/SI^x - 1) \quad (2)$$

$$\lambda_1 = (SI^{xyz}/SI^x) - (1 + \lambda_2) \quad (3)$$

$$\lambda_2 = (SI^{xyz}/SI^x) - (1 + \lambda_1) \quad (4)$$

For a given ground motion, the resultant inelastic velocity response ($\dot{x}_r(t)$) of a SDOF system can be calculated using the square root of the squares of each orthogonal component's contributions ($\dot{x}_1(t), \dot{x}_2(t), \dot{x}_3(t)$) as follows:

$$\dot{x}_r(t) = \sqrt{|\dot{x}_1(t)|^2 + |\dot{x}_2(t)|^2 + |\dot{x}_3(t)|^2} \quad (5)$$

The maximum values of the above equation for a given damping ratio and natural vibration period give the ordinates of the resultant velocity spectra. This is shown in (6).

$$(S_v)_r = \left| \dot{x}_r(t) \right|_{\max} \quad (6)$$

3 COMPUTER PROGRAM

To carry out the numerical computations, a special computer program that accepts strong ground motion data for the three components of the selected earthquakes, damping ratios, natural vibration periods, and mass as input, was coded. A flow-chart of the program is given in Figure 2. Both elastic and inelastic spectrum intensities are then calculated for the three orthogonal and resultant directions. Inelastic velocity response spectra for the selected

earthquakes are numerically obtained and plotted for damping ratios of $\xi=0.05$ and 0.20 , representing a wide range of damped and heavily damped like base isolated buildings or buildings with viscous or other type of dampers.

A similar way that was followed in the computation of spectrum intensities can be used in obtaining the maximum internal forces (E_{xyz}) in a structural member under tri-directional effects. This can be evaluated by the internal forces developed in the principal direction (E_x) plus the other direction's (both the other horizontal and vertical) contributions (λ_1, λ_2). For this purpose, α , λ_1 , and λ_2 obtained through the spectrum intensity concept can be used:

$$E_{xyz} = E_x + \lambda_1 E_x + \lambda_2 E_x \quad (7a)$$

$$E_{xyz} = \lambda_1 E_y + E_y + \lambda_2 E_y \quad (7b)$$

These equations and coefficients are actually defined in Eurocode 8 [5] to take into account the tri-directional earthquake effects on structures. λ_1 and λ_2 are proposed as 0.30 . On the other hand, for design purposes, the equal contributions of the other components can also be taken into account as given in (7c). Therefore, α coefficient is of special interest to evaluate the combination rules in structural codes.

$$E_{xyz} = E_x + 2\alpha E_x \quad (7c)$$

For the selected earthquake ground motions (a total of thirteen), inelastic velocity response spectra for each of the orthogonal, vertical directions and for the resultant direction are shown in Figure 3, following the procedure summarized above. Also, Figure 4 shows hysteretic curves of the elasto-plastic SDOF systems for selected earthquakes. α , λ_1 , and λ_2 are numerically calculated for each of the selected earthquakes and the results are also summarized in Table 2. If λ_1 is considered as a value of 0.30 (as given in many codes), λ_2 is generally obtained as negative values that can be interpreted as the %30 rule is sufficient on the basis of spectrum intensity concept followed in this work. Therefore, the contribution of the vertical component may be neglected in most cases.

4 MULTI-COMPONENT COMBINATION RULES IN CURRENT CODES

Most design codes that address the multi-component ground motion problem, specify that the contributions to a response quantity from the orthogonal components of seismic input be combined either by the square root of sum of squares (SRSS) rule or by a percentage rule. The 30% rule is a linear approximation of the combined response. The 40% rule is also a linear approximation recommended for the analysis of nuclear and bridge structures in the ATC-32. The SRSS and 30% rules are prescribed in Eurocode 8.

The unfavorable earthquake loads are produced by the following combinations.

$$\begin{aligned} &E_x, \lambda E_y, \mu E_z \\ &\lambda E_x, E_y, \mu E_z \\ &\lambda E_x, \lambda E_y, E_z \end{aligned}$$

Here, E_x , E_y and E_z are internal forces developed during an earthquake loading. For practical design purposes, the λ and μ coefficients are chosen as 0.30 and 0.20 respectively. The UBC97 requires the use of either the SRSS rule or the 30% rule, but only for structures having certain types of irregularities. The current (Caltrans) bridge design specifications require the 30% rule for all structures.

Table 3. Computed spectrum intensities and combination coefficients ($\xi=0.20$)

The Caltrans code does not specify the SRSS rule as an alternative. There are two alternative rules prescribed in IBC2003. One of the alternative rules combines the responses with two horizontal seismic components using the SRSS rule; the result is multiplied by the redundancy coefficient and added to the effect of the vertical component, which is written as a linear term in the design load combination. The other alternative rule combines the responses with two horizontal components using the 30% rule, and adds the effect of the vertical component in the same way. In the recent Turkish earthquake code of “Specification for buildings to be built in earthquake zones” the 30% rule is prescribed.

To compare the numerical results obtained from this study, the variation of α coefficients with respect to selected damping ratios is further illustrated in Figures 5a,b. For the selected earthquake ground motions, it is observed that, for inelastic analysis, the maximum value of the coefficient α is changing wide range between 0.05~0.23 for $\mu=2$, $\xi=0.05$ and 0.02~0.68 for $\mu=8$, $\xi=0.05$, 0.03~0.23 for $\mu=2$, $\xi=0.20$ and 0.01~0.43 for $\mu=8$, $\xi=0.20$. To evaluate the contribution of the vertical component to the combination rule, λ_2 values are obtained whilst λ_1 values are taken as a value of 0.30. The results show that most of the λ_2 values are negative, hence if the orthogonal components are combined with a %30 rule, vertical component of the strong ground motion can be neglected.

Figure 5. α coefficients for elastic ($\mu=1$) and inelastic ($\mu=2$ and $\mu=8$) systems.

5 CONCLUSIONS

Among several methods of analyses (e.g. the CQC, 30%), the Housner's spectrum intensity concept was used to investigate tri-directional earthquake effects for inelastic response of structures. For this purpose, inelastic velocity response spectra were plotted for a set of thirteen ground motions for structures having damping ratios of $\xi=0.05$, 0.20 , and first elastic vibration periods up to $T=5$ sec. Spectrum intensities for both orthogonal directions and for the resultant direction were obtained. Relevant coefficients commonly used in the percentage rules recommended in building codes were numerically calculated using the velocity spectrum intensities. Obtained numerical results show that the maximum value of the coefficient α is strongly earthquake dependent and varied between $0.05\sim0.23$ for $\mu=2$, $\xi=0.05$ and $0.02\sim0.68$ for $\mu=8$, $\xi=0.05$, $0.03\sim0.24$ for $\mu=2$, $\xi=0.20$ and $0.01\sim0.43$ for $\mu=8$, $\xi=0.20$, revealing that in some cases the code defined combination values may yield unconservative seismic designs.

Keywords: Seismic assessment, fluid structure interaction, model updating, time history analysis.

Abstract. *Seismic assessment of important existing structures what are designed according to prior seismic codes or even without considering any earthquake load is one of the most important issues for minimizing the seismic vulnerability. Within this work the seismic assessment of an existing building for radioactive waste management is presented. The investigated structure is designed as a water treatment plant consisting of six collecting tanks situated in a height of 4m and is supported by eight RC columns. The building is located in the area with the highest earthquake hazard in Austria. The main goal was to analyse the whole structure under dynamic excitation during an earthquake event and in case of overloading to give recommendations for possible retrofitting solutions. An improved method for the elaboration of precise structural models is presented, which combine dynamic in-situ measurements and FE-analysis. With dynamic in-situ tests under forced excitation by usage of a reaction mass exciter, the dynamic behaviour of the structures was determined. That followed a model updating procedure to increase the reliability of the numerical investigations. The main life loads of the building are the tanks filled with water. For consideration the fluid structure interaction (FSI) during dynamic excitation an approach with usage of adequate solid elements was implemented in the structural model. In order to assess the accuracy of the chosen approach and updated finite element model, linear spectrum analysis and time history analysis were carried out. In the parametric study, the influence of a number of parameters concerning earthquake and structural characteristics on the structural responses, especially the filling level of the collecting tanks, were investigated. For the nonlinear dynamic analysis a set of different artificial time-histories, which were generated fitting to the EC8 response, were used.*

1 INTRODUCTION

Seismic assessment of important existing structures what are designed according to prior seismic codes or even without considering any earthquake load is one of the most important issues for minimizing the seismic vulnerability. Further, there are several areas in Europe, where seismic zones were upgraded during the last decade according to recent research results. Hence, the seismic assessment of important existing structures like industrial facilities processing with toxic or nuclear materials are obviously to reduce the potential risk for the population and environment. Such structures with increased risk for the population are beyond the scope of the current design codes. Considering these aspects a more detailed approach as recommended in EC8 was carried out.

1.1 Seismic Assessment in combination with in-situ tests and FE calculations

The most accurate method to assess the seismic vulnerability of existing structures is to perform field investigations in combination with numerical calculations. The goal of the tests is to identify the modal parameters of the structure under consideration. A first model of the tested structure, which was elaborated on the basis of the design - documents can be fitted to measured results by an optimisation approach. This is done by minimizing the difference between measured and calculated modal parameters. This procedure is called “model updating”. In most cases for complex structures 3D – FE models will be used. The resulting model represents very well the status of the structure at the time of the investigation concerning mass, stiffness and boundary conditions. If no reliable information about strength can be found in the design documents, realistic assumptions must be used or adequate tests have to be carried out. The updated model means a realistic linear starting point even in the case of a strong earthquake. In the presented approach the investigations started with in-situ measurements of structural- and soil response using a reaction mass exciter VICTORIA of AIT.

1.2 Investigated structure

The investigated structure is situated in Austrians highest seismic region with a maximum horizontal peak ground acceleration of 2.15m/s^2 . With consideration the effective value and soil amplification factor a design ground acceleration of $a_g=1.8\text{m/s}^2$ results. The building is designed as a water treatment plant with six collecting tanks supported by eight RC columns. Each tank has a capacity of 80m^3 , with a restriction of maximum filling of five tanks at the same time it leads to additional mass of 400 to (see Figure 2). The tanks are constructed as upside down pyramids with a cubical base. The total height of the building is 7.2m, the centre of the mass in a height of about 4m. The structure is surrounded by two adjacent buildings with a height of 14.2m and the building in the background with a height of 3.3m (see figure 1). Due to different foundation and mass distribution the buildings are connected only with elastic building joints.

The main goal was to ensure the structural safety during an earthquake event. The work was done in following steps:

- FE - modelling of the building including the water tanks
- Dynamic measurement to determine the modal parameters of the building.
- Model updating approach
- Detailed investigation of the structure under the seismic loads according EC8
- Recommendations for retrofitting

2 NUMERICAL MODEL

For analysis, a three dimensional model of the building was created in ANSYS (Figure 1). This model includes only a few simplifications and thus provides very accurate results and information on the utilization of individual structural elements. For considering the real mass distribution the lightweight roof construction was modelled in a simplified manner as equivalent mass at the last slab. It was assumed that it has minor impact on dynamic and static properties of the whole building.

Figure 1: FE Model of entire building complex

Next to the structural system i.e. bearing walls, ceilings, beams and columns, also fluid elements (Fluid80) were implemented to model the realistic behaviour of water response in the tanks under dynamic excitation. The fluid elements are defined by eight nodes having three degrees of freedom at each node: translation in the nodal x, y, and z directions. The element input data includes eight nodes and the isotropic material properties. E_x , which is interpreted as the "fluid elastic modulus", should be the bulk modulus of the fluid ($E_x = 2.1E09$ Pascal for water). The viscosity property is used to compute a damping matrix for dynamic analyses. A typical viscosity value for water is $1E-03$ Pascal-sec. The connection between fluid and RC walls was conducted out with respect to the realistic behaviour of degree of freedom of fluid elements. At the boundary area the fluid elements have been coupled in perpendicular direction with the adjacent concrete surface elements. All other degrees of freedom are free and water can move in a realistic way under modal analysis (Figure 3) and transient analysis (Figure 8).

Figure 2: Fluid Elements

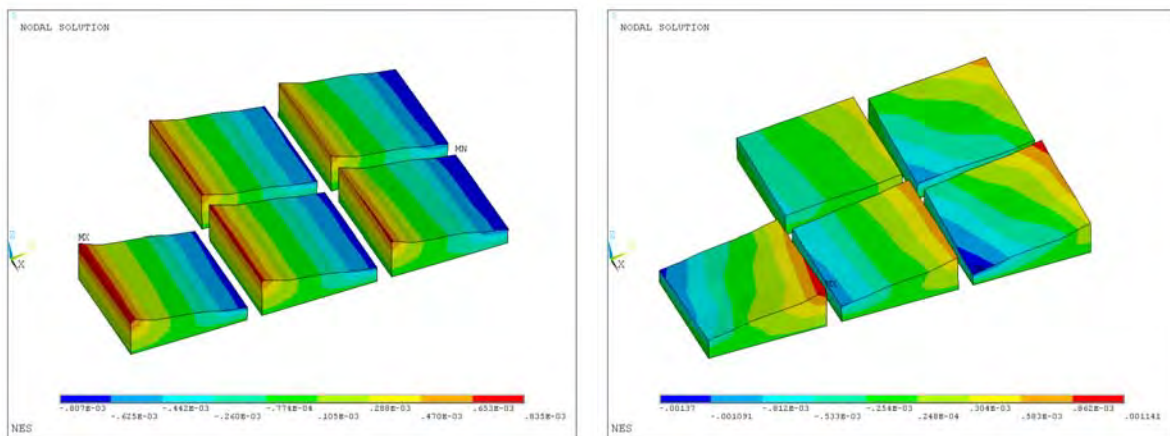

Figure 3: Movement of water – mode shapes

3 DYNAMIC MEASUREMENT

The reaction mass exciter “Victoria” was used as a vibration source to perform dynamic measurements of the building. To determine the vibration characteristics highly sensitive accelerometers were arranged at 34 points at four levels. The choice of the points was aligned to determine all representative natural frequencies and mode shapes.

Figure 4 left: connection with the building; right: position of the exciter mass

The excitation was carried out over an axial rod chain between the structure and the exciter mass (Figure 4). The excitation angle of about 45° ensures to excite as many natural modes as possible.

4 MODEL UPDATING

Natural frequencies and modes shapes of the building were calculated and compared with the obtained parameters from dynamic measurement. The amount of water in the tanks during FE calculation was set to be the same as it actually was during the measurement. The calibration of the FE model was carried out with respect of the first three measured eigenmodes. In this case, the most important updating parameters were: E-modul of RC, E-modul of elastic connection between buildings and ground stiffness. Realistic maximum and minimum values of these parameters were assumed, and through series of analysis, whereas they were ran-

domly changing, the most suitable solution was found. The natural frequencies, as well as the mode shapes of the FE model and measurement were in a good agreement (Table 1).

Mode	Natural frequency [Hz]		Deviation
	Measurement	FE model	
1	x	5.2	x
2	6,3	6,2	1,6%
3	8,7	7,6	12,6%
4	11,5	11,9	3.50%
		Average	5,9%

Table 1: Comparison of computed and measured natural frequencies

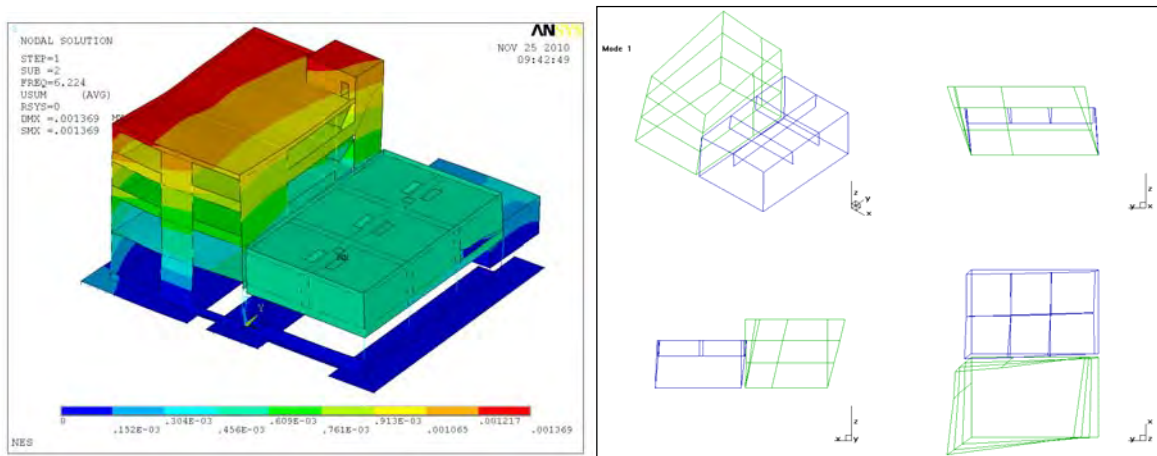

Figure 5: 2nd Mode: left: computed; right: measured

5 SEISMIC ASSESSMENT

First, a sensitivity study was carried out with the aim to identify the most unfavourable combination of filling levels. The positioning of the fulfilled tanks was varied with respect to maximum loading for each construction element and considering global torsion effects due to unsymmetrical set ups. The identification of the worst load case situations were obtained by linear spectrum analysis. Next to spectrum analysis, also transient time- history analysis was used. It was necessary to improve the behaviour of fluid elements and to allow material nonlinearities. For the nonlinear dynamic analysis a set of different artificial time-histories [1], which were generated fitting to the EC8 response, were used (Figure 6).

Figure 6: Response spectras

As mentioned in chapter 1.2 the building complex consists of three buildings, linked with a dilatation joint. Whereas the stiffness of this elastic material for small deformations was approximately identified by modal updating, it is difficult to assess its behaviour during the earthquake impact. Due to high deformations caused by seismic impact, connections to adjacent parts of the building may get lost during earthquake. The calculation was performed without connection to the adjacent buildings (Figure 7). Together with the high mass concentrated at the height of about 4 meters the building is extreme vulnerable to horizontal forces.

Figure 7: Water tank building treated as standing alone

The results from all transient analysis were averaged and the safety factors according the requirements of Eurocode 2 were calculated. The comparison between spectrum analysis and transient analysis types showed good agreement, with the differences about less than 20%. The deformation of the structure during time history analysis is plotted in Figure 8.

Figure 8: Deformation during time- history analysis

It is obviously that the most critical components of the structure in case of seismic impact are the eight columns in the ground floor. The structural design analyses were carried out according EC2 regarding possible shear and biaxial bending failure. An Important issue in post processing of transient analysis is the synchronism of the forces. Not only maximums are significant, but also the worst combination of all forces in time. For biaxial bending in every time step following simplified criterion (EC2) was used:

$$\left(\frac{M_{Edz}}{M_{Rdz}}\right)^a + \left(\frac{M_{Edy}}{M_{Rdy}}\right)^a \leq 1 \quad (1)$$

where:

$M_{Edz/y}$ is the design moment around the respective axis

$M_{Rdz/y}$ is the moment resistance in the respective direction

a is the exponent, which depends on the axial force

The example of time- depending bending moments (red and pink) and axial force (blue), as well as results from equation (1) are shown in Figure 9.

Figure 9 Left: bending moments and axial force; right: results of equation (1)

To assess the shear resistance, the equations (6.2), (6.8) and (6.9) from EC2 were used. Due to simultaneous dependency of shear and axial force, the calculation was carried out for every time step, and the worst case was taken for analysis. The structural design of the analysed columns doesn't fulfil the requirements according the standards. Furthermore the internal requirements regarding maximum deformation will exceed what will lead to damage of technical facilities and cause a potential risk for the environment.

6 STRENGTHENING RECOMMENDATIONS

Possible retrofitting designs were limited by requirement of the operator to minimize construction works inside the building due to interference with internal operation. The proposed strengthening solutions should take into account minimizing modifications for existing technical assets and facilities. Aware of these requirements also unorthodox seismic strengthening solutions, like asymmetric strengthening, were analysed. Due to asymmetric stiffening the dominant torsion mode increase the loading of the corner columns significantly. In fact of this, minor modifications of internal facilities were accepted by the operator and proper retrofitting solutions were investigated. All of the presented variants provide earthquake safety and fulfilled operator's requirements perfectly, so only simplicity of rebuilding will be the relevant criteria. Thank FE calculation a lot of various options could be investigated and optimised.

6.1 Variant 1: Additional walls

In Figure 10 the first variant is given. New walls to be built are marked in red. The torsion, caused by asymmetry, is reduced by the use of two outside walls, but could not be avoided. The big advantage is that the existing columns do not need to be replaced.

Figure 10: First retrofitting variant

6.2 Variant 2: Additional outside walls on the corners

This variant comprises adding strengthening short walls in each corner. The advantage is symmetry, disadvantage – demand to exchange of the existing columns (Figure 11).

Figure 11: Second retrofitting variant

6.3 Variant 3: Connection with the other building through a damper

It occurred that coupling of both buildings would assure the earthquake safety of the water tanks. It could be achieved by implementing at least four dampers, two in each direction. Exact optimisation of dynamic parameters of dampers was not carried out in this stage.

7 CONCLUSIONS

By means of experimental modal analysis and finite element calculation a very realistic computer model for the entire building complex was created. Due to artificial excitation three mode shapes could be identified. The model adjustment was made on these three modes, whereby in addition to the Young's modulus of the materials, the elastic bearing joints to adjacent building parts and the boundary condition at the base were used as model updating parameters. The comparison of calculated with the measured mode shapes shows a very good agreement. With the improved FE model, earthquake analysis under consideration the local conditions and historical seismic events were carried out. Moreover following issues can be highlighted:

- Considering fluid structure interaction allows an adequate simulation of water behaviour under dynamic excitation and increase the reliability.
- Post- processing of transient analysis provides information about simultaneity of bending, shear and axial forces.
- Thank FE calculation a lot of various strengthening possibilities could be investigated and optimized

ACKNOWLEDGEMENT

The authors want to thank Nuclear Engineering Seibersdorf, who gave kindly their permission to publish parts of the work contracted by them to AIT.

Keywords: Nonlinear Analysis, Seismic Assessment, RC Structures

Abstract. Many existing RC structures worldwide were designed for gravity loads only, with inadequate lateral load resistance, lateral stiffness and poor detailing of the reinforcement. Moreover, the concept of regularity both in plan and elevation that characterise a good conceptual design was, in most cases, not taken into account.

The introduction in Europe of the regulations for seismic assessment of existing structures imposed stricter performance requirements for building structures. In order to take into account the poor seismic behaviour of such buildings, recent seismic codes – namely EC8 and NTC08 (Italian code), introduce a number of prescriptions regarding issues such as analysis type, load distribution, accidental eccentricity, etc. At the same time, these codes give room for engineering judgment to be used with reference to the definition of structural and non-structural elements such as slabs or infill walls, and obviously leave it up to the analyst decisions regarding Finite Elements typology, meshing, mass modelling, etc.

The main goal of this work is thus to provide an extensive and wide evaluation on the influence of each of the abovementioned parameter on the seismic assessment of structures. For this purpose, nonlinear static procedures, as well as nonlinear dynamic analysis are performed on a real building that has also been experimentally tested in the past. The results will hopefully provide indications on the relative importance of each modelling parameter or decision.

1 INTRODUCTION

The existing building stock poses a much more serious and complex seismic safety problem when compared to safe earthquake design of new construction. Moreover, the past thirty years have witnessed such a significant increase of knowledge in the field of earthquake engineering, that even relatively modern structures may no longer meet the requisites of constantly developing regulations.

It has been recognised by the scientific community that force-based approaches for seismic assessment of structures are inappropriate. Instead, assessment methods employing displacement-based approaches, where member deformations are evaluated, tend to provide a more suitable estimation of the actual structure capacity. In order to implement this new philosophy and accurately estimate the members deformations, typically evaluated in terms of chord rotations, it is required advanced modelling capabilities that allows the structure to go behind the linear range.

Nonlinear dynamic analyses are, at the present time, the most accurate approach to evaluate the seismic response of structures. On the other hand, nonlinear static analyses (Pushover) are a simplified approach that allows the evaluation of the structure's behaviour when subjected to an increasing monotonic lateral load. Despite being considered a suitable approach for regular structures, its application on irregular structures has been pointed out as one of the main shortcomings of this type of analysis. Moreover, difficulties inherent to uncertainties in the definition of structural and non-structural elements such as slabs or infill walls, associated with modelling decisions regarding Finite Elements typology, meshing, mass modelling, etc., represents additional drawbacks.

The output of this study will hopefully provide some guidance on critical structural modelling issues that require urgent attention in order to overcome some uncertainties associated with the assessment of existing reinforced concrete (RC) structures.

2 STRUCTURAL BEHAVIOUR OF IRREGULAR RC STRUCTURES

Recent seismic events such as the 1985 Mexico, the 1994 Northridge, the 1995 Kobe and the 1999 Kocaeli earthquakes induced severe damage to non-ductile RC buildings proving that many constructions located in seismic zones are unable to withstand moderate to severe earthquakes and therefore observe significant damage and contribute to significant loss of lives.

Usually these structures were designed for gravity loads only, neglecting all the basic concepts for a good seismic behaviour such as regularity, both in plan and elevation, adequate lateral resistance systems, detailed reinforcement, etc. Because lateral actions were not taken into account in the design process, the columns cross-sections tend to be relatively small with insufficient longitudinal and transversal reinforcement. Very often these structures exhibit also a reduction in the columns cross-section over the high of the building. Consequently these elements possess reduced deformation capacity and, very often lead to soft-storey mechanisms and deformation shapes characterized by a strong torsional component.

In addition to the properties of the main structural system, there are other structural elements that, despite not being considered as part of the primary earthquake-resistant system, might modify the response of the building when the latter is subjected to lateral loads. For instance, infill panels are typically considered as secondary or non-structural elements, present only to provide a physical separation of spaces and insulation and, consequently, without any structural purpose. For this reason, generally they are not considered in the assessment procedure.

Nevertheless, in masonry-infilled RC frames, the infills might control the global response and often determine the performance and failure of the frame. Experience from earthquakes suggest that strong infill panels, although non-engineering and non-structural, often provide most of the earthquake resistance and prevent collapse of relatively flexible and weak RC structures [1]. However, very often, infills are not uniformly distributed over the plan and height, forcing the building to behave in an irregular fashion and, in this way, imposing high demands both in terms of forces and deformations, which may lead to local or global collapse of the structure. In this study, infill panels were modelled using the element proposed by Crisafulli [2].

An additional issue that requires particular attention is the way in which slabs are modelled. Very often ignored in the structural assessment process, the slab may play an important role, especially when associated to irregular buildings - its effect is mainly dependent on the relative in-plan stiffness compared with the stiffness of the vertical elements and its in-plan location. Typically three different solutions may be employed: no slab, rigid diaphragm, and an intermediate and perhaps more realistic solution, whereby the actual stiffness of the existing slab is considered. This latter solution can be implemented through the use of equivalent crossed trusses or, perhaps an easier and faster solution, by mean of nodal constraints with adjusted penalty functions. It must be pointed out that the aforementioned different assumptions do not only influence the structures global behaviour, but also at the elements level, as it will be demonstrated herein.

In order to account for uncertainties in the location of masses and in the spatial variation of the seismic motion, seismic codes such as EC8 [3] and NTC08 [4] introduce an “accidental eccentricity”, which imposes an additional torsional effect on the structure, and a number of lateral load distributions for static nonlinear analysis, aimed at reproducing higher mode effects in plan and elevation.

In summary, the importance and impact of the following structural parameters in the assessment of RC structures were assessed in the current parametric study:

- Infill panels
- Rigid/deformable slabs
- Accidental eccentricity
- Lateral distribution of loads for nonlinear static analysis

3 MODELING OF RC STRUCTURES

Supported on the exponential growth of computational capabilities witnessed in recent years, structural engineers are now able to make use of the on-going scientific developments. Moreover, practitioners are now enforced to keep themselves up to date on modelling developments and code requirements. Focused on this last observation, the present work intends to enlighten some clarification in some modelling issues, which have been proved to be crucial in seismic assessment of existing RC structures.

Nonlinear dynamic analyses are, currently, the most accurate approach to estimate the seismic behaviour of structures. Nevertheless, this advanced procedure requires high computational effort to process the analyses and, at the same time, the output extracted from the software provides information about a single seismic event. Therefore, in order to overcome these drawbacks, nonlinear static analysis, emerges as a simplified approach that allows the estimation of the capacity, defined in terms of base shear and lateral displacements, of structures subjected to increased lateral loads. The basic premise is that monotonic pushover can act as an envelope for the dynamic hysteresis.

In order to simplify the assessment procedure, a common approach consists in concentrating the mass of the structure at the beam-columns joints, rather than distributed along the elements. Following this procedure, the time taken to build-up the model as well as the processing phase might be substantially reduced. The employment of distributed mass represents a more suitable and accurate approach that enables the correct characterization of both global and local structural behaviour. On the other hand, according to previous studies, concentrating the masses at the structural joints is suitable for nonlinear static analysis since the evaluation of the mode shapes and global response of the building is consistent with the choice of distributing the lateral pushover forces in the structural joints [5]. However, because this assumption might lead to incongruences at the element level, a sensitive study making use of both approaches was carried out.

Previously, particular attention was addressed to modelling issues associated to computational performance. Nevertheless, it must be also emphasized that the time consumed during the pre- and post-processing phases may also be important. This way, and supported on the fact that beams damage are concentrated at the element ends for both static and seismic loads, a “simplified beam element”, consisting in one element defined with the beam-end-section through the entire member is evaluated. In this approach, the number of section as well as the number of elements is significantly reduced. Furthermore, the elements chord rotations can be directly obtained from the software without any additional calculations. Obviously, because in this approach the beams may not possess enough reinforcement to resist the positive moments at the mid-span, the use of concentrated mass at the beam-column joints is recommended.

In summary, the following model parameters were selected so that their influence upon the seismic response of existing RC structures is evaluated:

- Comparison between nonlinear static and dynamic analysis
- Mass modelling (lumped or distributed)
- Element meshing (“simplified beam element”)

There are many other structural issues, such as soil-structure interaction, beam-column joint behaviour, bar slippage, etc, that need also some clarification. However, due to their complexity and relative importance in practical terms, they were not included in the present parametric study.

4 PARAMETRIC STUDY

4.1 Overview

The structure under analysis in this study is the SPEAR building. The main goal of SPEAR project was contributing to the improvement of current design, assessment and retrofitting techniques and the development of new simplified approaches for the seismic assessment and rehabilitation of existing building structures [6]. To enhance the issues brought by plan-irregularity in older structures, the specimen was especially designed so as to represent a typical non-earthquake resistant construction: it is a “strong beam-weak column system”, adding to the drawbacks originating from the plan eccentricity, the problems of poor local detailing, under-designed elements or joints and older construction practice.

The analysis of the structure was carried out with SeismoStruct - Finite Element package capable of predicting the large displacement behaviour of space frames under static or dynamic loading, taking into account both geometric nonlinearities and material inelasticity [7].

Lanese *et al* [8] demonstrated a good agreement between the results observed in the experimental test and the analytical ones (obtained by modelling the building in SeismoStruct). Considering the model proposed by these authors as a starting point, the building was modified in

order to assess the importance of parameters mentioned before. An overview of the performed parametric study is presented in the Figure 1.

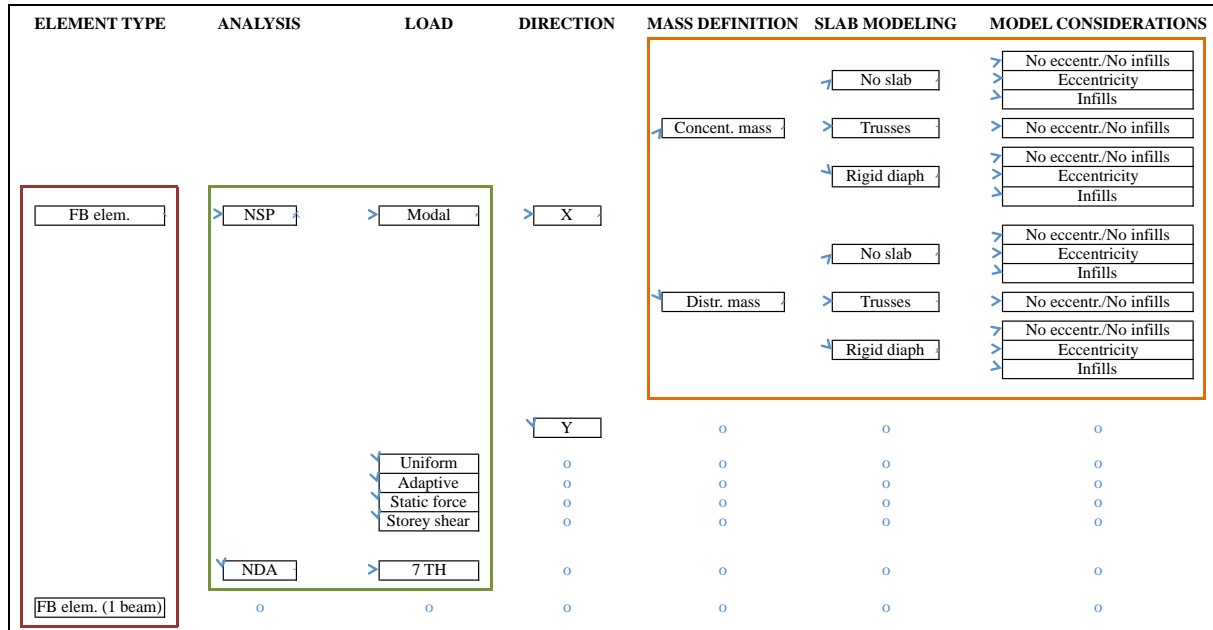

Figure 1: Parametric study flowchart.

It must be pointed out that the influence of each individual parameter was evaluated independently from the others. In order to obtain such detailed results, a total of 344 nonlinear static analyses and 224 nonlinear time-history analyses (NLTHAs) were carried out. For the sake of simplicity, only a selection of the representative results will be presented in this paper.

4.2 Building Description

The analysed structure is a three-storeys building, regular in elevation, with a storey height of 3 m. The plan configuration is non-symmetric in X and Y directions (Figure 2), with two-bay frames spanning from 3 to 6 metres.

Almost all columns have a square 250 by 250 mm cross-section; the only one that differs, column C6 in Figure 2, has a cross-section of 250 by 750 mm, which makes it much stiffer and stronger than the others along the Y direction.

The centre of stiffness (CR) (based on column secant-to-yield stiffness) is eccentric with respect to the mass centre (CM) by 1.3 m in the X direction (~13% of plan dimension) and by 1.0 m in the Y direction (~9.5% of plan dimension) [6].

Figure 2: Building properties

4.3 Analyses Definition

As mentioned above, the structure was subjected to both nonlinear static and dynamic analyses. Regarding the former, the recent Italian code, NTC08 [4], suggests to select two of the five lateral load distributions presented hereafter:

- Distribution proportional to the static forces (triangular)
- Distribution proportional to the first mode of vibration (modal)
- Distribution proportional to the storey shear obtained from a linear dynamic analysis
- Uniform distribution
- Adaptive distribution

Note the fact that adaptive pushover, which represents an improvement with respect to conventional pushover, is introduced in this code.

In order to acquire a realistic representation of the structural behaviour during a seismic event and evaluate the performance of simplified approaches such as nonlinear static analysis, 7 real accelerograms (not scaled nor matched) were selected to perform the nonlinear dynamic analysis. The selection was such that the average response spectrums of 14 records (7 accelerograms in 2 directions) would follow, in an approximate manner, the response spectrum defined for the study (Figure 3).

Figure 3: Individual and average acceleration spectrums selected for dynamic analysis.

The structure was then subjected, simultaneously, to pairs of bidirectional accelerations at the base in each direction (X and Y).

It must be pointed out that high deviation of individual response spectra with respect to the averaged one is difficult to avoid. Thus, high variation over the dynamic response is observed for the different accelerograms. Recall, however, that the main idea is to assess the reliability of different approaches, rather than a capacity/demand seismic compliance of the code requirements. The records main properties are presented in the following table:

Waveform ID	Earthquake Name	Date	Mw	Fault Mechanism	R (km)	PGA_X (g)	PGA_Y (g)	Site class
198	Montenegro	15/04/1979	6.9	thrust	21	0.18	0.22	A
228	Montenegro (aftershock)	24/05/1979	6.2	thrust	33	0.20	0.27	B
291	Campano Lucano	23/11/1980	6.9	normal	16	0.16	0.18	B
439	Spitak	07/12/1988	6.7	thrust	36	0.18	0.18	C
592	Umbria Marche	26/09/1997	6	normal	5	0.20	0.22	C
1228	Izmit	17/08/1999	7.6	strike slip	47	0.24	0.14	A
1314	Ano Liosia	07/09/1999	6	normal	17	0.12	0.11	B

Table 1: Main properties of selected accelerograms.

Finally, in order to make the analysis shorter, each of the records was bracketed to minimise the amount of computation required. The bracketed duration was taken to be between 5% and 95% of the total Arias Intensity as recommended by Bommer and Martinez-Pereira [9], and estimated through the software SeismoSignal [10].

4.4 Global Assessment

The first study that was carried out in order to evaluate the building response, when subjected to different modelling approaches, intends to estimate its behaviour in a global level. The results obtained through nonlinear static and dynamic analyses are presented in terms of base shear and top displacement. In the following sub-chapters, a more detailed discussion on the observed behaviour for different analysis and different parameters is presented.

4.4.1. Static and dynamic analyses comparison

Based on Figure 4, it is possible to verify that nonlinear static analyses can accurately estimate the global response of the building. In fact, the values obtained from nonlinear dynamic analyses fit in almost all cases within the five different pushover curves. Despite the difficulties to identify one pushover curve that would fit better the results obtain through nonlinear dynamic analysis, it becomes clear that the capacity curves obtained from adaptive pushover are more capable to capture the real dynamic behaviour, especially in the post-peak branch. It should be also emphasised that the capacity curves were estimated for each direction independently, whilst in the nonlinear dynamic analysis the base excitations were applied in the two directions simultaneously.

Figure 4: Comparison between nonlinear static and dynamic analysis - no slab (left) and equivalent trusses (right).

On the other hand, when in presence of infill panels within the external frames, a higher deviation from the two different approaches is identified as demonstrated in Figure 5.

Figure 5: Comparison between nonlinear static and dynamic analysis – model with infill panels.

The main reason for the lower capacity observed during dynamic analyses is the fact that nonlinear static analyses are not able to account for the cyclic degradation both in terms of strength and stiffness of the infill panels. This effect can be clearly observed from the hysteretic behavior obtained through nonlinear dynamic analysis presented in Figure 6.

Figure 6: Hysteretic behaviour - model with infill panels.

4.4.2. Influence of accidental eccentricity

According to code prescriptions [2, 3] two different eccentricities should be considered in both directions. In fact, the one imposing an “artificial rotation” opposed to the natural deformation of the building reduces its torsional component. The results presented in Figure 7 indicate that the accidental eccentricity contribution to the global capacity, both in terms of base shear and top displacement, is not significant. Moreover, when the torsional effect is added in

the opposite direction of the original building eccentricity (Acc. Ecc. 2), the buildings base shear as well as the deformation capacity is, naturally, increased.

Figure 7: Capacity curves obtained with and without accidental eccentricity.

4.4.3. Slab modelling

As mentioned above, the presence of an in-plan stiff slab has a major importance especially when significant stiffness variations of the vertical elements are observed. Thus, because in Y direction one column (C6) has a flexural stiffness significantly higher than the others, the base shear increases significantly, contrary to what is observed in X direction (Figure 8). The increase in strength in the model with stiff slab can go up to 20% in comparison with the one with no slab.

Figure 8: Capacity curves with different slab modeling in X (left) and Y (right) direction.

In the same fashion, the presence of infill panels within the RC frames will significantly increase the stiffness of the frames. However, because the panels were placed only at the external frames, the response of the building will be mainly controlled by the slab properties, rather than the infills, as illustrated in Figure 9.

Figure 9: Capacity curves considering infilled structure with and without in-plan stiff slab.

The reason behind this peculiar behavior is the fact that without an in-plan stiff slab, the inner frame is free to deform independently from the edge ones, whilst in presence of a stiff slab the edge frames “attract” more loads and, consequently, change the overall response of the structure.

4.4.4. Mass modelling

Since no remarkable differences were observed between the different load distributions, in order to present the results in a clearer manner, only the results obtained for the main distributions (modal, uniform and adaptive) are going to be presented.

Looking at the results presented in Figure 10, the definition of the mass as concentrated (darker color) yields slightly lower values of base shear when compared with the model with distributed mass (lighter color). These conservative results are, however, more noticeable in adaptive and modal distributions. This fact indicates that the results obtained with different mass approaches are affected, mainly due to variations in the modal properties of the structures, rather than different lateral load distribution.

Figure 10: Capacity curves considering concentrated mass (darker color) and distributed mass (lighter color) for three different load distributions.

4.4.5. Elements meshing

Finally, the behaviour of the structure considering the simplified beam-element is evaluated. Note that, as explained in Chapter 3, this comparison is made between models with concentrated mass in order to provide consistent results. It seems clear, according to Figure 11, that implementing simplified beams has negligible influence in the global capacity of the building. This indicates, as expected, that the beams seismic response of the beams is governed by the end-section properties.

Figure 11: Capacity curves considering real beam sections (darker color) and simplified beam section (lighter color) for three different load distributions.

4.5 Local Assessment

In the previous section, the performance of the building was assessed in a global level, comparing the results obtained by both nonlinear static and dynamic analyses. In this chapter, the building performance is evaluated at the element level, and more specifically in terms of elements chord rotations. For this purpose, the performance point (PP) estimated for each of the three Limit States (LS) prescribed by EC8 (Damage Limitation (DL), Significant Damage (SD), Near Collapse (NC)) is evaluated for each capacity curve. The nonlinear static procedure (NSP) employed for this purpose was the N2 method [11], also recommended by EC8.

Because the main goal of this work is to assess the influence of different parameters and provide recommendations on how the modification in some structural and modelling aspects will affect the response of the structures, the results are presented not in terms of code compliance (capacity verification) but, instead, through a direct comparison between the chord rotations obtained from different models.

Thus, for each PP, the chord rotations for both beams and columns were evaluated and plotted as a fraction between the parameters that are being evaluated. The results close to unit indicate that no significant differences were observed between different approaches. In the following paragraphs, the results plotted from left to right, as the elements are located from the bottom to the top of the building. For simplicity, only representative plots are presented.

4.5.1. Influence of accidental eccentricity ($\theta_{\text{original}} / \theta_{\text{w/acc. ecc.}}$)

The results observed in terms of chord rotation are in line with the ones observed at the global level, indicating that no significant differences are observed when accidental eccen-

tricity is considered. Further analyses on different structures should be performed in order to evaluate the need of considering this additional eccentricity.

Figure 12: Beam and columns chord rotations with and without accidental eccentricity.

4.5.2. Slab modelling ($\theta_{\text{rig, diaph}} / \theta_{\text{no slab}}$)

The introduction of an in-plan stiffness slab will provide an additional axial compression force in the beam increasing, this way, its deformation capacity. At the same time, as the beams stiffness was “artificially” increased, the columns are thus forced to deform more in comparison with the configuration without slab. In this particular case, this effect is more evident at the first storey because the building exhibits a soft-storey mechanism at the ground floor.

Figure 13: Beam and columns chord rotations with rigid diaphragm and without slab.

4.5.3. Mass modelling ($\theta_{\text{concentrated}}$ / $\theta_{\text{distributed}}$)

The major consequence of concentrating the mass at the beam-column joints is that no gravity moments will develop along the beams. Consequently, as seismic loads impose moments of opposite signs the both beam-ends, the deformations will also be different at each edge. Therefore, lower values of chord rotations are expected at the beam-end that has different moments signs in static and seismic load. On the other hand, in the opposite end, the results might be conspicuously non-conservative, especially in longer beams, where higher gravity moments are developed. Despite it is not possible to identify a clear trend in the columns results, it seems clear that for higher seismic intensity (NC-LS) the differences becomes less significant, indicating that, as the seismic moments are getting more relevant with respect to static ones, the outcoming variation decreases.

Figure 14: Beam and columns chord rotations with concentrated and distributed mass.

4.5.4. Elements meshing ($\theta_{\text{simp. beam}} / \theta_{\text{real beam}}$)

Finally, the substitution of the real beams with simplified elements with the same section throughout the entire element was evaluated. The results reveal show that no differences are observed between the two approaches. This means that, in general, no loss of accuracy is observed in terms of elements chord rotations. The only exceptions, represented as spike in Figure 15, are corresponding to indirectly supported beams, in which the absence of bottom reinforcement induces a significant change in the members' deformation capacity. Therefore this approach is not suitable for cases where indirect beam supports need to be modelled.

Figure 15: Beam and columns chord rotations with real beam sections and simplified beam section.

5 CONCLUSIONS

Based on the results presented in this work, the following conclusions can be made:

- The results extracted during this study indicate that nonlinear static analyses are able to accurately predict the behaviour of the buildings, even considering in-plan irregular structures.
- Between the five different load distributions used in pushover analyses, no significant differences were observed. Typically, the results obtained with adaptive distribution lie between the traditional extreme ones (modal and uniform) and seem to reproduce better the structural behaviour, especially in the post-peak branch.
- The consideration of an accidental eccentricity in the assessment of existing buildings, as prescribed by EC8, appears to have residual influence in the results obtained in both global and local analyses.
- Special attention should be addressed in the modelling of the structures slab. The results clearly indicate that both global and local behaviour of the building can be controlled by this parameter, especially because it might impose an artificial strengthening of the beams.
- The presence of infill panels significantly transforms the response of the building. The presence of these elements greatly increases the initial stiffness and strength of the structure and might attract higher seismic loads. Because infill panels lose most of its capacity after the first cycles, in order to properly capture behaviour of infilled RC structures, nonlinear dynamic analysis, rather than nonlinear static analysis should be performed in order to take into account the cyclic effects on the infill panels. Additional studies should be addressed to this topic.
- Especially when long beams are modelled, the consideration of an equivalent concentrated mass at the beam-column joints might overestimate the capacity of the elements. This issue might be bypassed if the equivalent point forces/moments obtained from gravity load are computed and applied at the joints before performing the seismic analysis. However, if this procedure is followed, the advantage (time consuming) of employing this simplification is lost.
- Finally, it was demonstrated that, in general, beams could be modelled as one equivalent element with the same section over its length. Nevertheless, this approximation is valid only if concentrated mass is implemented. Thus, because the latter approach may provide unrealistic results, the use of an equivalent beam element is not recommended.

Keywords: Vulnerability, Seismic Risk, School Buildings, Multiphase Analysis.

Abstract. *Most of the Italian school buildings were not designed according to seismic criteria and, therefore, they are vulnerable from a seismic point of view. A clear proof of this was the catastrophic collapse of the school at San Giuliano during the October 2002 earthquake: thirty people death, twenty seven of whom were young students and one their teacher. After this seismic event, the process for identifying the most seismic vulnerable school buildings was started in Italy, with the final aim of improving their strength. Furthermore, several school buildings, mainly located in the historical centre of the town, were damaged during the recent seismic event of L'Aquila (April 6, 2009), as reported by Salvatore et al. [1]. The proposed research work was driven by the idea of defining a methodology that implements different analysis phases with an increasing level of detail such that the number of buildings analysed decreases at each phase since only the buildings most at seismic risk are considered. The implemented procedure follows some well known works published in literature [2, 3]. The definition of a prioritisation scheme of intervention is strictly due to the high number of school buildings (almost 50000) that cannot be deeply analysed considering the limited available resources. The developed tool and procedure can be very helpful since they provide information extremely important for civil protection actions.*

1 INTRODUCTION

Italian seismic provisions and seismic zonation were updated several times during the last century. Therefore, a large portion of buildings has not been designed for an adequate level of seismic resistance required under modern design provisions. The majority of the Italian school buildings are especially vulnerable to seismic ground motion since they are judged to be seismically inadequate. An ad hoc seismic risk evaluation of the school buildings becomes therefore of fundamental importance for planning an accurate rehabilitation of these buildings and for saving their occupants.

The seismic vulnerability evaluation of the school buildings is a topic that has been discussed by several authors in the last decades [2, 3, 4, 5]. However, due to the limited amount of the available data, those methodologies were applied to a Regional level only.

To the authors' knowledge, the study presented herein is the first where the maps of conditional probability of damage and seismic risk are obtained at a national level, since it has been carried out considering most of the Italian school buildings. The available data refer to the survey of all school buildings ("Anagrafe Edilizia Scolastica") carried out by the Ministry of Education ("MIUR") to identify various safety-related parameters. The collected survey forms comprise about 70% of the Italian school buildings, and contain data that allow the geographical location of the building, as well as its structural characteristics (i.e., age, number of storeys, construction type, and preservation status), its security conditions and the features of rooms and sporting facilities.

2 ADOPTED PROCEDURE

This research work describes the method proposed for identifying the most seismic vulnerable Italian school buildings and for assigning priorities for the execution of detailed inspections and structural retrofitting measures. The adopted method is based on an initial proposal by Grant et al. [2]. It comprises multiple levels of assessment of increasing level of detail, each one substantially reducing the size of the building inventory since only the buildings most at seismic risk are considered. The procedure consists of two phases which correspond to the two levels of the available building information. In both phases the seismic risk is defined considering the probability of reaching or exceeding given limit states comparing the demand with the capacity in terms of displacements. The vulnerability of the school buildings is defined computing their capacity curves (known, in the technical literature, as pushover curves). The mechanics-based methodology SP-BELA (Simplified Pushover-Based Earthquake Loss Assessment), developed for large-scale vulnerability assessment, is used for performing the simplified pushover curves [6, 7] of the analysed buildings.

In the first phase of the assessment, the capacity is computed as a function of the number of storeys, structural vertical typology, and building age written in the questionnaires of the "Anagrafe Edilizia Scolastica". Based on these data, the buildings are subdivided in classes and random populations of buildings can be generated for each building class using Monte Carlo Simulation. For each randomly generated building, a simplified pushover analysis is carried out using SP-BELA (Figure 1), leading to the definition of the displacement capacity, vibration period and viscous damping of an equivalent single degree of freedom system [6, 7].

The second phase of the procedure is based on the data collected, at Regional level, through the 2nd Level Forms [8, 9, 10] of GNDT ("Gruppo Nazionale per la Difesa dai Terremoti"). In this second phase, only masonry buildings are taken into account since the information required, in the GNDT 2nd Level Form, for reinforced concrete (RC) buildings are not enough for defining their structural capacity, whereas they allow the Conventional Resistance

(“Resistenza Convenzionale”) to be calculated for masonry buildings. This Conventional Resistance is the lateral strength of the weakest storey of the building divided by the building weight. Therefore, the difference with respect to the first phase of the procedure is that the resistance factor of the capacity curve is computed directly with the data available within the form of the reference school building and not computed for each random generated building stock representative of the reference school building class.

Due to the incompleteness of the available database, the second phase of the procedure cannot be applied to the overall Italian school building stock. Therefore, the estimate of the reduction of the size of the building inventory moving from the first to the second phase of the procedure cannot be carried out. The study described herein does not apply the prioritization procedure as a whole, but represents its validation in order to identify some possible shortcomings that need improvements.

2.1 Definition of the building capacity

As discussed above, in order to compute capacity curves SP-BELA makes use of a simplified pushover methodology that can be employed in the assessment of a large number of buildings with reasonable computational effort. SP-BELA can be applied to RC [6] and masonry buildings [7], which are representative of the majority of the school buildings “as built” in Italy. The capacity curve is defined by means of the building resistance and the displacements associated to specific structural limit states (LS). Three LS conditions have been taken into account [11]:

- Light damage: the building can be used after the earthquake without the need for repair and/or strengthening.
- Significant damage: the building cannot be used after the earthquake without strengthening.
- Collapse: the building becomes unsafe for its occupants as it is no longer capable of sustaining any further lateral force or the gravity loads for which it has been designed.

The limit state conditions previously described can be related to specific prescriptions of Italian design code [12, 13]. In particular, the reference limit state conditions for RC buildings are defined in relation to the chord rotation. For masonry structures, the damage is usually related to interstorey drift capacity, and the limit conditions have been identified through results from experimental tests as described in [7].

Figure 1: Capacity curve for elastic-perfectly-plastic structural behavior [7].

Within such framework, an elastic-perfectly-plastic behaviour of the structure is assumed (Figure 1), which effectively means that, in order to define the pushover curve, only the displacement capacity Δ corresponding to the three LS and the lowest collapse multiplier λ of all the considered mechanisms need to be defined. Multiplying λ by the total weight of the build-

ing gives the lateral strength of the weakest storey of the building. Therefore, λ corresponds to the Conventional Resistance of the GNDT 2nd Level Forms for the masonry buildings.

2.2 Classes of buildings

The methodology proposed in this research study for seismic risk evaluation considers 37 classes of buildings as plotted in Figure 2.

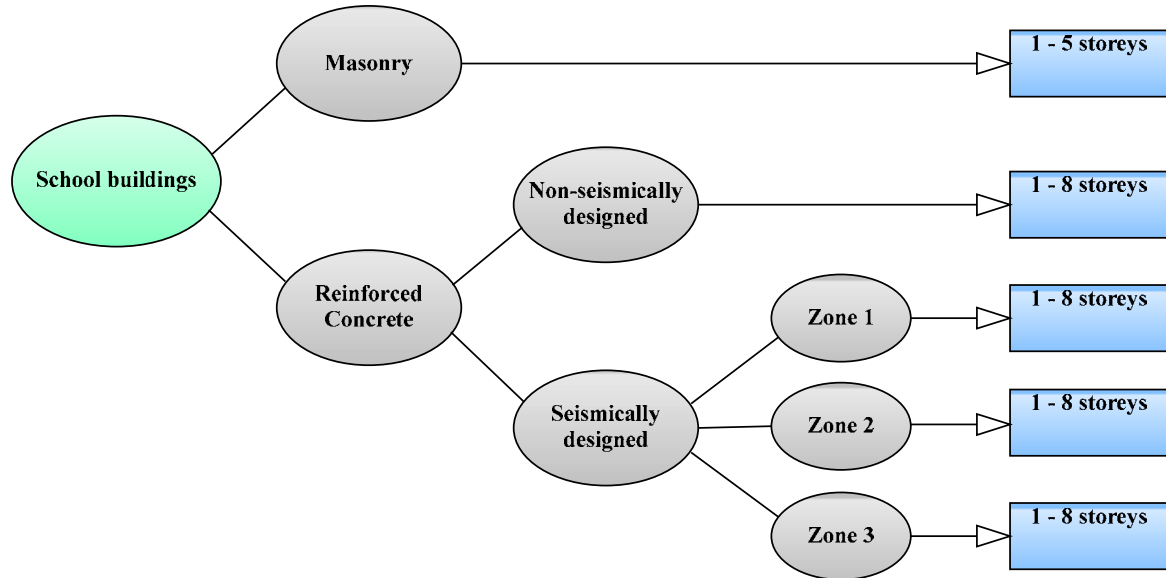

Figure 2: Classes of buildings considered in the study.

With reference to Figure 2, the masonry school buildings have been classified as a function of the number of stories (from 1 to 5), therefore five separate building classes have been defined. A different criterion has been applied for the RC buildings since they are subdivided in two main classes: RC buildings that have not been seismically designed and RC buildings seismically designed. Comparing the seismic zone to which the municipality has been assigned and the period of construction, it is possible to identify if a school building has been or not designed according to seismic design provisions. For seismically designed buildings, the seismic zone of the municipality at the period of the construction has to be taken into account since it can be used, together with the provisions of the design codes of the same period, for defining the value of the design lateral force as a percentage of the total building weight. Figure 2 refers to three seismic zones in Italy, since the fourth one [14] characterised by the smallest value of seismicity has been disregarded. In SP-BELA, the buildings are designed considering only gravity-load design before seismic classification; then following the classification and depending on the seismic zone to which the municipality was assigned, a base shear coefficient has been used to design the buildings. For buildings assigned to Zone 1, this coefficient has been taken as 10% of the weight, for buildings in Zone 2 as 7% and in Zone 3 as 4%. The number of storeys considered for RC school buildings is: 1, 2, 3, 4, 5, 6, 7, more or equal to 8 (Figure 2).

2.3 Conditional probability of damage

In SP-BELA the comparison between seismic capacity and demand is carried out in terms of displacement. The building displacement capacity has been introduced in Section 2.1. The

seismic demand imposed by the earthquake to the structure is calculated with reference to the elastic spectrum related to the school building location, computed according to the formulation proposed in [12, 13]. This formulation has been obtained after the least-square interpolation of the mean acceleration spectrum derived from the probabilistic hazard study performed by DPC-INGV project [14] for a grid of points (each one at distance of 0.05 degrees) used for the whole country. The formula and the coefficients given by the Italian code [12, 13] allow the computation of the mean spectral accelerations for each point of the grid and for seismic events characterised by a return period (T_r) of 30, 50, 72, 101, 140, 201, 475, 975 and 2475 years, respectively.

In this study, the least-square interpolation method has been applied to the mean acceleration spectrum (50th percentile) plus and minus one standard deviation for deriving the parameters that allow the computation of the 84th and 16th percentile spectral accelerations, respectively. Therefore, the seismic demand imposed by the earthquake to the structure is computed with respect to the 16th, 50th and 84th percentile acceleration spectra. Flat rock soil has been assumed for the Italian territory, since no data were available for the evaluation of the effects of the site conditions where the school buildings are located.

The seismic demand is derived from the elastic response spectrum knowing the location of the school building, for a given return period and a selected percentile (16th, 50th, and 84th). From SP-BELA method, the vibration period T of the building and the equivalent viscous damping ξ are computed for each limit state. Knowing the response period, the spectral ordinate is directly derived for each LS. Knowing the equivalent viscous damping, the spectra reduction factor η , used to take into account the energy dissipation capacity of a given structure for a given LS, is then computed, as suggested for instance in [15]:

$$\eta = \sqrt{\frac{7}{2 + \xi}} \quad (1)$$

For RC frames, the equivalent viscous damping ξ in Equation (1) has been obtained as a function of the ductility, using Equation (2) [15]. For masonry buildings, the damping values suggested in [16], for each limit state, have been adopted (5%, 10% and 15%, respectively).

$$\xi = 0.05 + 0.565 \left(\frac{\mu - 1}{\pi \mu} \right) \quad (2)$$

The displacement spectral ordinates are defined starting from the spectral accelerations:

$$S_d = S_a \left(\frac{T}{2\pi} \right)^2 \quad (3)$$

where S_d represents the displacement demand, S_a the acceleration demand and T the period of vibration of the building.

Based on the previously introduced ingredients, the conditional probability of damage, where the condition is that a given seismic event will occurs, can be computed for the nine return periods T_r considered in the Italian seismic code [12]. Random populations of buildings are generated for each building class (1000 buildings for each one of the 37 classes shown in Figure 2) using Monte Carlo Simulation. The period of vibration T and the displacement capacity Δ at the three different damage limit states (Figure 1) can be calculated for each randomly generated building through a simplified pushover analysis performed using SP-BELA (Section 2.1). Knowing T at each LS and for a given overdamped (using Equation 1) displacement response spectrum, the displacement demand of a given building in the random

population can be predicted and compared with its limit state displacement capacity. This procedure is repeated for the 1000 buildings randomly generated for each class of school buildings (Figure 2). The sum of all buildings whose displacement capacity is lower than the displacement demand divided by the total number of buildings gives an estimation of the probability of the exceeding a given limit state. The output of these computations is the conditional probability of damage, given the occurrence of a seismic event characterised by a given return period T_r .

2.4 Computation of the seismic risk

The seismic risk is computed knowing the hazard curve of the place where the school building is located. It gives the recurrence probability of a seismic event with a given level of severity in a specific exposure time t_d . Severity can be expressed in terms of the Annual Frequency of Exceedance (AFE), which is the reciprocal of the return period T_r . The hazard curve represents the relationship between AFE and a ground motion parameter, herein assumed as the spectral displacement S_d . The logarithm of the S_d and the logarithm of the corresponding AFE ($=1/T_r$) can be assumed to be linearly-related, at least for return periods of engineering interest. The gradient of the log-log hazard curve is named $-k$, according to the definition in Part 1 of the Eurocode 8 [17]. As an example, Figure 3 plots the spectral ordinates S_d for a vibration period of 0.1 seconds. Since the values are linearly related, the hazard curve is defined knowing a value of S_d corresponding to a return period T_r and the slope k of the line interpolating all the other points and passing from a reference point.

Figure 3: Relationship between the annual frequency of exceedance (AFE) and $S_d(T=0.1 \text{ sec})$.

This reference point is here conventionally assumed equal to value at 475 year return period, and the hazard curve is defined by the following relationship:

$$AFE = AFE_{475} \left(\frac{S_{d475}}{S_d} \right)^k \quad (4)$$

where AFE_{475} and S_{d475} are, respectively, the annual frequency of exceedance and the spectral displacement corresponding to the 475 year return period.

Knowing the vibration period T of the structure, nine values of spectral accelerations S_a are computed in correspondence of the nine return periods T_r listed in [12]; using Equation (3), the S_a values are converted in spectral displacements S_d ; the next step is the derivation, in a

log-log plane, of the line interpolating these points and passing for the point computed at a 475 year return period, and the slope k is finally derived. Therefore, the hazard curve is directly derived and the displacement demand can be computed whatever return period is considered. It derives that all the events that could happen in a specific exposure time t_d can be taken into account. Hence, the seismic demand is then computed and compared with the capacity for each event, obtaining the conditional probability of exceeding a given limit state.

The seismic risk is the unconditional probability of failure of the limit state condition, because the condition on the occurrence of the seismic event is removed by considering the probability that the event occurs in the selected exposure time. For its computation, the hazard curve previously expressed as a function of the frequency has to be given in terms of probability. The occurrence of the events is assumed to follow the Poisson process, that is a memoryless distribution such that each event occurs independently of one another. Therefore, the occurrence probability (q) of an event with severity AFE , in the exposure time t_d , is given by the following equation:

$$q = 1 - e^{-t_d AFE} \quad (5)$$

Since AFE is related to the spectral displacement S_d according to Equation 4, the probabilistic hazard curve can be expressed as a function of S_d :

$$q = 1 - e^{-t_d AFE_{475} (S_{d475} / S_d)^k} \quad (6)$$

Three exposure times t_d are taken into account in this study: 1 year, 10 years and 50 years. If, for example, the annual collapse risk has to be computed, the corresponding hazard curve is obtained from Equation 6 with $t_d = 1$. The derived curve gives the annual probability of occurrence of an event with severity AFE expressed as a function of S_d . The hazard curve has to be related to the conditional probability of collapse, i.e. the vulnerability, where the condition is the occurrence of an event for a given return period T_r . Knowing that T_r can be expressed as a function of AFE and AFE is related to S_d according to Equation 4, the conditional probability of damage is then obtained and the condition is expressed as a function of S_d . Therefore, since two curves are available – the hazard curve and the vulnerability curve – both expressed as a function of S_d , the exceedance curve of a given limit state in the exposure time t_d can be constructed as a discrete function.

Figure 4: Exceedance curve of the collapse limit state in an exposure time of 1 year, for a given class of buildings.

Shown in Figure 4 is the exceedance curve for a exposure time t_d of 1 year and the collapse limit state. The annual seismic risk is given by the analytical integration of this curve, using the following equation:

$$Seismic\ Risk = \sum_{i=0}^{+\infty} \left[\frac{APE_{2(i+1)} - APE_{2i}}{6} \right] \cdot \left[P_{collapse\ 2i} + 4P_{collapse\ 2(i+0.5)} + P_{collapse\ 2(i+1)} \right] \quad (7)$$

where APE is the annual probability of exceedance, and $P_{collapse}$ the probability of collapse.

If the exposure time t_d is different from 1 year, the ordinates of the derived plot are the probability of exceedance in the considered t_d .

3 AVAILABLE DATABASES

The procedure described for the evaluation of the seismic risk has been applied for processing the data of two databases: the survey forms of the “Anagrafe Edilizia Scolastica” (used in the first phase of the procedure) and the GNDT 2nd Level forms (used in the second phase of the procedure). The school buildings of the “Anagrafe Edilizia Scolastica” forms have been georeferenced based on the street address. Then, a correspondence between these buildings and the ones of the GNDT forms has been derived in order to compare the two sets of data. Since there is no a common identification to be associated to the school buildings of the two databases, the correspondence has been carried out using the geographical location. The georeferenced buildings belonging to the “Anagrafe Edilizia Scolastica” database are 49503, whereas the ones belonging to the GNDT database and with a correspondence in the first database are 3553.

3.1 School buildings analysed in the first phase of the procedure

As previously introduced with Figure 2, the school buildings of the “Anagrafe Edilizia Scolastica” database have been subdivided in 37 classes. However, there are 17328 buildings of this database without the specification of their structural typology or the number of storeys; therefore, they could not be introduced in one of the classes of Figure 2. Hence, some assumptions have been done in order to automatically assign the needed information for classifying these school buildings. Furthermore, additional hypotheses have been required for assigning one of the two main structural typology considered in this study (masonry and reinforced concrete) to those buildings with a mixed typology. The “reinforced concrete and masonry” or “masonry and other typology” structures have been analysed as masonry buildings, whereas the “reinforced concrete and other typology” structures have been classified as “reinforced concrete” buildings. With these assumptions, it was possible to include 7211 buildings of those 17328 without clear specifications. Therefore, there are 10117 school buildings of the “Anagrafe Edilizia Scolastica” database that cannot be analysed since there are not enough information for assigning a structural typology or because their assigned structural typology in the forms was “other”. Starting from the available 49503 school buildings of the “Anagrafe Edilizia Scolastica” database, the buildings analysed in the first phase of the procedure are 39386, subdivided in 19749 masonry structures and 19637 RC structures.

Figure 5 shows, on the left, the map with the location of the 49503 georeferenced school buildings of the “Anagrafe Edilizia Scolastica” database, and, on the right, a bar chart with the numbers of buildings considered (additionally subdivided according to their structural typology) or omitted in the proposed procedure.

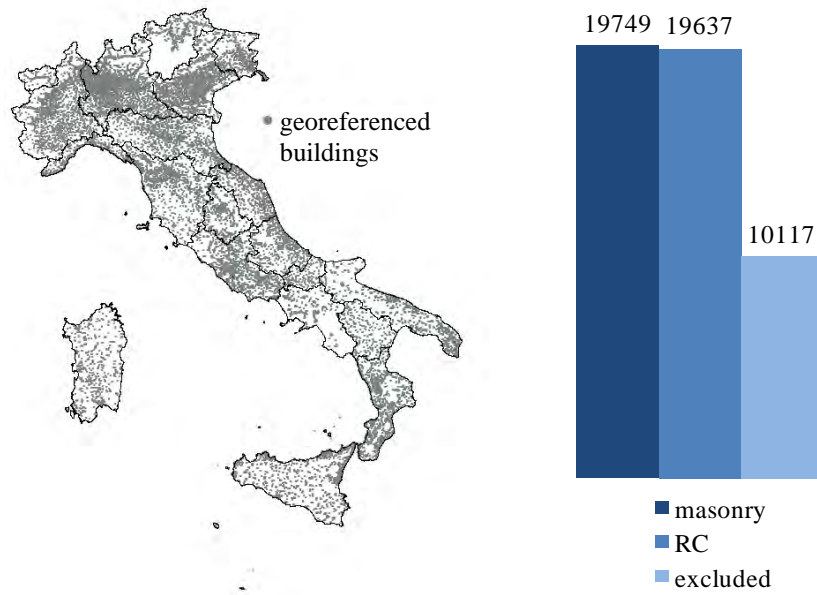

Figure 5: Georeferenced school buildings (on the left) and their classification as a function of their structural typology (on the right).

Figure 6: RC school buildings analysed in phase 1 and organised by the number of storeys.

Figure 7: Masonry school buildings analysed in phase 1 and organised by the number of storeys.

Shown in Figures 6 and 7 are the RC and masonry school buildings analysed in the first phase of the procedure and divided in classes according to the number of storeys.

3.2 School buildings analysed in the second phase of the procedure

The school buildings of the GNDT database whose data of the 2nd Level forms allow the calculation of the Conventional Resistance and with a correspondence in the “Anagrafe Edilizia Scolastica” database are 3553. However, five of these masonry buildings cannot be analysed since the data of the compiled survey forms are not coherent. Therefore, the school buildings considered in the second phase of the methodology are 3548, divided in five classes according to the number of storeys (Table 1).

N° of storeys	N° of buildings
1 storey	785
2 storeys	1215
3 storeys	1156
4 storeys	356
5 storeys	36

Table 1: Masonry school buildings analysed in the second phase of the procedure.

The map shown on the left of Figure 8 gives the location of the school buildings analysed in the second phase of the methodology. In addition, the following figure shows the distribution of such buildings for the different seismic zones (from 1 to 3). It has to be pointed out that there are no school buildings belonging to seismic zone 4 (characterised by the smallest seismic hazard) since the compilation of the GNDT 2nd Level forms has been carried out only for the buildings located in zones with medium – high seismicity.

Figure 8: School buildings analysed in the second phase of the procedure and organised by seismic zone.

The Conventional Resistance has been computed for each one of the 3548 school buildings previously described. Knowing this value and its correspondence with the collapse multiplier λ (as anticipated in Section 2.1), the plateaux of the simplified capacity curve is automatically defined for each one the analysed masonry school buildings.

4 DISCUSSION OF THE RESULTS

Using the data collected during the first phase of the procedure (Section 3.1), the maps of conditional probability of damage and seismic risk have been calculated for the three limit

state conditions (light damage, severe damage and collapse). The maps representing the conditional probability of damage have been computed for the 9 return periods recommended in [12]. The variability of the spectrum is taken into account considering the mean spectral accelerations plus and minus one standard deviation. Figure 9 shows the conditional probability of exceeding the severe limit state for a seismic event with a 475 year return period, computed with respect to the 16th, 50th and 84th percentile acceleration spectra.

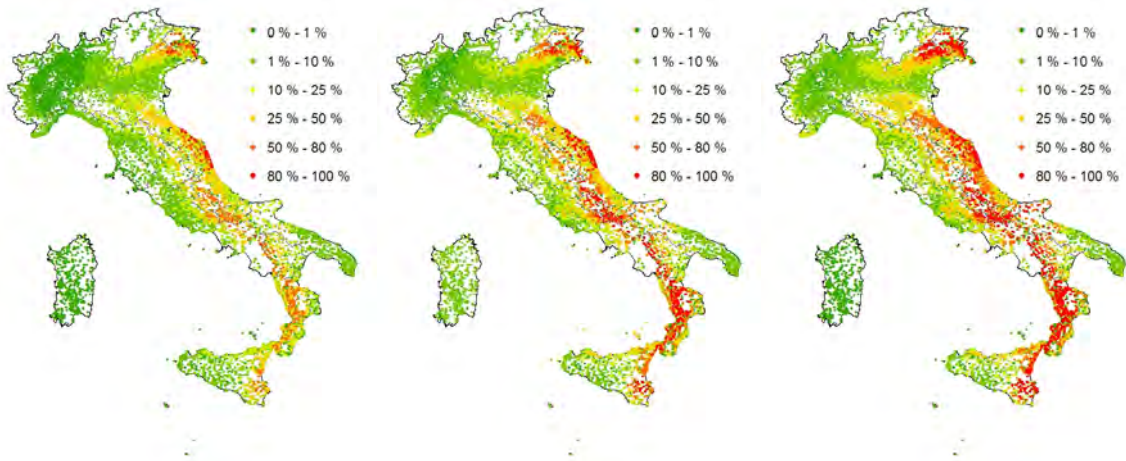

Figure 9: Conditional probability of exceeding the severe limit state computed in the first phase of the proposed procedure, for a 475 year return period (from the left: 16th, 50th and 84th percentile).

Unconditional failure probability has been then computed for the three limit state conditions and three exposure times ($t_d = 1$ years, 10 years, 50 years). The seismic risk maps obtained for the exposure time of 50 years are plotted in Figure 10.

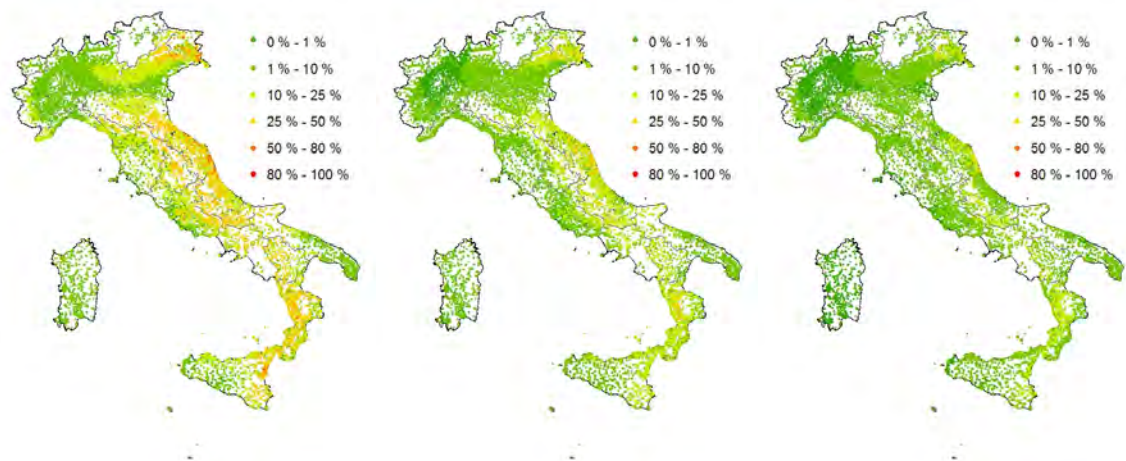

Figure 10: Seismic risk maps for the exposure time of 50 years computed in the first phase of the proposed procedure (from the left: light damage, severe damage and collapse limit state).

The results in Figures 9 and 10 show that the school buildings with the highest probability of exceeding a given limit state are located in Friuli Venezia Giulia, Marche, Umbria, Abruzzo, a reduced zone of Campania (since a small amount of “Anagrafe Edilizia Scolastica” forms have been collected in the whole of the region), the North of Puglia, Basilicata, Calabria and eastern Sicily.

As a result of the second phase of the proposed procedure, the maps of conditional probability of damage and seismic risk have been computed for the 3548 masonry school build-

ings accounted for. In particular, the plotted results have been calculated comparing the seismic displacement demand derived from the spectra with the seismic capacity obtained from the Conventional Resistance. The maps of Figure 11 show the conditional probability of exceeding the severe damage limit state for a seismic event with a 475 year return period (16th, 50th, and 84th percentile). The maps in Figure 12 show the unconditional failure probability for an exposure time of 50 years (light damage, severe damage, and collapse).

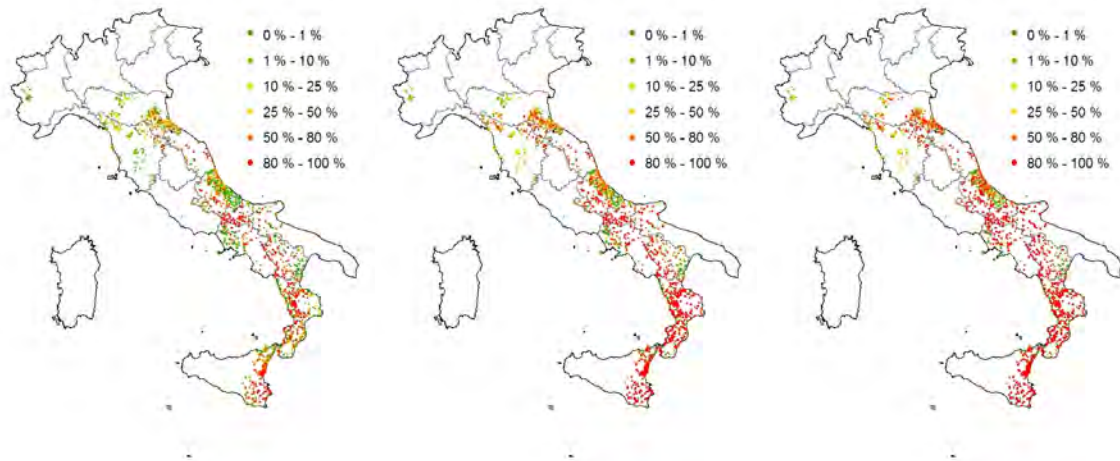

Figure 11: Conditional probability of exceeding the severe limit state computed in the second phase of the proposed procedure, for a 475 year return period (from the left: 16th, 50th and 84th percentile).

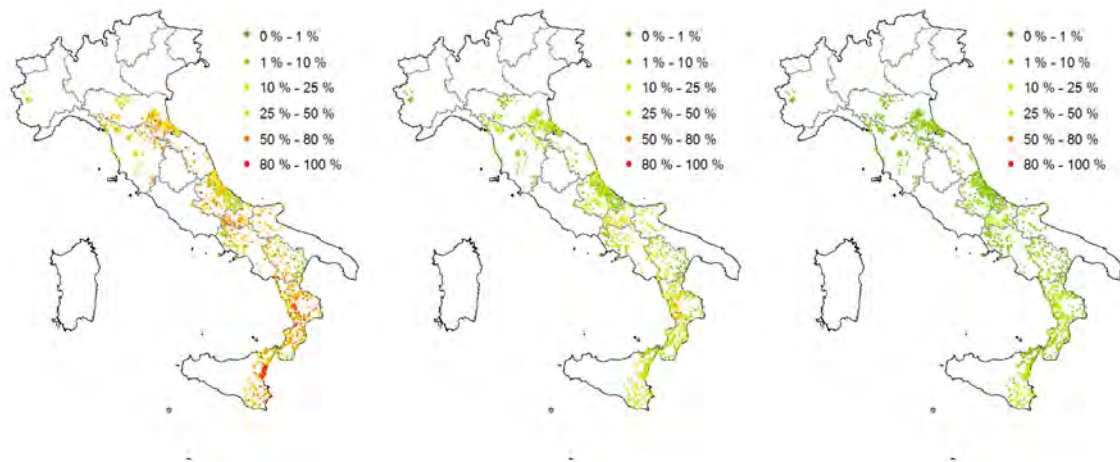

Figure 12: Seismic risk maps for the exposure time of 50 years computed in the second phase of the proposed procedure (from the left: light damage, severe damage and collapse limit state).

According to the results plotted in Figure 11 and Figure 12, the school buildings with the highest probability of exceeding a given limit state are located at the border between Emilia-Romagna and Marche, in Abruzzo, Molise, a zone of the Campania, the North part of the Puglia, Basilicata, Calabria and eastern Sicily. A further step for verifying the accuracy of the described multiphase procedure is the study of the correlation between the results of the first and second phase. The school buildings with high values of seismic risk in the second phase should be characterised by high values even in first phase; if not, it would mean that the first phase of the procedure does not allow the right identification of the highest seismic risk buildings. Therefore, the latter could not be investigated in the next phase of the analysis because they result safe.

The correlation between the results obtained in the two phases of the procedure for the 3548 masonry school buildings is plotted in Figure 13 in terms of seismic risk for an exposure time of 50 years.

Figure 13: Correlation between the results obtained from the two phases of the proposed procedure.

Figure 13 shows that the correlation between the results from the two phases of the procedure is quite satisfactory. The data points over the line of best fit represent an underestimation of the seismic risk in the first phase of the analysis. This finding could be due to the different evaluation of the seismic vulnerability of the masonry structures. In the first phase of the procedure, good mechanical characteristics have been assigned to all the masonry buildings of the analysed five classes. In the second phase of the procedure, the Conventional Resistance is computed from the data of the survey forms and this resistance could be less than the one assumed in the first phase of the procedure, leading to more vulnerable buildings.

In order to improve the correlation between the results of the two phases of the methodology and to increase the accuracy of seismic risk maps, a refined calibration procedure is under development. This latter could give the possibility to calibrate the seismic vulnerability evaluation of the first phase of the methodology taking into account different masonry typologies also belonging to the worst classes of vulnerability. The calibration could be carried out using additional information collected in the “Anagrafe Edilizia Scolastica” database, such as the typology of the horizontal structures (e.g. the floor stiffness).

5 CLOSURE

The novelty of this research study is represented by the maps of seismic risk for school buildings at a national scale. These maps give an overall view for the definition of a prioritisation procedure for surveys and detailed structural retrofitting measures.

A multiphase procedure has been proposed for the evaluation of the amount of school buildings requiring additional investigations. The methodology implements two analysis phases with an increasing level of detail such that the number of buildings analysed decreases at each step since only the buildings most at risk are considered.

The generation of seismic risk maps at a national scale is an outcome of the first phase of the proposed procedure. The data used for the map generation are based on the collected survey forms of the 70% of the Italian school buildings. However, a reduced number of school

buildings (3500) was available during the second phase of the procedure. In fact, additional information on the building resistance should be collected and used during this analysis phase. In this study, this information was available for the school buildings of some regions of Italy and for masonry structures only.

Further improvements of the proposed multiphase methodology are still required. In particular, the seismic vulnerability evaluation of the masonry structures carried out during the first phase has to be improved. The improvement should be related to the computation of the seismic vulnerability as a function of the number of storeys and additional parameters related to the quality of the masonry structures that could strongly affect the seismic response.

Finally, it should be extremely useful to complete the collection of the data related to the school building resistance in all Italian regions and for all the structural typologies in order to allow a more accurate estimate of the seismic vulnerability of these buildings and the application of the second phase of the procedure at a national scale. Therefore, it would be possible to apply the proposed procedure for the identification of the school buildings requiring priority of intervention.

ACKNOWLEDGEMENTS

The authors would like to thank the support of the Italian Department of Civil Protection (DPC – Dipartimento della Protezione Civile) through the financing of the project “Progetto Operativo d2 - Definizione delle Priorità di Intervento per Scuole Italiane”. The support of the Italian Ministry of Research and Higher Education (MIUR – Ministero dell’Università e della Ricerca) for the availability of the “Anagrafe Edilizia Scolastica” forms is also acknowledged. In closing, the authors are very grateful to Ms Miriam Colombi for the support related to the previously published works on the same topic, Ms Antonella Di Meo for finding the correspondence between the “Anagrafe Edilizia Scolastica” forms and the GNDT 2nd Level forms and Mr Marco Pagano for georeferencing the school buildings.

Keywords: Finite element, Reinforced Concrete, Shear-Flexure interaction, Bond-slip, Substandard detailing

Abstract. *The goal of this study is to investigate seismic behaviour of existing R/C buildings designed and constructed in accordance with standards that do not meet current seismic code requirements. In these structures, not only flexure, but also shear and bond-slip deformation mechanisms need to be considered separately and in combination. To serve this goal, a finite element model developed previously by the writers for individual non-ductile beam-column members is extended herein in order to cope with inelastic seismic analysis of complete planar R/C frames. The proposed finite element is able to capture gradual spread of inelastic flexural and shear deformations as well as their interaction in the end regions of R/C members. Additionally, it is capable of predicting shear failures caused by degradation of shear strength in the plastic hinges of R/C elements, as well as pullout failures caused by inadequate anchorage of the reinforcement in the joint regions. The finite element is fully implemented in the general inelastic finite element code IDARC2D. Then, the numerical model is calibrated against experimental data coming from three experimental plane frame structures with non-ductile detailing. It is shown that, in all cases, satisfactory correlation is established between the model predictions and the experimental evidence. The analytical results are in agreement with the experimental values in terms of stiffness, strength and displacement demands. The failure mechanism is predicted accurately for all experimental specimens. Finally, parametric studies illustrate the significance of each deformation mechanism in the seismic response of the experimental frames. It is concluded, that all deformation mechanisms, as well as their interaction, should be taken into consideration in order to predict reliably seismic damage of R/C structures with substandard detailing.*

1 INTRODUCTION

The vast majority of existing reinforced concrete (R/C) buildings was constructed prior to the development of modern seismic code provisions. The deficient design makes their structural elements susceptible to axial-flexural, shear or bond types of failure, which subsequently may lead to severe damage or collapse of the building.

Current research on seismic assessment of R/C structures is focused primarily on flexural response. Deformations caused by shear and bond-slip related mechanisms are either ignored or lumped into flexure. However, the necessary assumptions inherent to both of these approaches may drive the assessment procedure to erroneous results. This is especially the case for 'old type' existing R/C structures, where shear and bond types of failure cannot be precluded, due to the absence of ductile detailing and capacity design.

A significant number of analytical efforts have placed emphasis on seismic response of non-ductile R/C buildings. Among them, several studies [1-3] have demonstrated the necessity for treating individual deformation components (i.e. flexure, shear, anchorage bond-slip) in a distinct manner.

In this study, a finite element developed previously by the writers [4-7] for examining inelastic response of individual R/C beam-column members is extended herein to deal with seismic damage analysis of complete R/C frames with substandard detailing. The novel feature of the proposed finite element is the fact that it is capable of modelling gradual spread of inelastic flexural and shear deformations as well as their interaction in the end regions of R/C members. Furthermore, it has the ability of predicting shear failures caused by degradation of shear strength in the plastic hinges of R/C elements, as well as pullout failures caused by inadequate anchorage of the reinforcement in the joint regions.

The paper starts with a brief overview of the finite element model. Emphasis is placed on the abilities of the numerical model to predict brittle types of local failure (i.e. shear and bond). Moreover, the necessary alterations to the nonlinear solution algorithms are discussed in order for the proposed beam-column element to be fully implemented in a general inelastic damage analysis finite element code.

Then, with the aim to verify the capabilities of the proposed numerical model to reproduce all of the aforementioned phenomena strongly related to R/C buildings with deficient configuration, the proposed finite element is applied to the analysis of three well documented R/C frame specimens subjected to cyclic or seismic loading. Analytical results are compared with experimental recordings. It is shown that the numerical model is able to capture sufficiently experimental response in terms of strength, stiffness and displacements and to predict reliably the prevailing mode of failure for each specimen.

Finally, parametric analyses illustrate the relative importance of each deformation mechanism in the response of the examined specimens in the elastic and inelastic range. It is proven that proper modelling of all flexibility components, as well as their interaction, is a substantial prerequisite for reliable predictions of seismic response of R/C frames built with inadequate ductility capacity.

2 FINITE ELEMENT MODEL

The proposed, member-type, finite element is based on the flexibility method and belongs to the class of phenomenological models. It consists of three sub-elements representing flexural, shear, and anchorage bond-slip response (Fig. 1). The total flexibility of the finite element is calculated as the sum of the flexibilities of its sub-elements and can be inverted to produce the element stiffness matrix. Hence, it is

$$F_b = F^f + F^{sh} + F^{sl} \quad (1)$$

$$K_b = F^{-1} \quad (2)$$

Where, F_b , F^f , F^{sh} , F^{sl} are the basic total, flexural, shear and anchorage slip, respectively, tangent flexibility matrices. K_b is the basic tangent stiffness matrix of the element, connecting incremental moments ΔM_A , ΔM_B and rotations $\Delta \theta_A$, $\Delta \theta_B$ at the element flexible ends A and B respectively, with the following equation

$$\begin{bmatrix} \Delta M_A \\ \Delta M_B \end{bmatrix} = K_b \cdot \begin{bmatrix} \Delta \theta_A \\ \Delta \theta_B \end{bmatrix} \quad (3)$$

Figure 1: Proposed finite element model: a) geometry of R/C member; b) beam-column finite element with rigid arms; c) flexural sub-element; d) shear sub-element, e) anchorage bond-slip sub-element.

The local stiffness matrix K_e , relating displacements and forces at the element joints, is easily determined following standard structural analysis procedures. The components of the examined finite element, as well as their interaction, are described in the following sections.

2.1 Flexural Sub-Element

This sub-element (Fig. 1c) is used for modelling flexural behaviour of an R/C member before and after yielding of the longitudinal reinforcement. It consists of a set of rules governing the hysteretic moment-curvature ($M-\phi$) response of the member end sections and a spread inelasticity model describing flexural stiffness distribution along the entire member.

$M-\phi$ hysteretic model (Fig. 2) is composed by the skeleton curve and a set of rules determining response during loading, unloading and reloading. $M-\phi$ envelope curve is derived by section analysis and appropriate bilinearization. Loading response is assumed to follow the bilinear envelope curve. Unloading is based on the respective Sivaselvan & Reinhorn [8] hys-

teretic rule adjusted for mild stiffness degradation. Reloading aims at the point with previous maximum excursion in the opposite direction.

Figure 2: M- ϕ hysteretic model

In order to capture variation of section flexural stiffness along the concrete member, a gradual spread inelasticity model is assigned [9]. The stiffness distribution along the member is assumed to have one of the shapes shown in Fig. 3, where L is the length of the member; EI_A and EI_B are the current flexural rigidities of the sections at the ends A and B, respectively; EI_o is the stiffness at the intermediate part of the element; α_A and α_B are the yield penetration coefficients. The flexural rigidities EI_A and EI_B are determined from the M- ϕ hysteretic relationship of the corresponding end sections. The yield penetration coefficients specify the proportion of the element where the acting moment is greater than the end-section yield moment. These coefficients are first calculated for the current moment distribution and then compared with the previous maximum penetration lengths.

Stiffness distribution inside the inelastic zone depends on the loading state of the end section hysteretic response. In particular, Fig. 4 illustrates hysteretic response of four discrete sections located inside the plastic hinge region. It can be seen that when all sections remain in the strain hardening branch (loading state), flexural stiffness remains constant in the inelastic zone. However, in the unloading and reloading state, stiffness varies from a minimum value (corresponding to the end section) to a maximum value, which is equal to EI_o . Hence, under the general assumption that the loading state of all sections of the yielded region remains the same, it may be considered that when M- ϕ end section hysteretic response is on the strain hardening branch, stiffness distribution remains uniform in the inelastic zone. In the case where end-section M- ϕ behaviour is in the unloading or reloading state, it is assumed that the stiffness varies linearly from EI_A (EI_B) to EI_o .

Having established the stiffness distribution along the R/C member at each step of the analysis, the coefficients of the flexibility matrix of the flexural sub-element can be derived from the general Eq. (4) and Table 1, determined by applying the principle of virtual work.

$$f_{ij} = \frac{L}{12EI_o} (c_o + c_A \cdot \gamma_A + c_B \cdot \gamma_B); \quad \gamma_A = \frac{EI_o}{EI_A} - 1; \quad \gamma_B = \frac{EI_o}{EI_B} - 1 \quad (4)$$

Figure 3: Element a) bending moment diagram; b) stiffness distribution when ends A and B are in the loading state; c) stiffness distribution when ends A and B are in the unloading or reloading state; d) stiffness distribution when end A is in the loading and end B is in the unloading or reloading state; e) stiffness distribution when end A is in the unloading or reloading state and end B is in the loading state.

Table 1: Determination of flexural flexibility matrix coefficients

2.2 Shear Sub-Element

The shear sub-element represents hysteretic shear behaviour of the R/C member prior and subsequent to shear cracking, flexural yielding and yielding of the transverse reinforcement. This sub-element has been designed in a similar way to the flexural element described above. It consists of a hysteretic model determining V - γ (shear force vs. shear distortion) behaviour of the member ends and/or intermediate regions and a shear spread-plasticity model determining distribution of shear stiffness along the R/C member.

Shear hysteresis is determined by the V - γ skeleton curve and a set of rules describing response during unloading and reloading. The primary curve is first calculated without considering shear-flexure interaction effect. This initial envelope curve (Fig. 5) is valid for modelling shear behaviour outside the plastic hinge region for members that have yielded in flexure or the response of the entire element for members, where the longitudinal reinforcement remains in the elastic range.

Figure 5: Initial V - γ primary curve

The V - γ initial primary curve consists of four branches (Fig. 5), but only three different slopes, as explained later on. The first branch connects the origin and the shear cracking point, which is defined as the point where the nominal principal tensile stress exceeds the mean tensile strength of concrete [10]. The second and third branches of the initial primary curve have the same slope and connect the shear cracking point to the point corresponding to the onset of yielding of transverse reinforcement, or else the point of attainment of maximum shear strength (γ_{st} , V_{uo}). The second and third branches are separated at the point corresponding to flexural yielding (γ_y , V_y). This approach is adopted in order to distinguish hysteretic shear behaviour before and after flexural yielding.

Shear strength V_{uo} is calculated by the Priestley et al. [11] approach for curvature ductility demand $\mu_\phi \leq 3$ (i.e. no strength degradation). Shear strain γ_{st} is evaluated by the truss analogy approach and two modification factors for the member aspect ratio and normalized axial load, as proposed by the writers of this paper [5,7] on the basis of calibration studies with the experimental evidence.

The fourth branch is almost horizontal and describes shear response after yielding of transverse reinforcement and until onset of shear failure, corresponding to shear distortion γ_u . On the basis of experimental results coming from 25 R/C specimens failing in shear mode, the writers [5,7] have developed an empirical formula correlating γ_u with the level of the applied axial load, the amount of transverse reinforcement and the member shear-span. Conservatively, it is assumed in this study that shear failure coincides with onset of significant lateral strength degradation.

It is well documented [10-12] that shear strength degrades due to disintegration of the plastic hinge zones caused by inelastic flexural deformations. Hence, an R/C member originally

designed with shear capacity higher than the one corresponding to flexural yielding, may eventually experience a brittle shear failure. Additionally, it has been shown experimentally [13,14] that shear distortions in the plastic hinge regions may increase rapidly (shear yielding effect) after flexural yielding, despite the fact that shear force demand remains almost constant as it is controlled by flexural yielding.

The writers have developed a methodology according to which both of these phenomena can be modelled simultaneously and in a rational manner. Following this approach, effective tangent shear stiffness GA_{eff} after flexural yielding is evaluated as a function of μ_ϕ . This stiffness determines modified V - γ envelope curve inside the plastic hinge regions.

Fig. 6 illustrates variation of capacity of shear resisting mechanisms (concrete V_c and truss V_s) in the plastic hinge region of a single R/C column following the Priestley et al. [11] shear strength approach (for clarity, contribution of axial load is lumped into V_c). It can be seen that after $\mu_\phi > 3$, V_s increases to accommodate both additional shear demand ΔV and additional deterioration of the concrete resisting mechanism $\Delta deg V_c$.

Figure 6: Variation of shear resisting mechanisms with μ_ϕ in plastic hinges

Generally, after shear cracking, shear strain increment $\Delta\gamma_s$ is related to the additional shear force resisted by the truss mechanism ΔV_s by Eq. (5), where GA_1 is the cracked stiffness of the initial primary curve determined by the truss analogy approach.

$$\Delta\gamma_s = \frac{\Delta V_s}{GA_1} \quad (5)$$

After flexural yielding, ΔV_s can be considered as the sum of ΔV and $\Delta deg V_c$. Hence

$$\Delta V_s = \Delta V + \Delta deg V_c \quad (6)$$

If GA_{eff} is the tangent stiffness of the shear primary curve including shear-flexure interaction effect, it yields the same increment of shear distortions $\Delta\gamma_s$ only for the applied shear force increment ΔV (without $\Delta deg V_c$), as illustrated in Fig. 7. Consequently

$$\Delta\gamma_s = \frac{\Delta V}{GA_{eff}} \quad (7)$$

Figure 7: Definition of GA_{eff}

By joining Eqs (5-7), Eq. (8) is derived for determining stiffness of the shear envelope curve after yielding in flexure. This formula shows that GA_{eff} can only be either equal or

smaller than GA_1 . Equality holds only when the degradation of the concrete shear resisting mechanisms is negligible.

$$GA_{eff} = \frac{\Delta V}{\Delta V + \Delta \deg V_c} \cdot GA_1 \quad (8)$$

After determination of the initial and modified V - γ envelope curves, shear hysteretic response has to be established. This behaviour is characterized by significant stiffness degradation and pinching effect. In this study, the empirical model by Ozcebe and Saatcioglu (Fig. 8) is adopted for this response, properly modified by the writers [4] in order to be incorporated in the general inelastic structural analysis framework.

Figure 8: Shear hysteretic model

Figure 9: Spread inelasticity models: a) moment diagram; b) shear diagram; c) flexural model; d) shear model

Furthermore, following flexural deformations, inelastic shear strains tend to spread gradually from the ends to the member mid-span as the length of inelastic zones increases. The writers developed a shear gradual spread inelasticity model capable of monitoring variation of

shear stiffness along the concrete member throughout the response. This is achieved by a dual coupling procedure between the flexural and shear sub-element. According to this procedure, the lengths of the inelastic zones α_{As} and α_{Bs} of the shear sub-element are defined by the respective ones of the flexural sub-element (Fig. 9). In addition, the stiffness of these zones GA_A and GA_B are determined by the modified V- γ envelope curves calculated for the curvature ductility demands of the respective ends of the flexural member model. Shear stiffness GA_M of the intermediate part of the member is determined by the initial V- γ primary curve, without considering shear-flexure interaction effect.

After determining the distribution of GA along the R/C member at each step of the analysis, the coefficients of the flexibility matrix of the shear sub-element are given by Eq. (9).

$$f_{ij}^{sh} = \frac{a_{As}}{GA_A \cdot L} + \frac{1 - a_{As} - a_{Bs}}{GA_M \cdot L} + \frac{a_{Bs}}{GA_B \cdot L} \quad (i,j=1,2) \quad (9)$$

2.3 Bond-Slip Sub-Element

The bond-slip sub-element accounts for the fixed-end rotations (θ_{slip}) which arise at the interfaces of adjacent R/C members due to bond deterioration and slippage of the reinforcement in the joint regions. The proposed model consists of two concentrated rotational springs located at the member-ends. The two (uncoupled) springs are connected by an infinitely rigid bar (Fig. 1e). Following this formulation, the coefficients of the bond-slip flexibility matrix F^{sl} are given simply by Eq. (10), where f_A^{sl} and f_B^{sl} are the flexibilities of the concentrated rotational springs at the ends A and B respectively. These flexibilities depend on the envelope curve and the model used to represent hysteretic behaviour of each rotational spring.

$$F^{sl} = \begin{bmatrix} f_A^{sl} & 0 \\ 0 & f_B^{sl} \end{bmatrix} \quad (10)$$

The M- θ_{slip} skeleton curve is derived on the basis of a simplified procedure [15,16] assuming uniform bond stress along different segments of the anchored rebar (Fig. 10). These segments are the elastic region L_e , the strain strain-hardening region L_{sh} and the cone penetration zone L_{pc} . The average elastic bond strength τ_{be} of ACI 408 [17] is adopted here for the elastic region, while the frictional bond τ_{bf} of the C.E.B. Model Code [18] is assumed to apply within the strain-hardening region. In the cone penetration zone, it is assumed that the acting bond is negligible.

For various levels of the applied end moment and using the results of the M- ϕ analysis, the stress σ_s and strain ϵ_s of the reinforcing bar at the loaded end are first determined. Then, by equilibrium and applying the assumed bond distribution, variation of reinforcing bar stress $\sigma_s(x)$ along the embedment length is defined as shown in Fig. 10a, where σ_y is the yield strength of steel and σ_h is the stress at the end of the straight part of the rebar anchorage. Later, by assigning an appropriate constitutive material law [19], strain distribution $\epsilon_s(x)$ is determined, as shown in Fig. 10b, where ϵ_y and ϵ_{sh} are the steel strains at the onset of yielding and strain hardening and ϵ_h is the steel strain at the end of the straight part of the anchorage. It is important to note that nonlinearity of strain hardening material law should be taken into account because it influences significantly the final results [5].

Once $\epsilon_s(x)$ is determined, slip of the reinforcement δ_{slip} can be calculated by integration along the anchored length of the bar. In the case of hooked bars, local slip of the hook should be added. This can be evaluated by the force acting on the hook $P_h = A_b \cdot \sigma_h$, where A_b is the area of the anchored bar, and an appropriate hook force-hook slip relationship [20].

Upon determination of δ_{slip} , the respective fixed-end rotation can be calculated by Eq. (11), where $(d-x_c)$ is the distance between the bar and the neutral axis.

$$\theta_{slip} = \frac{\delta_{slip}}{d - x_c} \quad (11)$$

The envelope $M-\theta_{slip}$ curve constructed by the various points of the afore-described methodology is then idealized by a bilinear relationship for the purposes of analysis.

Figure 10: Reinforcing bar with 90° hook embedded in concrete; a) stress distribution; b) strain distribution; c) bond distribution.

In R/C structures with substandard detailing, anchorage-bond failures cannot be precluded. In case of straight anchorages, bond failure takes place when the anchorage length demand L_{dem} reaches the available straight embedment length $L_{straight}$. This occurs for $\sigma_s > \sigma_y$, when Eq. (12) holds, where d_b represents bar diameter. If σ_s exceeds the one corresponding to flexural failure, then bond is not the critical mode of failure for the examined anchorage.

$$\sigma_s = \sigma_y + \frac{4 \cdot \tau_{bf}}{d_b} \cdot \left(L_{straight} - L_{pc} - \frac{\sigma_y \cdot d_b}{4 \cdot \tau_{be}} \right) \quad (12)$$

For very short embedment lengths, where bond failure takes place for $\sigma_s < \sigma_y$, experimental evidence [17] shows that the assumption of uniform bond strength τ_{be} underestimates significantly the available anchorage capacity. To avoid over-conservative solutions, it is assumed in this study that actual available bond force T_d is derived from linear interpolation between the capacity bond forces corresponding to two well documented available anchorage bond lengths (Fig. 11). The first bond strength T_{d1} refers to $L_{straight} = 5d_b$, where the ultimate bond stress τ_{bu} of the local bond-slip constitutive law (C.E.B. Model Code [18]) is assumed to develop uniformly. Thus

$$T_{d1} = 5 \cdot d_b \cdot u \cdot \tau_{bu} \quad (13)$$

Where, u is the bar perimeter. The second bond strength $T_{d2}=A_b \cdot \sigma_y$ refers to $L_{straight}=l_d$, where l_d is the development length (Eq. 14) corresponding to yielding of the reinforcement. Along this length, uniform bond strength τ_{be} is considered.

$$l_d = \frac{\sigma_y \cdot d_b}{4 \cdot \tau_{be}} \quad (14)$$

Figure 11: Determination of available straight anchorage bond strength for very short embedment lengths

In the case of deficient end hooks, anchorage failure may be assumed to develop, when the force acting on the hook reaches ultimate hook capacity P_{hu} . Depending on the range of σ_s and the available straight anchorage length $L_{straight}$, Eq. (15) holds for determining σ_s , where $L_{sh}=(\sigma_s-\sigma_y) \cdot d_b/(4 \cdot \tau_{bf})$ for $\sigma_s > \sigma_y$.

$$\sigma_s = \frac{P_{hu} + \pi \cdot d_b \cdot \tau_{be} \cdot L_{straight}}{A_{sb}} \quad \text{for } \sigma_s \leq \sigma_y$$

$$\sigma_s = \sigma_y + \frac{4 \cdot \tau_{bf}}{d_b} \cdot \left(L_{straight} - L_{pc} - \frac{(A_{sb} \cdot \sigma_y - P_{hu})}{\pi \cdot d_b \cdot \tau_{be}} \right) \quad \text{for } \sigma_s > \sigma_y \text{ and } L_{straight} - L_{pc} - L_{sh} > 0 \quad (15)$$

$$\sigma_s = \frac{P_{hu} + \pi \cdot d_b \cdot \tau_{bf} \cdot (L_{straight} - L_{pc})}{A_{sb}} \quad \text{for } \sigma_s > \sigma_y \text{ and } L_{straight} - L_{pc} - L_{sh} < 0$$

After determining $M-\theta_{slip}$ bilinear skeleton curve, bond-slip hysteretic behaviour (Fig. 12) is modelled following the suggestions of Saatcioglu and Alsiwat [21].

Figure 12: $M-\theta_{slip}$ hysteretic model.

3 NUMERICAL IMPLEMENTATION

The finite element model, described above, requires additional modifications to the nonlinear analysis solution algorithms in order to be implemented with consistency. It is known that during nonlinear analysis the following equation is solved in incremental form.

$$K \cdot \Delta U = \Delta F \quad (16)$$

Where K is the overall tangent stiffness matrix of the structure, ΔU is the vector of unknown nodal displacement increments and ΔF is the vector of the applied external load in-

crements. The element stiffness matrices K_e are first calculated at the element level and later assembled into K .

In the case of dynamic analysis, the equivalent dynamic stiffness and external load matrices must be formed [22]. The solution of the incremental system is carried out using the unconditionally stable constant-average acceleration Newmark-Beta algorithm [23]. Viscous damping matrix is calculated by assigning the Rayleigh damping model with circular frequencies corresponding to the first and second mode of vibration.

The solution is performed assuming that the properties of the structure do not change during the analysis step. Since the stiffness of some elements is likely to change during the step t , the new configuration at $t+\Delta t$ may not satisfy equilibrium. If ΔF_{ln} is the force increment vector arising from the assumption of constant stiffness during Δt and ΔF_{nl} is the force increment vector determined by the element nonlinear hysteretic laws, then an unbalanced force vector ΔF_{ub} arises, given by the following equation

$$\Delta F_{ub} = \Delta F_{ln} - \Delta F_{nl} \quad (17)$$

Typically, in the nonlinear analysis scheme, this issue is resolved by applying the one step unbalanced force correction method [22,24]. According to this technique, the unbalanced force vector is subtracted from the right part of Eq. (16) at the next time step of analysis. Despite the fact that this procedure minimizes computational effort in nonlinear analysis, it cannot be applied with consistency for finite elements composed by different sub-elements connected in series.

Fig. (13) presents determination of unbalanced forces produced by two different hysteretic laws ($F-v_1$ and $F-v_2$), which are connected in series. The two hysteretic relationships have different elastic (k_{T1} and k_{T2}) and post-elastic stiffness ($r_1 \cdot k_{T1}$ and $r_2 \cdot k_{T2}$). It can be easily extracted that for the same force increment ΔF_{ln} the restoring force increments ΔF_{nl1} and ΔF_{nl2} and consequently unbalanced forces ΔF_{ub1} and ΔF_{ub2} become different, resulting in loss of member equilibrium.

Figure 13: Unbalanced forces for two hysteretic relationships connected in series

To overcome this problem, the ‘event to event’ solution strategy [25] is adopted herein. This method is enhanced to cope with the finite element model proposed in this study. In accordance with this procedure, the nonlinear response of the structure is subdivided into subsequent events, which mark the change of stiffness of the entire structure. Between these events, linear behaviour is considered. To achieve this goal, each step is divided (when required) into sufficient number of sub-steps, until no event takes place during the last sub-step. For the finite element developed herein, as an event is prescribed every change in stiffness of all hysteretic responses of all three sub-elements of each beam-column model.

If the incremental load vector ΔF yields the deformation increment Δv_{mn} for the hysteretic response n of the element m , assuming constant stiffness, then the next event e force scale factor λ_{mn} corresponding to this hysteretic response is determined by

$$\lambda_{mn} = \min \left(1, \frac{v_{mne} - v_{mn}}{\Delta v_{mn}} \right) \quad (18)$$

In Eq. (18), v_{mne} is the deformation marking this event and v_{mn} is the same deformation at the beginning of the loading step. It is obvious, that the immediate next event for the entire structure will correspond to the minimum value λ_{min} of all λ_{mn} . After calculating λ_{min} , the solution algorithm implemented to each nonlinear analysis step is presented in Fig. 14.

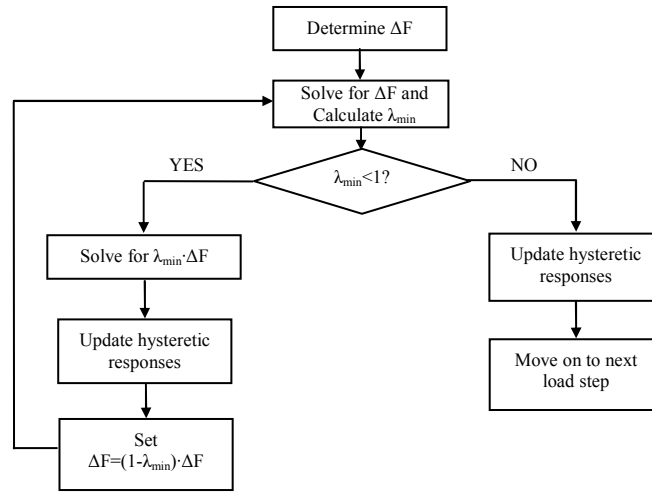

Figure 14: Event to event solution algorithm

Figure 15: Shear-flexure interaction implementation algorithm

Additionally, following the procedure adopted in this study for determining tangent shear stiffness GA_{eff} after flexural yielding when accounting for shear-flexure interaction effect, it is evident from Eq. (8), that GA_{eff} becomes a function of the element shear force increment ΔV .

But if it is to be applied in the analytical procedure, ΔV will be influenced by GA_{eff} as well, since the latter will affect the flexibility matrix of the element, as given by Eqs. (1) and (9). To resolve this issue, an iterative analytical scheme, applied in the respective load step of the nonlinear analysis, is proposed herein, as detailed in the algorithm shown in Fig. 15.

Applying this procedure, it was found that numerical convergence is almost immediate. The number of iterations may increase as the influence of shear deformations on element flexibility enhances, but the additional computational cost required is justified by the significance of calculating accurately shear response in this case.

4 VALIDATION OF THE PROPOSED MODEL

The numerical model described above is implemented in the general finite element code IDARC2D developed at the State University of New York at Buffalo [22]. Then, it is validated against experimental results coming from three well documented R/C frame specimens with substandard detailing.

In addition, parametric analyses reveal the necessity of incorporating each deformation mechanism in seismic assessment of ‘old type’ R/C structures in the linear and nonlinear range of response. To this purpose, each frame specimen is examined using four different beam-column models. The F model simulates only member flexural response. The FB model incorporates flexural and anchorage bond-slip response, while the FS one applies flexural and shear flexibility. Finally, the FSB model, which is the one proposed in this study, simulates all deformation mechanisms, as well as their interaction.

4.1 Frame specimen Duong et al. (2007) [26]

A single-span, two-storey, shear critical R/C frame with a fixed base condition was constructed and tested in the facilities at University of Toronto. This test frame was 2:3 in scale and stood approximately 4.6m tall and 2.3m wide. Beams and columns had dimensions 300mmX400mm. Frame reinforcement layout is depicted in Fig. 16 as well as cross-sections detailing. The average concrete compressive strength at the time of the test was 43MPa. No. 10, No. 20 and US No. 3 were used in the specimen, with yield strengths of 455, 447 and 506MPa respectively. Further information regarding material characteristics can be found in [26].

An axial load of 420kN was applied to the top of each column and maintained in a force-controlled manner. Lateral action was applied only at the top level of the frame. Initially, the specimen was subjected to a forward lateral drift of about 1.0% (44mm) by which point significant shear damage had occurred in the beam of the first storey and failure appeared imminent. Then, the specimen was unloaded and afterwards a reverse load was applied until the frame reached the same displacement as in forward cycle. Finally, the specimen was again unloaded until approximately zero lateral force.

Fig. 17 presents the analytical finite element model used for the analysis of the frame under examination. It solely consists of six beam column elements assuring high computational efficiency. Frame joints are modelled via rigid arms at the ends of each member. Columns are assumed to be fixed into the foundation beam.

Initially and in order to investigate specimen capacity, pushover analyses are conducted for all finite element model types (F, FB, FS, FSB). Fig. 18 illustrates the lateral force-lateral top displacement curves obtained. It is clear that considering only flexural deformations leads to significant overestimation of frame stiffness, strength and displacement capacity. Incorporating fixed end rotations arising from anchorage bond-slip in model FB, reduces substantially

the predicted initial frame stiffness. However, since no shear failure can be predicted, displacement capacity is grossly overestimated. Ultimate lateral strength capacity almost reaches the respective one coming from the F model. The FS analytical model predicts adequately initial frame stiffness. Nevertheless, since fixed-end rotations are not included, the model underestimates the level of lateral displacement at which shear failure is initiated (35mm instead of 44.7mm).

Figure 16: Duong et al. (2007) frame reinforcement layout and cross-section detailing

Figure 17: Duong et al. (2007) frame finite element model

The complete FSB model follows closely experimental response. Very small underestimation of initial stiffness may be attributed to the fact that the flexural pre-cracking response is not modelled in this study. The analytical model predicts accurately the lateral displacement corresponding to onset of shear failure (45mm instead of 44.7mm). Lateral strength capacity is slightly overestimated (about 10%).

For the same model, if degradation of shear strength with flexural demand is neglected, then displacement capacity becomes 159mm. On the contrary, if shear strength is assumed from the beginning of the analysis equal to its minimum value (corresponding to $\mu_\phi \geq 15$), then displacement capacity drops to 10mm. It is recalled that the latter approach is the one adopted by modern seismic codes.

Figure 18: Pushover curves for Duong et al. (2007) frame specimen

Fig. 19 illustrates the modes of failure predicted by all analytical models at the end of pushover analysis. It is shown that while the models including inelastic shear effect (FS and FSB) predict the experimental mode of failure, which is the development of shear failure at the first-storey beam after flexural yielding, the other two models foresee erroneously a flexural failure of the same beam.

Fig. 20 compares the experimental and analytical base shear vs. top displacement response derived by the analytical models F, FB and FSB. As explained before, FS model predicted a premature shear failure and analysis had to stop prior to unloading response. It can be seen that the FSB analytical model correlates well with the experimental evidence in the whole range of response. Residual displacement after first unloading is estimated 13.5mm instead of 10.8mm. At the end of loading in the negative direction lateral frame strength is again slightly overestimated (approx. 10%). During unloading in the negative direction, initial frame stiffness is underestimated, but as an average in the whole unloading range stiffness is calculated satisfactorily. Hence, residual displacement after second unloading is found equal to 10.5mm opposed to 7.5mm. The analytical models F, FB overestimate significantly frame lateral stiffness and strength yielding higher estimates regarding total energy dissipated by the specific specimen.

Figure 19: Predicted modes of failure for Duong et al. (2007) frame specimen by pushover analysis with a) F and FB; b) FS and FSB analytical model.

The hysteretic responses of the shear critical first storey beam produced by the FSB analytical model are presented in Fig. 21. Only one end-section is shown, since anti-symmetric response was predicted for this member. It can be inferred by this figure that the specific end-section yields first in positive bending developing high curvature ductility demand. Due to shear-flexure interaction effect, shear strains inside plastic hinge increase more rapidly than

outside plastic hinge region. This increase is followed by yielding of the transverse reinforcement, which differentiates substantially shear response inside and outside the inelastic region. At peak response, maximum shear strain is 1.8% and 0.7% in the yielded and non-yielded part of the member respectively. In the negative direction, the analytical model does not predict yielding of the transverse reinforcement, as observed experimentally. This is due to the fact that μ_ϕ demand is not calculated to be higher than 3 and shear-flexure interaction effect is not triggered according to [11]. Hence, shear strains inside and outside plastic hinge region are estimated to be equal.

4.2 Frame specimen 1 by Elwood & Moehle (2008) [27]

The specific half-scale specimen was constructed and tested on the shaking table at the University of California, Berkeley. It comprised three columns interconnected at the top by a 1.5m wide beam and supported at the bottom on footings (Fig. 22). The columns supported a total mass of 31t. To represent R/C columns typical of 1960s construction in the western United States, the central column was constructed with light transverse reinforcement having 90° hooks (Fig. 22). The outside columns were detailed with closely spaced spiral reinforcement to ensure ductile response and to provide support for gravity loads after shear failure of the central column. The specimen was subjected to one horizontal component of the ground

motion recorded at Viña del Mar during the 1985 Chile earthquake (SE32 component). The normalized central column axial load was 0.10. During testing, the central column of specimen 1 experienced a loss of lateral load capacity, apparently due to shear failure [27]. In Fig. 23, the finite element model applied for this analytical study is depicted. Its simplicity secures maximum computational efficiency. In the following, shear strength coming from transverse reinforcement of the central column is reduced to the half due to its deficient anchorage.

Figure 22: Elwood & Moehle (2008) frame reinforcement layout and cross-section detailing

Initially, modal response analyses were conducted including all four finite element models. Table 1 summarizes the vibration periods T estimated. The smallest period comes from the stiffest F model, which ignores shear and bond flexibility. Anchorage slip lengthens significantly the vibration period from 0.28sec to 0.33sec. On the contrary, shear deformations have minor effect on T . This is because of the fact that at this analysis stage uncracked shear stiffness is employed in the analytical model. The models FB and FSB predict well the experimental value of T ranging between 0.30sec and 0.35sec.

Figure 23: Elwood & Moehle (2008) frame finite element model

Model	F	FB	FS	FSB
T (sec)	0.283	0.333	0.285	0.335

Table 2: Elwood & Moehle (2008) frame predicted vibration periods

Fig. 24 presents base shear (V_{base}) vs. top displacement (Δ_{top}) relationships attained by pushover analysis of this frame as well as the experimental response recorded in the positive direction of loading. It can be seen that the F analytical model overestimates considerably initial lateral stiffness and undervalues very importantly displacement corresponding to onset of lateral failure. Inclusion of anchorage slip leads to sufficient prediction of initial stiffness until a value of $V_{base} \approx 150\text{kN}$. After this level, the analytical model fails to follow closely gradual

degradation of lateral stiffness and predicts a displacement capacity value of 38mm. The FS model prediction lies between the two aforementioned analytical curves. Lateral displacement capacity is found 29mm in this case. The FSB analytical model prediction converges adequately the experimental envelope for almost the entire range of response. Lateral displacement capacity is estimated equal to 46mm, which is in relatively good agreement with the experimental observation (approx. 55mm).

Figure 24: Elwood & Moehle (2008) frame predicted pushover curves

Fig. 25 illustrates the critical modes of failure as foreseen by the four analytical models. It is shown that the models not incorporating shear effect predict erroneously the development of flexural type of failure at the base of the central column. On the contrary, the FS and FSB analytical models drive to the experimentally observed final damage state composed by a shear failure at the top of the central column following flexural yielding.

Closing with pushover analysis, it is important to mention that if degradation of shear strength with flexural demand is neglected, the FSB analytical model predicts erroneously a flexural failure at the base of the central column for lateral displacement equal to 48mm. On the other hand, if shear strength is assumed from the beginning of the analysis equal to its minimum value (corresponding to $\mu_\phi \geq 15$), then a shear failure is predicted corresponding to a displacement demand of only 17mm.

Figure 25: Predicted modes of failure for Elwood & Moehle (2008) frame specimen by pushover analysis with a) F and FB; b) FS and FSB analytical model.

Fig. 26 compares the experimental recordings and the analytical predictions produced by the proposed FSB finite element model, when the examined specimen is subjected to the ground motion component. For the analysis purposes, time step is chosen to be 0.005sec and viscous damping coefficient equal to 1% of its critical value. It can be seen that the analytical model estimates very well the displacement and base shear time histories for the major part of the response. Deviations from the experimental measurements are observed between 18.6sec and 23.1sec and between 26.0sec and 28.6sec. These time periods follow sharp excursions during which yielding of transverse reinforcement has been observed. The deviations may be

attributed to the fact that the proposed finite element cannot model, in its present form, degradation of shear strength after yielding of the transverse reinforcement, as observed experimentally.

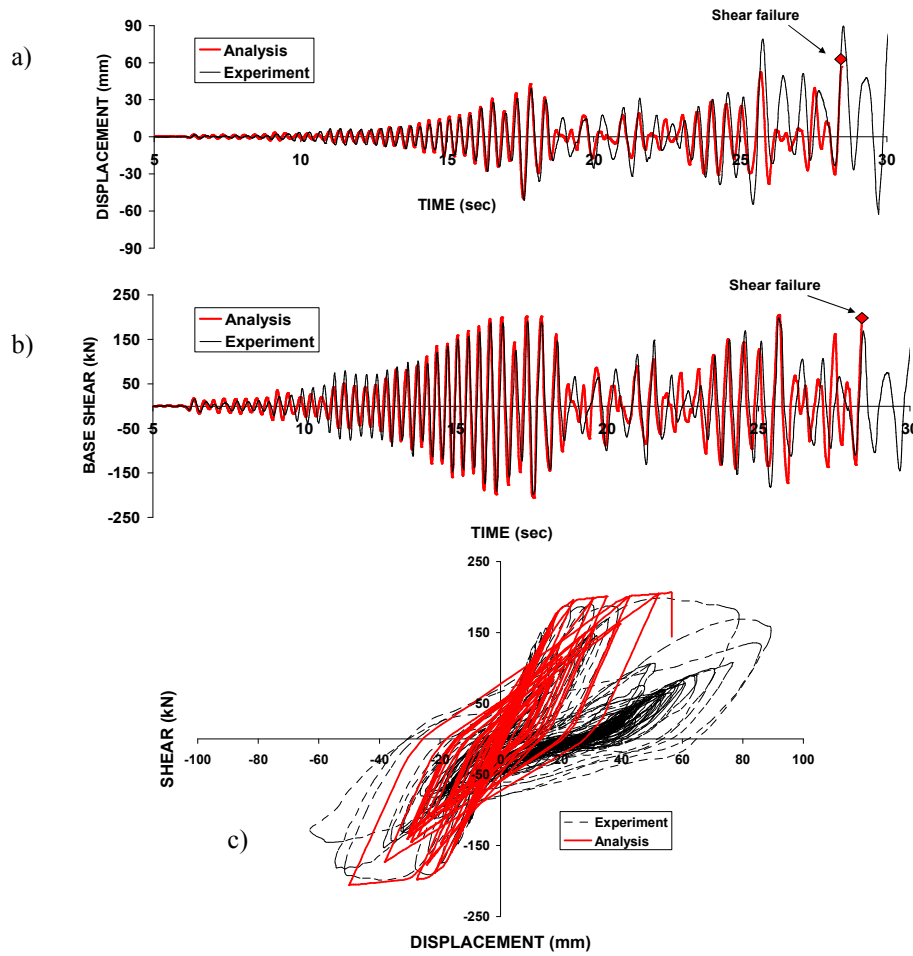

Figure 26: Elwood & Moehle (2008) frame specimen responses as recorded experimentally and predicted by FSB analytical model. a) lateral displacement time history; b) base shear time history; c) V_{base} vs. Δ_{top} response.

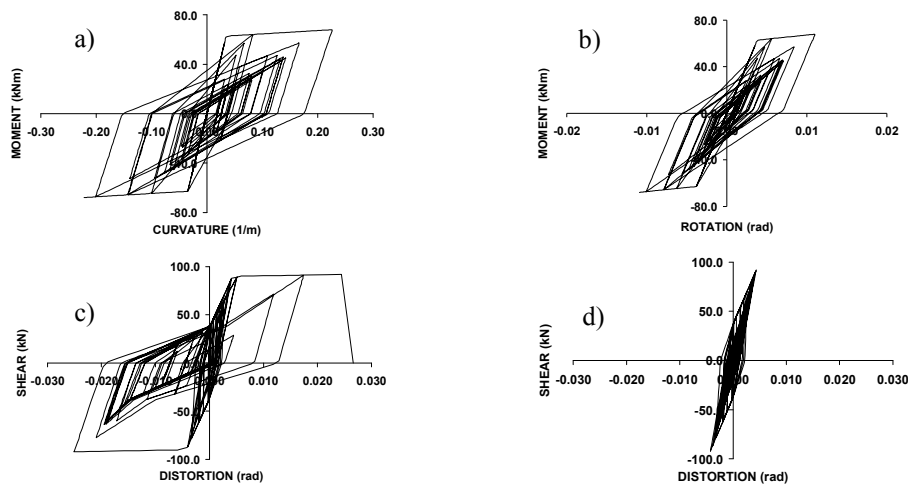

Figure 27: Elwood & Moehle (2008) central column predicted hysteretic responses. a) $M-\phi$ at the top; b) $M-\theta_{slip}$ at the top; c) $V-\gamma$ at the top plastic hinge; d) $V-\gamma$ outside plastic hinges

Fig. 26c compares the experimental and analytical $V_{\text{base}}-\Delta_{\text{top}}$ hysteretic relationships. It is evident that the proposed model captures sufficiently initial (elastic) stiffness, strength capacity as well as unloading and reloading response up to onset of lateral strength degradation. It must be emphasized that nonlinear dynamic analysis using the FSB model estimates accurately the magnitude of displacement corresponding to onset of shear failure and consequent lateral strength degradation, while pushover analysis yields approximately 17% underestimation of the specific response.

Fig. 27 presents hysteretic responses of the central shear-critical column, as derived by the analytical model. It can be seen that flexural yielding has been predicted at the top of the specific column followed by significant hysteretic response in flexure and anchorage slip. Due to inelastic flexural deformations, shear strength degrades in the plastic hinge of the member. Based on the shear-flexure interaction procedure proposed in this study, shear strains increase more rapidly inside than outside the inelastic zone. This phenomenon is accompanied by yielding of transverse reinforcement in the plastic hinge region driving to further differentiation of shear strains in the two discrete regions.

Finally, it is worth reporting that the predicted damage state of the examined frame from inelastic dynamic analysis is the same with the one shown in Fig. 25b, in agreement with the experimental evidence.

4.3 Frame specimen El-Attar et al. (1997) [28]

A 1/6 scale 2-storey one-bay by one-bay lightly reinforced concrete building was tested on the Cornell University shake table. The structure was designed solely for gravity loads, without regard to any kind of lateral loads. The reinforcement details (Fig. 28) were based on typical R/C frame structures constructed in the Central and Eastern United States since the mid 1900's. Model structure concrete strength was 32.3MPa (4.7ksi) and steel reinforcement yield capacity 414MPa (60ksi).

Figure 28: El-Attar et al. (1997) frame specimen configuration (values outside and inside parentheses correspond to prototype and model structure respectively).

The model structure was tested using the time-scaled Taft 1952 S69E earthquake with peak ground acceleration set in increasingly higher values. After running Taft 0.45g, wide, deep

cracks were observed in the beams around the locations of discontinuous positive beam reinforcement (at the joint panels), indicating bond failure and pending pullout of these bars [28].

Fig. 29 compares frame response histories derived by the FSB analytical model and experimental recordings for the 0.36g peak ground acceleration. It is evident that the proposed model follows closely the experimental response after the first 1.5sec. Small differentiations are justifiable considering the large scale (1/6) of the examined specimen.

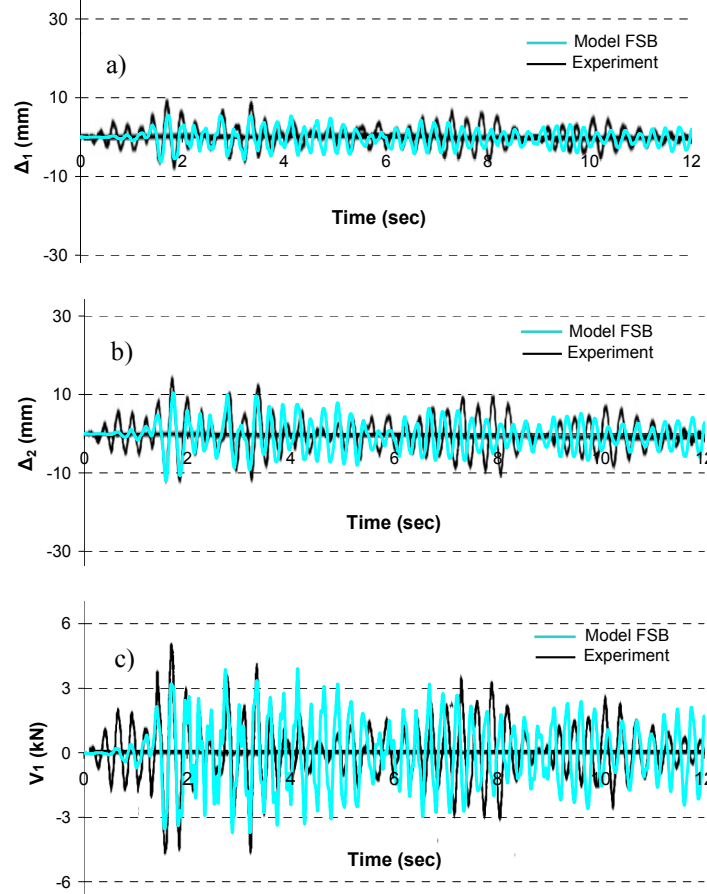

Figure 29: Comparison of El-Attar et al. (1997) frame specimen time history responses from the experimental recordings and analytical model FSB for Taft 0.36g acceleration record: a) 1st storey total displacement; b) 2nd storey total displacement; c) base shear

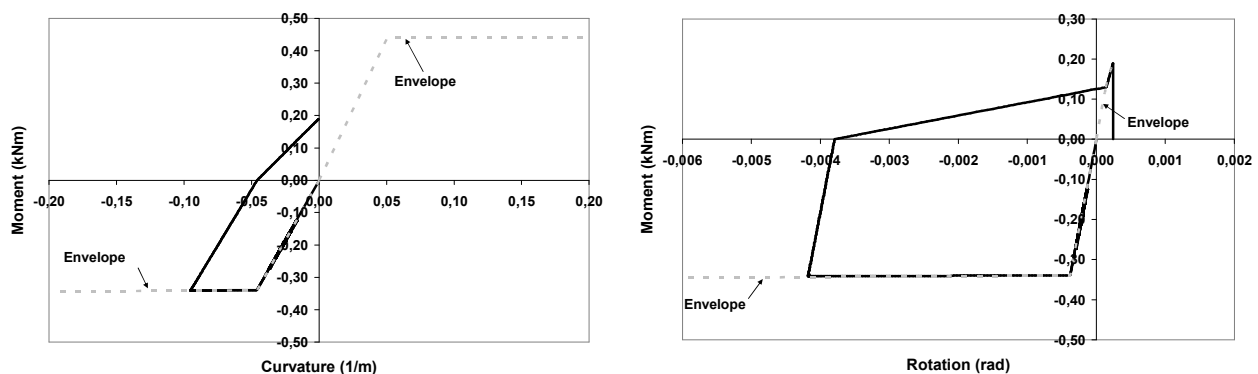

Figure 30: Hysteretic responses of left end of the 1st storey beam of the El-Attar et al. (1997) frame specimen predicted by the FSB analytical model for the 0.45g Taft acceleration record: a) $M-\phi$; b) $M-\theta_{slip}$

The FSB analytical model predicts the anchorage failure of the positive reinforcement at the left end of the first storey beam for the 0.45g Taft earthquake motion. This is clear by Fig.

30 presenting hysteretic $M-\phi$ and $M-\theta_{\text{slip}}$ responses of this end. It can be seen that while flexural response remains at the reloading stage, $M-\theta_{\text{slip}}$ concludes the reloading branch, moves on to the positive envelope curve and finally drives to failure, exceeding ultimate anchorage moment capacity.

5 CONCLUSIONS

A new beam-column model is introduced for seismic damage analysis of R/C frame structures with substandard detailing. This finite element models inelastic flexural, shear, and anchorage slip deformations, as well as their interaction in an explicit manner. Hence, it is capable of simulating with accuracy the seismic response of R/C frames with inadequate detailing, where shear flexibility and fixed end rotations caused by anchorage slip usually play a vital role in their response. Additionally, it is able to predict, in the general case, brittle types of failure that cannot be precluded in structures, which do not conform to modern seismic guidelines. The numerical model is implemented in a general finite element code and it is validated against experimental results from three well documented frame specimens with brittle detailing. It is concluded that the proposed model provides accurate and reliable predictions of the frame specimen responses.

SEISMIC SHEAR DEMAND ON RC STRUCTURAL WALLS: REVIEW AND BIBLIOGRAPHY

Avigdor Rutenberg

Technion – Israel Institute of Technology
Haifa 32000 Israel
avrut@technion.ac.il

Keywords: Earthquake engineering, structural walls & wall frames, higher modes, shear demand.

Abstract: Effect of higher vibration modes on the seismic shear demand of reinforced concrete cantilever walls has been studied since the 1970's. The shear amplification becomes more important with increasing fundamental period (tall buildings) and increasing ductility demand (R or q factors). Yet, studying the relevant recommendations of structural engineering researchers and provisions of various seismic codes reveals that there is no consensus regarding the extent of shear amplification and of the inter-wall distribution of shear demand in structural systems comprising walls of different lengths.

Paper presents the available formulas for predicting shear amplification in ductile walls and dual systems (wall-frames), as well as techniques for estimating the shear distribution among interconnected unequal walls. The consideration, or absence, of these effects by leading seismic code provisions is also noted.

One effect that impacts the shear amplification is shear cracking mainly in the plastic hinge zone of the wall near the base resulting in very low effective shear stiffness. Also, deliberately allowing development of plastic hinging along the wall height (contrary to standard code requirements) has been suggested. These appear to lead to appreciably lower shear amplification than previously predicted.

Finally, an extensive bibliography (circa 100 refs.) is provided.

1 INTRODUCTION

This paper reviews the literature on the seismic shear demand on RC cantilever walls. It is mainly concerned with shear amplification due to higher vibration modes, and it also reports on the post-yield redistribution of shear demand among the walls in systems comprising several walls of different lengths. Amplification of wall shear due to higher vibration modes in the *elastic range* was not widely recognized by structural engineers until the early 1970's, although it was, or at least should have been, a known phenomenon to users of modal analysis for the seismic design of RC walls in tall buildings. However, the larger shear magnification in *yielding* flexural walls due to higher modes was first observed by New Zealand consulting engineers, which led to the 1975 pioneering paper by Blakeley et al [9]. The problem was also studied by researchers at the Portland Cement Association, and these resulted in a series of PCA reports [21, 23] and papers [22, 24] by Derecho and coworkers. The amplification tables proposed by Blakeley et al [9], the charts by Derecho et al [23], as well as later amplification expressions or charts (e.g. [29, 36, 37, 79, 81, 88, 95, 96]; and for wall-frames: [4, 38, 39, 43, 56, 81, 89]) were mainly based on results of nonlinear response history parametric studies using suites of accelerograms. Obviously, the result depended on the choice of these suites. Theoretically oriented general formulation for the shear amplification was given by Keintzel [27, 50, 51]. Extensions were proposed by Priestley [79, 80, 81], and for wall-frames by Sullivan et al [100]. Very recently Fischinger et al [32] presented a correction to Keintzel's formula, and Pennucci et al [76] modification thereof.

Shear amplification becomes more important with increasing fundamental period (tall buildings) and increasing ductility demand (R or q factors). Yet, studying the relevant recommendations of structural engineering researchers and provisions of various seismic codes reveals that there is no consensus regarding the extent of shear amplification, its height-wise variations, and the inter-wall shear demand distribution when the structural system consists of interconnected wall of different lengths.

This paper is concerned only with *shear demand* amplification on structural walls due to the effects of higher modes, but not with moment magnification along the height, which derives from the same source. Issues related to the shear capacity and post-yield shear flexure interaction are beyond the scope of the present study.

The phenomenon is described first, then available procedures to predict the amplification are presented, and relevant code provisions are briefly discussed. Shear amplification in dual or wall-frame structures is also included in the review, and post-elastic shear demand redistribution among the walls in systems with walls of unequal length is considered. The paper closes with a discussion including some unresolved issues.

The structural engineering communities in North America and in many other countries have been slow in recognizing the need to amplify shear demand, if at all. The objection of many researchers and engineers to the rather large amplification in the nonlinear range obtained from numerical simulations may perhaps explain the plethora of publications as essays in persuasion, manifested by the quite long bibliography on this rather limited problem at the end of this paper.

2 THE SHEAR AMPLIFICATION PHENOMENON

In the *linear range* the amplification of shear demand in flexural walls due to higher vibration modes has been routinely accounted for by means of response spectrum analysis. This matter is well covered in standard textbooks. Figure 1, taken from Chopra [18], shows the base shear V_b normalized by the total weight W in buildings analyzed by the modal response spectrum technique for a typical design spectrum. It can be seen that for a flexural cantilever

wall ($\rho = 0$, ρ = beam to column stiffness ratio) the base shear increases appreciably with increasing natural period due the effect of higher modes compared with the design spectrum. This fact explains the requirement in many seismic codes (e.g. [16]) to permit use of the equivalent lateral force procedure only for buildings with $T_1 < \max(4T_c, 2.0 \text{ sec})$, T_c = corner period to the velocity related spectral acceleration region. As can be seen, in frame structures ($\rho \gg 0$) the shear amplification due to higher modes is appreciably much smaller. The main reasons for this difference are: (1) the combined effective mass of the higher modes in flexural walls is circa 35% of the total mass vs. circa 25% in frames; (2) the period ratios of the 1st mode to the higher ones is much larger for flexural walls (e.g. $1^{\text{st}}/2^{\text{nd}} \approx 6$ vs. ≈ 3 for ideal frames). Hence, when T_1 of a flexural wall is in the velocity spectral region, the higher modes - the spectral accelerations of which are usually located at the high acceleration plateau - have a larger effect on the shear than in frames. This effect is even more pronounced when T_1 is longer so that $S_a(T_2)$ and even $S_a(T_3)$ are in the velocity spectral region. Indeed, the main effect of the higher modes is due to the 2nd mode (e.g. [50, 66, 68]) and, to a much lesser extent, to the 3rd. mode. Evidently, the shape of the spectrum also strongly affects the extent of amplification. The reader is referred to Chopra [18] and Humar & Mahgoub [41] for detailed consideration of the phenomenon. The way seismic codes consider this effect is described subsequently.

Fig. 1: Normalized base shear V_b/W for 3 values of ρ ; for walls $\rho = 0$ (Chopra 2001).

As already noted, the shear amplification due to higher modes in the *nonlinear range* has attracted considerable interest since the Blakeley et al 1975 paper [9]. They showed, by means of nonlinear response history analysis (NLRHA), that shear demand increases with natural period and falling damping ratio. Similar results were obtained by Derecho et al [21], Keintzel [49] and Kabeyasawa [43, 44, 45], who also demonstrated that shear demand increases with ductility demand. The following explanation for the latter effect was given by Paulay & Priestley [75]. At some instants during the response the higher modes combine with the 1st

mode in a height-wise force distribution similar to the 2nd mode. The higher mode shapes of hinged and fixed base cantilever are quite similar, as shown in Fig. 2, suggesting that the formation of a plastic hinge at the wall base does not significantly affect the higher modes. Hence, while the plastic hinge reduces the 1st mode shear response to the level commensurate with its flexural capacity, the response of higher modes remains circa their elastic level. In other words, the shear response can be approximated as a superposition of the 1st mode shear reduced by the force reduction factor R (q in Europe), while the higher modes' response remains elastic, thereby amplifying their shear demand relative to that due to the first mode. Note that due to the plastic hinge formation and unloading/reloading softening the periods of higher modes are also elongated, hence amplification is likely to be somewhat lowered. Similar conclusions were drawn from the response of a flexural wall with substantially reduced stiffness at its base – the plastic hinge [66]. This approach forms the basis for several analysis procedures developed to predict shear amplification, as described subsequently. As in the linear range, the base shear amplification increases with increasing natural period since higher modes become more important, and as a result the shear resultant moves downwards. Also, as in the linear range, the spectral shape plays an important role.

Fig. 2: Fixed base and hinged cantilever mode shapes (Wiebe & Christopoulos 2009).

It is interesting to note that base shear amplification in dual wall frame systems (WFs) is lower than in structural walls. As already observed the period ratios in frames are much lower, and their 1st mode mass participation is higher. Also, the shear demand in frames depends mainly on moment demand. Indeed, shear amplification in WF's strongly depends on the wall-to-frame shear ratio. More details on WF's are given in Section 5.

3 PROCEDURES TO PREDICT HIGHER MODES SHEAR AMPLIFICATION

The work of Blakeley et al [9] brought about changes in the provisions of the New Zealand seismic code [63] and in European model codes [13, 14]. However, the latter provisions explicitly restricted the magnifications to the equivalent lateral force (or static) procedure. This

turned out to be unfortunate since the corollary was that amplification was understood not to be required when using modal analysis (as, e.g. the Israeli seismic code [97] without Amendment 3, is interpreted). It also led engineers to overlook the fact that a major part of the shear amplification due to higher modes takes place in the post-elastic range. This attitude still persists also in the National Building Code of Canada NBCC-2005 [61], which only accounts for linear multi-mode shear amplification. However, the present Canadian Concrete code CSA-A23.3-04 [19] requires considering nonlinear shear amplification, yet gives no guidance to that effect (see also [10]), although the commentary to the 1994 version of that code suggested adopting the New Zealand shear amplification formulas. Note that in the provisions and the proposals described subsequently it was tacitly assumed that the plastic hinge could form only at the wall base, and that the prescribed moment envelope took care of that.

The amplified shear V_a is given in terms of the base shear V_d from analysis, as follows:

$$V_a = \omega_v V_d \quad (1)$$

In the New Zealand code:

$$\omega_v = \begin{cases} 0.9 + \frac{n}{10} & n \leq 6 \\ 1.3 + \frac{n}{30} \leq 1.8 & n > 6 \end{cases}$$

. And in CEB:

$$\omega_v = \begin{cases} 0.9 + \frac{n}{10} & n \leq 5 \\ 1.2 + \frac{n}{25} \leq 1.8 & n > 5 \end{cases}$$

As can be seen the NZ code is somewhat more conservative than CEB for $5 < n < 15$.

In spite of their widespread use there are several problems with these formulas. First, the only governing parameter is the number of storeys, which is a crude proxy for the natural period. Also, the upper bound amplification is arbitrarily set at 1.8 for a 15 storey building. However, perhaps a more serious limitation is their independence of the excitation level, which affects the shear demand appreciably, and of the shape of the applicable response spectrum. Note also that, by today's standards, the Blakeley et al study [9] was based on a very limited data set: only 5 accelerograms, two of which were artificial. Also, bilinear moment-curvature hysteresis was assumed, while many modern studies use the modified Takeda model, considered to be more realistic. On the other hand, the bilinear model is somewhat more conservative [62].

Shear amplification design charts were presented by Derecho et al, e.g., [22, 24]. These are based on a parametric study on structural walls, 10 to 40 storey high, using the modified Takeda model for the NLRHA carried out for 6 earthquake records. They presented shear amplification relative to the base shear as evaluated by the then governing UBC provisions vs. fundamental natural period for several values of rotational ductility demand μ_r , as shown in Fig.3. Since the set of records was normalized for a given Housner spectral intensity (SI= 1.5) a correction factor (practically proportional) was provided for different SIs. One difficulty in applying this approach is its dependence on μ_r rather than on the strength reduction factor R , requiring making assumptions regarding the relation between these two parameters.

Fig. 3: Base shear demand amplification for several values of rotational ductility
(Derecho et al 1981)

Based on parametric NLRHA several investigators proposed simple expressions to estimate the maximum base shear V_a by decomposing it into the 1st mode and the higher modes responses. Kabeyasawa (e.g. [43], see also [4]) gave the following expression for wall frames:

$$V_a = V_d + D_m W A_e \quad (2)$$

in which V_d = base shear of an inverted triangular loading, W = total weight, A_e = peak ground acceleration and D_m is a given factor increasing with the number of storeys (i.e., period). Based on shake-table tests Eberhard & Sozen [25] proposed $D_m = 0.3$ for 9 and 10 storey wall frames, in agreement with Kabeyasawa's results. The actual amplification in wall frames depends to a large extent on the base shear share carried by the wall. Hence the predictive ability of formulas such as Eqn. 2 is rather limited.

A similar formula for isolated walls was presented by Ghosh et al [36, 37] based on a parametric study similar to that of Derecho et al [23]:

$$V_a = M_y / 0.67H + D_m W A_e \quad (3)$$

in which M_y = the yield moment at base and H = wall height. The advantage of this form is the explicit statement that the base shear is that at moment capacity level rather than at the design shear obtained from analysis, which is usually lower. For isolated walls the study by Seneviratna [95, 96], described subsequently, confirmed the equation *format* of Kabeyasawa and of Ghosh except for the short period range and for low values of R .

In 1988 Keintzel [27] proposed a simple expression for shear amplification by explicitly assuming that the 1st mode shear is limited by the flexural capacity of the wall at the base, and that the higher modes respond linearly. This formula was eventually incorporated into Eurocode 8 [15, 16]:

$$\omega_v = q \cdot \sqrt{\left(\frac{\gamma_{Rd}}{q} \frac{M_{Rd}}{M_{Ed}}\right)^2 + 0.1 \cdot \left(\frac{S_e(T_c)}{S_e(T_1)}\right)^2} \leq q \quad (4)$$

ω_v = 1st mode shear amplification factor – but see next paragraph

q = R = strength reduction (behaviour) factor

M_{Ed} = design bending moment at wall base

M_{Rd} = design flexural resistance at wall base

γ_{Rd} = overstrength factor due to steel strain-hardening

T_1 = fundamental period

T_c = higher period corner of the constant acceleration plateau (Fig. 2)

$S_e(T)$ = Spectral ordinate (Fig. 2).

This is a very useful formula since it considers most of the parameters governing shear amplification in structural walls. It does not require exact evaluation of the 2nd mode natural period, and is practically spectrum-shape independent, in contradistinction to parametrically evaluated amplification formulas or plots, which are not (e.g. [79, 88, 95, 96]). It also accounts for the two sources of overstrength. However, it is too conservative for very tall buildings, i.e., those with T_2 in the velocity spectral region, and it is sensitive to the calculated value of the 1st mode spectral acceleration S_a , which for RC walls depends on design assumptions. It is believed that S_a at the natural period based on yield displacement should be the appropriate one (e.g. [68]). In view of the extensive use of this formula (EC8 is now applied in circa 20 countries) some background information may be in order. Based on parametric studies Keintzel assumed that the SRSS modal combination can also be applied in the post-elastic range, and also that the contributions of the first two modes are important, hence:

$$V_a = \sqrt{(V_{Ed,1})^2 + (qV_{Ed,2})^2} \quad (5)$$

in which $V_{Ed,i}$ are the 1st and 2nd mode shear forces from analysis. He also assumed that the contribution of the 2nd mode is $0.1 S_e(T_1)/S_e(T_2)$, in which $0.1 \approx 0.32^2 \approx$ the 2nd to 1st mode mass contribution ratio squared. Considering that design flexural overstrength (M_{Rd}/M_{Ed}) affects only the 1st mode, and dividing by $V_{Ed,1}$, Eqn.4 is obtained. This development shows, as made clear by Fischinger et al [31, 32], that the amplification ω_v should factor only the 1st mode shear $V_{Ed,1}$. However, in EC8 ω_v amplifies V_{Ed} as evaluated either by the equivalent lateral force procedure (usually inversely triangular loading based on the total building weight) or by modal analysis, and, without making the distinction, evidently leads to different results. Keintzel concluded that ω_v should be bounded by q (R), but this is too low considering that the elastic bound should be based on the SRSS shear - not the 1st mode one. Note also that the present EC8 restricts the application of Eqn. 4 to walls designed for high ductility (DC-H), while for medium ductility walls (DC-M) $\omega_v = 1.5$. This has been found to be too low [31, 32, 88], suggesting that Eqn.4 should be applied also to DC-M walls, as indeed was the case in past versions of EC8.

Keintzel [50] already observed that Eqn. 4 is a simplification of an expression he considered to be more accurate. A different correction, which is based on an extensive parametric study using the Modified Takeda model and assuming hinge formation only at wall base, was proposed by Fischinger et al [32]. This correction affects the 2nd term in Eqn.4 when M_{Rd}/M_{Ed} is large, hence is of limited practical use.

A natural extension of Keintzel's formula proposed by Priestley [79], which can also predict the shear demand along the height of the wall and not only at base, is the following:

$$V_a = \sqrt{(V_{Ed,1}^*)^2 + \mu^2 \{(V_{Ed,2}^*)^2 + (V_{Ed,3}^*)^2 + \dots\}} \quad (6)$$

in which $V_{Ed,1}^*$ is the overstrength factored 1st mode design shear and μ is the displacement ductility demand. Priestley [79] reported satisfactory agreement with NLRHA results for a wide range of wall heights.

Another modification of Keintzel's formula was recently proposed by Pennucci et al [76]. The basic assumption therein is that the total response can be obtained as the absolute sum of the 1st mode shear reduced by q (denoted R_m), and of the higher modes SRSS response, which is reduced by another factor (R_p). It has similar format as Eqns. 2 and 3, and is given by:

$$V_a = \frac{V_{Ed,1}}{R_m} + \frac{\sqrt{(V_{pin,2})^2 + (V_{pin,3})^2 + \dots}}{R_p} \quad (7)$$

in which $V_{Ed,1}$ and $V_{pin,i}$ are the modal shear forces at their *elastic level*, and the subscript *pin* denotes pin-based modal shear response. Based on parametric studies Pennucci [76] found that, as expected, the higher modes reduction factor R_p is related to R_m : large when R_m is low, and becoming smaller with increasing R_m , asymptotically reaching 1.0, i.e. linear behaviour. A considerable improvement over Eqn. 6, particularly for long periods and large strength reduction factors, and very satisfactory agreement with NLRHA results along the building height were reported. Hence, it appears that the approach can make better allowance for the period elongation due to base hinging and for the lowered stiffness of the unloading/reloading hysteresis loop (Modified Takeda). Yet, since R_p is evaluated parametrically, it is to some extent spectrum shape dependent.

A simple formula also in the format of Eqns. 2 and 3 was proposed by Panagiotou & Restrepo [66]. It is based on the observation that the amplification can practically be accounted for by adding a factored 2nd mode shear envelope to that of the 1st mode shear at base yield. The shear demand at storey i can then be approximated as:

$$V_a = V_{Ed,1}^* + q\rho_{12} \left(\sum_{j=1}^n \Gamma_2 \Phi_2^j \right) mSa_2 \quad (8)$$

in which ρ_{12} is a factor to be determined, and $\Gamma_2 \Phi_2^i = \min[4.28h_i/H, 0.6; -2.5h_i/H + 1.85]$, Γ_2 = 2nd mode participation factor, Φ_2^i = mode shape ordinate at floor i , h_i = floor height from base, H = total wall height, Sa_2 = 2nd mode spectral acceleration. Good agreement with NLRHA results for near-fault records was reported. Note, however, that the application of the formula to other cases depends on ρ_{12} , which was provided only for a small number of pulse-type near-fault ground motions.

The amplification formulas or charts given subsequently are parametrically based; hence they are only applicable to spectra having shapes that are similar to the mean spectra of the suite of records forming the data base for the NLRHA. Also, they are sensitive to the chosen damping ratios.

Base shear demand amplification charts based on 15 records for wall structures having elastic-plastic moment-rotation hysteresis designed using SRSS load pattern were provided by Seneviratna [96]. Figure 4 presents the mean amplification, defined as the ratio of the maximum base shear of the multi-degree of freedom V_b (MDOF) to the single degree of freedom (SDOF) base shear $F_y(\mu)$, vs. T_1 . These are displayed for several values of μ (SDOF) - the ductility ratio of the SDOF system. It can be seen the amplification increases with T_1 and with μ (SDOF). As already observed, the amplification w.r.t the SRSS loading would be smaller since higher modes also amplify the shear in the linear range.

Fig.4: Base shear demand amplification for several values of displacement ductility (Seneviratna 1995)

The amplification formula provided by Priestley, [79] was based on NLRHA results for walls assuming Modified Takeda hysteresis. It has a very simple form, and is given in terms of the displacement ductility demand μ , and T_1 :

$$\omega_v = 1 + \mu B_{(T)}/\Phi; \quad B_{(T)} = 0.067 + 0.4(T_1 - 0.5) \leq 1.15. \quad (9)$$

in which Φ is the flexural overstrength. Evidently, in routine analysis, μ needs to be evaluated, unless the equal displacement approximation or another conversion formula is invoked.

Fig. 5: Eqn. 10 - Base shear demand amplification for several values of strength reduction factor $q (=R)$ (Rutenberg & Nsieri 2006)

A somewhat longer expression given in terms of q (or R), not incorporating flexural overstrength, was presented by Rutenberg & Nsieri [88]. It is given by:

$$V_a = [0.75 + 0.22(T_1 + q + T_1 q)] V_d \quad (10)$$

in which V_d is the base shear due to a triangularly distributed base shear. Eqn. 10 is shown in Fig. 5 by the straight lines. Elastic-plastic response and 5% tangent stiffness damping in the 1st and 5th modes were assumed. Note that 5% damping is now believed to be too high for very tall buildings (e.g. [92]), for which the major sources of damping have a lower effect.

4 STOREY SHEAR DEMAND

Whereas, as noted, Eqns. 6, 7 and 8 are able to predict the shear demand for the full wall height, this is not the case with the other design equations listed above, that apply only to the base shear. This is because in many cases the ω_v normalized SRSS storey shears overestimate the expected shear values for large wall portions of long period structures, as shown in Fig. 6.

Fig.6: 40-storey wall shear envelopes: code loading design pattern, $T = 2.05s$: mean for $S_{1,a}$ records, bilinear, $\alpha = 0\%$, damping 5% (Seneviratna & Krawinkler 1997)

Apparently, this problem was first addressed by Iqbal & Derecho [42] who provided a wall height shear demand envelope that has not changed appreciably since. A design envelope as function of the fundamental period T_1 is shown in Fig. 7, in which ξ is given by:

$$\xi = 1 - 0.3T_1 \geq 0.5 \quad (11)$$

Note that Eqn.11 resembles Fig. 5.4 in EC8 [16], but therein it is confined to walls in dual WF systems. A similar but straight-line envelope with the wall-top shear of:

$$(0.9 - 0.3T_1) V_a \geq 0.3 V_a, \quad (12)$$

was given by Priestley et al [81] and Model Code [56].

Fig.7: Shear force design envelope (Rutenberg & Nsieri 2006)

5 MORE ON DUAL WALL FRAME (WF) SYSTEMS

Some studies on dynamic shear demand amplification in WFs followed naturally from those on flexural walls, but not all. As already noted wall shear amplification in WFs was studied by Kabeyasawa (e.g. [44]) and Aoyama [4], see Eqn. 2. Paulay and his co-workers [38, 39] observed that, as in flexural walls, higher vibration modes amplified the shear force demand on the *walls* of WFs, but to a lesser extent, and proposed a simple prediction formula accounting for this response reduction. This extension of the shear amplification formula for flexural walls based on Blakeley et al [9] to walls of dual systems is also given by Paulay & Priestley [75]. This WF shear amplification factor ω_v^* is given by:

$$\omega_v^* = 1 + (\omega_v - 1)\eta \quad (13)$$

in which ω_v is the free standing wall shear amplification factor and η is the fraction of the base shear carried by the walls. Although the format of this formula is appealing its predictive capability appears to be limited [89].

Alwely [3] made ω_v^* dependent on the non-dimensional frame-to-wall stiffness ratio αH , as evaluated from the linear continuum approximation (e.g. [99]). Kappos & Antoniadis [46] proposed a procedure to estimate more realistically the shear demand in the upper storeys and also a modified version of the Goodsir et al [38, 39] formula (Eqn. 13) to account for shear amplification in WFs with unequal walls. Very recently Kappos & Antoniadis [47, 48] provided formulas to improve the shear distribution match with NLRHA results all along the wall height.

The codified guidance regarding the amplification factor ω_v^* is rather limited. The New Zealand seismic code NZS 3101- 2006 [63] refers only to Paulay & Priestley [75] where Eqn. 13 is presented. Note that therein ω_v is that given by Eqn. 1. It is clearly seen that when $\eta \leq 1.0$ then $1 \leq \omega_v^* \leq \omega_v$. Eqn. 13 assumes that ω_v^* , as ω_v , is independent of the expected ductility demand or q (R). Note also that Eqn. 1 depends indirectly on T_1 through its dependence on the number of storeys n .

EC8 [16] considers WFs in which $\eta > 50\%$ as “wall-equivalent”, hence in such cases wall shear in high ductility class (DC-H) systems should be amplified per Eqn. 4.

Applicable US codes do not include dynamic shear amplification requirements even for flexural walls (except the Commentary to the 1999 SEAOC code [93]). In practice, however,

amplification is considered in tall buildings design, as described subsequently. Quite recently Priestley et al [81], in the draft displacement-based seismic design code at the end of their book (also [56]), proposed a dynamic base shear amplification expression for WF walls, which requires predicting the displacement ductility demand μ_{sys} of the dual WF system. When $0.4 \leq \eta \leq 0.8$ the wall base shear amplification is given by:

$$\omega_v^* = 1 + \frac{\mu}{\Phi} C \quad (14)$$

$$C = 0.4 + 0.2(T_1 - 0.5) \leq 1.15$$

in which Φ is an overstrength factor (usually taken as 1.25). Note that ω_v^* is assumed independent of η , hence cannot be in agreement with Eq. 13.

Based on the deflected shapes observed in several time windows during NLRHA, Sullivan et al [100] recently proposed a variant of Keintzel's formula using so called "transitory inelastic modes". They concluded that the higher modes' periods elongated, and suggested that good agreement with NLRHA of the base shear per Keintzel could be obtained when the higher modes' periods were evaluated based on low post-yield secondary stiffness at wall base. This basically amounts to replacing the μ^2 factored higher modes fixed base shears (at design level) in Eqn. 6 by their thus computed counterparts.

A NLRHA based formula was very recently proposed by Rutenberg & Nsieri [89]:

$$V_a = 0.4 + 0.2(T_1 + q + \eta) + 0.13T_1q\eta \quad (15)$$

in which η is the elastic wall base shear to total base shear ratio. As all formulas based on NLRHA parametric studies it is applicable to design spectra similar to the mean spectrum of the suite of records used for their derivation. It was also found that the results are quite sensitive to the design yield levels of the girders over the frame height

6 EFFECTS ON SHEAR AMPLIFICATION: SEISMIC ISOLATION, MULTIPLE HINGES, ROCKING, AND SHEAR DEFORMATION

6.1 Seismic isolation, multiple hinges along height and rocking

It is often necessary to increase the strength over significant portions of the wall height if yield is to be confined - per capacity design - to the plastic hinge zone at the base; whereas allowing yield to propagate upwards (with base level flexural strength) leads to some reduction in the shear demand, e.g., as shown in Fig. 8. Adding another plastic hinge at wall mid-height, as proposed by Panagiotou & Restrepo [67], leads to more pronounced lowering of shear demand envelope. Furthermore, when the wall is designed such that plastic hinges can develop at several locations along the height as done by Rad [82, 84], the shear demand falls appreciably, as illustrated in Figs. 9 & 10. Evidently, the last approach requires special reinforcement detailing along all the wall height.

Wiebe & Christopoulos [103] proposed a design to allow rocking of several wall segments with respect to each other in order to reduce the contribution of higher modes, using unbonded post-tensioning. Appreciable reductions in shear and bending moment were reported.

Twenty storey seismically isolated cantilever wall buildings designed with lead-plug rubber bearings were studied by Calugaru & Panagiotou [12]. Three variants were considered: single isolator at base, isolators at base and at mid height, and isolators at base and at 0.7 of height. As expected, these buildings demonstrated significant reduction in the important response parameters compared with standard fixed base, i.e. with a single plastic hinge, buildings. The buildings with dual isolation led to a further reduction in shear demand on the upper 60% of the height.

Fig.8: Plastic hinge at base only vs. plastification at higher levels –base shear flexural strength assumed over building height (Rutenberg & Nsieri 2006)

6.2 Shear deformation

Already in 1988 Eibl & Keintzel [27] observed that smaller shear rigidity lowers the higher modes dynamic amplification. In their study on the shear distribution among wall of different lengths Rutenberg & Nsieri [88] noted a substantial lowering in shear demand in cracked sections when the effective shear rigidity GA_{ve} was evaluated based on the analogous truss model [72], which is appreciably smaller than the recommended values based on the gross section (GA_{vg}) for both cracked and uncracked walls by ASCE 41-06 [6], or 50% thereof for cracked walls by EC8 [16]. Gerin & Adebar [33] provided expressions to predict the shear deformation, including shear cracking and yielding, observing that a typical effective shear rigidity of diagonally cracked concrete could approximately be taken as 10% GA_{vg} , somewhat lower than the GA_{ve} assumed by [88]. Rad & Adebar [82, 84] used effective shear stiffness as a simple way to demonstrate the significant influence of cracking on shear amplification, as shown in Fig 11. Wallace [102] suggested modelling the post-cracking shear stiffness in the plastic hinge zone as circa 2.5% GA_{vg} .

7 NOTES ON PRACTICE IN THE USA

Seismic design practice in the US, particularly in California, is highly regarded worldwide and often adopted; hence it may be useful to comment on the situation there with respect to dynamic shear amplification.

It is interesting that although researchers, code-writers and practicing engineers were exposed to the many publications on the post-yield shear demand magnification of higher modes, this has not been manifested in US seismic codes, e.g., ASCE 7-05 [5], as would be expected, particularly, since other major codes such as NZ3101 [63] and EC8 [16] included such provisions for many years. As noted, only the Commentary to the 1999 SEAOC [93] considered this issue, referring the reader to the New Zealand code. Also, shear amplification is recognized, albeit to a limited extent, by ASCE 41-06 [6] code for upgrading of existing buildings:

Fig. 9: Shear force envelopes with hinging permitted only at wall base, $R = 5$ (Rad & Adebar 2008)

Fig. 10: Shear force envelopes, flexural hinging at many locations over height, $R = 5$ (Rad & Adebar 2008)

Fig. 11: Influence of effective shear stiffness on average shear force envelopes, flexural hinging at many locations along wall height, $R = 5$ (Rad & Adebar 2008)

the shear force at the wall base is calculated assuming uniform lateral force distribution over the wall height, i.e., the shear resultant is located at wall mid-height (clause 6.7.2.4 therein) rather than at approximately its 2/3rd, thereby increasing the base shear by circa 35%. It is only when NLRHA - one of the recommended procedures by US codes - is carried out that dynamic shear amplification is accounted for. However, code based analysis per this procedure appears to be the exception rather than the rule.

The resurgence in high-rise construction in the west coast of the United States during the early and mid-2000's has led to the application of performance-based non-prescriptive design procedures ([20, 54, 94]. Such design requires using a suite of at least seven pairs of appropriate ground motion histories; hence, dynamic amplification is thereby considered. Indeed, researchers and practitioners in California were soon reporting on large higher modes magnifications [53, 57, 58, 59, 105]. For very tall buildings, circa 40 storeys, these studies predicted shear amplifications on the order of 4 relative to code. It is interesting to note that one designer [52] observed, after designing over two dozen tall buildings, that *“design which follows the prescriptive provisions of the building code will likely result in a shear capacity that falls well short of the likely demands the structure will experience during a significant seismic event. As shear failure of a structural wall is typically viewed as non-ductile, undesirable response, this outcome raises serious concerns....”*

8 POST-ELASTIC REDISTRIBUTION OF SHEAR DEMAND AMONG WALLS IN SYSTEMS WITH INTERCONNECTED WALLS OF UNEQUAL LENGTH.

The shear force distribution among the walls in regular multistorey structures laterally supported by a number of reinforced concrete cantilever walls with markedly different lengths is strongly affected by the different yield displacement levels of the walls. In the post-elastic range the share of the shear force carried by the shorter walls is larger than their share in the bending moment.

In a single storey structure the shear distribution among the walls within the elastic range is proportional to their stiffness. Following yielding of the longer wall additional loads will be carried by the shorter ones. It is evident that design for shear on the basis of relative stiffness underestimates the forces on the shorter walls since shear capacity should be made proportional to flexural strength. However, the situation in a multistorey building is different as shown in Fig.12, showing a simplistic model of a two storey system supported by two walls. To fix ideas, assume Wall 2 is very much stiffer than Wall 1; hence, the horizontal force on Wall 1 is negligible so long as Wall 2 has not yielded. With Wall 2 yielding at base the force ΔH is distributed as shown in Fig.12b, where for simplicity it was assumed that the floor diaphragms are pin-connected to the walls and are infinitely rigid in plane. It can be seen that displacement compatibility requires a shear force redistribution resulting in a very large shear force acting on Wall 1.

Rutenberg and coworkers (e.g. [85, 86, 88]) demonstrated that the shear demand on the flexible walls could be very much larger than commensurate with their relative stiffness or even flexural strength. These studies were mainly carried out by means of cyclic pushover analysis on bilinear force-displacement hysteretic models. However, since redistribution is mainly due to compatibility enforcement rather than equilibrium it is sensitive to modelling assumptions. Hence further studies replaced the routine modelling ($G=0.4E$, in-plane floor rigidity, bilinear hysteresis) with more realistic models. Indeed, the earlier results were shown [7, 88] to overestimate the base shear demand on the shorter wall. Beyer [7] also observed that the greatest effect was due to “locking in” of compatibility forces transmitted by the floor diaphragms. Yet, it appears that the effect of this relaxation depends on the extent of plasticity

Fig. 12: Two-storey wall system: (a) properties and loading, (b) floor forces and deflected shapes (Rutenberg 2004)

propagation along the wall's cross-section, which in turn depends on whether the longitudinal reinforcement is mainly concentrated at the wall ends (flanges) or is uniformly distributed, which was not considered. Also, Beyer's conclusions were obtained from a two-wall model with modest lengths ratio (1.5: 6.0m & 4.0m respectively); more pronounced stiffness differences are likely to increase the share of the short wall shear force. However, Priestley et al [81] concluded, based on Beyer's work [7], that these compatibility induced forces might normally be ignored in design. Further study on redistribution, including these effects, is now under way [8].

Beyer [7] proposed using the pushover analysis [85] to test the propensity of the shorter wall for excessive shear demand. In that procedure the resultant lateral force is located at the minimum dynamic effective height $h_{eq, dyn}$ given by Eqn.16:

$$h_{eq, dyn} = h_{eq, static} / \omega_v \quad (16)$$

In which $h_{eq, static}$ is the height of the statically computed shear resultant, and ω_v is the dynamic amplification factor. Alternatively, $h_{eq, dyn}$ may be taken for the applicable spectrum from plots such as Fig. 2 in [91], if available. If the base shear on the short wall sharply increases while the base shear of the long wall drops off after formation of the plastic hinge at the base of the long wall, coupling effects are expected to be significant. Note that ω_v in Eqn. 16 is predicated on the assumption that the total base shear on a group of walls is equal to that on an isolated wall whose strength and stiffness equal the respective sums of these properties of the individual walls. This was found to be justified for the record suites used by Rutenberg & Nsieri [88].

Adebar & Rad [1], using pushover analysis, studied a two-wall system with markedly different properties (a long flanged wall and a short rectangular one). They were mainly interested in the effect of shear deformation on the response, modelling both flexure and shear with tri-linear force displacement relations, i.e., a kink at cracking and a yielding plateau (very short for shear). As expected, cracking and yielding were found to affect the shear force redistribution along the height, in some cases predicting shear failure. In particular, diagonal shear

cracking led to significant shear force increase in the short wall at the 2nd floor level. Note, however, that concentrated plasticity was not accounted for.

9 DISCUSSION

In many countries dynamic shear amplification is now routinely accounted for in wall design, yet, as shown, there are large differences in the extent of amplification - from relatively low ω_v in the New Zealand code to quite high ones in EC8. As already noted, the Canadian code requires considering amplification only when the equivalent lateral force procedure is carried out, and then only the linear multi-modal effect. Interestingly, the Romanian seismic code P100-1/2006 [64], while generally adopting the EC8 provisions for RC structures, excluded Eqn. 4, based mainly on the peculiarities of the 1977 Vrancea earthquake record. Instead, it specifies $\omega_v = 1.5$ for statically computed base shear or 1.2Φ (Φ = flexural overstrength), whichever is larger [77, 104].

The very large amplifications predicted by NLRHA were met in many instances with some skepticism. For a widely expressed attitude it is perhaps best to quote Paulay [74], who wrote w. r. t. computed magnifications much larger than given in the New Zealand provisions: “*I found at that time (early 1980’s, AR) that the duration of predicted extremely high shear demands was typically 0.02 to 0.03 seconds. So we pacified our conscience with the unanswered question: ‘is this time interval long enough to enable a wall region to fail in shear?’*”. On the other hand, ignoring shear peaks with durations less than 0.03 seconds do not appear to lead to substantial reduction in shear demand. A preliminary study by Panagiotou & Calugaru [65] on records of three earthquakes showed that demand was lowered only by 6%-15%.

It has often been observed that the maximum shear may not occur simultaneously with maximum moment over the wall height; hence the large amplification factors could be questioned (e.g. [55]). Yet, simultaneous peaks at wall base level were observed in analyses by Rad [82] and Tremblay et al [101] for several historical records; and the large amplifications were evaluated for the wall base. No doubt these two issues deserve study.

The main reason for the skepticism appears to be the feeling that standard nonlinear modelling of RC walls, particularly in the plastic hinge zone, does not capture faithfully the complex response. As noted above, using the Takeda rather than the bilinear hysteresis lowers computed shear demand somewhat, and more importantly, realistic shear behaviour modelling results in substantial fall in shear demand (Fig. 11); considering shear-flexure interaction might lower it further. On the other hand, it has been demonstrated that the 5% damping routinely assumed in NLRHA is quite unconservative for tall buildings design, and damping ratios lower than 2% were reported (e.g. [92]).

Another important issue is the experimental and historical evidence for nonlinear dynamic shear amplification. The study by Eberhard [25, 26, 98] on wall frames suggests that the formula proposed by Kabeyasawa (e.g. [43]) and Aoyama [4] is in approximate agreement with the experimental results. The experimental study by Panagiotou et al [66, 68, 69] did not focus on shear amplification per se, yet this phenomenon has been observed in their shake table tests. Shear amplification was also observed by Tremblay, Leger and their co-workers in an on-going shake-table testing program [55]. The large dynamic amplifications predicted by the many parametric studies listed in the bibliography and by Keintzel’s formula, or variations thereof, were not observed in these studies.

On the whole it appears that the seismic performance of well-designed and constructed cantilever wall buildings has been satisfactory. Yet, damage to shear walls was reported after several earthquakes. Blakeley et al [9] referred to reports on two cases of extensive diagonal tension cracking; however, it is not clear whether those or other such failures can be attributed to dynamic shear amplification. Shear failures in walls were observed after the February 2010

Chile earthquake, but these were attributed mainly to discontinuities and similar effects such as stress concentrations near openings. Targeted studies are now under way [11].

The reader who chooses not to perform NLRHA with refined modelling may well ask which of the several formulas reviewed here he/she should adopt. In order to answer this question it is necessary to perform extensive parametric studies. On the other hand it does not appear that the differences among the several variants of Keintzel's formula are excessive. Strictly speaking, parametrically derived formulas and design charts are applicable only to the mean spectrum of their data base.

These design procedures do not account for multiple hinges when the vertical wall reinforcement follows approximately (in several steps) modal analysis moment envelope. They also do not consider wall shear cracking, which has significant effect on shear amplification, and on the response of interconnected walls. The actual impact of shear cracking on amplification depends on cyclic shear-flexure coupling; but such a model is not yet available [102].

In view of the above, it is believed that judiciously conceived NLRHA-based design can better account for the many variables affecting dynamic shear amplification.

10 ACKNOWLEDGEMENTS

The author is indebted to T. Postelnicu and D. Zamfirescu for explaining the relevant provisions in the Romanian code P100-1/2006, to M. Panagiotou for providing peak shear plots for several US records and to K. Beyer for her comments on interconnected walls. The help of R. Adoni, A. Aines and I. Elkayam is gratefully acknowledged.

Abstract. *In this paper, application of a rapid, yet efficient methodology for the evaluation of failure modes of lightly reinforced substandard buildings is presented. The method determines the limiting shear resistance of the structure as the least value supported by the columns' pure flexural, degraded shear, anchorage or lap-splice and joint shear resistance mechanisms. For application of the methodology only knowledge of the basic geometric and material properties of the building is required. The proposed methodology is applied to a number of Reinforced Concrete buildings that failed during past strong earthquakes for verification reasons. It is shown that the proposed methodology is ideal for rapid preliminary seismic assessment and it can be used both as a diagnostic tool for identification of the building's fragility and the prevailing mechanism of building failure.*

1 INTRODUCTION

Recent earthquakes have repeatedly illustrated the deficiencies of brittle reinforced concrete (RC) buildings built according to earlier design codes. This class of buildings, which today represents the majority of the built environment in the greatest part of the world, is typified by a number of features such as small section columns, relatively stiff beams, inadequately confined joints and insufficient anchorage of longitudinal and transverse reinforcement. Although the application of detailed assessment procedures for seismic evaluation of every single existing structure is of vital importance, the immense volume of required work makes it seem an unrealistic scenario. This difficulty could be removed by applying a rapid evaluation procedure where information readily available for most buildings will be used; in such a rapid assessment, critical features of the structure that render it more vulnerable, could be immediately identified thereby simplifying the process of singling out those structures that represent a major threat to human life in the event of an earthquake.

The objective of this paper is to present a methodology where the building's geometrical characteristics, material properties and reinforcement detailing of the structural elements are considered sufficient information so as to single out the most vulnerable buildings that are likely to collapse in a potential strong earthquake, but can also be used to determine the objectives for their rehabilitation. Existing RC buildings, "non-conforming" according to modern standards, are assessed based on prioritizing of the various alternative modes of failure. Mechanisms considered refer to column flexure, degraded shear, anchorage and lap-splice development, connection punching and exceedence of joint shear capacity; the rate of degradation of these mechanisms with increasing displacement amplitude and number of cycles is idealized through simplified mechanistic constructs which allows the prioritizing of failure modes as degradation proceeds. Furthermore, the seismic vulnerability of this category of buildings is assessed as a function of interstorey drift demand imposed by the design earthquake [1]. For confirmation, the methodology is applied to a number of RC buildings that collapsed during the 1999 Athens earthquake. Results indicated that in all cases, buildings failed in a brittle manner due to anchorage failure of column longitudinal reinforcement in the joints' regions.

2 METHODOLOGY FOR RAPID EVALUATION OF FAILURE MODES

2.1 Background information

In the first 2/3rds of the 20th century, when massive rebuilding and urbanization of cities took place throughout Southern Europe, construction details were not strictly addressed by the design codes and as such, they were seldom specified in design drawings of that era. Implementation in practice was, to a large extent, determined by the experience of the laborers and the foreman responsible for the site. Credentials were never questioned and supervision was relatively lenient; the reinforcing cages were usually assembled on site, empirically in most cases and often using makeshift tools for hook bending and bar cutting. Today, even in the rare occasion where a plan drawing from the 1960's specifies details for stirrup placement, it is questionable whether these stirrups had been actually placed as specified. Reconnaissance studies from collapsed buildings in major earthquake events suggest that at least in those, collapsed cases, there was a marked lack of, or primitive use of stirrups. But underuse of stirrups was the prevalent practice of the era. Usually stirrups were rectangular, with 90° hooks in the ends, made of smooth reinforcement, using bar sizes of \varnothing_t equal to 6 mm or at best 8 mm, spaced at 250 mm to 300 mm; however, occasional examples of even wider spacing have also been cited. Steel quality was StIII ($f_{yk}=420$ MPa) for longitudinal reinforcement and StI

($f_{yk}=220$ MPa) for stirrups, concrete quality ranged between Bn150 to Bn200 [2] (i.e. a concrete characteristic strength of 12 to 16 MPa according to today's standards). Lap splices were usually unconfined, whereas starter bars had random lengths. Joints, being considered points of reinforcement congestion since they accommodated both beam and column primary reinforcement, were usually left without stirrups, for convenience of construction. Single column footings were mostly used and, in well-attended structures, they were joined at the column base with lightly reinforced, small section connecting beams.

Despite these systematic inadequacies, the percentage of buildings that have collapsed in major earthquakes in the Mediterranean basin is relatively low when compared to the total number of available buildings that belong to this substandard construction category; this is not true in other parts of the world such as in Haiti (Port-au-Prince 2010, [3]) One issue that can be concluded, however, from post-earthquake reconnaissance evidence and forensic evaluations of collapsed buildings which led to loss of human life, is that collapse usually occurs by the formation of a mechanism before the development of any form of ductility. In this work it is demonstrated by paradigm that in most cases of such "killer collapses", displacement at the onset of failure is lower than the nominal yield displacement of the structure. This is contrary to the focus of most modern assessment methodologies that are based on comparisons between ductility demand and supply. Note that the usual point of reference in these procedures is columns where transverse reinforcement is not adequate to support shear strength under displacement reversals beyond flexural yielding of the individual members of a structure. For this reason, values of rotation capacity in what is termed "non-conforming" members are usually deemed in the range of 1% to 1.5%. This focus could be justifiable for structures with columns where the member size (in the range of 500 mm or higher) is twice that of typical stirrup spacing used in the 1960's, so that a nominal 45° shear plane in a column would intersect at least two stirrups. But in case of structures with smaller column sizes, in the range of 350 mm, as is often encountered in older residential buildings, the practical spacing of stirrups from the 1960's (250 mm) could mean that a nominal potential sliding plane could be formed, intersecting no stirrup at all and therefore being unable to mobilize any form of shear resistance.

Other unfavourable characteristics of RC concrete buildings constructed prior to the introduction of capacity design principles and modern detailing practices are the relatively stiff beams intended to control serviceability requirements. For this class of buildings, a rapid evaluation for the potential mode of failure could be focused on the calculation of the limiting strength of building columns, since post-earthquake reconnaissance reports illustrate column failure as the primary cause of building collapse, being associated with the loss of gravity load-carrying capacity.

2.2 Available diagnostic tools

In light of the limited knowledge of actual construction details in older structures, preliminary assessment targeted toward identification of the most vulnerable buildings must necessarily rely on a marginal collection of data that is readily available, such as the overall geometric details of the structure (number of floors, floor height, floor area, location and gross geometry of load carrying members in plan), on the implicit assumption that all reinforcing details are represented by the historical construction information for the period and region of construction of the building studied. With these data, building seismic vulnerability is based on the following two criteria:

(a) A *stiffness index assessment*, which is used to quantify interstorey drift demand.

(b) A *strength assessment*, which is used to determine the weakest mechanism of resistance, likely to control the sequence of failure of the vertical elements of the structure.

(a) Stiffness Index Assessment: From the earliest earthquake studies the area ratio of the load-bearing elements in a structure has been used to quantify the magnitude of lateral stiffness. The importance of this parameter was reflected in the very first Seismic Codes worldwide, whereby the required floor area ratio of walls was set proportional to the number of floors in the structure, to secure adequate seismic performance. Recent studies have systematically explored the relationship of generalized stiffness, K^* , to the floor area ratios of columns, ρ_c , walls, ρ_{wc} , and infill walls, ρ_{wm} , in a structure [1]. It was shown by systematically exploring the relationship between stiffness and fundamental period, T ($T \approx 2\pi\sqrt{[0.8W/(gK^*)]}$), that the displacement demand under the design earthquake, S_d , could be expressed in terms of ρ_c , ρ_{wc} , and ρ_{wm} (where the seismic hazard is given in relative displacement vs. period spectrum coordinates). Using an estimate of the morphology of the shape of vibration of the structure (Fig. 1) it is possible to develop generic charts of the type shown in Fig. 2 that relate drift demand in the critical floor of the structure to a combined stiffness geometric index, defined as:

Dual systems:
$$k = \rho_c + \eta_{wm} \rho_{wm}^e \quad (1a)$$

$$\eta_{wm} = \frac{25E_{wm}}{E_c \left(\frac{h_i^2}{l_{m,ave}^2} + 2.5 \right)} ; \rho_{wm,i}^e = \rho_{wm,i} + \left(\frac{4 \frac{h_i^2}{l_{m,ave}^2} + 2.5}{4 \frac{h_i^2}{l_{w,ave}^2} + 2.5} \right) \frac{E_c}{E_{wm}} \rho_{wc,i} \quad (1b)$$

Frames:
$$k' = \rho_c + \eta_{wm}' \rho_{wm} \quad (2a)$$

$$\eta_{wm}' = \frac{10 \cdot f_{wk} \sqrt{\left(1 + \frac{h_i^2}{l_{w,ave}^2} \right)}}{E_c \theta_1} \quad (2b)$$

where E_c , E_{wm} are the elastic moduli of concrete and masonry, respectively, ρ_c is the columns' area ratio in the floor plan, ρ_{wm}^e is an equivalent compound dimensionless area index that represents both masonry walls and RC walls expressed in terms of masonry wall properties, h_i is the storey height, $l_{m,ave}$, $l_{w,ave}$ are the average length of masonry and RC wall, respectively, f_{wk} is the compressive strength of masonry and θ_1 is the estimated chord rotation demand of the first storey.

Because of inadequate shear resistance, collapse of substandard buildings in a critical earthquake could be prevented if the interstorey drift demand, θ_u , in the critical floor (if the critical floor is the first floor, $\theta_u = \theta_1$), is below the estimated drift at failure, which is given by:

$$\theta_{fail} = \frac{V_{u,lim}}{V_{y,flex}} \cdot \theta_{y,crit} \leq \theta_{y,crit} \quad (3)$$

Figure 1: Lateral displacement profiles; (a) shear-type; (b) soft-storey.

In the above, $\theta_{y,crit}$ is the estimated interstorey drift at longitudinal reinforcement yielding of the critical floor – for typical frame structures (with floor heights around 3m) this is usually in the range of 0.5%. Values $V_{y,flex}$ and $V_{u,lim}$ are the estimated base shear strengths at the onset of yielding of column reinforcement and of transverse reinforcement, respectively. For typical older construction, this ratio is usually in the range of 30% - 60%, depending on the size of the columns for the typical details used in the period of reference (the ratio $\approx 30\%$ for column section sizes in the range of 300 mm, to 60% for larger column sections in the range of 500 mm – detailed expressions for calculating these terms for each individual column are given in the following section). The plot in Fig. 2 has been drawn for the EC8 design spectrum (Type 1) using a peak ground acceleration of 0.36g; thus, demand (ordinate in the graph) should be scaled down by the ratio of $a_g/(0.36g)$ for lower levels of peak ground acceleration coefficient, a_g .

Figure 2: Vulnerability curves that relate the required composite floor area ratio of vertical members to levels of interstorey drift, $\theta_1 \leq 0.5\%$, which are of interest for buildings susceptible to brittle failures. Note that the baseline value of 0.1% is the estimated drift limit associated with diagonal cracking of unreinforced concrete flexural members.

(b) Strength Assessment: Collapse occurs when the vertical elements of the critical floor lose their load carrying capacity. This process may be initiated either by loss of lateral load resistance of the columns, or by punching and loss of support of the floor diaphragms. To be able to establish a hierarchy of possible failure modes which threatens the integrity of a structure under lateral sway, all mechanisms of response must be compared on a common basis of

reference. In this study, the typical form of a moment diagram along the column lines of a swaying structure is used to establish this common frame of reference. As depicted in Fig. 3, the typical column experiences a moment reversal at the ends, owing to the transfer of moment from the horizontal to the vertical elements, occurring at the beam-column joints (in frame structures) or at the slab-column connections in flat-slab structures. The approximate location of points of inflection (zero moment) along the column length enables the establishment of a static relationship between the critical strengths of various mechanisms that could be responsible for column failure along the line of a single column, and the column shear sustained when any of these phenomena is occurring, as follows:

- (i) Plastic hinging at the column end (i.e. $M_{col} = M_y$), $V_{y,flex}^{col} = 2 \cdot M_{col} / h_{st}$, where h_{st} is the deformable length of the column (i.e. the clear storey height, or free column length in captive columns).
- (ii) Exhaustion of column shear strength, $V_{u,shear}^{col}$
- (iii) Exhaustion of column lap-length development capacity of tension reinforcement F_b :

$$V_{u,lap}^{col} = 2 \cdot [F_b \cdot d \cdot (1 - 0.4 \cdot \xi) + N_{g+0.3q} \cdot (0.5 \cdot h_{st} - 0.4 \cdot \xi \cdot d_{col})] / h_{st}$$
 where ξ is the depth of compression zone normalized with respect the column section depth, d_{col} , and $N_{g+0.3q}$ is the axial compression load in the column owing to the combination of unfactored gravity loads plus a reduced contribution of live load (this is the average column axial load; the column axial load fluctuates about this value due to the overturning effects of the earthquake). The value of ξ ranges between 0.22 and 0.30 for columns with a reinforcing ratio of less than 1.5% and a variety of normalized axial load ratios, and for this reason the above result is not very sensitive to this parameter (Fig. 4).
- (iv) Exhaustion of joint shear strength (in frame structures), $V_{j,u}$. Column shear is estimated from equilibrium of moment transfer: $V_{u,joint}^{col} = [V_{j,u} \cdot d_{beam}] / h_{st}$.
- (v) Exhaustion of slab punching strength (in flat slab construction), $M_{u,slab}$. The associated column shear is again estimated from equilibrium of moment transfer (assuming this is an intermediate floor of the structure, i.e., not a roof connection): $V_{u,slab}^{col} = M_{u,slab} / h_{st}$ where $M_{u,slab}$ the strength for moment transfer of the critical punching perimeter at the slab – column connection.

Evaluation of the prevalent failure mode is obtained from the inequality:

$$V_{u,lim}^{col} = \min \{ V_{y,flex}^{col}, V_{u,shear}^{col}, V_{u,lap}^{col}, V_{u,joint}^{col} \text{ or } V_{u,slab}^{col} \} \quad (4)$$

Expressions for calculating the individual strength terms are given in the appendix. These may be subject to change as the knowledge base in reinforced concrete leads to improved models for the individual mechanisms of resistance and may differ between established code frameworks.

Figure 3: Moment distribution and possible failure modes of a reinforced concrete column.

 Figure 4: Relationship between ζ , $\rho_{t, tot}$ and normalized axial load, v , for columns.

In the following, a number of buildings collapsed during the 1999 Athens earthquake are used to illustrate performance of the proposed rapid screening approach.

3 APPLICATION OF THE METHODOLOGY

The proposed methodology for rapid evaluation of the limiting resistance of “non-conforming” RC buildings through systematic prioritizing of the individual column shear strengths is applied to two RC buildings that collapsed during the 1999 strong ground motion of Athens. Both buildings were located in the northern region of Athens, where the ground motion possessed “near-field” characteristics. The methodology is applied so as to estimate the buildings’ drift at the state of their failure as well as to calculate the limiting base shear that the buildings could sustain upon failure, but also to test the ability of the methods to identify the high seismic vulnerability of such structures.

Building A was a two-storey fully symmetric in plan, industrial building, with external plan dimensions of 38.00 m by 26.00 m (Fig. 5). The first and the second storey heights were 5.40 m and 5.30 m, respectively. Building A was separated by seismic gaps from two adjacent wing buildings along the two smaller sides. The structural system was formed as an orthogonal grid of columns, beams and slabs, according to typical construction practice of RC frame structures in Southern Europe. Details of the column geometry and longitudinal reinforcement

are presented in Table 1. Column stirrups were smooth, rectangular ties, approximately categorized based on site reconnaissance as $\text{Ø}8/300$ mm. Slab thickness was 0.15 m. All perimeter beam (PB) cross sections were 0.70 m (height) by 0.30 m (width), 0.70×0.45 m for beams spanning between columns (MB) and 0.70×0.25 m for the secondary beams (SB). During the earthquake the building collapsed without any horizontal dislocations of its structural elements, whereas the two adjacent buildings were intact. From tests of core samples, the mean value of concrete compressive strength was determined as 18.7 MPa, whereas steel yielding and ultimate stresses were found to be for the longitudinal reinforcement 431.5 MPa and 512.0 MPa, respectively, and for the stirrups 402.0 and 553.0 MPa, respectively.

Figure 5: Plan configuration of Building A.

Column	Dimensions(mm)	Long. Reinforcement (mm)
C ₁ , C ₅ , C ₁₆ , C ₂₀	450 / 300	4 Ø20
C ₂ , C ₃ , C ₄ , C ₁₇ , C ₁₈ , C ₁₉	450 / 300	8 Ø20
C ₆ , C ₁₀ , C ₁₁ , C ₁₅	300 / 450	8 Ø20
C ₇ , C ₈ , C ₉ , C ₁₂ , C ₁₃ , C ₁₄	450 / 450	12 Ø20

Table 1: Column dimensions and longitudinal reinforcement of Building A.

The results of the *strength assessment* of the first storey columns in *x* and *y* direction for Building A (Fig. 6) are presented herein. The prevailing failure mechanism for all the columns of the first storey was failure due to exhaustion of column lap-length development capacity of tension reinforcement. The total base shear that the building could sustain at the onset of this mode of failure was 1022 kN and 891 kN in *x* and *y* direction, respectively, whereas the flexural strength was estimated equal to 2094 kN and 1845 kN in *x* and *y* direction, respectively. Hence, failure was expected to occur when the imposed base shear reached 49% and 48% of the flexural resistance in *x* and *y* direction, respectively. Given the

axial load of the first storey columns for the $g+0.3q$ load combination (the normalized axial load ratio was estimated as $v_{ave}=0.22$, $W=13000$ kN), the maximum peak ground acceleration that Building A could sustain was only 7.9%(=1022/13000) and 5.9%(=891/13000) of g , in the x and y directions, respectively (note that the 1999 Athens earthquake had a peak ground acceleration, $pga=0.38g$ (Sepolia station)).

Figure 6: Strength of the columns of building A against the various mechanisms of failure; each group of bars in the chart represents the estimated column strengths against alternative failure modes, for a given column type and direction of seismic action (x or y). Labels under the bar charts identify the columns that fall under the specific category.

As calculated from the building's properties, the area ratio of the columns in both x and y directions was $\rho_{c,x}=\rho_{c,y}=0.3\%$. The average nominal drift at yield, $\theta_{y,nom}$, was estimated equal to 1.26% and 1.10% in x and y direction, respectively (Table 2). Due to the premature failure of columns, failure is expected to occur at earlier drift levels. According to Eq. (3) and the results of the *strength assessment* presented in the previous paragraph, those drift levels are determined as $\theta_{fail}^x=1.26 \cdot 1022/2094=0.62\%$ and $\theta_{fail}^y=1.10 \cdot 891/1845=0.53\%$ in x and y direction, respectively.

Column	$\theta_{y,nom}^{x*}$	$\theta_{y,nom}^{y*}$
C ₁ , C ₅ , C ₁₆ , C ₂₀	1.54%	0.99%
C ₂ , C ₃ , C ₄ , C ₁₇ , C ₁₈ , C ₁₉	1.54%	0.99%
C ₆ , C ₁₀ , C ₁₁ , C ₁₅	0.99%	1.54%
C ₇ , C ₈ , C ₉ , C ₁₂ , C ₁₃ , C ₁₄	0.99%	0.99%
Average	1.26%	1.10%

$\theta_{y,nom} = (2.14\varepsilon_y/d) \cdot (L_s/3)$ [4], where ε_y : steel strain at yield, d : depth of the cross section, L_s : clear shear span length

Table 2: Nominal drift at yield for the columns of Building A.

According to the methodology developed by Thermou and Pantazopoulou [1], the vulnerability curve for Building A was estimated for Type I elastic spectrum of EC8 [5] using as peak ground acceleration the magnitude recorded in the Athens 1999 earthquake (Sepolia station) ($p_{ga}=0.38g$) and $\rho_{wm}=0$ in Fig. 7. For a drift value equal $\theta_{fail}^x=0.62\%$ and $\theta_{fail}^y=0.53\%$ (as defined after the reduction of nominal drift at yield due to premature failure of the columns, see Fig. 6) demand in terms of ρ_c is defined by the horizontal dashed lines in Fig. 7. The percentage of columns required in order to maintain the drift levels in the x and y direction below the failure limit would have to be equal to 0.64% and 0.75%, respectively (i.e. in order to survive the earthquake the building should have 2.1 and 2.5 times the available area ratios of columns in Building A). This leads to the conclusion that the area ratio of nonductile columns in the existing building ($\rho_c=0.3\%$) was insufficient for the seismicity level of the Athens 1999 earthquake as evidenced by its dramatic collapse.

The vulnerability curve of Fig. 7 may be used alternatively to assess the performance of Building A by estimating the demand in terms of drift at the first storey given the percentage of columns. The vertical dashed line depicts the demand in terms of drift of the first storey, which is equal to 1.33% for $\rho_c=0.3\%$. This means that the earthquake would require from the structure, if the structure possessed ductility, a displacement ductility value of $\mu=1.33\%/1.26\%=1.05$ and $\mu=1.33\%/1.10\%=1.2$ in x and y direction, respectively. If this assessment tool would be used in practical preliminary retrofit design, it would suggest the required ductility level that should be targeted for in retrofitting the columns. This ductility limit is within the range that could be attained by the use of local interventions for seismic upgrading such as FRP jacketing, a finding that points to the criteria for establishing a retrofit scenario for structures assessed prior to the occurrence of a threatening earthquake event.

Figure 7: Vulnerability curve for Building A subjected to Athens 1999 earthquake estimated according to the methodology of Thermou and Pantazopoulou [1].

Building B was also an industrial building, having a 37.60 m by 22.80 m orthogonal plan (Fig. 8). The building had two basements and four storeys, each 2.85 m high. The structural system comprised a grid of columns which were connected with beams only along the buildings' perimeter, the beams having a section height of 0.60 m and 0.20 m web width. In the centre of the typical floor plan, columns supported a flat-plate Zoellner system, having a thickness of 0.22 m. During the earthquake the building collapsed, except for the stairwell in the corner of the plan. After tests conducted on material samples, the concrete was found to have a mean compressive strength of 20 MPa, while longitudinal reinforcement and stirrups were found to have smooth surface and were classified as S400 ($f_y = 400$ MPa) and S220 ($f_y = 220$ MPa) respectively. Column dimensions and longitudinal reinforcement details are presented in Table 3, whereas transverse reinforcement comprised $\varnothing 6/300$ mm rectangular, smooth stirrups.

Figure 7: Plan configuration of Building A.

Column	Dimensions (mm)	Long. Reinforcement (mm)
C ₁ , C ₂ , C ₃ , C ₄ , C ₅ , C ₆ , C ₁₉ , C ₂₀ , C ₂₁ , C ₂₂	750 / 400	8 $\varnothing 16$
C ₇ , C ₁₂ , C ₁₃ , C ₁₈	400 / 750	8 $\varnothing 16$
C ₈ , C ₉ , C ₁₀ , C ₁₁ , C ₁₄ , C ₁₅ , C ₁₆ , C ₁₇	650 / 650	8 $\varnothing 20$

Table 3: Column dimensions and reinforcement of Building B.

Strength assessment has revealed that the prevailing failure mechanism of the first storey columns was failure due to exhaustion of slab punching strength. Note that this type of failure (lowest green bars in Fig. 8) concerns all interior columns in directions where they were not

connected with beams but also exterior columns in the direction of action that bent them about their weak axis (e.g. C1 for seismic action in the y-direction). The total base shear that Building B could sustain at the onset of slab punching was 1477 kN and 861 kN in x and y directions, respectively, whereas the flexural strength was estimated equal to 4487 kN and 4136 kN in x and y direction, respectively. Thus, when the imposed base shear reached only 33% and 21% of the flexural resistance in x and y direction, respectively, failure would be anticipated. The maximum peak ground acceleration that Building B could sustain (direction y) for the $g+0.3q$ load combination (average normalized axial load ratio $v_{ave}=0.21$, $W=32500\text{kN}$) was only 4.5 % ($=1477/32500$) and 2.6% ($=861/32500$) of g , in the x and y directions, respectively (1999 Athens earthquake, $pga=0.38g$, Sepolia station).

Figure 8: Strength of the columns of building B against the various mechanisms of failure; each group of bars in the chart represents the estimated column strengths against alternative failure modes, for a given column type and direction of seismic action (x or y). Labels under the bar charts identify the columns that fall under the specific category.

Stiffness assessment of Building B follows, where, according to the building's characteristics, the columns' area ratio in both x and y directions was $\rho_{c,x}=\rho_{c,y}=0.88\%$, whereas the wall area ratio in x and y direction was $\rho_{w,x}=0.35\%$ and $\rho_{w,y}=0.24\%$, respectively. In the following calculations, and in order to keep the procedure simple, only the area of columns was taken into account (the influence of the wall was considered low and further burdening the structure with torsional action due to its eccentric placement). The average nominal drift at yield, $\theta_{y,nom}$, was estimated equal to 0.42% and 0.35% in the x and y direction, respectively (Table 4). The drift levels at which failure due to premature failure of columns would be expected to occur were $\theta_{fail}^x = 0.42 \cdot 1477 / 4487 = 0.14\%$ and $\theta_{fail}^y = 0.35 \cdot 861 / 4136 = 0.07\%$ in the x and y directions, respectively.

Column	Drift at x-direction, θ_x^*	Drift at y-direction, θ_y^*
C ₁ , C ₂ , C ₃ , C ₄ , C ₅ , C ₆ , C ₁₉ , C ₂₀ , C ₂₁ , C ₂₂	0.55%	0.28%
C ₇ , C ₁₂ , C ₁₃ , C ₁₈	0.28%	0.55%
C ₈ , C ₉ , C ₁₀ , C ₁₁ , C ₁₄ , C ₁₅ , C ₁₆ , C ₁₇	0.33%	0.33%
Average	0.42%	0.35%

$\theta = (2.14\varepsilon_y/d) \cdot (L_s/3)$ [4], where ε_y : steel strain at yield, d : depth of the cross section, L_s : clear shear span length

Table 4: Column dimensions and reinforcement of Building B.

Limiting demand to avoid failure, is defined in terms of ρ_c by the horizontal dashed lines in Fig. 9 for $\theta_{fail}^x=0.14\%$ and $\theta_{fail}^y=0.07\%$ (these values point to significantly reduced drifts compared to the nominal drift at yield, owing to the premature failure of the columns, see Fig. 8). Thus, utilizing the vulnerability curve extracted for Type I elastic spectrum of EC8 [5] for the recorded peak ground acceleration in the 1999 Athens earthquake ($p_{ga}=0.38g$, Sepolia Station), it is concluded that: According to the characteristics of Building B, the percentage of required columns with the available brittle details in order to keep the drift levels in the x and y directions below the failure values would have to be 8.67% and 16.57%, respectively (9.8 and 18.7 times higher than the available area ratios of columns in the actual building). From the above, it is evident that the percentage of columns, given the mode of construction (brittle details) in the existing building ($\rho_c=0.88\%$) was entirely insufficient for the seismicity level of the Athens 1999 earthquake.

If reversely, Fig. 9 is used to define demand in terms of drift at the first storey for the existing area ratio of columns ($\rho_c=0.88\%$), in the hypothetical case where these possessed displacement ductility, then the vertical dashed line indicates the demand in terms drift equal to 1.36% (Fig. 9). This means that the earthquake would require from the structure, if the structure possessed ductility, a displacement ductility value of $\mu=1.36\%/0.42\%=3.2$ and $\mu=1.36\%/0.35\%=3.9$ in x and y direction, respectively, a value that is somewhat excessive to be attainable by local interventions such as FRP-jacketing should such have been implemented prior to the earthquake; rather, these ductility values point to a deficiency in stiffness that could have been supplemented by infill walls in some critical bays of the lower floors, thereby mitigating the ductility demands to lower, more attainable through proper retrofit, values.

Figure 9: Vulnerability curve for Building B subjected to Athens 1999 earthquake estimated according to the methodology by Thermou and Pantazopoulou [1].

4 CONCLUSIONS

A methodology for determining the ultimate storey drift at the state of maximum seismic response and prioritizing the potential failure mechanisms in the load carrying system of concrete buildings classified as “non-conforming” according to modern standards was presented in this paper. Mechanisms considered refer to column flexure, shear, anchorage lap/splice development capacity and joint shear or slab punching strength, as failure of vertical structural elements is directly related to building severe damage or collapse. The methodology can be applied to every individual column of the building, regardless of its location; if flexural strength may be supported by the shear, anchorage, joint resistance and slab punching mechanisms, the calculated limiting strength can be compared to the developing shear force derived from a seismic analysis. However, in most cases of existing structures, brittle failure modes are prioritized to occur prior to flexural yielding, so that no ductility may be realized, whereas the building collapses at displacements lower than the yield point. In this case, the methodology may also be applied for the determination of the maximum ground acceleration that the building could sustain prior to retrofit, as illustrated in the former examples, thereby serving as a tool of rapid evaluation of the buildings’ seismic vulnerability. It is also possible to obtain, through this method, the magnitude of displacement ductility that would be required through column retrofit, in order to eliminate the risk of collapse due to excessive displacement demand.

APPENDIX

The following expressions can be used for calculating the individual strength terms of a column. These expressions represent the present state of the art at the field. Nevertheless, they may be subject to change as the knowledge base in reinforced concrete leads to improved models for the individual mechanisms of resistance.

(i) Calculation of column flexural yield:

Uniaxial bending [6]:

$$V_{y,flex}^{col} \approx \left[\rho_{l,tot} \cdot \frac{f_y}{f_c} \cdot (1 - 0.4 \cdot \xi) + v \cdot \left(\frac{h_{st}}{d_c} - 0.8 \cdot \xi \right) \right] \cdot b_c \cdot d_c^2 \cdot f_c / h_{st} \quad (A1)$$

Biaxial bending: $V_{y,flex}^{col}$ can be considered equal to the 70% of the respective value of uniaxial bending.

where $\rho_{l,tot} = A_{s,tot}/A_g$; $A_{s,tot}$: total area of longitudinal reinforcement; f_y : steel yield stress, f_c : concrete compressive strength; ξ from Fig. 4; $v = N/(A_g f_c)$; N : compression force acting in the section from $g+0.3q$ load combination (compression as a positive value); h_{st} : clear storey height; d_c : column depth; b_c : column width.

(ii) Calculation of column shear strength [6]:

Monotonic loading:

$$V_{u,shear}^{col} = V_w + V_c \quad (A2)$$

$$V_w = \begin{cases} 0 & \text{for } d_c < S \\ A_{st} \cdot f_{st} \cdot \frac{d_c}{S} & \text{for } d_c \geq S \end{cases} \quad (A3)$$

Note: For 90° stirrup anchorage V_w must be reduced by 50%

$$V_c = \begin{cases} 0.5 \cdot \sqrt{f_c} \cdot \left(\frac{d}{L_s} \cdot \sqrt{1 + \frac{N}{0.5 \cdot \sqrt{f_c} \cdot A_g}} \right) \cdot A_g & \text{if } v \geq (\rho_{s1} - \rho_{s2}) \cdot f_y / f_c \\ 0 & \text{if } v < (\rho_{s1} - \rho_{s2}) \cdot f_y / f_c \end{cases} \quad (A4)$$

Postyielding response:

$$V_{u,shear} = 0.6 \cdot (V_w + V_c) \quad (A5)$$

where, A_{st} : area of stirrup leg; f_{st} : yield stress of stirrups; S : spacing of stirrups; L_s ($\approx h_{st}/2$): shear span length; $\rho_{s1} = A_{s1}/A_g$; $\rho_{s2} = A_{s2}/A_g$; A_{s1} , A_{s2} : area of tension and compression reinforcement, respectively.

(iii) Calculation of the longitudinal bar development capacity [6]:

At lap:

$$F_s = 1.4 \cdot (A_{tr} \cdot f_{st} \cdot n_{st} / n_b + p \cdot f_t \cdot L_b) \leq f_y \cdot (\pi \cdot D_{b,l}^2 / 4) \quad (A6)$$

where, A_{tr} : total area of stirrup legs along one direction of restrain; n_b : total number of bars restrained by a total of n_{st} stirrups, $p = 2\sqrt{2}(c+D_{b,l})$; c : concrete cover; $D_{b,l}$: longitudinal bar diameter; f_t : concrete tension strength.

At anchorage in beam-column joint:

Calculate F_s as if at lap, by substituting p by the concrete cover, c , which is the actual length of the crack path.

At ultimate conditions:

$$F_s = 1.4 \cdot (A_{tr} \cdot f_{st} \cdot n_{st} / n_b) \leq f_y \cdot (\pi \cdot D_{b,l}^2 / 4) \quad (A7)$$

(iv) Calculation of joint shear strength [7]:

$$V_{j,u} = \gamma_j \cdot \sqrt{f_c} \cdot b_c \cdot d_c \quad ; \quad \gamma_j = \begin{cases} 1.6 & \text{for interior joints} \\ 1.0 & \text{for exterior joints} \\ 0.6 & \text{for corner joints} \end{cases} \quad (A8)$$

(v) Calculation of slab punching strength [8]:

$$V_{u,slab}^{col} = 0.12 \cdot \min \left\{ 1 + \sqrt{\frac{200}{d}}, 2 \right\} \cdot (100 \cdot \rho_l \cdot f_c^{1/3}) \cdot d_{slab} \cdot 0.25 \cdot u_{crit} \cdot (d_c + 4 \cdot d_{slab}) / h_{st} \quad (A9)$$

where, d_{slab} : slab depth; u_{crit} : the critical punching perimeter around the typical column in flat plate construction.

COMPUTATIONAL DAMAGE MEASURE FOR RC FRAME STRUCTURES UNDER SEISMIC LOADING

Keywords: damage measure, reinforced concrete frames, nonlinear dynamic analysis.

Abstract. *In the earthquake areas, the priority task in seismic design is to fulfill the safety requirements with respect to the expected earthquakes. These safety requirements will differ from each other according to the type of the earthquake and structure. For that reason, most codes for seismic design, assessment and retrofitting use the performance-based seismic design concept. In that concept, performance levels are specified ranging from fully operational to near collapse and earthquake design forces are classified. Such performance levels are then associated with a damage state with respect to a given earthquake. At that, either descriptive criteria or displacements are utilized for the damage extent instead of an explicit damage index. The aim of this work is to overview existing damage indices and to define new explicit damage indices which may be used as seismic design criteria for reinforced concrete frames.*

Both local and global damage indices to be defined will range between 0 (no damage) and 1 (failure or collapse). They will be suitable for static, cyclic and dynamic computer analysis in order to be used with various existing design procedures.

The necessary computer analyses are carried out by means of the finite element program (FRAME) developed in-house within the MATLAB environment. In that program, classical rectangular beam elements are used. Elasto-plastic bilinear moment-curvature relationships are used for the nonlinear material model including hysteretic behaviour under cyclic and dynamic loading. The stiffness matrices of the elements are obtained by use of the spread plasticity model along the length. The Newmark-Beta method with constant average acceleration is applied for the step-by-step time integration of the governing equations.

The cyclic global damage index is proposed to be composed of the separate global damage indices during positive and negative load cycles. Several test problems have been analysed to check the sensitivity of the computational global damage measure for cyclic and dynamic loadings.

1 INTRODUCTION

In the seismically active areas, it is necessary to estimate the damage level of the existing and new structures that have experienced or will experience one or more earthquakes. Most codes for seismic design, assessment and retrofitting use performance-based seismic design concept for that estimation. In that concept, various performance levels are associated with a limitation of the damage state with respect to a given earthquake. However, displacement limits are utilized for the damage state instead of computational damage measures.

The aim of this work is, therefore, to define explicit damage indices, which may be used as seismic design criteria for reinforced concrete frames. Such explicit damage criteria for design, assessment or retrofitting need mechanically well-founded damage measures, which are applicable both to individual members and entire structures.

Several damage indices for seismic assessment have previously been developed and are already well-known. A comprehensive overview can be found for example in [1, 2]. The damage indices giving quantitative information of the damage state can be local or global. A majority of the well-known damage indices usually refer to the local state of a cross-section or a structural member. Most of them are obtained from the ductility ratio or the stiffness ratio or the energy ratio defined within the moment-curvature relationship.

Only a few of the known damage indices are global, and they are usually empirical. Sometimes, they are even mechanically inconsistent, such as the combined index by [3] defined as a sum of a relative displacement and a relative energy measure. One of the consistent damage measures has been proposed by [4] for the finite element structural analysis and monotonic loading. Another consistent damage measure has been proposed in [5, 6] based on the reduction of structural stiffness. However, the structural stiffness is a multi-dimensional function and several difficulties appear by derivation of a scalar global damage index from a multi-dimensional functional.

Apparently, seismic design needs not only proper local damage indices, but also proper global ones. It is, however, hardly possible to define a global damage measure for all structural types and all structural materials such as reinforced concrete, steel and masonry. The objective of the present work is, therefore, to define proper local and global damage indices only for reinforced concrete structures. They shall vary between 0 (state without damage) and 1 (failure or collapse).

For the current study, the finite element program FRAME has been developed within the Matlab environment [7] using classical beam elements. In this program, elasto-plastic bilinear moment-curvature relationships are used for the nonlinear material model including hysteretic behaviour under cyclic and dynamic loading. The stiffness matrices of the elements are obtained by use of the spread plasticity model along the length. The Newmark-Beta method with constant average acceleration is applied for the step-by-step time integration of the governing equations. A variety of examples has been analysed by the program to check out the sensitivity of the global damage indices for reinforced concrete moment frames.

2 COMPUTATIONAL MODELS FOR MATERIAL AND MEMBER BEHAVIOUR

Both static (push-over) and dynamic nonlinear analysis procedures can be used in seismic design. The relevant nonlinear material and member models have to be defined for the nonlinear analysis. In the present work, the nonlinear material model of a reinforced concrete member is defined on the level of the moment-curvature relationship of its cross-section. For monotonic loading, the moment-curvature relationship can be defined as a piecewise linear diagram containing the characteristic points associated with the cracking, yielding and failure states of the member. However, the key issue in material modeling for cyclic and dynamic

The obvious advantage of this definition is a scalar damage index, D , ranging from 0 (no damage) to 1 (failure).

At the cross-section level, for example, at pure bending, the damage index can be derived in a similar way from the reduction of the bending stiffness EI of the beam elements:

$$D = \frac{(EI)_0 - (EI)_x}{(EI)_0 - (EI)_f} \quad (2)$$

However, these damage measures are local and it is a challenge to define a similar scalar global damage index for the entire structure. [5] showed that a scalar global damage index can be quantified by the reduction of the structural stiffness represented by some scalar characteristic values λ :

$$D = \frac{\lambda_0 - \lambda_x}{\lambda_0 - \lambda_f} \quad (3)$$

Nevertheless, the choice of λ characteristic values is a challenge. It is more suitable to define a damage index based on scalar deformation energy. [4] proposed to define a global damage index as the relative reduction of the whole structural deformation energy (W_p) with respect to an initial value in the non-damaged state (W_p^0):

$$D = \frac{W_p^0 - W_p}{W_p^0} = 1 - \frac{W_p}{W_p^0} \quad (4)$$

At that, the global damage index is a scalar varying between 0 (state without damage) and 1 (failure state). By use of the finite element simulation, this energy-based global damage index can be calculated from the actual displacement field as follows:

$$D = 1 - \frac{W_p}{W_p^0} = 1 - \frac{\sum_e \mathbf{a}^T \int_{V_e} \mathbf{B}^T \boldsymbol{\sigma} dV_e}{\sum_e \mathbf{a}^T \int_{V_e} \mathbf{B}^T \boldsymbol{\sigma}_0 dV_e} \quad (5)$$

where \mathbf{a} stands for the nodal displacement vector, \mathbf{B} for the strain shape matrix and V_e for the volume of each finite element e . Further, $\boldsymbol{\sigma}$ denotes the actual stress vector and $\boldsymbol{\sigma}_0$ the stress vector calculated for the undamaged material and the same global displacement \mathbf{a} . Herein, the total potential energy W_p as well as W_p^0 is accumulated over all finite elements.

However, the local and global damage indices discussed above are suitable for the monotonic loading. They can be mainly used in the push-over analysis. Damage indices suitable for cyclic and dynamic analysis shall be properly defined. Several empirical local damage indices for cyclic or dynamic loading have previously been proposed. [10] proposed a theoretical local cyclic damage index by using the absorbed energy calculated from the moment-curvature relationship. At first, the damage indices for the positive and negative directions are separately calculated. Then, the cyclic local damage index is defined by their superposition as follows:

$$D = D^+ + D^- - D^+ D^- \quad (6)$$

This local damage index is defined on the cross-sectional level and cannot be used for the damage state of the whole structure. Nevertheless, the idea of defining two separate damage indices for positive and negative directions can be combined with the monotonic energy based global damage index [11]:

$$D_G^{\pm} = 1 - \frac{\sum_e (a^{(e)T} - a_0^{(e)T}) \cdot K_d^{\pm(e)T} \cdot (a^{(e)T} - a_0^{(e)T})}{\sum_e (a^{(e)T} - a_0^{(e)T}) \cdot K_0^{\pm(e)T} \cdot (a^{(e)T} - a_0^{(e)T})} \quad (7)$$

The cyclic or dynamic global damage index can be then obtained in a similar manner from the superposition of the two separate global damage indices:

$$D_G = D_G^+ + D_G^- - D_G^+ D_G^- \quad (8)$$

4 EXAMPLES

4.1 RC Column

The new proposed global cyclic damage measure is applied on a canti-lever reinforced concrete column which is originally tested by [12]. The column was subjected to horizontal cyclic loading. Its geometry, reinforcement and cross-sectional properties are shown in Fig. 3 and its material properties are given in Table 1.

Figure 3: Geometry, cross-section and reinforcement of the RC column.

Concrete	Reinforcing steel
Young's modulus $E_c = 29634 \text{ M N/m}^2$	Young's modulus $E = 201000 \text{ M N/m}^2$
compressive strength $f_{cm} = 35,6 \text{ MN/m}^2$	yielding strength $f_y = 514 \text{ M N/m}^2$
	ultimate strength $f_u = 593 \text{ M N/m}^2$
	ultimate tensile strain $\epsilon_{su} = 0.0044$

Table 1: Material properties of the RC column

The moment-curvature diagram of the section at the base is given in the Fig. 4. It is in a good agreement with the bilinear hysteretic material model. It can be seen from the calculated force-displacement diagram of the upper corner that the obtained structural response correlates well with the experiment (Fig. 5). In Fig. 5, the variation of the cyclic global damage index is also shown. With each loading cycle, its value gradually increases and becomes close to 1 at failure, as expected.

Figure 4: Moment-curvature relationship of the cross-section at the base of the RC column.

Figure 5: Force-horizontal displacement of the upper corner of the RC column.

4.2 Portal Frame

The new proposed global dynamic damage measure is applied on a reinforced concrete portal frame which is tested by [13]. The portal frame was subjected to a steady-state harmonic ground acceleration given in Fig. 8. Its geometry is given in Fig. 6 and its material properties in Table 2. The reinforcement and cross-sectional properties are shown in Fig. 7.

Figure 6: Geometry and mass distribution of the portal frame.

Figure 7: Reinforcement and cross-sections of the portal frame

$E_s = 199948 \text{ MN/m}^2$
$E_c = 21836 \text{ MN/m}^2$
$f_{sy} = 351.63 \text{ MN/m}^2$
$f_{cy} = 32.75 \text{ MN/m}^2$
$M = 972 \text{ kg}$
$A_s = 1.43 \text{ cm}^2$

Table 2: Material properties of the portal frame.

Figure 8: Base acceleration applied to the portal frame

The time-maximum horizontal displacement diagrams of the recorded and calculated response are shown in Fig.9 and 10 respectively. It can be seen from these diagrams that the obtained structural response correlates well with the experiment. In Fig. 11, the variation of the dynamic global damage index (D_G) is also shown. During the first loading cycle, the value of D_G gradually increases. After the first loading phase it becomes 0.42 and after the loading in the opposite direction it increases rapidly to 0.69. During the following loading cycles the value of D_G increases firstly by a small amount then it remains constant as expected.

Figure 10: Calculated response.

Figure 11: Displacement and global damage index under dynamic loading.

5 CONCLUSIONS

Damage measures for cyclic and dynamic loading have been proposed for reinforced concrete frames. These damage measures have been tested and compared to experiments. The proposed damage indices stand in a good agreement with the observed damage in experiments and provide a reliable damage measure for seismic design.

Keywords: Curved Bridges, Nonlinear Analysis, N2 Pushover Method, Local and Global Capacity Demands.

Abstract. *The seismic safety assessment of bridges using nonlinear static analysis methods is not straightforward. Not only an accurate modelling of the structural frames inelastic behaviour is required, but also a correct definition of the force distribution patterns, analysis directions, reference points and target displacements that best represents its seismic structural performance. This difficulty on the pushover parameters definition increases when irregular-in-plan bridges are considered, namely curved bridges. Hence, the aim of this study is to assess the seismic safety of a set of curved bridges using the eurocode's pushover analysis method. Particular attention is paid to the RC columns biaxial behaviour modelling. The bridge structural response is evaluated in terms of global and local capacities. Comparative evaluation of the calculated response of the bridges illustrates the applicability of the N2 pushover method and the influence of the different directions of analysis in its local and global capacity demands definition.*

1 INTRODUCTION

Since the early 1960s, irregular-in-plan curved bridges have gained high popularity, particularly in the highway interchanges and urban expressways, as a result of geometric constraints, limitations of space and high density of urban traffic [1].

However, due to the relative particularity of its forms, curved bridges present an apparently different dynamic response when compared to common straight bridges, which may naturally affect its seismic behaviour. Indeed, in view of the collapse of some curved bridges during the 1971 San Fernando earthquake, United States of America, D. Williams and W. Godden [2] conducted a shaking table test study of a scaled microconcrete curved bridge model, which main objective was to evaluate the effects of both linear and nonlinear dynamic behaviour and the influence of the expansion joints to its resistance capacity. W. Tseng and J. Penzien [3] have also studied the nonlinear seismic response of long, multiple-span, reinforced concrete curved and straight bridges, and concluded, alike [2], that the ductility requirements at the column bases of curved bridges are not so critical and important compared to the levels observed in long straight bridges.

Likewise, N. Burdette and A. Elnashai [4] observed that, in the transverse direction, the curved decks provide greater stiffness to the structure through arch or catenary action, while the straight decks resists transverse forces in flexure, which allows more of the pseudostatic displacements to be absorbed by the bridge deck. However, when the longitudinal direction was analysed, the opposite was observed, that is to say, curved bridges resists inertial forces by a combination of flexural and axial stiffness of the deck, while the straight bridge deck resists these forces efficiently in pure tension and compression, giving the structure a greater stiffness longitudinally.

Therefore, the seismic response of curved bridges usually should be considered in both longitudinal and transverse directions, having the direction of the input seismic action, the planar irregularity and the two-axis related bending a great role on the maximum values of the response [5-8].

The use of nonlinear dynamic time-history analysis (THA) is, by far, the most reliable method to assess the seismic behaviour of structures, particularly the irregular ones. However, it requires a high effort of computational capacity and time, which increases when multi-directional seismic actions are considered. Thus, nonlinear static pushover analysis (PA) appears as an interesting alternative, more simple and expeditious.

The applicability of PA method to bridges has been extensively studied recently and numerous variants of the traditional method, with increasing accuracy and complexity, are available today [9-11]. However, a limited number of studies focused the use of pushover analysis in curved bridges [5, 12-14].

The seismic assessment of bridges using PA methods is not straightforward. Not only an accurate modelling of the structural frames inelastic behaviour is required, but also a correct definition of the force distribution patterns, analysis directions, reference points and target displacements that best represents its seismic structural performance. This difficulty increases when irregular-in-plan bridges are considered, since the columns tend to present biaxial behaviour and the critical input angle of the seismic action, as well as the respective direction of analysis, vary with the type and curvature of the structure.

In view of the previous considerations, the present study attempts to assess the seismic response of a set of curved bridges using the Eurocode's [15, 16] pushover method. Some practical procedures that take into account the different directions of analysis are presented and the results obtained compared to those obtained using THA. Special attention is paid to the evaluation of the seismic action critical input angle and to local and global capacities.

2 PUSHOVER ANALYSIS PROCEDURE

The PA method proposed by the Eurocode 8 is the well known N2 method, firstly developed by P. Fajfar and M. Fishinger [17] to assess the seismic behaviour of regular buildings. The Eurocode 8 presents the PA procedure for bridges in both Parts 1 [15] and 2 [16], defining, in the first, the method to determine the target displacement from the structures capacity curve and, in the second, the parameters that allow the capacity curve definition, such as the directions of analysis, reference points and load distributions.

As mentioned above, with the increasing of the curved bridges radius of curvature, the dynamic response tends to change significantly. In these cases, the principal direction of analysis is no longer the transversal one and a set of different oriented directions of analysis should be considered, in order to obtain the critical response direction. According to Eurocode 8, only two horizontal directions of analysis should be considered: a longitudinal X-direction, defined by the centres of the two end-sections of the deck; and a transverse Y-direction, that should be assumed to be orthogonal to the first.

Additionally to these directions of analysis, the Caltrans SDC [18] recommends the application of the ground motion along the principal axes of individual components. The ground motion must be applied at a sufficient number of angles to capture the maximum deformation of all critical components.

Therefore, having both normative recommendations in consideration, the steps of the PA adopted procedure are summarized in the following:

- Once defined the geometry and the structural models of all analysed bridges (Figure 2 (A)), the first step consists on the selection of the PA load distribution patterns (Figure 2 (B)). According to Eurocode 8 the pushover curves must be obtained by pushing the entire bridge structure with two load distributions patterns: a constant along the deck pattern (Pac) and a proportional to the first mode shape pattern (PAm). In spite of not being mentioned by the European Standard, it is recommended [12, 13] to carry out the pushover analysis in both positive and negative transverse direction when irregular-in-plan structures are not symmetric. Since the importance of the longitudinal response of curved bridges increases with the radius of curvature, a third pushover pattern (proportional to the mode with higher mass participation factor in the X-direction) is also proposed by some researchers [12,13] (PAxm). Finally, with the objective of capture the critical direction of the curved bridges response, a constant along the deck pattern with a variable local axis orientation (PAvoc) will be adopted as well. It should be noted that the global X-Y axis is defined by the Eurocode's directions of analysis and the local X'-Y' axis by the principal axes of individual columns elements and abutments, as presented in Figure 1.

Figure 1: Local and Global axes.

- The second step concerns the construction of the total base shear vs displacement of reference point pushover curve for each considered load distribution pattern (the reference point, according to Eurocode 8, should be the centre of mass of the deformed deck) and for the various directions of analysis. The local $X'-Y'$ axis capacity curves are obtained from converted deck displacements and shear forces, as it is represented in Figure 2 (C).
- The last step of the presented PA procedure refers to the determination of the earthquake displacement demand associated with each pushover curve obtained previously (Figure 2 (C)). For such, the multi-degree-of-freedom (MDOF) system pushover curves must be transformed into equivalent single-degree-of freedom (SDOF) system pushover curves through a transformation factor, Γ , as it is proposed in [15]. This transformation factor depends on the normalized displacements, which should be taken as local axis converted normalized displacements depending on the direction of analysis. Once determined the target displacement for the SDOF system, d_t^* , using an idealized elasto-perfectly plastic force-displacement relationship, the final MDOF system target displacement of the control node, d_t , is given by Γd_t^* (Figure 2 (C)).

Previous studies [9-11] have shown that traditional PA methods generally works reasonably well when applied to bridges of regular configuration. However, T.S. Paraskeva *et al* [12] concluded that a single mode-based load pattern should not be used in bridges with strong curvature in plan, even when they qualify as regular. Hence, the results obtained using the presented PA procedures should be evaluated by comparisons with those obtained using a more accurate THA (Figure 2 (D)).

3 STRUCTURAL MODELING AND DYNAMIC CHARACTERISTICS OF THE ANALYSED CURVED BRIDGES

This study considered six different curved bridges, defined from the well-known P232 PREC8 regular bridge [19], with infinite, 1000m, 700m, 420m, 240m and 130m radius of curvature of the deck, as represented in Figures 2 (A).

The bridges were modelled using the SAP2000 analysis program considering concentrated plasticity at the columns base (Figure 3), so as to represent the Eurocode's idealized local ductility cantilever model. SAP2000 allows the definition of lumped inelastic rotational hinges through backbone uncoupled or interaction MM models and fiber models [20]. Although the use of backbone models, with Takeda's hysteretic model, ensures a lower effort of time and processing capacity, they fail to perform a 3-dimensional dynamic analysis. Thus, knowing the importance of the columns biaxial behaviour in curved bridges, a more accurate fiber hinge model was adopted. The fiber hinge computes a moment-curvature relation in any bending direction for varying levels of axial load by assigning particular material stress-strain relationships to individual discretized fibers in the cross section. The longitudinal column reinforcement stress-strain relationship was defined by a bilinear model with kinematic hysteretic behaviour, while the confined and unconfined concrete stress-strain relationships were defined by the J. Mander *et al* [21] model with Takeda's hysteretic behaviour. The lumped plasticity is assumed to occur over a plastic hinge length and is specified at the middle of the plastic hinge. The plastic hinge length was defined by the Eurocode's Annex E [16] expression. The remaining elements of the structure were taken as linear-elastic and the masses were lumped at the top of the columns and midspans (Figure 3).

The individual capacity curves of each column of the P232 Bridge, defined in terms of moment-displacement and force-displacement relationships, for both longitudinal and transverse directions, are presented in Figure 4.

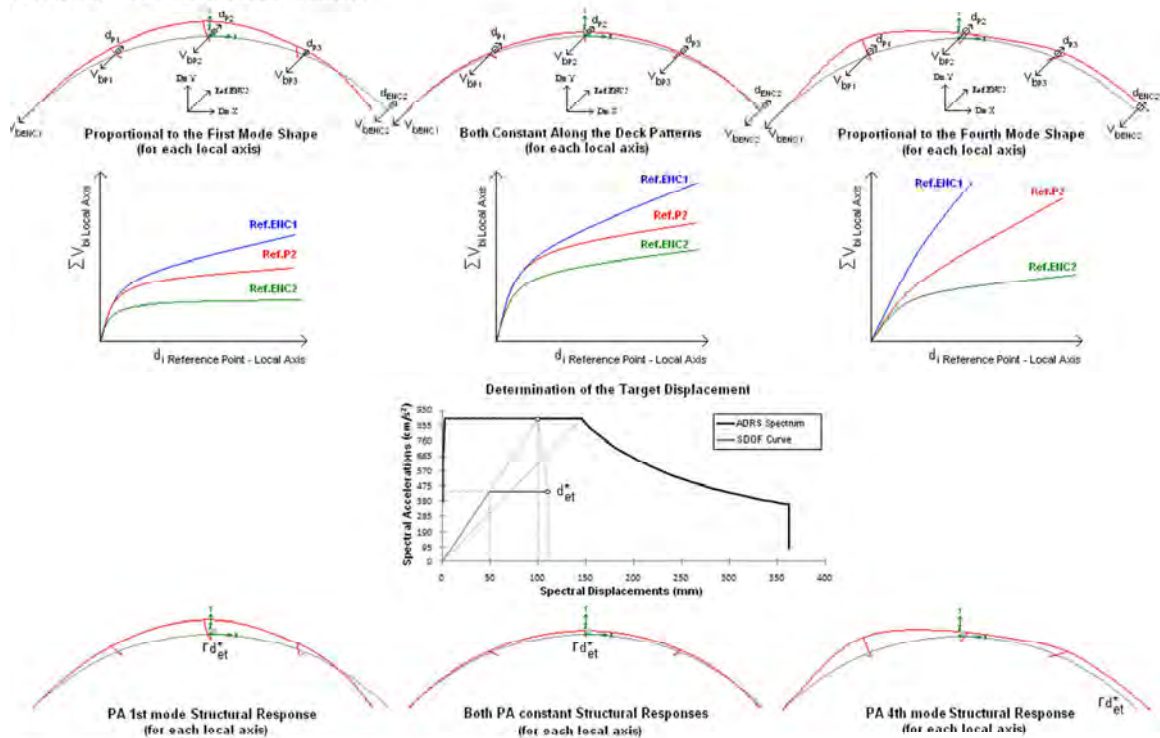

(A) Geometry and Structural Models Definition

(B) Lateral Load Patterns Adopted

(D) Comparison with the Time-History Nonlinear Analysis (THA) Method

Figure 2: Analysis procedure adopted.

Figure 3: Structural model with concentrated plasticity at the columns base.

Figure 4: Capacity curves of each column in both longitudinal and transverse directions.

It is also presented in Figure 4 the yield displacements values of the RC columns in both directions, evaluated by idealising the actual F-d diagram by a bilinear diagram of equal area beyond the first yield of reinforcement, as it is proposed in [16].

With regard to the dynamic characteristics of the analysed curved bridges, it can be seen from Figure 5 a significant and expected variation on the modal eigenvalue properties with the increase of the radius of curvature. Likewise, Table 1 exhibits the evolution of the modal mass participation ratios of the 1st and 4th modes of vibration (which represents, respectively, the bridges responses on the transverse and longitudinal directions) with the curvature of the deck, being evident a counterbalanced decrease of the 1st mode importance with the increase of the 4th mode importance in the Y-direction, and the opposite in the X-direction.

Modal Mass Participation Ratios (%)				
Bridges	1 st Mode of Vibration		4 th Mode of Vibration	
	Y-Direction	X-Direction	Y-Direction	X-Direction
Straight Bridge	91	0	0	90
Radius = 1000m	89	1	0	64
Radius = 700m	89	2	0	58
Radius = 420m	85	5	13	40
Radius = 240m	76	14	20	42
Radius = 130m	54	34	36	23

Table 1: Evolution of the modal mass participation ratios with the curvature of the deck.

Figure 5: Transverse and longitudinal mode shapes and respective frequencies of vibration.

Before presenting the main results obtained through the adoption of the previously exposed PA procedures, some preliminary values, in terms of target displacements, are displayed in Figure 6. An evident divergence between the PAM, PAC and PAXm results is observed, particularly in the case of the PAXm results, which are well below the expected. Hence, as the PAXm results are not representative, from now on they will not be considered.

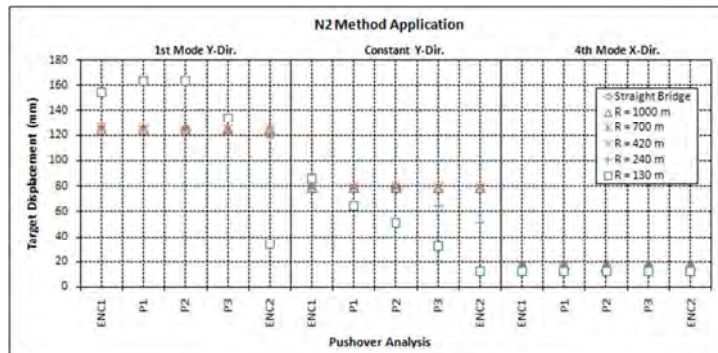

Figure 6: N2 Method application: target displacement values.

4 PUSHOVER CAPACITY CURVES

The pushover capacity curve definition step is one of the most important in the PA procedure, since it is the step that defines the structures characteristics through their total base shear vs displacements of the control node curves. As mentioned above, in order to represent the behaviour of the bridges in several directions of analysis, the construction of the capacity curves will be conducted from local axis converted deck displacements and shear forces, being the chosen local axis systems defined by the principal axes of the individual columns elements and the abutments (Figure 1). These local axis systems were obtained from the rotation of the generic global X-Y axis, with the rotation angles presented in Table 1 for each analysed curved bridge.

Bridges	Local Axis Rotation (°)				
	ENC1	P1	P2	P3	ENC2
Straight Bridge	0	0	0	0	0
Radius = 1000m	5,5	3,0	0	-3,0	-5,5
Radius = 700m	8,0	4,3	0	-4,3	-8,0
Radius = 420m	13,4	7,2	0	-7,2	-13,4
Radius = 240m	23,9	12,6	0	-12,6	-23,9
Radius = 130m	44,9	23,8	0	-23,8	-44,9

Table 1: Global to local axis rotation.

Therefore, the PAm, PAc and PAvoc capacity curves, for each local axis systems and both X' and Y' directions, are plotted in Figures 7 to 12. Two major conclusions can be drawn by the analysis of these figures, concerning the influence of the local axis and the curvature of the deck.

Firstly, and as aforementioned above, it is easy to verify a significant variation in the curved bridges structural response with the increase of radius of curvature. If one only considers the local P2 axis results, which are identical to the global axis results, an important divergence in the Y'-direction pushover curves can be noted in the case of the PAc and PAvoc (Figures 9 and 11). For instance, under these circumstances, a similar 0,1m displacement demand at the top of the P2 central pier leads to a 25000 kN base shear in the stronger curved-in-plan bridge, while in the straight bridge it only leads to a 15000 kN base shear, representing a 40% variation. On the other hand, the X'-direction capacity curves revealed a higher divergence in the PAm (Figure 8), as expected with the evolution of the modal mass participation ratios. Thus, it can be seen that the longitudinal capacities of the analysed bridges increased, from zero (straight bridge), with the increase of the first mode X'-direction participation ratios.

The second major conclusion concerns the influence of the local axis systems in the definition of the analysed bridges pushover curves, and, consequently, on their structural capacities along the various directions of analysis. Not only can be observed from Figure 12 that bridges with stronger deck curvature tend to be more affected by different directions of analysis, but also that the direction of analysis defined by the ENC2 local axis seems to lead to lower capacity curves, while the ENC1 local axis direction of analysis lead to higher capacity curves, which is due to the higher longitudinal displacements of the ENC2 roller support.

The sequence of plastic hinge formation was also derived for both straight and higher curved bridges, as presented in Figure 13, which allows us to understand the latter conclusions. It can be noted that the sequence of plastic hinge formation is much closer to being simultaneous in the transverse direction of the straight bridge, behaving practically like an SDOF system, than in the transverse direction of the bridges with higher deck curvature for each local Y' axis, wherein hinging is also affected by higher modes, like the longitudinal mode, and takes place at differently stages of the response. Furthermore, as also displayed in Figure 13, the hinging formation inverts its sequence with the various directions of analysis, in agreement with the respective local axis converted first mode shapes. Thus, the P3 column reaches the yielding point (at a 0,5m displacement, Figure 4) earlier in the ENC1, P1 and P2 directions, while the P2 column is the one to first yield in the P3 and ENC2 directions, wherein the bridge response has rotated from its transverse response to its longitudinal response.

Interesting results were also observed through the application of the alternative constant along the deck patterns, PAC and PAVOC, whereby the forces acting at each node are proportional to the nodal mass in the considered directions of analysis. These patterns are mainly used as a mean of identifying critical combinations of shear and flexure in each vertical element of bridge structures. The PAC and PAVOC capacity curves bring forward a higher overall strength of the system when compared to the PAM capacity curves, which may be explained by the fact that, while the first mode shape tends to present a single column with a significantly larger displacement, and so with a higher modal force, the constant patterns tends to equally distribute the inertial force at all columns, if the masses at each one are similar. As a result, for the same displacement demand, higher forces are developed in the PAC and PAVOC cases.

In terms of PAC and PAVOC capacity curves comparison, it can be verified that, as the curvature of the bridges increase, the capacity curves tend to diverge, particularly in the case of the P3 and ENC2 local axis.

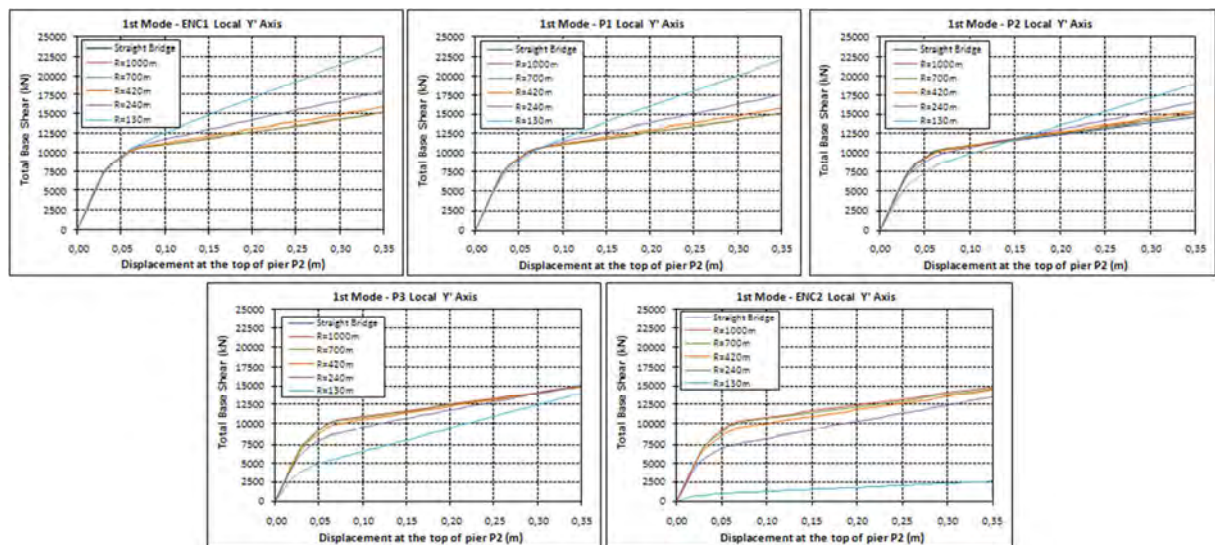

Figure 7: PAm capacity curves for each local Y' axis.

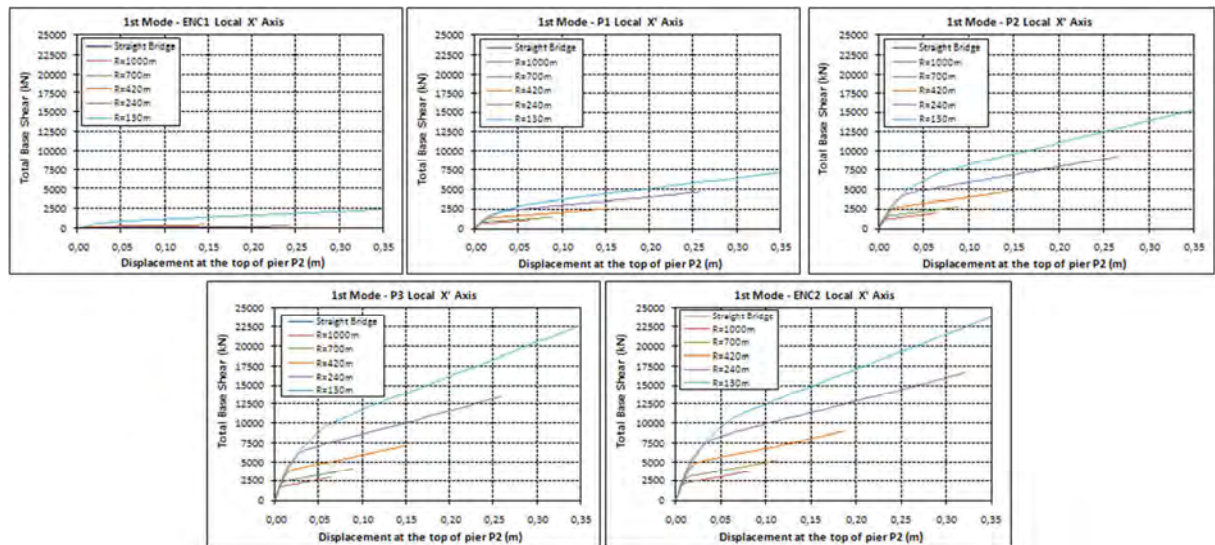

Figure 8: PAm capacity curves for each local X' axis.

Figures 9 and 11 demonstrate that the overall strength of the bridges grows with the rotation of the local axis from ENC2 axis to ENC1 axis, namely in the case of the more curved bridges. As said before, this grow can be explained by the change in the type of the response, what, in other words, means that ENC1, P1 and P2 local axis seems to characterize the transverse response of the bridges, while P3 and ENC2 local axis seems to represent their stiffer longitudinal response. Unlike the PAc procedure, that considers converted local axis capacity curves from the global axis capacity curve, and so equally converted inertial forces, the PAvoc method admits that the same inertial forces are applied in each direction, proportionally to the lumped masses. For this reason, the PAvoc capacity curves present a higher overall strength of the system comparatively to the PAc capacity curves. This may suggest that the PAc procedure loses feasibility when applied to bridges with strong curvature in plan.

5 APPLICABILITY OF N2 PUSHOVER METHOD

Previous studies [11, 12, 22] have shown that, for bridges with an effective modal mass of the fundamental mode equal or greater than 80% of its total mass, the N2 method in general works fine. Once, in short bridges the effective mass of the fundamental mode increases together with the seismic intensity, in this cases the accuracy of the N2 method also increases. Therefore, good results are expected with the application of the N2 method to bridges with high first mode modal mass participation ratios (Table 1).

However, when this fundamental mode mass ratios decrease, the higher modes start to significantly influence the response, regardless of the seismic intensity. Hence, according to [12], simplified pushover procedures should not be used in bridges with high curvature in plan.

In line with the latter considerations, a most reliable analysis procedure must be used in order to correctly evaluate the applicability of the N2 method to all analysed bridges. Thus, the nonlinear dynamic time-history analysis (THA) will serve as a benchmark for this evaluation.

5.1 Nonlinear Time-History Analysis (THA)

Contrarily to the nonlinear static analysis methods, the THA accounts for strength degradation of different elements of the bridge, as well as the influence of all modes and the characteristics of the dynamic response, making it the more accurate method of analysis. The general approach for the solution of the dynamic response of structural systems is the direct numerical integration of the dynamic equilibrium equations at a discrete point in time. Several time-integration methods are available, such as the Newmark and Hilber-Hughes-Taylor (HHT) algorithms. According to [13], the latter is more beneficial under high input ground motions, because it can reduce the high short-duration peaks in the solution, therefore it will be employed in this study. It should be noted that, if convergence problems occur during nonlinear analysis, the HHT method should be used initially with an $\alpha = -1/3$ to get an approximate solution. The analysis should then be repeated with decreasing α values to obtain greater accuracy in the results [20]. Moreover, as the results are extremely sensitive to time-step size, a time step of 0,0001s is recommended to ensure a consistent convergence of displacements [22]. A uniform damping value of 5% was assumed for all modes of vibration, as proposed by [16] for reinforced concrete structures, through the use of the Rayleigh damping coefficients. The THA was conducted considering a set of artificial records compatible with the Portuguese EC8 elastic spectrum, as presented in Figure 14.

In spite of the SAP2000 fiber model ability to represent successfully the degradation and softening after yielding, it not includes the pinching and bond slip effects. Moreover, SAP2000 requires a high effort of processing time for a cross-section discretization number of 200 fibers and the referred time step size. Therefore, the THA analysis was conducted using the SeismoStruct analysis program, well known by the scientific community.

Figure 14: Seismic action adopted: EC8 response spectrum (Type 1 seismic action, Zone 1 and Ground Type D of the Portuguese National Annex) and respective generated artificial accelerogram and response spectrum.

Figures 15 and 16 depict the THA results, being evident the same conclusions drawn in the previous analysis of the pushover capacity curves. In agreement with the dynamic characteristics of the studied curved bridges, as the curvature in plan increases, the higher modes of the structure gain importance, namely the longitudinal mode of vibration. Thus, it may be seen from Figure 15 a reduction on the bridges Y-direction flexural bending moments and a contrary increase in the X-direction flexural bending moments, of approximately 40% in the P1 pier and 70% in the P3 pier, respectively. From Figure 16 it can also be observed the evolution of the longitudinal response of the various studied bridges.

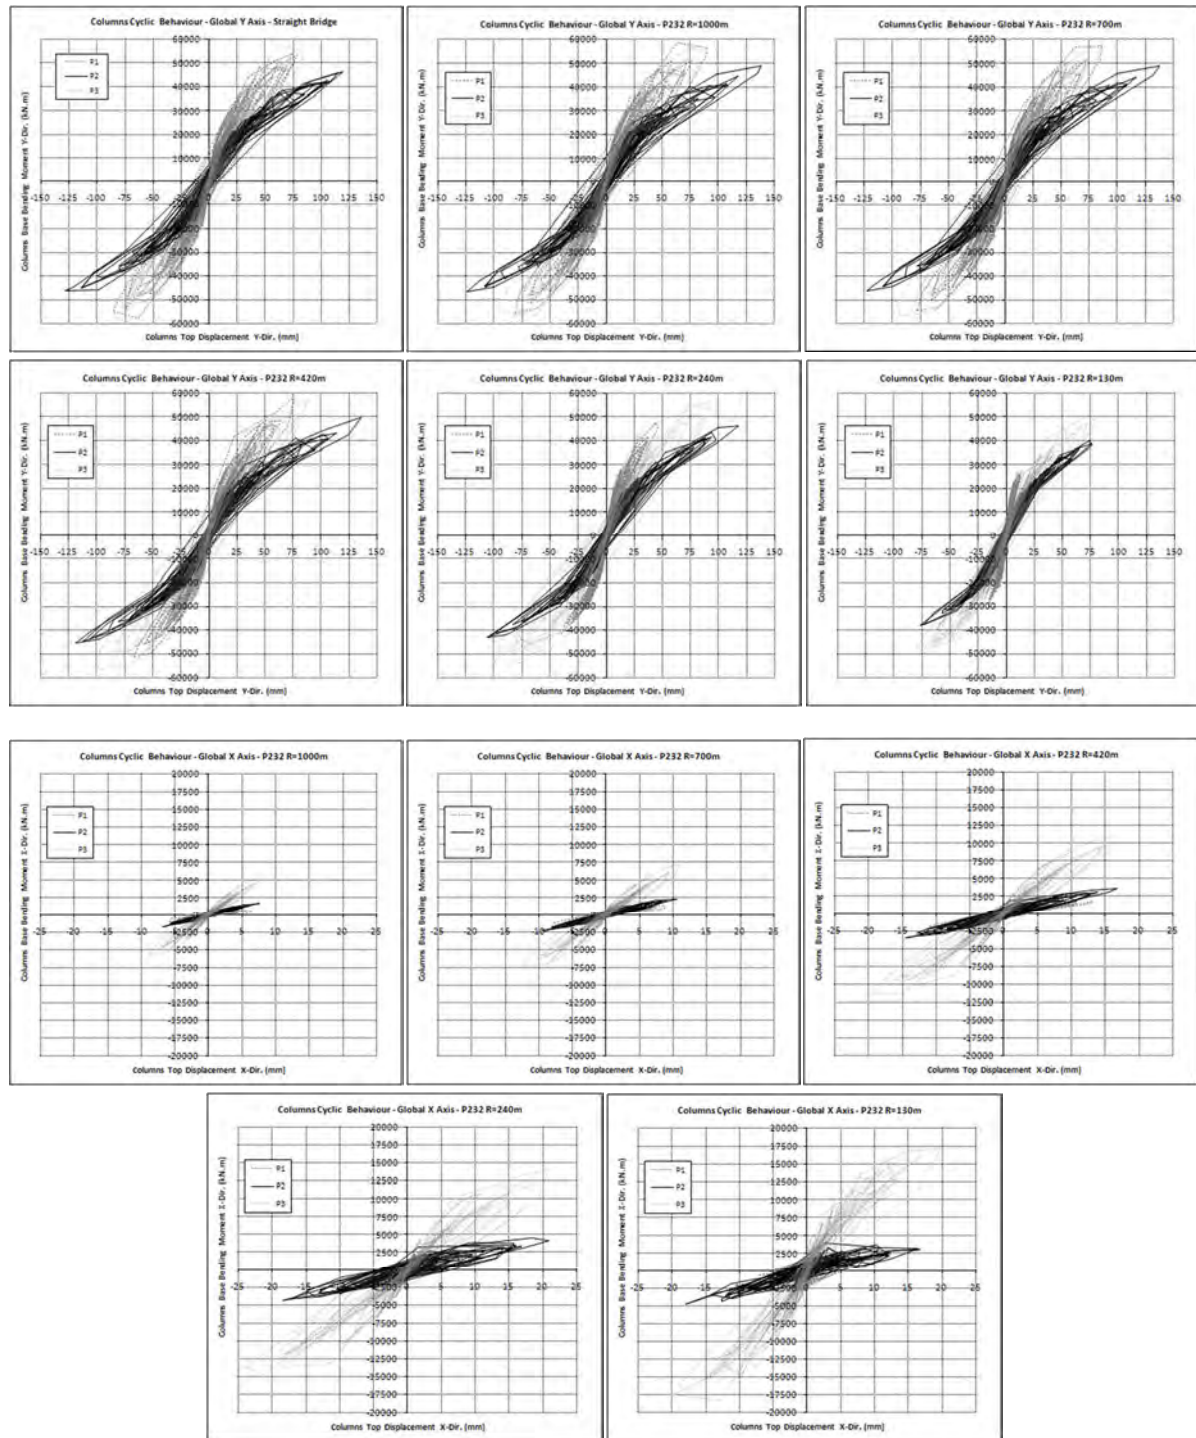

Figure 15: Columns cyclic behaviour for each analysed bridges using THA applied along the global Y axis.

Figure 16: Influence of the seismic action input angle on the R=700m, R=240m and R=130m bridges response using the THA.

Notwithstanding, special attention should be given to the influence of the local axis systems on the bridges response. In this case, displacements variations of approximately 80%, 50% and 3% between ENC1 and ENC2 local axis systems can be observed for the Y-direction and for the bridges with radius of curvature of 130m, 240m and 700m, respectively.

5.2 Evaluation of the N2 Pushover Method by Comparisons with Time-History Analysis

During the feasibility assessment of the previously presented pushover procedures, two main comparison criteria should be taken into account: a first PA vs THA comparison criteria, which seeks the evaluation of the simplified pushover procedures by comparisons with a more refined method of nonlinear analysis; and a second PAc and PAvoc comparison criteria, which intends to evaluate the applicability of the deck displacements and shear forces conversion technique.

As mentioned above, it can be seen from Figure 17 that the PAm procedure worked very well in the case of the P232 straight viaduct, in accordance with the 91% value of the 1st mode mass participation ratio (Table 1). The bridges response is thus clearly governed by its transverse direction fundamental mode. On the contrary, the PAc procedure underestimated the deck displacements values, with an approximately 30% variation with regard to the THA result. This expected variation is due to the equal distribution of the inertial forces along the bridges piers, which allows the structure to develop a higher overall strength.

For its part, Figures 18, 19 and 20 present the response in terms of deck displacements of the bridges with a smaller curvature in plan and with a 1st mode mass participation ratio high-

er than 80%. In accordance with both comparison criteria, it can be firstly concluded that, in spite of the direction of analysis (seismic action input angle), the PAm procedure is the one that best fits the THA results; however a 16% variation in the Y'-direction P2 top displacements of the bridge with a radius of curvature of 420m can be observed between the use of the ENC1 and the ENC2 local axis systems, which was considered negligible. Once more, the PAc results are considerably below the THA results. Secondly, it can be observed that, not only the PAc results are identical to the PAvoc results, but also that the X'-direction displacements obtained using the PAm procedure fit quite well with the THA longitudinal displacements. Therefore, it can be concluded that the deck displacements and shear forces conversion technique leads to good results under these conditions.

Similar conclusions can be drawn from the analysis of Figure 23, where it can be seen that the differences between the PAm and the THA results are, in general, not higher than 20% (higher values are due to ENC2 local axis and to the slight stronger curvature of the R=420m bridge, which tend to increase the importance of the longitudinal response), and that the PAc vs THA displacements ratios overlap the PAvoc vs THA ratios.

Figure 17: Response of viaduct P232, in terms of Y-direction deck displacements, calculated from PAm, PAc and THA.

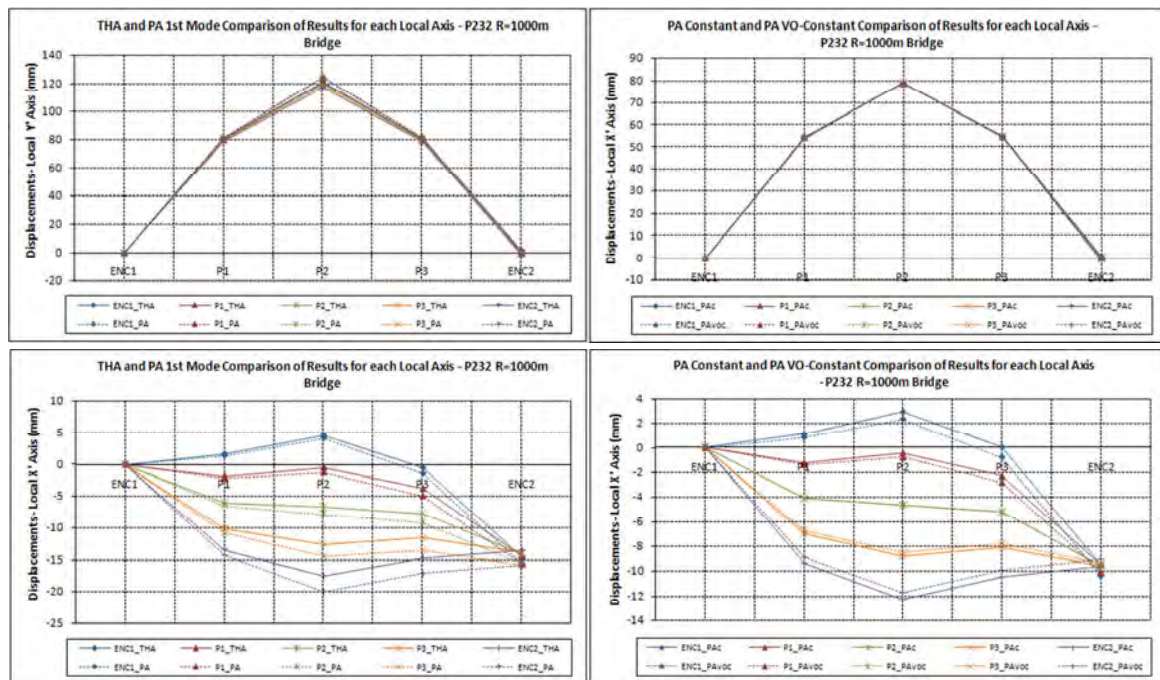

Figure 18: Response of viaduct P232 with a radius of curvature of 1000m, in terms of Y-direction and X-direction deck displacements, calculated from PAm, PAc, PAvoc and THA.

It should be noted that the outliers X'-direction ratios observed in the bridges with radius of curvature of 1000m and 700m are owing to the ratio of values that are close to zero, and so have no significance.

On the other hand, it is interesting to observe from Figure 21 that, in the case of the bridge with the radius of curvature equal to 240m, nor the application of the PAm, or the application of the PAc, leded to perfectly good results, being evident the influence of both curvature of the deck and local axis systems in the bridge response.

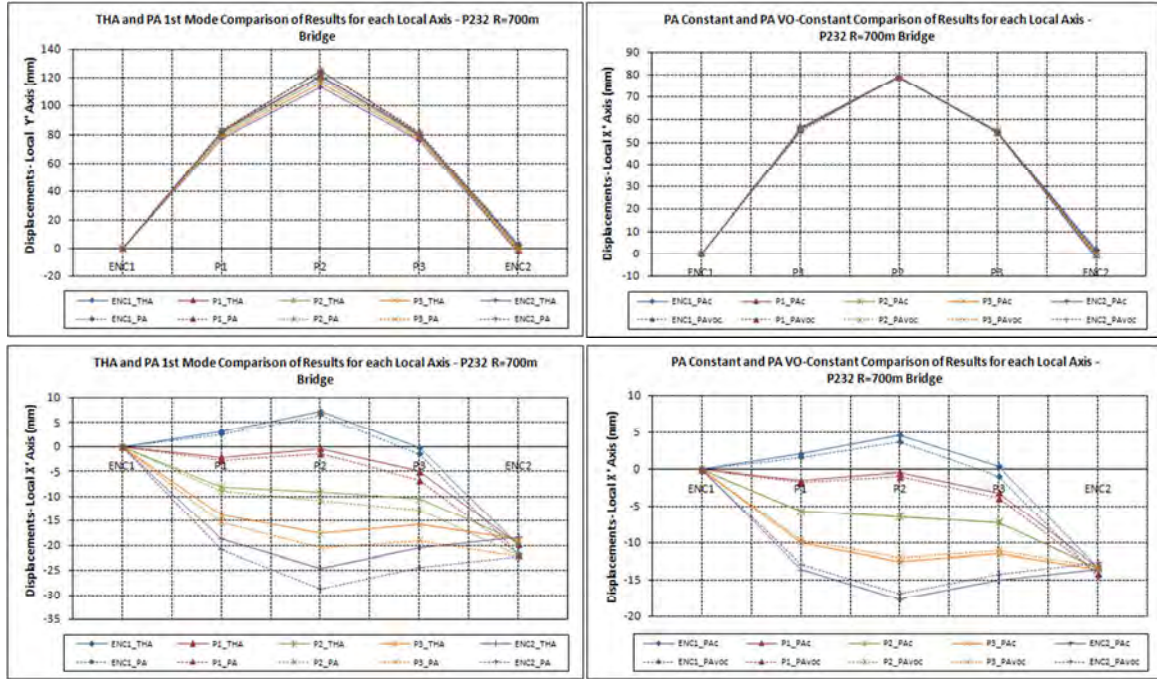

Figure 19: Response of viaduct P232 with a radius of curvature of 700m, in terms of Y-direction and X-direction deck displacements, calculated from PAm, PAc, PAVoc and THA.

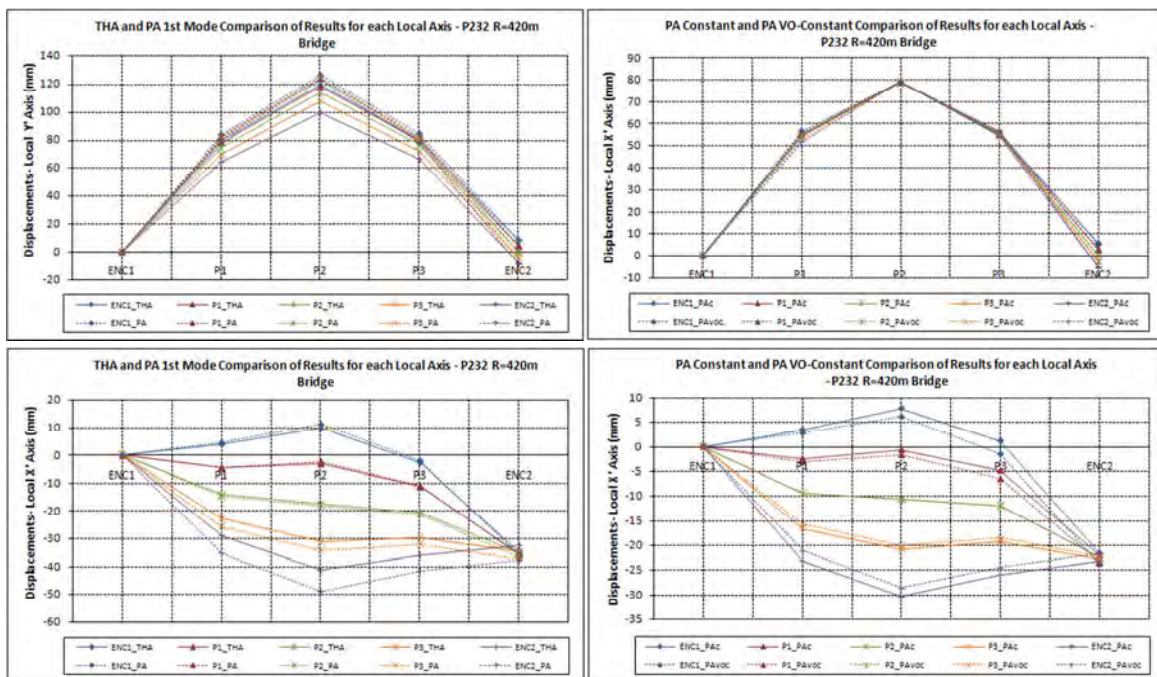

Figure 20: Response of viaduct P232 with a radius of curvature of 420m, in terms of Y-direction and X-direction deck displacements, calculated from PAm, PAc, PAVoc and THA.

Thus, while the PAm drove to relatively good results for ENC1, P1 and P2 local axis systems in both transverse and longitudinal displacements, for P3 and ENC2 local axis systems the PAm significantly overestimated the displacement demands, with a variation of 50% from the THA results in the latter case. The PAm procedure proved to be incapable of correctly reproducing the effect of the various directions of analysis in bridges with stronger curvature in plan. Although the PAc and the PAvoc procedures still to underestimate the response of the bridge, it may be noted that the results are getting closer to the THA results (Figure 23).

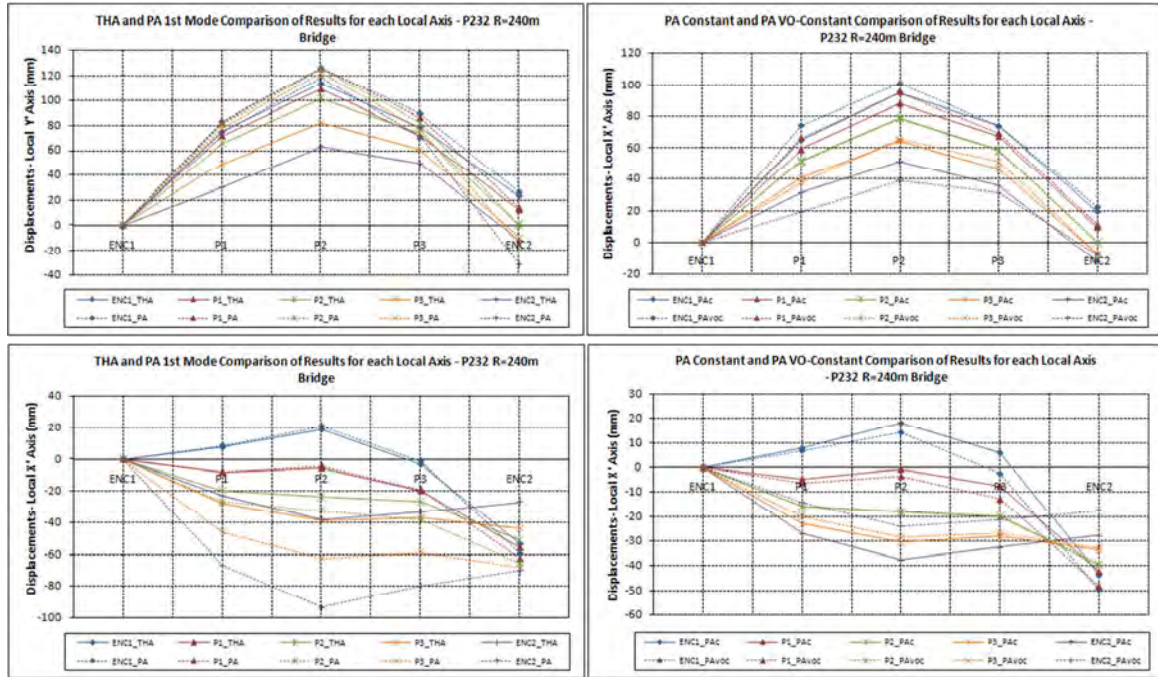

Figure 21: Response of viaduct P232 with a radius of curvature of 240m, in terms of Y-direction and X-direction deck displacements, calculated from PAm, PAc, PAvoc and THA.

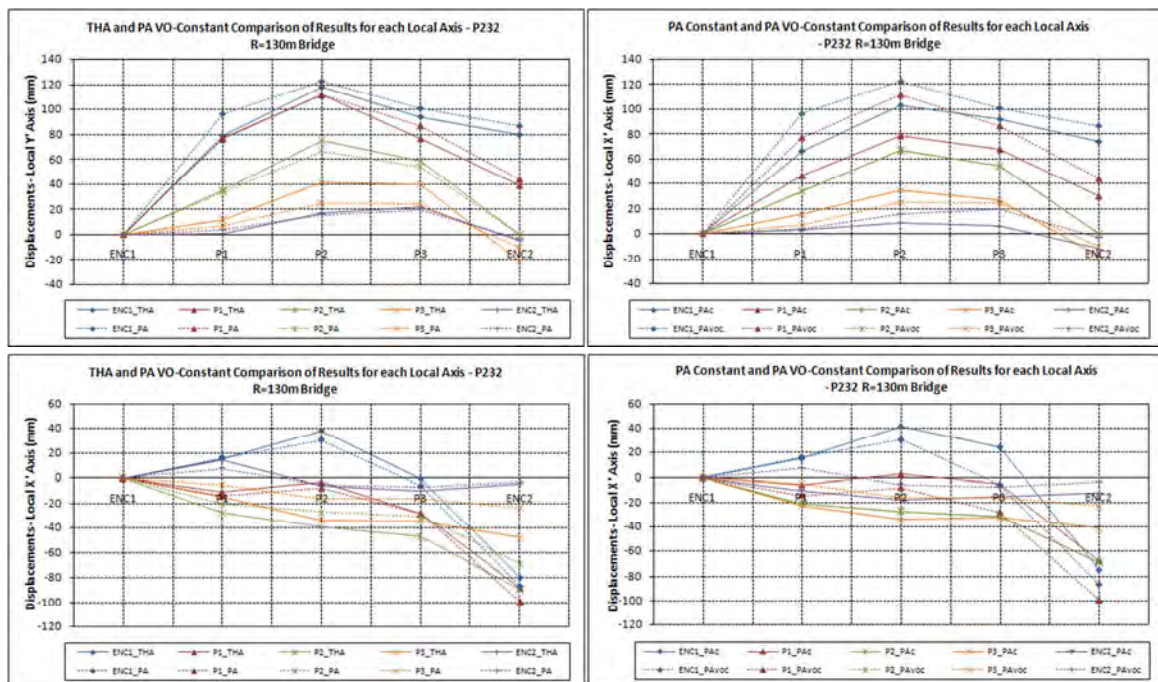

Figure 22: Response of viaduct P232 with a radius of curvature of 130m, in terms of Y-direction and X-direction deck displacements, calculated from PAc, PAvoc and THA.

It has been seen throughout this work that, for the geometric characteristics of the analysed bridges, the greater the inclination of the seismic action input angle in the direction of the left abutment, the more the curved deck will behave in flexure. Thus, the bridge response will be governed by its transverse response. On the contrary, when the seismic action is applied in the direction of the right abutment the bridge deck will behave in pure tension and the bridge response will be governed by its longitudinal response. Naturally, the validity of this statement increases with the curvature in plan of the bridge deck, such as the importance of the higher modes.

From Figures 22 and 23 it can easily be observed this influence of the local axis systems in the response of the bridge with the stronger curvature in plan, as well as the excellent approximation of the PAvoc results to the THA results and the contrary divergence of the PAm results, as already presented in Figure 6. Likewise, it can be noted that, in spite of the ability to predict the influence of the local axis systems, the PAc procedure loses accuracy when applied to bridges with a strong curvature in plan, being recommended the use of the PAvoc method in this circumstances.

A final remark regarding the third step of PA procedures, which refers to the determination of the earthquake displacement demand from the idealized SDOF system, should be taken. Not only the variation of the capacity curves with the directions of analysis (Figure 12) has an important role in the final target displacement values, but also the normalized displacements and the respective transformation factors. Thus, it was observed in stronger curved bridges that the transformation factors values decreased as the direction of the seismic action input angle rotated from the left to the right abutment, which leads to higher SDOF system idealized relationships and so to higher values of deformation energy up to the formation of the plastic mechanism, reducing the value of the target displacements. Moreover, as the final MDOF system target displacement of the control node is given by Γd_t^* , smaller values of Γ conducts to smaller final displacement values. For instance, in the case of the bridge with the radius of curvature of 130m, its ENC2 local axis system transformation factor of 0,42 led to a higher SDOF capacity curve from a MDOF capacity curve that was significantly lower than the others (Figure 12) and to a similar SDOF target displacement comparatively to the other bridges and local axis systems. However, when the transformation factor multiplied the SDOF target displacement, it led to a lower final MDOF target displacement value, as displayed in Figure 6. On the contrary, bridges with not so stronger curvature in plan and identical transformation factors and capacity curves exhibit similar target displacements values.

5.3 Local and Global Capacity Demands

The modern structural design for earthquake resistance of bridges is based on the capacity design approach, which involves three main steps: (1) choose of the desirable mechanisms that best dissipate the most energy, in the present work, the plastic hinges were only considered at the columns base; (2) verification of deformation demands, the ductility demands, in terms of plastic hinge rotations or displacements, should be safely lower than the capacities of the plastic hinges; and, (3) verification of member against non-ductile failure modes, such as shear failure or joint failure. No reference will be made to step (3) in this work, however particular attention will be paid to the verification of the deformation demands of the bridge columns (step (2)) as a mean of identify the critical seismic action input angles. Therefore, Figure 24 presents the local ductility demands at the plastic hinges of the various analysed bridges, which is expressed in terms of displacement ductility factor, given by μ_d/μ_y , where μ_d is the displacement demand at each column and μ_y the yielding displacement of the same column (Figure 4).

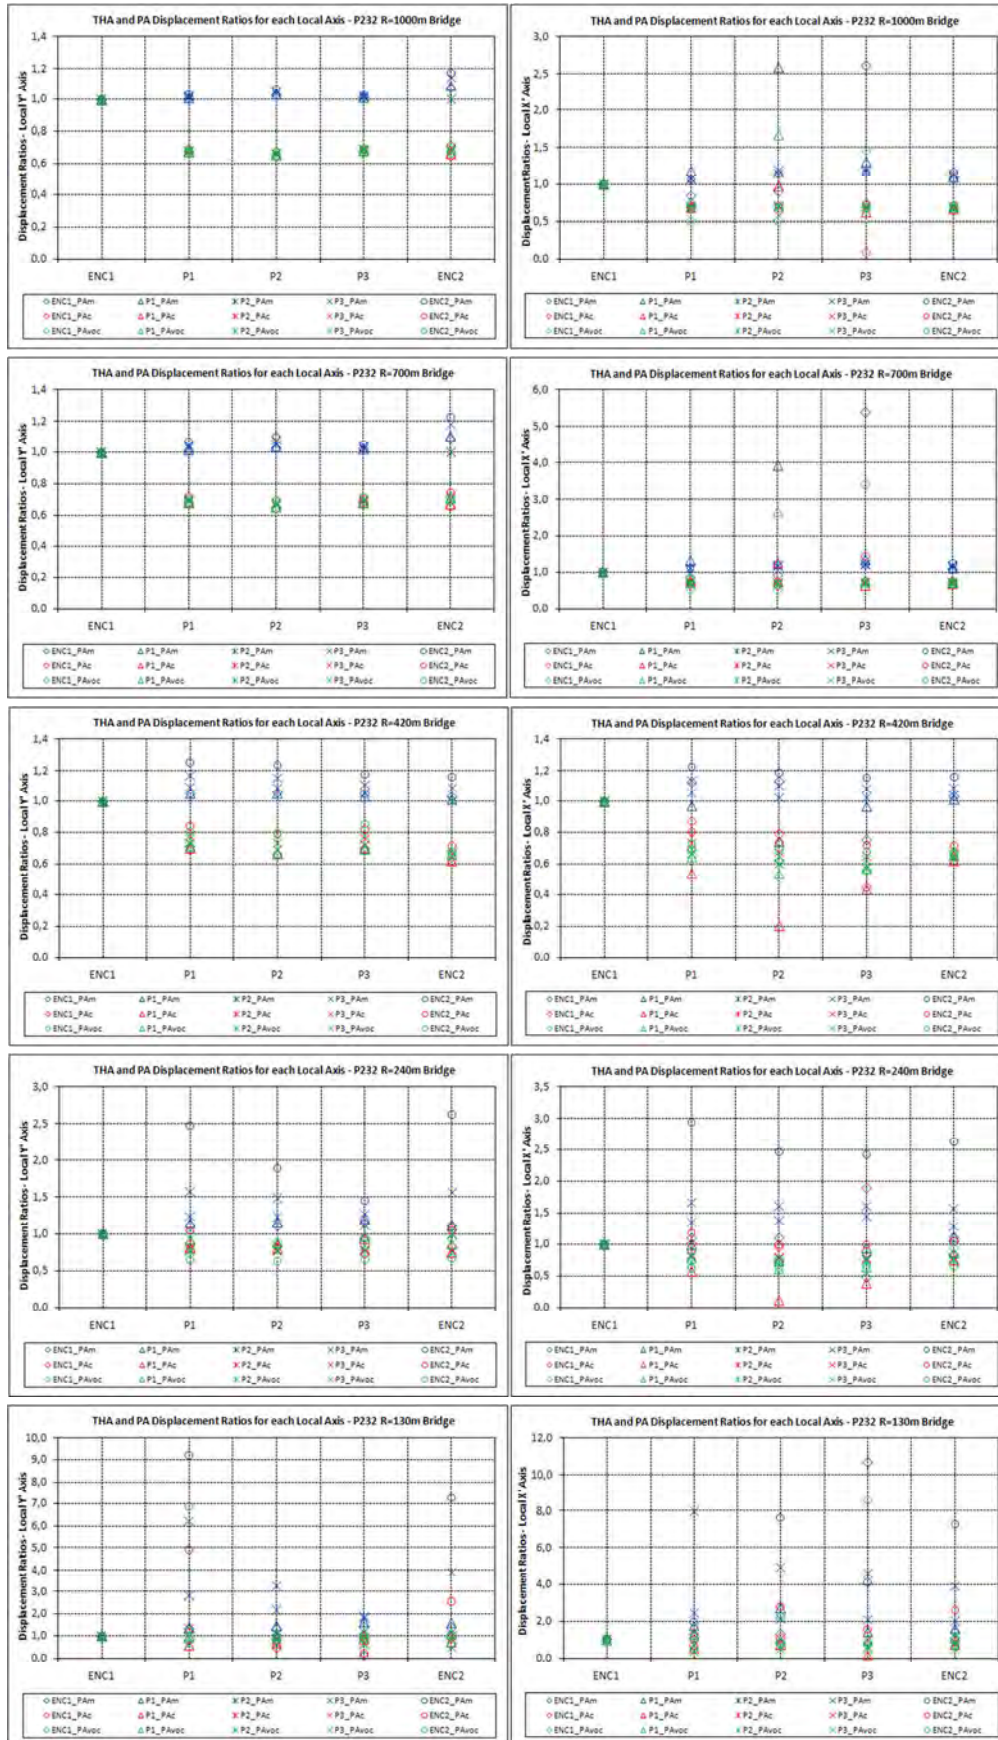

Figure 23: THA and PA displacement ratios for the various analysed bridges and for both local Y'-X' axis.

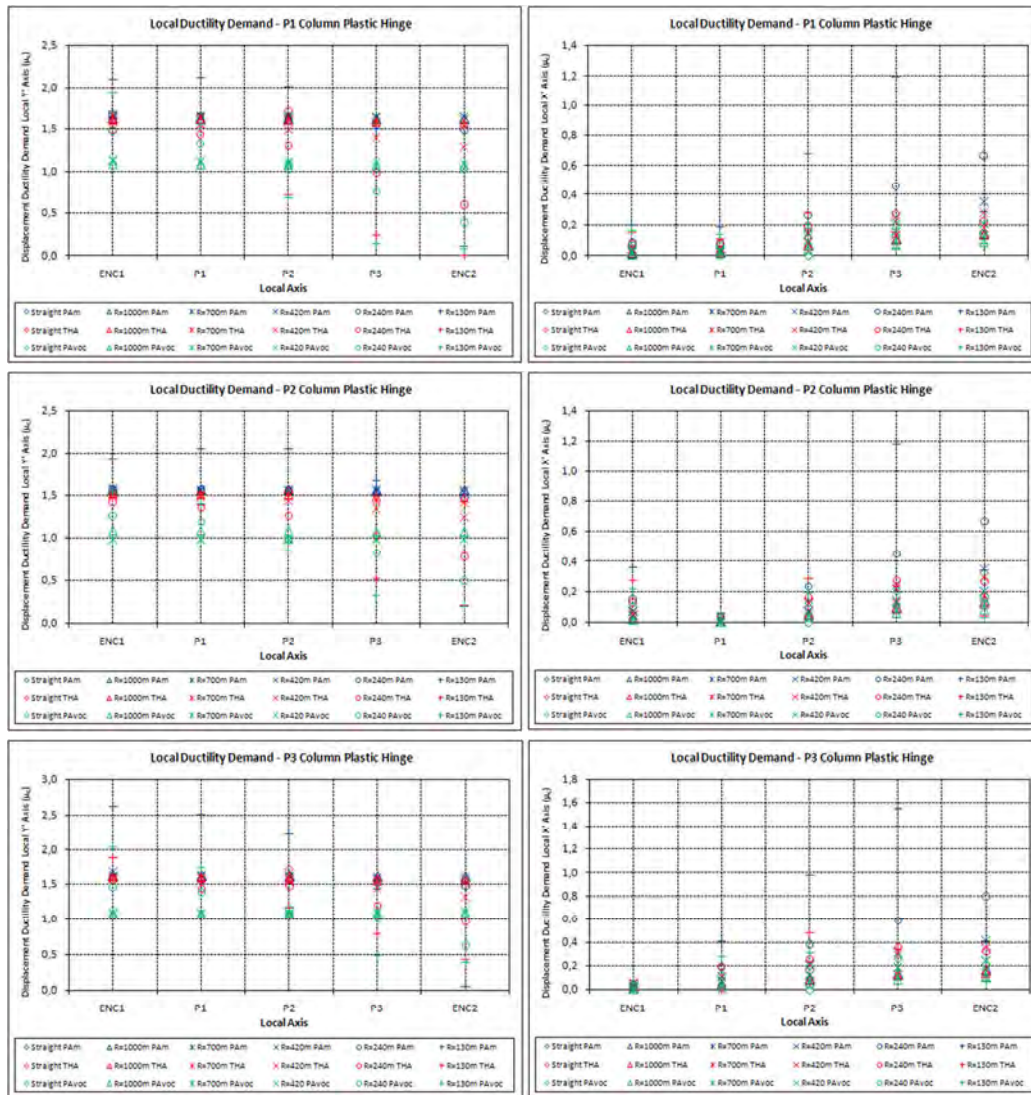

Figure 24: Local ductility demands at the columns of the various analysed bridges in both transverse and longitudinal directions.

Giving greater relevance to the THA local displacement demands, once they represent more realistically the actual seismic response of the bridges, it can be observed that, on the one hand, the transverse local ductility demands of bridges with smaller curvature in plan is similar along the various direction of analysis for each column, with a ductility factor of about 1,7. In the case of bridges with higher curvature in plan, like the bridge with a radius of curvature of 130m, the ENC1 direction of analysis is the critical one, increasing to approximately 1,9 the ductility factor of the P3 column. It should be noted that the P3 and the ENC2 directions of analysis led to markedly lower values of ductility demands in this type of bridges. On the other hand, the longitudinal local ductility factors are higher in bridges with stronger curvature in plan and for the P2, P3 and ENC2 directions of analysis. However, for the considered intensity level of the seismic action, the columns never experienced plastic incursions in the longitudinal direction, remaining with linear-elastic behaviour.

Finally, a global ductility demand analysis was also conducted and the results presented in Figure 25. The global ductility factors were obtained from the PAm and PAc equivalent SDOF system force-displacement relationships, as recommended in [16].

Identical conclusions may be taken regarding the local ductility demand analysis in terms of the influence of the directions of analysis and the curvature of the bridges. As mentioned above, the PAm procedure led to higher structural responses and to an average global ductility factor of 2,5, while the PAc procedure led to a lower average global ductility factor of 2, which decreased to approximately 0,5 in the bridge with a radius of curvature of 130m and for the ENC2 direction of analysis.

Figure 25: Global ductility demands at the various analysed bridges obtained from an equivalent SDOF system with the Eurocode's idealised elastic-perfectly plastic force-displacement relationship.

6 CONCLUSIONS

A set of short regular bridges with a radius of curvature in plan ranging between straight and 130m was selected to investigate the feasibility of the application of the N2 pushover method to curved bridges. A key issue in this work was the attempt to include the influence of different directions of analysis and seismic action input angles in the simplified PA procedures, so as to make them a reasonable alternative to the more complex and demanding, but yet reliable, THA method. The seismic response of the bridges was also evaluated in terms of its local and global capacity demands.

By applying the presented PAm, PAc and PAvoc procedures, as well as the THA, to the set of straight and curved bridges, the following conclusions were drawn:

- Complex three-dimensional structures, such as curved bridges, exhibit a multidirectional dynamic response that is more and more sensitive to earthquake directions as the level of curvature in plan increases. In the case of the bridge with the higher curvature in plan a 80% response variation between two different seismic action input directions has been observed. Therefore, a careful seismic safety assessment analysis must be conducted in these cases, otherwise the seismic response demands could be significantly underestimated.
- The Eurocode's PAm procedure proved to be quite accurate when applied to bridges with a regular curvature in plan and with a fundamental mode mass participation ratio equal or greater than 80%. On the other hand, for the same geometric type of bridges, the PAc procedure considerably underestimated its structural response, and so have no practical value. Equally, the PAm procedure conducted to significantly low values of the response and, therefore, its use is not representative.
- With regard to bridges with a stronger curvature in plan, characterized by a decreasing importance of the fundamental mode in the dynamic response and a counterbalanced increase of the higher modes importance, the PAm provided an inaccurate estimate of the seismic response, generally overestimating it. On the contrary, as the irregularity of the

curved bridges grows the PAvoc procedure is the one that best fits the more reliable THA results.

- The proposed deck displacements and shear forces conversion method, which seeks the inclusion of the various directions of analysis in the simplified pushover procedures, led to quite good results in bridges with regular curvature in plan and whose response is governed by its fundamental mode. However, its accuracy decreased when applied to bridges with stronger curvature in plan. Thus, its application is not recommended in the latter case.
- More work is clearly required, not only to continue the investigation of the effectiveness of the Eurocode's pushover analysis method, but also the feasibility of the "conversion technique" by applying them to curved bridges with a higher degree of irregularity and different dynamic characteristics

Keywords: End-Plate connections, seismic analysis, fatigue, damage seismic, nonlinear modes, hysteretic model.

Abstract. *Analyzing damage seismic in large and complex structures is one of the most challenging problems in steel moment-resisting frame with end-plate bolted connections. The existence of structural damage in an engineering structure leads to the modification of vibration modes and global eigenvalues are usually sensitive to the degree of local damage seismic in bolted connections.*

In this analytical study, a nonlinear time history analysis which takes into account nonlinear modes and frequencies was adopted. According to this approach, the nonlinear modes and frequencies can be determined by an iterative procedure which based on the method of equivalent linearization.

However, the damage analysis of seismic response requires the introduction of efficient structural models capable of describing actual behaviour and the application of an adequate algorithm. The paper presents a Fatigue Damage-Based Hysteretic FDBH model to evaluate the seismic performance of steel moment-resisting frames. The FDBH model is an evolutionary-degrading hysteretic model based on the low-cycle fatigue LCF damage index. Hence an algorithm was developed to characterize nonlinear behaviour in structures for the purpose of either damage identification of these structures.

1 INTRODUCTION

Steel moment-resisting frame structures often are used as part of the seismic force-resisting systems in buildings designed to resist earthquakes with substantial inelastic energy dissipation. End-plate bolted connections are one of the safest and most economical options for structural steel erection. It is therefore desirable to maintain the use and economy of bolted connections as an option for seismically loaded structures [3].

Beam-column connections in steel moment frames are proportioned and detailed to resist flexural, axial, and shearing actions that result as a building sways through multiple inelastic displacement cycles during strong earthquake ground shaking. However, such inelastic action causes fatigue damage and if long enough the cumulative effect may exhaust the ductile capacity leading to fracture [4].

However, analyzing damage seismic in large and complex structures is one of the most challenging problems in steel frames with end-plate connections. Many experimental approaches confirm the presence of changes in modal parameters such as natural frequencies, mode shapes because of the damaged elements of the structure [25]. The concept of nonlinear modes was introduced for the first time by Rosenberg in 1960 [24] and has a particular interest in the study of forced responses because there are close links between the properties of the modes (shape, number) and topology forced response curves of dynamical system. In general, to access the exact solutions of nonlinear system, complex nonlinear differential equations must be solved. The nonlinear systems do not generally have access to their exact solutions in the form. Then approached methods can be used such as Ritz-Galerkin method in which the nonlinear response of the system in the physical basis is approximated by a linear combination of the normal modes and the response of the system in modal coordinates [6].

Stupnicka [26] was assumed that the nonlinear normal coordinates are associated with nonlinear normal modes. Following, the principle of nonlinear modes is used by many researchers to analyze nonlinear systems with multiple degrees of freedom [25, 21]. Dynamic analysis by finite element FE is one means of estimating the changes in the modal parameters such as natural frequencies, mode shapes and modal damping. Global eigenvalues and nonlinear modes can be determined by an iterative procedure [25].

In this paper, a nonlinear time history analysis which considers the nonlinear modes and frequencies was adopted. According to this approach, the nonlinear modes and frequencies can be determined by an iterative procedure which based on the method of equivalent linearization [25].

Moreover, the damage analysis of seismic response requires the introduction of efficient structural models capable of describing actual behavior. The paper presents a Fatigue Damage-Based Hysteretic FDBH model to evaluate the seismic performance of steel moment-resisting frames. The FDBH model is a degrading model based on two damage indices. The plastic damage index (the first index) in this model is combined with a low-cycle fatigue LCF damage index (the second index). The model can be able to calculate the fatigue-accumulated damages of structures. Hence, an algorithm was developed to evaluate the nonlinear seismic behavior of steel moment frames. Finally, a two-story steel frame will be used as an example to illustrate the proposed technique.

2 STRUCTURAL DAMAGE OF STEEL MOMENT FRAMES

The problem of damage in steel moment frames, particularly due to seismic excitation is still a challenge for engineer and researchers to investigate [16]. To understand the damage in the

bolted connection, the researchers distinguish between two phenomena of damage.

The first one is the damage due to the phenomena of elasto-plasticity behaviour of the bolted connection under repeated seismic efforts. The earthquake forces cause inelastic deformations in the components of bolted connection [22]. The accumulation of plastic strains is one phenomenon of cyclic plasticity. Inelastic deformation in the end plate, in the bolts and in flanges of beams and columns can change the mechanical properties of bolted connection like the strength and the stiffness [27].

The nonlinear behaviour is mainly resulted from gradual yielding of connection and can lead to hysteretic loops at a connection under repeated loading [17]. This important feature of nonlinear connections in ductile steel frames has the capability of dissipating excitation energy by an amount equal to the enclosed loop area to stabilize the response under cyclic loading.

To describe the nonlinear behaviour of semi-rigid connection like the end-plate connection, the relationship between the moment and the relative rotation angle is used. Richard and Abbott [14] propose to represent the moment-rotation relationship by four parameters. The Richard-Abbott model represents only the monotonically increasing loading portion of the $M - \theta$ curves. However, the unloading and reloading behaviour of the $M - \theta$ curves is also essential for nonlinear seismic analysis. The subject was extensively addressed in the literature ([9]) where the unloading and reloading parts of the $M - \theta$ curves are theoretically developed using the Masing rule (see Fig.1). The unloading and reloading behaviour of an end-plate connection based on the Richard-Abbott model is described as:

$$M = M_a - \frac{(R_0 - R_p) \cdot (\theta_a - \theta)}{\left(1 + \left| \frac{(R_0 - R_p) \cdot (\theta_a - \theta)}{2M_0} \right|^\gamma\right)^{\frac{1}{\gamma}}} - R_p \cdot (\theta_a - \theta) \quad (1)$$

$$R = \frac{(R_0 - R_p)}{\left(1 + \left| \frac{(R_0 - R_p) \cdot (\theta_a - \theta)}{2M_0} \right|^\gamma\right)^{\frac{\gamma+1}{\gamma}}} + R_p \quad (2)$$

where M is the connection moment, θ is the relative rotation between the connecting elements, R_0 is the initial stiffness, R_p is the plastic stiffness, M_0 is the reference moment, and γ is the curve shape parameter. (M_a, θ_a) is the load reversal point as shown in Fig.1.

Figure 1: Nonlinear hysteretic model of end-plate connection.

The second phenomena of damage is the damage caused by low cycle fatigue. This type of fatigue causes progressive and cumulative damage in the stiffness of the bolted connection [5, 15]. Because of the stress concentration, cracks may appear in the welds which is characterised by the different stages of micro and macro crack propagation and final fracture [23]. Moreover, Bolts can loosen over time because micro-macro slip in the bolt-nut and the assembled plates [18]

Many mathematical relations have been proposed, particularly Manson-Coffin relation which describes linearly this function between the applied rotation and the number of cycles to rupture on a double-logarithmic scale [10, 11]. The information provided by the Rotation-Number of cycles curve is mainly used by engineers for the prediction of the lifetime and resistance of structures under repeated loading.

To evaluate damage more precisely, Miner's rule [11] is commonly used. According to this rule, applying a cycle n_x times with a stress amplitude which corresponds to a lifetime of N_x cycles is equivalent to consuming a portion n_x/N_x of the whole lifetime. This rule implies that rupture occurs when 100% of the lifetime is consumed. It describes also the phenomena of the cumulative linearity of fatigue damage if another application stress is employed. Though many models of damage have been proposed, Miner's rule is still widely used in the engineering field [15].

The fatigue problem occurs in the weaker parts of a structure and in the case of steel frames, as used in civil engineering, fatigue damage generally occurs at its connections. This indicates the importance of studying the resistance and fatigue damage of the beam-column connection in portal frame structures. Experimental tests for predicting the resistance of the beam-column connection have been published [19, 27] with the aim of identifying the key parameters of resistance of the beam-column connection. Some numerical studies have also been carried out using the finite element method to observe the behaviour of the fracture mechanism [20, 22].

The damage phenomena of elasto-plasticity behaviour and LCF due to cyclic loading may occur simultaneously. There is a strong interaction and a separation of the damage processes is impossible. Furthermore, each phenomenon alone is characterised by different aspects.

3 FBDH MODEL OF END-PLATE CONNECTION

In this study, The Richard-Abbott model has been modified to include degrading in the stiffness of the connection produced by the cumulative phenomenon of LCF. An evolutionary-degrading hysteretic model can be developed based on the LCF damage index D_n . In Richard-Abbott model, the cycle in $M - \theta$ curve begins with a secant stiffness R_0 and it changes in nonlinear way to R_p . But the connection loses part of its life in each cycle of excitation applied because of the cumulative phenomenon of LCF. For this reason the secant stiffness of the connection must be changed at the end of each cycle using an index of fatigue damage D_n to take into consideration the past lost life of the connection. The initial stiffness can be modified with the factor $(1 - D_n)$ that takes into account the effect of cumulative fatigue (see Fig.2). The following equations present the developed model for the moment-rotation relationship and the secant stiffness:

$$M^* = M_a - \frac{(R_0 \cdot (1 - D_n) - R_p) \cdot (\theta_a - \theta)}{\left(1 + \left| \frac{(R_0 \cdot (1 - D_n) - R_p) \cdot (\theta_a - \theta)}{2M_0} \right|^\gamma\right)^{\frac{1}{\gamma}}} - R_p \cdot (\theta_a - \theta) \quad (3)$$

$$R^* = \frac{(R_0 \cdot (1 - D_n) - R_p) \cdot (\theta_a - \theta)}{\left(1 + \left| \frac{(R_0 \cdot (1 - D_n) - R_p) \cdot (\theta_a - \theta)}{2M_0} \right|^\gamma\right)^{\frac{\gamma+1}{\gamma}}} + R_p \quad (4)$$

where M^* is the degraded connection moment and R^* is the degraded secant stiffness.

Figure 2: Fatigue Damage-Based Hysteretic model of end-plate connection.

It should be noted that the secant stiffness in Eq.(4) is modified and also with this idea, it is possible to combine the two indices by the equation:

$$D_p = 1 - \frac{R^*}{R_0} \quad (5)$$

where R_0 is the initial stiffness of the connection of connection and R^* is the tangent stiffness of the connection which depends on the index D_n .

To calculate the LCF damage index D_n , an analogous models based on the plastic connection rotation are used therein. A useful means of describing the LCF is expressed by Mander et al. [10] for a bolted connection. Thus using the well known Manson-Coffin relationship [7], the plastic rotation may be related to the number of cycles Nf by the following equation:

$$Nf = c.(\Delta\theta)^{-b} \quad (6)$$

where $\Delta\theta$ is the range of variation of rotation and c, b are parametres which depend on both the typology and the mechanical properties of the considered steel element. The parametres of Manson-Coffin relationship adopted in this study are ($c = 2.10^{-4}$) and ($b = 3$) [10].

Moreover, cumulative damage models should be used to assess deterioration and failure in structural components under arbitrary loading histories. Miner's rule is still the most used cumulative damage rule for its simplicity and efficiency in LCF region [11]. In the case of connection subjected to many cycles of rotation, Miner's rule is expressed by the following equation:

$$D_n = \sum_{x=1}^X \frac{n_x}{Nf_x} \quad (7)$$

where D_n is the LCF damage index, n_x is the numbre of applied cycles for a given rotation level x and Nf_x (see Eq.6) is the number of cycles to failure for roation level x according to the rotation-cycle curve given by Mander et al [10]. The rule is usually employed with the rainflow algorithm since it seems the best counting method [13].

The purpose of such model for the end-plate connection is to simulate inelastic response of structure under dynamic loading by combined damage indices.

4 NONLINEAR MODES AND FINITE ELEMENT

If a structure is properly modeled using finite element, structural damage manifests itself mathematically in the stiffness and mass matrices, and physically in its dynamic properties such as natural frequencies and mode shapes. Finite element methods (FEM) have become a standard technique for structural analyses for more than three decades. In this study, the damage in the structure is identified as a change in stiffness of the finite elements in the different beams of the FE model. The FE model of the structure is a two-dimensional model (see Fig.3) developed using the FE structural analysis program Structural Dynamics Toolbox (SDT) [28].

Consider a structure which is composed of a foundation r and a subset l of free-to-vibrate degree-of-freedom, shown in Fig.3. Ω is the interface between r and l . The equation of motion for a damped structure with N degrees-of-freedom (dof) is given as follows:

$$M\ddot{q} + \bar{C}\dot{q} + \bar{K}q = F(t) \quad (8)$$

where M , \bar{C} , \bar{K} are respectively the mass, nonlinear damping and nonlinear stiffness matrix of the structure and $F(t)$ is the applied forces.

In this study, we adopt the hypothesis that the stiffness matrix of system is nonlinear and depends on the response of system and the nonlinear normal modes. In the case of seismic excitation applied to the foundation r , the only dynamic force of structure is the inertia force produced by basic movement. Consider the foundation of structure as immensely rigid. Therefore, the movement of the foundation r is defined as the rigid body displacements of structure.

The response of system in normal coordinate is defined as:

$$q(t) = \begin{Bmatrix} q_l \\ q_r \end{Bmatrix} \quad (9)$$

where q_l is the response of subset l and q_r is the response of foundation r .

The corresponding partitions of the mass, stiffness matrix and the vector of external force are:

$$M = \begin{bmatrix} M_{ll} & M_{lr} \\ M_{rl} & M_{rr} \end{bmatrix}, \quad \bar{K}(q) = \begin{bmatrix} \bar{K}_{ll} & \bar{K}_{lr} \\ \bar{K}_{rl} & \bar{K}_{rr} \end{bmatrix}, \quad F(t) = \begin{Bmatrix} F_l = 0 \\ F_r \end{Bmatrix} \quad (10)$$

where F_r is the vector of reaction forces at the foundation r .

Figure 3: MDOF system

Rayleigh damping is used to represent damping in the structure. It can be written as:

$$\bar{C} = \alpha.M + \beta.\bar{K} \quad (11)$$

where α and β are the proportional constants.

According S. Setio [25], eigenvalues and eigenvectors for a nonlinear system cannot be obtained by solving the standard eigenvalue problem. As the solution of a nonlinear system depends heavily on the amplitude of motion, the frequencies and normal modes depend on the nonlinear modal amplitude. The introduction of the notion of nonlinear modes permits an extension of the method of linear modal synthesis to nonlinear cases in order to obtain the dynamical response of nonlinear multi-degree-of-freedom systems.

The nonlinear normal modes and nonlinear frequencies must be calculated by an iterative procedure. In this paper, we adopted a procedure which is based on the method of equivalent linearization. For each time step of calculation, the stiffness and damping matrices of the system will be obtained which transform the nonlinear system into an equivalent linear system. The frequencies and nonlinear normal modes can then be calculated using a standard solution to the eigenvalues. A set of N nonlinear modes and frequencies are obtained according to their modal amplitudes.

Considering the FEM characteristic equation for the structure in Fig.3, the nonlinear modal problem can be written as following:

$$[\bar{K}(\eta_p, \bar{\varphi}_p(\eta_p)) - \bar{\omega}_p^2(\eta_p)M]\bar{\varphi}_p(\eta_p) = 0 \quad (12)$$

Where η_p , $\bar{\omega}_p(\eta_p)$, $\bar{\varphi}_p(\eta_p)$ are respectively the fixed structure response in modal coordinate, the nonlinear frequencies and the nonlinear normal modes.

S. Setio [25] assumes that the normal coordinates nonlinear are associated with nonlinear normal modes. In this case, the orthogonality property of eigenvectors used to treat the linear problem can be extended to nonlinear problems. This option allows to transform a system of N coupled equations of a system with N degrees of freedom in the physical basis of a set of N decoupled equations in the modal basis.

In the case of excitation at the base, the movement of the structure is the superposition of a movement training of rigid body and a movement relative to the base that can be expressed by the modes of structure fixed at the foundation r . Finally, the response of nonlinear system in normal coordinate can be obtained efficiently by superposition of modal response as follows:

$$q(t) = \Phi_r q_r + \bar{\varphi}_p(\eta_p) \eta_p \quad (13)$$

where Φ_r is rigid body modes matrix defined by the r dof of the foundation.

The mode shapes matrix of a nonlinear structure fixed at the foundation is expressed as following:

$$\bar{\varphi}_p = \begin{bmatrix} \bar{\varphi}_{lp} \\ 0 \end{bmatrix} = \begin{bmatrix} \bar{x}_l^{(1)} & \bar{x}_l^{(2)} & \dots & \bar{x}_l^{(p)} \\ 0 & 0 & \dots & 0 \end{bmatrix} \quad (14)$$

After substituting the transformation of Eq.(13) in the equation of motion (see Eq.(8)), we obtain the following system (given the properties of rigid modes $\bar{K}\Phi_r = 0$, $\bar{C}\Phi_r = 0$):

$$\begin{bmatrix} \Phi_r^t M \Phi_r & \Phi_r^t M \bar{\varphi}_p \\ \bar{\varphi}_p^t M \Phi_r & \bar{\varphi}_p^t M \bar{\varphi}_p \end{bmatrix} \begin{bmatrix} \ddot{q}_r \\ \ddot{\eta}_p \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & \bar{\varphi}_p^t \bar{C} \bar{\varphi}_p \end{bmatrix} \begin{bmatrix} \dot{q}_r \\ \dot{\eta}_p \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & \bar{\varphi}_p^t \bar{K} \bar{\varphi}_p \end{bmatrix} \begin{bmatrix} q_r \\ \eta_p \end{bmatrix} = \begin{Bmatrix} F_r \\ 0 \end{Bmatrix} \quad (15)$$

And also we can write:

$$\begin{bmatrix} m_{rr} & L_{pr}^t \\ L_{pr} & [m_p] \end{bmatrix} \begin{bmatrix} \ddot{q}_r \\ \ddot{\eta}_p \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & [\bar{c}_p] \end{bmatrix} \begin{bmatrix} \dot{q}_r \\ \dot{\eta}_p \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & [\bar{k}_p] \end{bmatrix} \begin{bmatrix} q_r \\ \eta_p \end{bmatrix} = \begin{Bmatrix} F_r \\ 0 \end{Bmatrix} \quad (16)$$

where:

$m_{rr} = \Phi_r^t M \Phi_r$ is the rigid body mass matrix.

$\bar{L}_{pr} = \bar{\varphi}_p^t M \Phi_r$ is modal participation factors matrix.

$[\bar{m}_p] = \bar{\varphi}_p^t M \bar{\varphi}_p$ is the generalized mass matrix.

$[\bar{c}_p] = \bar{\varphi}_p^t \bar{C} \bar{\varphi}_p$ is the generalized damping matrix.

$[\bar{k}_p] = \bar{\varphi}_p^t \bar{K}(\eta_p, \bar{\varphi}_p(\eta_p)) \bar{\varphi}_p$ is the generalized stiffness matrix.

Eq.(16) can be expressed as the following developed form:

$$[\bar{m}_p] \ddot{\eta}_p + [\bar{c}_p] \dot{\eta}_p + [\bar{k}_p] \eta_p = -\bar{L}_{pr} \ddot{q}_r \quad (17)$$

$$F_r = m_{rr} \ddot{q}_r + \bar{L}_{pr}^t \ddot{\eta}_p \quad (18)$$

Modals movement equations of the excited structure are given by Eq.(17) where η_p is the fixed structure response in modal coordinates. The system is subjected to modal inertia forces $\bar{f}_p = -\bar{L}_{pr} \ddot{q}_r$. The equation of movement for mode i has the following form:

$$\bar{m}_i \ddot{\eta}_i + \bar{c}_i \dot{\eta}_i + \bar{k}_i \eta_i = -\bar{L}_{ir} \ddot{q}_r \quad (19)$$

where \bar{m}_i , \bar{c}_i , \bar{k}_i , are respectively the modal mass, nonlinear modal damping and nonlinear modal stiffness and they can be calculated by the following equations:

$$\bar{m}_i = \bar{x}^{(i)t} M \bar{x}^{(i)} \quad (20)$$

$$\bar{c}_i = \bar{x}^{(i)t} \bar{C} \bar{x}^{(i)}$$

$$\bar{k}_i = \bar{x}^{(i)t} \bar{K}(\eta_p, \bar{\varphi}_p(\eta_p)) \bar{x}^{(i)}$$

In Eq.(19), $\bar{L}_{ir} = \bar{x}^{(i)t} M \Phi_r$ is the i^{th} row of the matrix \bar{L}_{pr} and $-\bar{L}_{ir} \ddot{q}_r = \bar{f}_i(t)$ is generalized force of the i^{th} mode. After solving the modal equations of motion (see Eq.(17)), the reactions at the base and the displacement of the system can be calculated.

To calculate the response of dynamical system, such as the system given by Eq.(19), which subjected to arbitrary seismic loads, temporal integration methods are considered the only methods applicable to nonlinear systems with many degrees of freedom. In this study, the Runge-Kutta method is adopted for the numerical solution of differential equations.

The incremental equilibrium equation of the dynamic system during the time Δt_n can be writhed as following:

$$\bar{m}_i \cdot \Delta \ddot{\eta}_i + \bar{c}_{n,i} \cdot \Delta \dot{\eta}_i + \bar{k}_{n,i} \cdot \Delta \eta_i = \Delta \bar{f}_i(t) \quad (21)$$

where $\bar{c}_{(n,i)}$, $\bar{k}_{(n,i)}$ are the tangent properties defined at the time t_n .

In general, $\eta_{(n,i)}$, $\dot{\eta}_{(n,i)}$, $\ddot{\eta}_{(n,i)}$ at time t_n is known and Range-Kutta algorithm can be used to calculate $\eta_{(n+1,i)}$, $\dot{\eta}_{(n+1,i)}$, $\ddot{\eta}_{(n+1,i)}$ at time t_{n+1} . Once the modal displacements are obtained, the relative response of system in normal coordinates at the time t_{n+1} can be calculated by Eq.(13) as follows:

$$q_{n+1} = \sum_i^N \bar{x}^{(i)} \cdot \eta_{n+1,i} \quad (22)$$

The stiffness matrix of system should be recalculated taking consideration nonlinear behaviour of connections. For this reason, the calculated displacements are used to calculate the internal forces of elements. From Eq.(22), the rotations of bolted connections are known and using the hysteretic model represented by Eqs.(1), (2) and (5), the connection moment $M_{j(n+1)}$,

the tangent stiffness $R_{j(n+1)}$, the LCF damage index $D_{nj(n+1)}$ and the plastic damage index $D_{pj(n+1)}$ of each bolted connection of the beam element (j) will be calculated at the time t_{n+1} .

A correction matrix Cr proposed by Monfortoon and Wu ([12, 8]) is adopted and it is used to modify each matrix beam of the system at the time t_{n+1} . It can take account of the flexibility of semi-rigid connections. The correction matrix Cr for the element (j) at the time t_{n+1} is presented as follows:

$$Cr_{j(n+1)} = \sum_q \sum_s c_{qs,j(n+1)} \text{ with } c_{qs,j(n+1)} = f(D_{pj,l(n+1)}, D_{pj,r(n+1)}, L_b) \quad (23)$$

where $D_{pj,l(n+1)}$, $D_{pj,r(n+1)}$ are the plastic damage indices of the connections (left l and right r , respectively) for the element (j) at the time t_{n+1} . L_b is the length of the beam element (j). The values of c_{qs} are represented by R. Hasan et al. [8] for a beam element with bolted connection at its ends.

The nonlinear matrix for the beam element (j) at the time t_{n+1} can be calculated using the correction matrix with the following equation:

$$\bar{k}_{j(n+1)} = k_j \cdot Cr_{j(n+1)} \quad (24)$$

where k_j the standard elastic stiffness matrix for the beam element (j) [8].

The matrix \bar{K} can be assembled by the stiffness matrices of each beam and column element in the system with the following equation:

$$\bar{K}_{(n+1)} = \sum_{e=1}^{n_e} \bar{k}_{e(n+1)} \quad (25)$$

where n_e is the total number of elements in the MDOF system and members are generically identified by index e .

Because we do not have nonlinear behavior in the columns, the stiffness matrix of each column element \bar{k}_e is equal to the standard elastic stiffness matrix for the column element k_e .

5 ALGORITHM OF ANALYSIS

An algorithm was developed to evaluate the seismic performance of steel moment resisting frames with end-plate connections (see Fig.4). Using this algorithm, the influence of the LCF damage on the behaviour of end-plate connection is studied. To evaluate the accumulation of LCF damage, two phases of analysis have been conducted in this algorithm.

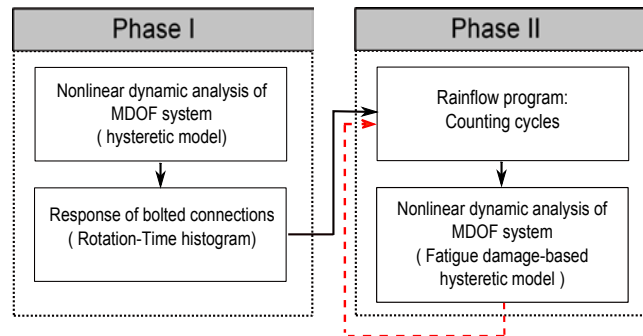

Figure 4: Flowcharte of the proposed algorithm

The objective of the first one is to prepare a nonlinear modal analysis of the structure using the hysteretic model. This phase is important to prepare the necessary data for the second phase. In this phase, the rotation-time histograms will be obtained. These histograms are necessary to prepare an analysis of LCF damage.

In the second phase, a cycle counting program (rainflow program) will be used through the Matlab toolbox offered by A. Nieslony [13]. This program analyzes the histograms to find the number of cycles counted, the corresponding rotational levels and the corresponding times. A FDBH model will be used, following in the second phase, to prepare a nonlinear modal analysis of the structure and to combine the damage caused by elasto-plastic behaviour and LCF.

In both phases, a modal analysis based on finite element code of SDT Toolbox is performed to find the dynamic response of the steel frame subjected to seismic excitation.

6 NUMERICAL EXAMPLE

In order to illustrate the application of the proposed method, a two-story steel frame is presented. The frame has end-plate bolted connections and fixed supports. The geometric, sectional properties and other pertinent information of the frames are given in Fig.5.

Figure 5: Two-story steel frame structure.

Figure 6: Parameters of the end-plate connection (in mm).

The cross sections are selected from the European section profiles. The important properties of steel used in this study are summarized in Table 1. The end-plate connection was designed for the required strength using yield-line theory.

Modulus of elasticity E (GPa)	Yield stress f_y (MPa)	Material density ρ (kg/m ³)
210	280	7850

Table 1: Properties of steel materials.

The connection parameters are represented in Fig.6 and they are set by the code EC3 to ensure a good ductile behaviour of the connection. The structure is subjected to gravity loads of the dead load plus a 10 (kN/m) live load, according to Fig.5, followed by an earthquake with a peak ground acceleration of $\ddot{q}=0.1$ g, 0.2 g and 0.36 g. An earthquake record (normalized El Centro) is used as ground motion input. A damping ratio of $\xi=0.05$ is considered throughout.

The nonlinear behaviour and design limit states of the elements were modelled in accordance with the models presented above and the calculations were carried out by the code SDT Toolbox on Matlab 7.6 (R2008a).

The moment capacity of a connection depends on the strength of the individual connection elements. Various investigations have shown that the connection will begin to lose its ability to

Initial stiffness R_0 (KN.m/rad)	Maximum moment M_u (MPa)	Yielding moment M_y (MPa)
1.528×10^4	23.86	15.91

Table 2: Mechanical properties of the end-plate connection.

sustain further loading when one or more of the following failure modes occur: bolt failure (in tension), end plate plastic mechanism, beam and column flanges buckling. The lowest values of the moment corresponding to these failure modes will present the ultimate connection moment M_u . The equations used to evaluate M_u were adopted from EC3. The yielding moment of the connection can be evaluated as $M_y = 2/3 M_u$.

Initial rotational stiffness of a connection is important and essential for the analysis semi-rigid frames. The rotational stiffness is directly related to the stiffness of each element in the connection. To evaluate the initial stiffness, the equations of EC3 are used. Based on the parameters of the connection (see Fig.6), the mechanical properties of the connection can be calculated (see Table 2). The plastic stiffness R_p is considered to be 0.

Figure 7: Low-cycle fatigue damage index of the connections (1), (2) for $\ddot{q}=0.2$ g considering the linear modes.

Figure 8: Low-cycle fatigue damage index of the connections (1), (2) for $\ddot{q}=0.2$ g considering the non-linear modes.

Two types of failure criteria are considered. The first one is the rotation of the connection and it must not exceed the maximum value given by the EC3 code. The maximum rotation of the connection in this study is $\theta_{max} = 0.025 d_c / d_b$, according to the EC3. The second is the index D_n and it must not exceed the value of (1). If both criteria are not met, the connection will consider as a hinge. The index D_p can take value (1) but must not exceed it. In the other hand, the rigidity R_0 will be 0.

The LCF damage index of the connections (1), (2) for $\ddot{q}=0.2$ g is traced with considering and non-considering the nonlinear modes (see Figs.7 and 8). The cumulative index D_n reaches a value of 11% in the case of linear modes and it increases to a value of 32% in the case of nonlinear modes because of the modes and frequencies changes (see Figs.9).

To show the influence of the nonlinear mode in the behavior of the frame, the natural frequency of the structure as a function of time for the mode $i = 1$ is traced in Figs.9. The results are plotted for three levels of seismic excitation ($\ddot{q} = 0.1$ g, 0.2 g and 0.36 g). In the case $\ddot{q} = 0.1$ g, we note that the frequency remains constant over time (see Fig.9-a). This is because

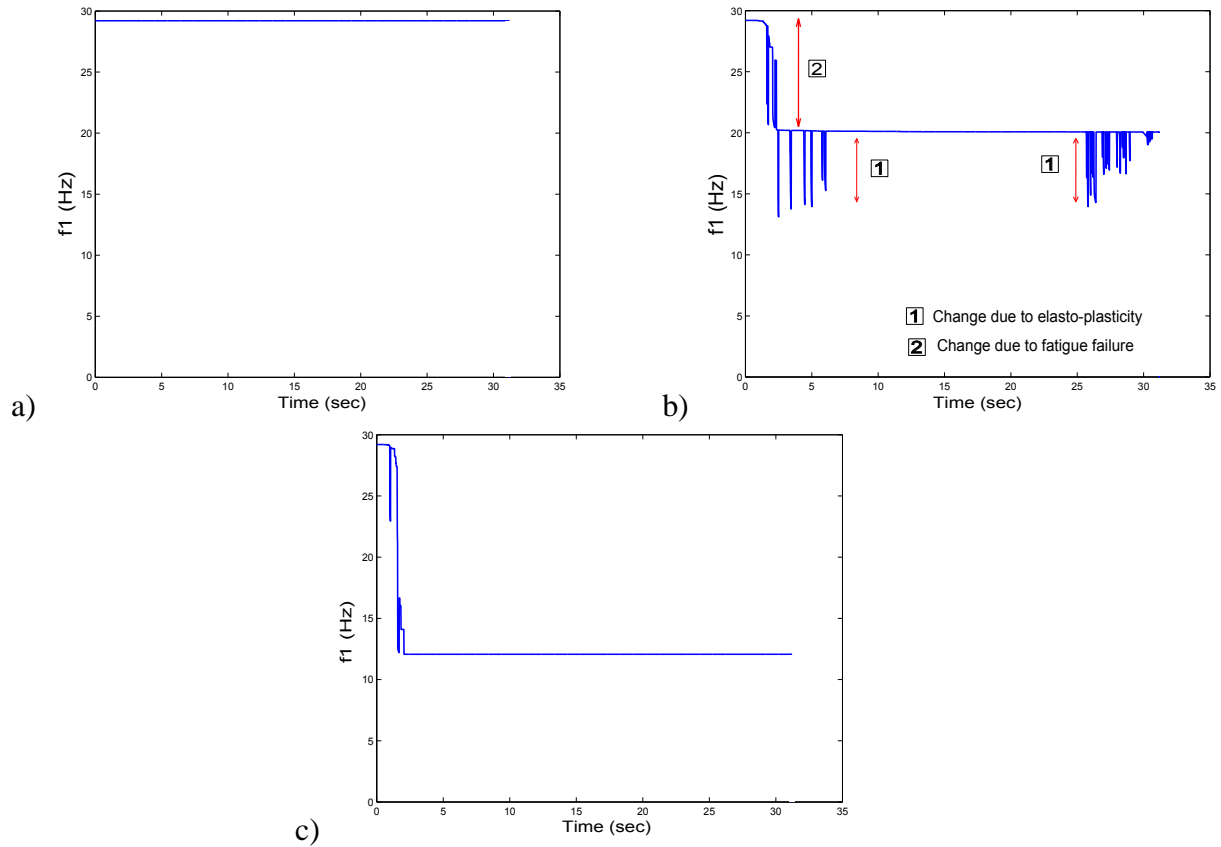

Figure 9: Natural frequency of the structure as a function of time for the mode $i = 1$ and for three cases: (a) $\ddot{q} = 0.1$ g, (b) $\ddot{q} = 0.2$ g and (c) $\ddot{q} = 0.36$ g.

the applied excitation is not very strong and it does not generate damage in modes. For the case $\ddot{q} = 0.2$ g, we can notice that two kinds of changes in the frequency of the frame (see Fig.9-b). The first is a drop in the value of frequency because the bolted connections in the frame are subjected to significant damage due to fatigue damage. The second is a cyclical change due to cyclic elasto-plastic behaviour of bolted connection into the frame.

The cyclical changes are less visible in the case of seismic excitation $\ddot{q} = 0.36$ g (see Fig.9-c). Because bolted connections (1), (2) are completely damaged and rotations reach the limit of ruin. It can also be seen that a greater drop in frequency is happened in this case.

It can be seen from Figs.9 that the analysis with nonlinear mode causes more damages in the system responses that were not taken into consideration before with the linear mode (see Figs.11 and 10).

7 CONCLUSIONS

This paper uses recent concepts in the structural damage evaluation to analyze structures under earthquake. An algorithm to study the influence of the LCF damage on the behavior of end-plate connection is used in this article and a FDBH model is adopted.

The results of this study confirm the presence of changes in modal parameters such as natural frequencies, mode shapes because of the damaged elements of the structure. Further, a drop in frequency due to the development of plastic hinges during the seismic excitation is observed in the proposed steel frame example.

Figure 10: Rotation responses of the connections (1), (2) for $\ddot{q}=0.2$ g considering the nonlinear modes.

Figure 11: Rotation responses of the connections (1), (2) for $\ddot{q}=0.36$ g considering the nonlinear modes.

Moreover, the paper presents a contribution to the solution of nonlinear steel frame structures subjected to seismic excitation by the method of nonlinear modal synthesis. The introduction of the concept of nonlinear mode leads to the possibility of extending the most procedures of the method of linear modal synthesis to nonlinear cases, which involves considerable simplification in the context of the analysis of nonlinear steel frame structures.

Keywords: Flanged Cruciform Column, Moment Resisting Connection, Panel Zone Region, Inclined Vertical Plates, Accordion Load Path.

Abstract. *It is common in structural design to use separate load resisting system in each principal direction of the buildings. In these systems, columns which are located in the intersection of two perpendicular axes play a significant role in resisting gravitational loads as well as seismic demands in both directions. In seismic design, it is necessary to use practically similar sections for columns in both axes.*

Flanged cruciform sections, having relatively similar behavior about both principal axes, seem to be a proper choice for this purpose. They have apparently much simpler fabrication process in beam-column joint regions than the closed box sections. Since having two perpendicular webs, usage of common doublers plates leads to discontinuation of load paths and is not applicable. On the other hand, the local increase in the web thickness is not possible in the cruciform sections built using hot rolled sections. Therefore, it is necessary to consider an alternative path to provide a suitable performance in the beam column joints.

In this paper, by means of nonlinear numerical analysis, influences of connection details on the behavior of flanged cruciform column are studied. Since dynamic behavior of flanged cruciform column is depended on the connection behavior, in order to detect column behavior, it is subjected to monotonic and cyclic lateral displacement loading. Analysis shows connection details play a significant role in moment distribution of column parts. In addition, a new load path is suggested to provide a proper way to transfer panel zone's shear force and its effectiveness in improving behavior of flanged cruciform column is presented.

1 INTRODUCTION

1.1 Column sections

It is common in structural design to use separate load resisting system in each principal direction of the buildings. In these systems, columns which are located in the intersection of two perpendicular axes play a significant role in resisting gravitational loads as well as seismic demands in both directions. In seismic design, it is necessary to use practically similar sections for columns in both axes.

W sections are not suitable since having one strong principle axis and a weak one. Their strength and stiffness about their weak principal axis is low. In addition, design and application of seismic connection to this weak axis is a complicated issue.

Box sections, although having two similar high bending and torsional strength as well as high stiffness, are not supposed as an ideal choice for above mentioned performance, due to difficulties in continuity plate fabrication and out of plane action of the column flanges in beam-column joint regions.

Flanged cruciform sections, having relatively similar behavior about both principal axes, seem to be a proper choice for this purpose. They have apparently much simpler fabrication process in beam-column joint regions than the closed box sections.

In the following the characteristics and weaknesses of flanged cruciform sections are reviewed.

1.2 Fabrication of flanged cruciform columns

This section consist of two W sections where one of these sections is cut into two pieces symmetrically at the centre line of the web along its longitudinal axis, and connected to the mid-depth of other section with welding. Fabrication procedure for this section is complicated because enough space is needed for welding of two W shape sections. Most of W12 and W14 sections are not suitable for making flanged cruciform sections due to their geometric dimensions.

1.3 Axial capacity and lateral stiffness of flanged cruciform columns

The axial capacity of column is usually calculated based on the area and compression resistance. The compression resistance depends on the effective length of the column and the radius of gyration of column section. Since this section has not minor axis and behaves similarly in both principal axes, there is no reduction in axial capacity of this columns due to buckling about minor axis.

Tahir et al, conducted experimental program to study axial capacity of these sections. They demonstrated that the behavior of the flanged cruciform column made up uniform beam sections is similar to behavior of uniform beam section with axial load bending on the major axis. Due to high lateral stiffness of this section, they suggested it for using in unbraced frames to increase stiffness of the frame and decrease sway of frame [1].

1.4 Bending capacity of flanged cruciform columns

This section consists of two W sections that are perpendicular to each other. In bending about principal axis of flanged cruciform sections, one of them bends about its major axis and other bends about its minor axis. In the analysis and design of this section ,it is assumed that plane section of the column remains plane, so moment distribution in each part of column section follows proportionally the weak axis stiffness to strong axis stiffness ratio of W sections.

1.5 Connection of flanged cruciform columns

In order to use of flexure capacity of both perpendicular W sections at the same time, the connection of beam to columns must have enough strength and stiffness to constrain two W sections together. As the strong axis connections are investigated extensively, prequalified connections for seismic moment frames are represented in AISC prequalified connections [2, 3].

This standard mentions that the behavior of the prequalified connections with flanged cruciform columns is expected to be similar to that of a rolled wide-flange column and the behavior of the assemblies employing this section would be acceptable, as long as such column sections meet the limitations for I-shaped sections and connection assemblies are designed to ensure that most inelastic behavior occurred within the beam as opposed to the column [2].

It is necessary to study the connection characteristics needed to push two parts of section to behave in the same manner in order to whole section plane remains plane.

1.6 Panel zone regions of flanged cruciform columns

Since having two perpendicular webs, usage of the common doublers plates in both directions leads to discontinuity of load paths and is not applicable. On the other hand, the local increase in the web thickness is not possible in the flanged cruciform sections with hot rolled sections.

Therefore, in order to reduce the shear force demands on the column's web, it is necessary to consider an alternative path that can transfer the panel zone shear force and provide a suitable performance in the beam column joints.

1.7 Objective

In this paper several moment resisting connections of beams to flanged cruciform column are developed to study their seismic performance. The design of the connection details is based on AISC prequalified procedure. A model of each connection was created and analyzed, using the finite element analysis program ABAQUS and their behavior to monotonic and cyclic lateral loading was studied. A new load path is suggested to provide a proper way to transfer panel zone shear force and its effectiveness is evaluated. In addition, moment resisting participation of each part of column section as well as shear resisting are studied.

2 DESIGN OF MOMENT CONNECTION DETAILS

Three separate specimens are adopted to examine performance of flanged cruciform column. First specimen (specimen 1) is without continuity plates, the second one (specimen 2) includes continuity plates and the third specimen (specimen 3) including continuity plates and inclined vertical plates. The details of the moment connection for specimen 1, specimen 2 and specimen 3 are shown in Figures 1(a),(b) and (c) respectively.

Figure 1. The details of the moment connection: (a) for specimen 1, (b) for specimen 2 and (c) for specimen 3.

As shown in Figure 1(c), inclined vertical plates with similar thickness of column flange plates, connected to flange edges of two perpendicular W sections in the panel zone region, provide a proper additional path to transfer panel zone's shear forces. Also these inclined vertical plates are welded to continuity plates. In order to show details of this specimen clearer, the details of the moment connection of specimen 3 in panel zone region are shown in Figure 2(a) and (b).

Figure 2. (a) and (b): The details of specimen 3 in panel zone region.

The specimens consist of cruciform interior connection subassemblies with beams attached to the column opposite faces. The subassemblies are extracted from interior joints of moment frames. The height of column is 160 in. and two beams 120 in. long framed into both face of column at mid height. In moment frames, deflected under lateral load, the inflection points are formed near the mid-span of beams and mid-height of columns. By this assumption, the inflection points of moment frames are considered to be the ends of subassembly beams and columns with hinged supports. The column base is supported by a hinged connection and the beam ends were supported by adjustable ones with lateral movement capability to provide the roller boundary condition. The column top end is subjected to horizontal displacement-controlled loading.

In order to avoid global and local instabilities, lateral bracing of beams and column are provided as requirements of AISC seismic provisions [4].

The flanged cruciform column consists of two W18*143 section which are suitable sections to be fabricated as flanged cruciform section. The beams in opposite side of the column are W10*88 sections. The geometric properties of the sections are shown in Table 1.

Section	d (in.)	b _f (in.)	t _w (in.)	t _f (in.)	I _x (in. ⁴)	I _y (in. ⁴)	Z _x (in. ³)	Z _y (in. ³)
W18*143	19.5	11.2	0.73	1.32	2750	311	322	85.4
W10*88	10.8	10.3	0.605	0.99	534	179	113	53.1
Flanged cruciform column(W18*143)	19.5	11.2	0.73	1.32	3061	3061	407.4	407.4

Table 1: Geometric properties of sections

To calculate geometric properties of flanged cruciform section, it is assumed that plane section of column remains plane so the second moment of area for flanged cruciform column as well as plastic section modulus are calculated by the summation of properties of area of the x-x axis and y-y axis of the corresponding w sections.

According to the AISC seismic provisions, width-thickness ratios for the flanges and web of the beam and column conform to the requirement of the seismically compact elements [4].

Material properties of all elements in the specimens are according to ASTM-A36 and showed in Table 2 [4, 5].

$F_y(\text{ksi})$	$F_u(\text{ksi})$	$E(\text{ksi})$	ν	R_y
36	58	29000	0.3	1.5

Table 2: Material properties of all elements

In accordance with the requirements of AISC prequalified connection, the web of the tee-shaped sections shall be welded to the web of the continuous I-shaped section with CJP groove welds with a pair of reinforcing fillet welds within a zone extending from 12 in. above the upper beam flange to 12 in. below the lower beam flange [2, 3].

Welded Unreinforced flange–welded web (WUF–W) moment connections are selected to connect the beams to the column faces. In this type of connection, Beam flanges and beam web are connected to column flanges using complete-joint penetration (CJP) groove welds. These welds conform to the requirements for demand critical welds in the AISC seismic provisions. The plastic hinge location is taken to be at the face of the column [3].

The probable maximum moment at the plastic hinge, M_{pr} , is calculated in accordance with AISC prequalified connections with

$$M_{pr} = C_p R_y F_y Z_x = 8,543 \text{ kip} - \text{in.} \quad (1)$$

where

F_y = specified minimum yield stress of the yielding element, ksi

R_y = ratio of the expected yield stress to the specified minimum yield stress F_y , as specified in AISC seismic provisions (presented in Table 1)

Z_x = beam plastic section modulus x-axis, in.³

C_{pr} = factor to account for the peak connection strength, including strain hardening, local restraint, additional reinforcement, and other connection conditions. Since experimental data shows a high degree of strain hardening, AISC prequalified connections demonstrate that the value of C_{pr} shall be taken as equal to 1.4 [3].

By dividing this value (M_{pr}) by the distance from the plastic hinge to the beam end, the corresponding shear force at the column faces (V_h) found to be 71.2 kips. The beam design shear strength (V_b) is larger than required shear strength at the column faces (V_h).

For special moment frames (SMFs), the panel zone shear force demand, per the AISC seismic provisions [4], are determined from the summation of the probable maximum moments at the face of the column and then using

$$V_{pz} = \frac{2M_{pr}}{d_b - t_{bf}} = 1,743 \text{ kips} \quad (2)$$

where

d_b = overall beam depth

t_{bf} = beam flange thickness

and M_{pr} is as defined previously.

The design panel zone shear strength are calculated per AISC prequalified connections with

$$V = \phi_v R_n = \phi_v 0.6 F_y t_{cw} d_c \left(1 + \frac{3b_{cf} t_{cf}^2}{d_c d_c t_{cw}} \right) = 424.6 \text{ kips} \quad (3)$$

where

d_c = overall column depth

b_{cf} = width of column flange

t_{cf} = column flange thickness

t_{cw} = column web thickness Main headings

ϕ_v =Resistance factor for shear strength of panel zone of beam-to-column connections, AISC prequalified connections demonstrate that the value of ϕ_v shall be taken as equal to 1.0 and d_b , F_y are as defined previously [2,3,6].

Since the panel zone shear force demand are larger than the design panel zone shear strength, providing doubler plates is necessary. To detect influences of inclined vertical plates in resisting panel zone shear force demand of connection, doubler plates are not provided intentionally either specimen 1 or specimen 2.

According to AISC seismic provisions, providing continuity plates is needed in these connections [4]. In specimen 1, the continuity plates are not provided to investigate its influences on mobilizing of each part of column section. All Continuity plates are 1-1/4 in. thick which are 1/4 in. thicker than beam flange thickness and welded to column flanges and column web and inclined vertical plates with CJP groove welds.

The connection satisfy the strong column-weak beam requirement given by AISC seismic provisions [4].

$$\frac{\sum M_{pc}^*}{\sum M_{pb}^*} = 1.11 \geq 1 \quad (4)$$

Where

$\sum M_{pb}^*$ = the sum of the moments in the beams at the intersection of the beam and column centerlines

$\sum M_{pc}^*$ = the sum of the moments in the column above and below the joint at the intersection of the beam and column centerlines with a reduction for the axial force in the column

By extrapolation of the probable maximum moment at the plastic hinge (M_{pr}) to the centerline of the column, $\sum M_{pb}^*$ is calculated with

$$\sum M_{pb}^* = 2(M_{pr} + \frac{V_u d_c}{2}) = 18,474 \text{ kips} - \text{in.} \quad (5)$$

$\sum M_{pc}^*$ is calculated, assuming axial load is $P_{uc} = 0.3F_y A_g$, with

$$\sum M_{pc}^* = 2Z_c(F_{yc} + \frac{P_{uc}}{A_g}) = 20,533 \text{ kips} - \text{in.} \quad (6)$$

where

Z_c =plastic section modulus of the column, in.³

F_{yc} =specified minimum yield stress of column, ksi

P_{uc} =required compressive strength using LRFD load combinations, kips

A_g =gross area of column, in.²

3 ANALYTICAL STUDY

3.1 Finite element modeling

The model of each connection was created and analyzed, using the finite-element analysis program ABAQUS. In this regard the shells elements were used for modeling in order to achieve a computationally efficient model. Here, a quadrilateral four-node shell elements (S4 element) is used.

Analysis have two steps, first only column is subjected to the axial load, the top column end is loaded by imposing lateral displacement. Nonlinear geometric behavior is considered in analysis. Each model is analyzed twice, once in order to evaluate the elastic performance of connections, considering only the elastic properties of the material. An additional analysis is carried out for each model to investigate the influences of plasticization of material in connection assemblies.

While it is assumed that the connected parts were completely joined together by the welds, neither complete joint penetration welds nor fillet welds were explicitly modeled. Additionally, beam weld access holes are not included in the models.

In order to avoid global and local instabilities, the out-of-plane movement of the beam flange is restrained near the plastic hinges and beam ends. In addition lateral bracing of column is provided at the both ends of the column and near connection region.

The overall view of the finite element model of specimen 3 is shown in Figure 3.

Figure 3: The overall view of the finite element model of specimen 3

3.2 Finite element analysis

A tri-linear stress-strain curve was used to represent the material properties. The Von Mises yield criterion and kinematic hardening rule were adopted to consider the plasticity behavior. The yield strength ($F_y=36,000$ ksi) and the ultimate strength ($F_u=58,000$ ksi) of the materials were considered. The Young's modulus of elasticity, tangent modulus and Poisson's ratio were assumed as 29,000 ksi, 0.01 Young's modulus and 0.3, respectively, for all materials of the analysis.

As requirements of AISC seismic provisions [4], the connection used in SMFs, must accommodate a story drift angle at least 0.04 rad. and the measured flexural resistance of the connection, determined at the column face, shall equal at least $0.80M_p$ of the connected beam at an interstory drift angle of 0.04 rad.. In all models, the top column end is loaded monotonically by imposing a displacement until 0.04 rad. of story drift angle.

Since neither specimen 1 nor specimen 2 provide sufficient panel zone shear strength, only in specimen 3, the top column end is loaded axially by $P_{uc}=0.3F_yA_g$ accompanied by a prescribed quasi-static cyclic lateral displacement. The total story drift was calculated by dividing the column tip displacement by the height of column.

3.3 Finite element analysis results

Specimen 1

As there is no continuity plate placed in this specimen, parts of section are joined by webs, the compatibility of two parts of section is not taken place sufficiently due to low out-of-plane strength of webs. Shear force and flexural moment of each part of column are presented separately to investigate moment and shear resisting participation of each part of column. Maximum shear force in the column developed in the mid height of panel zone region (Section 1) and maximum flexural moment developed in the level of continuity plates (Section 2). In both elastic and plastic analysis of specimen 1, the W section part of flanged cruciform column bent about its strong principal axis, named herein after as "strong part", resists major portion of shear force and flexural moment in the column section and the W section part of flanged cruciform column bent about its weak principal axis, named herein after as "weak part", resists only minor portion of flexural moments as well as shear forces.

The developed shear force and shear force participation ratio of each part of column at section 1 versus column tip displacement are shown in Figures 4(a) and 4(b) respectively.

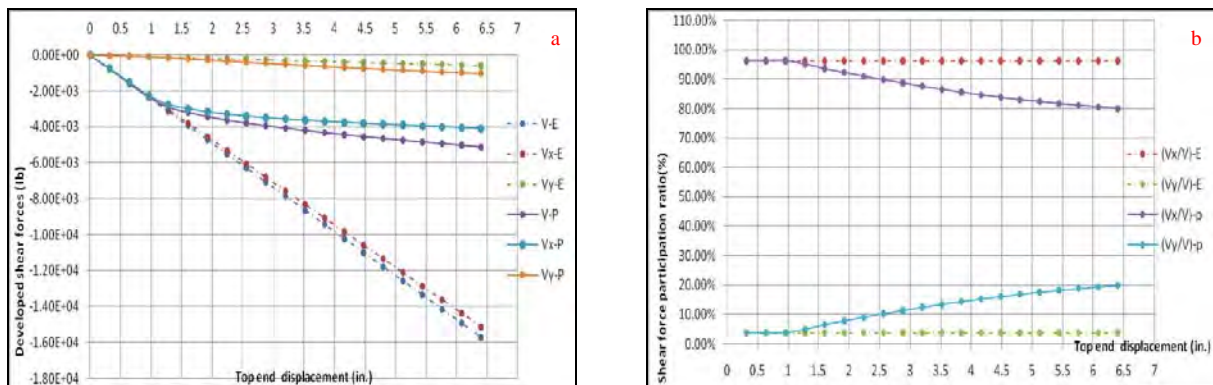

Figure 4. (a): The developed shear force of each part of column at section 1 versus column tip displacement; (b): Shear force participation ratio of each part of column at section 1 versus column tip displacement.

These figures include results of both elastic and plastic analysis to determine yielding effect of connection parts. The elastic analysis results are shown with suffix (-E) and plastic analysis results are shown with suffix (-P). In these figures (Mx) and (Vx) show flexural moment and shear forces, developed in strong part of column and (My) and (Vy) show flexural moment and shear forces, developed in weak part of column. Also (M) and (V) are resultant flexural moment and shear force, developed in the whole section of column.

In addition, the developed flexural moment and flexural moment participation ratio of each part of column at section 2 versus column tip displacement are shown in Figures 5(a) and 5(b) respectively.

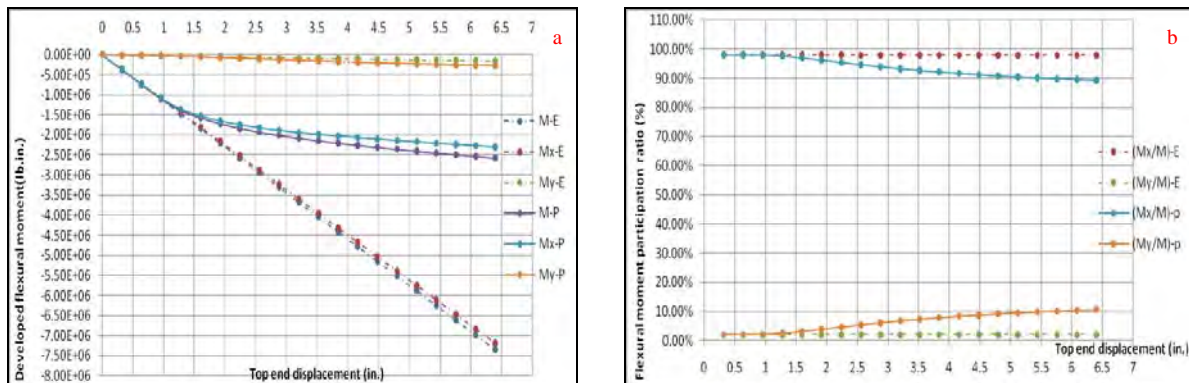

Figure 5 (a): The developed flexural moment of each part of column at section 2 versus column tip displacement; (b): Flexural moment participation ratio of each part of column at section 2 versus column tip displacement.

As shown, the compatibility of two parts of section are not remained the same which means the plane of the whole section does not remains plane and flexural moment distribution of column do not follow proportionally the weak axis stiffness to strong axis stiffness ratio of each W sections .

Due to yielding of panel zone and decrease in stiffness of strong part, the weak part participation in resisting flexural moment and shear force is higher in plastic analysis, as compared to results from elastic analysis.

Specimen 2

In this specimen which strong part and weak part are joined together through the continuity plates at beam flanges level as well as webs of two parts. Because of high in-plane capacity of continuity plates, it is predicted that the weak part has reasonably more share in the resisting flexural moment and shear force than specimen 1.

The developed shear force and shear force participation ratio of each part of column at section 1 versus column tip displacement are shown in Figures 6(a) and 6(b) respectively.

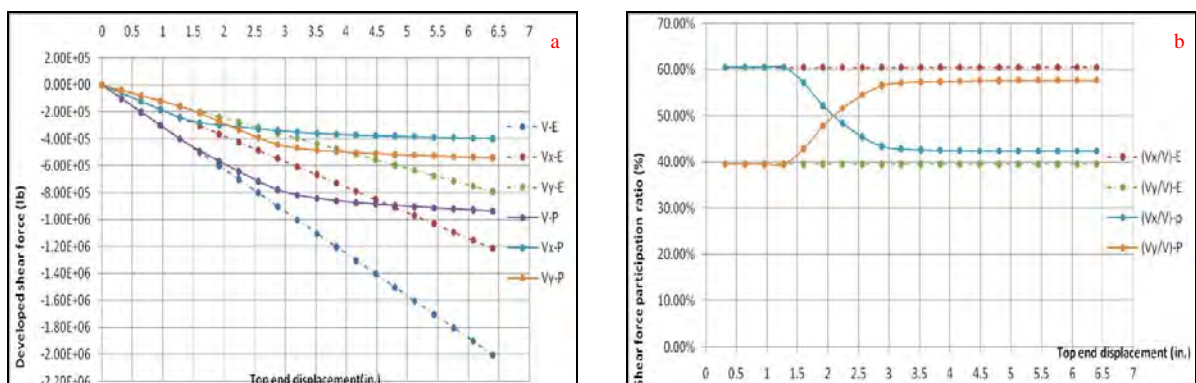

Figure 6. (a): The developed shear force of each part of column at section 1 versus column tip displacement; (b): Shear force participation ratio of each part of column at section 1 versus column tip displacement.

In addition, the developed flexural moment and flexural moment participation ratio of each part of column at section 2 versus column tip displacement are shown in Figures 7(a) and 7(b) respectively.

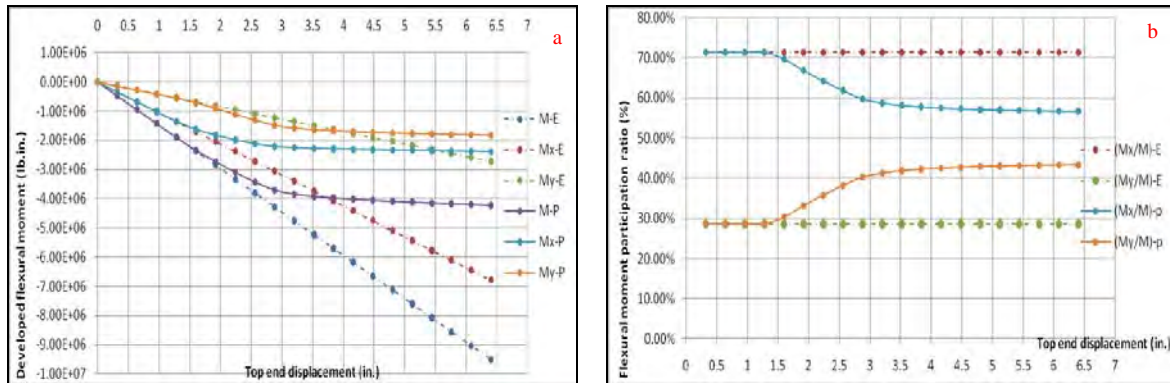

Figure 7. (a): The developed flexural moment of each part of column at section 2 versus column tip displacement; (b): Flexural moment participation ratio of each part of column at section 2 versus column tip displacement.

As shown, flexural moment distribution of column do not follow proportionally the weak axis stiffness to strong axis stiffness ratio of each W sections, so column section plane does not remains plane.

In the plastic analysis of specimen 2, as soon as panel zone start to yield, Stiffness of panel zone decreases so weak part resist more flexural moment as well as shear forces. Unlike specimen 1, panel zone yielding plays more important role in specimen 2.

Specimen 3

In this specimen, inclined vertical plates as well as continuity plates are provided. This inclined plates and flange plates of weak part create two extra load paths to transfer panel zone shear forces. In other word, there are three parallel load paths to resist shear forces of panel zone region, one directly through web of strong part and two accordion load path through inclined and flange plates.

The developed shear force and shear force participation ratio of each part of column at section 1 versus column tip displacement are shown in Figures 8(a) and 8(b) respectively.

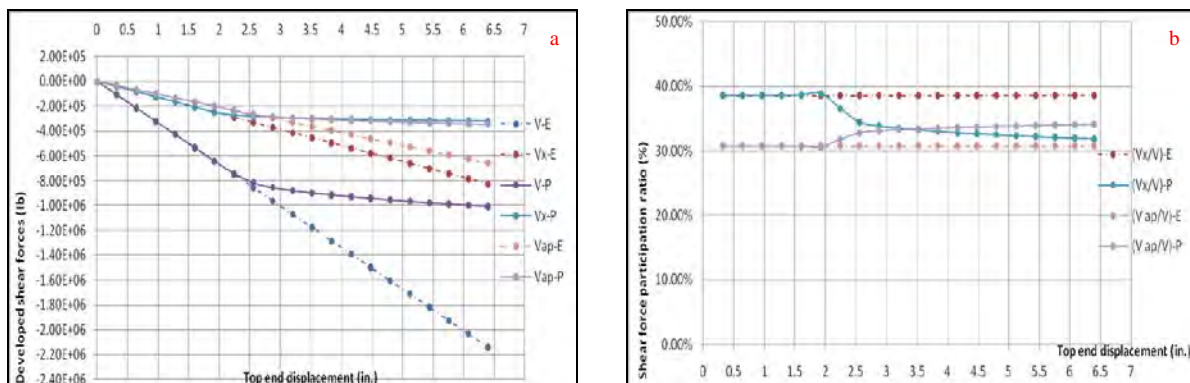

Figure 8. (a): The developed shear force of each part of column at section 1 versus column tip displacement; (b): Shear force participation ratio of each part of column at section 1 versus column tip displacement.

In these figures and (Vap) shows shear forces, developed in each accordion path of the panel zone regions. In addition, the developed flexural moment and flexural moment participation ratio of each part of column at section 2 versus column tip displacement are shown in Figures 9(a) and 9(b) respectively.

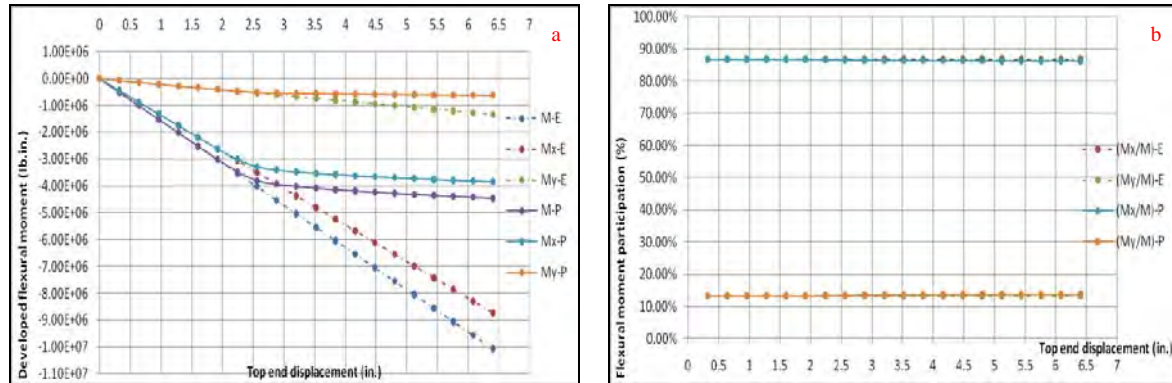

Figure 9. (a): The developed flexural moment of each part of column at section 2 versus column tip displacement; (b): Flexural moment participation ratio of each part of column at section 2 versus column tip displacement.

In the plastic analysis of specimen 3, after the yielding of web of the strong part, the flanges of weak part and inclined plates start to yield.

As shown, Although strong part web yielding cause decrease in panel zone shear stiffness, but does not considerably influence the flexural stiffness of the strong part of column, due to presence of two parallel accordion load path.

To examine connection performance in cyclic loading, this specimen is subjected to the cyclic lateral displacement loading. specimen shows quite stable inelastic behaviors and favorable energy dissipation capacities throughout cyclic loading. The connection performance exceeded the AISC seismic provision requirements.

The developed flexural moment of each part of column at section 2 versus total story drift angle of the specimens is shown in Figure 10.

Figure 10: The developed flexural moment of each part of column at section 2 versus total story drift angle of the specimens in cyclic loading.

4 CONCLUSIONS

- While in the bending of flanged cruciform column, there is only out-of-plane bending of column web to constrain two section together and Due to low out-of-plane bending capacity of webs, extra measures is needed to push the two parts of section to behave in the same manner in order to whole section plane remains plane.
- The placement of the continuity plates in connection regions is necessary to mobilize flexural capacity of both W sections.
- Although providing continuity plates causes to develop flexural moment in both w sections, but column section plane does not still remains plane and flexural moment distribution of column does not follow proportionally the weak axis stiffness to strong axis stiffness ratio of each W sections.
- Due to the discontinuity of the load paths, it is not possible to use common doubler plates to reduce panel zone shear force in two directions and also local increase in column web thickness in the panel zone region is not possible for flanged cruciform section are fabricated from rolled sections, so it is needed to provide other paths to transfer the shear demands in panel zone regions.
- Inclined vertical plates with same thickness of column flanges, provide effective parallel accordion paths to resist panel zone shear forces. In addition, these plates cause that flexural moment participation of each part of flanged cruciform section becomes closer to the assumption of the weak axis stiffness to strong axis stiffness ratio of two perpendicular W sections.
- Due to existence of inclined vertical plates in panel zone regions, web shear yielding of strong part of column does not affect the flexural moment distribution in each part.
- These new load paths show quite stable inelastic behavior when subjected to cyclic lateral displacement loading.

Abstract. *The papers investigate the behavior of steel frames of dissipative steel shear walls. Both numerical and experimental analyses have been conducted in order to characterize in terms of energy dissipation and to evaluate the q -factor for design of these structures. The tests have been realized for two series of three-bay and two-storey frames, stiffened of Steel Plate Shear Walls. Specimens have been half-scaled and tested under monotonic and cyclic loading. A numerical model has been calibrated via test results for push over and IDA analyses. Parametric studies have been done on different frame typologies in order to obtain the q factor for such systems.*

1 INTRODUCTION

Steel plate shear walls SPSW have been used as lateral force resisting systems since 70's, but the design specifications were rather incomplete at that time. Throughout the last four decades, numerous research programs and also seismic experiences have confirmed their effectiveness. A major role on their development can be attributed to the introduction of design rules in the code provisions, e.g. AISC, 2005 [1] or NBCC, 2006 [2]. The application of SPSW system in Europe is limited, partly due to the lack of design provisions in seismic code EN 1998-1 [3]. Particularly, there are no recommendations for behavior factor and system overstrength factor, respectively. An additional problem refers to the prediction of the strength and stiffness capacity of the SPSW structures. Design practice requires simple models and conventional analysis software that are available and relatively simple to use. One of the models used to represent the behavior of SPSW is the strip model, developed by Thorburn et al., 1983 [4]. Thus, in order to model the steel plate shear walls, the steel plates are replaced by a series of truss members - strips, parallel to tension fields. A minimum of ten strips per panel are required to adequately represent the tension field action developed in the plate.

In order to address the issues presented above with regards to the performances of SPSW systems, an experimental program was developed at the Politehnica University of Timisoara, Steel Structures Laboratory. Previous research of the authors was focused on numerical investigations on SPSW systems (Dinu et al., 2009, [5]) and comparison to conventional braced systems (i.e. centrically braced frames and eccentrically braced frames). In order to evaluate the influence of beam-to-column connections on the response of the structure, two connection typologies were used, i.e. flush end plate bolted connections and extended end plate bolted connections. Structures were tested monotonically and cyclically. Behavior factors were evaluated from the cyclic test. The strip model developed by Thorburn et al. was modified based on the experimental results. In order to extend the behavior factors evaluated experimentally, a numerical study was performed. The paper summarizes the experimental program and presents the results of the numerical study.

2 EXPERIMENTAL TEST ON STEEL PLATE SHEAR WALLS

2.1 Test specimens

The steel plate shear wall specimens were extracted from a six story frame structure (Figure 1.a). The two actuators used for the tests have 1000 kN and 500 kN capacity and 360mm stroke, respectively. Due to the stroke limitation, the specimens were half-scaled. The infill plates had thickness of 2mm and 3mm, respectively. The frames are 3500 mm height and 4200 mm wide (between member centerlines) (Figure 1.b). The slenderness ratio of shear walls L/t_w amounted 595 for 2 mm panels and 397 for 3 mm panels, while the aspect ratio L/h was 0.75. In order to evaluate the contribution of the boundary frames to the strength and stiffness of the structure, two types of beam-to-column connections were used. According to EN1993-1-8 [6] classification, flush end plate connection was semi-rigid and weak partial strength ($M_{j,Rd}=0.4M_{b,Rd}$) (further refereed as semi-rigid) and extended end plate connection was rigid and strong partial strength, with a capacity almost equal to that of the connected beam ($M_{j,Rd} = 0.9M_{b,Rd}$) (further refereed as rigid). The infill panels were bolted connected to the boundary members using fish plates. Table 1 shows the thickness of the infill plates, boundary elements, beam-to-column connection types and type of loading. Table 2 shows the material properties of the specimens. As expected, the actual yield strength of the infill plates and boundary elements are much larger than the nominal values.

Table 2: Material properties

All specimens were tested monotonically and cyclically using ECCS procedure [7] but adapted to particular behavior of steel plate shears walls. The difference is the slope of initial stiffness. Thus, in the original procedure, a monotonic test is done first, in order to evaluate the force-displacement curve that is used to evaluate the equivalent yield displacement. Yield displacement D_y and corresponding yield force F_y are obtained by intersecting the initial stiffness α_y and a tangent at the curve $F-D$ with a slope of 10% of the initial stiffness. Yield displacement D_y is then used to calibrate the cyclic loading history. This contains four elastic cycles ($\pm 0.25D_y$, $\pm 0.5D_y$, $\pm 0.75D_y$ and $\pm 1.0D_y$), followed by groups of 3 cycles of amplitudes multiple of $2D_y$ ($3 \times 2D_y$, $3 \times 4D_y$, $3 \times 6D_y$, ...). Based on experimental results, the evaluation of yield displacement was adjusted to take into account the specific behavior of SPSW. Thus, the slope of initial stiffness was corrected and amounted 20% of the initial stiffness.

2.2 Monotonic test

All specimens exhibited stable force-displacement behavior. Figure 2 shows the behavior of the specimen R-M-T2 during the monotonic test. VIC-3D digital image correlation system was used for measurement of shape, displacement and strain. Areas delimited by dashed lines, magnified and represented at the right-hand side of the figures, have the dimensions of 450

mm by 550mm. As the infill plate thickness was small, some out-of-plane deflections occurred due to the fabrication (Figure 2.a), amounting approximately 8.8 mm ($0.0065\sqrt{Lh}$), where L is the distance between boundary columns centerlines and h is the story height. Up to inter-story drifts of about 0.5%, specimens were almost elastic. After this drift, some yield lines appeared in the infill plates (Figure 2.b). Out-of plane deflections corresponding to this drift were about $0.017\sqrt{Lh}$. Some local cracks were initiated at the corners of the panels at interstory drifts of approximately 2%. The beam-to-column connections presented no damages before plastic deformations took place in panels. Local plastic deformations started to initiate at the beam flange in compression for drifts larger than 2%. For the peak capacity, the interstory drift amounted 6% approximately, while out of plate deflections amounted $0.02\sqrt{Lh}$ (Figure 2.c). The test was stopped at a top displacement of 240mm as the force started to drop, before the attainment of full shear wall capacity (Figure 3).

Figure 2: General view and details of the R-M-T2 specimen (VIC measurements with the scale on the right): a) initial state; b) yielding state; c) peak capacity

Results of the monotonic test were compared with the results of a pushover analysis. The strip model used in the pushover analysis was in good agreement with the initial stiffness but underestimated the strength with about 42%. When the plastic hinge was calibrated according to experimental behavior, the accuracy of the model was very much improved (Figure 3). This reduction of the panel area conservatively reduces the design strength and stiffness of the structure.

Figure 3: Comparison of experimental results for rigid specimen with 2mm thick panel and numerical results using the strip model

If Figure 2 and Figure 3 are compared, it may be seen the infill plate has out-of-plane deflections in the initial state, see Figure 2.a (it corresponds to point (a) in Figure 3). At yielding, the multiple buckle wavelengths are already visible, see Figure 2.b (it corresponds to point (b) in Figure 3). When the peak capacity is reached, the maximum out-of-plane deflections are doubled compared to yielding state, see Figure 2.c (it corresponds to point (c) in Figure 3).

2.3 Cyclic tests

In the cyclic tests, all specimens exhibited stable behavior up to cycles of 4% interstory drift. Panels yielded at approximately 0.005 of the story height. Some local cracks were initiated at the corners of the panels at drifts of approximately 2%. Local plastic deformations were observed at the beam flange in compression for rigid connections. Bolted connections between infill panels and the fish plates shown small slippages but no plastic deformations either in plates or bolts. This enabled a very easy dismantling of the steel panels after the test. Associated with a small residual drift (for rigid structure), this can assure an easy intervention to replace the damaged panels after a moderate earthquake. Some pinching was recorded in the hysteresis loops for large drifts and semi-rigid specimens, only. This can be attributed to the bolted connection between boundary beams and columns and not the slippage of the connection between infill panels and fish plates. This is particularly important at the evaluation of the q factor, as the pinching need to be taken out at the evaluation of the ultimate displacement.

Figure 4 (left) plots the hysteresis of rigid and semi-rigid specimens. Contribution of rigid connections on the ultimate capacity of the specimens is larger than in the monotonic tests. As the initial stiffness is mainly attributed to the panels, differences between rigid and semi-rigid specimens in terms of stiffness are not as important as differences in terms of strength.

The main parameters associated to the global performance of the SPSW systems are the energy dissipation and global ductility (given by behavior factor q). The cyclic tests on three SPSW systems with coupling beams have shown significant ductility and energy dissipation

capacity. The specimens were capable of following large number of inelastic cycles, reaching relatively large drift values (beyond 4%). The area enclosed by a hysteresis curve is a measure of the energy dissipated by the system during a loading cycle. The hysteresis curves of all specimens are fairly wide, indicating good energy absorption of the system. In order to assess quantitatively the performance of the test specimens, the energy dissipation was calculated for each test specimen (Figure 4, right).

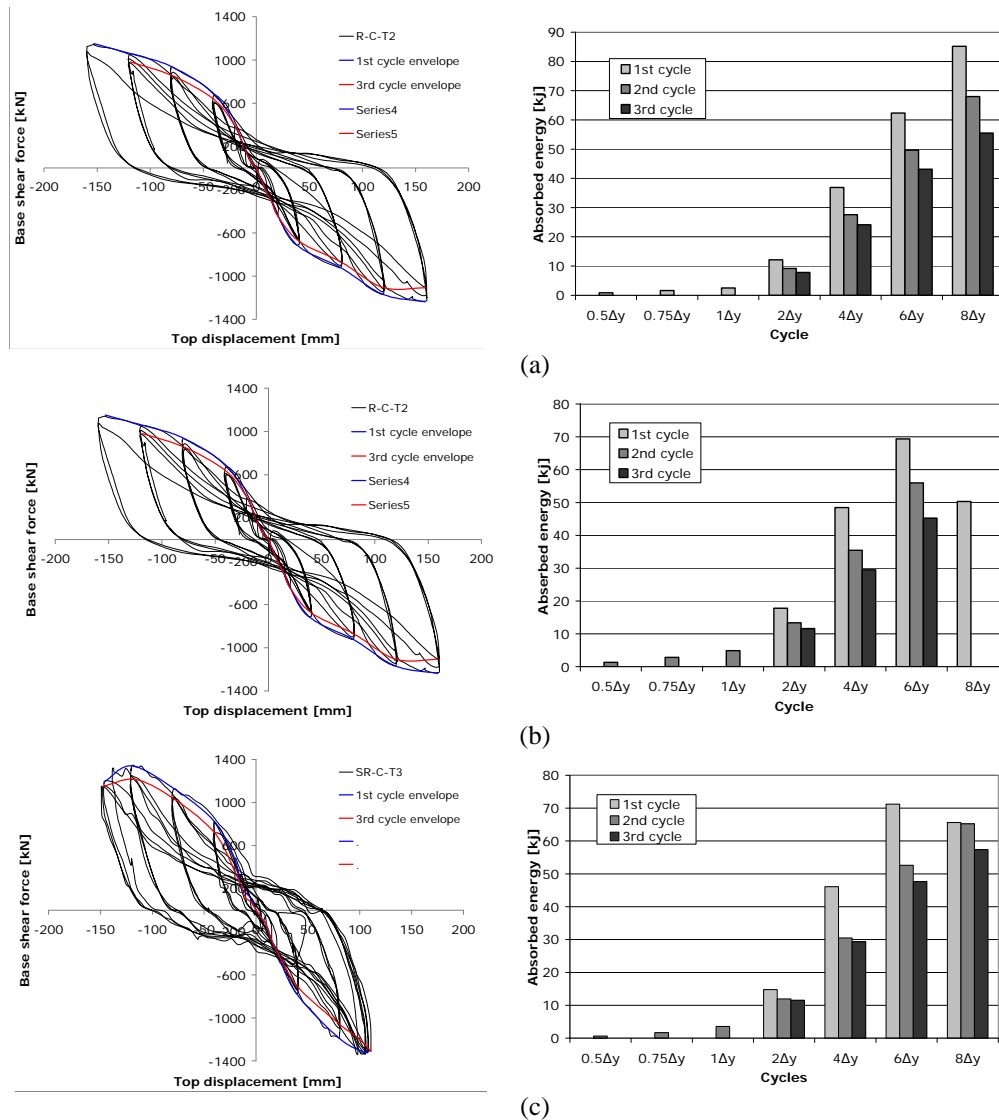

Figure 4: Hysteresis curve and energy dissipation per cycles: a) R-C-T2 specimen; b) SR-C-T2 specimen; c) SR-C-T3 specimen;

An important objective of the experimental program was, also, the evaluation of the behavior factor q . The q factor can be expressed as a product of the ductility factor, q_μ , that accounts for the ductility of the structure and the overstrength factor, q_s , that accounts for the strength reserve of the structure. The overstrength may vary significantly and is affected by the contribution of gravity loads, material overstrength, structural redundancy, etc. Therefore, in order to calibrate the behavior factor q , it is more important to focus on the ductility component, which can be taken equal to the displacement ductility factor, μ . The ductility reduction factor q_μ is therefore defined as the ratio of the ultimate displacement D_u and the yield displacement

D_y . The parameter D_u corresponds to a reduction of the load carrying capacity of 10% compared to the maximum one. This reduction could be also 20%, but 10% was also imposed by the stroke limitation. The yielding displacement D_y was evaluated with ECCS methodology and the "stiffness method", where the yield point corresponds to the modification of the elastic stiffness. Based on the observation of the hysteresis curves, the ultimate displacements D_u for SR-C-T2 and SR-C-T3 were corrected to take into account the pinching during the load reversal. Table 3 presents the q_u factor values for the specimens. Comparing the values obtained with the two methods, it may be seen the specimens have different ductility factors q_u , with values of 4.2 and 5.2. As mentioned before, overstrength factor, q_s , depends on many factors but for a structural system it can be conservatively evaluated and prescribed in codes. For example, [2] indicates for ductile steel plate shear walls overstrength factor R_s (equivalent to q_s) equal to 1.6. Similar recommendations are given by Berman and Bruneau [8], who recommend an overstrength factor $R_s=1.5$. These values show SPSW structures can provide q factors similar to those corresponding to other dissipative structure, like for example moment resisting frames or eccentrically braced frames.

Structure	D_y		D_u	q_u	
	CEN	stiffness		CEN	stiffness
R-C-T2	38	31	153	4.0	4.9
SR-C-T2	33	26	163	4.9	6.3
SR-C-T3	40	33	147	3.7	4.5
Average value				4.2	5.2

Table 3: q factor values

3 EVALUATION OF PERFORMANCE OF STEEL PLATE SHEAR WALL FRAMES

3.1 Design and modeling

In order to assess the performance of steel plate shear wall structures, numerical studies using a nonlinear dynamic procedure were conducted. The geometry of the structure is presented in Figure 5. The interior bays with infill plates consist of either pinned or rigid connections. All stories are 3.5m height. The steel material for the members is S235 ($f_y=235\text{N/mm}^2$), S355 ($f_y=355\text{N/mm}^2$) and S460 ($f_y=460\text{N/mm}^2$). The slenderness ratio L/t_w and the aspect ratio L/h of shear walls amount 420 and 0.8, respectively. The design was carried out according to EN1998-1 **Error! Reference source not found.** and P100-1 [9]. For dual frame systems of moment frames and shear walls, EN1998-1 does not provide any recommendations regarding the q factor. Thus, the results of the experimental program were taken into account, q factor of 6. A 4 kN/m^2 dead load on the typical floor and 3.5 kN/m^2 for the roof were considered, while the live load amounts 2.0 kN/m^2 . The buildings are located in a high seismic area (i.e. the Romanian capital, Bucharest), which is characterized by a design peak ground acceleration $0.24g$ for a returning period of 100 years, and soft soil conditions, with a corner period $T_C=1.6\text{sec}$. It is noteworthy the long corner period of the soil, which in this case may affect flexible structures. For serviceability check, the returning period is 30 years, while for collapse prevention it is 475 years. Beams and columns were modeled with plastic hinges located at both ends. The shear walls were modeled with dual strip model, using 10 inclined pin-ended strips, oriented at angle α in both sides.

Figure 5: Structural systems investigated in the numerical study

3.2 Ground motion records

A set of seven ground motions were used. Spectral characteristics of the ground motions were modified by scaling Fourier amplitudes to match the target elastic spectrum from [9], see Figure 6. This results in a group of semi-artificial records representative to the seismic source affecting the building site and soft soil conditions in Bucharest. The procedure was based on the SIMQKE-1 program (Gasparini & Vanmarcke, 1976) [10].

Figure 6: Elastic response spectra of semi artificial records and P100-1/2006 elastic spectrum

3.3 Analysis procedure and results

For the evaluation of the behavior factor q , acceleration time history motion records have been scaled to multiple levels, up to the collapse or the attainment of certain limiting criteria (eg. exhaustion of rotation capacity in elements). Figure 7, Figure 8 and Figure 9 show the maximum interstory drift ratio vs. spectral acceleration S_a for all structures and records. It can be seen the structure with rigid connections has smaller interstory drifts compared to the structure with pinned connections. The q factor was defined as the ratio between the acceleration leading to collapse and the acceleration leading to first yielding. Based on the results of the experimental test, first yielding forms in infill plates and corresponds to an interstory drift of 0.5%. The collapse criterion is given by the attainment of dynamic instability or plastic de-

formation capacity of dissipative members, steel panels and beams. For the beams, the plastic rotation capacity was considered 0.035rad. The experimental tests demonstrated that steel panels can sustain an interstory drift of 4%, which is equivalent to 0.035 radian plastic deformation in beams. Table 5 shows the values of q_μ for rigid and pinned structure. The type of ground motion affects the behavior factor q_μ . The mean values of the q_μ factor vary with the height of the structure. 12 and 18 storey structures present almost constant q factors while the 6 storey structure presents slightly lower values. If these values of the ductility factor q_μ are combined with the overstrength factors q_s (see section 2.3) the total q factor is obtained. It may be seen the design of SPSW structures may use similar behavior factors q as other dissipative structures, i.e. moment resisting frames.

4 CONCLUSIONS

Experimental and numerical investigations were conducted on dual steel plate shear wall structures. A total of 4 specimens were designed and fabricated, which included specimens of semi-rigid and rigid connections. Specimens were tested monotonically and cyclically. Rigid connections increased the “yield resistance” and the ultimate capacity of the structures. The initial stiffness was also improved when rigid beam-to-column connections were used. Behavior factor q (considering the contribution of the ductility, only) was evaluated, based on two methods. The q factor values indicate that SPSW structures exhibit a dissipative behavior, similar to other dissipative structures, like for example moment resisting frames. For extending the results on the behavior factor q for SPSW structures, a numerical study on different structures was performed. Behavior factor q varies with the height of the structures and type of ground motion. The mean values of q factors obtained via numerical analysis are very closed to those resulted from experimental tests.

Keywords: steel bracing, friction damper, .strain hardening.

Abstract. *The papers investigates the behavior of steel frames with friction dampers connected to steel braces. Both numerical and experimental analyses have been conducted in order to characterize in terms of energy dissipation capacity such a type of systems and obtain an equivalent hysteric model to be used in numerical simulations. Tests have been realized for two series of brace members equipped with strain hardening friction dampers: 1st series with the brace designed to avoid buckling; 2nd series with the brace working and prone to post-elastic buckling after the damper consumed its stroke. The equivalent brace-damper model experimentally calibrated has been applied in numerical simulation of multi-storey frames in order to observe their performance in comparison with conventional centric braced systems. In the paper the test results and numerical simulations are summarized as well as the resulted conclusions.*

1 INTRODUCTION

In general damping devices can be classified according to their behavior as follows:

1. Velocity dependent devices

These devices are dependent of the velocity of application of the load. They modify their hysteretic behaviour according to velocity (Figure 1). As an example we can mention here fluid viscous dampers and fluid spring dampers.

Figure 1: Influence of velocity on hysteretic behavior of fluid viscous dampers [1]

2. Displacement dependent devices

In the category enter devices non-linear behaviour such as: steel hysteretic dampers, shape memory alloy devices, and with linear behaviour such as: elastomeric viscoelastic devices. The damper to be used in the research is a strain hardening friction damper of SERB type manufactured in Romania with the hysteretic behaviour described in Figure 2.

Figure 2: Hysteretic behavior of SERB type friction damper prototype

The paper analyses the behavior of steel dual frames with centrally braced frames in the mid span. The aim is to study and analyze new systems to improve the seismic behavior of steel structures

The studied frame is a dual frame with moment resisting frames and concentrically braced frames equipped with friction dampers at the base of the braces to improve their seismic response. The frame was designed according to EC3, EC8 and special considerations from the Romanian seismic design standard P100-2006 [3] for response spectra with TC=1.6.

For the experimental program a part of the braced frame was extracted and tested in laboratory both with and without damping devices (Figure 3).

Figure 3: part of the braced frame extracted for experimental tests

2 DESIGN PRINCIPLES

For braced structural systems the seismic design concept translates in designing the braces to dissipate the energy induced by the earthquake through the formation of plastic hinges protecting the elements that are considered non-dissipative from degradation. This concept leads to the introduction of the behavior factor q that reduces the design seismic forces. Introducing damping devices in the structure leads to an increase in energy dissipation capacity of the structure. For these structures the energy dissipation devices represent „sacrificial” elements that assume the role of energy consumers entirely by plastic deformations that occur in the devices. The device prototype that is being analyzed here presents a particular pseudo-elastic behavior. This device does not have elements that yield. Instead, it consumes energy through friction from the elongation and compression of a set of steel rings around a steel core. The structures equipped with this particular type of dampers can be designed using two different concepts. A first concept is to design the braces to remain in elastic domain controlling the response of the structure solely through the friction dampers. In this case the structure has no ductile elements and is designed with a behavior factor corresponding to low dissipative structures of $1 < q < 2$ and benefits from the reduction of design seismic forces due to the increase in global damping. However, introducing supplemental damping in the structure leads to a much smaller reduction of design seismic loads compared to the reduction that comes from using a higher behavior factor value that corresponds to a dissipative design approach in which the brace itself is the main energy consuming element. For example an increase of damping in the structure to 15% critical damping leads to a reduction of the loads with only 35% [2]. Furthermore these types of dampers have a brittle failure that must be avoided in all configurations. All the above mentioned lead to a second design concept in which the damper has sufficient over strength compared to the brace to assure that the brace has deformation in the plastic domain and is the weaker element in the configuration. This concept should benefit in theory from both the energy dissipation capacity of the brace and the supplemental damping from the device, and the failure will occur in the brace and not in the device. For seismic motion levels corresponding to ultimate limit state the brace is the „active” element according to the dissipative design concept and for service limit state the damper is the „active” element ensuring that the brace remains in elastic domain and providing an overall damping increase. According to P100/2006 [3] the relative story drift criteria for SLS is $0.008h$, where h is the story height. For the structure analyzed here this translates in a drift value of 28mm which

leads to a displacement of 20mm in the brace. The damping devices were selected to satisfy this displacement criteria corresponding to SLS. Both design concept presented above will be used in the configuration of the experimental tests that will be presented further on.

3 EXPERIMENTAL PROGRAM

The experimental program is divided in two parts:

- (1) experimental tests on friction dampers;
- (2) experimental tests on single brace configuration with and without dampers.

3.1 Experimental tests on friction dampers

Experimental tests were performed on two dampers with maximum capacity of 800kN and 1500kN. The tests were performed in the CMMC laboratory using a cyclic load protocol. The tests were done using a load control protocol having as reference the maximum capacity of each damper. Three cycles were considered at each force level (Figure 4a).

Figure 4: Cyclic force control load protocol (a) and force displacement curve obtained for 800kN damper (b)

The hysteretic curves obtained experimentally were in accordance to those supplied by the manufacturer (Figure 4b).

3.2 Experimental tests on single brace configuration with and without dampers

The experimental model is made from half of the beam and the brace, hinged at both ends with or without dampers installed. In the experimental program the two design concepts presented before can be found. The first concept is based on a design of the system so that energy dissipation occurs in the damper alone. This was achieved by designing the brace with sufficient over strength relative to the maximum capacity of the device. The second design concept follows both the behavior of the damper and of the beam in post-elastic domain. This was achieved by choosing the device with sufficient over strength with respect to the brace. According to these principles the cross sections of the brace were chosen as follows:

- (1) „Strong” brace configuration (HEA240);
- (2) „Weak” brace configuration (CHS D133x5 and HEA100)

The experimental program is detailed in Table 1:

No	Brace	Specimen	Damper	Type	Tests	Measured Parameters
1.	HEA 240	BDE-C	YES	cyclic	2	-relative displacement of the brace -total displacement -brace force -damper displacement -global behavior
2.	CHS, D133,t=5	B-MT, B-MC	NO	monotonic	2	
3.	CHS, D133,t=5	B-C	NO	cyclic	2	
4.	CHS, D133,t=5	BDY	YES	cyclic	2	
5.	CHS, D133,t=5	BDY	YES	cyclic	2	
6.	HEA100	HB-MT, HB-MC	NO	monotonic	2	
7.	HEA100	HB-C	NO	cyclic	1	
8.	HEA100	HBDY-C1	YES	cyclic	1	
9.	HEA100	HBDY-C2	YES	cyclic	1	

Table 1 : Experimental program for brace tests with and without dampers

3.3 „Strong” brace configuration with damper (BDE)

In order to validate the experimental behavior of the test configuration in this stage is based on the „strong” brace concept in which the brace is designed to remain in elastic domain. The aim of these tests is to study the behavior of the damper with the brace as the element with over strength. The load protocol used is identical with that used for the single damper having as reference the maximum force capacity of the damper. The experimental test configuration (Figure 5a) and total force-displacement recorded for the HEA240 brace (Figure 5b) are presented below.

a.

b.

Figure 5: Experimental test configuration (a) and global force-displacement curves for specimen BDE (b)

The total response of the system is governed by the behavior of the damper resulting in a symmetrical behavior both in tension and in compression without strength and stiffness degradation. The brace remains in elastic domain for the entire test duration. The test was stopped when the device reached its maximum capacity. For the “weak” brace configuration two types of cross-sections for the brace were used as it was presented in the summary of experimental program. The procedure of experimental investigation was the same for the two brace types and the results showed the same global behavior of the brace with and without damper. For this reason only the experimental data obtained on HEA100 braces will be presented here.

3.4 HEA100 brace with and without damper

Monotonic tests were conducted at first for the brace without damper in order to determine the yield displacement and yield force which was used to construct the load protocol according to ECCS procedure that was used for the cyclic tests that followed. The experimental test setup had the same general configuration as the one described in the paragraph above. The behavior curves obtained for the monotonic tests and buckling of brace is presented in Figure 6a,b.

a.

b.

Figure 6: Monotonic test results on HEA brace without dampers (a) and buckling of the brace in compression (b)

The load protocol for the cyclic tests was constructed using the results from the monotonic tests. The loading protocol is made according to ECCS procedure with cycles at steps of magnitude 0.25, 0.5, 0.75, 1.0, 2, 4, 6, 8 times e_y with 3 cycles at each step following e_y (e_y -yield displacement of brace obtained from monotonic tests). The hysteretic behavior of the HEA brace without damper under cyclic load with $e_y=4$ mm is presented in Figure 7a and the brace equipped with damper under cyclic load in Figure 7b.

a.

b.

Figure 7: Hysteretic behavior of the HEA100 beam without damper under cyclic load(a) and with damper under same cyclic load(b)

4 DISCUSSION

In order to analyze the influence of the damper on the global behavior of the brace the hysteretic behavior of the brace without damper is taken as reference curve. The behavior of the

brace with damper obtained for the two design concepts of „weak” and „strong” brace is therefore compared with the hysteretic behavior of the brace without damper.

4.1 „Strong” brace with damper configuration

The behavior of the brace with dampers taken as reference is considered that recorded for double T section profile of the brace (HB-C) mainly following two parameters: recorded total force in the brace and total displacement of the brace. This is compared to the behavior recorded for the system comprised of „strong” brace (HEA240) with damper (BDE).

In this design concept the global behavior of the system of brace and damper is completely governed by the constitutive law of the damper and its properties. The system does not suffer any degradation in terms of strength and stiffness these being strictly dependent on the damper properties. The system will continue to take on load until the maximum capacity of the device is reached, with the brace remaining in elastic range. This high load carrying capacity without strength and stiffness degradation represents the advantage of this type of design concept but can also lead to an increase of the load levels in the beams and columns of the braced frame due to the pseudo-elastic behavior of the damper. Furthermore failure of this type of system is a brittle one due to failure of the device and must be avoided.

4.2 „Weak” brace with damper configuration

In this design concept the brace is allowed to have plastic deformation and the global behavior of the damper brace system is a mixed one. The weak element in this configuration is the brace which will ultimately fail. The behavior of this system is presented in Figure 8a in comparison with the behavior of the same brace, under the same load protocol but without damper.

Figure 8: Comparison between the total hysteretic behaviors of the “weak” brace with damper and without damper (a) and hysteretic behaviors up to $2\epsilon_y$ (b)

In both configurations the force level drops significantly after the first cycle at each load step and the next two cycles of the same load step. The brace with damper has a higher flexibility and yields at the same load step but at a displacement of approximately 50% higher. For this system up to a level of $2\epsilon_y$ the global behavior is governed by the behavior of the damper and by the behavior of the simple brace at higher load steps. The difference between these two systems can be observed more closely up to a level of $2\epsilon_y$ (Figure 8b).

Up to this level the behavior is that given by the damper parameters. At tension cycles the brace remains in elastic domain and the load level in the system is significantly smaller than that of the brace without damper with a higher overall flexibility. For compression cycles the brace with damper buckles at the same load level as the one without damper but has a higher deformation capacity due to the damper properties. The experimental results are in agreement with the two design concepts considered. For the starting load levels of up to $2d_y$ the brace remains in elastic domain and has a lower level of energy dissipation but there is a significant decrease in load level due to the damper and also an increase in flexibility. After this level the hysteretic behavior of the system is very similar to that of the brace without damper, with energy dissipation due to the formation of a plastic hinge in the brace. Failure in this design concept is represented by the failure of the brace in compression. As a preliminary conclusion it is expected that this type of damper could improve the behavior of rigid structures that are sensitive to formation of plastic hinges at levels corresponding to service limit state.

5 NUMERICAL MODELLING

The numerical modeling can be split mainly in two independent parts or stages. The first stage consists of numerical simulation of the behavior of the two elements, the brace and the damper separately, but most importantly their behavior as a whole. The second stage consists of a series of numerical simulation on the full dual frame with and without dampers in the braces. Numerical time-history analysis will be conducted using a set of recorded seismic motions scaled to the design spectra. The final stage consists of performance base evaluation of the structure with this type of damping devices and the comparison with other types of damping devices used for seismic protection.

5.1 Brace modeling

The main issue that arises with brace modeling is the accurate modeling of brace behavior at buckling. For the numerical simulation SEISMOSTRUCT version 5.5 Build 10 software was used, a finite element package that uses fiber formulation. The buckling behavior of brace was modeled using geometric imperfections computed according to EN1993 1-1[4]. The brace element was divided into segments with each point having corresponding values of the imperfections computed based on a parabolic shape of the deflection with the value of the imperfection computed at midpoint of the element $e_0 = 26.54$ mm. A parametric study was conducted to determine the optimum number of elements in which the brace is to be divided and the value of the imperfections to be adopted comparing the cyclic behavior of the brace with the behavior obtained from experimental tests. The brace was divided in 2 and 4 elements and for each of the 2 models 4 values of the imperfections were considered: e_0 , $e_0/2$, $e_0/3$, $e_0/4$ (Figure 9a). The material properties used were also obtained experimentally from tension tests on steel samples from the HEA100 brace.

The best results were obtained for the 2 element brace with a value of imperfection at midpoint of $e_0/2$ (Figure 9b). Parametric studies conducted by Landolfo et.al.2010 [6] also recommended the use of 2 element division for modeling cyclic behavior of brace

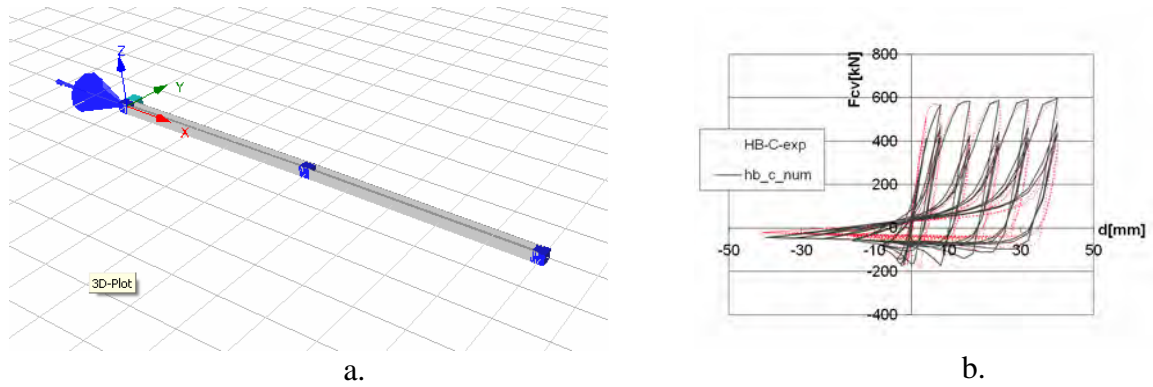

Figure 9: Brace model in SeismoStruct (a) and comparison between cyclic behavior of brace from the numerical model with the one obtained experimentally

5.2 Damper modeling

For modeling of devices SEISMOSTRUCT software offers the use of link elements that have the possibility of defining different hysteretic behavior for each of the 6 degrees of freedom. To model the behavior of the SERB damper a combination of two parallel link elements was used. The hysteretic loops of the damper were modeled using a bilinear symmetric behavior type link (Figure 10b) combined with a gap-hook element that is employed to model the pinching of the curve (Figure 10a). These types of behavior laws were defined only for the degree of freedom corresponding to axial deformation, the other 5 degrees having a linear elastic behavior with sufficiently high stiffness as to ensure their restraint.

Figure 10: Gap-hook behavior (a) and bilinear symmetric behavior of link element (b) [5]

The behavior obtained in the numerical model using the combined behavior these 2 types of link elements provide a satisfactory model behavior of the damper (Figure 11b)

5.3 Brace with damper model

The behavior of the brace with damper is obtained combining the models discussed above for the brace and the damper. The results from the numerical model were compared to the experimental results HBDY-C1 (Figure 11a).

Figure 11: Comparison between experimental and numerical behavior of HEA brace with damper (a) and comparison of the experimental and numerical damper behavior (b)

The numerical model presents the same global behavior as the one obtained from experimental data with a damper governed behavior up to $2\epsilon_y$ and a brace governed behavior afterwards, reaching the same peak values of force for each tension cycle and with sufficiently accurate modelling of sliding of the damper at zero force point transition. This two models for the brace and for the damper as presented above are employed in the overall assesment of the behavior of the full frame.

5.4 Numerical simulation on the full frame

The structure analyzed is a 5 storey plane frame extracted from a 3x3 layout with 3 spans of 6m with chevron bracing in the mid-span and a storey height of 3.5m (Figure 12a). The frame was design according to EC3 and EC8 with some special considerations from the Romanian seismic design code P100/2006 considering the design spectra for Bucharest with a corner period of $TC=1.6s$. Time-history analyses are conducted using two sets of seismic motions recordings scaled to the design spectra as follows: 7 recorded seismic motion characteristic for soft soil type (Bucharest) and 7 artificially generated seismic motions characteristic for stiff soil (Class B soil according to SREN1998-1) both with and without dampers (Figure 12b). The two target spectra were scaled to the fundamental period of vibration of the analyzed structure, so as to yield roughly the same design seismic forces. Three performance levels were considered for each seismic motion having an acceleration multiplier of 0.5, 1.0, 1.5 corresponding to serviceability limit state (SLS), ultimate limit state (ULS) and collapse prevention (CP) respectively. Performance based evaluation was performed using acceptance criteria for plastic deformation in the braces and plastic rotation for beams and columns according to FEMA356

Figure 12: Analyzed frame geometry (a) and design spectra used (b)

For the first set of time-history analysis the 7 seismic motion recordings for a soft soil type scaled for the Bucharest response spectra were used. For all 7 seismic motions used the results showed that for all performance levels the building with dampers exhibited a significant increase in drift for all 5 storeys. For SLS (0.5) the building without dampers does not form any plastic hinges in elements while the building fitted with dampers forms plastic hinges in the bracing with values of plastic deformation that check the acceptance criteria for immediate occupancy (IO) from FEMA. At ULS (1.0) both frames with and without dampers form plastic hinges in braces and in the central beams. At this level the structure with dampers has a higher number of plastic hinges in elements and a higher value of plastic deformation/rotation in elements then the structure without dampers. The values of plastic rotation for the beams exceed the acceptance criteria corresponding to life safety (LS) from FEMA 356. At collapse prevention (1.5) the behavior of both types of frames is considered unsatisfactory due to the formation of plastic hinges in central columns at most levels. As example max drift values for 3 of the 7 seismic motions with $T_C=1.6$ s are shown in Figure 13 and values of plastic deformation/rotation for first seismic recording VR-77-INC-NS at SLS (Table 2) and ULS (Table 3, Table 4, Table 5) with and without dampers in the braces are presented.

For the second set of time history analysis the 7 seismic motion recordings for a hard soil type scaled for the Type 1 response spectra and Class B soil according to EN 1998 were used. For all 7 seismic motions used the results showed that the building with dampers exhibited a decrease in maximum drift values for SLS and an increase for the other 2 performance levels. For SLS the frame with dampers does not form any plastic hinges in the braces as opposed to the one without dampers (Figure 14a, b). At ULS the presence of dampers continues to improve the behavior of the structure by reducing the number of plastic hinges in elements but

with higher values of drift at each storey (Figure 14c, d). As example max drift values for 3 of the 7 seismic motions with $T_C=0.5s$ are shown in Figure 15 and values of plastic deformation/rotation for first seismic recording at SLS (Table 6) and ULS (Table 7, Table 8, Table 9) with and without dampers in the braces are presented.

Table 9: Plastic rotation at ULS for central beams for B1 seismic recording (stiff soil)

At CP the global behavior of the two structures is similar, however for some of the seismic recordings for which the structure without dampers forms plastic hinges in central columns at the base of the structure the structure with dampers has no plastic hinges in columns. For all performance levels the recorded plastic deformations/rotations satisfy the acceptance criteria.

6 CONCLUSION

Experimental tests were conducted on SERB type friction damper and on damper with brace configuration. Two design concepts with “weak” and “strong” brace configuration were proposed and tested. The main purpose of the experimental program was to obtain the hysteretic behavior of the friction damping devices and the global behavior of the ensemble of brace together with damper in the two design concepts. A numerical model was developed for the brace with damper assembly and used in a performance based evaluation of the building under 2 sets of 7 recorded seismic motions scaled on 2 types of response spectra. The first set of numerical analyses showed that the frame equipped with dampers increases the flexibility of the structure, forming plastic hinges at SLS with a higher number of plastic hinges with higher values of plastic deformation/rotation in braces and beams respectively that no longer satisfy the performance criteria and generally a worse global behavior. The conclusion is that this particular type of damper is not efficient in reducing the seismic response of a building for earthquakes characterized by a high value of corner period $T_C=1.6s$ (soft soil). The second set of numerical analyses showed that the frame equipped with dampers has a better performance avoiding the formation of plastic hinges at SLS and reducing the values of maximum drift, reducing the number of plastic hinges in elements at ULS and for some recordings avoiding the formation of plastic zones in columns at CP. The conclusion is that this particular type of damper is efficient in reducing the seismic response of a building for earthquakes characterized by short corner period $T_C=0.5s$ (stiff soil).

Keywords: reinforced concrete structure, strengthening, concentric brace, buckling restrained brace, energy dissipation, q factor.

Abstract. *Many reinforced concrete structures built before 1960's were designed to resist mainly gravity loads and wind, even if they were located in seismic zones. That is why when subjected to earthquakes of intensities even below the design level, they are at risk because of poor detailing and lack of capacity. Evaluation of such type of structures according to the present seismic design provisions leads, in most cases, to the necessity of strengthening.*

In the paper, the strengthening of non-seismic reinforced concrete frames with dissipative inverted V bracing systems is presented. Conventional concentric V braces and buckling restrained V braces are used. Portal frames with and without bracings are isolated from a real structure and tested experimentally under monotonic and cyclic loading. The tests aimed to offer information related to the real dissipation capacity of the initial unretrofitted structure and the retrofitted structures, including the effectiveness of connecting details of pre-stressed tendons, specifically designed for connecting braces in an existing frame. Both test results and numerical simulations on portal frames and on strengthened building frames have been used to evaluate the q factors.

1 INTRODUCTION

In many areas with seismic risk, the reinforced concrete structures (RC) built before 1960's were designed to resist mainly gravity loads. The main deficiencies of these structures are linked to low quality of material (poor concrete) and insufficient detailing (insufficient confinement and anchorage of the reinforcements), and thus leading to reduced local and global ductility and, finally, to a poor seismic response. When such types of structures are evaluated according to the present seismic design provisions, one finds out that, in almost all cases, strengthening is needed. Intervention strategies must be appropriately selected and applied but at the same time they must be linked to the available capacity of existing structure in terms of strength, stiffness and ductility. Reinforced concrete jacketing or FRP wrapping of existing members are among the most used strategies. Disadvantages of these strategies are linked to their irreversibility and lack of efficiency when lateral stiffness is insufficient. In these cases, the system can be improved by adding new structural elements, e.g. steel bracings, with or without local strengthening of elements with deficiencies. The main objective of the study is to validate a seismic strengthening technique for non-seismic reinforced concrete frame buildings that consists of conventional concentric V braces (CBS) or buckling restrained V braces (BRB). Numerical and experimental investigations were carried out at Politehnica University of Timisoara, within CEMSIG Research Centre (<http://cemsig.ct.upt.ro>) in order to study and realize this intervention [1]. The case study is represented by a historical building, erected in the first half of the XXth century. The reinforced concrete building was designed according to the Italian design code at the time but is characteristic of many reinforced concrete buildings constructed before 1970 both in Italy and in other southern European countries.

2 PERFORMANCE BASED EVALUATION AND RETROFIT OF A REINFORCED CONCRETE FRAME BUILDING

The 3 story building has plan dimensions of 23.4 by 18.4 m and 11.95 m height (Figure 1). The characteristics of rebars and concrete were considered those used in that period, i.e. concrete characteristic compressive strength $f_{ck}=20\text{N/mm}^2$, rebars with a characteristic yield strength $f_{sk}=230\text{N/mm}^2$. The specific detailing of the reinforcement is also characteristic for the design practice at that time, with poor anchorage length of the rebars at the external beam-to-column joint, the use of plane rebars (not ribbed), inclined reinforcement used for shear resistance and large spaced stirrups (15cm for columns and 25cm for beams) in plastic zones.

In the first step, the evaluation of the structural system of existing building was performed, to decide the locations of intervention. The seismic response was first evaluated using a response spectrum analysis. The seismic load for ultimate limit state verifications was defined through an elastic spectrum with the following parameters: peak ground acceleration (PGA) of 0.23g, $\gamma_I=1.0$, $T_B=0.15\text{s}$, $T_C=0.5\text{s}$, $T_D=2.0\text{s}$ and $S=1.2$, where the periods T_B , T_C and T_D and the soil factor S describe the shape of the elastic response spectrum and depend upon the ground type. Considering the very poor ductility of the structure, a seismic behavior factor $q = 1.5$ was used. For structure strengthened with BRB, the seismic behavior factor q amounted 4, while for structure strengthened with CBS, the seismic behavior factor q amounted 2. For the steel braces, the cross sections requirements were: in X direction, ground floor = 8 cm^2 , 1st level = 4 cm^2 , 2nd level = 3 cm^2 ; in Y direction, ground floor = 6 cm^2 ; 1st level = 5 cm^2 and 2nd level = 3 cm^2 .

Then, a detailed seismic evaluation using a static nonlinear analysis, both for initial structure and for strengthened structure, was performed. The static nonlinear procedure was based on the N2 method (EN 1998-1, 2004) [2]. Three limit states, defined as immediate occupancy (IO), life safety (LS) and collapse prevention (CP) were used. The performance based seismic

evaluation implied the verification of behavior at three performance levels introduced above (i.e. IO, LS, CP), using three target displacements, one for each level. The design seismic hazard (associated to LS) corresponds to a recurrence interval of 475 years. For IO and CP, the recommendation is to use hazards with 95 years return period and 975 years return period, respectively. Table 1 shows the simplified coefficients for conversion of the peak ground acceleration (PGA) corresponding to a recurrence interval (IR) of 100 years to values of PGA corresponding to IR of 30 and 475 years. The 2D analysis was done separately on X and on Y directions for all three structural systems (MRF, MRF+BRB and MRF+CBS). The concrete material was considered unconfined and modeled using nonlinear model of Kent and Park, with no tension. Reinforced concrete members were modeled with plastic hinges concentrated at both ends. The bracing system was applied on the external frames of the RC building as an inverted V system pinned at the ends. The inelastic behavior of BRB system was modeled considering the concentrated tri-linear plasticity curve with strain hardening and strength degradation of 0.8 from maximum capacity, according to FEMA356/ASCE-41 [3]. For steel braces in tension, the modeling parameters and the acceptance criteria were based on [3] and on previous experimental tests on BRB elements (see [3]) and are summarized in Table 2. Modeling parameters and acceptance criteria for CBS were also based on [3], see Table 3.

Ratio of seismic hazard/design seismic hazard	$a_g(95 \text{ years})/a_g(475 \text{ years})$	$a_g(975 \text{ years})/a_g(475 \text{ years})$
Conversion coefficient	0.5	1.50

Table 3: CBS modeling parameters for the analysis

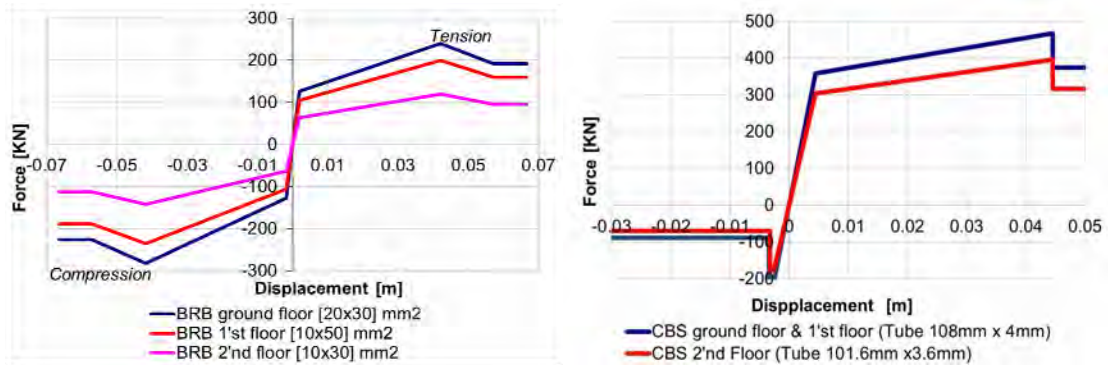

Figure 2: a) Tri-linear modeling on Y direction of: a) BRB system; b) CBS system

The results of the pushover analysis on Y direction are presented in Figure 3.a. Figure 3.b, Figure 3.c and Figure 3.d show the history of plastic hinge in the structures for LS performance level. Different symbols were used to plot the plastic rotation demand in elements: triangle shape is associated to IO, circular shape to LS and rhomb shape to CP.

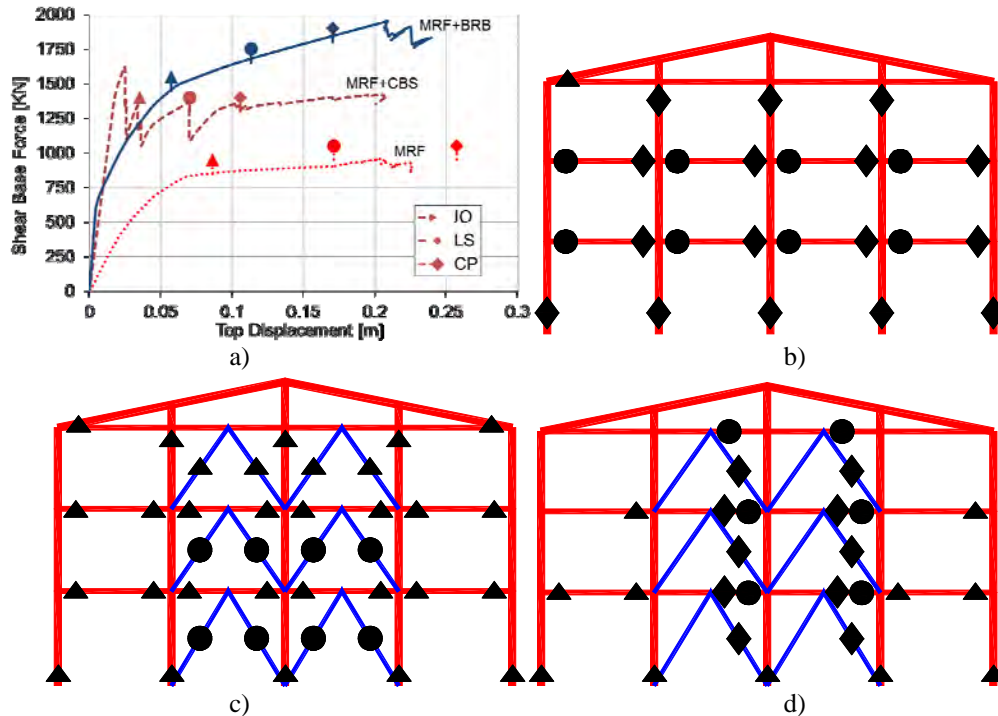

Figure 3: a) Pushover curves on Y direction; Location and stage of plastic hinges corresponding to a LS performance level for; b) MRF (frontal view on Y direction); c) MRF+BRB; d) MRF+CBS

It may be seen the initial structure MRF (Figure 3.b) has a limited ductility and does not attain the performances required for LS, as the plastic rotation demand in beams and columns exceed even CP criteria. When the structure is strengthened with BRB, the behavior is much improved. The stiffness and the strength increase and for LS performance level (Figure 3.c) there are no elements where the acceptance criteria are exceeded. When the strengthening system with CBS is used, the result is a structure with a good stiffness and strength. After the compression brace buckles, there is a reduction of the capacity. It may be noticed that even if less plastic hinges occurred in columns, beams requirements are beyond the acceptance criteria (Figure 3.d). Thus, the unbalanced vertical action effect is transferred to the beam and plastic hinges develops at the beam end and in the vicinity of brace-to-beam connection.

3 EXPERIMENTAL VALIDATION OF STRENGTHENING SYSTEMS FOR SEISMIC RETROFIT OF A REINFORCED CONCRETE FRAME STRUCTURE

3.1 Test Specimen

Following the results of the nonlinear static analysis, a RC portal frame was isolated from the case study building (Figure 1). Six reinforced concrete frames of 3.2m height and 4.5m span were tested under monotonic and cyclic loads: two RC frames (MRF), two RC frames strengthened with BRB (MRF+BRB) and two RC frames strengthened with CBS (MRF+CBS). Results of materials testing are presented in Table 4. The BRB steel core plate (Figure 4) was divided into three main segments: the end segment (connection), the transition segment and the yielding segment. Based on the experimental results obtained on BRB elements only ([1], [5]), polyethylene foil of 1 mm thick was used as unbonding material. It should be mentioned here the BRB systems must be subjected to a technical validation procedure before intended use, which includes relevant type tests and factory control tests (see EN 15129, [4]). The core was designed for S235, but the material supplied shown larger values by more than 40% (or 100 N/mm²).

Material		Nominal values [N/mm ²]	Test results [N/mm ²]
RC frame	Concrete (R_c)	20.5	35.5
	Beam rebars (f_y)	235	497
	Beam rebars (f_y)	235	402
	Stirrups (f_y)	235	290
BRB	Concrete (R_c)	20.5	35.1
	Steel Plate (f_y)	235	335
CBF	Tubular section (f_y)	235	248

Table 4: Material test results

Figure 4: Details and geometry of BRB (unbonding material – polyethylene foil, 1mm thick)

The CBS were realized from circular hollow sections with S235 steel (Figure 5). The material supplied indicated the steel yield strength is very closed to the nominal values.

Figure 5: Details and geometry of conventional brace

3.2 Test set-up

The test set-up, the loading system and the specimens installed in testing rig are presented in Figure 6. The connection details for BRB and CBS systems are similar and use pinned connections between the brace elements and the beam and at the base of the columns. In order to prevent the slip of the connection between the braces and the RC beam, high strength pre-loaded ties have been used. The effectiveness of the connecting device has been preliminary checked by FEM simulation. Thus, a numerical simulation aimed to calibrate the level of pre-stressing forces applied in the brace - frame connecting device. Local pressure on the concrete was also checked, in order to keep the connection “elastic” (Figure 7, Figure 8).

Figure 6: Test set-up: a) initial RC frame without strengthening; b) RC frame strengthened with BRB; c) RC frame strengthened with CBS

During tests, the vertical and horizontal displacements of the connections were continuously recorded and plotted. Three monotonic tests have been carried out in order to evaluate

the yielding point of each type of frame. The yielding displacements measured in the monotonic tests are then used in the subsequent cyclic tests to calibrate the cyclic loading history. The strain rate in the monotonic and cyclic tests was 5mm/min, so that the application of the load can be considered quasi-static.

Figure 7: Column base and brace to column connection

Figure 8: Beam – brace connection: pressure under the steel plate due to bolts pre-stressing

3.3 Results of monotonic tests

Figure 9 shows the force–displacement curves for the initial and strengthened frames. The effectiveness of BRB system is confirmed by the increase of both stiffness and strength. The ultimate load increases from 40kN to approximately 200 kN. The conventional brace system brings more strength and stiffness to the structure, but less dissipation capacity. The capacity increases to 230kN but the displacement corresponding to this ultimate capacity is about 50 mm, almost three times less then that corresponding to the BRB system. For the evaluation of the yield displacement (D_y) and the yield force (F_y), the ECCS methodology is used. According to this approach, yield displacement D_y and yield force F_y are obtained by intersecting the initial stiffness α_y and a tangent at the curve $F - D$ with a slope of 10% of the initial stiffness. With the yielding point defined in this way, results $D_y=29$ mm and $F_y=126$ KN for the MRF+BRB system and $D_y=24$ mm and $F_y=213$ KN for MRF+CBS system, respectively.

Figure 9: Force-displacement curves from monotonic tests

3.4 Results of cyclic tests

The modified ECCS loading protocol was applied in the cyclic tests. This modified procedure is characterized by a single loading at $D_y/4$, $2D_y/4$, $3D_y/4$ and D_y , followed by three repetitions of the cycles increased by $0.5D_y$ ($1.5D_y$, $2D_y$). The contribution of the strengthening systems is clearly indicated in Figure 10. The conventional brace system increases the capacity but, after few cycles in plastic range, there is an abrupt degradation in the hysteretic behavior due to the failure of the brace in compression. The frame strengthened with the BRB system has a much better behavior in terms of dissipation capacity.

Figure 10: Hysteresis curves for initial RC frame and strengthened frames

Figure 10 shows the frames strengthened with BRB and CBS after the cyclic test. The brace in compression of the CBS system buckles and softens after few cycles and therefore the unbalanced vertical action effect is transferred to the beam. On contrary, the BRB system has a better behavior as the two braces have similar behavior and the brace in compression is protected from buckling.

Figure 11: Photos after the test with frame strengthened with CBS a) and strengthened with BRB b)

The next photos show the cyclic damage that occurs in concrete elements, steel elements and their connections. Figure 12.a shows the crack development in initial RC frames. Bending cracks occurred first and were followed by shear cracks. The development of the shear cracks is mainly due to the inadequate distribution of stirrups. Figure 12.b and Figure 12.c show the crack development at both ends of the concrete beam and the brace connection after the test. The occurrence and development of cracks is similar to those of the initial RC frame, and were caused by the same inadequate confinement of the plastic zone. All the connections between BRB system and RC frame showed a very good behavior and there was no slippage

recorded. In case of CBS system, the slippage of the brace to beam connection was about 25 mm in one direction and 10 mm in the opposite direction and is mainly due to the horizontal component of the unbalanced load that occurs after the buckling of diagonal in compression.

Figure 12: Cracks in the concrete elements after the test: a) initial RC frame; b) frame strengthened with BRB; c) strengthened with CBS

4 EXPERIMENTAL EVALUATION OF Q FACTOR

The results of the experimental program were used also for the evaluation of the behavior factor q for tested structures. The q factor can be expressed as a product of the ductility factor q_μ , that accounts for the ductility of the structure and the overstrength factor q_s , that accounts for the reserve in strength of the structure (due to structural redundancy, material overstrength, member oversize due to design, other non-seismic load combinations and serviceability requirements). The overstrength may vary significantly and is affected by the contribution of gravity loads, material overstrength, etc. Therefore, in order to calibrate the behavior factor q , it is more important to focus on the ductility component, which can be taken equal to the displacement ductility factor μ . The displacement ductility factor q_μ is therefore defined as the ratio of the ultimate displacement D_u and the yield displacement D_y . Yield displacement D_y was evaluated with ECCS method (see section 3.3).

For the initial RC frame, the ultimate displacement D_u corresponds to the attainment of the ultimate strength (shear strength, Figure 12.a) and amounts 150 mm. For the frame strengthened with BRB, D_u corresponds to the failure of the BRB in tension (Figure 12.b) resulting an ultimate cycle of 86 mm. Taken into account the effect of slippage, which produces pinching in the hysteresis curve (see Figure 13), D_u needs to be reduced to a value of 71 mm. For the frame strengthened with CBS, D_u corresponds to the failure of the diagonal in compression (Figure 12.c) and amounts, after the correction due to slippage, 42.2 mm. For the definition of the envelope curve, the third cycle of each step was considered. The values of the yield displacements D_y are 69.4 mm for MRF, 16.3 mm for MRF+BRB and 22.5 for MRF+CBS. The values of the behavior factor q are then calculated and results are presented in Table 5. The original unretrofitted structure has a poor behavior, characterized by a low stiffness and low

dissipation capacity. As expected, the stable behavior and large ductility of BRBs leads to a q factor that can classify the strengthened structure as a medium ductility structure. When strengthened with conventional braces (CBS), the structure gains rigidity but the q factor is low, classifying the system as low dissipative.

Figure 13: Envelope of the MRF+BRB cyclic test

MRF			MRF+BRB			MRF+CBS		
Dy [mm]	Du [mm]	q	Dy [mm]	Du [mm]	q	Dy [mm]	Du [mm]	q
69.4	150	2.16	16.3	71	4.3	22.5	42.2	1.8

Table 5: q factor values

In order to extend the investigation on the behavior factor q , a nonlinear dynamic analysis was employed. The results obtained so far confirmed the values obtained via experimental tests [6]. For example, for the structure strengthened with BRB, the results had shown a good agreement with experimental tests, with a mean value of q factor of 3.9.

5 CONCLUSIONS

Experimental and numerical investigations were conducted to evaluate the seismic behavior of RC frame buildings, designed for gravity loads, before and after strengthening with steel bracing systems. The preliminary analysis has shown that the RC structure is vulnerable and does not meet the seismic requirements for a moderate seismic zone. Therefore, the structural system should be adequately strengthened in order to attain the desired level of seismic resistance. Two types of strengthening techniques were considered, one with buckling restrained V braces (BRB) and one with conventional concentric V braces (CBS). The results have shown that the structure has a limited capacity, mainly due to poor detailing of the plastic zones (lack of stirrups). When the global strengthening technique is accomplished, the behavior is much improved.

A portal frame was then extracted from the building and studied experimentally. Six frames were tested, two for each type of frame, one monotonically and one cyclically. Tests have shown a very poor behavior of RC frame. The structural system should be strengthened in order to attain the desired level of seismic resistance.

Structure strengthened with BRB had a good behavior, larger rigidity, capacity and ductility compared to the initial structure. The failure was caused by the failure of the steel brace in tension. The connections between BRB and RC elements performed very well. It was also tested the workability of the system with pre-stressed ties. The connection devices used for installing BRBs within the frame took benefit from the friction resistant forces induced by the

ties pretension and showed a very good behavior. In fact, reduced slips – with very small influence on the hysteretic loops of BRB system – were observed. Results recommend the application of this connecting system for such interventions. Moreover, in case of multi-story frames, such connecting systems also provide a beneficial confining effect at the frame joints, enhancing both strength and ductility of the MRF+BRB system.

Conventional brace system increases the strength and stiffness but is less ductile compared to BRB. In addition, the concrete beam should be able to support the vertical component of the unbalanced load when the compression brace buckles. The horizontal component of the same unbalanced load did also overstressed the brace-to-beam connection causing its slip. The application of such strengthening technique should therefore be done with caution, to avoid concentration of stresses and to reduce the ductility demands in critical sections.

Acknowledgement

The experimental program was done in the framework of RFCS project “STEELRETRO”: Steel solutions for seismic retrofit and upgrade of existing constructions. This project was developed in the period 2007-2010 and involved 11 partners from 8 European countries.

This work was partially supported by the strategic grant POSDRU/89/1.5/S/57649, Project ID 57649 (PERFORM-ERA), co-financed by the European Social Fund – Investing in People, within the Sectoral Operational Programme Human Resources Development 2007-2013.

Abstract. *This study presents the preliminary numerical and experimental results of the project Fuseis carried out with the financial grant of the Research Programme of the Research Fund for Coal and Steel of the European Union (RFSR-CT-2008-00032) , initiated in July 2008 and supposed to end in July 2011, which aims at developing two innovative types of seismic resistant steel frames with dissipative fuses. The numerical model is developed using the commercial software package Perform 3D Nonlinear Analysis and Performance Assessment for 3D Structures by CS&I. The analyses are carried out using inelastic fiber sections for the fuse elements and the composite slab, and elastic steel column elements for the columns.*

1 INTRODUCTION

Steel structures in seismic zones are designed for stiffness, strength and ductility. Stiffness is required for limitation of damage of non-structural elements and reduction of the 2nd order effects. Strength is required for a safe transmission of the acting forces and moments. Ductility under cyclic loading leads to the dissipation of the input seismic energy and results in a reduction of the seismic forces. The demand for strength is therefore closely connected to the provision of ductility. The latter may result in a considerable reduction of the acting seismic forces by a factor of up to 6, according to the European and 12 according to the American Codes.

Obviously, not the entire structure shall exhibit uncontrollable inelastic deformations during a strong earthquake. Such deformations are associated with damage and shall be limited into specific zones, the dissipative zones. For that reason, the elements of the dissipative zones are weaker than their connections and the adjacent members. The latter are designed for higher forces and moments according to capacity design criteria. Table 1 shows an evaluation of the existing conventional structural systems in respect to stiffness and ductility. Strength is not evaluated since it is accepted that all systems, if properly designed, are able to resist the acting action effects. It can be seen that conventional systems have advantages and disadvantages. Moment resisting frames are ductile but usually flexible. Concentric braced frames are stiffer but less ductile due to buckling of braces. The properties of eccentric braced frames are something between the other two types. Table 1, columns 1 to 3, summarizes the properties of conventional steel frames.

	1	2	3	4
	Moment Resisting Frames	Concentric Braced Frames	Eccentric Braced Frames	FUSEIS Frames
Stiffness	-	+	0	+
Ductility	+	-	+	+
Reparability	0	-	0	+
Dissipative zones	Beams	Braces	Links	Fuses

Table 1: Stiffness, ductility, reparability properties and dissipative zones of several structural systems

Inelastic deformations may develop not only under seismic loading but also in other design situations in structures exploiting plastic resistances, i.e. in frames designed according to plastic hinge theory. However, such design refers to the ultimate limit state, where the actions are magnified by the relevant safety factors. Under service conditions, inelastic deformations that may result in damage do not generally occur. Inelastic deformations leading to damage are allowed also in accidental design situations (fire, explosions etc.). When such situations actually occur, repair works are needed. However, accidental situations happen very rarely and refer only to individual structures.

Seismic loading represents a special design situation. For normal buildings, structural safety shall be assured for the design earthquake, which corresponds to rare earthquakes with usual return periods of about 500 years. Damage shall be limited for frequent earthquakes with return periods around 50 years. However, the international experience shows that the above fundamental requirements are very often not fulfilled. All over again, earthquakes occur that are much stronger than those for which the design was made. The results are well known: Structural collapses leading to loss of human life and, in much wider range, damages

that require repair at high costs. Due to the population increase and the concentration in large cities, it may be stated that the seismic risk and the financial consequences increase rather than reduce over time.

For the population, and the judges, it is difficult to understand that the earthquake which had happened was the *rare* one with a return period of 500 years. This is due to the fact that the Codes rely on instrumental measurements of at most 50 years and historical data that extend over a longer period but cannot be directly transformed into engineering figures. They are therefore based rather on statistical extrapolations of natural hazards. It is observed that after a strong earthquake the region where it happened is often upgraded in the higher seismic zone.

The above descriptions and the experience show that unlike accidental loading, earthquakes lead *frequently* to damages in *large* extent. It is therefore advisable to develop structural systems that are simple to *repair*, i.e. to introduce the *reparability* as a new property. An evaluation of the conventional frames in respect to this property is made in Table 1. It may be seen that conventional frames are not well positioned according to reparability. In moment resisting frames the beams or, more usually, their connections shall be repaired. Both are elements that resist gravity loading and are difficult to repair. The same happens with eccentric braced frames where the links, the short parts of the beams, have to be repaired. In concentric braced frames, it is the braces that shall develop inelastic deformations. Damage is therefore expected in the braces, which are long and heavy elements, difficult to handle and repair.

Furthermore it has to be pointed out that, in reality, “steel structures” rarely exist by themselves (eventually just in the case of industrial buildings). Most often, in the case of high-rise buildings, housing, as well as commercial buildings, the steel beams support r.c. slabs. In this case, damage to the steel members results in damage in the r.c. slabs and in the finishes, so that repair works will be increased together with the related costs.

From other engineering disciplines, e.g. mechanical, electrical and automobile or aircraft engineering, it is well known that the best way of repair is the complete replacement of a damaged part with a new one. Such a strategy could be also envisaged in civil engineering, especially for buildings in seismic areas that are more susceptible to damage for the reasons described above. Like bumpers in cars that absorb the crash energy and are replaced afterwards, innovative devices will be developed that dissipate energy, protect the overall structure and may be dismantled and replaced after a strong earthquake.

The research proposal aims at developing two innovative types of seismic resistant steel frames with dissipative fuses. In case of strong earthquakes, damage will concentrate only in the fuses, which will be exchangeable. Repair work after a strong seismic event, if needed, will be limited only to replacing the fuses.

This study presents the preliminary numerical and experimental results of one of the two types of devices, that can be applied to the beam to column connection of moment resisting frames, as sketched in figure 1.

Figure 1: Fuse device placed in a moment resisting composite steel frame

2 FULL SCALE TESTS

A two dimensional composite steel frame with fuse devices has been tested in the structural engineering laboratory of the Politecnico di Milano University. The outline of the frame and its elements can be seen in figure 2.

Figure 2 Full Scale Test Frame

A cyclic loading history shown in figure 3 is applied at top joint of the right side column through a load cell. The load is applied in cycles in +x and -x direction. Therefore in each cycle, in the beam and eventually in the fuse element, a positive and negative bending are observed. A maximum deflection of 110 mm (corresponding to 42 mrad in the fuse element) is imposed to the top joint.

Figure 3 Cyclic loading history applied in the tests

3 NUMERICAL SIMULATION

For the design of the test specimens, a refined numerical model was set-up at Politecnico di Milano, using ABAQUS software. Such a detailed model, however, can be used only for specific research applications, but it is not a feasible model to use for engineering purposes. Therefore, the simplified model hereafter described was set up and calibrated, with the aim of using it for the simulation of multistory frame structures.

The simplified nonlinear model is developed using the commercial software package Perform 3D Nonlinear Analysis and Performance Assessment for 3D Structures by CS&I (Figure 4). The analyses are carried out using inelastic fiber sections for the fuse elements and the composite slab, and elastic steel column elements for the columns.

Figure 4 Perform 3D Nonlinear Analysis Software

A fiber segment is a finite length of constant cross section in a frame compound component. The key aspect of a fiber segment is how it behaves when the fiber section becomes nonlinear, through yield of it several fiber elements. In a beam fiber section, the cross section shape of the element is divided into a number of fibers, and material properties

are assigned to each fiber. Each fiber segment is defined by associating it with a fiber cross section and specifying the segment length.

The behavior of a fiber segment is similar to that of a tributary length of beam with a hinge at its midpoint. Such a segment becomes nonlinear only when the hinge becomes nonlinear.

In physical terms, in a fiber segment, the cross section behavior is monitored at only one point, namely the midpoint of the segment. For instance, if a fiber section is made up entirely of steel fibers(i.e., if it models a steel section), the fiber segment yields only when the combination of axial force and bending moment at the midpoint of the segment is large enough to cause a fiber to yield.

The material types that are allowed for the fibers are: Steel material, tension-only material, buckling material and concrete material. [2]

Nonlinear element and material properties are assigned to the composite beams and the fuse elements to observe their contribution to the energy dissipation of the whole frame, during a dynamic lateral loading event. The scope is to attain the plastic behavior only at the fuse elements, and let the columns and beams of the structure behave elastically.

3.1 Properties of Structural Elements

The cross sections and material properties used in the numerical model are the same ones that are used in the full scale test model (Figure 2). HEB240 column elements are chosen as elastic type, considering that the test frame will not be suffer large axial forces. The beams and the fuses are modeled with inelastic fiber segments.

In the frame, there are three different types of beam sections. Main beams are composite steel beams that are composed of an IPE300 steel section, and a reinforced concrete slab of 150 mm thickness. The inelastic fiber section that is used for main beams are seen in the figure 5.

Figure 5 Cross Section Properties of fiber beam element

The short beams located between the fuse parts and the columns are also designed as fiber elements, to represent the behaviour of a composite section which consists of an IPE300 beam, steel plates attached to the flange and the web of the beam, and the concrete slab. The properties of the this beam element can be seen in figure 6.

Figure 6 Cross Section Properties of fiber beam element

3.2 Fuse Element

In the model, fuse devices are modeled as short beam segments with fiber cross sections in order to simulate the plastic hinge behaviour. The fiber section used in the model can be seen in the figure 7.

They are modeled with two different fibers:

- i) *Inelastic steel material, non buckling type*, representing the reinforcement of the slab (seismic bars) (Figure 8)
- ii) *Inelastic steel steel material, buckling type*, representing the connection part composed of web and bottom flange plates (Figure 9)

Figure 7 Definition of fibers in the fuse part

Figure 8 Force-Deformation Relationship of inelastic steel material, non buckling type used for steel reinforcement

Figure 9 Force-Deformation Relationship of inelastic steel material, buckling type used for web and bottom plates of the fuse devices

The fiber of the steel reinforcement is expected to stay in the elastic range, whereas the fibers of the steel plates connected to the web and the bottom flange are expected to yield and hence dissipate energy during cyclic loading. The locations of the fiber sections can be seen in figure 10.

Figure 10 Fiber Segment Scheme of the Frame Model

The output time-force history of the displacement controlled push-over experiment is used

as input loading history in the numerical dynamic push-over analysis. Therefore numerical analysis is carried out as force controlled push over analysis (Figure 11).

Figure 11 Force controlled push over analysis scheme

The force-time history of the cyclic loading case can be seen in figure 12.

Figure 12 Cyclic loading record used in the model

4 CALIBRATION OF THE NUMERICAL MODEL

The conformity of numerical and experimental results in terms of maximum plastic moment capacity referring to the maximum rotations that the device undergo can be observed in the superposed experimental and numerical global force-displacement plots in the figure 13. The differences in the initial stiffness and amplitude of the hysteresis plots are due to inelastic effects occurring in the connections between the fuse device and the beams, that were not accounted for in the numerical model.

Figure 13 Experimental vs Numerical Moment-Rotation Plots

Within the remaining period of the research project, elaborating the numerical analyses further, the calibration between the analyses and experimental results are going to be improved and necessary design guides to implement the system in practice will be developed.

5 NUMERICAL ANALYSIS OF MULTISTOREY FRAMES WITH FUSES

The expected behavior of a moment resisting multistorey frame under lateral loading is shown in figure 14, where a plastic hinge mechanism under collapse load is likely to occur near the beam ends at the floor levels.

Figure 14 Deformed shape, moment diagram and location of plastic hinges observed under horizontal loading of a 5 storey moment resisting steel structure.

In order to extend the results of the numerical analyses carried for the test structure to multistorey building frames and to observe the behaviour of the fuses under horizontal seismic excitations, nonlinear fiber analyses are carried out for two composite steel building frames:

- 1) A conventional moment resisting composite steel structure building frame
- 2) A moment resisting composite steel structure building frame having fuse devices, near the end of its beams.

The scope is to observe the behavior of steel building frames using inelastic fiber sections at the parts of the beams where a plastic hinge mechanism is expected to occur, and examine the contribution of fuse devices to the energy dissipation and reduction of earthquake forces in multistorey buildings under horizontal earthquake excitations.

The analyses are carried out under the horizontal acceleration time history data of Kobe 1995, Aquila 2009 and Chile 2010 earthquakes. The element types and the cross sections are the same with the ones used in the numerical model of the test frame, which are described in section 2.1.

5.1 Composite Steel Building Frame without Fuses

The composite steel multistorey model is analyzed with HEB240 column elements, and a composite slab element that consist an IPE360 steel beam and 150 mm thick reinforced concrete slab.

Under three earthquake excitations, the moment curvature hysteresis plots of composite beam elements are obtained. As can be understood from the moment-curvature diagrams shown in figure 15, the segments of the composite beams where the maximum moments are observed, eventually near beam ends, are plasticized.

Figure 15 Moment-Curvature diagrams observed in the composite beam under three earthquake excitations

5.2 Composite Steel Building Frame with Fuses

The same building is modeled with placing the fuse devices near the end of the beams, where the plasticization is observed in the previous analysis (Figure 16). The same earthquake excitations are applied to this model as well, and the moment curvature hysteresis plots of composite beam elements and fuses are obtained.

Figure 16 Moment resisting steel building frame model

As expected, the composite beams and columns showed elastic behaviour with no yielding, while the fuse parts yielded and contributed to the energy dissipation. In figure 17 and 18, the moment-curvature diagrams of the composite beams and fuse elements of the structure under lateral loading can be seen respectively.

Figure 17 Moment-Curvature diagrams observed in composite slabs under three earthquake excitations

Figure 18 Moment-Curvature diagrams of the fuse devices under three earthquake excitations

From the hysteresis plots, it is seen that the plastic deformations are concentrated only in the fuse elements, whereas the composite beams remain elastic.

5.3 Comparisons between Two Building Models

A comparison between a conventional building model and a building model with fuses is made in terms of base shear forces. In figure 19, the reduction of the maximum base shear forces that take place in the building with fuses can be observed under three different earthquake excitations. Combined with the dissipative behavior of the devices, these results confirm that the fuses have an important effect in reducing the seismic forces transmitted to the structure during strong earthquakes.

Figure 19 Comparison of maximum base shear forces between conventional and innovative structures

6 CONCLUSIONS

In this study, the preliminary results of the experimental and numerical analyses carried out for one of the two types of innovative fuse devices are presented. The ability of the fuse devices to dissipate energy and reduce the horizontal earthquake forces in steel frames is investigated. The possible damage that the main structural elements of a moment resisting steel frame would suffer during a strong earthquake is aimed to be concentrated in the fuse devices. While in the conventional moment resisting steel frames, the beams and their connections – the elements that resist gravity loading and are difficult to repair- must be repaired after a strong earthquake. In the innovative type seismic resistant steel frames with dissipative fuses, the repair work, if needed, will be limited only to the replacement of the fuses.

From the results of the nonlinear numerical analyses carried out for a simple test structure and a composite steel building frame, it can be concluded that the idea of avoiding the plastic deformations in the main structural elements of a moment resisting building frame can be achieved through concentrating the plastic deformations in “weak” elements which are to be mounted between the beam and column elements of the structure. These comparatively weaker elements, so called fuses, must be stiff enough to let the frame be stable under service loads, and also they must be the principal elements in the structure to show inelastic behaviour and dissipate the energy caused by a strong earthquake.

The numerical analyses carried out for a simple test structure which is loaded in a cyclic manner, showed that among the three elements: composite slab, column, and fuse device, the plastic deformation is observed only in the fuse device, whereas the column and the slab elements remained perfectly elastic. Finally, in order to extend these results for a multistory building frame and to observe the behaviour of the fuses under seismic excitations, a nonlinear fiber analysis is carried out for a two dimensional composite steel building frame consisting steel column elements, composite beam elements and fuse elements, under horizontal acceleration time history data of three different earthquakes. In compatibility with the results of the test structure, also in this case, the plastic deformations are only seen in the fuse devices. Moreover, through the comparison between the numerical analysis results of a conventional steel frame and an innovative type of steel frame with dissipative fuses, it is seen that the base shear forces induced by the strong earthquake motions can be reduced using fuse devices.

Abstract. *Dampers are used in structures to dissipate input energy caused by severe earthquakes. They can also reduce seismic demands on other structural elements. So dampers' life is a significant parameter to prevent the structural damages. One of the failure modes observed in the steel dampers during earthquakes, is the damage caused by cumulative effects due to few cycles of high strain amplitudes. This undesirable effect is called Low-Cycle Fatigue (LCF). In buckling restrained braced frames (BRBFs), brace element acts as a hysteretic damper and dissipates high amount of input energy by plastic axial deformations. To ensure satisfactory operation of BRB with no failure during earthquake, it is necessary to investigate LCF effects. On the other hand smaller yielding length of BRB cores imposes higher strain amplitudes and makes the LCF failure more probable.*

In the present study, a criterion to control LCF failure in BRB has been selected based on fatigue life equations recommended in the previous experimental researches. A 7 story benchmark building with BRBs as the lateral resisting system is selected. Then the yielding length of BRB has been reduced to the minimum possible based on the fatigue criterion and the building has been redesigned. Fatigue analysis has been performed on both buildings to evaluate LCF capacity. In order to evaluate fatigue effects, time history analysis have been conducted on both buildings using the open source finite element platform, OpenSees (2005). Strain history demands in each yielding segments of the braces have been extracted and the cumulative damage index of Palmgren-Miner has been calculated to estimate LCF damage index.

Results of this study show that despite the high cumulative plastic deformations the yielding segments experiences, both BRBs have proper fatigue damage indices. Also it has been proved that developed criterion for controlling LCF failure is conservative for selected time histories and has appropriate safety factor for defining reduced core length of BRB.

1 INTRODUCTION

Braces are usually designed to act as energy dissipating members in seismic design of concentrically bracing systems. Therefore a brace is anticipated to have a stable cyclic behavior with high damping hysteresis loops. Due to buckling, the majority of the energy that could be damped in compression is lost and the brace stability is jeopardized. In Buckling Restrained Braces (BRBs), by preventing the buckling of the brace, a symmetric and stable hysteresis curve is achieved that dissipates high amount of energy in every single cycle (figure 1).

Figure 1: Cyclic behaviour of a typical BRB versus a conventional brace [1].

BRBs brilliantly solve problems of classic concentric braces, which are characterized by a pinched hysteresis loop and a small ductility due to the concentration of strain occurring when braces buckle [2]. In common BRBs, the axial deformation is distributed in a large length, so the peak strain amplitude typically falls in the range of 0.01–0.02 for usual structural applications [3]. On the other hand, the results of experimental studies on BRBs proved the capacity of core to endure the strains of higher ranges up to 0.03 or even 0.06 [3, 4]. The capacity of withstanding high strains insures the feasibility of reducing the length of the yielding segment of BRBs. Reducing the length of yielding segment in BRBs has a number of advantages. By reducing the yielding segment higher axial stiffness in brace is achieved. On the other hand, the restrained length is reduced so global encasing member can be replaced by a local one that has less weight and cost. Yielding part of BRB is the structural fuse in BRBFs and its length reduction causes a more flexible designing since in small sizes a variety of core lengths and cross sectional areas can be provided. If a fuse replacement is needed after sever earthquakes, it is enough to replace damaged fuse with a new one (only at the end of the brace) and it is not necessary to replace the whole brace [1].

The above advantages raised the interest of many researchers to investigate the possibility of reducing core length in BRBs. The majority of these studies have been carried out in recent 5 years. Table 1 summarizes some of these studies.

Researcher	Year	Location	L_c/L	Model	Max Strain
Tremblay et al.	2006	Canada	25%	Experimental & Analytical	3.4%
Mirghaderi & Ahlehagh	2008	Iran	35%	Analytical	4.3%
Ning Ma et al.	2009	China	20%	Experimental	3.4%
Mazzolani et al	2009	Italy	40%	Experimental	3.5%
Razavi & Mirghaderi	2009	Iran	20-40%	Analytical and Experimental	3-4%
Di Sarno & Manfredi	2010	Italy	20%	Analytical	1.5%

Table 1: Summary of some studies on BRB with reduced core length [3-7].

Nevertheless, reducing the yielding length imposes large strain demands on this segment which poses some concerns about Low-Cycle Fatigue (LCF) failure. However, a minimum core length is required to keep inelastic strain demand low enough such that LCF fracture of the core does not occur under a severe earthquake [3].

Since various ranges of BRB core length can be used, it is necessary to consider the effects of LCF on BRBs. Unfortunately seismic codes and specifications have not presented any distinct criterion to control these effects. So, in recent years, a series of experimental studies was accomplished on the possibility of fracture of BRBs caused by LCF. Moreover, some qualification tests with respect to LCF effects have been developed.

In the present study a series of LCF tests on BRBs are mentioned. Based on the tests results, an index to estimate fatigue life of BRBs is selected. Using this index, a criterion is presented to determine the minimum needed yielding length to prevent LCF failures. The next step is to redesign a benchmark 7 story BRBF utilizing BRBs with minimum yielding length. Time history analyses were conducted on the two buildings using the open source finite element platform, OpenSees (2005). Based on the results, an index of LCF damage is calculated for each brace to evaluate the accuracy of the presented criterion. To compare ductility demands on the primary and secondary frames, the maximum and the cumulative ductility in yielding length of BRBs were calculated.

2 LOW CYCLE FATIGUE

Common plasticity models used in civil engineering normally predict the nonlinear behavior of metallic elements under cyclic loading and commonly do not address the fatigue failure. The issue of LCF is not explicitly mentioned in seismic design standards such as Seismic Provisions for Structural Steel Buildings (AISC/ANSI 341-05) [8] and Seismic Rehabilitation of Existing Buildings (ASCE/SEI 41-06) [9]. However one of the most important issues in cyclic behavior of the metallic dampers can be the failure caused by repetitive large inelastic strains. This phenomenon is called LCF and usually occurs in members under severe cyclic loadings such as earthquake loading.

BRB dissipate energy by formation of plasticity in their core segment. As the strain amplitudes in normal BRBs are minimal, no many researches have been conducted on the LCF of normal BRBs. However when the length of the core segment is reduced the strain amplitudes rise and LCF failure could be a concern. Evaluating LCF effects requires enough data about the LCF capacity based on tests and selecting a damage evaluation process.

2.1 Low-Cycle Fatigue Capacity of BRBs

The capacity of metallic material against LCF is commonly expressed by Coffin-Manson equation [10].

$$\frac{\Delta \epsilon_p}{2} = \epsilon'_f (2N)^c \quad (1)$$

where:

- $\Delta \epsilon_p / 2$ is the plastic strain amplitude
- ϵ'_f is fatigue ductility coefficient
- $2N$ is the number of reversals to failure (N cycles)
- c is the fatigue ductility exponent

This equation is usually used to estimate the fatigue life of a specimen under constant plastic strain amplitudes. The parameters of this equation are extracted from tests. Material tests are typically conducted on small specimens which greatly differs from BRB specimens. LCF life has found to depend on many factors such as specimen shape and size, and stress concentrations [10]. Thus individual tests on steel material in BRB scale is needed to evaluate the LCF capacity of a BRB. Many researchers have attempted to investigate LCF effects in steel material or members and present a Coffin-Manson type equation to predict the fatigue life (N_f). A number of these studies will be presented.

In 2000 Nakamura et al tested five BRBs on behalf of Nippon Steel. This research intended to clarify hysteresis stability and fatigue failure characteristics of the braces by performing fatigue tests on practical scale unbounded braces [11]. Based on the test results of BRBs with different core steel grades including JIS SN400B, and LYPI00 and LYP235 a relationship between applied strain and fatigue life was presented:

$$\Delta\epsilon_c = 0.2048 (N_f)^{-0.49} \quad (2)$$

Where $\Delta\epsilon_c$ is the strain amplitude of the core.

Figure 2: TP-5 specimen detail [11].

Most of failures occurred near the welding areas or reinforcing ribs that indicates stress concentration greatly decreases the fatigue properties of a BRB. The test results showed that the values of the failure cycle number (N_f) in the core model tests were 1/2 to 1/5 of those in the material tests, and those in the practical-scale tests were 1/6 to 1/10, presumably because of influences of stress concentration at the ends of the reinforcing ribs or that caused by local buckling. LYP100 and SN400B showed nearly identical plastic fatigue characteristics.

In 2002 S. L. Lin and Keh-Chyuan Tsai conducted performance tests on an all metallic detachable buckling restrained braces some of which included fatigue tests [12]. Various strain amplitudes were experimented and based on the results the following fatigue life equation was presented:

$$N = 0.0007 (\epsilon_c)^{-2.25} \quad (3)$$

Where N is the maximum tolerable cycles in strain of ϵ_c that occurs in BRB core.

Figure 3: Number of fatigue strain cycles versus core strain relationship [13].

Other researchers have evaluated the fatigue properties of different type of BRBs. Table 2 shows a summary of the BRB fatigue studies which have presented a Coffin-Manson type equations.

Researcher	Year	Location	Equation	Material	Test Type
Nakamura et al	2000	Japan	$\Delta \varepsilon_c = 0.2048(N_f)^{-0.49}$	SN400B LYP100 LYP235	Uniaxial
Isoda et al	2002	Japan	$\Delta \varepsilon_c = 0.20(N_f)^{-0.39}$	LY225	Uniaxial
Nariharah (22278)	2002	Japan	$\Delta \varepsilon_p = 0.3770(N_f)^{-0.602}$	SN400B	Sub-assembly
Horie et al	2003	Japan	$\Delta \varepsilon_c = 0.2(N_f)^{-0.41}$	SNB400	Uniaxial
Tsai	2003	Taiwan	$N_f = 0.0007(\varepsilon_c)^{-2.25}$	A572 GR50	Frame
Kamura et al	2009	Japan	$\Delta \varepsilon_t = 0.1128(N_f)^{-0.4129}$	LY100	Uniaxial

Table 2: Fatigue life prediction equations [11, 13-17].

The fatigue behavior of BRBs has been studied in other researches too. In these researches usually some extra load cycles have been exerted on the specimen after the specimen has withstood the total loading protocol for qualification test according to relevant code [18-20].

Some other researchers have reported the cumulative inelastic axial ductility capacity (η) and have compared it to 200 which is noted in AISC 341-05 as a satisfactory fatigue property. It seems evaluating LCF failure only based on the cumulative inelastic axial ductility cannot consider the LCF effects completely, since strain amplitudes are of great importance in LCF failure.

From the LCF experimental studies of BRBs the following conclusions can be derived:

- LCF capacity depends on various factors such as: the shape of core segment, the stiffness of buckling restraining mechanism, the width-thickness ratio of the axial member, clearance between the axial member and the restraining mechanism, eccentricity in the core segment, overall detailing of the BRB, the quality of manufacturing.
- Presence of any discontinuities, tack welds, attachments in core segment which is identified as protected zone per AISC 341-05 severely degrades the LCF life.

- LCF failure occurs soon after the formation of local buckling in the core segment.
- The local buckling of the core is more probable to happen at the ends of core segment [3, 21].
- Using flat plates in core segment show better fatigue properties in comparison to cruciform sections [11].
- The strain rate has minimal effect on hysteretic behavior, cyclic stress, and fatigue life for the steel plate especially when the core can dissipate heat through connections or proximity to elastic members [22].
- The overall fatigue life is somehow similar for different steel grades.

In this study the equation for fatigue life prediction presented by Nippon is adopted. Nevertheless the LCF capacity can be greatly increased if enough attention is paid to the results noted above. Though this equation is extracted for specific BRB with a special detailing, but it has been adopted for this study since it holds rational conservativeness.

2.2 Low-Cycle Fatigue Damage Evaluation

Evaluating the damage resulted from repeated cyclic loads commonly follows the Palmgren-Miner rule [23]. According to this theory the damage caused by a strain cycle is defined by the following equation:

$$D = \frac{1}{N_f} \quad (4)$$

So damage caused by “n” strain cycles is equal to:

$$nD = \frac{n}{N_f} \quad (5)$$

In order to calculate the damage index in case of several strain series with different amplitudes the, damage caused by n_i cycles at the strain of ε_{ai} is $n_i D_i = n_i / N_{fi}$. Then the overall damage of the member is equal to the summation of calculated damages [10].

$$\sum \frac{n_i}{N_{fi}} = \frac{n_1}{N_{f1}} + \frac{n_2}{N_{f2}} + \dots + \frac{n_i}{N_{fi}} \quad (6)$$

Failure is probable when this summation becomes greater than 1.

When a brace is evaluated under a time history, the number of different strain amplitude is not distinctly recognized. In such cases the Rain Flow Counting Method can be applied. Rain Flow counting method is a process to calculate equivalent constant amplitude cycles for a strain or stress time history. This method has been successful [24] and is frequently used in fatigue analysis of seismic resistant systems [25, 26].

In this study the combination of Rain Flow Counting method and the Palmgren-Miner cumulative rule is applied to determine the damage index of the braces in the time history analyses.

2.3 The criterion to determine the yielding length in design procedure of the reduced core BRB

Based on the results of LCF studies, fatigue life of an element under high strain demands depends on the strain history it experiences rather than the maximum amplitude of strain. So at the first step the applicable displacement loading history on the specimen should be determined for designing purposes.

AISC 341-05 [8] suggests a loading protocol for qualification test of BRBs. When these provisions suggested, BRBs with reduced core length were not widely in use. The strain amplitudes in common BRBs are limited to 1% or 2%. Therefore seemingly the suggested protocol has not included the LCF effects. In absence of a specific criterion to control LCF failure, some researchers considered the cumulative inelastic axial deformation of the brace [4]. If the value from BRB test was much greater than 200 (AISC recommended value), they concluded that LCF failure is not probable.

In 2006 another loading protocol was presented by Tremblay et al [3] for testing series of all-steel BRBs some of which had reduced yielding length.

According to provisions of ASCE 41-06 [27], each energy dissipation device shall be loaded with 20 fully reversed cycles at the displacement in the energy dissipation device corresponding to the BSE-2 which represents an earthquake with 2% probability of exceedance in 50 years.

The provision of ASCE 41-06 which defines 20 cycles is based on the earthquake duration of the earthquake not its severity. On the other hand, the provisions of common seismic design codes are usually for design earthquakes corresponding to the BSE-1 which represents an earthquake with 10% probability of exceedance in 50 years. So in order to make the design assumptions of BRB compatible with common seismic systems, the provision of ASCE41-06 can be considered in BSE-1 instead of BSE-2. Table 3 shows loading protocols recommended by various references.

	Recommended Loading Protocol				
AISC	$2 \times \Delta_{by}$	$2 \times 0.5 \Delta_{bm}$	$2 \times \Delta_{bm}$	$2 \times 1.5 \Delta_{bm}$	$2 \times 2 \Delta_{bm}$
Tremblay	$6 \times \Delta_{by}$	$4 \times 0.5 \Delta_{bm}$	$4 \times \Delta_{bm}$	$2 \times 1.5 \Delta_{bm}$	$4 \times \Delta_{bm}$
ASCE 41-06	-	-	$20 \times \Delta_{bm}$	-	-

Table 3: Comparison of loading protocols for BRB tests recommended by different references.

Δ_{by} is the projection of the story drift corresponding to the yielding of the brace on the brace direction and Δ_{bm} is the projection of design story drift on the brace direction.

As mentioned previously, the overall damage of a member is equal to the summation of calculated damages of different cycles. So the damage during the loading protocol should be calculated cumulatively. For this purpose, for each loading protocol the Palmgren-Miner equation is calculated and the result is controlled to be less than one.

3 DESIGNING AND MODELING OF A BRBF BUILDING USING REDUCED CORE BRB AND

The LCF failure is most probable in BRB with reduced yielding length, as the strain amplitudes increase. BRB with reduced yielding segment has two main parts: a short part and a long part. The short part is the restrained yielding part that yields in both tension and

compression like a short BRB. This part acts as a structural fuse and is the displacement controlled (D.C.) component of the brace. The long part is the unrestrained non-yielding part without yielding or buckling. This part is expected to be elastic and is the force controlled (F.C.) component [28]. Figure 4 shows the schematic model of the Reduced Length BRB (RL-BRB), where P_y is yielding load of the brace, ϵ_c is maximum strain of the core, P_{cr} is critical buckling load of the whole BRB and FS is factor of safety.

Figure 4: Schematic model of the recommended brace versus schematic model of a conventional BRB [29].

Reducing the yielding part of the BRB will affect the overall behavior of BRBF and also will make the LCF damage more possible since the core strain amplitudes will increase [30]. So the LCF property of frame with RL-BRB is investigated via nonlinear analyses. For this purpose a benchmark BRBF building was redesigned using RL-BRBs. The step by step design procedure for RL-BRBFs was completely discussed in another study by Razavi et al [28].

The original building had been selected from a Steel Tips report entitled as "Seismic Design of Buckling Restrained Braced Frames" [31]. The building is a 7 story BRBF with official application. Four sets of diagonal bracing (BF-1) in X direction and two sets of chevron bracing (BF-2) in Y direction is applied as the lateral resisting frames for a rectangular plan of 40m×25m. The total length of BF-1 braces is 7.5m in the first story and 7m in other stories. For BF-2 braces the lengths are 6.25m and 5.75m respectively. Figure 5 shows the geometry of bracing bays. ASCE 7-02 [32] specifications had been used for the loading and the design procedure was originally performed according to FEMA 450 section 8.6 [33].

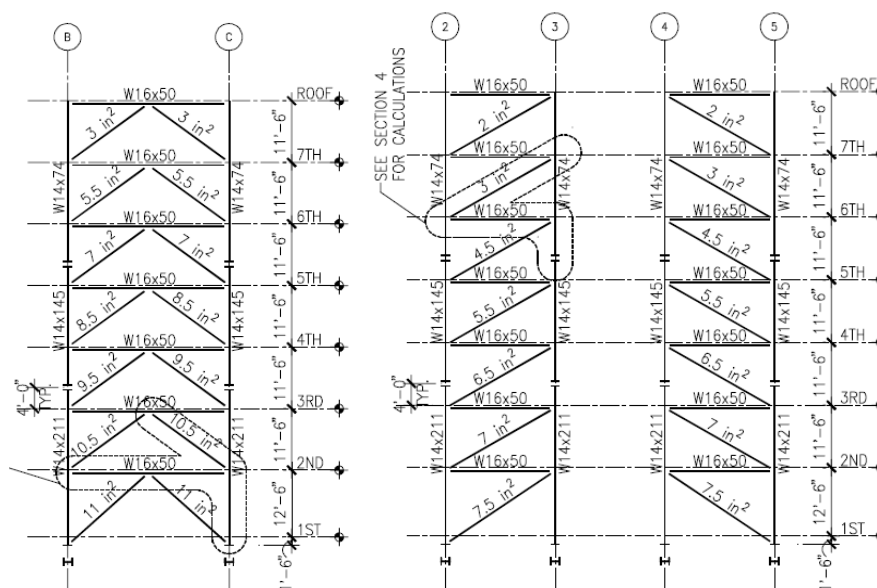

Figure 5: The elevation view of BRBF building. BF-1(left) and BF-2(right) [31].

As this study intends to study the LCF effects of the RL-BRB, the minimum length required is calculated according to the assumptions of previous sections.

In previous sections recommended equations to calculate fatigue life (N_f) of BRBs were presented. N_f can be extracted for every BRB detailing by conducting special fatigue tests. ATC 24 recommends a testing protocol for extracting the parameters in fatigue life estimation equation for steel structural elements. [34]

Tables 4 and 5 show calculated yielding lengths using different loading protocols and different N_f by applying Palmgren-Miner rule for the brace in 5th story and 4th and 5th story of BF-1 and BF-2 respectively. The lengths in the tables are calculated so that the LCF index equals 1. This means no safety factor is adopted in this stage.

	AISC	Tremblay	ASCE 41-06 (BSE-1)
Nippon	130	124	150
Isoda	115	100	171
Narihara	87	89	170

Table 4: Different yielding lengths calculated for BF-1 (cm).

	AISC	Tremblay	ASCE 41-06 (BSE-1)
Nippon	93	88	105
Isoda	81	71	122
Narihara	62	63	121

Table 5: Different yielding lengths calculated for BF-2 (cm).

Table 4 and 5 show that that different loading protocols lead to almost the same results. Using ASCE 41-06 leads in slightly longer yielding segment. In this study, yielding length calculated from the combination of AISC loading protocol and N_f from Nakamura study is selected.

Based on the selected reduced length the building with RL-BRB was analyzed and designed. Comparison of the design results showed that replacing common BRB with RL-BRB does not make a significant change in beams and columns designing. The same cross sectional area of the BRB core also obtained. The comprehensive comparison of design results is discussed by Shemshadian [30].

4 NONLINEAR DYNAMIC ANALYSES OF FRAME WITH RL-BRB

In order to investigate the LCF effects in BRBs of original and redesigned buildings, 28 nonlinear dynamic analyses (Time History Analyses) were conducted on 4 BRBFs. A set of 7 different records were used to consider the average results. These records were selected from PEER database. It was tried to select records with various frequency contents and durations in order to estimate ductility and LCF damage index more accurately. These records are introduced in table 6.

No.	Name	Year	Magnitude	Duration(sec)	Dist. (km)	PGA (g)	PGV (cm/s)	PGD (cm)
1	Duzce	1999	7.1	56	17.6	0.203	17.3	14.29
2	Imperial Valley	1979	6.5	100	43.6	0.145	14.8	8.62
3	Kobe	1995	6.9	41	15.5	0.059	6.4	2.16
4	Kocaeli	1999	7.4	30	17	0.086	8.6	5.52
5	Landers	1992	7.3	28	21.2	0.174	9.9	4.01
6	Northridge	1994	6.7	30	19.6	0.326	16.9	2.56
7	San Fernando	1971	6.6	28	21.2	0.136	4.3	1.52

Table 6: Characteristics of selected ground motions.

Since site parameters in Steel Tips report was given according to ASCE 7-02 [27], the design spectrum of this code was used for record scaling.

Figure 6: Response spectrum of the selected records with mean and ASCE spectrums.

The results of nonlinear time history analyses show that the maximum and residual drifts of the RL-BRBF are less than the original frame. This is the result of using RL-BRBs instead of common BRBs since RL-BRBs are stiffer [1]. On the other hand the pattern of interstory drifts is almost unchanged that indicates that replacing common BRBs with RL-BRBs does not influence the general behavior of the structure.

5 LOW CYCLE FATIGUE EFFECTS IN YIELDING LENGTH OF BRBS

The strain history of each yielding segment of BRB under each record is extracted. Then the Rain Flow Counting Method is used to calculate the equivalent strain history with complete cycles.

According to the definition of AISC 341-05, cumulative inelastic ductility under a loading is the summation of plastic ductility occurred in the member divided to deformation at beginning of yielding. The loading sequence requires each tested brace to achieve ductilities corresponding to a cumulative inelastic axial ductility capacity of 200 per AISC 341-05 specifications, [8]. Table 7 presents the cumulative inelastic ductilities for strain history of

RL-BRBs yielding length. The values justified that the yielding length of RL-BRBs will undergo large inelastic deformations under selected earthquakes .

Story	Reduce Length	
	BF-1	BF-2
7	193	241
6	321	351
5	303	363
4	294	360
3	337	349
2	368	262
1	187	209
Average	286	321

Table 7: Cumulative inelastic ductility in yielding length of RL-BRBs.

In order to control the LCF failure in a reduced yielding segment, LCF damage index should be calculated for equivalent strain history based on the Palmgren-Miner rule. Table 8 shows the results for RL-BRBFs considering Nakamura et al fatigue life equation. Since the tension and the compression braces behaved similarly, a single damage index was presented for every story.

Story	Reduce Length	
	BF-1	BF-2
7	0.05	0.07
6	0.12	0.14
5	0.12	0.16
4	0.12	0.15
3	0.14	0.13
2	0.13	0.07
1	0.05	0.06
Average	0.10	0.12

Table 8: LCF damage index for RL-BRBs.

The results confirm that LCF criterion used in design procedure of RL-BRB has an acceptable safety factor (about 6), so LCF failure does not occur under selected records. On the other hand, low damage indices show that ductility demands resulted from loading protocols in design procedure of the yielding length are much higher than ductility demands from analysis.

As an example as noted in table 9 the damage index for the brace in fifth story of RL-BRBF is 0.97. The majority of this (about 88%) is due to strain amplitudes of $1.5\Delta_{bm}$ and $2\Delta_{bm}$. It can be concluded that LCF damage is the result of multiple cycles in great amplitudes.

AISC Protocol	$2 \times 2\Delta_{bm}$	$2 \times 1.5\Delta_{bm}$	$2 \times \Delta_{bm}$	$2 \times 0.5\Delta_{bm}$
Strain in yielding segment	5.4	4.1	2.7	1.4
Palmgren-Miner fatigue index in each cycle	0.5 3	0.30	0.11	0.03
Palmgren-Miner fatigue in the whole protocol	0.97			

Table 9: Palmgren-Miner damage index for the brace of fifth story in RL-BRBF.

On the other hand, based on nonlinear dynamic analyses the mean calculated damage index for this brace is 0.12. For more investigation, the strain histories of this brace under Imperial Valley and Northridge records are considered (Figure 7, 8). These two records have the maximum damage indices.

Figure 7: Strain history of fifth story brace in RL-BRBF under Imperial Valley record.

The strain history of Imperial Valley shows that the majority of strain amplitudes are less than 1% and rarely reach 2%. In other words, although the number of cycles is high (the duration of earthquake is 100 seconds) but the strain amplitudes are small.

Figure 8: Strain history of fifth story brace in RL-BRBF under Northridge record.

The strain history of Northridge shows that the maximum strain amplitude is greater than 4%, but it only happens one time during the whole earthquake. Also the number of cycles in this strain history is low (the duration of earthquake is 30 seconds). In other words, although there are high strain amplitudes in strain history, but the number of these cycles is low. So, neither Imperial Valley nor Northridge record has a high damage index.

The clear difference between the damage indexes of designing and analysis is due to two possibilities. The selected records are not enough to give a general conclusion or AISC loading protocol does not include the LCF effects. It seems that AISC 341-05 does not represent a distinct criterion to control LCF failure in BRBs (especially RL-BRBs); while selecting a very short length can result in LCF failure. This topic could be a subject of research in future studies.

Finally it can be mentioned that, considering the sensitivity of LCF effects in RL-BRBs and the advantages of reducing yielding length in BRBs, there is an open space for the available seismic design codes to present some specific provisions regarding this issue.

For each brace, the mean value of maximum ductility demands from applied records were calculated and presented in Table 10. As expected the ductility demands in yielding length of RL-BRBs were much greater than the steel tips BRBs because a shorter yielding length is used. Previous studies confirm the high ductility values for BRBs with reduced yielding length [7].

Story	Steel Tips		Reduce Length	
	BF-1	BF-2	BF-1	BF-2
7	3	4	11	11
6	5	4	16	12
5	6	4	19	18
4	6	5	19	20
3	6	6	20	22
2	5	6	19	21
1	3	4	13	15

Table 10: The maximum ductility in yielding length of BRBs.

6 CONCLUSIONS

In present paper, different LCF studies on BRBs were presented and the suggested equations to estimate fatigue life of BRBs were mentioned. Using these equations and based on the rules of LCF damage estimation, a criterion was developed to determine the minimum of yielding length of the core in BRBs. This criterion was a single step of a step by step design procedure for RL-BRBFs. In order to evaluate the fatigue properties of the BRB with minimum yielding length through a time history analysis, a benchmark 7 story BRBF building was redesigned using RL-BRBs and it was tried to use the minimum possible yielding length. Then nonlinear dynamic analyses were conducted on both original and redesigned buildings. 28 analyses showed that reducing the yielding length of BRB increases the ductility demands on this part. Also the results of this damage index showed that in spite of high ductility demands, LCF effects are not critical and there is enough safety factor for LCF failure prevention. The maximum ductility of 11 to 22 (times of deformation at first yielding) and the cumulative inelastic ductility of 187 to 368 (times of deformation at first yielding) were imposed to the yielding length. The results of present study are valid for the selected records and can be extended for similar earthquakes with scientific judgments.

Key points were presented to reduce the risk of LCF failure for the BRBs. For future researches it is recommended to consider other records including artificial ones. Moreover developing a global loading protocol with enough safety factor for evaluating the LCF effects of BRBs is recommended for further researches.

Keywords: Semi-rigid Connections, Steel Frames, Finite Element Model, Non-linear dynamic, Time-history Analysis.

Abstract. *Early work on predicting the moment-rotation response of semi-rigid connections was conducted through simplified linearized and curve fitting models compared to experimental data. The models were developed using monotonic tests with ambiguity in the loading and boundary conditions used. As a result of such, the models often failed to predict the actual response of the connection particularly when the connection is cyclically loaded. With advancements in computational techniques and power, attention was shifted to developing 3D models which have proven to be capable of capturing the true behavior of the connection. Notwithstanding their effectiveness, 3D models are hard to construct and are computationally expensive, thus their ability to conduct large parametric studies is limited. This paper presents an overview of a new 2D inelastic finite element model (FEM) for predicting the monotonic and cyclic response of semi-rigid connections with top-and-seat angle with double web angle. The model comprises 2D plane strain elements and includes various behavioral features including bolt preload, friction between faying surfaces, connection slip, the effect of bolt-hole ovalization and hot-rolling residual stresses in the angles. Characterized by its reduced number of nodes and elements, the model is computationally inexpensive and is capable of capturing the true behavior of the connection.*

1 INTRODUCTION

The integrity of fully-welded connections in the beam-to-column joints of steel frames under earthquake loading has come under question as many steel and composite buildings suffered severe damage in connections during the Northridge (1994) and Hyogo-ken Nanbu (1995) earthquakes. Forensic investigations following the earthquake identified failed welded beam-column connections in more than 200 buildings [1]. The failure was attributed to poor connection detailing practices and inadequate weld material properties that were common prior to the earthquake [2]. The backing bars and weld runoff tabs used to make the groove welds connecting the beams to the columns were normally left in place after completion of the weld. The existence of backing bars or weld tabs created a lack-of-fusion defect, which was large enough to originate crack growth which propagated in the heat affected zone of the weld metal and in the column flange. Studies on the weld metal used in construction, E70T-4, revealed that the weld had very low Charpy toughness [3]. Subsequently, there has been a tendency to be overly conservative in the design and detailing of these connections. Figure 1 shows a typical fractured beam-column connection in a steel moment frame during the 1994 Northridge Earthquake.

Figure 1: Fractured connection in a steel moment frame during the 1994 Northridge earthquake (crack propagated at backing bar detail and propagated in the column flange and web)

Uncertainty in the performance of welded connections spiked interest in investigating the use of bolted connections in the construction of steel frames in seismic regions. Bolted partial-strength semi-rigid connections were evaluated as a viable alternative due to their lower construction costs and simple fabrication process. Analytical and experimental studies were carried out to assess the fundamental characteristics of the connection. The cyclic behavior of the connection was evaluated through testing of beam-column subassemblies. The experimental results demonstrated the large energy absorption capabilities of these connections under cyclic loading with stable hysteretic behavior [4, 5].

The experimental results were used to develop simplified analytical and power models aimed at capturing the connection response [6, 7, 8]. The models were however developed using old tests in which high degree of uncertainty exist regarding the degree of bolt pretension and actual material properties. In addition, the tests did not cover a wide range of specimen sizes and focused on small specimens with shallow beams and thin angles. As a consequence, test data for specimens comprising deep beams and thick angles did not show good agreement with the curve-fitting models [9].

Two and Three-dimensional finite element models were developed to capture the complicated behavior of the connection such as slip, friction between surfaces in contact and prying action [10, 11, 12, 13, 14]. The component level experimental and finite element results were used for developing frame models for assessing the seismic performance of steel frames. In these models, line elements are used to represent the beams and columns and rotational springs with idealized moment-rotation relationships, obtained from the experimental results or the finite element models, are used to represent the connections [15, 16, 17]. The drawback of using such approach, in addition to idealizing the moment-rotation relationships, is that the interaction between the beam and column flanges and the angles comprising the connection is not captured. Such interaction is essential as it influences the spread of yielding in the beam. This paper presents an overview of new 2D finite element model of top-and-seat angle with double web angle connections and its use in frame analysis for the seismic evaluation of steel frames with such connections.

2 DESCRIPTION OF THE STRUCTURE

The structure considered is a 2-story, 4-bay (longitudinal) and 2-bay (transverse) steel frame. The height of the first and second story is 15 ft and 13.5 ft, respectively and the bay width is 30 ft. The outer frames are special moment resisting frames (SMRF) designed according to the Structural Seismic Design Manual, Volume 3 [18] while the inner frames are only responsible for carrying their share of gravity load.

The strong-column weak-beam design approach was used for sizing the beams and columns in the SMRFs and resulted in W18 x 40 for the beams and W14 x 159 for the columns. Following the sizing of the beams and columns, the assumed rigid connections in the frame were redesigned to reflect semi rigidity and partial strength. Three different frames are considered with the connections in each frame designed as top-and-seat angles with double web angles according to Eurocode 3 [19]. The sizes of the angles and the bolts were optimized such that the resulting connection capacity in frame 1, 2 and 3 is 30%, 50%, and 70%, respectively, of the plastic moment capacity of the beam. Plan view of the structure, an elevation of a typical SMRF, and a zoom-in of a typical connection topology are shown in Figure 2.

Figure 2: Plan view of the structure, an elevation of the SMRF and a zoom-in of a typical connection topology

3.2 Frame model

Analytical models of frames have utilized line elements connected with springs representing the load deformation characteristics of the connection. Due to its minimal computational demands, this modeling approach has been viewed as the best alternative for conducting frame analysis. However, the models typically represent idealized behavior and in many cases cannot capture the local response of the various connection components. Furthermore, the deformation and the spread of yielding in the beams or columns are not well represented since the interaction between the beam flanges and the top and seat angles is neither physically modeled nor accounted for. Therefore, the use of 2D or 3D finite element models when conducting time-history analysis can pay significant dividends since the localized connection behavior and its interaction with the beam and column is physically modeled.

In light of the above arguments, a multi-resolution inelastic 2D finite element model is employed for conducting time-history analysis of the steel frames with top-and-seat angles with double web angle connection as shown in Figure 5. The connections in the frame are represented through the detailed 2D finite element formulation of the beam-column subassembly described above while the beams and columns in the frame are represented using line elements.

Figure 5: Frame model including a leaner column representing the gravity system.

Prior to starting the simulations, gravity loads were applied to the system using the loading combination of:

$$1.0DL + 10psf + 0.25LL \quad (2)$$

Where the DL indicates dead load, the 10 pfs is used for partition walls, and LL indicates live load. The resulting distributed load is listed in Table 2. Gravity loads carried by the core gravity frames were considered through the application of point loads on a leaning column modeled as a pinned rigid element and connected to the frame through tie multi point constraints.

Level	1.0 DL + Partitions (kip/in)	0.25 LL (kip/in)
Roof	0.0863	0.0013
1st	0.095	0.05

Table 1: Distributed gravity loads applied to the frames during the simulations.

4 PRELIMINARY RESULTS

4.1 Selected record and scaling

Non-linear dynamic time-history analysis was conducted to evaluate the seismic response of the frame. The structure was excited using the Northridge earthquake of 17 January 1994 with M_w of 6.69. The station used is the Arleta - Nordhoff Fire Station which is located 8.66 km away from the epicenter and measured a PGA of 0.332. To speed up the analysis, the original record was truncated where only the first 20 seconds of the record were used in the analysis since the main earthquake activities are concentrated in the first 20 seconds. In addition, to truncating the record, a scaling factor of 1.989 was applied to the record to represent a maximum considered earthquake (MCE) as per ASCE 07 [22]. The original and modified records are shown in Figure 6 (a) and (b) respectively.

Figure 6: The Northridge earthquake used in the simulation. (a) original record. (b) modified record.

4.2 Roof displacement and Interstory drift ratios

The analysis was conducted on frames with varying connection capacity, yield strength of the connecting angles, slip in the connection and friction coefficient between the faying surfaces. Specifically, the frames were characterized by connection capacities of 30% MP_b , 50% MP_b and 70% MP_b with yield strength of 36 ksi and 50 ksi for the angles and beam elements, respectively, a friction coefficient of 0.33 and 1/16" bolt hole (i.e., a slip 1/32" on both sides of the bolt hole). The roof displacement and the interstory drift ratio of all three frames are shown in Figure 7. The maximum roof displacement experienced by the frames was 4.06 in, 5.82 in and 6.54 in, for the 30% MP_b , 30% MP_b and 30% MP_b , respectively. The resulting first floor interstory drift ratio was calculated to be 2.51%, 3.59% and 4.04% for the 30% MP_b , 30% MP_b and 30% MP_b , respectively. The roof interstory drift ratio was calculated to be 1.53%, 2.78% and 3.15% for the 30% MP_b , 30% MP_b and 30% MP_b , respectively. The

calculated interstory drift ratios for all frames are below the 5% limit specified by FEMA 356 [23]

Figure 7: Roof displacement and intersotry drift ratios for all three frames

5 CONCLUSIONS

- A new beam-column connection model for top-and-seat angle with double web angle connections has been developed.
- Many inelastic features are represented in the model including hot-rolling residual stresses in the angles, bolt preload, friction between faying surfaces, connection slip and the effect of bolt-hole ovalization,
- The beam-column model was integrated in a frame model
- Non-linear dynamic time-history analysis was conducted on three different frames with varying connection capacities (30% MP_b , 50% MP_b and 70% MP_b)
- The analysis results showed that the 30% MP_b frame experienced the least roof displacement and interstory drift ratio followed by the 50% MP_b frame and the 70% MP_b frame respectively.
- The interstory dirft ratio for all three frames did not exceed the 5% limit defined by FEMA for MCE.

Keywords: Seismic Retrofit, Steel Moment Frames, Hybrid Testing, High Performance Fiber Reinforced Cementitious Materials.

Abstract. *This paper discusses the experimental validation of a new system for seismic retrofit of existing steel moment resisting structures. The system consists of infill panels made of a High Performance Fiber Reinforced Concrete (HPFRC) that is able to strain harden in tension. A two-phase experimental program was designed and conducted at the Network for Earthquake Engineering Simulation (NEES) facility at the University of California, Berkeley. This program utilized large-scale hybrid simulations of a 2/3-scale, 2-story steel moment frame designed in 1980s retrofitted with HPFRC infill panels. The numerical challenges during the experimental program including the development of a phenomenological model that is able to simulate cyclic deterioration of the HPFRC infill panels are summarized and validated with the available experimental data.*

1 INTRODUCTION

The goal of seismic rehabilitation strategies is to effectively upgrade seismically deficient structures that do not meet a designated performance objective. The performance objective could be achieving a specified performance level such as Immediate Occupancy (IO), Life Safety (LS) or Collapse Prevention (CP). Guidelines for seismic evaluation and rehabilitation are summarized in ATC 40 [1], FEMA 356 [2] and FEMA 440 [3].

A common way to improve the seismic performance of an existing steel moment resisting frame (MRF) involves the modification of the structural system to enhance its global strength and/or stiffness in order to avoid excessive story drift ratios during an earthquake (see FEMA 351 [4] and FEMA 547 [5]). Because MRFs are more flexible compared to other types of lateral resisting systems such as steel braced frames, an additional concern is the concentration of plastic deformations at the bottom stories due to P-Delta effects. Another common seismic deficiency in steel MRFs is brittle beam-to-column connections that are not able to develop sufficient plastic deformation capacity during an earthquake. Such types of component failures were notable during the Northridge 1994 earthquake in California (see FEMA 351 [4]) and also the Kobe 1995 earthquake in Japan. Pre-Northridge welded moment resisting connections typically consist of bolted shear tabs with full penetration welded flanges. Typical rehabilitation techniques summarized in [5] are concerned with the addition of a steel braced frame, concrete or masonry shear wall to the existing steel MRF to control excessive story deformations. Another way to improve the seismic performance of an existing steel MRF is to enhance the beam-to-column moment connections to develop a minimum plastic deformation of 2% radians. Typically, the bolted bracket (Adan and Gibb [6]) welded hunch (Gross et al. [7], Civjan et al. [8]) and RBS approach (Uang et al. [9]) are three standard connection rehabilitation techniques that are used.

Recently, High Performance Fiber Reinforced Concrete (HPFRC) materials have been utilized for seismic retrofit applications including reinforced concrete (RC) and coupled wall systems (Hung and El-Tawil [10, 11]), and steel moment resisting frames (Kesner and Billington [12]). The advantage of these composites is that they are characterized by pseudo-ductile tensile strain hardening behavior and energy absorption prior to crack localization and they exhibit little to no spalling in compression.

This paper discusses the development and experimental validation of the seismic retrofit system originally developed by [12]. A two-phase testing program was designed and executed that utilized large-scale hybrid simulations of an existing 2-story steel MRF designed in 1980s and retrofitted with the HPFRC infill panel system. These tests were conducted at the large-scale facility at the Richmond Field Station of the University of California at Berkeley, which is part of the Network for Earthquake Engineering Simulation (NEES). The hybrid simulation tests together with the experimental program that was conducted on single and double HPFRC infill panel components offered the opportunity to develop and validate 2-dimensional numerical models of retrofitted existing steel MRF with HPFRC infill panels.

2 HIGH PERFORMANCE FIBER REINFORCED CONCRETE

A modified version of the self-compacting high performance fiber-reinforced concrete mix that was developed by Liao et al. [13] at University of Michigan is used in this research. This mix has self-compacting properties and very minimal vibration is used to aid in consolidation. The mix proportion that is used has a water-to-binder ratio of 0.40 with the binder consisting of 80% type I-II Portland cement and 20% Class C fly ash. The super plasticizer used is ADVA Cast 530 and is added at 0.4% of the binder weight. A viscous agent is also used and is added at 0.49% of the binder weight. The fine aggregate is regular sand of uniform size dis-

tribution that can be easily found in any commercial precasting plant in California. A 12.7mm maximum coarse aggregate is also used, which is locally available. High strength hooked steel fibers marked as Dramix RC-80/30-BP are used in the HPFRC mix at 1.2% of the mix by volume. The minimum specified tensile strength of the fibers is 2300MPa. A regular concrete mixer that can be found in a precast plant can be utilized to mix the HPFRC material. In addition, Olsen and Billington [14, 15] and Hanson and Billington [16] have also used typical drum mixers to mix the same material. The mixing sequence is described in detail in [14, 16]. For the concrete mixes 102mmx203mm cylinders are cast and tested in compression to obtain the compression strength of the mix. A typical compression stress versus strain deformation curve for the HPFRC mix is shown in Figure 1a. To obtain the tensile properties of the same mix 76mmx76mmx305mm beams are cast and tested using 3-point bending following ASTM standard C 1609/C (ASTM [17]). The equivalent stress versus strain of a set of 4 of those beams is shown in Figure 1b. The equivalent stress is computed based on the following relationship,

$$\sigma_{b,equiv.} = \frac{Pl}{bd^2} \quad (1)$$

in which, P is the actuator load, l is the clear span length, d and b are the depth and width of the beam, respectively. As seen from the same figure the mix can carry flexural tension with a ductility range from 3 to about 6. Here, ductility is defined as the ratio between ultimate deformation prior to strength deterioration and the yield deformation of the HPFRC beam.

Figure 1: Mechanical properties of High Performance Fiber Reinforced Concrete.

3 PROPOSED RETROFIT SYSTEM FOR SEISMIC REHABILITATION

The design mix discussed in Section 2 is used for the fabrication of the proposed HPFRC infill panel system for seismic retrofit of steel MRFs. This system is shown in Figure 2a. The HPFRC infill panels utilize Welded Wire Fabric (WWF) to aid in shear reinforcement and bolster flexural strength. The WWF is a single layer of 10 gauge wire on a 76mmx76mm grid. Grade 50 #3 deformed mild steel consists the primary reinforcement. Each set of two vertical HPFRC infill panels are first grouted into each of two steel channel connections that are shown in Figures 2a and 2b. These connections are pre-tensioned to about 150kN in order to avoid any slip in the connection. For this purpose a load-indicating washer is used. The top steel channel connection is field welded at the bottom flange of the upper floor steel beam.

The bottom channel connection is bolted to threaded studs that are welded to the top flange of the steel beam of the bottom story. The procedure to be used to weld these studs on the top flange of the bottom steel beam is a proven construction technique referred to by Nelson Stud Welding Inc. Holes are cored into the existing slab of a building exposing the top flange of the steel beam, and new headed studs are welded through the cored hole and then grouted in place to achieve composite construction where non-composite action was originally designed.

The two HPFRC panels are connected at mid-height of a story with a slotted connection shown in Figure 2a. This connection is utilized in order to prevent any build up of axial load in the HPFRC panels and subsequently any out-of-plane movement of the double panel system. The middle connection also guarantees that the inflection point of the bending diagram of the HPFRC double panel system stays at mid-height during the entire response history of the retrofitted steel MRF. The bolted connection details allow for damaged panels to be removed and replaced quickly after a major earthquake event provided that the residual story deformations are not large after that major earthquake event.

For panel fabrication, the infill panels are cast into plywood molds (see Figure 2c). The exposed surface of the HPFRC infill panel is finished relatively smooth without much difficulty. A number of single and double infill panels have been tested at University of Michigan in order to investigate their hysteretic response [14, 15, 16]. An example can be seen in Figure 2d. In the same figure, we have superimposed the simulated response of these panels with a phenomenological model that can capture pinching and cyclic deterioration and is utilized later to investigate numerically the seismic performance of the retrofitted steel MRF.

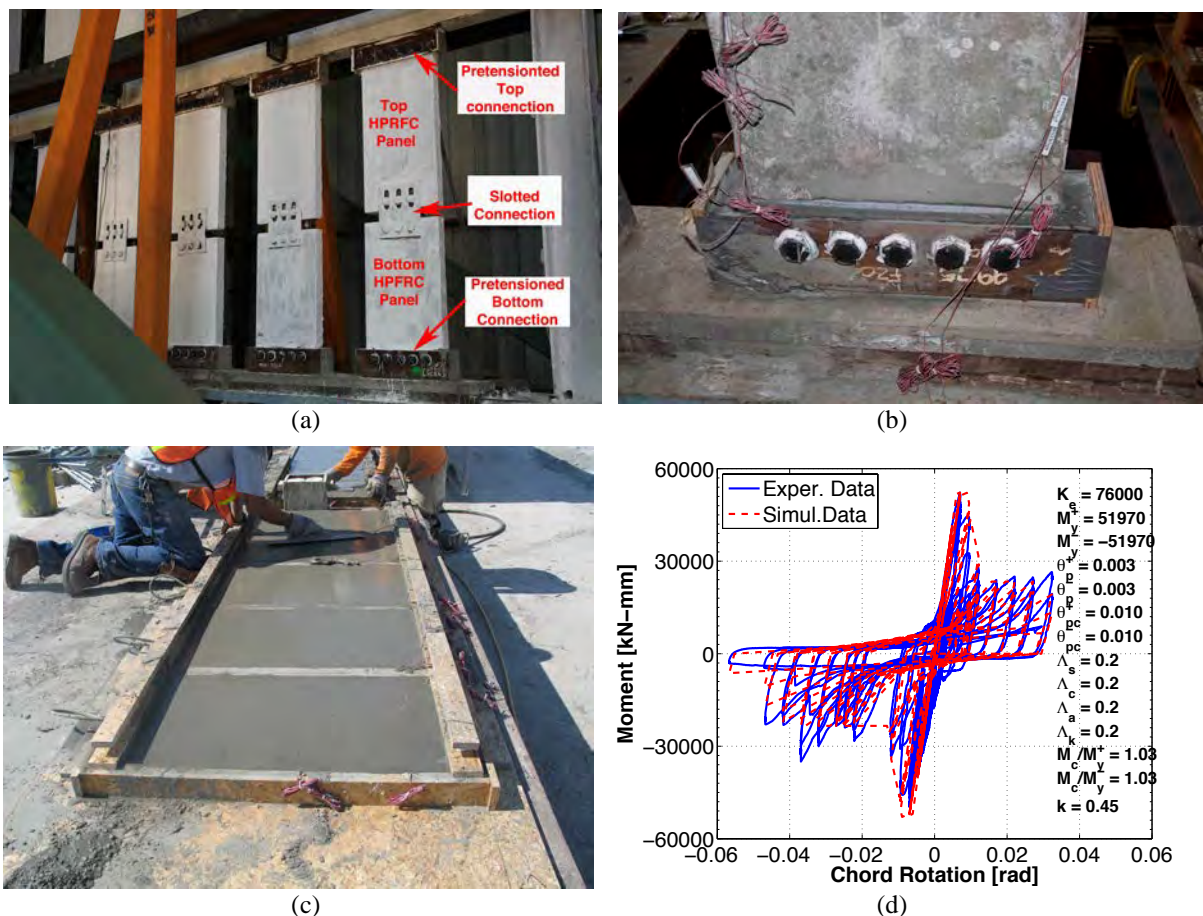

Figure 2: Installation, fabrication and hysteretic performance of the HPFRC infill panel system for seismic retrofit applications.

4 PROTOTYPE STEEL STRUCTURE

In order to evaluate the performance of the infill panel system as part of a structural system, a prototype steel structure that was designed in California in 1980s is used. This structure, which is shown in Figure 3a in plan view, consists of perimeter steel moment resisting frames. The geometry of the East West (EW) steel MRF of the steel structure is shown in elevation in Figure 3b. The predominant period of this structure is 0.75sec. This structure does not meet the retrofit objectives per ASCE 41 [18] and FEMA 356 [2]. The EW steel MRF is modeled in the OpenSees [19] simulation platform using elastic beam column elements with nonlinear rotational springs at their ends. These springs can simulate component deterioration based on the modified Ibarra-Krawinkler (IK) model (Ibarra et al. [20], Lignos and Krawinkler [21, 22]). Panel zones are modeled with the Krawinkler model [23] as discussed in Gupta and Krawinkler [24]. The modified IK model is able to simulate fracture of steel connections based on a Coffin-Manson fracture rule that was implemented by Lignos et al. [24]. Information related to premature steel beam-to-column connection fractures is obtained from a recently developed steel database for deterioration modeling of steel beams [21, 22].

In order to retrofit the 2-story building shown in Figure 3, a set of five panels is installed in the exterior left bay of the EW steel MRF of the prototype structure. Since there are no established design guidelines for this type of retrofit, the HPRFC infill panel system is assumed to be a deteriorating element. This assumption is valid since this retrofit system dissipates energy through multi-cracking of the HPRFC infill panels. After a few number of cycles the infill panels deteriorate as shown in Figure 2d.

Figure 3: Plan view and elevation of the prototype steel office building designed in 1980s in California.

5 LARGE SCALE HYBRID SIMULATIONS

In order to validate experimentally the seismic performance of the retrofitted EW steel MRF discussed in Section 4, a 2/3-scale model of this moment frame is designed and fabricated. Strength and stiffness of this frame are scaled based on similitude rules discussed in

Moncarz and Krawinkler [25] and Harris and Sabnis [26]. The web and flange slenderness ratios of these sections were carefully selected in order to match the target deterioration parameters of the steel components of the prototype building shown in Figure 3b. State-of-the-art hybrid simulations are utilized in order to test experimentally the retrofitted steel MRF. The subsequent sections present aspects of hybrid testing including the hybrid model, experimental setup, and instrumentation.

5.1 Hybrid Model

Hybrid simulation is utilized in order to evaluate the seismic performance of the retrofitted steel MRF with HPFRC infill panels. Hybrid simulation is an experimentally based method for investigating the response of a structure to dynamic excitation using a hybrid model that consists of a physical and a numerical subassembly [27, 28]. The physical subassembly is tested in the laboratory. In this case, the physical subassembly is the first bay of the retrofitted steel MRF with the HPFRC panels installed. Typical A992 Gr. 50 steel is used for fabrication of the steel beams and columns of the 2/3-scale steel MRF shown in Figure 4a. Based on tensile coupon tests the yield and ultimate strengths of these components are summarized in Table 1. In order to simulate as realistically as possible the HPFRC pre-tensioned connection boundary conditions a 60mm concrete slab is cast at the base and second and third floor beams as shown in Figure 4b. In order to secure fixed conditions at the base a 51mm steel plate is used and the steel columns are welded with a typical CJP weld as shown in Figure 4c. The bolted web-welded flange beam-to-column connections of the test subassembly are welded in the field with a typical CJP weld. Figure 4d shows an example of these connections.

Figure 4: Erection and typical connection details of the physical subassembly part of the hybrid model.

Table 1: Material properties of W sections of the physical subassembly tested in the laboratory.

The numerical portion of the hybrid model is modeled in the OpenSees [19] analysis platform in the same way that was previously discussed in Section 4. A schematic representation of the hybrid simulation technique is shown in Figure 5. As diagrammed in this figure, from a known state at instance i we use a numerical technique to compute a target displacement at instance $i+1$, then we use the two actuators assigned to the two horizontal degrees of freedom to impose the target displacements and measure forces and then compute the new state at instance $i+1$. The Open-source Framework for Experimental Setup and Control (OpenFresco) [29, 30] is utilized in order to conduct the hybrid simulations. As seen in Figure 5, the implementation strategy that is used separates the integrator and sub-structure processes. A three-loop architecture starts issuing actuator commands using a local estimator (predictor) of the new (target) state and then corrects the trajectory when the true target state arrives from the integrator. It should be noted that in this process the error accumulates. More details about an advanced implementation of hybrid simulation can be found in [30].

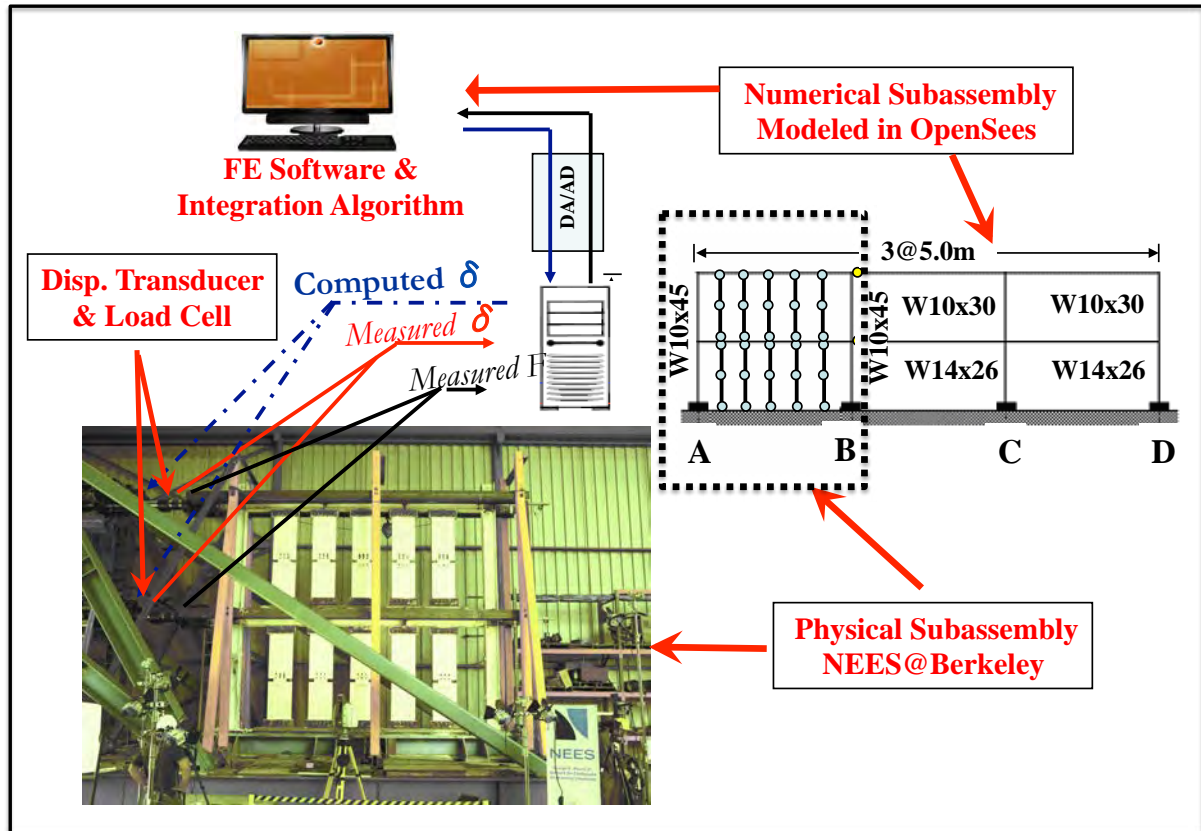

Figure 5: Schematic representation of hybrid simulation

5.2 Coupled Simulation

Prior to conducting the hybrid simulations with the physical subassembly in the laboratory, a coupled simulation was conducted with OpenFresco. The numerical subassembly of the 2-story steel MRF shown in Figure 6 is connected with a generic Super-Element within OpenSees that represents the physical subassembly tested in the laboratory. In this discussion, this is noted as the “Master Program”. The physical subassembly is also modeled in OpenSees with a separate input file that herein is called the Slave Program. The HPFRC infill panels are modeled with rigid links connecting deteriorating springs that can simulate the hysteretic response and flexibility of the HPFRC panels as shown in Figure 2d. The Master Program is responsible for imposing boundary conditions on both subassemblies. The 2-node adapter element shown in Figure 6 imposes trial displacements on the “physical subassembly”. The main information extracted from the coupled simulation is an estimate of the initial 2x2 stiffness matrix of the “physical subassembly” by holding one-degree-of-freedom at a time and applying a unit displacement to the other one. This matrix is,

$$K = \begin{bmatrix} 58.1 & -27.4 \\ -27.4 & 15.3 \end{bmatrix} \text{ kN/mm} \quad (2)$$

Additional information that is extracted from the coupled simulation results is the integration method that is used during the hybrid simulation. A Newmark beta hybrid simulation implicit integrator is used with a constant number of sub-stepping [30]. Details about the assessment of coupled simulation results are given in Lignos and Billington [31].

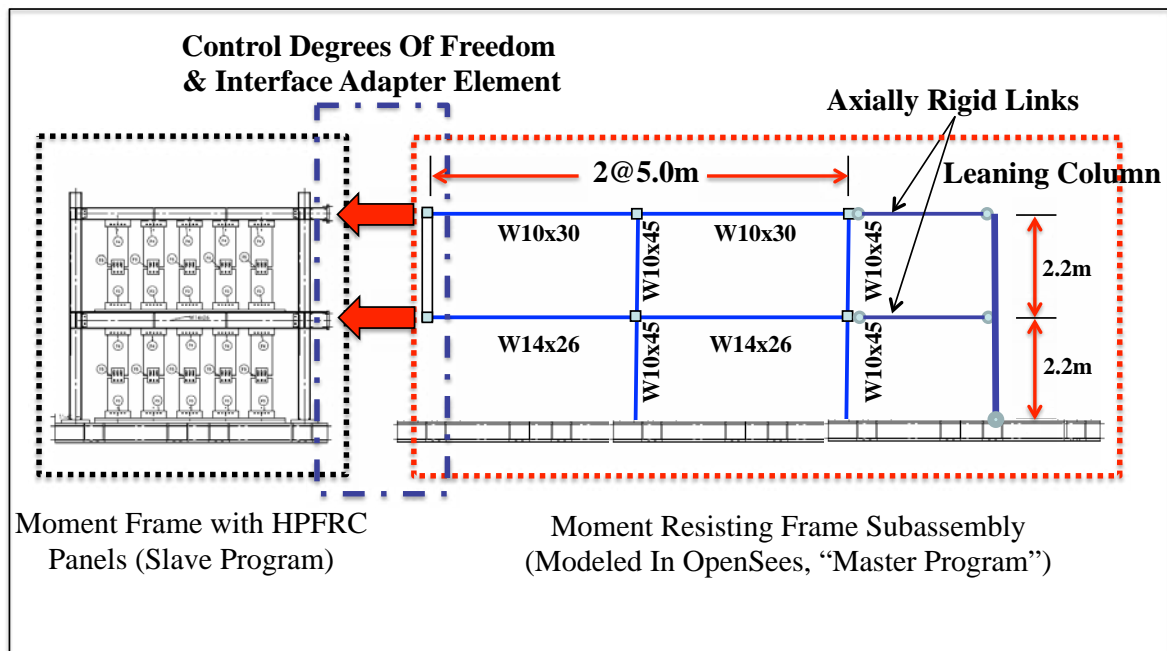

Figure 6: Schematic representation of hybrid simulation

5.3 Experimental Setup

The experimental setup of the physical subassembly tested in the Richmond Field Station at the University of California at Berkeley consists of three main parts, which are a self-reacting platform (see Figure 4a), the test frame and the lateral support system. The latter prevents any out-of-plane deformations of the test frame during the unidirectional earthquake

simulation. All parts of the test setup are shown in Figure 7. Two 980kN (220-kips) dynamic actuators are connected with the test frame per floor as shown in the same figure. The self-reacting frame shown in Figure 4a was analyzed and fabricated in such a way that vertical deformations are minimized during the hybrid simulation tests. Vertical deformations of the self-reacting platform are measured with vertical LVDTs in order to make sure that they stay minimal. This platform consists of W21x166 steel sections connected together with full penetration weld. The platform is able to safely resist up to 1500kN base shear. The test frame is welded on the self-reacting platform with a 6.35mm continuous weld around the W14x311 supporting beam to guarantee full composite action between the middle interior W21x166 and W14x311 steel sections. The lateral support system consists of six triangular frames made of HSS6x6x3/8 (three on each side) and connected to each other with a longitudinal W12x26 steel beam. Lateral resistance of the lateral support frame is provided through two diagonal steel angles L6x3x1/2 that are connected at the base of the self-reacting platform. The test frame slides against this beam. The gap between the slider and the longitudinal steel beams was designed to be 6.35mm (1/4"). In order to eliminate friction due to possible contact between the test frame sliders shown in Figure 4d and the W12x26 longitudinal steel beam teflon is installed in between these components. Friction forces during the hybrid simulation tests are measured through the diagonal angles that are strain gaged and calibrated to measure the force transferred to the platform due to sliding. However, during the two testing phases almost zero friction force was measured.

Figure 7: Experimental setup for hybrid simulation of the 2/3 retrofitted steel MRF.

5.4 Instrumentation

A total of 150 and 90 instruments are used to instrument the test frame for testing Phase I and Phase II, respectively. A laser scanner is also used that perform scan measurements of pre-defined infill panels that are likely to be damaged based on pre-test analysis predictions. The majority of instruments are strain gages to obtain strain measurements of the steel reinforcement and to obtain moment gradients in the steel columns of the test frame. One LVDT per floor is used to obtain the absolute floor displacements with respect to the “ground floor”.

Thirty-six LVDTs are attached to diagonal plastic strips to measure shear deformations in every other set of double panels per floor. A typical arrangement of these LVDTs is shown in Figure 8. Two Data Acquisition (DAQ) systems are synchronized together for the instrumentation needs of this testing series. The experimental data from both testing phases are available through the NEES central repository (www.nees.org).

Figure 8: Typical instrumentation layout of HPFRC infill panel system.

6 EXPERIMENTAL PROGRAM

Two testing phases are designed for the retrofitted steel MRF discussed in Sections 4 and 5. After the completion of testing Phase I all the HPFRC infill panels are replaced with a new set with nominally identical material properties to the ones used in testing Phase I. However, due to material variability some minor differences are noticed in the measured compressive strengths of the HPFRC panels after 28 days (see [32]). This section discusses the testing protocol used and the seismic response of the retrofitted steel MRF during the two testing phases.

6.1 Testing Protocol

Two testing phases are designed in order to conduct the large scale hybrid simulation tests of the retrofitted 2-story steel MRF. In both phases, the ground motion records are scaled appropriately to represent levels of intensity that are of particular interest to the engineering profession. Two ground motions are used for these phases. The first one is the fault normal component of the Petrolia record from the Cape Mendocino earthquake in California in 1992. The unscaled record represents a Maximum Considered Earthquake (MCE) in California with 2% probability of exceedence in 50 years at the period of interest. The second earthquake used, is the fault normal component of the Canoga Park record from the Northridge 1994 earthquake. The unscaled record of this motion represents a Design Level Earthquake (DLE) in California with 10% probability of exceedence in 50 years. The unscaled absolute acceleration and relative velocity spectra of these two motions are shown in Figures 9a and 9b, respectively. For reference, we have superimposed the predominant period of the bare steel MRF.

Testing Phase I, consists of (1) a Service Level Earthquake (SLE) with intensity equal to the 30% of the unscaled Petrolia record. This event corresponds to a 50% probability of exceedence in 50 years; (2) a DLE equal to the 70% of the unscaled Petrolia record and (3) a second DLE equal to the unscaled Canoga Park record. This event is used in order to investigate the effect of a major aftershock on the retrofitted steel MRF without replacing the

HPFRC infill panels that is likely to occur as has been illustrated during the latest earthquakes in New Zealand and Japan in 2011. Similarly, testing Phase II consists of the same SLE with testing Phase I. This part is repeated for comparison purposes. The testing protocol for this phase also consists an MCE with intensity equal to the unscaled Petrolia record in order to evaluate the seismic performance of the retrofitted steel MRF to an extreme earthquake event.

Figure 9: Acceleration and velocity spectra of the two ground motions used in testing Programs I and II.

7 RESULTS AND DISCUSSION

7.1 Seismic Response of the Test Frame During the Testing Program

Prior to the main testing phases the initial 2x2 stiffness of the physical subassembly was obtained by applying about one third of the yield story force per degree-of-freedom (DOF) and measuring back the relative displacements. Using the flexibility method (McGuire et al. [33]) the initial stiffness matrix is determined after coupling of the two DOF of the test frame. This matrix, which represents the Jacobian is,

$$K = \begin{bmatrix} 60.4 & -24.4 \\ -25.4 & 19.4 \end{bmatrix} \text{ kN/mm} \quad (3)$$

After comparing this matrix with the one from (2) the estimated initial stiffness K based on coupled simulation is fairly close with the experimentally obtained one.

Figure 10 shows the roof drift ratio of the retrofitted steel MRF during testing Phases I and II. As seen from these figures, for both SLE phases the retrofitted test frame did not exceed more than 1% roof drift ratio. During the SLE loading, micro-cracking occurred in the HPFRC infill panels. The effect of micro cracking of HPFRC panels on the hysteretic response of the retrofitted frame can be seen in Figure 11a. This figure shows a comparison of the normalized base shear V/W versus first story drift ratio (SDR_1) during SLE for testing Phases I and II. During DLE-I (70% Petrolia) the retrofitted test frame reached slightly more than 2% rad in absolute maximum roof drift ratio and a minor residual roof drift ratio equal to 0.4% radians. Few flexural cracks were observed in the HPFRC panels. Three HPFRC infill panels failed completely at their base connection due to bending and after this failure the HPFRC panels were rocking. This implies that after DLE-I minimal to no replacement of HPFRC infill panels is needed. Without replacing any panels, the retrofitted steel MRF is subjected to a new design level earthquake (DLE-II). During DLE-II, the test frame reached a 2.5% absolute maximum roof drift ratio as shown in Figure 10a and a residual roof drift ratio of about 0.5% radians in the opposite direction compared to DLE-I. More distributed cracking was observed to the edge infill panels compared to the ones that were closer to the center of the steel beams. When reaching about 2.5% story drift ratios most of the HPFRC panels were severally damaged as discussed in [32]. These results are comparable with earlier findings of the hysteretic response of the HPFRC single and double component tests discussed in [14, 15, 16]. A comparison of peak story drift ratios between and the retrofitted steel MRF and the bare steel MRF during DLE-II is shown in figure 11b.

Figure 10: Roof drift histories of retrofitted steel MRF during testing Phases I and II.

After the completion of testing Phase I all the HPFRC infill panels were replaced by a new set with nominally identical material properties. However, due to material variability the compressive and tensile strength of the new set was slightly lower compared to the first set of infill panels [32]. During testing Phase II, a Maximum Considered Earthquake followed the

SLE in order to investigate the performance of the retrofitted steel MRF when subjected to an extreme earthquake event. Figure 10b shows the roof drift ratio of the test frame for the MCE. In the same figure we have superimposed the simulated roof drift history of the numerical model used to simulate the seismic response of the retrofitted steel MRF during both testing phases. As seen from Figure 10 the numerical simulation results match relatively well the measured experimental data.

Figure 11: Seismic performance of retrofitted steel MRF during testing Phase I; (a) normalized base shear versus first story drift ratio; (b) comparison of peak story drift ratios between retrofitted and bare steel MRF.

Due to large inelastic cycles prior to the main pulse of the Petrolia record (MCE) more distributed flexural cracks were developed in the HPFRC infill panels compared to Phase I. A typical damage pattern of the HPFRC infill panels after the MCE event is shown in Figure 12a. The final failure mode of a panel is the same with the one observed in Figure 12b. In some panels spalling of the reinforcement cover was observed (see Figure 12b). After the MCE event all the panels were severely damaged. The damage pattern in the HPFRC infill panels was consistent for both testing Phases I and II.

Figure 12: Damage pattern of HPFRC infill panels after the MCE during testing Phase II.

7.2 Structural Damage Observations and Comparison with Bare Frame Response

During testing Phase I, the structural damage that was observed to the retrofitted steel MRF was light. Yielding occurred at both the first and second floor steel beams of the steel MRF. Figures 13a and 13b shows a typical damage pattern of the first floor steel beam and column base, respectively, after the completion of testing Phase I. From Figure 13a there is no indication of local buckling in the steel beam. The hysteretic response of the corresponding numerical portion of the hybrid model indicated the same observation as shown in Figure 14a that shows the moment rotation relationship of one of the first floor steel beams that were part of the numerical portion of the hybrid model.

Looking at the normalized based shear versus first story drift ratio during testing Phase I (see Figure 14a), it can be seen that there is no indication of cyclic deterioration. The observed relatively small stiffness deterioration is attributed to the loss of stiffness from the severe damage of the HPFRC panels after DLE-II.

Figure 13: Structural damage observations during testing Phase I.

During testing Phase II, the structural damage that was observed to the steel MRF was very similar to that observed in testing Phase I. Again, no indication of local buckling was notable in any of the steel beam-to-column connections of the retrofitted steel frame. The lack of local buckling is confirmed from Figure 14c that shows the normalized base shear versus first story drift ratio for both the SLE and MCE loadings during testing Phase II. From this figure, there is no indication of cyclic strength deterioration. The unloading stiffness deterioration that is shown in this figure is attributed to the stiffness loss from the failure of HRFRC panels. An interesting observation during this testing phase is a dissipated energy mechanism because of yielding of the bottom flanges of the portions of the first and second floor steel beams between the steel channels. This yielding is attributed due to bending that was caused from the shear force that the individual panels carried during the MCE event (about 50kN). This yielding mechanism acted beneficially to the overall seismic behavior of the steel MRF since dam-

age was distributed away from its the steel beam-to-column connections of the test frame. This yield mechanism is illustrated in Figure 14b.

8 CONCLUSIONS

This paper discusses the development of an innovative seismic retrofit system for existing steel moment resisting frames designed in accordance with old seismic provisions. This system utilizes High Performance Fiber Reinforced Concrete and through multi-cracking dissipates energy during an earthquake. The proposed retrofit system was validated both numerically and experimentally through large-scale hybrid simulation tests at the NEES facility at University of California at Berkeley. Two testing phases were designed and conducted that included earthquake events of particular interest to the engineering profession. In this paper, the major computational challenges for numerical modeling of the steel moment frame and execution of the large-scale hybrid simulations were also summarized. The main findings from this research program are summarized as follows:

- Through micro cracking, the proposed infill panel system dissipates energy during service level earthquakes.
- During a Design Level or a Maximum Considered Earthquake the HPFRC infill panel system reduces seismic demands in terms of story and residual drift ratios compared to the un-retrofitted bare frame.

- Without replacing any of the HPFRC infill panels after a Design Level Earthquake the effect of an aftershock on the seismic response of a retrofitted steel MRF was simulated with a second Design Level Earthquake and its seismic performance was judged to be better compared to the bare frame.
- Regarding structural damage of the steel moment resisting frame, there was no indication of local buckling to the steel beams in any of the testing phases. The lack of local buckling in part, is attributed to the energy dissipation through micro-cracking in the HPFRC panels during the earthquake. Another reason was due to yielding of the bottom flange of the steel beams in the bare portions between the HPFRC infill panels.
- The numerical models developed to simulate the seismic response of the steel MRF and HPFRC infill panels were validated with the experimental data that became available from the large-scale hybrid simulation tests. These models can be used for further evaluation of a variety of steel buildings retrofitted with HPFRC panels in a performance-based earthquake-engineering context.

9 ACKNOWLEDGEMENTS

This study is based on work supported by the United States National Science Foundation (NSF) under Grant No. [CMS-0530383](#) within the George E. Brown, Jr. Network for Earthquake Engineering Simulation (NEES) Consortium Operations. The Herrick Corporation in Stockton generously donated the steel frame and associated parts of the test setup, including erection. Midstate Precast generously donated the fabrication of the HPFRC infill panels. The financial support of NSF, Herrick and Midstate Precast is gratefully acknowledged. The authors also thank the undergraduate students A. Cantu, D. Ouyang, E. Flores, J. Dory, K. Morales, S. Vanderboll, William Tressler, M.S. (Stanford University), Dr. Andreas Schellenberg, Dr. Selim Gunay, Dr. Shakhzod Tachirov and the rest of the technical staff at the NEES facility at the University of California at Berkeley for their assistance with many aspects of the hybrid simulation testing program. The authors would also like to thank Mr. Ron Hamburger, Mr. David Mar and Dr. Greg Luth for their valuable input regarding the proposed testing phases of the experimental program. Any opinions, findings, and conclusions expressed in this paper are those of the authors and do not necessarily reflect the views of the sponsors.

Keywords: Dynamic Variability Response Functions; Stochastic finite element analysis; upper bounds; stochastic dynamic systems.

Abstract. *The concept of the so called Variability Response Function (VRF), recently proposed for statically determinate and indeterminate stochastic systems [1, 2], is extended in this work to linear dynamic stochastic systems. An integral form for the variance of the dynamic response of stochastic systems is considered, involving a Dynamic VRF (DVRF) and the spectral density function of the stochastic field modeling the uncertain system properties. As in the case of static systems, the independence of the DVRF to the spectral density and the marginal probability density function of the stochastic field modeling the uncertain parameters is validated using brute-force Monte Carlo simulations as well as a series of different moving power spectral density functions for the calculation of the DVRF. The uncertain system property considered is the inverse of the elastic modulus (flexibility). It is demonstrated that DVRF is a function of the standard deviation of the stochastic field modeling flexibility. The same integral expression can be used to calculate the mean response of a dynamic system using the concept of the so called Dynamic Mean Response Function (DMRF), which is a function similar to the DVRF [3]. These integral forms can be used to efficiently compute the mean and variance of the transient system response at any time of the dynamic response together with spectral-distribution-free upper bounds. They also provide an insight into the mechanisms controlling the dynamic mean and variability response. In this work this methodology is effectively utilized to estimate the stochastic dynamic response of a single degree of freedom system subjected to a) sinusoidal load at the end of its length and b) El Centro earthquake. In both cases results are drawn for different values of the stochastic field standard deviation and for various Gaussian and non-Gaussian probability distributions.*

1 INTRODUCTION

Over the past two decades a lot of research has been dedicated to the stochastic analysis of structural systems involving uncertain parameters in terms of material or geometry with the implementation of stochastic finite element methodologies (SFEM) to numerically solve the stochastic partial differential equations (PDE's) governing the respective problems. The most commonly used SFEM methods are expansion/perturbation-based [12, 13] and Galerkin-based Spectral SFEM (SSFEM) approaches [10]. Although such methods have proven to be highly accurate and computationally efficient for a variety of problems, there is still a wide range of problems in stochastic mechanics involving combinations of strong non-linearities and/or large variations of system properties as well as non-Gaussian system properties that can be solved with reasonable accuracy only through a computationally expensive Monte Carlo simulation approach [12, 11, 14, 15], limited works are dealing with the dynamic propagation of system uncertainties, most of them reducing the stochastic dynamic PDE's to a linear random eigenvalue problem [16, 17].

In all aforementioned cases, the spectral/correlation characteristics and the marginal probability distribution function (pdf) of the stochastic fields describing the uncertain system parameters are required in order to estimate the response variability of a stochastic static or dynamic system. As there is usually a lack of experimental data for the quantification of such probabilistic quantities, a sensitivity analysis with respect to various stochastic parameters is often implemented. In this case, however, the problems that arise are the increased computational effort, the lack of insight on how these parameters control the response variability of the system and the inability to determine bounds of the response variability.

In this framework and to tackle the aforementioned issues, the concept of the variability response function (*VRF*) has been proposed in the late 1980s [4], along with different aspects and applications of the *VRF* [18, 19]. A development of this approach was presented in a series of papers [1-3], where the existence of closed-form integral expressions for the variance of the response displacement of the form

$$Var[u] = \int_{-\infty}^{\infty} VRF(\kappa, \sigma_{ff}) S_{ff}(\kappa) d\kappa \quad (1)$$

was demonstrated for linear stochastic systems under static loads using a flexibility-based formulation. The basic difference of this approach with respect to previous work is that by using a flexibility-based formulation, no approximations were involved in the derivation of the resulting integral expression in Eq. (1). It was shown that the *VRF* depends on standard deviation σ_{ff} but appears to be independent of the functional form of the spectral density function $S_{ff}(\kappa)$ modeling the inverse of the elastic modulus. The existence however of this integral expression had to be conjectured for statically indeterminate as well as for general stochastic finite element systems. A rigorous proof of such existence is available only for statically determinate systems for which *VRF* is independent of σ_{ff} as well [1]. Further investigations [7] verified the aforementioned results but showed that *VRF* has a slight dependence on the marginal pdf of the stochastic field modeling the flexibility. In [3] results were presented for general linear stochastic Finite Element systems including beams, space frames, plane stress and shell-type structures under static loads. Another important extension of the concept of *VRF* has been recently drawn [20] to determine effective material properties in homogenization problems.

The present paper extends the aforementioned approach to linear statically determinate stochastic systems under dynamic excitations. Although the derivation of an analytic expression for the variability response function of the dynamic system (*DVRF*), if possible at all, is

extremely cumbersome, a numerical computation of the *DVRF* can be easily achieved to provide results for the variance time history of the dynamic system response. As in previous works [1-3], the existence of the *DVRF* and a similar to Eq. (1) integral form expression has to be conjectured. This assumption is numerically validated by comparing the results from Eq. (1) with brute force Monte Carlo simulations. It is demonstrated that the *DVRF* is highly dependent on the standard deviation σ_{ff} of the inverse of the elastic modulus and, based on numerical evidence further presented but, to this point, not to a full proof verification technique, appears to be almost independent of the functional form of $S_{ff}(\kappa)$ as well as of the marginal *pdf* of the flexibility. In addition, an integral expression similar to that of Eq. (1) is proposed for the mean system response involving a Dynamic Mean Response Function (*DMRF*), which is a function similar to the *DVRF*.

Both integral forms for the mean and variance can be used to efficiently compute the first and second order statistics of the transient system response with reasonable accuracy, together with time dependant spectral-distribution-free upper bounds. They also provide an insight into the mechanisms controlling the uncertainty propagation with respect to both space and time and in particular the mean and variability time histories of the stochastic system dynamic response.

2 DYNAMIC ANALYSIS OF A STOCHASTIC SINGLE DEGREE OF FREEDOM OSCILLATOR

For the single degree of freedom statically determinate stochastic oscillator of length L and mass M_s in Figure 1a, loaded with a dynamic deterministic load, the inverse of the elastic modulus is considered to vary randomly along the length of the beam according to the following expression:

$$\frac{1}{E(x)} = F_0(1 + f(x)) \quad (2)$$

where $E(x)$ is the elastic modulus, F_0 is the mean value of the inverse of $E(x)$, and $f(x)$ is a zero-mean homogeneous stochastic field modeling the variation of $1/E(x)$ around its mean value F_0 .

Figure 1. One degree of freedom oscillator: (a) Geometry and loading (b) Static displacement for unit load

The displacement time history of the oscillator can be derived from the solution of Duhamel's integral:

$$u(t) = \frac{1}{\omega_D} \int_0^t P(\tau) e^{-\xi\omega(t-\tau)} \sin(\omega_D(t-\tau)) d\tau \quad (2)$$

where ξ is the damping ratio and $\omega_D = \omega\sqrt{1-\xi^2}$ with ω being the circular frequency of the system. Due to the system uncertainty in Eq. (2), the circular frequency ω is a random variable given by the following relation:

$$\omega = \sqrt{k / M_s} \quad (2)$$

where k is the stiffness of the oscillator which can be derived from the static displacement of the oscillator for a unit static deterministic load at the end of the beam (Figure 1b) as follows:

$$k = \frac{1}{u_{st}} = \left[-\frac{F_0}{I} \int_0^L (x-\alpha) M(\alpha) (1+f(\alpha)) d\alpha \right]^{-1} \quad (2)$$

where I is the moment of inertia of the beam and $M(\alpha)$ is the moment at position α .

In the general case where the load is arbitrary and the system is initially at rest, the deterministic displacement at the right end of the beam can be derived by numerically solving the Duhamel's integral. In the special case of a sinusoidal $P(t) = P_0 \sin(\bar{\omega}t)$ the solution of Eq. (3) leads to the following expression for $u(t)$:

$$u(t) = u_0(t) + u_p(t) \quad (2)$$

where

$$u_0(t) = e^{-\xi\omega t} (A \sin \omega_D t + B \cos \omega_D t) \quad (2)$$

$$u_p(t) = C_1 \sin \bar{\omega}t + C_2 \cos \bar{\omega}t \quad (2)$$

$$A = \frac{P_0}{K} * \frac{1}{(1-\beta^2)^2 + (2\xi\beta)^2} * \frac{2\beta\xi^2 - (1-\beta^2)\beta}{\sqrt{1-\xi^2}} \quad (2)$$

$$B = -\frac{P_0}{K} * \frac{2\xi\beta}{(1-\beta^2)^2 + (2\xi\beta)^2} \quad (2)$$

$$C_1 = \frac{P_0}{K} * \frac{1}{(1-\beta^2)^2 + (2\xi\beta)^2} (1-\beta^2) \quad (2)$$

$$\beta = \bar{\omega} / \omega \quad (2)$$

In the trivial case in which a static load $P(t) = P_0$ is suddenly applied, the response displacement is given by

$$u(t) = \frac{P_0}{k} \left[1 - \left(\cos \omega_D t + \frac{\xi}{\sqrt{1-\xi^2}} \sin \omega_D t \right) e^{-\xi\omega t} \right] \quad (2)$$

3 RESPONSE VARIANCE AND MEAN VALUE OF THE DYNAMIC RESPONSE

Following a procedure similar to the one presented in [1] for linear stochastic systems under static loading, it is possible to express the variance of the dynamic response of the stochastic system in the following integral form expression:

$$\text{Var}[u(t)] = \int_{-\infty}^{\infty} \text{DVRF}(t, \kappa, \sigma_{ff}) S_{ff}(\kappa) d\kappa \quad (2)$$

where *DVRF* is the dynamic version of a *VRF*, assumed to be a function of deterministic parameters of the problem related to geometry, loads and (mean) material properties and the standard deviation σ_{ff} of the stochastic field that models the system flexibility. A similar integral expression can provide an estimate for the mean value of the dynamic response of the system using the Dynamic Mean Response Function (*DMRF*) [3]:

$$\varepsilon[u(t)] = \int_{-\infty}^{\infty} DMRF(t, \kappa, \sigma_{ff}) S_{ff}(\kappa) d\kappa \quad (2)$$

DMRF is assumed to be a function similar to the *DVRF* in the sense that it also depends on deterministic parameters of the problem as well as σ_{ff} . It is extremely difficult however, to prove that the *DVRF* (same counts for *DMRF*) is independent (or even approximately independent) of the marginal pdf and the functional form of the power spectral density of the stochastic field $f(x)$. As in [1-3], the aforementioned assumptions are considered to form a conjecture which is numerically validated here by comparing the results from Eqs (8a) and (8b) with brute force MCS.

The derivation of an analytic expression for the *DVRF* and *DMRF*, if possible at all, is an extremely cumbersome task. A numerical computation, however can be easily achieved, as described in the following section and then fed into the Eqs (8a) and (8b) to provide estimates of the mean and variance of the dynamic system response.

3.1 Numerical estimation of the DVRF and the DMRF using fast Monte Carlo simulation

The numerical estimation of *DVRF* and *DMRF* involves a fast Monte Carlo simulation (FMCS) whose basic idea is to consider the random field $f(x)$ as a random sinusoid [1, 2] and plug its monochromatic power spectrum into Eqs (8a) and (8b), in order to compute the respective mean and variance response at various wave numbers. The steps of the FMCS approach are the following:

- (i) Generate N (10-20) sample functions of the below random sinusoid with standard deviation σ_{ff} and wave number $\bar{\kappa}$ modeling the variation of the inverse of the elastic modulus $1/E$ around its mean F_0 :

$$f_j(x) = \sqrt{2}\sigma_{ff} \cos(\bar{\kappa}x + \varphi_j) \quad (2)$$

where $j=1,2,\dots,N$ and φ_j varies randomly under uniform distribution in the range $[0, 2\pi]$.

- (ii) Using these N generated sample functions it is straightforward to compute their respective dynamic mean and response variance, $\varepsilon[u(t)]_{\bar{\kappa}}$ and $Var[u(t)]_{\bar{\kappa}}$, respectively for a given time step t .

- (iii) The value of the *DMRF* at wave number $\bar{\kappa}$ can then be computed as follows

$$DMRF(t, \bar{\kappa}, \sigma_{ff}) = \frac{\varepsilon[u(t)]_{\bar{\kappa}}}{\sigma_{ff}^2} \quad (2)$$

and likewise the value of the *DVRF* at wave number $\bar{\kappa}$

$$DVRF(t, \bar{\kappa}, \sigma_{ff}) = \frac{Var[u(t)]_{\bar{\kappa}}}{\sigma_{ff}^2} \quad (2)$$

Both previous equations are direct consequences of the integral expressions in Eqs. (8a) and (8b) in the case that the stochastic field becomes a random sinusoid.

- (iv) Get *DMRF* and *DVRF* as a function of both time t and wave number κ by repeating previous steps for various wave numbers and different time steps. The entire procedure can be repeated for different values of the standard deviation σ_{ff} of the random sinusoid.

3.2 Bounds of the mean and variance of the dynamic response

Upper bounds on the mean and variance of the dynamic response of the stochastic system can be established directly from eqs (8a) and (8b), as follows:

$$E[u(t)] = \int_{-\infty}^{\infty} DMRF(t, \kappa, \sigma_{ff}) S_{ff}(\kappa) d\kappa \leq DMRF(t, \kappa^{\max}(t), \sigma_{ff}) \sigma_{ff}^2 \quad (2)$$

$$Var[u(t)] = \int_{-\infty}^{\infty} DVRF(t, \kappa, \sigma_{ff}) S_{ff}(\kappa) d\kappa \leq DVRF(t, \kappa^{\max}(t), \sigma_{ff}) \sigma_{ff}^2 \quad (2)$$

where $\kappa^{\max}(t)$ is the wave number at which *DMRF* and *DVRF*, corresponding to a given time step t and value of σ_{ff} , reach their maximum value. An envelope of time evolving upper bounds on the mean and variance of the dynamic system response can be extracted from Eqs. (11a) and (11b). As in the case of linear stochastic systems under static loads [1-3], this envelope is physically realizable since the form of the stochastic field that produces it is the random sinusoid of Eq.(9) with $\bar{\kappa} = \kappa^{\max}(t)$.

4 NUMERICAL EXAMPLE

For the cantilever beam shown in Fig. 1 with length $L=4\text{m}$, the inverse of the modulus of elasticity is assumed to vary randomly along its length according to Eq. (2) with $F_0 = (1.25 \times 10^8 \text{ KN/m})^{-1}$ and $I = 0.1 \text{ m}^4$. A concentrated mass $M_s = 3.715 \times 10^3 \text{ Kg}$ is assumed at the right end of the beam. The damping ratio is taken as $\zeta=5\%$ and the mean eigenperiod of this one d.o.f oscillator is calculated at $T_0=0.5\text{sec}$.

Three load cases are considered: LC1 consisting of a constant load $P(t)=100$, LC2 consisting of a concentrated dynamic periodic load $P(t)=100\sin(\bar{\omega}t)$ and LC3 consisting of $P(t)=-M_s \ddot{U}_g(t)$ where $\ddot{U}_g(t)$ is the acceleration time history of the 1940 El Centro earthquake.

The spectral density function (*SDF*) of Figure 2 was used for the modeling of the inverse of the elastic modulus stochastic field, given by:

$$S_{ff}(\kappa) = \frac{1}{4} \sigma^2 b^3 \kappa^2 e^{-b|\kappa|} \quad (2)$$

with $b=10$ being a correlation length parameter.

Figure 2. Spectral density function for stochastic field $f(x)$ standard deviation $\sigma_{ff}=0.2$

In order to demonstrate the validity of the proposed methodology, a truncated Gaussian and a lognormal pdf were used to model $f(x)$. For this purpose, an underlying Gaussian stochastic field denoted by $g(x)$ is generated using the spectral representation method [9] and the power spectrum of Eq. (12). The truncated Gaussian field $f_{TG}(x)$ is obtained by simply truncating $g(x)$ in the following way: $-0.9 \leq g(x) \leq 0.9$, while the lognormal $f_L(x)$ is obtained from the following transformation as a translation field [8]:

$$f_L(x) = F_L^{-1}\{G[g(x)]\} \quad (2)$$

The *SDF* of the underlying Gaussian field in Eq.(12) and the corresponding spectral densities of the truncated Gaussian and the Lognormal fields denoted $S_{f_{TG}f_{TG}}(\kappa)$ and $S_{f_Lf_L}(\kappa)$, respectively, will be different. These are computed from the following formula

$$S_{f_i f_i}(\kappa) = \frac{1}{2\pi L_x} \left| \int_0^{L_x} f_i(x) e^{-i\kappa x} dx \right|^2 ; i = TG, L \quad (2)$$

where L_x is the length of the sample functions of the non-Gaussian fields modeling flexibility. As the sample functions of the non-Gaussian fields are non-ergodic, the estimation of power spectra in Eq.(14) is performed in an ensemble average sense [8].

4.1 LC1: Constant load at the end of the beam

This load case scenario has been selected in order to further demonstrate the validity of the methodology and establish a logical continuation with previous studies related to the current work. In the case when the excitation is constant $P(t)=P_0$, and the load P_0 is suddenly applied, the response displacement is given by Eq. (7h). From this equation it can be seen that the solution degenerates to the static solution $u(t) = P_0 / k$ as time t tends to infinity. Accordingly the *DVRF* should converge to the respective static *VRF* of a cantilever beam loaded with a concentrated load at its end, given by Eq. (15) [1].

$$VRF(x, \kappa) = \left| \frac{F_0}{I} \int_0^x h(x, \xi) M(\xi) e^{i\kappa \xi} d\xi \right|^2 \quad (2)$$

where $h(x, \xi)$ is the Green function of the beam given by

$$h(x, \xi) = x - \xi \quad (2)$$

and $M(x)$ is the bending moment function given by

$$M(\xi) = -P_0(L - \xi) \quad (2)$$

Validating the aforementioned expectations, figure 3 presents a 3D plot of the *DVRF* with an initial transient phase and afterwards the phase where the system is almost at rest, while figure 4 presents the coinciding *VRF* and *DVRF* obtained from Eq. (15a) and *FMCS*, respectively, when the system has approached the stationary condition at $t=10\text{sec}$ and $\sigma_{ff} = 0.2$.

Figure 3. 3D plot of *DVRF*, as a function of frequency κ (rad/m) and time t (sec) for LC1 and $\sigma_{ff}=0.2$

Figure 4. Values of *VRF* for static load P_0 and *DVRF* for constant load $P(t)=P_0$ at $t=10\text{sec}$.

4.2 LC2: Dynamic periodic load at the end of the beam

Figures 5 and 6 present $DMRF$ and $DVRF$, respectively, computed with FMCS for a periodic load with frequency $\bar{\omega} = 2$ and three different values of the standard deviation $\sigma_{ff} = 0.2$, $\sigma_{ff} = 0.4$ and $\sigma_{ff} = 0.6$. From these figures it can be observed that $DVRF$ do not follow any particular pattern with respect to any increase or decrease of σ_{ff} in contrast to $DMRF$ and to what has been observed in Papadopoulos and Deodatis [2] for the corresponding static problem, albeit the mean and variability response increases as σ_{ff} increases, as shown below (Figure 8). Figures 7(a) and (b) present plots of $DMRF$ and $DVRF$ as a function of t for a fixed wave number $\kappa = 2$ and $\sigma_{ff} = 0.2$. From the above Figures (5, 6 and 7) it appears that $DMRF$ and $DVRF$ have a significant variation along the wave number κ axis and the time axis t . Both functions and especially $DVRF$ have an initial transient phase and then appear to be periodic. It is reminded here that $DVRF$ and $DMRF$ are functions of the imposed dynamic loading. This explains the fact that they do not approach zero with t increasing, since the applied dynamic load is periodic with constant amplitude which does not decay.

(b)

Figure 7. DMRF (a) and DVRF (b) as a function of t for $\kappa=2\text{ rad/sec}$ and $\sigma_{ff} = 0.2$

Figures 8(a), (b) and (c) present comparatively the results of the computed response variance time histories using the integral expression of Eq.(8a) and MCS, for three different standard deviations of a truncated Gaussian stochastic field used for the modeling of flexibility. The underlying Gaussian field is modeled with the power spectral density of Eq.(12) and three different standard deviations $\sigma_{gg}=0.2$, $\sigma_{gg}=0.4$ and $\sigma_{gg}=0.6$. The corresponding standard deviations of the truncated Gaussian field $f(x)$ are computed as $\sigma_{ff}=0.2$, $\sigma_{ff}=0.3912$ and $\sigma_{ff}=0.5286$, respectively. Figures 9(a), (b) and (c), present the same results with Figure 6 but for the mean response of the oscillator. The deterministic displacement time history is also plotted in figure 9(d) for comparison purposes. From these figures it can be observed that the mean and variability response time histories obtained with the integral expressions of Eqs (8a) and (8b) are in close agreement with the corresponding MCS estimates. In all cases examined the maximum error in the computed $\text{Var}[u(t)]$, observed at the peak values of the variance, is

less than 25%, while in all other time steps this error is less than 3-4%. In the case of $\varepsilon[u(t)]$, the predictions of Eq. 8(b) are almost identical to the ones obtained with MCS, with an error of less than 3% in all cases. From Figures 9(a-d), it can be observed that in all cases, the mean response time history for all cases examined is almost identical to the deterministic one, with the exception of the first cycle where slight differences in the peak values are observed.

4.3 LC3: El Centro earthquake

Figures 11 and 12 present plots of $DMRF$ and $DVRF$, respectively, for the load case of the acceleration time history of the 1940 El Centro Earthquake. As in previous load case scenario, three different values of the standard deviation were used, $\sigma_{ff} = 0.2$, $\sigma_{ff} = 0.4$ and $\sigma_{ff} = 0.6$. From these figures it can again be observed that $DVRF$ does not follow any pattern with respect to an increase or decrease of σ_{ff} , while in this case this is also observed for the $DMRF$ at Figure 11(c) for $t=5\text{sec}$.

(a)

(b)

(c)

(b)

(c)

Figure 12. $DVRF$ as a function of the σ_{ff} for (a) $t=1\text{sec}$, (b) $t=3\text{sec}$ and (c) $t=5\text{sec}$

Figures 13(a) and (b) present 3D plots of the *DMRF* and *DVRF* as a function of frequency κ and time $t(sec)$ for $\sigma_{ff}=0.2$. From these figures, as well as from figures 11 and 12, it can be observed that again *DMRF* and *DVRF* have a significant variation in both κ and t axis, without being periodic in contrast to what has been observed in LC2. In addition, both *DMRF* and *DVRF* approach a zero value with time increasing due to the fact that ground accelerations decay and vanish after some time.

(a)

(b)

Figure 13. 3D plots of (a) *DMRF* and (b) *DVRF*, as a function of frequency κ (rad/m) and time $t(sec)$ for LC3 and $\sigma_{ff}=0.2$

Figures 14(a), and 14(b) present a comparison of the response variance computed with Eq.(8a) and MCS, in the case of a truncated Gaussian stochastic field modeling flexibility

with $\sigma_{gg} = 0.4$ and 0.6 , while figures (15a) and (15b) present the same results for the mean dynamic response of the stochastic oscillator along with the corresponding deterministic displacement time history (figure 15(c)). Figures 16(a) and (b) repeat the same comparisons for the case of a lognormal stochastic field used for the modeling of flexibility and $\sigma_{ff} = 0.3$ and lower bound $l_b = -0.8$.

(a)

(b)

Figure 14. Time histories of the variance of the response displacement for a truncated Gaussian field for (a) $\sigma_{gg} = 0.4$ and (b) $\sigma_{gg} = 0.6$. Comparison of results obtained from eq.8(a) and MCS.

(a)

(b)

(c)

Figure 15. Time histories of the mean response displacement for a truncated Gaussian field with (a) $\sigma_{gg} = 0.4$, (b) $\sigma_{gg} = 0.6$ and (c) of the deterministic response displacement. Comparison of results obtained from eq.(8b) and MCS.

(a)

(b)

Figure 16. Comparative results from eq. 11 and MCS for a lognormal field with $\sigma_{ff} = 0.3$ for (a) the variance and (b) the mean of the response displacement time history

From the above figures it can be observed that, as in LC2, the mean and variability response time histories obtained with the integral expressions of Eqs (8a) and 8(b) are in close agreement with the corresponding MCS estimates, in all cases. Again, the maximum error in the computed $Var[u(t)]$ was observed at the peak values of the variance and is less than 25%, while in all other time steps this error is less than 3-4%. In the case of $\varepsilon[u(t)]$, the predictions of Eq. 8(b) are very close to the ones obtained with MCS, with a error of less than 3% in all cases. From Figures 13(a-c), it can be observed that, in contrast to what was observed in LC2, the mean response time history differs significantly from the corresponding deterministic one, in terms of both frequencies and amplitudes.

4.4 Upper bounds on the mean and variance of the response of LC3

Spectral-distribution-free upper bounds on both the mean and variance of the response are obtained via Eqs. (11a) and (11b), respectively. Results of this calculation are presented in figures 17(a) and (b), in which the time dependant upper bounds on the mean and variance of the response displacement are plotted against time for a standard deviation $\sigma_{ff} = 0.4$.

(a)

(b)

Figure 17. Upper bounds on the (a) mean and (b) variance of the response displacement for LC3 and $\sigma_{gg}=0.4$

4.5 Sensitivity analysis for LC3 using the integral expressions in Eqs 8(a) and (b)

Finally, a sensitivity analysis is performed using Eqs. (8a) and (8b) at minimum computational cost, with respect to three different values of the correlation length parameter of the *SDF* in Eq. (12) and $\sigma_{ff}=0.2$.

5 CONCLUDING REMARKS

In the present work, Dynamic Variability Response Functions and Dynamic Mean Response Functions are obtained for a linear stochastic single d.o.f. oscillator with random material properties under dynamic excitation. The inverse of the modulus of elasticity was considered as the uncertain system parameter.

It is demonstrated that, as in the case of stochastic systems under static loading, *DVRF* and *DMRF* depend on the standard deviation of the stochastic field modeling the uncertain parameter but appear to be almost independent of its power spectral density and marginal *pdf*. The results obtained from the integral expressions are close to those obtained with MCS reaching a maximum error of the order of 20-25%.

As in the case of stochastic systems under static loading, the *DVRF* and *DMRF* provide with an insight of the dynamic system sensitivity to the stochastic parameters and the mechanisms controlling the response mean and variability and their evolution in time.

Keywords: Stochastic dynamics, random field, spectral decomposition, Karhunen-Loève Expansion, stochastic subspace projection

Abstract. *This article provides the theoretical development and simulation results of a novel Galerkin subspace projection scheme for damped dynamic systems with stochastic coefficients. The fundamental idea involved here is to solve the stochastic dynamic system in the frequency domain by projecting the solution into a reduced finite dimensional spatio-random vector basis to approximate the response. A Nueumann expansion type of approach is used to generate the complex stochastic basis functions. The proposed method is applicable to linear dynamic systems with Gaussian and non-Gaussian random fields. Galerkin weighting coefficients have been employed to minimize the error induced due to the reduced basis and finite order spectral functions and hence to explicitly evaluate the stochastic system response. The statistical moments of the solution have been evaluated at all frequencies to illustrate and compare the stochastic system response with the deterministic case. The results have been compared to direct Monte-Carlo simulation for different correlation lengths and variability of randomness.*

1 INTRODUCTION

Due to the significant development in computational hardware it is now possible to solve very high resolution models in various computational physics problems, ranging from fluid mechanics to nano-bio mechanics. However, the spatial resolution is not enough to determine the credibility of the numerical model, the physical model as well its parameters are also crucial. Since neither of these may not be exactly known, there has been increasing research activities over the past three decades to model the governing partial differential equations within the framework of stochastic equations. We refer to few recent review papers [1–3]. Consider a bounded domain $\mathcal{D} \in \mathbb{R}^d$ with piecewise Lipschitz boundary $\partial\mathcal{D}$, where $d \leq 3$ is the spatial dimension and $t \in \mathbb{R}^+$ is the time. Further, consider that (Θ, \mathcal{F}, P) is a probability space where $\theta \in \Theta$ is a sample point from the sampling space Θ , \mathcal{F} is the complete σ -algebra over the subsets of Θ and P is the probability measure. We consider a linear stochastic partial differential equation (PDE) of the form

$$\rho(\mathbf{r}, \theta) \frac{\partial^2 U(\mathbf{r}, t, \theta)}{\partial t^2} + \mathfrak{L}_\alpha \frac{\partial U(\mathbf{r}, t, \theta)}{\partial t} + \mathfrak{L}_\beta U(\mathbf{r}, t, \theta) = p(\mathbf{r}, t); \quad \mathbf{r} \in \mathcal{D}, t \in [0, T] \quad (1)$$

with the associated Dirichlet condition

$$U(\mathbf{r}, t, \theta) = 0; \quad \mathbf{r} \text{ on } \partial\mathcal{D}. \quad (2)$$

In the above equation $\rho(\mathbf{r}, \theta)$ is the random mass distribution of the system, $p(\mathbf{r}, t)$ is the distributed time-varying forcing function, \mathfrak{L}_β is the spatial self-adjoint stochastic stiffness operator, \mathfrak{L}_α is the spatial self-adjoint stochastic damping operator and $U(\mathbf{r}, t, \theta)$ is the stochastic response quantity to be obtained. Note that $\mathfrak{L}_\alpha(\bullet)$ and $\mathfrak{L}_\beta(\bullet)$ involve linear stochastic differential operators with coefficients $\alpha(\mathbf{r}, \theta)$ and $\beta(\mathbf{r}, \theta)$ as the second order random fields such that $\alpha, \beta : \mathbb{R}^d \times \Theta \rightarrow \mathbb{R}$. We assume the random fields to be stationary and square integrable. The purpose of this paper is to investigate a new solution approach for Eqn. (1) after the discretization of the spatio-random fields using the well established techniques of stochastic finite element method (SFEM) as can be found in references [4–6].

The random fields in Eqn. (1) can be discretized to represent them as spectral functions using a finite number of random variables using one of the established techniques available in literatures [4, 7]. Hence the stochastic PDE along with the boundary conditions would result in an equation of the form

$$\mathbf{M}(\theta) \ddot{\mathbf{u}}(\theta, t) + \mathbf{C}(\theta) \dot{\mathbf{u}}(\theta, t) + \mathbf{K}(\theta) \mathbf{u}(\theta, t) = \mathbf{f}_0(t) \quad (3)$$

where $\mathbf{u}(\theta, t)$ is the discretized response vector, $\mathbf{M}(\theta) = \mathbf{M}_0 + \sum_{i=1}^p \mu_i(\theta_i) \mathbf{M}_i \in \mathbb{R}^{n \times n}$ is the random mass matrix, $\mathbf{K}(\theta) = \mathbf{K}_0 + \sum_{i=1}^p \nu_i(\theta_i) \mathbf{K}_i \in \mathbb{R}^{n \times n}$ is the random stiffness matrix along with $\mathbf{C}(\theta) \in \mathbb{R}^{n \times n}$ as the random damping matrix. Here the mass and stiffness matrices have been expressed in terms of their deterministic components (\mathbf{M}_0 and \mathbf{K}_0) and the corresponding random contributions (\mathbf{M}_i and \mathbf{K}_i) obtained from discretizing the stochastic field with a finite number of random variables ($\mu_i(\theta_i)$ and $\nu_i(\theta_i)$) and their corresponding spatial basis functions. This has been elaborated in subsection 2.1. In the present work proportional damping is considered for which $\mathbf{C}(\theta) = \zeta_1 \mathbf{M}(\theta) + \zeta_2 \mathbf{K}(\theta)$, where ζ_1 and ζ_2 are deterministic scalars. For the harmonic analysis of the structural system considered in Eqn. (3), it is represented in the frequency domain as

$$[-\omega^2 \mathbf{M}(\theta) + i\omega \mathbf{C}(\theta) + \mathbf{K}(\theta)] \tilde{\mathbf{u}}(\theta, \omega) = \tilde{\mathbf{f}}_0(\omega) \quad (4)$$

where $\tilde{\mathbf{u}}(\theta, \omega)$ is the complex frequency domain system response amplitude, $\tilde{\mathbf{f}}_0(\omega)$ is the amplitude of the harmonic force.

Now we group the random variables associated with the mass and damping matrices of Eqn. (3) as

$$\xi_i(\theta) = \mu_i(\theta) \quad \text{and} \quad \xi_{i+p}(\theta) = \nu_i(\theta) \quad \text{for} \quad i = 1, 2, \dots, p$$

following which the expression for the linear structural system in Eqn. (4) can be expressed as

$$\left(\mathbf{A}_0(\omega) + \sum_{i=1}^{2p} \xi_i(\theta_i) \mathbf{A}_i(\omega) \right) \tilde{\mathbf{u}}(\omega, \theta) = \tilde{\mathbf{f}}_0(\omega) \quad (5)$$

where \mathbf{A}_0 and $\mathbf{A}_i \in \mathbb{C}^{n \times n}$ represent the complex deterministic and stochastic parts respectively of the mass, the stiffness and the damping matrices ensemble. For the case of proportional damping the matrices \mathbf{A}_0 and \mathbf{A}_i can be written as

$$\mathbf{A}_0(\omega) = [-\omega^2 + i\omega\zeta_1] \mathbf{M}_0 + [i\omega\zeta_2 + 1] \mathbf{K}_0 \quad (6)$$

$$\mathbf{A}_i(\omega) = [-\omega^2 + i\omega\zeta_1] \mathbf{M}_i \quad \text{for} \quad i = 1, 2, \dots, p \quad (7)$$

$$\text{and} \quad \mathbf{A}_j(\omega) = [i\omega\zeta_2 + 1] \mathbf{K}_j \quad \text{for} \quad j = p+1, p+2, \dots, 2p.$$

The paper has been arranged as follows. In section 2 a brief overview of spectral stochastic finite element method is presented. The projection theory in the vector space is developed in section 3. In section 4 an error minimization approach in the Hilbert space is proposed. The idea of the reduced orthonormal vector basis is introduced in subsection section 5. The post processing of the results to obtain the response moments are discussed in section 6. Based on the theoretical results, a simple computational approach is shown in section 7 where the proposed method of reduced orthonormal basis is applied to the stochastic mechanics of an Euler-Bernoulli beam. From the theoretical developments and numerical results, some conclusions are drawn in section 8.

2 Overview of the spectral stochastic finite element method

2.1 Discretization of the stochastic PDE

First consider $a(\mathbf{r}, \theta)$ is a Gaussian random field with a covariance function $C_a : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$ defined in the domain \mathcal{D} . Since the covariance function is square bounded, symmetric and positive definite, it can be represented by a spectral decomposition in an infinite dimensional Hilbert space. Using this spectral decomposition, the random process $a(\mathbf{r}, \theta)$ can be expressed [see for example, [4, 8]] in a generalized Fourier type of series known as the Karhunen-Loève (KL) expansion

$$a(\mathbf{r}, \theta) = a_0(\mathbf{r}) + \sum_{i=1}^{\infty} \sqrt{\nu_i} \tilde{\xi}_i(\theta) \varphi_i(\mathbf{r}) \quad (8)$$

Here $a_0(\mathbf{r})$ is the mean function, $\tilde{\xi}_i(\theta)$ are uncorrelated standard Gaussian random variables, ν_i and $\varphi_i(\mathbf{r})$ are eigenvalues and eigenfunctions satisfying the integral equation

$$\int_{\mathcal{D}} C_a(\mathbf{r}_1, \mathbf{r}_2) \varphi_j(\mathbf{r}_1) d\mathbf{r}_1 = \nu_j \varphi_j(\mathbf{r}_2), \quad \forall j = 1, 2, \dots \quad (9)$$

The Gaussian random field model is not applicable for strictly positive quantities arising in many practical problems. Eqn. (8) could also represent the Karhunen-Loève expansion of a non-Gaussian random field, which is also well defined. Alternatively, when $a(\mathbf{r}, \theta)$ is a general non-Gaussian random field, it can be expressed in a mean-square convergent series in random variables and spatial functions using the polynomial chaos expansion. For example Ghanem [9] expanded log-normal random fields in a polynomial chaos expansion. In general, non Gaussian random fields can be expressed in a series like

$$a(\mathbf{r}, \theta) = a_0(\mathbf{r}) + \sum_{i=1}^{\infty} \xi_i(\theta) a_i(\mathbf{r}) \quad (10)$$

using Wiener-Askey chaos expansion [10–12]. Here $\xi_i(\theta)$ are in general non-Gaussian and correlated random variables and $a_i(\mathbf{r})$ are deterministic functions. In this paper we use this general form of the decomposition of the random field.

Truncating the series in Eqn. (10) upto the M -th term and using the same approach for the governing PDE (1) with boundary conditions, the discretized system equation in the frequency domain (3) can be represented by Eqn. (5), with $M = 2p$ as

$$\left[\mathbf{A}_0 + \sum_{i=1}^M \xi_i(\theta) \mathbf{A}_i \right] \mathbf{u}(\theta, \omega) = \mathbf{f}_0(\omega). \quad (11)$$

The ‘tilde’ sign has been omitted from the notations of the frequency domain quantities of $\mathbf{u}(\theta, \omega)$ and $\mathbf{f}_0(\omega)$ for the sake of notational convenience and this shall be followed henceforth. The necessary technical details to obtain the discrete stochastic algebraic equations from the stochastic partial differential equation (1) have become standard in the literature. Excellent references, for example [4, 13–15] are available on this topic. In Eqn. (11), \mathbf{A}_0 is a complex symmetric positive definite matrix, $\mathbf{A}_i \in \mathbb{C}^{n \times n}; i = 1, 2, \dots, M$ are complex symmetric matrices, $\mathbf{u}(\theta, \omega) \in \mathbb{C}^n$ is the solution vector and $\mathbf{f}_0(\omega) \in \mathbb{C}^n$ is the input vector. For most practical applications, uncertainties are small compared to the deterministic values. Therefore, we normally have

$$\|\mathbf{A}_0\| \geq \left\| \sum_{i=1}^M \xi_i(\theta) \mathbf{A}_i \right\|; \forall \theta \in \Theta \quad (12)$$

Here by $\|\bullet\|$ we imply the Frobenius matrix norm [16], defined as $\|\mathbf{A}\| = \text{Trace}(\mathbf{A}\mathbf{A}^T)$ for any $\mathbf{A} \in \mathbb{R}^{n \times n}$. The number of terms M in Eqn. (11) can be selected based on the accuracy desired for the representation of the underlying random field. One of the main aim of a stochastic dynamic analysis is to obtain $\mathbf{u}(\theta, \omega)$ for $\theta \in \Theta$ and for all frequency value ω from Eqn. (11) in an efficient manner and is the main topic of this paper. We propose a solution technique for Eqn. (11) when $\xi_i(\theta)$ are in general non-Gaussian and correlated random variables.

2.2 Brief review of the solution techniques

The solution of the set of stochastic linear algebraic equations (11) is a key step in the stochastic finite element analysis. As a result, several methods have been proposed. These methods include, first- and second-order perturbation methods [5, 17], Neumann expansion method [18, 19], Galerkin approach [20], linear algebra based methods [21–23] and simulation methods [24]. More recently efficient collocation methods have been proposed [25, 26]. Another class of methods which have been used widely in the literature is known as the spectral methods (see [1] for a recent review). These methods include the polynomial chaos (PC)

expansion [4], stochastic reduced basis method [27–29] and Wiener–Askey chaos expansion [10–12]. According to the polynomial chaos expansion, second-order random variables $u_j(\theta)$ can be represented by the mean-square convergent expansion

$$\begin{aligned} u_j(\theta) = & u_{i_0} h_0 + \sum_{i_1=1}^{\infty} u_{i_1} h_1(\xi_{i_1}(\theta)) \\ & + \sum_{i_1=1}^{\infty} \sum_{i_2=1}^{i_1} u_{i_1, i_2} h_2(\xi_{i_1}(\theta), \xi_{i_2}(\theta)) + \sum_{i_1=1}^{\infty} \sum_{i_2=1}^{i_1} \sum_{i_3=1}^{i_2} u_{i_1 i_2 i_3} h_3(\xi_{i_1}(\theta), \xi_{i_2}(\theta), \xi_{i_3}(\theta)) \quad (13) \\ & + \sum_{i_1=1}^{\infty} \sum_{i_2=1}^{i_1} \sum_{i_3=1}^{i_2} \sum_{i_4=1}^{i_3} u_{i_1 i_2 i_3 i_4} h_4(\xi_{i_1}(\theta), \xi_{i_2}(\theta), \xi_{i_3}(\theta), \xi_{i_4}(\theta)) + \dots, \end{aligned}$$

where u_{i_1, \dots, i_r} are deterministic constants to be determined and $h_r(\xi_{i_1}(\theta), \dots, \xi_{i_r}(\theta))$ is the r^{th} order homogeneous Chaos. When $\xi_i(\theta)$ are Gaussian random variables, the functions $h_r(\xi_{i_1}(\theta), \dots, \xi_{i_r}(\theta))$ are the r^{th} order Hermite polynomial so that it becomes orthonormal with respect to the Gaussian probability density function. The same idea can be extended to non-Gaussian random variables, provided more generalized functional basis are used [10–12] so that the orthonormality with respect to the probability density functions can be retained. When we have a random vector, as in the case of the solution of Eqn. (11), then it is natural to replace the constants u_{i_1, \dots, i_r} by vectors $\mathbf{u}_{i_1, \dots, i_r} \in \mathbb{R}^n$. Suppose the series is truncated after P number of terms. The value of P depends on the number of basic random variables M and the order of the PC expansion r as

$$P = \sum_{j=0}^r \frac{(M+j-1)!}{j!(M-1)!} = \binom{M+r}{r} \quad (14)$$

After the truncation, there are P number of unknown vectors of dimension n . Then a mean-square error minimization approach can be applied and the unknown vectors can be solved using the Galerkin approach [4]. Since P increases very rapidly with the order of the chaos r and the number of random variables M , the final number of unknown constants Pn becomes very large. As a result several methods have been developed (see for example [27–31]) to reduce the computational cost. In the polynomial chaos based solution approach, the *only* information used to construct the basis is the probability density function of the random variables. In the context of the discretized Eqn. (11), more information such as the matrices $\mathbf{A}_i, i = 0, 1, 2 \dots M$ are available. It may be possible to construct alternative basis using these matrices. Here we investigate such an approach, where instead of projecting the solution in the space of orthonormal polynomials, the solution is projected in an orthonormal vector basis generated from the coefficient matrices.

3 Spectral decomposition in the vector space

3.1 Derivation of the spectral functions

Following the spectral stochastic finite element method, or otherwise, an approximation to the solution of Eqn. (11) can be expressed as a linear combination of functions of random variables and deterministic vectors. Recently Nouy [32, 33] discussed the possibility of an optimal spectral decomposition. The aim is to use small number of terms to reduce the computation without losing the accuracy. Here an orthonormal vector basis is considered. Fixing a

value of θ , say $\theta = \theta_1$, the solution of Eqn. (11) $\mathbf{u}(\theta_1)$ can be expanded in a complete basis as $\mathbf{u}(\theta_1) = \alpha_1^{(1)} \phi_1 + \alpha_2^{(1)} \phi_2 + \dots \alpha_n^{(1)} \phi_n$. Repeating this for $\theta_1, \theta_2, \dots$ eventually the whole sample-space can be covered and it would be possible to expand $\mathbf{u}(\theta), \forall \theta \in \Theta$ as a linear combination of $\phi_1, \phi_2, \dots, \phi_n$.

We use the eigenvectors $\phi_k \in \mathbb{R}^n$ of the generalized eigenvalue problem

$$\mathbf{K}_0 \phi_k = \lambda_k \mathbf{M}_0 \phi_k; \quad k = 1, 2, \dots, n \quad (15)$$

Since the matrices \mathbf{K}_0 and \mathbf{M}_0 are symmetric and generally non-negative definite, the eigenvectors ϕ_k for $k = 1, 2, \dots, n$ form a complete basis. Note that in principle any complete basis can be used. This choice is selected due to the analytical simplicity as will be seen later. For notational convenience, define the matrix of eigenvalues and eigenvectors

$$\boldsymbol{\lambda}_0 = \text{diag} [\lambda_1, \lambda_2, \dots, \lambda_n] \in \mathbb{R}^{n \times n} \quad \text{and} \quad \boldsymbol{\Phi} = [\phi_1, \phi_2, \dots, \phi_n] \in \mathbb{R}^{n \times n} \quad (16)$$

Eigenvalues are ordered in the ascending order so that $\lambda_1 < \lambda_2 < \dots < \lambda_n$. We use the orthogonality property of the modal matrix $\boldsymbol{\Phi}$ as

$$\boldsymbol{\Phi}^T \mathbf{K}_0 \boldsymbol{\Phi} = \boldsymbol{\lambda}_0, \quad \text{and} \quad \boldsymbol{\Phi}^T \mathbf{M}_0 \boldsymbol{\Phi} = \mathbf{I} \quad (17)$$

Using these we have

$$\begin{aligned} \boldsymbol{\Phi}^T \mathbf{A}_0 \boldsymbol{\Phi} &= \boldsymbol{\Phi}^T ([-\omega^2 + i\omega\zeta_1] \mathbf{M}_0 + [i\omega\zeta_2 + 1] \mathbf{K}_0) \boldsymbol{\Phi} \\ &= (-\omega^2 + i\omega\zeta_1) \mathbf{I} + (i\omega\zeta_2 + 1) \boldsymbol{\lambda}_0 \end{aligned} \quad (18)$$

$$\text{which gives, } \boldsymbol{\Phi}^T \mathbf{A}_0 \boldsymbol{\Phi} = \boldsymbol{\Lambda}_0 \quad \text{and} \quad \mathbf{A}_0 = \boldsymbol{\Phi}^{-T} \boldsymbol{\Lambda}_0 \boldsymbol{\Phi}^{-1} \quad (19)$$

where $\boldsymbol{\Lambda}_0 = (-\omega^2 + i\omega\zeta_1) \mathbf{I} + (i\omega\zeta_2 + 1) \boldsymbol{\lambda}_0$ and \mathbf{I} is the identity matrix. Hence, $\boldsymbol{\Lambda}_0$ can also be written as

$$\boldsymbol{\Lambda}_0 = \text{diag} [\lambda_{01}, \lambda_{02}, \dots, \lambda_{0n}] \in \mathbb{C}^{n \times n} \quad (20)$$

where $\lambda_{0j} = (-\omega^2 + i\omega\zeta_1) + (i\omega\zeta_2 + 1) \lambda_j$ and λ_j is as defined in Eqn. (16). We also introduce the transformations

$$\tilde{\mathbf{A}}_i = \boldsymbol{\Phi}^T \mathbf{A}_i \boldsymbol{\Phi} \in \mathbb{C}^{n \times n}; i = 0, 1, 2, \dots, M. \quad (21)$$

Note that $\tilde{\mathbf{A}}_0 = \boldsymbol{\Lambda}_0$ is a diagonal matrix and

$$\mathbf{A}_i = \boldsymbol{\Phi}^{-T} \tilde{\mathbf{A}}_i \boldsymbol{\Phi}^{-1} \in \mathbb{C}^{n \times n}; i = 1, 2, \dots, M. \quad (22)$$

Suppose the solution of Eqn. (11) is given by

$$\hat{\mathbf{u}}(\omega, \theta) = \left[\mathbf{A}_0(\omega) + \sum_{i=1}^M \xi_i(\theta) \mathbf{A}_i(\omega) \right]^{-1} \mathbf{f}_0(\omega) \quad (23)$$

Using Eqs. (16)–(22) and the orthonormality of $\boldsymbol{\Phi}$ one has

$$\hat{\mathbf{u}}(\omega, \theta) = \left[\boldsymbol{\Phi}^{-T} \boldsymbol{\Lambda}_0(\omega) \boldsymbol{\Phi}^{-1} + \sum_{i=1}^M \xi_i(\theta) \boldsymbol{\Phi}^{-T} \tilde{\mathbf{A}}_i \boldsymbol{\Phi}^{-1} \right]^{-1} \mathbf{f}_0(\omega) = \boldsymbol{\Phi} \boldsymbol{\Psi}(\omega, \boldsymbol{\xi}(\theta)) \boldsymbol{\Phi}^T \mathbf{f}_0(\omega) \quad (24)$$

where

$$\boldsymbol{\Psi}(\omega, \boldsymbol{\xi}(\theta)) = \left[\boldsymbol{\Lambda}_0(\omega) + \sum_{i=1}^M \xi_i(\theta) \tilde{\mathbf{A}}_i(\omega) \right]^{-1} \quad (25)$$

and the M -dimensional random vector

$$\boldsymbol{\xi}(\theta) = \{\xi_1(\theta), \xi_2(\theta), \dots, \xi_M(\theta)\}^T \quad (26)$$

Now we separate the diagonal and off-diagonal terms of the $\tilde{\mathbf{A}}_i$ matrices as

$$\tilde{\mathbf{A}}_i = \mathbf{\Lambda}_i + \mathbf{\Delta}_i, \quad i = 1, 2, \dots, M \quad (27)$$

Here the diagonal matrix

$$\mathbf{\Lambda}_i = \text{diag} [\tilde{\mathbf{A}}_i] = \text{diag} [\lambda_{i1}, \lambda_{i2}, \dots, \lambda_{in}] \in \mathbb{C}^{n \times n} \quad (28)$$

and the matrix containing only the off-diagonal elements $\mathbf{\Delta}_i = \tilde{\mathbf{A}}_i - \mathbf{\Lambda}_i$ is such that $\text{Trace}(\mathbf{\Delta}_i) = 0$. Using these, from Eqn. (25) one has

$$\Psi(\omega, \boldsymbol{\xi}(\theta)) = \left[\underbrace{\mathbf{\Lambda}_0(\omega) + \sum_{i=1}^M \xi_i(\theta) \mathbf{\Lambda}_i(\omega)}_{\mathbf{\Lambda}(\omega, \boldsymbol{\xi}(\theta))} + \underbrace{\sum_{i=1}^M \xi_i(\theta) \mathbf{\Delta}_i(\omega)}_{\mathbf{\Delta}(\omega, \boldsymbol{\xi}(\theta))} \right]^{-1} \quad (29)$$

where $\mathbf{\Lambda}(\omega, \boldsymbol{\xi}(\theta)) \in \mathbb{C}^{n \times n}$ is a diagonal matrix and $\mathbf{\Delta}(\omega, \boldsymbol{\xi}(\theta))$ is an off-diagonal only matrix. In the subsequent expressions we choose to omit the inclusion of frequency dependence of the individual matrices for the sake of notational simplicity, so that $\Psi(\omega, \boldsymbol{\xi}(\theta)) \equiv \Psi(\boldsymbol{\xi}(\theta))$ and so on. Hence, we rewrite Eqn. (29) as

$$\Psi(\boldsymbol{\xi}(\theta)) = [\mathbf{\Lambda}(\boldsymbol{\xi}(\theta)) [\mathbf{I}_n + \mathbf{\Lambda}^{-1}(\boldsymbol{\xi}(\theta)) \mathbf{\Delta}(\boldsymbol{\xi}(\theta))]]^{-1} \quad (30)$$

The above expression can be represented using a Neumann type of matrix series [18] as

$$\Psi(\boldsymbol{\xi}(\theta)) = \sum_{s=0}^{\infty} (-1)^s [\mathbf{\Lambda}^{-1}(\boldsymbol{\xi}(\theta)) \mathbf{\Delta}(\boldsymbol{\xi}(\theta))]^s \mathbf{\Lambda}^{-1}(\boldsymbol{\xi}(\theta)) \quad (31)$$

Taking an arbitrary r -th element of $\hat{\mathbf{u}}(\theta)$, Eqn. (24) can be rearranged to have

$$\hat{u}_r(\theta) = \sum_{k=1}^n \Phi_{rk} \left(\sum_{j=1}^n \Psi_{kj}(\boldsymbol{\xi}(\theta)) (\phi_j^T \mathbf{f}_0) \right) \quad (32)$$

Defining

$$\Gamma_k(\boldsymbol{\xi}(\theta)) = \sum_{j=1}^n \Psi_{kj}(\boldsymbol{\xi}(\theta)) (\phi_j^T \mathbf{f}_0) \quad (33)$$

and collecting all the elements in Eqn. (32) for $r = 1, 2, \dots, n$ one has

$$\hat{\mathbf{u}}(\theta) = \sum_{k=1}^n \Gamma_k(\boldsymbol{\xi}(\theta)) \phi_k \quad (34)$$

This shows that the solution vector $\hat{\mathbf{u}}(\theta)$ can be projected in the space spanned by ϕ_k .

Now assume the series in Eqn. (31) is truncated after m -th term. We define the truncated function

$$\Psi^{(m)}(\xi(\theta)) = \sum_{s=0}^m (-1)^s [\Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta))]^s \Lambda^{-1}(\xi(\theta)) \quad (35)$$

From this one can obtain a sequence for different m

$$\hat{\mathbf{u}}^{(m)}(\theta) = \sum_{k=1}^n \Gamma_k^{(m)}(\xi(\theta)) \phi_k; \quad m = 1, 2, 3, \dots \quad (36)$$

Since $\theta \in \Theta$ is arbitrary, comparing (11) and (23) we observe that $\hat{\mathbf{u}}^{(m)}(\theta)$ is the solution of Eqn. (11) for every θ when $m \rightarrow \infty$. This implies that

$$\text{Prob} \left\{ \theta \in \Theta : \lim_{m \rightarrow \infty} \hat{\mathbf{u}}^{(m)}(\theta) = \hat{\mathbf{u}}(\theta) \right\} = 1 \quad (37)$$

Therefore, $\hat{\mathbf{u}}(\theta)$ is the solution of Eqn. (11) in probability. In this derivation, the probability density function of the random variables has not been used. Therefore, the random variables can be general as long as the solution exists.

Remark 1. The matrix power series in (31) is different from the classical Neumann series [18]. The classical Neumann series is a power series in $\mathbf{A}_0^{-1} [\Delta \mathbf{A}(\xi(\theta))]$, where the first term is deterministic and the second term is random. The elements of this matrix series are polynomials in $\xi_i(\theta)$. In contrast, the series in (31) is in terms of $[\Lambda^{-1}(\xi(\theta))][\Delta(\xi(\theta))]$, where both terms are random. The elements of this matrix series are not simple polynomials in $\xi_i(\theta)$, but are in terms of a ratio of polynomials as seen in Eqn. (39). The convergence of this series depends of the spectral radius of

$$\mathbf{R} = \Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta)) \quad (38)$$

A generic term of this matrix can be obtained as

$$R_{rs} = \frac{\Delta_{rs}}{\Lambda_{rr}} = \frac{\sum_{i=1}^M \xi_i(\theta) \Delta_{irs}}{\lambda_{0r} + \sum_{i=1}^M \xi_i(\theta) \lambda_{ir}} = \frac{\sum_{i=1}^M \xi_i(\theta) \tilde{A}_{irs}}{\lambda_{0r} + \sum_{i=1}^M \xi_i(\theta) \tilde{A}_{irr}}; r \neq s \quad (39)$$

Since \mathbf{A}_0 is positive definite, $\lambda_{0r} > 0$ for all r . It can be seen from Eqn. (39) that the spectral radius of \mathbf{R} is also controlled by the diagonal dominance of the $\tilde{\mathbf{A}}_i$ matrices. If the diagonal terms are relatively larger than the off-diagonal terms, the series will converge faster even if the relative magnitude of λ_{0r} is not large.

The series in (36) approaches to the exact solution of the governing Eqn. (11) for every $\theta \in \Theta$ for $m \rightarrow \infty$. For this reason it converges in probability 1. The convergence in probability 1 is a stronger convergence than, for example, the mean-square convergence often used in the stochastic finite element analysis. Since the convergence in probability 1 automatically implies the mean-square convergence, the series in Eqn. (34) is also a mean-square convergent series.

Definition 1. The functions $\Gamma_k(\xi(\theta))$, $k = 1, 2, \dots, n$ are called the spectral functions as they are expressed in terms of the spectral properties of the coefficient matrix \mathbf{K}_0 and \mathbf{M}_0 arising in the discretized equation.

For certain class of problems the series in Eqn. (34) can give useful physical insights into the uncertainty propagation. For structural mechanics problems, the eigenvectors ϕ_k are vibrational modes [34]. Eqn. (34) says that the response of a stochastic system is a linear combination of fundamental vibrational modes weighted by the random variables Γ_k .

3.2 Properties of the spectral functions

In this section we discuss some important properties of these functions. From the series expansion in Eqn. (31) we have

$$\begin{aligned} \Psi(\xi(\theta)) &= \Lambda^{-1}(\xi(\theta)) - \Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta)) \Lambda^{-1}(\xi(\theta)) \\ &\quad + \Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta)) \Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta)) \Lambda^{-1}(\xi(\theta)) + \dots \end{aligned} \quad (40)$$

Since $\Lambda(\xi(\theta))$ is a diagonal matrix, its inverse is simply a diagonal matrix containing the inverse of each of the diagonal elements. Also recall that the diagonal of $\Delta(\xi(\theta))$ contains only zeros. Different terms of the series in (40) can be obtained using a simple recursive relationship [18]. The numerical computation of the series is therefore computationally very efficient. For further analytical results, truncating the series upto different terms, we define spectral functions of different order.

Definition 2. The first-order spectral functions $\Gamma_k^{(1)}(\xi(\theta))$, $k = 1, 2, \dots, n$ are obtained by retaining one term in the series (40).

Retaining one term in (40) we have

$$\Psi^{(1)}(\xi(\theta)) = \Lambda^{-1}(\xi(\theta)) \quad \text{or} \quad \Psi_{kj}^{(1)}(\xi(\theta)) = \frac{\delta_{kj}}{\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k}} \quad (41)$$

Using the definition of the spectral function in Eqn. (33), the first-order spectral functions can be explicitly obtained as

$$\Gamma_k^{(1)}(\xi(\theta)) = \sum_{j=1}^n \Psi_{kj}^{(1)}(\xi(\theta)) (\phi_j^T \mathbf{f}_0) = \frac{\phi_k^T \mathbf{f}_0}{\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k}} \quad (42)$$

From this expression it is clear that $\Gamma_k^{(1)}(\xi(\theta))$ are correlated non-Gaussian random variables. Since we assumed that all eigenvalues λ_{0_k} are distinct, every $\Gamma_k^{(1)}(\xi(\theta))$ in Eqn. (42) are different for different values of k .

Definition 3. The second-order spectral functions $\Gamma_k^{(2)}(\xi(\theta))$, $k = 1, 2, \dots, n$ are obtained by retaining two terms in the series (40).

Retaining two terms in (40) we have

$$\Psi^{(2)}(\xi(\theta)) = \Lambda^{-1}(\xi(\theta)) - \Lambda^{-1}(\xi(\theta)) \Delta(\xi(\theta)) \Lambda^{-1}(\xi(\theta)) \quad (43)$$

$$\text{or} \quad \Psi_{kj}^{(2)}(\xi(\theta)) = \frac{\delta_{kj}}{\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k}} - \frac{\sum_{i=1}^M \xi_i(\theta) \Delta_{i_{kj}}}{\left(\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k} \right) \left(\lambda_{0_j} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_j} \right)} \quad (44)$$

Using the definition of the spectral function in Eqn. (33), the second-order spectral functions can be obtained in closed-form as

$$\Gamma_k^{(2)}(\xi(\theta)) = \frac{\phi_k^T \mathbf{f}_0}{\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k}} - \sum_{\substack{j=1 \\ j \neq k}}^n \frac{(\phi_j^T \mathbf{f}_0) \sum_{i=1}^M \xi_i(\theta) \Delta_{i_{kj}}}{\left(\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k} \right) \left(\lambda_{0_j} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_j} \right)} \quad (45)$$

The second-order function can be viewed as adding corrections to the first-order expression derived in Eqn. (42).

Definition 4. The vector of spectral functions of order s can be obtained by retaining s terms in the series (40) and can be expressed as

$$\Gamma^{(s)}(\xi(\theta)) = [\mathbf{I}_n - \mathbf{R}(\xi(\theta)) + \mathbf{R}(\xi(\theta))^2 - \mathbf{R}(\xi(\theta))^3 \dots s^{\text{th term}}] \Gamma^{(1)}(\xi(\theta)) \quad (46)$$

where \mathbf{I}_n is the n -dimensional identity matrix and \mathbf{R} is defined in Eqn. (38) as $\mathbf{R}(\xi(\theta)) = [\Lambda^{-1}(\xi(\theta))][\Delta(\xi(\theta))]$. Different terms of this series can be obtained recursively from the previous term [18].

4 Error minimization using the Galerkin approach

In subsection 3.1 we derived the spectral functions such that a projection in an orthonormal basis converges to the exact solution in probability 1. The spectral functions are expressed in terms of a convergent infinite series. First, second and higher order spectral functions obtained by truncating the infinite series have been derived. We have also showed that they have the same functional form as the exact solution of Eqn. (11). This motivates us to use these functions as ‘trial functions’ to construct the solution. The idea is to minimize the error arising due to the truncation. A Galerkin approach is proposed where the error is made orthogonal to the spectral functions.

We express the solution vector by the series representation

$$\hat{\mathbf{u}}(\theta) = \sum_{k=1}^n c_k \hat{\Gamma}_k(\xi(\theta)) \phi_k \quad (47)$$

Here the functions $\hat{\Gamma}_k : \mathbb{C}^M \rightarrow \mathbb{C}$ are the spectral functions and the constants $c_k \in \mathbb{C}$ need to be obtained using the Galerkin approach. The functions $\hat{\Gamma}_k(\xi(\theta))$ can be the first-order (42), second-order (45) or any higher-order spectral functions (46) and ϕ_k are the eigenvectors introduced earlier in Eqn. (15). Substituting the expansion of $\hat{\mathbf{u}}(\theta)$ in the governing equation (11), the error vector can be obtained as

$$\varepsilon(\theta) = \left(\sum_{i=0}^M \mathbf{A}_i \xi_i(\theta) \right) \left(\sum_{k=1}^n c_k \hat{\Gamma}_k(\xi(\theta)) \phi_k \right) - \mathbf{f}_0 \in \mathbb{C}^n \quad (48)$$

where $\xi_0 = 1$ is used to simplify the first summation expression. The expression (47) is viewed as a projection where $\{\hat{\Gamma}_k(\xi(\theta)) \phi_k\} \in \mathbb{C}^n$ are the basis functions and c_k are the unknown constants to be determined. We wish to obtain the coefficients c_k using the Galerkin approach so that the error is made orthogonal to the basis functions, that is, mathematically

$$\varepsilon(\theta) \perp (\hat{\Gamma}_j(\xi(\theta)) \phi_j) \quad \text{or} \quad \langle \hat{\Gamma}_j(\xi(\theta)) \phi_j, \varepsilon(\theta) \rangle = 0 \quad \forall j = 1, 2, \dots, n \quad (49)$$

Here $\langle \mathbf{u}(\theta), \mathbf{v}(\theta) \rangle = \int_{\Theta} P(d\theta) \mathbf{u}(\theta) \mathbf{v}(\theta)$ defines the inner product norm. Imposing this condition and using the expression of $\varepsilon(\theta)$ from Eqn. (48) one has

$$\mathbb{E} \left[\left(\hat{\Gamma}_j(\xi(\theta)) \phi_j \right)^T \left(\sum_{i=0}^M \mathbf{A}_i \xi_i(\theta) \right) \left(\sum_{k=1}^n c_k \hat{\Gamma}_k(\xi(\theta)) \phi_k \right) - \left(\hat{\Gamma}_j(\xi(\theta)) \phi_j \right)^T \mathbf{f}_0 \right] = 0 \quad \forall j \quad (50)$$

Interchanging the $E[\bullet]$ and summation operations, this can be simplified to

$$\sum_{k=1}^n \left(\sum_{i=0}^M (\phi_j^T \mathbf{A}_i \phi_k) E \left[\xi_i(\theta) \hat{\Gamma}_j^T(\xi(\theta)) \hat{\Gamma}_k(\xi(\theta)) \right] \right) c_k = E \left[\hat{\Gamma}_j^T(\xi(\theta)) \right] (\phi_j^T \mathbf{f}_0) \quad (51)$$

$$\text{or } \sum_{k=1}^n \left(\sum_{i=0}^M \tilde{A}_{ijk} D_{ijk} \right) c_k = b_j \quad (52)$$

Defining the vector $\mathbf{c} = \{c_1, c_2, \dots, c_n\}^T$, these equations can be expressed in a matrix form as

$$\mathbf{S} \mathbf{c} = \mathbf{b} \quad (53)$$

with

$$S_{jk} = \sum_{i=0}^M \tilde{A}_{ijk} D_{ijk}; \quad \forall j, k = 1, 2, \dots, n \quad (54)$$

where

$$\tilde{A}_{ijk} = \phi_j^T \mathbf{A}_i \phi_k, \quad (55)$$

$$D_{ijk} = E \left[\xi_i(\theta) \hat{\Gamma}_j^T(\xi(\theta)) \hat{\Gamma}_k(\xi(\theta)) \right] \quad (56)$$

$$\text{and } b_j = E \left[\hat{\Gamma}_j^T(\xi(\theta)) \right] (\phi_j^T \mathbf{f}_0). \quad (57)$$

Higher order spectral functions can be used to improve the accuracy and convergence of the series (47). This will be demonstrated in the numerical examples later in the paper.

Remark 2. (Comparison with the classical spectral SFEM) We compare this Galerkin approach with the classical spectral stochastic finite element approach for further insight. The number of equations to be solved for the unknown coefficients in Eqn. (53) is n , the same dimension as the original governing equation (11). There are only n unknown constants, as opposed to nP unknown constants arising in the polynomial chaos expansion. The coefficient matrix \mathbf{S} and the vector \mathbf{b} in Eqn. (53) should be obtained numerically using the Monte Carlo simulation or other numerical integration technique. In the classical PC expansion, however, the coefficient matrix and the associated vector are obtained exactly in closed-form. In addition, the coefficient matrix is a sparse matrix whereas the matrix \mathbf{S} in Eqn. (53) is in general a fully populated matrix.

It can be observed that the matrix \mathbf{S} in Eqn. (53) is symmetric. Therefore, one need to determine $n(n+1)/2$ number of coefficients by numerical methods. Any numerical integration method, such as the Gaussian quadrature method, can be used to obtain the elements of D_{ijk} and b_j in Eqn. (55). In this paper Monte Carlo simulation is used. The samples of the spectral functions $\hat{\Gamma}_k(\xi(\theta))$ can be simulated from Eqn. (42), (45) or (46) depending on the order. These can be used to compute D_{ijk} and b_j from Eqn. (55). The simulated spectral functions can also be ‘recycled’ to obtain the statistics and probability density function (pdf) of the solution. In summary, compared to the classical spectral stochastic finite element method, the proposed Galerkin approach results in a smaller size matrix but requires numerical integration techniques to obtain its entries. The numerical method proposed here therefore can be considered as a hybrid analytical-simulation approach.

5 Model reduction using a reduced number of basis

The Galerkin approach proposed in the previous section requires the solution of $n \times n$ algebraic equations. Although in general this is smaller compared to the polynomial chaos approach, the computational cost can still be high for large n as the coefficient matrix is in general a dense matrix. The aim of this section is to reduce it further so that, in addition to large number of random variables, problems with large degrees of freedom can also be solved efficiently.

Suppose the eigenvalues of \mathbf{A}_0 are arranged in an increasing order such that

$$\lambda_{0_1} < \lambda_{0_2} < \dots < \lambda_{0_n} \quad (58)$$

From the expression of the spectral functions observe that the eigenvalues appear in the denominator:

$$\Gamma_k^{(1)}(\boldsymbol{\xi}(\theta)) = \frac{\boldsymbol{\phi}_k^T \mathbf{f}_0}{\lambda_{0_k} + \sum_{i=1}^M \xi_i(\theta) \lambda_{i_k}} \quad (59)$$

The numerator $(\boldsymbol{\phi}_k^T \mathbf{f}_0)$ is the projection of the force on the deformation mode. Since the eigenvalues are arranged in an increasing order, the denominator of $|\Gamma_{k+r}^{(1)}(\boldsymbol{\xi}(\theta))|$ is larger than the denominator of $|\Gamma_k^{(1)}(\boldsymbol{\xi}(\theta))|$ according a suitable measure. The numerator $(\boldsymbol{\phi}_k^T \mathbf{f}_0)$ depends on the nature of forcing and the eigenvectors. Although this quantity is deterministic, in general an ordering cannot be easily established for different values of k . Because all the eigenvectors are normalized to unity, it is reasonable to consider that $(\boldsymbol{\phi}_k^T \mathbf{f}_0)$ does not vary significantly for different values of k . Using the ordering of the eigenvalues, one can select a small number ϵ such that $\lambda_1/\lambda_q < \epsilon$ for some value of q , where λ_j is the eigenvalue of the generalized eigenvalue problem defined in Eqn. (15). Based on this, we can approximate the solution using a truncated series as

$$\hat{\mathbf{u}}(\theta) \approx \sum_{k=1}^q c_k \hat{\Gamma}_k(\boldsymbol{\xi}(\theta)) \boldsymbol{\phi}_k \quad (60)$$

where c_k , $\hat{\Gamma}_k(\boldsymbol{\xi}(\theta))$ and $\boldsymbol{\phi}_k$ are obtained following the procedure described in the previous section by letting the indices j, k only upto q in Eqs. (54) and (55). The accuracy of the series (60) can be improved in two ways, namely, (a) by increasing the number of terms q , or (b) by increasing the order of the spectral functions $\hat{\Gamma}_k(\boldsymbol{\xi}(\theta))$.

Model reduction techniques have been widely used within the scope of proper orthogonal decomposition (POD) method [35–37]. Here the eigenvalues of a symmetric positive definite matrix (the covariance matrix of a snapshot the system response) are used for model reduction. In spite of this similarity, the reduction method proposed here is different from a POD since it only considers the operator and not the solution itself. Reduction based on eigen-solution is of classical nature in various areas of applied mathematics, engineering and physics and extensive studies exist on this topic. It should be noted that the truncation in series (60) introduces errors. A rigorous mathematical quantification of error arising due to this truncation is beyond the scope of this article. The ratio of the eigenvalues λ_1/λ_q gives a good indication, but the projection of the force on the eigenvector $(\boldsymbol{\phi}_k^T \mathbf{f}_0)$ is also of importance. Since this quantity is problem dependent, care should be taken while applying this reduction method.

6 Post processing: Moments of the solution

For the practical application of the method developed here, the efficient computation of the response moments and pdf is of crucial importance. A simulation based algorithm is proposed

in this section. The coefficients c_k in Eqn. (51) can be calculated from a reduced set of equations given by (53). The reduced equations can be obtained by letting the indices j, k upto $q < n$ in Eqns. (54) and (55). After obtaining the coefficient vector $\mathbf{c} \in \mathbb{C}^q$, the statistical moments of the solution can be obtained from Eqns. (61) and (62) using the Monte Carlo simulation. The spectral functions used to obtain the vector \mathbf{c} itself, can be reused to obtain the statistics and pdf of the solution. The mean vector can be obtained as

$$\bar{\mathbf{u}} = \mathbb{E} [|\hat{\mathbf{u}}(\theta)|] = \sum_{k=1}^q |c_k| \mathbb{E} \left[\left| \hat{\Gamma}_k(\boldsymbol{\xi}(\theta)) \right| \right] \boldsymbol{\phi}_k \quad (61)$$

where $|\bullet|$ is the absolute value of the complex quantities. The covariance of the solution vector can be expressed as

$$\Sigma_u = \mathbb{E} [(|\hat{\mathbf{u}}(\theta)| - \bar{\mathbf{u}}) (|\hat{\mathbf{u}}(\theta)| - \bar{\mathbf{u}})] = \sum_{k=1}^q \sum_{j=1}^q |c_k c_j| \Sigma_{\Gamma_{kj}} \boldsymbol{\phi}_k \boldsymbol{\phi}_j \quad (62)$$

where the elements of the covariance matrix of the spectral functions are given by

$$\Sigma_{\Gamma_{kj}} = \mathbb{E} \left[\left(\left| \hat{\Gamma}_k(\boldsymbol{\xi}(\theta)) \right| - \mathbb{E} \left[\left| \hat{\Gamma}_k(\boldsymbol{\xi}(\theta)) \right| \right] \right) \left(\left| \hat{\Gamma}_j(\boldsymbol{\xi}(\theta)) \right| - \mathbb{E} \left[\left| \hat{\Gamma}_j(\boldsymbol{\xi}(\theta)) \right| \right] \right) \right] \quad (63)$$

Based on the results derived in the paper, a hybrid reduced simulation-analytical approach can thus be realized in practice. The method is applicable to general structural dynamics problems with general non-Gaussian random fields. In the following section this approach has been applied to a physical problem.

7 Illustrative application: The stochastic dynamics of an Euler-Bernoulli beam

In this section we apply the computational method to a cantilever beam with stochastic bending modulus. Fig. (1) shows the configuration of the cantilever beam with a harmonic point load at its free end. We assume that the bending modulus is a homogeneous stationary Gaussian ran-

Figure 1: Schematic diagram of the Euler-Bernoulli beam with a point load at the free end.

dom field of the form

$$EI(x, \theta) = EI_0(1 + a(x, \theta)) \quad (64)$$

where x is the coordinate along the length of the beam, EI_0 is the estimate of the mean bending modulus, $a(x, \theta)$ is a zero mean stationary Gaussian random field. The autocorrelation function of this random field is assumed to be

$$C_a(x_1, x_2) = \sigma_a^2 e^{-(|x_1 - x_2|)/\mu_a} \quad (65)$$

where μ_a is the correlation length and σ_a is the standard deviation. We use the base-line parameters as the length $L = 1m$, cross-section $(b \times h) 39 \times 5.93mm^2$ and Young's modulus $E = 2 \times 10^{11}$ Pa. In study we consider deflection of the tip of the beam under harmonic loads of amplitude $\tilde{f}_0 = 1.0N$. The correlation length considered in this numerical study is $\mu_a = L/2$. The number of terms retained (M) in the Karhunen-Loève expansion (8) is selected such that $\nu_M/\nu_1 = 0.01$ in order to retain 90% of the variability. For this correlation length the number of terms M comes to 18. For the finite element discretization, the beam is divided into 40 elements. Standard four degrees of freedom Euler-Bernoulli beam model is used [38]. After applying the fixed boundary condition at one edge, we obtain the number of degrees of freedom of the model to be $n = 80$.

7.1 Results

The proposed method has been compared with a direct Monte Carlo Simulation (MCS), where both have been performed with 10,000 samples. For the direct MCS, Eqn. (23) is solved for each sample and the mean and standard deviation is derived by assembling the responses. The calculations have been performed for all the four values of σ_a to simulate increasing uncertainty. This is done to check the accuracy of the proposed method against the direct MCS results for varying degrees of uncertainty.

Fig. 2(a) presents the ratio of the eigenvalues of the generalized eigenvalue problem (15) for which the ratio of the eigenvalues is taken with the first eigenvalue. We choose the reduced basis of the problem based on $\lambda_1/\lambda_q < \epsilon$, where $\epsilon = 0.01$, and they are highlighted in Fig. 2(b) shows the frequency domain response of the deterministic system for both damped and undamped conditions. We have applied a constant modal damping matrix with 1% damping

(a) Ratio of eigenvalues of the generalized eigenvalue problem. (b) Frequency domain response of the tip of the beam under point load for the undamped and damped conditions (constant modal damping)

Figure 2: The eigenvalues of the generalized eigenvalue problem involving the mass and stiffness matrices given in Eqn. 15. For $\epsilon = 0.01$, the number of reduced eigenvectors $q = 7$ such that $\lambda_1/\lambda_j < \epsilon$.

factor for all the modes. Here the mass and damping matrices are assumed to be deterministic in nature. However, the proposed theoretical approach is general and equally applicable for random mass, stiffness and damping matrices. The frequency range of interest for the present study is 0 – 600 Hz with an interval of 2 Hz. In Fig. 2(b), the tip deflection is shown on a log

scale for a unit amplitude harmonic force input. The resonance peak amplitudes of the response of the undamped system definitely depends on the frequency resolution of the plot.

The frequency response of the mean deflection of the tip of the beam is shown in Fig. 3 for the cases for cases of $\sigma_a = \{0.05, 0.10, 0.15, 0.20\}$. The figures show a comparison of the direct MCS simulation results with different orders of the solution following Eqn. (31), where the orders $s = 2, 3, 4$. A very good agreement between the MCS simulation and the proposed

Figure 3: The frequency domain response of the deflection of the tip of the Euler-Bernoulli beam under unit amplitude harmonic point load at the free end. The response is obtained with 10,000 sample MCS and for $\sigma_a = \{0.05, 0.10, 0.15, 0.20\}$. The proposed Galerkin approach needs solution of a 7×7 linear system of equations only.

spectral approach can be observed in the figures. All the results have been compared with the response of the deterministic system which shows that the uncertainty has an added damping effect at the resonance peaks. This can be explained by the fact that the parametric variation of the beam, results in its peak response for the different samples to get distributed around the resonance frequency zones instead of being concentrated at a particular frequency, and when the subsequent averaging is applied, it smooths out the response peaks to a fair degree. The same explanation holds for the anti-resonance frequencies. It can also be observed that increased variability of the parametric uncertainties (as is represented by the increasing value of σ_a) results

in an increase of this added damping effect which is consistent with the previous explanation.

The standard deviation of the frequency domain response of the tip deflection for different spectral order of solution of the reduced basis approach is compared with the direct MCS and is shown in Fig. 4, for different values of σ_a . We find that the standard deviation is maximum

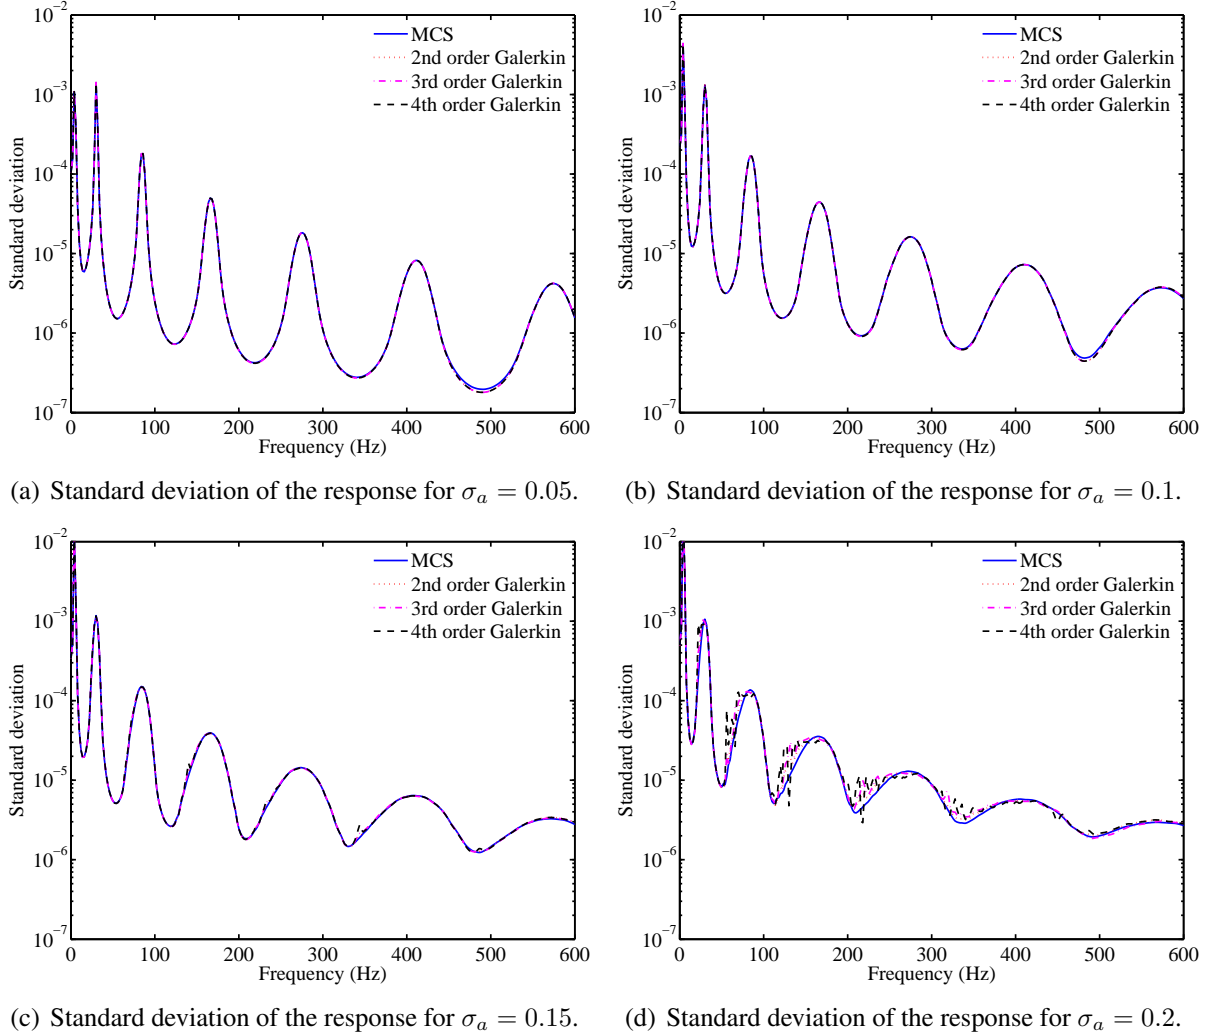

Figure 4: The standard deviation of the tip deflection of the Euler-Bernoulli beam under unit amplitude harmonic point load at the free end. The response is obtained with 10,000 sample MCS and for $\sigma_a = \{0.05, 0.10, 0.15, 0.20\}$.

at the resonance frequencies which is expected due to the differences in the resonance peak of each sample. It is again observed that the direct MCS solution and the reduced order approach give almost identical results, which demonstrate the effectiveness of the proposed approach.

Fig. 5 shows the relative standard deviation of the response of the beam at two frequencies 154 Hz and 412 Hz, which correspond to the anti-resonance and resonance frequencies of the cantilever beam respectively. The relative standard deviation values have been obtained for a set of 4 values of σ_a , which represents the different degrees of variability of the system uncertainty. The results obtained with the Galerkin approach for the different order of spectral functions have been compared to the direct MCS, and a good agreement between the two results have been obtained. It is interesting to point out here that the standard deviation decreases with the values of σ_a for the anti-resonance frequency while it increases for the resonance frequencies.

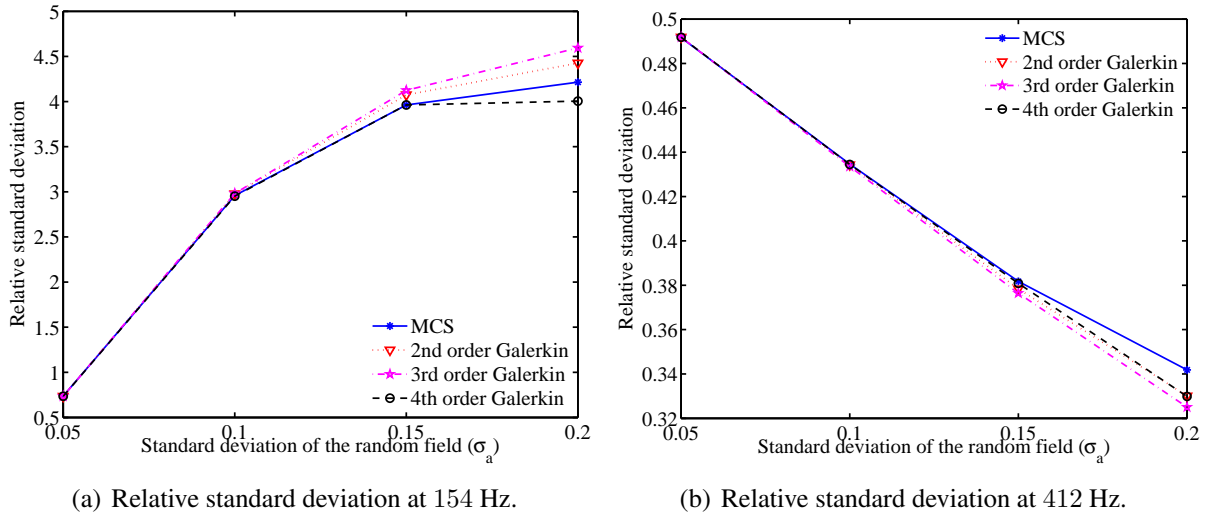

Figure 5: The relative standard deviation of the deflection of the tip (which has been obtained by normalizing the value of the standard deviation with the deterministic system response at the same frequency) versus the standard deviation (σ_a) of the random field of the Euler-Bernoulli beam under unit amplitude harmonic point load at the free end. The two frequencies, namely 154Hz and 412Hz are considered. They correspond to off-resonance and resonance frequencies respectively. The plots are shown for 4 different values of $\sigma_a = \{0.05, 0.10, 0.15, 0.20\}$ and calculated with 10,000 random samples.

This is consistent with the results shown in Fig. 4 which shows that an increased value of the variance of the random field has the effect of an increasing added damping on the system, when an averaging is done over the sample space. Thus the resonance response is expected to reduce with the increased variability of the random field while the anti-resonance response will increase.

The probability density function of the deflection of the tip of the cantilever beam for different degrees of variability of the random field is shown in Fig. 6. The probability density functions have been calculated at the frequency of 412 Hz, which is a resonance frequency of the beam. The results indicate that with the increase in the degree of uncertainty (variance) of the system, the lower values of deflection has a higher probability which is absolutely consistent with the standard deviation curve shown in Fig. 5(a) and the comparison of the mean deflection of the stochastic system with the deterministic response in Fig. 3. This shows that the increase in the variability of the stochastic system has a damping effect on the response.

The results establish the applicability of this spectral reduced basis method with Galerkin error minimization technique as a satisfactory working model for providing solution of the stochastic structural systems. The method is found to be consistent with the direct MCS approach, while being much more computationally efficient than the latter.

8 Conclusions

We have considered the discretized stochastic partial differential equation for structural dynamic systems with generally non-Gaussian random fields. In the classical spectral stochastic finite element approach, the solution is projected into an infinite dimensional orthonormal basis functions and the associated constant vectors are obtained using the Galerkin type of error minimization approach. Here an alternative approach in the frequency domain is proposed. The solution is projected into a finite dimensional reduced vector basis and the associated complex coefficient functions are obtained. The coefficient functions, called as the *spectral functions*, are

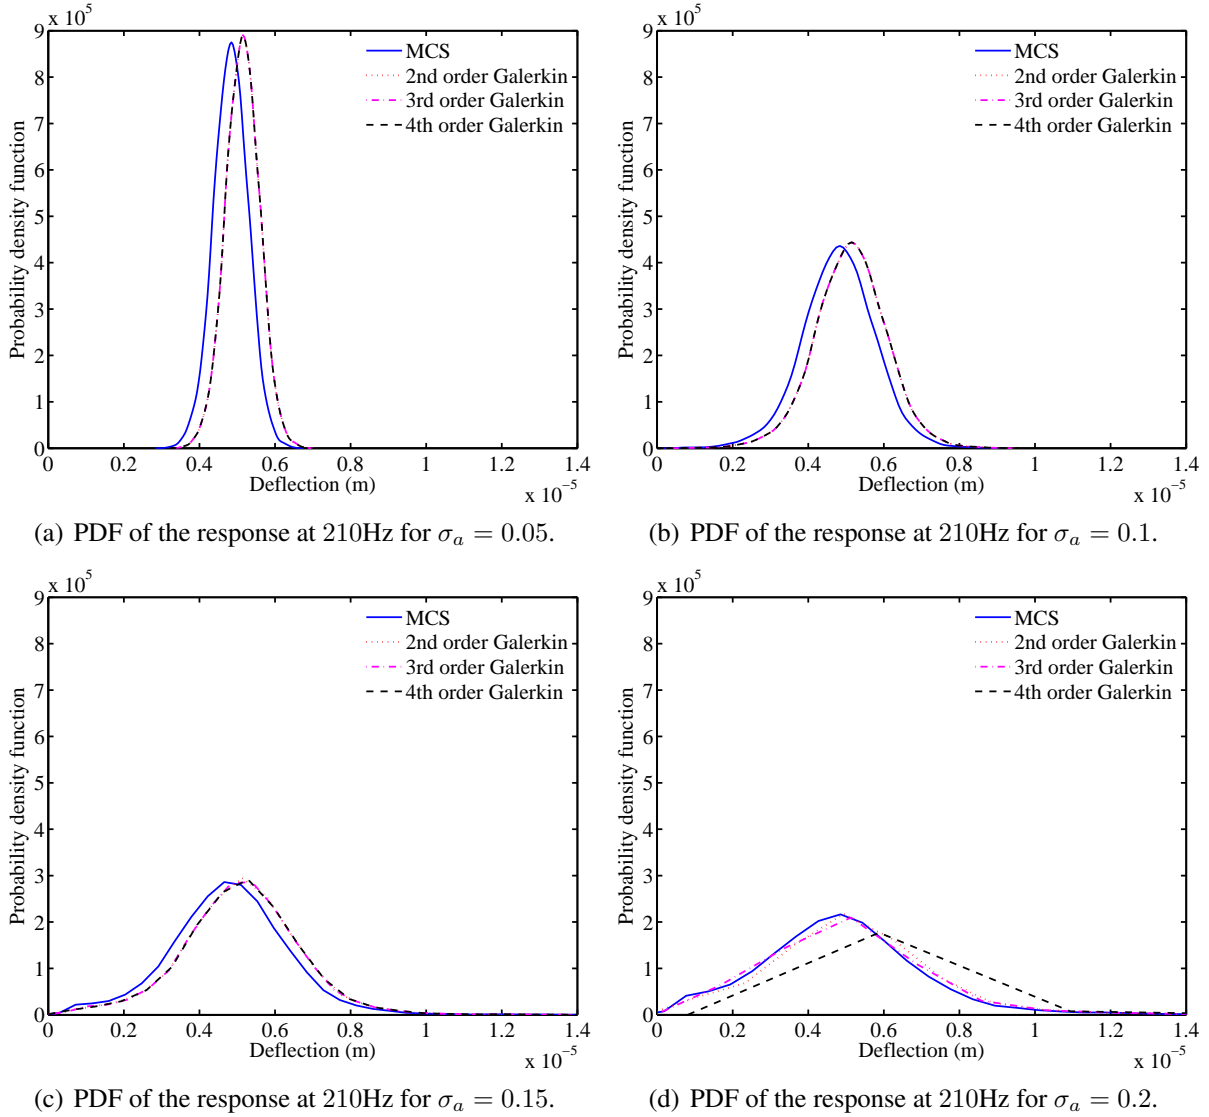

Figure 6: The probability density function (PDF) of the tip deflection of the Euler-Bernoulli beam at 210 Hz under unit amplitude harmonic point load at the free end. The response is obtained with 10,000 samples and for $\sigma_a = \{0.05, 0.10, 0.15, 0.20\}$.

expressed in terms of the spectral properties of the mass and stiffness matrices appearing in the discretized governing equation. It is shown that then the resulting series converges to the exact solution in probability 1. This is a stronger convergence compared to the classical polynomial chaos which converges in the mean-square sense in the Hilbert space.

Using the spectral functions, a Galerkin error minimization approach in the complex domain has been developed in a reduced vector basis. It is shown that the number of unknown constants can be obtained by solving a system of linear equations which have a dimension much smaller than the dimension of the original discretized equation. A simple numerical approach to obtain the reduced dimension has been suggested based on the ratio of the eigenvalues of the stiffness matrix corresponding to the baseline model. A numerical approach using a general-order spectral function has been developed. Based on these, a hybrid analytical-simulation approach is proposed to obtain the statistical properties of the solution.

The computational efficiency of the proposed reduced spectral approach has been demon-

strated for large linear systems with non-Gaussian random variables. It may be possible to extend the underlying idea to the class of non-linear problems. For example, the proposed spectral approach can be used for every linearisation step or every time step. Further research is necessary in this direction.

Abstract. *Predicting vibration performance of civil engineering structures due to human-induced rhythmic loading is an increasingly critical aspect of the design process of structures such as sports stadia used for pop/rock concerts, floors accommodating gym and aerobic classes, and footbridges used as spectator galleries during regatta events. Two main reasons for this trend are (1) structures are becoming more slender with improvements in materials and construction techniques and modern trends in architectural design, and (2) groups/crowds are in general becoming livelier than previously was the case, i.e. their activities can become better synchronised due to the presence of various auditory and visual stimuli at above mentioned events. This paper addresses the latter issue by presenting a method to measure human bouncing and jumping forces induced by groups and ultimately crowds using motion capture technology, transferred and adapted from biomedical research.*

Compared with traditional force platform measurements, the key advantage and novelty of this method is a possibility to measure individual forces of each group/crowd member in natural environments, including real life structures. Constraints imposed by artificial laboratory settings and small size of force plates can significantly affect the quality of the force data. Results show that the new method can be used successfully to study area of significant interest and uncertainty for structural dynamics, particularly synchronisation of individual forces when people bounce and jump in groups on more or less perceptibly moving structures.

The new approach presented in this paper is a step towards more thorough and realistic mathematical models of group/crowd rhythmic loading that can be used to simulate more reliably dynamic response, thereby assessing vibration serviceability of above mentioned civil engineering structures convincingly at the design stage.

1 INTRODUCTION

In the last decade, there have been rapidly growing numbers of grandstands and entertainment venues that have failed to perform satisfactorily when occupied and dynamically excited by multiple persons and large crowds bouncing and/or jumping in unison [1-3]. These mostly vibration serviceability problems have indicated high level of uncertainty with which civil structural engineers are faced nowadays when designing any of the above mentioned structures which require vibration performance assessment.

There have been numerous attempts to provide reliable and practical descriptions of human bouncing and jumping loads by measuring the contact forces between the ground and test subjects, hence generally known as ground reaction forces (GRFs). For this purpose Ebrahimpour et al. [4] and Pernica [5] designed a 'force platform', whereas Rainer et al. [6] used the continuously measured reaction of a floor strip having known dynamic properties. Much research into GRFs has been done in the biomechanics community, as GRF patterns provide useful diagnostics in medical and sports applications [7, 8]. Therefore, it is not surprising that the present state-of-the-art equipment for the force measurements, i.e. the 'force plate', emerged from the field of biomechanics of human gait. However, there are a few disadvantages of force plates that make them less suitable in vibration serviceability assessment of civil engineering structures. Firstly, standard dimensions of force plates (typically 0.6x0.4 m) are not large enough to accommodate jumping for some individuals who must control and target their jumps to the relatively small force plate area so as to allow adequate recordings. As a result, this targeting effort can affect ability to jump naturally and therefore alter GRF patterns [8]. Secondly, force plates cannot provide accurate measurements when mounted on a flexible structure due to self-inertia. This is because they behave like 'accelerometers' and produce outputs including inertia forces of the moving support surface [9]. Therefore, a typical experimental setup includes force plates mounted on a rigid laboratory floor. However, when investigating issues related to vibration serviceability there is a growing need for measuring human-induced dynamic loading on more or less flexible surfaces in natural environments, such as office, sport facility, or a footbridge. Finally, when it comes to measuring group bouncing/jumping loads, each individual in the group must be given (at least) a force plate, which often gives financial problems.

Bearing all this in mind, one way forward is an alternative experimental approach to account for all drawbacks of force plates. Several biomechanical studies designed to estimate the contribution of motion of various body segments to vertical GRFs [10-12] offer a step in this direction. Using these biomechanical studies as a solid foundation, this paper aims to present a reader, conversant with vibration serviceability problems of civil engineering structures, with a novel method, in the context of a civil engineering application, to utilise 'free-field' measurement to obtain bouncing and jumping GRFs in a wide range of conditions. The free-field measurement applies the method to estimate the forces in the real world (i.e. naturally-occurring environments) rather than in a constrained laboratory setting. The method will also enable study of areas of significant interest and lack of knowledge, specifically human-structure dynamic interaction and coordination of movements between a number people bouncing/jumping on more or less perceptibly moving structures.

In the context of this paper, human-structure dynamic interaction aims to address two related key issues. Firstly, how perceptible structural vibrations can influence forces induced by active human occupants, and secondly, how active human occupants influence the dynamic properties (e.g. damping) of a civil engineering structure they occupy and dynamically excite.

2 THEORETICAL BACKGROUND

According to Newton [13], the origin of dynamic forces is in momentum changes, which, for constant mass, means that the force is product of mass and acceleration. As applied to the human body, the vertical force acting upon the body (i.e. vertical ground reaction force F_{GR}) can be defined as [3]:

$$F_{GR} = \sum_{i=1}^s m_i (a_i - g) \quad (1)$$

where g is the static acceleration due to gravity (noting that upward accelerations are defined as positive, hence $g = -9.81 \text{ m/s}^2$ in the UK), m_i and a_i are mass and acceleration of the centre of the mass of the i -th body segment and s is the total number of body segments. This relation implies that the force a person generates against the surface must react against inertia of their body, so the sum of products of masses and accelerations for all body parts must equal the GRF at all times. Similar to earthquake engineering, the only source of external excitation is the inertial force, which then generates other forces through the human body, being transmitted ultimately to the support of the body and resulting in the GRF. This is the key principle behind the idea of estimating GRFs via measuring motion of the body segments.

In this study, physical parameters associated with each rigid segment, such as mass and position of its centre, are estimated using regression equations proposed by de Leva [14], while measurement of body motion was considered using Coda [15] optical motion capture technology. More detailed explanation of different methods for estimating anthropometry of human bodies and technology for body motion tracking can be found in a comprehensive literature review article published recently by the authors [16].

3 DATA COLLECTION

Figure 1: Human body model and arrangement of markers.

Two male volunteers (age 27 and 30 years, body mass 70 and 67 kg) participated in the experiment. Using the modelling strategy proposed by de Leva [14], 15 body segments and corresponding segmental masses and positions of segmental mass centres of each participant were defined. The segmentation comprised the pairs of the feet, the shanks, the thighs, the hands, the forearms, the upper-arms, as well as the pelvis, the trunk, and the head. The segmental ends were defined via nine motion tracking markers (also called ‘target’ markers) stuck to the head and major body joints such as ankle, wrist, knee or elbow, as illustrated in Figure 1. Because the number of available markers is limited, as well as to reduce the sub-

ject's preparatory time and to enable simple and time-efficient experiments, symmetry of motion in the vertical plane between the left and right body segments was assumed.

3.1 TEST STRUCTURE AND EXPERIMENTAL MODAL ANALYSIS

The test structure is a 15-tonne pre-stressed concrete slab strip situated in the Light Structure Laboratory of the University of Sheffield, UK. The slab strip is 11 m long and 2 m wide and, structurally, it presents a simply supported beam (Figures 2 and 3).

The natural frequencies, modal masses, modal damping ratios and mode shapes of the structure were determined by shaker modal testing. The modal testing is described in [3] and results are presented in Figure 2.

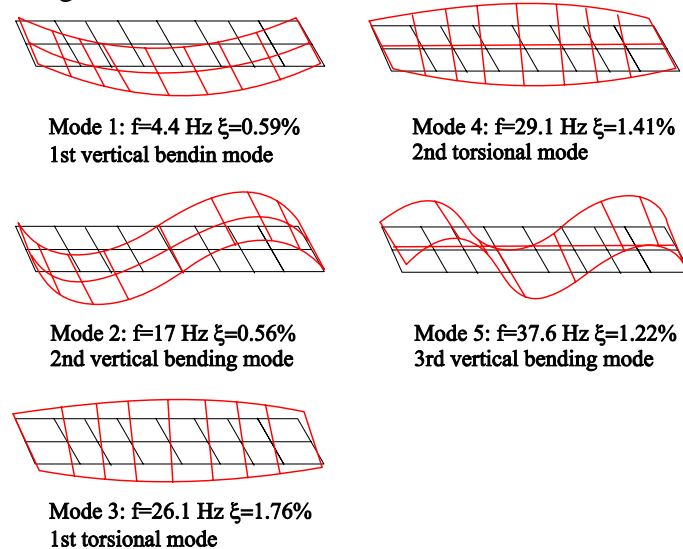

Figure 2: Experimentally estimated modal properties on the test structure (first three vertical bending modes, first two torsional modes).

Figure 3: Two test subjects jumping together on the slab strip.

3.2 BODY MOTION DATA COUPLED WITH RESPONSE MEASUREMENTS OF THE STRUCTURE

The test subjects (TSs), fully instrumented with the Coda markers, were asked to either jump or bounce alone in the mid-span of the structure (Figure 3) in response to regular metronome beats at three different tempos: 2, 2.2 and 2.5 Hz. Note that jumping and bouncing at 2.2 Hz excited the structure as near to resonance as possible by the second harmonic of the corresponding forces. On the other hand, closely spaced tempos at 2 and 2.5 Hz excited the structure out of resonance.

The Codamotion host computer enabled simultaneous acquisition of vertical movement of the body markers and response of the structure measured in the middle of the span by both a QA750 [17] accelerometer and a tracking marker. Both body motion data and vibration response were sampled at 200 Hz.

The aim was to calculate response of the structure by using the forces reproduced from the body motion data and the modal properties of the first vertical mode determined in Section 3.1. A good match between the calculated and directly measured accelerations should provide a proof that the forces can be reproduced successfully. This is the key aspect outlined in the next section, together with the possibility to use the reproduced forces in a study of human-structure dynamic interaction and synchronisation of people when jumping/bouncing in groups.

3.3 BASIC DATA PROCESSING

Movement of the skin relative to the underlying bone is one of the major sources of error when reconstructing human-induced forces from body motion data [16]. This is known as “soft tissue artefact” and is dominant during highly accelerated movements, e.g. when the feet abruptly hit the ground. Skin markers then oscillate considerably in an unsteady way with respect to the underlying bone, inducing high-frequency noise in the marker data. To filter out the noise, a fourth order low-pass digital Butterworth filter (LPF) having cut-off frequency 15 Hz was applied to accelerations of all markers. Figure 4 illustrates accelerations of the hip marker obtained with and without filtering out the noise above 15 Hz from the displacement data. It can be seen that the main visible features of the markers’ accelerations representing the whole body segment motion remain intact after the filtering.

Figure 4: Raw and filtered accelerations (CF=15Hz) of a hip marker due to jumping at 2 Hz.

4 SYNCHRONIOUS VERTICAL EXCITATION

The force time histories generated in the mid-span of the structure when the test subjects were bouncing or jumping together in response to the regular metronome beats (at 2, 2.2 and 2.5 Hz) were reproduced according to Equation (1) from filtered body motion data of a kind given in Figure 4 and information about the values and locations of the segmental masses (Section 3). As an illustration, the reproduced force signals are given in Figure 5.

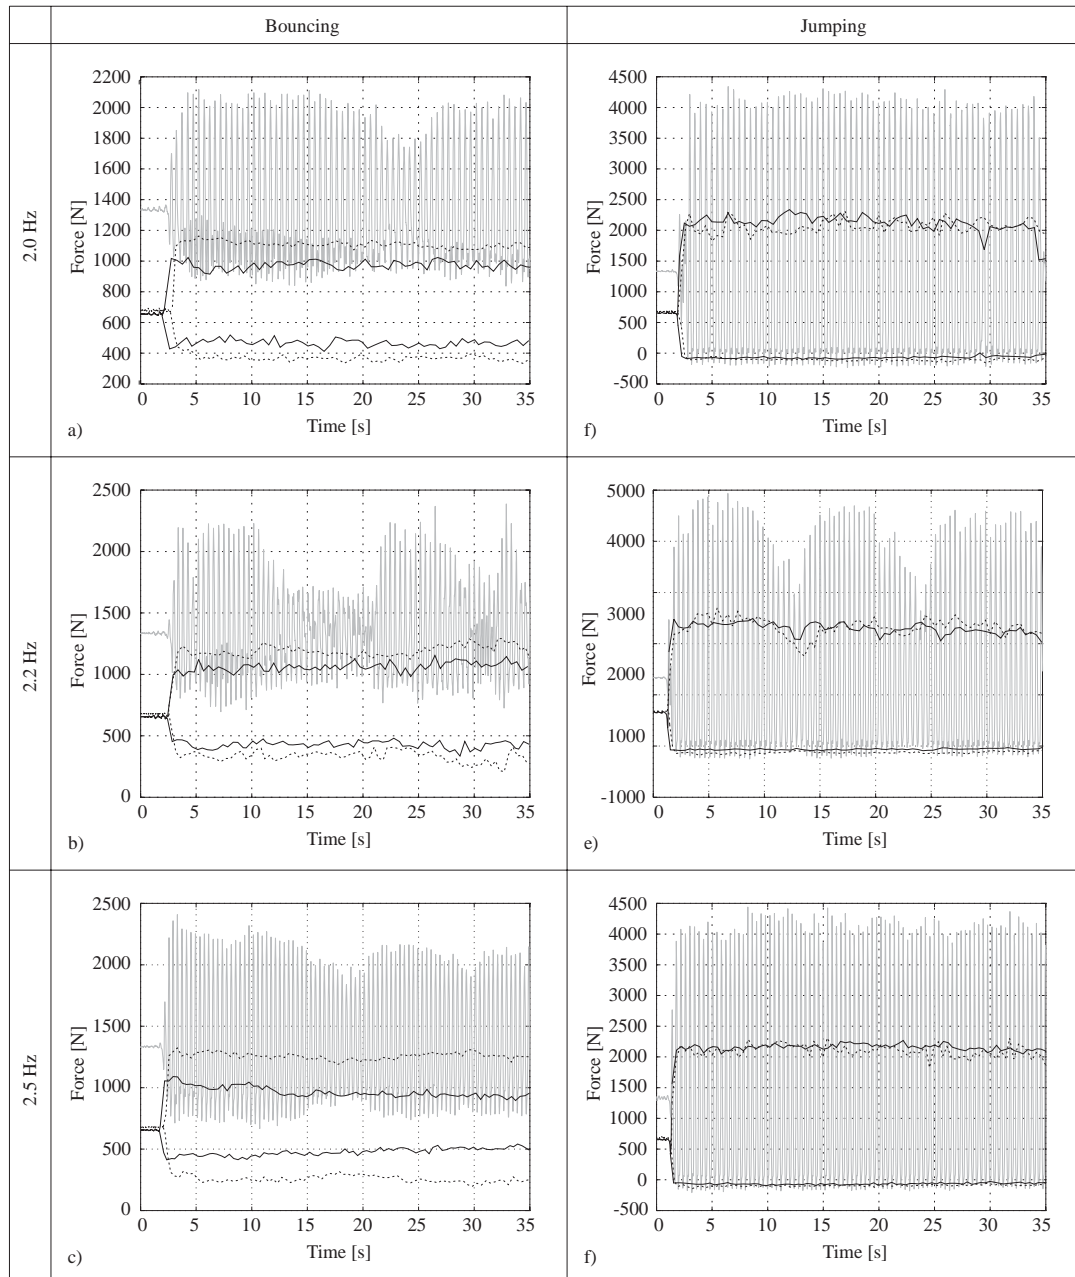

Figure 5: Force time histories generated by TS1 (black), TS2 (dashed) and their sum (grey) when (a-c) bouncing and (d-f) jumping in response to regular metronome beats at 2, 2.2 and 2.5 Hz.

The best way to check if the reproduced forces are correct is to compare responses of the structure measured directly by the accelerometers (Section 3.2) and those calculated from the corresponding SDOF model of the structure. The latter can be obtained using the reproduced

forces as the forcing function together with the nonlinear modal properties of the first vertical mode given in [3].

A good match between the calculated and directly measured accelerations in the mid-span of the structure (Figure 6) strongly suggests that the forces have been reproduced successfully.

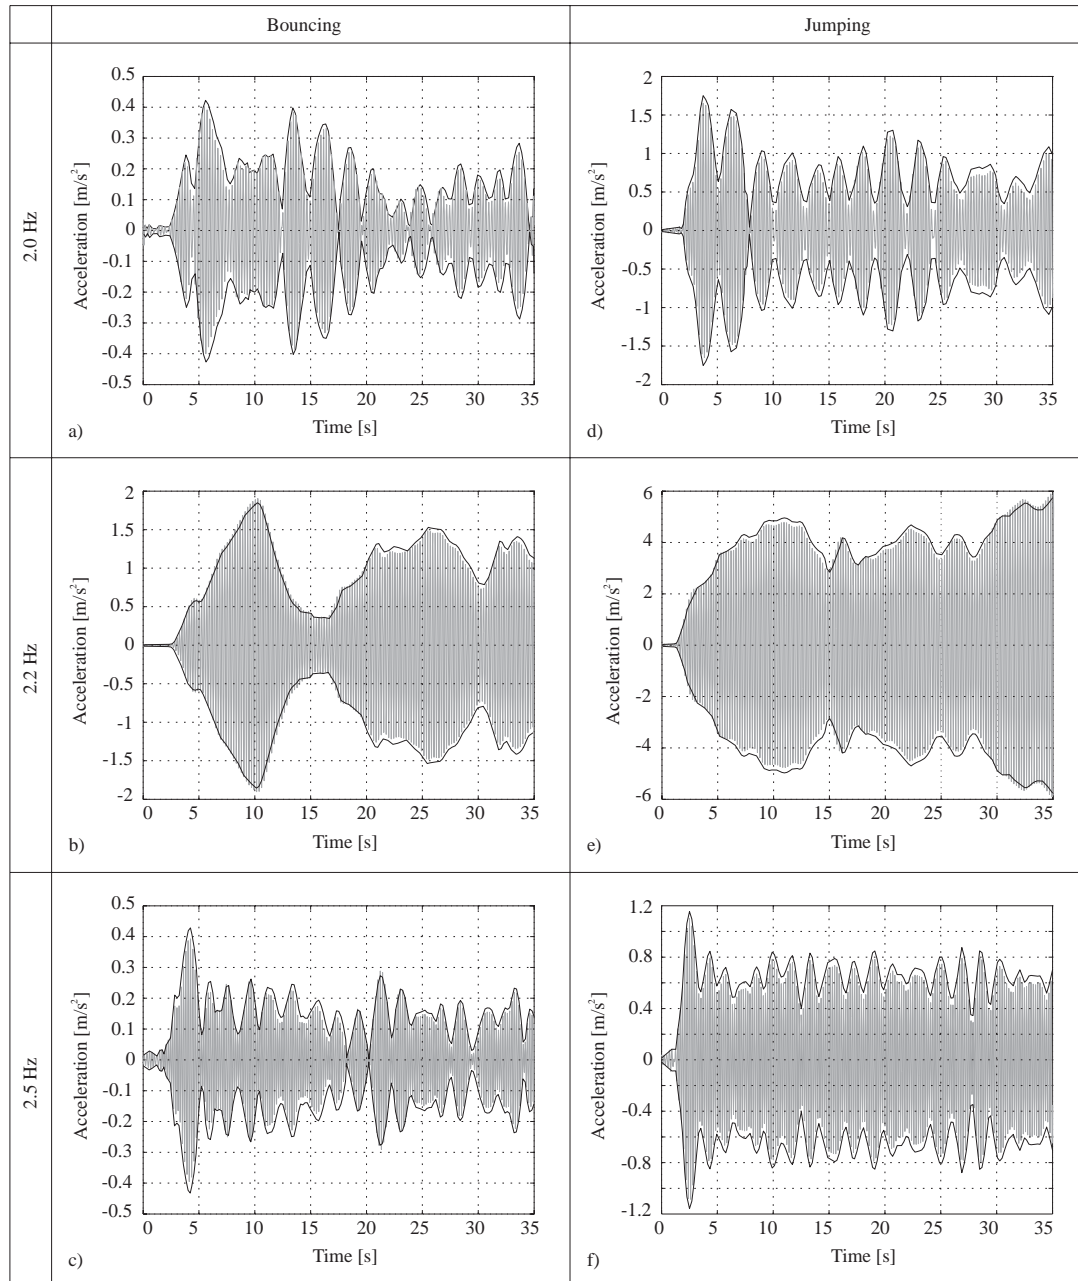

Figure 6: Measured (grey) and envelope of simulated (black) mid-span vibration response of the structure due to two persons (a-c) bouncing and (d-f) jumping together at given regular metronome beats.

Although the test subjects were following the same metronome beats when jumping and bouncing together, there was a sporadic lack of coordination between their movements, which is reflected in a lack of synchronisation of the corresponding peak force amplitudes on a cycle-by-cycle basis. Here, one jumping or bouncing cycle corresponds to a period needed to complete one jump or bounce.

In Figure 7, there are cycles for which time instants of individual peak amplitudes match well, indicating a high synchronisation level. Also, this resulted in large peak amplitudes of the total sum force for these cycles. However, because humans are not machines, despite the metronome beat they could not keep moving in synchronisation for a long time, causing peaks to diverge and their sum to decrease. After a while, the process starts to reverse, i.e. the peaks start moving towards each other and finally meet, being synchronised again. Therefore, the lack of synchronisation can be quantified through relative changes of time lags Δt_i between peaks of individual force signals on a cycle-by-cycle basis (Figures 7b and 7d). A summary of mean values and standard deviations of Δt_i values extracted from 30 s duration of all group force signals is given in Table 1.

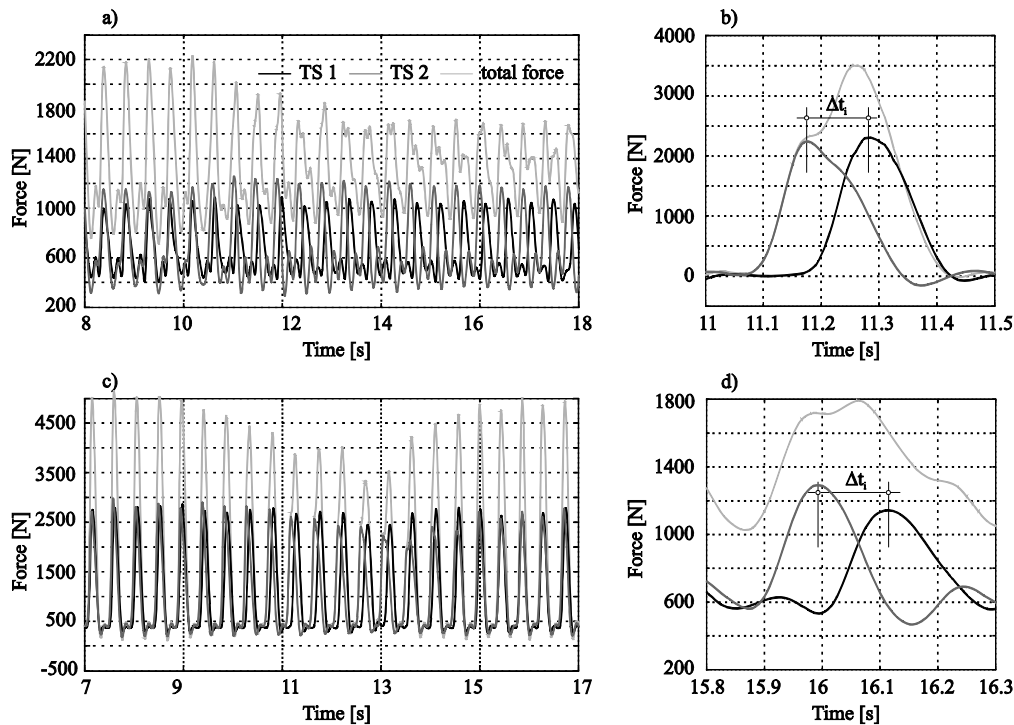

Figure 7: Synchronisation of (a-b) bouncing and (c-d) jumping forces at 2.2 Hz. Figures 5 and 7 illustrate the same data.

Table 1: Summary of statistics (mean \pm standard deviation) of Δt_i :

Frequency [Hz]	bouncing [s]	jumping [s]
2.0	0.052 ± 0.036	0.039 ± 0.020
2.2	0.076 ± 0.076	0.073 ± 0.036
2.5	0.049 ± 0.024	0.022 ± 0.012

The largest values of the mean and standard deviation are for the excitation causing near-resonant response for both bouncing and jumping indicating that the synchronisation was most affected by the large structural vibrations. Also, for both resonant and non-resonant rates, synchronisation during jumping was better compared with the bouncing counterparts.

In qualitative feedback after the experiments, both test subjects agreed that non-resonant vibrations of the structure were barely perceptible, whereas the resonant response levels were perceived as rather excessive, sometimes even “scary”, thus influencing the way they were moving on the structure. Moreover, they reported that the effect was dominant for bouncing, where the feet are in permanent contact with the vibrating structure.

5 ENERGY FLOW AND POWER

A useful technique for studying human-structure dynamic interaction involves analysis of the power developed by human occupants moving on a structure and the power represented by the rate of internal energy dissipation in a structure conceptualised via damping forces [20]. Energy, with the units of Joules [J] or [Nm], is the time integral of power and is a more familiar quantity whose flow is easy to visualise. However graphical representation using power, with units of Watts [W] or [Nm/s], is simpler to study for comparative purposes.

For the slab strip, supply of energy to the structure at the point of contact is the instantaneous product of velocity $\dot{x}(t)$ and contact force $f(t)$. The contact force $f(t)$ could be obtained either directly by a load cell or reproduction from the marker motion, while velocity could be obtained by integrating accelerometer signals or differentiating contact point marker displacements. Here, the contact force is measured indirectly using Equation (1) and the velocity is obtained from displacements of a marker attached to the middle of the span where the activity was happening.

Consider an equation of motion of a SDOF system, e.g. the first mode of vibration of the slab strip excited by a jumping force at the midpoint (antinode). If the mode shape is unity scaled at the midpoint then modal and physical displacements at the mid-point are identical and can both be represented by $x(t)$ which is a solution of the following well known differential equation [21]:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f(t) \quad (2)$$

where, m , c and k are the modal mass, damping and stiffness, respectively.

Multiplying by the modal/physical velocity $\dot{x}(t)$, the equation of motion can be used to calculate instantaneous power $f(t)\dot{x}(t)$:

$$m\ddot{x}(t)\dot{x}(t) + c\dot{x}(t)\dot{x}(t) + kx(t)\dot{x}(t) = f(t)\dot{x}(t) \quad (3)$$

Here, $m\ddot{x}(t)\dot{x}(t)$ is kinetic power, $c\dot{x}(t)\dot{x}(t)$ is damping power and $kx(t)\dot{x}(t)$ is potential power.

In resonance it is well known that the inertia and stiffness forces are perfectly balanced with the interchange of kinetic and potential energy resulting in a constant value of energy and no net supply to either of them. Simultaneously, the external force simply provides positive power to compensate for the energy dissipated internally via damping (damping power):

$$\begin{aligned} m\ddot{x}(t)\dot{x}(t) &= kx(t)\dot{x}(t) \\ c\dot{x}^2(t) &= f(t)\dot{x}(t) > 0 \end{aligned} \quad (4)$$

Away from resonance in steady state the damping power is always positive (due to the square term in $c\dot{x}^2(t)$) but the external power has a zero-mean oscillating component which supplies and withdraws power during a cycle due to the imbalance of inertia and stiffness forces. During build up of response towards resonance the external force only supplies and never withdraws power to build up the constant level of total (i.e. kinetic plus potential) energy.

For the two TSs bouncing/jumping together (Figures 8 and 9), the individual cycle-by-cycle average power plots show that TS 1 was supplying energy to the system most of the time during the tests, while TS 2 was often acting as the strong damping element. This clearly explains why the resonance was very difficult to maintain for both activities. These tests also confirmed findings elsewhere [22] that the humans are characterised by huge inter-subject differences between their abilities to induce dynamic loads, to change the dynamic properties

and to respond to nominally the same vibrations of the structure they occupy and dynamically excite.

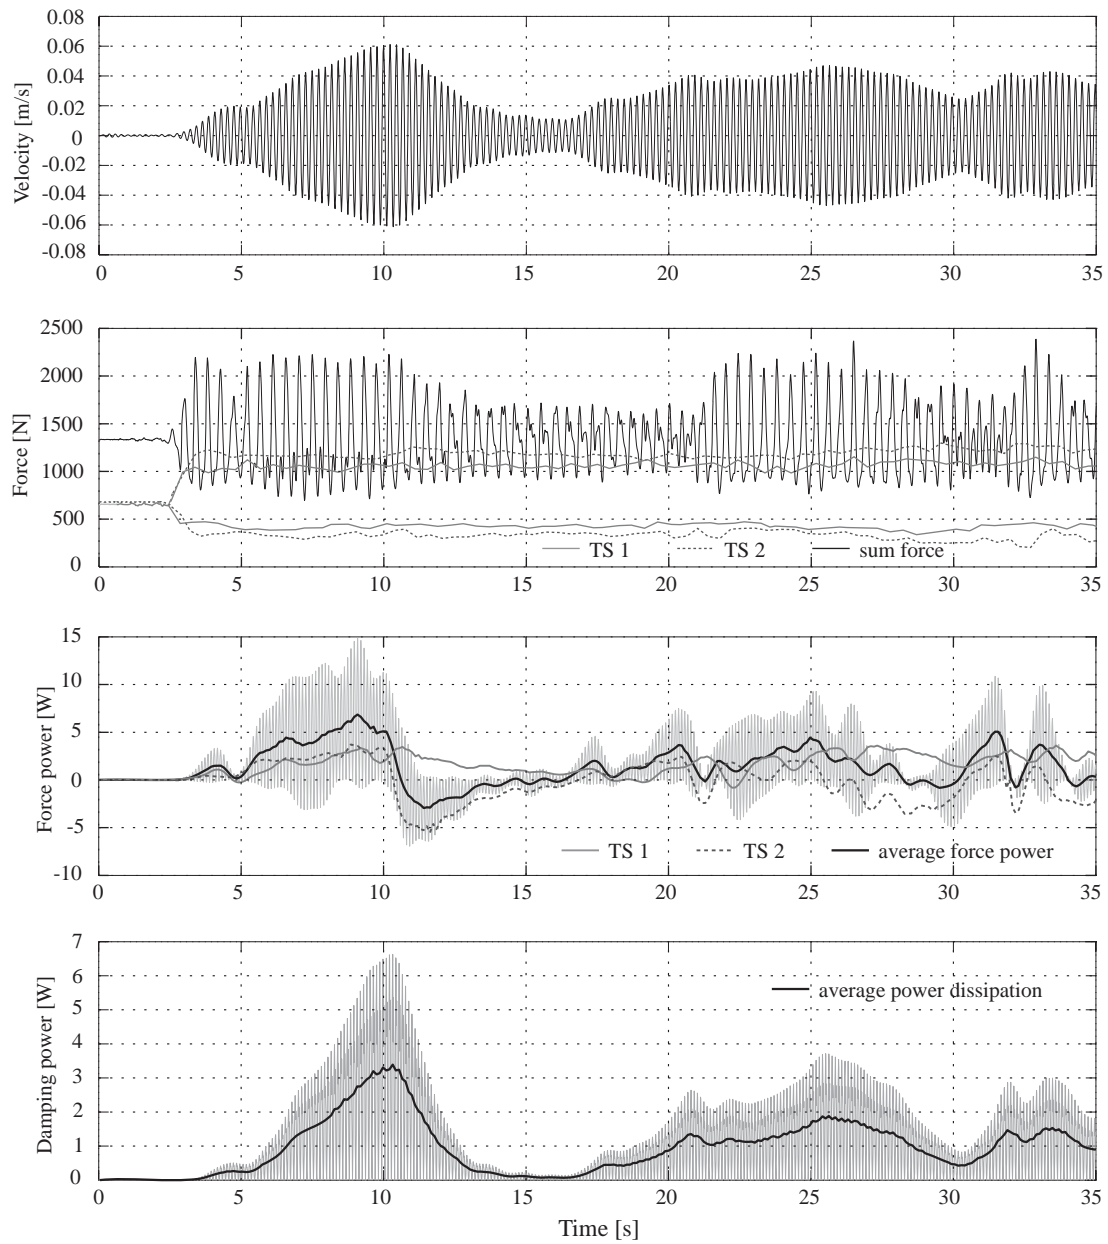

Figure 8: Energy flow and power due to both TSs bouncing together in the middle of the span at resonant rate of 2.2 Hz.

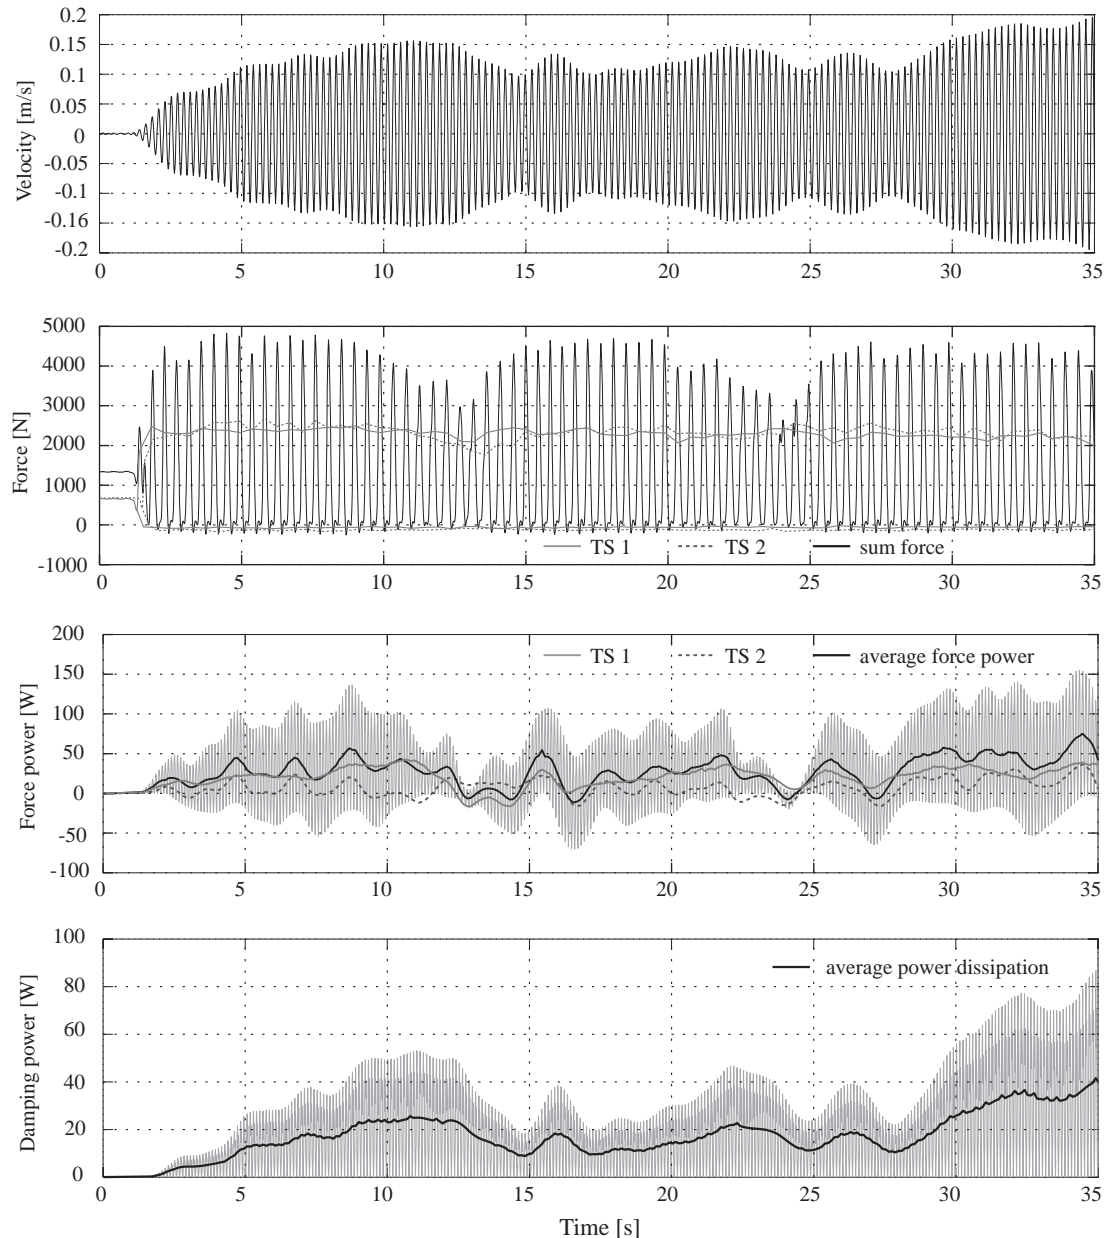

Figure 9: Energy flow and power due to both TSs jumping together in the middle of the span at resonant rate of 2.2 Hz.

6 CONCLUSIONS

This paper presents a novel method in the civil engineering context to measure indirectly bouncing and jumping GRFs by combining human body motion tracking data and known/assumed body mass distribution.

When compared with the traditional direct force measurements on floor-mounted force plates, a key advantage of the method proposed is utilisation of ‘free-field’ measurement of continuous bouncing and jumping GRFs. As demonstrated, indirect force measurements enable monitoring of people performing rhythmic activities in their natural environments, such as footbridges, grandstands, staircases and open-plan floors. Moreover, the method enables study areas of significant interest and uncertainty, specifically human-structure dynamic interaction and synchronisation between occupants when bouncing and jumping on flexible structures. Measurements have been able to show the negative cue effect of perceptible vibrations

on the GRFs. Also, they indicated that in the joint human-structure dynamic system an active human can not only be the source of energy but they can also act as the strongest damping element. This happens either because the response is off-resonance or because they are out of phase with the structural motion resulting in net removal of energy. The effect is even stronger for multiple occupants due to the lack of synchronisation of their movements.

The method piloted in this paper has been validated using two male participants, who were jumping or bouncing either individually or as a pair on a realistic test structure. This means that there remains a requirement to carry out similar tests for single individuals and multiple occupants moving on a number of different, more or less vibrating real-life structures. Measurements can be used to develop and calibrate a new generation of badly needed models of rhythmic crowd loads. Therefore, this approach presents a timely opportunity to advance the whole field of vibration serviceability assessment of structures predominantly occupied and dynamically excited by bouncing/jumping humans, such as grandstands and entertainment venues.

7 ACKNOWLEDGEMENTS

The authors would like to thank Mr Christopher Middleton, Dr Ivan Munoz-Diaz and Dr Stana Zivanovic for their help in collecting the data. Also, the authors would like to acknowledge the financial support provided by the UK Engineering and Physical Sciences Research Council (EPSRC) for grant reference EP/E018734/1 ('Human Walking and Running Forces: Novel Experimental Characterisation and Application in Civil Engineering Dynamics').

Keywords: crowd-structure interaction, complex system, synchronisation, crowd dynamics, footbridges, lateral vibrations.

Abstract. *This paper aims to provide a review and critical analysis of the state of the art concerning crowd-structure interaction phenomena on footbridges. The problem of lateral vibrations induced by synchronised pedestrians, namely the Synchronous Lateral Excitation, is specifically addressed. Due to the multi-physic and multi-scale nature of the complex phenomenon, several research fields can contribute to its study, from structural engineering to biomechanics, from transportation engineering to physics and applied mathematics. Among the different components of the overall coupled dynamical system - the structure, the crowd and their interactions - the latter ones are separately analysed from both a phenomenological and modelling point of view. A special attention is devoted to those models, which explicitly account for the interaction between mechanical and living systems.*

1 INTRODUCTION

The interaction between the structure and the crowd walking on it, and among the pedestrians within the crowd, gives rise to a multi-scale multi-physic complex dynamic system. The latter is characterised by collective phenomena that are not only due to the features of the single system components but also to their interactions. Specifically, the crowd behaviour, in particular the pedestrian force exerted on the structure, affects the structural dynamic properties and response, and the latter modifies the behaviour of the pedestrians walking on the moving structural surface.

This contribution provides a review and critical analysis of the state of the art on the modelling of the interactive dynamics involving crowds and structures, specifically focused on the so-called lively footbridges. Indeed, a specific kind of crowd-structure interaction phenomenon, the so-called Synchronous Lateral Excitation (SLE), is likely to occur on lively footbridges in the lateral direction, due to the pedestrian sensitivity to lateral vibrations which affect their balance during gait. The SLE has attracted the increasing attention of structural engineers and researchers in the last few years. While all over the 20th century the research was mainly directed towards the effects of pedestrian vertical excitation, the closure of the London Millennium Footbridge in 2000 [1, 2] focused the attention towards the problem of lateral vibration due to synchronised pedestrians. The frequency of occurrence of SLE has recently grown due to the construction of a great number of lively footbridges. In fact, because of the aesthetic requests for greater slenderness and lightness, newly built footbridges are often characterised by reduced mass, stiffness and damping, so that they are extremely prone to vibration.

The increasing interest for footbridge dynamics in the Civil Engineering field is testified by the growing number of papers published in international journals: a non-exhaustive survey of the number of peer-reviewed papers cited in this review versus time is provided in Figure 1a. The organisation since 2002 of a specific international conference named ‘Footbridge’ mainly devoted to this issue, the recent publication of guidelines for the design of footbridges under human action [3, 4] and the start-up of dedicated European research projects [5, 6] confirm that the crowd-structure interaction is one of the topical research subjects in structural dynamics.

According to the writers’ opinion, in spite of the great scientific effort in this field and the significant advances in the comprehension of the phenomenon, the study could benefit of the contribution of other research fields to achieve general and conclusive results. First, the understanding and modelling of the multi-scale multi-physic phenomena involved by crowd-structure interaction makes it necessary to collect contributions from several research fields in a multi-disciplinary frame, besides that of structural engineering: for instance, the pedestrian walking behaviour has been extensively studied in the field of biomechanics, while crowd modelling belongs to transportation, physics and applied mathematics research fields. This review aims to offer a contribution to the convergence of these knowledges: the distribution of the references cited in this work among the above mentioned research fields is shown in Figure 1b, where the papers are classified according to the journal or authors main scientific affiliation. Second, engineering and, more in general, technological sciences traditionally experience some difficulties in considering the peculiar behaviour of living systems in the interaction between inner mechanical systems and outer systems, even though this aspect is relevant in some specific cases such as the modelling of crowd and structures. It is well understood, in the case of crowd, that human and animal behaviour follow specific strategies, in some cases we can call it intelligent behaviours, that modify laws of classical mechanics [7, 8, 9, 10, 11, 12]. This is a specific characteristic of all living systems even in the case of low scales such as insects [13]

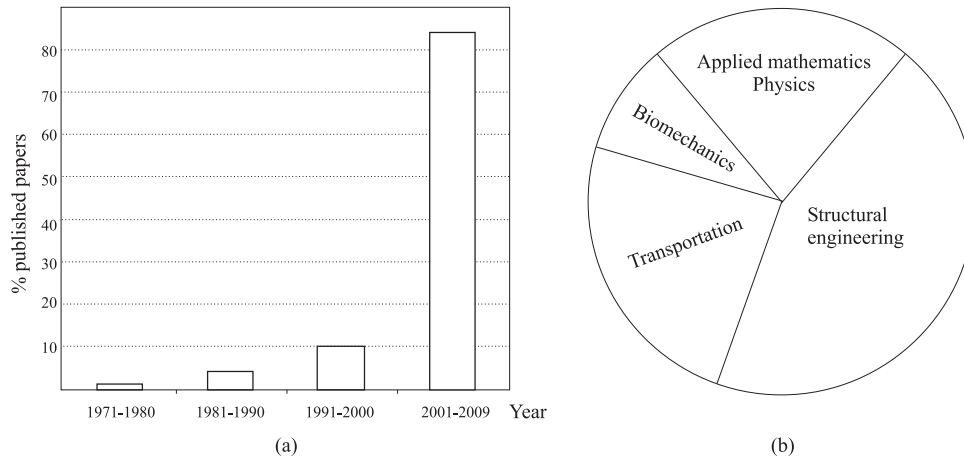

Figure 1: Published paper in the Civil Engineering field (a) and scientific affiliation of the cited references (b)

or cells [14, 15]. It is worth stressing that the coupling of living and mechanical systems is characterised by peculiar issues that have to be carefully taken into account in a comprehensive modelling approach. Summarising two specific aspects:

- (i) The dynamics of living systems follows rules generated by self-organised ability, while mechanical systems follow rules of continuum mechanics according to conservation laws that provide background paradigms that are constant in time.
- (ii) The overall system shows hybrid multi-scale characteristics considering that the crowd appears as a discrete system, that is, a system with finite degrees of freedom, while the modelling of structures is developed by continuum models, namely by a system with an infinite number of degrees of freedom.

Both above specific aspects are taken into account in the review proposed in this contribution.

The paper is inspired to the authors' previous review paper [16] and develops in three more Sections. Section 2 is devoted to the state of the art concerning the phenomenological analysis of the behaviour of the crowd dynamics and of the crowd-structure interaction (CSI). Section 3 is addressed to the mathematical models proposed so far to describe the different components of the overall crowd-structure system and the crowd-structure interaction models. Finally, the conclusions and some research perspectives are discussed in Section 4.

2 PHENOMENOLOGICAL ANALYSIS

This section is devoted to a review of the studies that are useful for the understanding and phenomenological description of the crowd-structure interaction phenomenon, named SLE. In the following the studies relative to the crowd behaviour, and those relative to the crowd-structure interaction are briefly analysed. A review of the studies concerning the behaviour of a single pedestrian can be found in [16] and [17].

2.1 Crowd behaviour

Crowds are complex systems, that is, large ensemble of individuals interacting in a non-linear manner. Some of the peculiar features of the pedestrian behaviour are outlined in the following [18]:

1. pedestrians in a crowd represent an example of *collective behaviour*, that is, an individual's action is dominated by the influence of his neighbours, so that the individual behaves differently from the way he/she would behave on his/her own;
2. pedestrians are *active* agents, i.e., under normal conditions without panic onset, they share the same objective of walking with the maximum velocity towards a target (e.g., doors, exit, displays), bypassing possible obstacles and avoiding the most crowded zones (see the concept of *personal space* developed in human sciences and psychology, e.g. in [19]). These strategies enable them to determine actively their walking direction and velocity, without being passively subject to the laws of inertia;
3. pedestrians are *intelligent* agents, i.e., their mind evaluates, selects, and/or makes synthesis of what it perceives according to various psychological criteria (e.g., the level of anxiety [20] or the capacity to perform ensemble evaluations [21]).
4. under normal external and subjective conditions (e.g., the area where pedestrians walk is illuminated allowing visual perception), pedestrians do not perceive the real world locally in space, due to their ability to see up to a given extent around them (the so-called *sensory region* [22]). Moreover, pedestrians react after a time interval has elapsed from the perception time (see e.g., [23, 21]). Therefore, pedestrians in a given position at a given time react to the conditions perceived in front of them at a delayed time, i.e., in a *non-local* way in both space and time ;
5. pedestrians are *anisotropic* agents, i.e., they are not equally affected by stimuli coming from all directions in space. Specifically, they distinguish between ahead and behind, in normal situations being essentially sensitive to what happens in a symmetric visual field focused on their direction of movement;
6. walking pedestrians adapt the depth and width of the sensory region to their travel purpose and to their walking speed (e.g., a pedestrian walking for leisure purposes is expected to scan a wider field than a commuter attaining a train, and the faster a pedestrian walks the deeper the space required to evaluate and react is).

Because of the crowd intrinsic multiscale features, crowd related phenomena can be schematically observed with reference to three different scales [24]:

- *macroscopic scale*, which describes the state of the ensemble of individuals with averaged quantities.
- *mesoscopic scale*, where the state of the system is identified by the probability distribution functions of the microscopic state of the individuals.
- *microscopic scale*, where the contribution of each single individual to the behaviour of the system is described.

Nevertheless, it is worth stressing that this classification obeys to conceptual, experimental and modelling requirements, while unexpected emerging phenomena, especially in out-of-equilibrium conditions, can result from a mix of individual and collective behaviour involving several scales. In the following, the crowd behaviour is analysed from a macroscopic point of view, since experimental measurements found in literature usually refer to averaged variables, namely the crowd density, velocity and flow, which describe the macroscopic state of the

crowd. In this macroscopic framework, the single pedestrian behaviour can be recovered in a limit sense, i.e. when density tends to zero.

In the following, a stationary and homogeneous pedestrian traffic flow described by macroscopic quantities is considered. The so-called *fundamental relation* is valid:

$$q = \rho v, \quad (1)$$

where q is the flow, intended as the number of pedestrians passing a cross-section of an area in a unit of time [ped/ms]; ρ is the crowd density [ped/m²]; v is the average walking velocity [m/s]. The three variables are macroscopic characteristics of the flow: the graphical representations of their relations are called *fundamental diagrams*. It reflects one of the main feature of crowd behaviour, that is the walking velocity is affected by the crowd density, namely the higher the crowd density, the lower the walking velocity.

Looking at the flow-density diagram in Fig. 2, some relevant quantities can be identified [25]:

Figure 2: Flow-density fundamental diagram

- free speed v_M : the slope of the function $q(\rho)$ at the origin that corresponds to the velocity if $q = 0$ ped/ms and $\rho = 0$ ped/m², that is to the walking velocity of the single unimpeded pedestrian (a review of the available statistics about the single pedestrian velocity can be recovered in [16]);
- critical density ρ_c : the lower bound for unconstrained free walking. For $\rho < \rho_c$, pedestrians walk with constant free speed $v = v_M$ (*stable region*); for $\rho > \rho_c$, the walking speed decreases with increasing density (*unstable region*);
- capacity speed v_{ca} and density ρ_{ca} : the speed and density when $q = q_{ca}$, that is, the maximum flow. The region of density below ρ_{ca} is called *free flow region*, while the *congestion region* corresponds to a higher density than the capacity density;
- jam density ρ_M : the maximum admissible density corresponding to null speed and flow.

The values of the aforementioned variables are not expected to be universal, since walking behaviour is influenced by a great number of microscopic factors, such as age, culture, gender, travel purpose, type of walking facility and single or multiple walking direction [25, 26]. Many studies have been directed to the determination of a law that links the walking velocity to the crowd density. Most of these studies [26, 25] belong to the transportation research field, with the aim of controlling the layout and dimensions of pedestrian walking facilities.

As far as the jam densities are concerned, they have been estimated to vary between 4 and 5.4 ped/m² [27]. The average human body has a width of 45.6 cm and a depth of 28.2 cm [27]. These dimensions refer to a motionless pedestrian. The maximum pedestrian density could be derived from the minimum average body surface (0.13 m²): this leads to a density of 7.69 ped/m², that is difficult to obtain in practice, since people can hardly move at densities over 5 ped/m². When pedestrians are walking they require more lateral and forward space than a motionless person. The required lateral additional space has been estimated to be about 62% of the average width of pedestrians [26]. The required forward space (distance among pedestrians d) instead depends on the walking velocity: a linear relation has been proposed by Seyfried et al. [28], as a fitting to experimental data, which is valid in the $0.1 < v < 1$ m/s domain:

$$d = 0.36 + 1.06v. \quad (2)$$

The distance among pedestrians can be expressed as the sum of the step length l_p and the so-called *sensory zone* d_s , defined by Fruin [22] as "the area required by the pedestrians for perception, evaluation and reaction". The pioneering Fruin's definition of this *buffer zone* quantifies one of the distinctive properties of pedestrians as active particles, i.e. their bounded visual field over which environmental information are obtained in order to draw specific, real-time strategies.

Because of the great number of factors affecting pedestrian flows, rather different experimental data and fundamental diagrams can be found in literature. Looking at the experimental data classified with respect to the kind of pedestrian traffic [29, 28, 30] (Fig. 3), it is clear that the Reimer's measurements, reported in [29], are different from the other ones, since they refer to fast pedestrian transit in train stations and the author himself refers to them as exceptional cases: it is odd that a recent design guideline [3] only reports Reimer's diagram. One of the first studies, which explicitly accounts for the travel purpose as a parameter that affects the fundamental diagram, was developed by Oeding [29]. He proposed an interesting diagram (Fig. 4), recently recovered in [3] and [34], which graphs the capacity of pedestrian walkways as a function of density and traffic type. In particular he distinguished four types of pedestrian traffic (shopping, event, rush hour and factory traffic), corresponding to increasing walking velocity and capacity. The diagram also allows a classification of walking regimes to be outlined, that is: free ($\rho < 0.3$ ped/m²); acceptable ($0.3 < \rho < 0.6$ ped/m²); dense ($0.6 < \rho < 1$ ped/m²); very dense ($1 < \rho < 1.5$ ped/m²); crowded ($\rho > 1.5$ ped/m²).

An exhaustive survey of the speed-density relations proposed so far can be found in [25] and [27]. They are graphically represented in Fig. 5a, which plots the linear relations [25, 27], and in Fig. 5b, where the non-linear laws [7, 26] are reported. It should be reminded that all graphics refer to steady uniform conditions described by macroscopic quantities, therefore fluctuations are lost. Many of the studies report a linear relationship between velocity and density (Fig. 5a), according to the following form:

$$v = v_M - k\rho; \quad k > 0. \quad (3)$$

Figure 3: Speed-density relation: experimental data [31, 22, 32, 29, 33, 28]

Figure 4: Relationship between bridge capacity, pedestrian density and their velocity, after Oeding [29]

Other authors have proposed non linear laws (e.g. [26]) or multi-regime models (e.g. [7]). In general, the non-linear multi-regime models are more accurate than the linear laws, since they better capture the almost constant speed at low densities and they have the upward concave form that better fits the observation data. In particular, the law proposed by Weidmann, called *Kladdek formula*, has the advantage of being a continuous function of ρ , avoiding unrealistic discontinuities, such as in the Hughes' diagram. A parametrical form of the Kladdek formula has been proposed in [42], in order to account for the influence on the walking velocity of both psychological and physiological factors, represented by the travel purpose and geographic area,

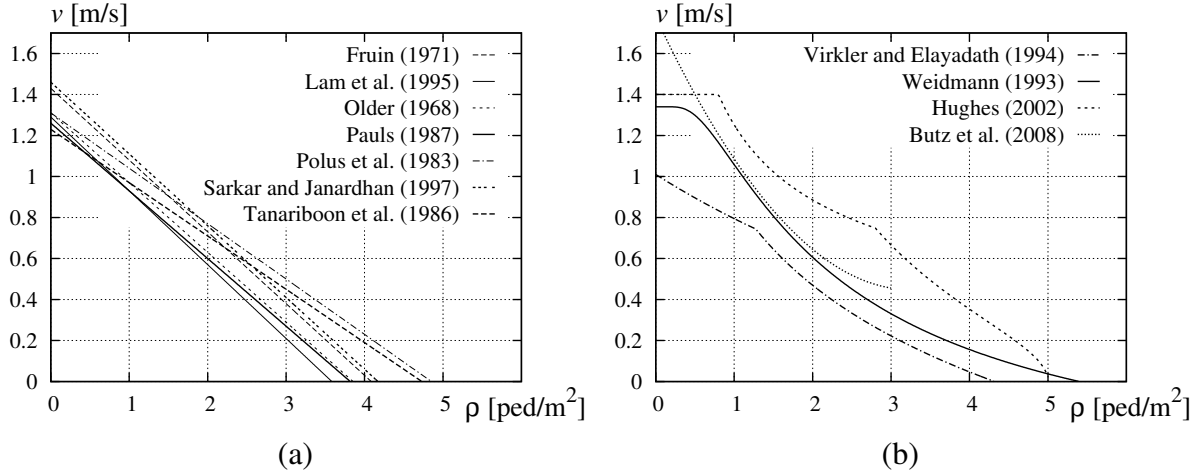

Figure 5: Speed density relations in literature [7, 5, 26, 22, 35, 36, 37, 38, 39, 40, 41]: linear (a) and non linear (b)

respectively:

$$v = v_M \left\{ 1 - \exp \left[-\gamma \left(\frac{1}{\rho} - \frac{1}{\rho_M} \right) \right] \right\}, \quad (4)$$

where γ is an exponent that makes the relation sensitive to different travel purposes (leisure/shopping, commuters/events, rush hour/business), which is obtained through a fitting of the data in [22, 29]. The jam density ρ_M is expressed as:

$$\rho_M = \frac{1}{\beta_G S_m}, \quad (5)$$

where $S_m = 0.13 \text{ m}^2$ is the mean surface occupied by a motionless pedestrian and the geographic area coefficient β_G is derived, considering the dimension occupied by the human body in different countries [27], as the ratio between the surface averaged per geographic area and the mean surface. It results that β_G equals 1.075 for the European and American case, while it equals 0.847 for Asian countries. The free speed v_M is expressed in the general form:

$$v_M = \bar{v}_M \alpha_G \alpha_T, \quad (6)$$

where $\bar{v}_M = 1.34 \text{ m/s}$ is the average free speed [27] and the coefficients α_G and α_T , which make the velocity sensitive to the geographic area and travel purpose, are determined analysing the data reported in [27] as the ratio between the proposed free speeds and \bar{v}_M (Table 1).

Table 1: Coefficients of geographic area and travel purpose

Travel purpose				Geographic area			
	Rush hour/ Business	Commuters/ Events	Leisure/ Shopping		Europe	USA	Asia
α_T	1.20	1.11	0.84	α_G	1.05	1.01	0.92
γ	$0.273\rho_M$	$0.214\rho_M$	$0.245\rho_M$				

It is worthwhile pointing out that the speed-density relations described so far refer to a one-directional flow. In a bi-directional flow, the effects due to passing pedestrians lead to a reduction of the flow capacity. Weidmann [26] estimates a capacity loss of about 4-9% in the case

of equal flows in both directions (50%/50% or directional ratio = 1) and a higher capacity loss (about 14.5%) for a directional ratio of 10%/90%. This result has to be ascribed once more to the pedestrian intelligent behaviour and it follows from the self-organised phenomena which take place in the crowd: a directional ratio close to unit induces a two-lane natural configuration, where each pedestrian tends to keep his/her right due to cultural influences; low directional ratios and wide pedestrian walkways do not allow the upstream pedestrians to organise together, so that they are viewed by the main stream as moving obstacles, involving a significant capacity loss.

Finally, it is worth drawing some considerations about flow dimensionality. Many of the proposed relations refer to pedestrian movement on a plane. Seyfried et al. [28] showed that the measurement of the speed-density relation for a single-file movement of pedestrians leads to results in complete agreement with Weidmann's diagram: this means that specific two-dimensional features, such as internal friction and lateral interference, do not have a strong influence on the fundamental diagram in the considered density range.

In conclusion, it can be stated that it is not possible to determine a universally valid speed-density relation, since the pedestrian behaviour is affected by a great amount of parameters. For this reason, a specific law should be tuned in order to characterise a particular crowd condition. Furthermore, it should be borne in mind that the fundamental diagrams are derived in steady state conditions: this means that the quantities characterising the system vary slowly with respect to space and time. Therefore, fundamental diagrams, like the ones presented in this section, are not suitable for direct use in out-of-equilibrium conditions.

Although density and velocity are the main macroscopic state variables of the crowd, other quantities are of interest in the perspective of the modelling of the crowd dynamic load acting on a structure and of the crowd-structure interaction. Among these quantities, let us recall the walking frequency, which affects in turn the pedestrian force frequency content, and a measure of the degree of synchronisation among pedestrians (e.g., the walking phase, the standard deviation of the walking frequency or, more in general, a correlation coefficient).

As for the walking frequency, it has to be intended as a vertical one f_{pv} , that is, the number of times a foot touches the ground in a time unit, while the horizontal or lateral walking frequency f_{pl} is intended as the number of times the same foot touches the ground. At the individual level (single unimpeded pedestrian at $\rho = 0$), the former depends on the free walking velocity v_M and on the step length l_s according to the fundamental walking law

$$f_{pv} = \frac{v_M}{l_s}, \quad (7)$$

where the mentioned walking parameters are random variables whose statistical moments are obtained by ensemble averaging of experimental measurements [5, 43, 44, 45, 46, 47, 48]. In the case of constrained pedestrians in a crowd ($\rho > 0$), the free speed v_M in Eq. 7 should be replaced by $v(\rho)$ and all the walking parameters should be intended as macroscopic averaged quantities. In this macroscopic framework, different empirical $f_{pv} - v$ laws have been proposed as a fitting to experimental measurements. Linear relations have been proposed, for instance, by Butz et al. [5], on the basis of the Oeding's measurements [29]:

$$f_{pv} = 0.7886 + 0.7868v, \quad (8)$$

and by Ricciardelli et al. [46]:

$$f_{pv} = 0.024 + 0.754v, \quad (9)$$

 Figure 6: Examples of $f_{pv} - v$ relations

who observed that the constant value 0.024 m/s derived from the fitting can be neglected for engineering purposes. A non linear relation based on a cubic fitting to the data of Bertram and Ruina [49] has been proposed in [50]:

$$f_{pv} = 2.93v - 1.59v^2 + 0.35v^3. \quad (10)$$

The three $f_{pv} - v$ laws are compared in Fig. 6.

As for the degree of synchronisation among pedestrians in a crowd, when a pedestrian's walking is constrained because of high density values, people tend to walk with the same frequency and a null relative phase angle, that is, they synchronise to each other [51]. This behaviour is due to the attempt to avoid foot-to-foot contact in the forward direction and shoulder-to-shoulder contact in the lateral direction. Some experimental evidence of the former attempt has been obtained by Seyfried et al. [28] who observed that pedestrians tend to optimise the available forward space in case of high density, giving some overlap in the space occupied with the pedestrian in front.

So far a limited number of experimental tests has been devoted to the investigation and quantification of the synchronisation among pedestrians in dense crowds, even though it could play a crucial role in crowd-structure interaction, acting as a inner trigger of the pedestrian-structure synchronisation. In the last two years some new studies [5, 52, 53] have been carried out by means of experimental tests performed within different ranges of the crowd density. Arajo *et al.* [52] found that, in the crowd density range 0.3-0.9 ped/m², there is no evidence of synchronisation among pedestrians, since the standard deviation of the walking frequencies is almost constant for different densities and the phase angles are totally random. Ricciardelli and Pizzimenti [53] observed that, in the crowd density range 0.5-1.5 ped/m², initially different walking frequencies and phases tend to get closer for increasing crowd densities, giving rise to synchronisation nuclei within the crowd. Finally, Butz *et al.* [5] performed tests in which pedestrian streams with densities varying between 1.2 and 3 ped/m² walked along a 30 m long and 1.5 m wide path and their walking frequencies were measured with pressure sensors located in the right shoes. They found that the standard deviation of step frequencies for high crowd density was lower than for low density, indicating a higher correlation among pedestrians in the first case.

Besides the above mentioned experimental approach, some interesting suggestions to the comprehension of the phenomenon can be found in the fields of physics and applied mathemat-

ics. In fact, the synchronisation among pedestrians can be ascribed to *collective synchronisation* phenomena, which have been studied from the Sixties in the pioneering works of Winfree [54] and Kuramoto [55]. Collective synchronisation occurs when "an enormous system of oscillators spontaneously locks to a common frequency, despite the inevitable differences in the natural frequencies of the individual oscillators" [56]. Several examples can be found in the natural world, from the pacemaker cells in the heart, to flashing fireflies. Winfree studied the behaviour of a large population of weakly-coupled, nearly identical limit-cycle oscillators: when the spread of natural frequencies is large with respect to the coupling strength K , the system behaves uncoherently; as the spread decreases, the system behaves uncoherently until a threshold K_c is crossed (Fig. 7). Then, a small cluster of oscillators synchronises and the coherency grows towards perfect synchronisation: the threshold K_c , therefore, corresponds to a *phase transition*.

Figure 7: Schematic representation of the Winfree's model after Pizzimenti [57]

Pizzimenti [57] observed that the phase transition described by Winfree could interpret what has been observed on the London Millennium Bridge in its opening day: first, small groups of pedestrians started to synchronise; then, when the number of pedestrians exceeded a critical value, most of them were captured in the synchronisation phenomenon.

2.2 Pedestrian behaviour on a vibrating platform: crowd-structure interaction

When a pedestrian crosses a lively footbridge, he walks on a vibrating surface, therefore, if the vibrations become perceptible, human-structure interaction can occur. As stated in the Introduction, pedestrians are more sensible to lateral vibrations of the walking surface, therefore they are more likely to synchronise with the deck lateral motion. Indeed, because of the attempt to maintain body balance, the pedestrians unconsciously adapt their lateral frequency to the lateral natural frequency of the moving surface. A scheme of the pedestrian-structure synchronisation, also known as *lock-in* in structural engineering, is represented in Figure 8 [5]: if the lateral movement of the torso has the same frequency and is in phase with the deck lateral velocity, the work $W = \int_T F \dot{z} dt$ is always positive, that is, the pedestrian provides positive energy input, causing the vibrations to enlarge. As a consequence, pedestrians walk with their

legs more widespread, the lateral motion of the upper part of the torso increases and the resulting lateral force grows in turn in a self-excitation mechanism, which characterises the SLE. This phenomenon is amplified if the pedestrian walks in a dense crowd, since the synchronisation among pedestrians (§2.1) can trigger or increase the effects of the pedestrian-structure synchronisation [58, 59]. So far, the phenomenon has never led to structural failure since it has a self-limited nature, that is, when the vibrations exceed a limit value pedestrians detune, stop walking or touch the handrails, causing the vibrations to decay. It is worth pointing out that the above mentioned phenomena responsible for the self limited nature of SLE are essentially due to the intrinsic features of the pedestrians that behave as active and intelligent agents (see the beginning of §2.1). Nevertheless, the resulting reduced comfort for the users has often led to a temporary closure of the footbridge in order to provide proper countermeasures, with consequent economic and social repercussions.

It is worth pointing out that human-structure interaction has also been observed by some authors in the case of vertical vibrations [60, 61]. In particular, humans' inability to synchronise their pace with vertically moving surfaces causes the vibration to diminish, as if pedestrians provide additional damping to the system. This effect, which is well-known in the case of stationary people, is not completely understood in the case of moving people and needs further investigations.

Figure 8: Schematic representation of pedestrian-structure synchronisation after Butz et al. [5]

The SLE is not related to a specific structural type, but it "could occur on any bridge with a lateral frequency below about 1.3 Hz loaded with a sufficient number of pedestrians" [1] (see [61] for a review of bridges exhibiting SLE). In the last few years, many studies have been devoted to the understanding of the SLE, mainly through an empirical approach. The experimental studies can be roughly divided into the following categories: i) laboratory tests on moving treadmills or long vibrating platforms; ii) field tests on real footbridges; iii) observation of videos recorded during real world crowd events; iv) analysis of similar phenomena occurring in nature and studied in different scientific fields.

The first laboratory experiments in the structural engineering field were carried out at London Imperial College and at the University of Southampton to explain what had happened on the London Millennium Bridge [1]. The tests at the University of Southampton involved a person walking "on the spot" on a small shaking table. The tests at Imperial College involved persons walking along a 7.2 m long platform which could be driven laterally at different frequencies and

amplitudes. Similar tests on a moving treadmill were also performed by Pizzimenti [57]: the specially built treadmill (Fig. 9a) was laterally driven at different amplitude-frequency configurations. On one hand, treadmill devices permit a steady-state walking behaviour to be easily reached; on the other, they only allow the walking behavior of a single pedestrian to be explored. Moreover, the pedestrian is forced to walk at a given velocity and his/her natural behaviour is affected by the small treadmill surface. Even though these tests did not permit the behaviour of people walking in a crowd to be investigated, they allowed important results to be obtained about the behaviour of a single pedestrian, that is, the amplitude of the exerted lateral force for increasing amplitude of the platform oscillation and the probability that he/she would synchronise his/her pace to the frequency of the moving platform.

In order to better simulate the conditions that can occur on a footbridge, on which groups of pedestrians walk continuously, Setra [4] built a 7 m long and 2 m wide slab on 4 flexible blades moving laterally, in order to measure the horizontal load exerted by pedestrians and to estimate the threshold of motion perception corresponding to the triggering of the lock-in. The device was provided with access and exit ramps in order to maintain walking continuity. These tests showed that there is an acceleration threshold (around $0.1\text{--}0.15\text{ m/s}^2$) above which some synchronisation arises and causes uncomfortable vibrations. A longer platform has been built during the Synpex European project [5]. The 12 m long and 3 m wide test rig was designed to vibrate both in the vertical and horizontal direction (Fig. 9b). One of the main limits of the vibrating platforms built so far is that their reduced length does not permit the synchronisation phenomena to fully develop, so that constitutive relations between the pedestrian state variables and platform motion cannot be drawn in equilibrium conditions. On the other hand, they allow experiments to be performed in a controlled environment, so that the effect of different factors can be isolated.

The phenomenon has also been studied by means of field tests. The tests carried out on

Figure 9: Example of treadmill and moving platform after Pizzimenti [57] and Butz et al. [5]

the Millennium Bridge during the closure period [1] (Fig. 10) evidenced an almost linear dependence of the pedestrian force on the deck lateral velocity. In addition, the deck acceleration abruptly increased when the number of pedestrians exceeded a critical value. Several test campaigns were also carried out on the Solferino footbridge [4], leading to the following conclusions: the lock-in occurred for the first lateral mode and appeared to start and develop more easily when the step lateral frequency was lower than the deck lateral frequency; lock-in occurred beyond a particular threshold, that can be determined in terms of critical number of pedestrians (as proposed in [1]) or critical value of acceleration, which seems more relevant;

Figure 10: Lateral force per person per vibration cycle vs deck velocity, after Dallard et al.[1]

below 0.1 m/s^2 , the pedestrian behaviour may be considered not related to the structure motion. Field measurements were also conducted by Nakamura [62] on the M-bridge in Japan. Accelerometers in the lateral direction were attached to the base of the handrails at five positions and accelerometers were also attached to the waist belt of a person, who walked on the bridge among other pedestrians. The measurements confirmed that the pedestrian walked at the same frequency as the girder and showed that the pedestrian's phase is between 120° and 160° ahead of the girder. A comparison between the time histories of the girder and pedestrian lateral motion also showed that the pedestrian was sometimes no longer tuned to the structure (Fig. 11): this means that he sometimes lost his balance because of large girder vibrations. By analysing the behaviour of three footbridges (Millennium Bridge, T-bridge and M-bridge), Nakamura proposed a serviceability limit for lateral vibration, that is, a displacement of 45 mm (a velocity of about 0.25 m/s and an acceleration of about 1.35 m/s^2). Nakamura also observed that synchronisation is unlikely to occur at a deck natural frequency under 0.6 Hz. The same conclusion can also be inferred from the tests performed by Pizzimenti on the moving treadmill [57]. Finally, it is worth citing the experimental campaigns conducted during the Synpex project, which involved field tests on several footbridges, such as the Pedro and Ines footbridge in Coimbra (Portugal) [63] or the stress ribbon bridge at the campus of the University of Porto [64], with the aim of characterising the pedestrian perception of footbridge vibrations, validating load models and identifying the most relevant footbridge dynamic properties. Even though field tests give further information with respect to laboratory tests, it has to be pointed out that in both kind of tests the pedestrians do not walk in a completely natural way, since they are conditioned by several constraints (for instance they are asked to tune their pace to the sound of a metronome): this fact should be considered in the interpretation of the test results.

Other suggestions come from the observation of the videos recorded during crowd events or experimental campaigns. Fujino et al. [65] were the first to observe the SLE on the T-bridge in Japan, which connects a boat race stadium to a bus terminal. They recorded human passage during a congested period by means of three cameras installed on the stadium roof, synchronised to each other and connected to a computer. The motion of a selected number of pedestrians' heads were digitised from the video by means of a microcomputer [66]. The head motion time histories showed a surprising similarity, i.e. they were synchronised although the amplitudes were different. Fujino et al. estimated a percentage of synchronised pedestrians of about 20%.

Finally, as in the case of the synchronisation among pedestrians, some useful hints can be found in the wide literature about synchronisation in natural sciences [67]. The pedestrian-

 Figure 11: M-bridge: lateral displacements of girder and pedestrian at the $L/4$ position, after Nakamura [62]

structure synchronisation is, in fact, an example of entrainment of a self-sustained periodic oscillator by an external force, where the pedestrian is the oscillator, while the external force is represented by the structure inertial force, which is proportional to the structure acceleration. Let ω_p be the circular frequency of the autonomous oscillator, Ω_p the frequency of the driven oscillator and ω_s the frequency of the external force. For a fixed value of the force amplitude \bar{F} , the frequency of the driven oscillator depends on the *frequency detuning*, i.e. on the difference $\Omega_p - \omega_s$: for small absolute value of the detuning, the external force entrains the oscillator (i.e. $\Omega_p = \omega_s$) even for low value of the force amplitude; if the detuning is above a critical threshold, the synchronisation occurs only by increasing the value of the force amplitude \bar{F} . Fig. 12a plots the frequency difference $\Omega_p - \omega_s$ versus ω_s for a fixed value of \bar{F} : the identity of frequencies that holds within a finite range of the detuning is called *frequency locking*. The trend of the frequency detuning $\Omega_p - \omega_s$ versus ω_s and \bar{F} is sketched in Fig. (12b): the domain where $\Omega_p = \omega_s$ is called *synchronisation region* or *Arnold tongue* and is highlighted in grey.

Figure 12: Frequency locking (a) and Arnold tongue (b) [67]

This framework applies to another phenomenon which has some similarities with the SLE and for this reason has inspired some authors [68, 69, 70]: it is a fluid-structure interaction (FSI) phenomenon commonly known as lock-in in Wind Engineering. In this case, the cross-flow oscillations of a bluff structure are due to and interact with the shedding of vortices in its wake. Even though the vortex-induced and crowd-induced oscillations differ in their causes and in the kind of physics they belong to (i.e. purely classical fluid and solid mechanics for FSI, hybrid classic and physics of life for CSI), they show analogous features about the structural response. In a given range of the incoming wind velocity (i.e. the synchronisation region), the vortex-shedding frequency is in fact constant and equal to the frequency at which the structure oscillates, rather than being a linear function of the wind velocity, as stated by the well-known

Strouhal law [71]. In other terms, the structural motion affects the wind flow so that synchronisation occurs and the resonance condition takes place. Furthermore, both phenomena are self-limited, in the sense that structural oscillations do not proceed to divergent amplitudes but enter a limit cycle even though the structural damping is null. These similarities brought some authors [69, 68] to propose the definition of a *pedestrian Scruton number*, in analogy to the Scruton number used in wind engineering. This number, which depends on the structural damping and on the ratio between the structure and crowd mass, can be used as an indicator of the likeliness of occurrence of SLE on a particular footbridge. According to the writers, the introduction of this synthetic number in CSI is somewhat questionable, because the specific features of the crowd behaviour are not included in.

3 MODELLING STRATEGIES

The earlier and most common approach to deal with the problem of crowd-structure interaction considers and models the pedestrians as a simple action applied to the structure. The problem, therefore, reduces to the calculation of the structural response under the action of a suitable load model. According to this approach, several load models have been proposed (reviewed e.g. in [17]): some of them try to take into account the synchronization by means of empirical coefficients and to establish a dependence of the force on the structural response, giving rise to non linear load models. A different and more recent strategy is inspired to the one adopted for flow/wind-structure interaction problems, that is, the pedestrians are considered as a dynamical system, which has its own governing rules and that interacts with the structure system. This approach results in coupled models characterized by non-linear, multi-physic and multi-scale features and therefore require a computational approach to be solved. Moreover, special attention must be paid to the modelling of the crowd and of the interaction terms because of the special features of the crowd subsystem already mentioned in the previous sections. These modelling issues are treated in the following sections.

3.1 Crowd models

Crowd dynamics modelling is quite recent and is mainly derived from vehicular traffic modelling, which has been widely analysed in the field of applied mathematics and transportation engineering since the pioneering work of Prigogine and Herman at beginning of the Seventies [72]. An up-to-date review and critical analysis of the traffic and crowd models so far proposed can be found in Bellomo and Dogbé [73]. The literature on crowd dynamics, which has been arguably initiated by the works of Henderson (e.g. [8]), has undergone a rapid development in recent years, being motivated by the engineering demand for dimensioning of large transportation facilities, such as underground stations or airport terminals, and by safety problems, such as evacuation under panic conditions in case of danger or structural collapses.

According to the observation scales introduced in §2.1, three different kinds of modelling framework can be derived, corresponding to microscopic, mesoscopic or macroscopic description. It should be pointed out that each type of representation is characterised by advantages and disadvantages and, at the present state of the art, it is not possible to establish the validity of a class of models with respect to the others [73]. This section is mainly devoted to the macroscopic modelling framework, since it is the only one so far used in crowd-structure interaction literature. Nevertheless, a brief description of the mesoscopic and microscopic mathematical structures is given at the end of the section in the perspective of their future application to this kind of problems. It is worth pointing out that what follows refers to modelling in normal flow

condition, that is, in absence of panic, coherently with the subject of this contribution.

The representation of crowds is usually performed in two space dimension. In the writers' opinion, the particular case of interest, namely dense crowds crossing footbridges, can be represented as a monodimensional and unidirectional flow, as in the case of vehicular traffic dynamics. The flow along footbridges is mainly monodimensional because of their line-like geometry (the footbridge length is one or two order of magnitude larger than the width of the walkway) and because pedestrians usually share the main objective of crossing the bridge with maximum efficiency and minimum time [74]. Unidirectional crowd flow frequently occurs on footbridges due to the occurrence of particular events (opening day, demonstrations) or due to their specific function and location (link to transport facilities, such as railway stations or bus terminals). Indeed, most of the SLE occurrences have taken place in one of the above described conditions: for instance, the Maori demonstration on the Auckland Harbour Bridge in 1975, the London Millenium Bridge opening day in 2000 [1], the evacuation from a boat race stadium to the bus terminal in the T-bridge in Japan in 1989 [65]. Nevertheless, the more general description in two space dimension is reported in the following: the monodimensional one can be easily derived as a particular case. Therefore, let us consider the system in two space dimension and let D be the domain occupied by the crowd, that can be either bounded or unbounded (Fig. 13).

Figure 13: Geometry of the domain occupied by the crowd (P =position, T =target)

3.1.1 Macroscopic models

Macroscopic models, in analogy with the principles of fluid dynamics, refer to the derivation, on the basis of conservation equations and material models, of an evolution equation for the mass density and linear momentum, regarded as macroscopic observable quantities of the flow of pedestrians assumed to be continuous. Macroscopic models are based on the hypothesis that the crowd as a whole acts in a rational way and that all individuals have the same characteristics and share the same goal, called 'target' (T). In addition, the possibility of the presence of objects or persons that the pedestrians want to avoid should be considered in the model by introducing their repulsive effect. The general mathematical framework is given by the system of partial differential equations (PDEs), that express the conservation of mass and momentum, written in two space dimension:

$$\begin{cases} \partial_t \rho + \nabla_{\mathbf{x}} \cdot (\rho \mathbf{v}) = 0, \\ \partial_t \mathbf{v} + \mathbf{v} \cdot \nabla_{\mathbf{x}} \mathbf{v} = \mathbf{A}[\rho, \mathbf{v}], \end{cases} \quad (11)$$

where $\rho = \rho(\mathbf{x}, t)$ and $\mathbf{v} = \mathbf{v}(\mathbf{x}, t)$ are the crowd density and velocity, respectively; $\mathbf{x} = \{x, y\}$ and t are the space and time independent variables, respectively; $\mathbf{A}[\rho, \mathbf{v}]$ models the mean

acceleration and square brackets indicate that it may be a functional of its arguments; the *dot-product* denotes inner-product of vectors. The functional dependence of \mathbf{A} on its arguments is called a constitutive assumption. Different constitutive assumptions lead to different models, describing different actual situations. According to the specific constitutive assumption, models can be derived that involve only some of the two equations in (11), namely:

- First order models: only described by the first equation with a closure $\mathbf{v} = \mathbf{v}_e[\rho]$ that links the local velocity to the crowd density (e.g. [7]), where the subscript e refers to the equilibrium conditions;
- Second order models: obtained from both equations with the addition of a phenomenological relation that describes the psycho-mechanic action $\mathbf{A} = \mathbf{A}[\rho, \mathbf{v}]$ on the pedestrians, that is, the internal driving force or motivation of the pedestrian.

First order models First order models, which are reviewed in [75], need plugging experimental data into the model through the definition of a suitable closure equation. Different models can be proposed to describe the closure equation, which can be rewritten in the form:

$$\mathbf{v} = v[\rho]\mathbf{u}(\mathbf{x}), \quad (12)$$

where $\mathbf{u}(\mathbf{x})$ indicates a unit vector in the direction of \mathbf{v} . Three different models can be distinguished:

1. *Models of first kind.* They assume that the velocity is only a function of the local density, therefore $v(\rho)$ can be simply given by one of the speed-density relations discussed in §2.1. The pedestrians move from position P towards the target T , therefore the direction $\mathbf{u}(\mathbf{x})$ is given by:

$$\mathbf{u}(x, y) = \frac{\overrightarrow{T - P}}{|\overrightarrow{T - P}|}. \quad (13)$$

2. *Models of second kind.* They are based on the more realistic assumption that the pedestrians move towards the target with a speed that depends not only on the density but also on its gradient:

$$\mathbf{v} = v[\rho, \nabla \rho]\mathbf{u}(\mathbf{x}). \quad (14)$$

This can be achieved, for instance, by using an apparent density model [76] which is based on the concept that the pedestrians feel an apparent density ρ^* , which is larger than the real one, if the local density gradient is positive (trend to jam conditions), while it is smaller than the real one if the gradient is negative (trend to vacuum). The apparent density can be expressed in analogy with the De Angelis' proposal [77] for vehicular traffic as:

$$\rho^* = \rho [1 + \eta(1 - \rho)\nabla \rho \cdot \mathbf{u}], \quad (15)$$

where η is a positive parameter. Similar effects can be achieved through a non-local model, namely by introducing in the closure equation a space dislocation $\delta \geq 0$, as suggested in [76], so that $v = v[\rho(x + \delta, t)]$. From a phenomenological point of view, the dislocation length takes into account the non local and anisotropic pedestrian behaviour described in §2.1. A similar assumption has been made in [78] for a kinetic vehicular model, where δ is referred to as *visibility length*. A non-local crowd model has been

developed by the writers and coworkers in [18]. The space dislocation introduces in the mass conservation equation a diffusive term that has the effect of turning the hyperbolic equation into a parabolic one. The diffusive term prevents the occurrence of unrealistic shock wave phenomena, due to the fact that equilibrium conditions that correspond to a steady uniform flow are instantaneously imposed in unsteady out-of-equilibrium conditions.

3. *Models of third kind.* First-order models of crowds dynamics can be further improved observing that, in the reality, the pedestrians in a crowd do not follow a straight line towards their target. Rather, in their motion they try avoiding high density zones, in this way following minimum density paths. In this case, also the direction vector depends on the density ($\mathbf{u} = \mathbf{u}(\rho)$).

Second order models Second order models, which are reviewed in [24], need the description of the acceleration term $\mathbf{A}[\rho, \mathbf{v}]$. The acceleration can be viewed as the sum of two contributions:

$$\mathbf{A}[\rho, \mathbf{v}] = A_F[\rho, \mathbf{v}]\mathbf{u}(\mathbf{x}) + A_P[\rho, \mathbf{v}]\mathbf{u}(\mathbf{x}), \quad (16)$$

where A_F is the frictional acceleration, due to the adaptation to the mean flow velocity v_e in steady uniform flow condition, and A_P is the acceleration between pedestrians, due to the adaptation to local density gradients. For a complete review of the specific models that can be obtained from the above general expressions, the interested reader is addressed to [24, 73].

In conclusion, it should be kept in mind that the macroscopic description represents only a rough approximation of the physical reality, since the system under consideration does not satisfy the classical continuity assumption. The flow is in fact granular, which means that distances among pedestrians may not be negligible with respect to the length of the walkway, especially in low density regimes. Another drawback is that macroscopic models assume all pedestrians behaving in the same averaged way. On the other hand, these kinds of models allow a quite immediate application and are characterised by a lower computational complexity with respect to microscopic or kinetic models. Therefore, to the authors' opinion, they are suitable to be used when they have to be coupled with models describing mechanical systems, as in the case of crowd-structure interaction.

3.1.2 Mesoscopic or kinetic models

The so-called generalised kinetic models [73] describe the evolution of the probability distribution functions of the velocity and position of the pedestrians. The mathematical structure is given by a set of non-linear integro-differential equations of the type:

$$\partial_t f(\mathbf{x}, \mathbf{v}, t) + \mathbf{v} \cdot \nabla_{\mathbf{x}} f(\mathbf{x}, \mathbf{v}, t) = \mathcal{J}[f](\mathbf{x}, \mathbf{v}, t), \quad (17)$$

where $f(\mathbf{x}, \mathbf{v}, t)$ is the distribution function over the microscopic state, being \mathbf{x} and \mathbf{v} the position and velocity of the pedestrians at time t , and $\mathcal{J}[f]$ is an operator, in general non linear, which models the interactions among pedestrians.

The existing literature on the application of this approach to crowd dynamics is still in progress (e.g. in [80]). Guidelines and perspective ideas are reported in [73], where some kinetic models developed for vehicular traffic, such as the so-called *models with weighted binary interactions* [81] or *models with long range interaction*, are suggested as suitable to be adapted to pedestrian traffic since they include the concept of visibility zone.

3.1.3 Microscopic models

Microscopic models describe the dynamics of each single pedestrian under the action of the surrounding people. The state of the system is described by the position and velocity of each pedestrian as a function of time. Models developed at a microscopic scale are generally described by a system of ordinary differential equations (ODEs). The structure, analogous to that of Newtonian dynamics, is as follows:

$$\begin{cases} \frac{d\mathbf{x}_i}{dt} = \mathbf{v}_i, \\ \frac{d\mathbf{v}_i}{dt} = \mathbf{F}_i(\mathbf{x}_1, \dots, \mathbf{x}_N, \mathbf{v}_1, \dots, \mathbf{v}_N), \end{cases} \quad (18)$$

where $\mathbf{x}_i(t) = \{x, y\}_i$ is, for $i = 1, \dots, N$, the position in D of each i th individual of a crowd of N individuals; $\mathbf{v}_i(t) = \{v_x, v_y\}_i$ is the velocity of each person; t is the time independent variable; x and y are the space independent variables.

Different modelling approaches correspond to different ways of representing the acceleration term \mathbf{F}_i on the basis of the interpretation of individual behaviours. Among the different microscopic models that have been developed (e.g. [11]), it is worth citing the *social force models* (e.g. [9, 10, 82]), the *cellular automata models* (e.g. [83]) and the *magnetic force models* (e.g. [84]).

The solution of Eq. (18) provides the time evolution of position and velocity of pedestrians. Macroscopic quantities, such as density and mass velocity, are then obtained by suitable averaging processes performed either at fixed time over a suitable space domain or at fixed space over a suitable time interval.

The main critical aspects related to microscopic modelling consist in dealing with a large number of equations and in transferring the microscopic information to macroscopic quantities that can be observed or measured. Another issue that should be carefully considered is the heterogeneous behaviour of pedestrians, due to a change in the environmental conditions, such as the transition from normal to panic conditions.

3.2 Force models

A suitable load model should be defined in order to describe the external action that the pedestrians exert on the structure. Force models are generally classified into two main categories [85]: time domain and frequency domain force models. Time domain force models usually describe the pedestrian action as a periodic force: they can be deterministic, when a general model is proposed for each human activity (i.e. walking, running, jumping), or probabilistic, when they take into account the fact that most of the parameters that influence the human force (like body weight or walking frequency) are random variables that should be described in terms of their PDF. Assuming that the structure is a linear or linearized system, frequency domain force models could be alternatively proposed: they are based on the more realistic assumption that pedestrian loads are random processes and walking forces are represented by their PSD. This approach, which is widely used in earthquake engineering, represents a topical research axis in the case of the pedestrian vertical action [86, 87] but, to the authors' knowledge, it has never been directly applied to the SLE.

In the following, the attention will be focused on the time domain force models that have been proposed to describe the action of several pedestrians. Specifically, this section deals with those models that are specifically addressed to the SLE or that try to account for one or both

synchronisation phenomena (among the pedestrians and between the pedestrians and the structure), while a critical review extended also to vertical force models can be found in [61, 17].

Bearing in mind the observation scales introduced in 2.1, it is worth pointing out that most of the design-oriented compact force models come from empirical data obtained for the single pedestrian and hence the crowd force is obtained by multiplying the single pedestrian force by an equivalent number of pedestrians. The latter is usually estimated from observation of real crowd events and, according to the authors, it can be considered as an implicit way to tackle the scaling problem involved by passing from the microscopic to the macroscopic description.

Most of the load models proposed in literature are based on some common simplifying assumptions:

- the crowd-footbridge system is modelled as a structural oscillator to which some external load is applied, therefore the crowd is viewed as an imposed load, rather than as a dynamical system;
- the structural response is dominated by one mode, therefore the structure dynamics is described by the following equation of motion:

$$\ddot{p}_j(t) + 2\xi_j\omega_j\dot{p}_j(t) + \omega_j^2 p_j(t) = \frac{1}{M_{sj}} F_j(t), \quad (19)$$

where $p_j(t)$ is the principal coordinate of the j th mode, ξ_j is the j th modal damping ratio, $\omega_j = 2\pi f_{sj}$ is the j th natural circular frequency being f_{sj} the natural frequency, M_{sj} is the modal mass and $F_j(t)$ the modal force;

- the crowd is uniformly distributed along the footbridge span;
- the force is periodic and represented by a Fourier series [88, 89]. Usually only a single harmonic, having the same frequency as the footbridge frequency, is retained.

In order to give a homogeneous description of the selected models, a common notation is introduced. The percentage of synchronised pedestrians is generally indicated as S , while the nomenclature S_{ps} and S_{pp} is introduced when the authors explicitly refer to the synchronisation between the pedestrians and the structure or among the pedestrians, respectively.

Before focusing on the lateral force models, it is worth citing the Matsumoto et al.'s [44] model, firstly derived for bridges vibrating in the vertical direction, since it represents one of the first attempts to model the action of several pedestrians. Assuming that the number of pedestrians per second that enter the bridge follows a Poisson distribution and that they walk with the same frequencies and random phases, the total structural response can be obtained by multiplying a single pedestrian's response by the multiplication factor \sqrt{N} , where N is the number of pedestrians on the bridge at any time instant. Therefore, the force exerted by N pedestrians can be expressed as:

$$F(t) = \sqrt{N}\alpha G \sin(2\pi f_p t), \quad (20)$$

where α is the Dynamic Load Factor (DLF) - i.e. the ratio of the force amplitude to the weight G of a single pedestrian ($\bar{G} = 700N$) and f_p is the walking frequency. This model considers all pedestrians as uncorrelated, therefore it is not suitable for use in the presence of synchronisation phenomena due to lateral vibrations. In fact, the application of the model to estimate the structural response on SLE test-cases [65] significantly underestimated the measured lateral vibration amplitude.

The possibility of synchronisation among pedestrians due to high crowd density (0.6-1 ped/m²) is envisaged by Grundmann et al. [90]. Piccardo and Tubino [91] report a force model which interpret this assumption:

$$F(x, t) = S_{pp} \alpha m_c(x) g \sin(2\pi f_p t), \quad (21)$$

where g is the gravity acceleration and $m_c(x)$ is the distribution of crowd mass along the bridge. In case of uniform crowd distribution, $m_c(x)g = NG/L$. Grundmann et al. explicitly ascribe the synchronisation phenomenon to the constrained movement of pedestrians due to high crowd density: for this reason the S_{pp} notation is introduced in Eq. (21). It is worth pointing out that Grundmann et al. disregard the occurrence of crowd-structure synchronisation in the case of perceptibly moving surface: on one hand, the latter phenomenon was described for the first time in the same year by Fujino and co-workers [65] and, on the other hand, the clear distinction between the two kinds of synchronisation has been introduced later [85, 58, 59].

Since the observation of the first SLE occurrences, several models have focused the attention on the synchronisation between the pedestrians and the structure. They generally express the lateral force as a function of the structural response and assume that the pedestrians are synchronised to the structure (i.e. walk with the same frequency as the structure, that is, $f_{pl} = f_s$). Fujino et al. [65] adopted a model similar to Eq. (21), where a guess value of the DLF α has been assumed higher than the one measured on a motionless platform, in order to recover a good estimate of the structural response measured on the T-bridge. After the closure of the London Millennium Bridge and the field tests performed on it, Dallard et al. [1] observed a linear relationship between the lateral force and the local lateral velocity of the deck \dot{z} (Fig. 10), after the pedestrians had synchronised to the structure. Hence, the force exerted by N uniformly distributed pedestrians synchronised to the structure is empirically modelled as:

$$F(x, t) = k_1 \frac{N}{L} \dot{z}(x, t), \quad (22)$$

where the proportionality factor k_1 has to be determined experimentally and set equal to 300 Ns/m for the Millennium Bridge. Bearing in mind that the viscous damping force is proportional to the structural velocity as well as the pedestrian force, the moving pedestrians can be viewed as negative dampers (i.e. amplifiers), providing positive energy input in agreement with the phenomenological observation described in §2.2. If the magnitude of the structural damping force is lower than the one of the pedestrian force, the system is unstable, that is, the structural response tends to infinity for small perturbations. This is not in line with the actual self-limited nature of the force, discussed in §2.2. Another drawback of the model is that it describes the pedestrian action after the lock-in triggering, while it does not permit the pre-lock-in and triggering phases to be modelled. The Dallard et al.'s load model is well-suited to obtain a stability condition for the occurrence of SLE, based on the derivation of a critical number of pedestrians N_c that trigger the lock-in. The latter is derived by setting the equality between the structural modal damping force $2\xi_j \omega_j \dot{p}_j(t) M_{sj}$ and the pedestrian modal force $F_j(t)$, where $F_j(t) = \int_0^L F(x, t) \varphi_j(x) dx$, being L the span length and $\varphi_j(x)$ the mode shape. Other authors have proposed alternative stability criteria [56, 69, 92, 93], which are useful for design purposes, but out of the scope of this review.

Piccardo and Tubino [91] proposed a refinement of Eq. (21), by expressing the DLF α as a linear function of the footbridge lateral displacement z :

$$F(x, t) = S[\alpha + k_2 z(x, t)] m_c(x) g \sin(2\pi f_{pl} t), \quad (23)$$

where $k_2 \cong 2 \text{ m}^{-1}$ from the experimental data in [1]. Such a simple model allows to express the pedestrian force in both cases of motionless or moving platform accounting for the self-excitation mechanism. A single synchronisation coefficient S is introduced, which seems to include both kinds of synchronisation effects. This model shows the same shortcoming as the Dallard et al.'s model, that is, the linear dependence of the DLF on the structural response causes the force to have no upper limit when the pedestrian force is higher than the damping force.

Nakamura and Kawasaki [94] proposed an improvement of the Dallard et al.'s model, in order to account for the force self-limiting. The modal force is expressed as:

$$\begin{cases} F_j(t) = S_{ps} H(\dot{p}_j) k_3(f_{sj}) \alpha M_{pj} g, \\ H(\dot{p}_j) = \frac{\dot{p}_j(t)}{k_4 + |\dot{p}_j(t)|}, \end{cases} \quad (24)$$

where the DLF α is taken equal to 0.04 and M_{pj} is the modal mass of the pedestrians. The percentage of pedestrians synchronised to the structure S_{ps} is assumed equal to 0.2 from the laboratory tests of Dallard et al. [1]. The function $k_3(f_{sj})$ describes how pedestrians synchronise with the bridge natural frequency f_{sj} : the authors assume that "pedestrians are most likely to synchronise at the frequency around 1.0 Hz, but it is unknown how wide the bridge frequency range around 1.0 Hz affects the synchronisation nature", so that k_3 is set constant and equal to unit in absence of experimental data. The function $H(\dot{p}_j)$ describes the "pedestrians synchronisation nature": the authors assume that the pedestrians synchronise proportionally with the girder velocity at low velocity values, while, for higher values, the pedestrians feel uncomfortable or unsafe and they detune. The value of $k_4 = 0.01$ is determined by trial and error based on the T-bridge data. This model, in spite of its compact expression, provides a more accurate description of the pedestrian-structure synchronisation mechanism, which is recognised to be a function of both the deck velocity and the frequency detuning. A comparison between the force per person obtained with the models of Dallard et al. and Nakamura and Kawasaki is shown in Fig. 14.

Figure 14: Comparison between the models in [1] and [94]

The models described so far explicitly take into account only one of the two synchronisation phenomena. A more advanced model was proposed by Newland [69], who expressed the lateral load as the sum of two terms, the first representing the force exerted by pedestrians on a fixed

ground and the second being the component due to the deck lateral motion, under the hypothesis of small amplitudes of the deck motion ($z < 10$ mm):

$$F(x, t) = S_{pp}m_c(x)\ddot{z}_p(x, t) + S_{ps}\alpha_{ps}m_c(x)\ddot{z}(x, t - \tau), \quad (25)$$

where $z_p(x, t)$ is the displacement of the pedestrian's centre of mass on a fixed ground, α_{ps} is the ratio between the motion amplitude of the pedestrian's centre of mass and the platform (taken equal to $2/3$) and τ is the time lag between the motion of the pedestrian's centre of mass and pavement. Because of the lack of data, Newland assumes $S_{ps} = S_{pp} = S$ constant in time and space. The model has the merit of recognising the different contribution of the two kinds of synchronisation and of considering the time delay of the pedestrian reaction with respect to the structural response. On the other hand, Newland assumes that the presence of the pedestrians does not modify the structural modal properties, which is questionable in the case of high crowd to structure mass ratio.

A quite different approach to account for synchronisation phenomena in the force model has been proposed by Strogatz et al. [56]. The model is explicitly formulated in a microscopic framework, where the force exerted by N pedestrians is expressed as:

$$F(t) = \sum_{i=1}^N F_i = \alpha G \sum_{i=1}^N \sin \Theta_i, \quad (26)$$

where Θ_i is the phase of the i th pedestrian, viewed as a weakly-coupled limit-cycle oscillator, according to the Kuramoto model [55]. This model expresses the Winfree's intuition about collective synchronisation (§2.1) in the phase equation

$$\frac{d\Theta_i}{dt} = \omega_i + Kr \sin(\Psi - \Theta_i), \quad i = 1, \dots, N, \quad (27)$$

where Θ_i and ω_i are the phase and natural frequency of the i th oscillator, respectively; Ψ is the mean phase; the product Kr is the effective coupling, where K is the coupling strength and r the coherence. As the population becomes more coherent, the effective coupling increases and more oscillators are involved in the synchronisation process, that is, their phases Θ_i tend to the mean phase Ψ . In the Strogatz model, the bridge motion is assumed to alter the pedestrian's gait according to a modified version of Eq. (27):

$$\frac{d\Theta_i(t)}{dt} = \omega_{pi} + k_5 z(t) \sin(\Psi_s(t) - \Theta_i(t) + k_6), \quad (28)$$

where the walking circular frequencies ω_{pi} are distributed with a Gaussian PDF; k_5 models the pedestrian sensitivity to the bridge motion analogously to the coupling strength in the Kuramoto equation; $\Psi_s(t)$ is the phase of the footbridge vibration; k_6 is a phase lag parameter. The most valuable aspect of the model lies in its reference to a well-established research field about collective synchronisation, which recognises the SLE phenomenon among other well-known examples of synchronisation in physics of life. The main shortcoming is due to the difficulty in measuring the parameters k_5 , tuned according to the Millennium Bridge case study $k_5 \approx 16 \text{ m}^{-1}\text{s}^{-1}$, and k_6 , assumed equal to $\pi/2$. Moreover, this model does not account for the synchronisation among pedestrians induced by dense crowd. The same model has been rewritten by Bodgi et al. [95] in a macroscopic form and neglecting the phase lag parameter.

The load model proposed by the writing authors [96], unlike the ones previously described,

has been conceived within the framework of a crowd-structure interaction model (§3.3). In this perspective, the scaling problem has been explicitly considered in order to assure a consistent modelling scale. Specifically, the force model is based on a macroscopic description of crowd dynamics, which means that the crowd is characterised by its density, averaged walking velocity and step frequency. Both the two types of synchronisation and the contribution of the uncorrelated pedestrians are considered. Hence, the force per unit length exerted by the crowd walking along the bridge span is given by the sum of three components:

$$F(x, t) = F_{ps}(x, t) + F_{pp}(x, t) + F_s(x, t), \quad (29)$$

where F_{ps} is the term due to the synchronisation between the pedestrians and the structure, F_{pp} is due to the synchronisation among pedestrians and F_s is the part due to uncorrelated pedestrians. F_{ps} has the same frequency f_s as the excited lateral structural mode, while the other two terms have the same frequency f_{pl} as the lateral pedestrian footstep. f_{pl} is assumed to vary as a function of the walking velocity v according to Eq. (10). It is worth stressing that the pedestrians who walk with a step frequency equal to f_{pl} are the ones not synchronised to the structure, that is, they are not made sensitive to the deck lateral motion.

Each term of the overall force is weighted on the basis of phenomenological considerations, by means of three weights, N_{ps} , N_{pp} and N_s :

$$\begin{aligned} N_{ps} &= \rho B S_{ps}, \\ N_{pp} &= \rho B S_{pp} (1 - S_{ps}), \\ N_s &= \rho B - N_{ps} - N_{pp}, \end{aligned} \quad (30)$$

where the crowd density $\rho = \rho(x, t)$ is one of the state variables of the crowd system, B is the width of the footbridge walking path, S_{ps} and S_{pp} are the synchronisation coefficients, which both vary in the $[0, 1]$ range. It is worth pointing out that these weights can be viewed, at the microscopic scale, as the number of pedestrians that are synchronised with the structure, synchronised to each other and uncorrelated, respectively. Thanks to the distinction of pedestrians in three populations, the model is able to describe the triggering of lock-in: even though no one is synchronised to the structure, the presence of a high crowd density results in a lateral force that triggers the lateral vibration of the bridge.

The pedestrian-structure coefficient S_{ps} is a function of two variables: the envelope of the deck lateral acceleration time history $\tilde{z} = \tilde{z}(x, t)$ and the frequency ratio defined as $f_r = f_{pl}/f_s$. The variation of S_{ps} versus \tilde{z} is given by means of the piecewise function:

$$S_{ps}(\tilde{z}) = \begin{cases} 0 & \tilde{z} \leq \tilde{z}_c, \\ 1 - e^{-b(\tilde{z} - \tilde{z}_c)} & \tilde{z} > \tilde{z}_c, \end{cases} \quad (31)$$

where the second branch is obtained from a fitting of the Dallard et al.'s experimental data [1], with $b = 2.68$. Pedestrians start to synchronise with the structure for values of \tilde{z} higher than a critical acceleration value \tilde{z}_c , and everyone is synchronised when \tilde{z} reaches the maximum value \tilde{z}_M . $S_{ps}(f_r)$ is supposed to have a Gaussian distribution, with a variance that grows when \tilde{z} increases:

$$\begin{aligned} S_{ps}(f_r) &= e^{[-\eta(f_r - 1)^2]}, \\ \eta(\tilde{z}) &= 50e^{(-20\tilde{z}/\pi)}. \end{aligned} \quad (32)$$

This means that, for increasing values of the deck vibration, the pedestrians who walk with a step frequency that is different from f_s gradually become involved in the synchronisation

phenomenon. For $\tilde{z} = \tilde{z}_M$, everyone is synchronised to the structure, whatever the value of f_r . This assumption is in agreement with Fig. 12: in case of large frequency detuning, pedestrians synchronise only for high values of the driving force amplitude, that is, for high values of the deck lateral acceleration. The synchronisation coefficient $S_{ps}(\tilde{z}, f_r)$ is given by the product of Eq.s (31) and (32). It is worth pointing out that the proposed form of S_{ps} can be compared to the product $S_{ps}H(\dot{p}_j)k_3(f_{sj})$ in the Nakamura and Kawasaki's model (Eq. (24)).

The coefficient S_{pp} represents the degree of synchronisation among pedestrians and has been derived through a fitting of the experimental data in [5, 52], concerning standard deviation of walking frequencies as a function of the crowd density [97]. The fitting function is inspired to the trend of the coherence against the coupling strength in the Kuramoto model [55] (see Fig. 7): the coherence (i.e. S_{pp} herein) is null until the coupling strength (i.e. ρ herein) reaches a threshold value (ρ_c), which corresponds to a phase transition; for $\rho < \rho_c$ the coherence grows towards perfect synchronisation. S_{pp} is therefore expressed as:

$$S_{pp}(\rho) = \begin{cases} 0 & \rho \leq \rho_c, \\ 1 - e^{a(\rho - \rho_c)} & \rho > \rho_c, \end{cases} \quad (33)$$

where $a=8.868$ and ρ_c is set equal to 0.6 ped/m^2 [97]. The synchronisation coefficients S_{ps} and S_{pp} can be viewed, in a statistical framework, as cumulative density functions of an exponential and a Gaussian PDF, respectively.

Hence, the components of the total force are expressed as follows:

$$F_{ps} = N_{ps}G[\alpha(\tilde{z})\sin(2\pi f_s t + \pi) + \alpha(\tilde{z})\cos(2\pi f_s t)], \quad (34)$$

$$F_{pp} = N_{pp}\alpha G \sin(2\pi f_{pl} t), \quad (35)$$

$$F_s = \sqrt{N_s}\alpha G \sin(2\pi f_{pl} t). \quad (36)$$

The F_{ps} component is written, according to Pizzimenti [57], as the sum of a component 180° out-phase of the acceleration and another in-phase with the lateral velocity. The DLF of the two components are expressed as piecewise functions of the envelopes of the deck lateral acceleration and velocity time history $\tilde{z} = \tilde{z}(x, t)$ and $\dot{\tilde{z}} = \dot{\tilde{z}}(x, t)$, respectively. Their detailed description can be found in [98]: herein it is worth pointing out that their trend comes from a fitting to experimental data for moderate deck vibration and guarantees that the amplitude of F_{ps} is self-limited for higher values of the deck motion. The last feature aims at reaching the same objective as in Nakamura and Kawasaki's model, even though through a different modelling approach. The expressions of F_{pp} and F_s are inspired to the models of Grundmann et al. (Eq. 21) and Matsumoto et al. (Eq. 20), respectively. Nevertheless, it is worth recalling that these two force components vanish in congested traffic condition, due to the dependence of the walking frequency on the crowd velocity v , which is in turn dependent on the crowd density ρ (Eq. 4).

With respect to the previously described force models, the last one is based on the phenomenological description of the components of the coupled crowd-structure system in their fundamental constitutive laws, rather than being empirically derived from a single case study. This feature is expected to assure a more general applicability, as shown in [96], where the model is applied to two real cases. Moreover, this model allows several features of the SLE to be accounted for: the dependence of the pedestrian force on the state variables of crowd and structure systems, namely the crowd density and footbridge lateral response; the possibility of a inhomogeneous distribution of the crowd along the deck; the existence of two kinds of synchronisation; the presence of different frequency components in the overall force; triggering of the lock-in phenomena and the resulting self-limited oscillations. On the other hand, some

shortcomings should be highlighted: the validity of the basic modelling assumptions expressed in Eq.s (29,30) should be demonstrated; the model is less design-oriented than the previous ones, which have the merit of being expressed by very compact formulas; the introduction of a greater amount of constitutive laws, with respect to the previous compact models, makes it more expensive its validation since several parameters have to be experimentally measured; many of the introduced fundamental laws are expressed in a qualitative way, due to the uncomplete knowledge of the synchronisation mechanisms that drive the SLE and the scarce availability of experimental data. This latter drawback is common to all the reviewed models and makes it difficult both the modelling and the tuning of the introduced parameters.

Finally, it should be reminded that all the reviewed models neglect both the inter-subject and intra-subject variability [99]: this means that, on one hand, all the pedestrians are supposed to exert the same dynamic force and, on the other, that each feet of a single pedestrian produce exactly the same periodic force (deterministic models). These two features could be taken into account by introducing a probabilistic approach, analogously to what proposed in recent codes of practice [5, 4, 100] for both vertical and lateral action of pedestrians not synchronised to the structure: in other words, the parameters that mainly affect the human load (walking frequency, step length, dynamic load factors) are random variables and should be expressed in probabilistic terms.

3.3 Crowd-Structure Interaction models

To the authors' knowledge, the first attempt to propose a crowd-structure interaction model was made by the writing authors in [59, 101], successively developed in [42, 79] and recently adopted by other authors [102, 95] with slightly different formulation of the subsystem models. The framework is based on the so-called *partitioned approach*, which was first proposed by Park and Felippa [103, 104] and is widely used to model multi-physic coupled systems in the aerospace, mechanical and civil engineering fields, e.g. in fluid-structure interaction. According to this approach, systems are analysed through decomposition or partitioning, which is the process of spatial separation of a system into interacting components, called *partitions* or *fields*. One of the main advantages of the partitioned approach is the possibility to separately model each part of the system and to solve it with the most suitable numerical procedures. In such a way, each system component can undergo successive improvements as soon as new experimental data and modelling strategies become available. Furthermore, new components that account for emerging features of the phenomenon can be easily added to the original framework. In the case of crowd-structure interaction, the coupled system is decomposed into two physical subsystems, the Structure (S) and the Crowd (C), which interact between each other by means of forcing terms. In the following, each part of the model is described referring to the framework schematised in Fig. 15.

The Structure subsystem is modelled as a non-linear 3D damped dynamical system, whose equation of motion can be written as:

$$[m_s + m_c(\rho)] \partial_{tt} \mathbf{d} + \mathcal{C} [\partial_t \mathbf{d}] + \mathcal{L} [\mathbf{d}] = F(\rho, \tilde{z}), \quad (37)$$

where $\mathbf{d} = \mathbf{d}(\mathbf{x}, t)$ is the structural displacement, $\mathbf{x} = \{x, y, z\}$ and t are the space and time variables, m_s is the structural mass, m_c is the crowd mass, \mathcal{C} and \mathcal{L} are the damping and stiffness operators, respectively, and $\tilde{z} = \tilde{z}(x, t)$ is the envelope of the lateral acceleration of the deck. Eq. (37) is non-linear for two reasons: first, the forcing term F is a function of both the crowd density and the lateral acceleration of the deck; second, the overall mass m is given by the sum of the structure and the crowd mass. The latter derives from the solution of the PDE

Figure 15: Framework of the time-domain coupled model

that governs the Crowd subsystem, in turn dependent on the solution of Eq. (37).

The crowd is described through a first order hydrodynamic model in the one-dimensional (1D) spatial domain. Even though crowd modelling is usually developed in 2D spatial domain, the mono-dimensional representation is more suitable to describe the phenomenon of interest, that is, dense crowd crossing footbridges, as already highlighted in §2.1. In addition, in spite of the coarse approximation of physical reality implied by the use of first order models, a relatively simple model is preferable to study the complexity of the crowd-structure coupled system. It follows that the reference framework describing the crowd dynamics is given by the 1D mass conservation equation in its Eulerian dimensional form, closed by a phenomenological relation (the closure equation) that links the mean velocity v to the mass density ρ and the lateral acceleration of the deck \ddot{z} :

$$\begin{cases} \partial_t \rho + \partial_x (\rho v) = 0, \\ v = v[\rho, \ddot{z}]. \end{cases} \quad (38)$$

The Structure-to-Crowd action is, therefore, expressed through the dependence of the walking velocity on the platform acceleration. Specifically, the pedestrians are assumed to adjust their step to the deck motion with a synchronization time delay τ , which is expected to be greater than the time interval between two succeeding steps ($\tau \geq 1/f_{pl}$). Therefore, bearing in mind that the pedestrians react to what they see in a suitable stretch of walkway in front of them (§3.1.1), both a space dislocation δ and a time delay τ are introduced in the closure equation:

$$v = v[\rho(x + \delta, t)] g[\ddot{z}(x, t - \tau)], \quad (39)$$

where the first term $v(\rho)$ is the speed-density relation of Eq. (4), and the second term $g(\ddot{z})$ is a slowing function that takes into account the sensitivity of v to the deck acceleration. The latter has a qualitative trend because of the lack of experimental data and is based on the following hypotheses:

- below the threshold of motion perception \ddot{z}_c , the pedestrians are not affected by the platform acceleration;
- the lateral motion of the deck reduces the walking velocity;
- after the pedestrians have stopped because of excessive lateral acceleration \ddot{z}_M at time t_s , a stop-and-go time interval Δt_r should elapse before they start walking again.

It follows:

$$g(\ddot{z}) = \begin{cases} 1 & \ddot{z} \leq \ddot{z}_c \cap t \geq t_s + \Delta t_r, \\ (\ddot{z}_M - \ddot{z}(x, t - \tau)) / (\ddot{z}_M - \ddot{z}_c) & \ddot{z}_c < \ddot{z} < \ddot{z}_M \cap t \geq t_s + \Delta t_r, \\ 0 & \ddot{z} \geq \ddot{z}_M \cap t_s < t < t_s + \Delta t_r, \end{cases} \quad (40)$$

where $\ddot{z}_c \cong 0.2 \text{ m/s}^2$ [105] and $\ddot{z}_M = 2.1 \text{ m/s}^2$ [62].

As far as the Crowd-to-Structure action is concerned, the scheme in Fig. 15 shows that it takes place in two ways. On one hand, the mass m is constantly updated by adding the pedestrian mass m_c to the structural mass m_s ; on the other hand, a force model is proposed to determine the lateral force exerted by pedestrians on the footbridge deck [96]. The force model is the one described in §3.2 from Eq.s (29) to (36), with the following peculiarities: the space distribution of the crowd density along the bridge in any time instant is determined through the solution of Eq. (38); all the variables describing the deck motion that are introduced in the force model equations refer to the time $t - \tau$.

Further developments to this approach to crowd-structure interaction, together with proper numerical solution techniques, could provide a complementary tool to the experimental approach and a useful research tool to validate simplified load models, to reproduce the conditions of in situ tests with lower costs, to simulate scenarios which are difficult to reproduce in full scale, to simulate expected real events and to highlight emergent phenomena.

4 CONCLUSIONS

In this paper a review of the state of the art concerning the phenomenological analysis and modelling of the SLE has been proposed. Due to the multi-scale and multi-physic features of the involved complex phenomena, several scientific fields have been investigated, from biomechanics to structural engineering, from applied mathematics to transportation engineering.

The review has highlighted the still uncomplete knowledge of the mechanisms that drive the SLE, namely the synchronisation phenomena, the dependence of the force exerted by the pedestrians on the structural response, the triggering of the lock-in and the force self-limitation. The importance of a multidisciplinary approach has been outlined in this review, since many interesting suggestions can come from different research fields. Moreover, further experimental campaigns are needed in order to improve the comprehension of the phenomenon, to develop reliable models and to tune the existing ones.

As for the modelling of the parts of the complex crowd-structure system, the structural dynamic models are well-established in literature and widely applied in practice. The situation is different for the crowd models. Three modelling frameworks can be found in literature on the basis of the different observation scales (macro, meso, microscopic), but none of them have so far proved to be the most suitable to describe pedestrian traffic dynamics. The main drawback related to macroscopic models lies in the continuity assumption, which does not hold in case of very low density. On the other hand, microscopic models require handling a large number of model free parameters and equations. A further possibility for future research developments could be the proposal of a hybrid multi-scale approach: the latter could be based on the space and time combination of a microscopic description of the pedestrians in low density regime, through discrete models, with a macroscopic description of the dense crowd, through continuous first or second order models. In this framework, the hybrid approach would be dynamic, in the sense that the switch from one description to the other depends on the time and space evolution of the crowd density, that is, one of the crowd subsystem state variables. In general terms, this approach could be addressed to cope with the difficulty to describe the transition from individual to collective behaviour. Some suggestions in this direction can be found in the approach proposed in [106].

As far as the force models are concerned, the main deterministic time-domain load models specifically addressed to SLE have been reviewed. The difficulty in coupling the need for synthetic formulas to be used in design practice and the accuracy in the description of all the

involved phenomena emerges from the review. On one hand, the compact models are not able to account for many of the SLE main features and are often tuned on a specific as-built structure; on the other hand, the load models proposed to tackle the above mentioned shortcomings are more demanding to be validated, due to the large number of constitutive laws introduced, and to be applied for engineering purposes. The difficulty in proposing a reliable load model for SLE is mainly related to the still uncomplete knowledge of the phenomenon. Most of the presented models can be ascribed to a macroscopic description, where inter-subject and intra-subject variability are neglected and all pedestrians are assumed to behave in the same averaged way. This assumption, which is very practical for engineering purposes, is now considered by several authors as not suitable to represent the actual nature of the pedestrian load. Therefore, a probabilistic approach to SLE could be developed.

Finally, the modelling framework proposed by the authors to develop a crowd-structure interaction model on the basis of the partitioned approach has been presented. The approach main advantage lies in the possibility to separately model each system components, which can be characterised to solve a particular problem. In the specific case dealt with in this paper, the framework has been adapted to describe the SLE phenomenon on footbridges. Both the crowd system and the interacting terms have been modelled within a macroscopic description. Even if a macroscopic approach seems more suitable in view of its practical application since it provides synthetic results on the crowd state, the coupling between the structural dynamics and a microscopic crowd modelling could be envisaged for future research perspectives. As for the interacting terms, the general framework could be improved by including new components that should account for some features so far not considered. Among others, the effects of the deck slope on the crowd dynamics is of interest due to the frequent use in civil engineering of structural types (arch structures, cable structures), which imply a deck with variable slope. The effects due to the presence of obstacles could also be modelled, since obstacles can be included in the footbridge design for architectural reasons (such as benches or lighting systems) or their presence could be used to allow control strategies of the pedestrian flow and, in turn, of the structural response.

Keywords: Vortex-induced vibration, nonlinear dynamics, wake oscillator, frequency dependent coupling, fluid-structure interaction.

Abstract. *The aim of this paper is to improve the wake oscillator concept for the modeling of vortex-induced vibration of an elastically mounted cylinder in a fluid flow. To this end an attempt is made to introduce a coupling term in the wake oscillator model, that is based on a set of frequency dependent coefficients. Theoretically, it should be possible to determine these coefficients on the basis of so-called forced vibration measurements. In doing so a number of challenges are encountered. A consistent set of frequency dependent coefficients should conform to the forced vibration experiments at all amplitudes of cylinder motion and additionally it should satisfy the Kramers-Kronig relations. It has been found that it is not possible to find a set of frequency dependent coefficients with the wake oscillator model at hand that satisfies these requirements. The sensitivity of the frequency dependent coefficients to the presence of the dominant non-linearity in the wake oscillator at hand has been examined. On the basis of this analysis a new form for the wake oscillator model has been proposed.*

1 INTRODUCTION

1.1 Vortex-induced vibration

Flow over a bluff cylinder separates and vortices are formed in the wake behind the cylinder. The alternate shedding of these vortices results in an oscillating cross-flow force on the cylinder. The shedding frequency of the vortices follows the Strouhal relation and increases with increasing flow velocity. If the cylinder is mounted flexibly and the frequency of vortex shedding is close to the resonance frequency of the mounted system, the cylinder will start to vibrate in cross-flow direction. With an increase of the flow velocity the vortex shedding frequency does no longer follow the Strouhal relation, but *locks onto* the resonance frequency of the cylinder, thereby causing violent vibration of the cylinder over a wide range of flow velocities. This phenomenon is known as vortex-induced vibration (VIV). The occurrence of VIV can cause severe fatigue problems for long cylindrical structures that are exposed to air or water flow such as chimneys, railroad contact wires, the cables of stay bridges and free-hanging offshore pipelines. Recent reviews on VIV have been given by Sarpkaya [1] and Williamson and Govardhan [2].

1.2 VIV experiments

Vortex-induced vibration experiments on rigid, spring mounted cylinders can be divided into two groups, the so called *free* and *forced vibration* experiments. In a typical free vibration experiment a flexibly mounted rigid cylinder is placed in a wind tunnel or water channel. For a range of flow velocities V , the amplitude \hat{y} and the frequency $f_c = \omega_c/(2\pi)$ of cylinder motion are measured. Results of two free vibration experiments performed by Khalak and Williamson [3] are plotted in Figs. 1 and 2. In these figures the flow velocity has been made non-dimensional by dividing it by the natural frequency of the spring mounted cylinder f_n and by the cylinder diameter D , that is, $V_n = V/f_n/D$. The frequency f_n is given by: $f_n = \sqrt{k/m}$, in which k is the spring stiffness of the mounted system and m the cylinder dry mass.

Figure 1: Amplitude and frequency of cylinder motion from the measurements of Khalak et al. [3] for $m^* = 2.4$.

Figure 2: Amplitude and frequency of cylinder motion from the measurements of Khalak et al. [3] for $m^* = 20.6$.

The amplitude plot in Figs. 1 and 2 consists of three distinct branches, the initial, upper and lower branch, that have been marked IB, UB and LB, respectively. In the upper branch the frequency of vortex shedding f_s is very close to the natural frequency of the mounted cylinder, resulting in the cylinder motion with the largest amplitude. The frequency of vortex shedding is given by the Strouhal relation $f_s = St \cdot V/D$, in which St denotes the Strouhal number. The upper branch is found for $f_s \approx f_n$ and since $St \approx 0.2$, this takes place when $V_n \approx 1/St \approx 5$. In the lower branch the amplitude of cylinder motion is constant over a range of flow velocities. The vortex shedding frequency is locked-in with the frequency of cylinder motion. The width of the lock-in range is dependent on the mass ratio m^* , see Figs. 1 and 2. For lower mass ratios the lock-in range is wider. The mass ratio is defined as the ratio of the cylinder mass and the mass of the displaced fluid: $m^* = 4m/(\pi\rho D^2 L)$, in which ρ denotes the density of the fluid and L the length of the cylinder.

Whereas in free vibration experiments, the coupled cylinder-fluid system sets its own frequency and amplitude, in forced vibration experiments amplitude and frequency are forced onto the system. In these experiments a cylinder is placed in a flow while it is at the same time being forced to vibrate sinusoidally in cross-flow direction with an amplitude \hat{y} and a frequency $f_c = \omega_c/(2\pi)$. Typically the fluid force on the cylinder in cross-flow direction $F_y^y = \frac{1}{2}\rho D V^2 L C_y^y$ and in in-line direction $F_x^y = \frac{1}{2}\rho D V^2 L C_x^y$ are measured. In our notation C_y^y and C_x^y denote the non-dimensional fluid forces. To prevent confusion the following notation will be used consistently:

- A subscript 'x' or 'y' denotes the direction in which the fluid force is measured.
- A circumflex '^' denotes an amplitude or a processed coefficient.
- A superscript 'x' or 'y' denotes the direction in which the cylinder is forced to vibrate in the forced vibration experiment. A superscript '0' denotes a stationary cylinder.
- A second subscript '0', '1', '2', etc. denotes the harmonic component for which the Fourier coefficient of the forced vibration time series has been determined.

Figure 3: The cross-flow fluid force component in-phase with the cylinder acceleration from the measurements of Gopalkrishnan [4, 5].

Figure 4: The cross-flow fluid force component in-phase with the cylinder velocity from the measurements of Gopalkrishnan [4, 5].

In Fig. 3 and 4, some of the results of the forced vibration measurements of Gopalkrishnan are depicted. These results have been reported in his PhD thesis [4], as well as in [5]. Gopal-

krishnan measured the fluid forces on a cylinder that was pulled through a water channel and at the same time was forced to vibrate in cross-flow direction. The motion of the cylinder is given by:

$$y = \hat{y} \sin(\omega_c t) \quad (1)$$

Among other results he reported in his thesis, for a range of forced amplitudes and forced frequencies, the constant fluid force coefficient in x-direction \hat{C}_{x0}^y and the fluid force coefficient at the first harmonic in y-direction \hat{C}_{y1}^y . He decomposed \hat{C}_{y1}^y in a part in-phase with the cylinder acceleration (or in anti-phase with the cylinder displacement): \hat{C}_{y1a}^y , depicted in Fig. 3, and a part in phase with the cylinder velocity: \hat{C}_{y1v}^y , depicted in Fig. 4. The flow velocity in Figs. 3 and 4 is made non-dimensional by dividing it by the cylinder diameter and the frequency of forced vibration: $V_c = V/f_c/D$. Approximating C_y^y with only the first Fourier component, results in:

$$\begin{aligned} C_y^y &\approx \hat{C}_{y1}^y \sin(\omega_c t + \varphi) = \hat{C}_{y1}^y \cos(\varphi) \sin(\omega_c t) + \hat{C}_{y1}^y \sin(\varphi) \cos(\omega_c t) \\ &= \hat{C}_{y1a}^y \sin(\omega_c t) - \hat{C}_{y1v}^y \cos(\omega_c t) \end{aligned} \quad (2)$$

1.3 Semi-empirical modeling of VIV

For the description of VIV engineers rely mainly on semi-empirical models, as Computational Fluid Dynamics (CFD) codes are still computationally too expensive for the determination of fluid forces on long cylinders such as the vertical riser pipelines at sea, that are being used in the offshore oil industry. These risers can have unsupported lengths of up to 2000 meters.

The semi-empirical models can be divided into two types. The first type of semi-empirical modeling consists of applying the fluid forces measured in forced vibration experiments directly on the right-hand side of the structural equation of motion. As the force coefficient \hat{C}_{y1v}^y is in phase with the cylinder velocity, it acts as an added damping force. So in this model cylinder motion is possible when $\hat{C}_{y1v}^y < 0$. Since it is not known in advance with which amplitude and frequency the cylinder will vibrate and hence which values of \hat{C}_{y1a}^y and \hat{C}_{y1v}^y from the measurements have to be taken, an iterative procedure is needed. The drawback of this method is that it relies on the assumption that there will be a dominant mode of vibration, as the measurements that are being used have been carried out at a single frequency of forced vibration. This assumption is questionable in the case of very long pipes, such as the deepwater risers mentioned before. These pipes have a dense spectrum of resonance frequencies and will vibrate in a combination of several modes together. The presence of a sheared incoming flow will increase the complexity of finding the dominant modes even further.

The second type of semi-empirical model is the so-called oscillator model. In this type of model, the oscillating lift force is modeled by a non-linear oscillator equation, which contains a limit cycle, so that for a stationary cylinder an oscillating lift force is found. Oscillator equations that are commonly used are the Van der Pol equation and the Rayleigh equation. A Van der Pol equation that could be used is:

$$\ddot{C}_y + \varepsilon \omega_s \dot{C}_y \left(C_y^2 - \frac{1}{4} \hat{C}_{y1}^2 \right) + \omega_s^2 C_y = A \frac{\ddot{y}}{D} + \omega_s B \frac{\dot{y}}{D}, \quad (3)$$

where \hat{C}_{y1}^0 is the amplitude of the limit cycle of the unforced oscillator, which should be equal to the cross-flow fluid force coefficient at the first harmonic on a stationary cylinder, $\omega_s = 2\pi f_s$ is the vortex shedding frequency, ε is a non-dimensional tuning parameter and overdots denote derivatives with respect to time t . The right-hand side of eq. (3) models the coupling between the structural displacement y and the fluid and contains the constant non-dimensional coupling coefficients A and B .

When the model predictions are compared with free vibration experiments, it is found that the oscillator model can produce acceptable results for structures experiencing VIV in air, in which the mass ratio of the structure and the surrounding fluid is high. A major drawback of most of the existing oscillator models is however that they do not scale correctly with the mass ratio and the damping ratio of the structure and the surrounding fluid. This means that these models have to be tuned separately for every possible combination of mass and damping ratio. This severely limits the predictive capabilities of these models. Moreover, existing oscillator models are not capable of describing the amplitude branches as found in the free vibration experiments at low mass ratios and hence underpredict the amplitude of the upper branch. Because of these shortcomings oscillator models are seldom used for engineering applications.

Oscillator models do have the favorable characteristic that they do not require an assumption of a dominant frequency. They consist of a system of coupled differential equations that can simply be solved in the time domain without any initial guess of frequency or amplitude. An oscillator model that can produce acceptable results over a range of mass and damping ratios on the basis of one set of tuning parameters, could therefore be useful as an engineering tool as it can deal with motion at multiple frequencies in a computationally inexpensive manner.

In [6], we have improved the existing oscillator model of Facchinetti et al. [7] by taking account of the relative velocity between cylinder and fluid. Subsequently, we tried to improve this model by making the coupling coefficients A and B frequency dependent by means of introducing a convolution integral into the time-domain model. We strived to derive a model that scales correctly with mass ratio, can describe the results of the forced vibration measurements and can describe the upper and lower branch of free vibration. We found, however, that with using a Van der Pol or Rayleigh equation and by trying to determine the frequency dependencies of A and B on the basis of the forced vibration measurements of Gopalkrishnan, we could not find a set of consistent frequency dependencies that could be used to determine the convolution kernel that is needed. The frequency dependencies appeared to be very sensitive to the non-linearities that are present in the model.

1.4 Objective of this paper

In this paper we will give a description of the challenges that are associated with the inclusion of a frequency dependent coupling between wake and structural oscillator. Specifically, we will focus on the sensitivity of the frequency dependencies to the presence of the non-linearity in the wake oscillator. On the basis of the results, we will make a first attempt at improving the existing model.

In Section 2, the wake oscillator model that will be used is discussed and the derivations that are needed, to include frequency dependent coupling coefficients in the wake oscillator, are given. In Section 3, the frequency dependent coefficients A and B are determined and the sensitivity of these coefficients to the presence of the non-linearity in the wake oscillator is investigated and on the basis of the results of this, in Section 4 a new wake oscillator model is proposed. The conclusions are presented in Section 5.

2 WAKE OSCILLATOR MODEL WITH FREQUENCY DEPENDENT COUPLING

2.1 The wake oscillator model

The wake oscillator model that will be used is based on the model of Facchinetti et al. [7] with the additional inclusion of the relative velocity between moving cylinder and fluid. Details of the model are given in [6]. The structural equation of motion is given by:

$$m\ddot{y} + b\dot{y} + ky = F_y, \quad (4)$$

in which b denotes the structural damping coefficient. The cross-flow fluid force F_y is assumed to consist of a part due to vortex shedding F_{VY} and a part due to potential added mass F_{AY} :

$$F_y = F_{VY} + F_{AY} = \frac{1}{2} \rho D V^2 L C_{VY} - m_a \ddot{y} \quad (5)$$

The potential added mass m_a is given by: $m_a = \hat{C}_a \pi \rho D^2 L / 4$, in which the potential added mass coefficient \hat{C}_a has the value of 1.0. In [6] we have assumed that the non-dimensional cross-flow vortex force C_{VY} consists of a component C_{VD} in-line with the relative velocity $U = \sqrt{V^2 + \dot{y}^2}$ between moving cylinder and incoming flow and a component C_{VL} perpendicular to this relative velocity:

$$C_{VY} = (C_{VD} \sin \beta + C_{VL} \cos \beta) \frac{U^2}{V^2} \quad (6)$$

The angle β is the angle between the direction of the relative velocity and the horizontal. See Fig.5. It is given by:

$$\begin{aligned} \beta &= -\arctan(\dot{y}/V), \quad \sin \beta = -\dot{y}/U = -\dot{y}/\sqrt{V^2 + \dot{y}^2}, \\ \cos \beta &= V/U = V/\sqrt{V^2 + \dot{y}^2} \end{aligned} \quad (7)$$

Figure 5: Definition of the angle and the decomposition of the vortex fluid force in drag, lift, horizontal and vertical direction

To complete the model description, the vortex force components C_{VD} and C_{VL} have to be defined. In [6] we have made the assumption that C_{VD} is constant and is equal to the mean drag force on a stationary cylinder and that C_{VL} can be calculated with a Van der Pol equation:

$$C_{VD} = \hat{C}_{x0}^0 \quad (8)$$

$$\ddot{C}_{VL} + \varepsilon \omega_s \left(C_{VL}^2 - \frac{1}{4} (\hat{C}_{y1}^0)^2 \right) \dot{C}_{VL} + \omega_s^2 C_{VL} = \left(\frac{A}{D} \ddot{y} + \frac{B}{D} \omega_s \dot{y} \right) \cos \beta \quad (9)$$

The right-hand side of eq. (9) contains an acceleration coupling $A\ddot{y}$ and a velocity coupling $B\dot{y}$. Facchinetti et al. [7] have compared the differences on the free vibration modeling of using acceleration, velocity and displacement couplings and found that an acceleration coupling gave the best results. We have included the velocity coupling in eq. (9) for completeness, so that we have a coupling term $A\ddot{y}$ in (anti-)phase with the cylinder motion and a coupling term $B\dot{y}$ out-of-phase with the cylinder motion.

The constant coupling coefficients A and B will be made frequency dependent in Section 3. To this end we have pretuned the model to the free vibration measurements of Khalak et al. There are two ways to pretune the model. The first is to tune the model to the upper branch of free vibration and hope that by including the frequency dependencies the lower branch of free vibration can be described as well and the second way is to tune the model to the lower branch and hope that by including the frequency dependencies the upper branch can be described as well. We will call the first option *Case U* and the second one *Case L*. The values for the force coefficients \hat{C}_{x0}^0 and \hat{C}_{y1}^0 and the Strouhal number have been taken from the measurements of Gopalkrishnan.

To pretune the model, the coupled system consisting of the wake and structural oscillators, given by eq. (4) and (9) has been solved in the time domain with a fifth order Runge-Kutta routine. The initial conditions that have been used are $y(0) = \dot{y}(0) = \dot{C}_{VL}(0) = 0$ and $C_{VL}(0) = 0.01$. After a few periods of calculation the steady state is reached and the amplitude of cylinder motion has been determined by searching for the maximum recurring displacement and the frequency of cylinder motion has been determined by searching for the highest peak in the Fourier spectrum of the cylinder displacement. The results of the pretuning are presented in Figs. 6 and 7. In these figures solid lines depict results for increasing flow velocity and dashed lines results for decreasing flow velocity. The tuning parameters for the two cases are:

Case U:	Case L:	
$\hat{C}_{x0}^0 = 1.1856$	$\hat{C}_{x0}^0 = 1.1856$	
$\hat{C}_{y1}^0 = 0.3842$	$\hat{C}_{y1}^0 = 0.3842$	
$St = 0.1932$	$St = 0.1932$	(10)
$A = 4.0 \cdot \frac{\hat{C}_{y1}^0}{2} = 0.7684$	$A = 12.0 \cdot \frac{\hat{C}_{y1}^0}{2} = 2.3052$	
$B = 0$	$B = 0$	
$\varepsilon = 0.05 \cdot \left(\frac{2}{\hat{C}_{y1}^0} \right)^2 = 1.3549$	$\varepsilon = 0.7 \cdot \left(\frac{2}{\hat{C}_{y1}^0} \right)^2 = 18.9690$	

Figure 6: Pretuning of the wake oscillator model to the measurements of Khalak et al. [3] for $m^* = 2.4$.

Figure 7: Pretuning of the wake oscillator model to the measurements of Khalak et al. [3] for $m^* = 20.6$.

2.2 Derivation of frequency dependent coupling

We strive to improve the wake oscillator presented in Section 2.1, by making the coupling coefficients functions of the cylinder frequency of vibration. These frequency dependent coefficients will be denoted by \tilde{A} and \tilde{B} for the moment. They will be determined over a range of cylinder frequencies on the basis of the forced vibration experiment of Gopalkrishnan, as will be explained in Section 3.1. The problem that is then encountered, is that if the coupled system consisting of the structural and wake oscillator is solved in the time domain, it is not known which values of the frequency dependent coefficients should be used, as the frequency of cylinder motion is not known in advance. The coupling term on the right-hand side of eq. (9) should therefore be replaced by a convolution integral. It is thus needed to derive the relation between the frequency dependent coefficients and the kernel of the convolution integral. To simplify the derivations, non-dimensional time $\tau = \omega_s t$ and non-dimensional cylinder frequency $\Omega_c = \omega_c / \omega_s$ are introduced. Substituting non-dimensional time into eq. (9) and dividing by ω_s^2 results in:

$$\frac{d^2 C_{VL}}{d\tau^2} + \varepsilon \left(C_{VL}^2 - \frac{1}{4} (\hat{C}_{y1}^0)^2 \right) \frac{dC_{VL}}{d\tau} + C_{VL} = \left(\frac{\tilde{A}}{D} \frac{d^2 y}{d\tau^2} + \frac{\tilde{B}}{D} \frac{dy}{d\tau} \right) \cos \beta \quad (11)$$

Our goal is to replace the term $\frac{\tilde{A}(\Omega_c)}{D} \frac{d^2 y}{d\tau^2} + \frac{\tilde{B}(\Omega_c)}{D} \frac{dy}{d\tau}$ in eq. (11) with the convolution $\frac{1}{D} \int_0^\tau K(\tau - \tilde{\tau}) \frac{dy(\tilde{\tau})}{d\tilde{\tau}} d\tilde{\tau}$, in which $K(\tau)$ denotes the convolution kernel. The lower limit of integration starts at $\tilde{\tau} = 0$, as the cylinder cannot force the fluid, before it is moving itself. For large τ these two term should give the same results. This can be expressed as:

$$\begin{aligned}
 \frac{\tilde{A}(\Omega_c)}{D} \frac{d^2 y}{d\tau^2} + \frac{\tilde{B}(\Omega_c)}{D} \frac{dy}{d\tau} &= \lim_{\tau \rightarrow \infty} \frac{1}{D} \int_0^\tau K(\tau - \tilde{\tau}) \frac{dy(\tilde{\tau})}{d\tilde{\tau}} d\tilde{\tau} \\
 &= \frac{1}{D} \int_0^\infty K(\tau - \tilde{\tau}) \frac{dy(\tilde{\tau})}{d\tilde{\tau}} d\tilde{\tau} = \frac{1}{D} \int_0^\infty K(\tilde{\tau}) \frac{dy(\tau - \tilde{\tau})}{d\tilde{\tau}} d\tilde{\tau}
 \end{aligned} \tag{12}$$

Substitution of the expression $y = \hat{y} \sin(\Omega_c \tau)$ results in the following relations:

$$\Omega_c \tilde{A}(\Omega_c) = - \int_0^\infty K(\tau) \sin(\Omega_c \tau) d\tau = A(\Omega_c) \tag{13}$$

$$\tilde{B}(\Omega_c) = \int_0^\infty K(\tau) \cos(\Omega_c \tau) d\tau = B(\Omega_c) \tag{14}$$

Eq. (13) and (14) show that, since $A(\Omega_c)$ and $B(\Omega_c)$ are the inverse sin- and cos-transform of the same kernel $K(\tau)$, these functions are not independent functions, but are in fact related to each other. This relation is known as the Kramers-Kronig relation. It can be expressed as follows, where attention has been paid to correctly include the boundaries at $\Omega = 0$ and $\Omega \rightarrow \infty$:

$$\frac{A(\Omega)}{\Omega} - \lim_{\Omega \rightarrow \infty} \frac{A(\Omega)}{\Omega} = \frac{1}{\Omega} \frac{2}{\pi} \int_0^\infty \frac{(B(\tilde{\Omega}) - B(\Omega)) \Omega}{\tilde{\Omega}^2 - \Omega^2} d\tilde{\Omega} \tag{15}$$

$$B(\Omega) - B(0) = - \frac{2\Omega^2}{\pi} \int_0^\infty \frac{A(\tilde{\Omega})/\tilde{\Omega} - A(\Omega)/\Omega}{\tilde{\Omega}^2 - \Omega^2} d\tilde{\Omega} \tag{16}$$

More details on the relations between $A(\Omega_c)$ and $B(\Omega_c)$ are given in [6].

3 DETERMINATION OF THE FREQUENCY DEPENDENT COEFFICIENTS $A(\Omega)$ AND $B(\Omega)$

3.1 Method of determining the frequency dependent coefficients $A(\Omega_c)$ and $B(\Omega_c)$

It will be tried to determine the frequency dependent coefficients $A(\Omega_c)$ and $B(\Omega_c)$ on the basis of the forced vibration measurements of Gopalkrishnan. To this end, the forced vibration experiments need to be modeled with the wake oscillator model presented in Section 2. The forced vibration cross-flow fluid force C_y^y can be expressed as:

$$C_y^y = C_{VY} + C_{AY} = C_{VY} - \frac{m_a}{\frac{1}{2} \rho D V^2 L} \ddot{y}, \tag{17}$$

in which C_{VY} is again given by eq. (6) :

$$C_{VY} = (C_{VD} \sin \beta + C_{VL} \cos \beta) \frac{U^2}{V^2} \tag{6}$$

By assuming a forced vibration in the form of: $y = \hat{y} \sin(\Omega_c \tau)$, the forced vibration coefficients \hat{C}_{yla}^y and \hat{C}_{ylv}^y can be calculated with:

$$\begin{aligned}\hat{C}_{y1a}^y &= \frac{2}{T_c} \int_{\tau_0}^{\tau_0+T_c} C_y^y \sin(\Omega_c \tau) d\tau \\ &= \frac{2}{T_c} \int_{\tau_0}^{\tau_0+T_c} C_{VY} \sin(\Omega_c \tau) d\tau + \hat{C}_a 2\pi^3 \text{St}^2 \Omega_c^2 \hat{y} / D\end{aligned}\quad (18)$$

$$\hat{C}_{y1v}^y = -\frac{2}{T_c} \int_{\tau_0}^{\tau_0+T_c} C_y^y \cos(\Omega_c \tau) d\tau = -\frac{2}{T_c} \int_{\tau_0}^{\tau_0+T_c} C_{VY} \cos(\Omega_c \tau) d\tau, \quad (19)$$

in which $T_c = 2\pi/\Omega_c = 2\pi\omega_s/\omega_c$ is the non-dimensional period of forced vibration. The value of the component of the vortex fluid force in the direction of the relative velocity is again given by: $C_{VD} = \hat{C}_{x0}^0$. The component of the vortex fluid force perpendicular to the relative velocity will now be calculated with:

$$\frac{d^2 C_{VL}}{d\tau^2} + \varepsilon \left(C_{VL}^2 - \frac{1}{4} (\hat{C}_{y1}^0)^2 \right) \frac{dC_{VL}}{d\tau} + C_{VL} = \left(-\Omega_c A \frac{\hat{y}}{D} \sin(\Omega_c \tau) + \Omega_c B \frac{\hat{y}}{D} \cos(\Omega_c \tau) \right) \cos \beta \quad (20)$$

It is now possible to model the forced vibration with the help of eq. (6), (18), (19) and (20). By changing A and B in this model an error function will be minimized that characterizes the discrepancy between the model predictions and the measurements of Gopalkrishnan. The equations have been solved numerically in a similar manner as described in Section 2.1 with the value for ε and the initial values for A and B equal to the values given by (10). Then, the fluid force coefficients \hat{C}_{y1a}^y and \hat{C}_{y1v}^y have been calculated. When these values are known, the error can be determined as follows:

$$\text{error} = \left(\hat{C}_{y1a;\text{model}}^y - \hat{C}_{y1a;\text{measured}}^y \right)^2 + \left(\hat{C}_{y1v;\text{model}}^y - \hat{C}_{y1v;\text{measured}}^y \right)^2 \quad (21)$$

Subsequently, the error is minimized with a one-dimensional procedure that brackets the minimum and then performs a golden section search to find this minimum. This procedure is explained in detail by Press et al. in [8]. The procedure starts with changing A and keeping B constant and when under these conditions a minimum has been found, A is kept constant and B is changed. This is repeated over and over again until the error given by (21) is smaller than a preset value. Starting at $V_c = 3$ (with $\Omega_c = 1/\text{St}/V_c$) and $\hat{y}/D = 0.2$, the error is minimized until it is smaller than 10^{-6} . Then at the same amplitude the reduced velocity V_c is increased with $dV_c = 0.1$ and the calculations are repeated until the whole frequency range at this amplitude is covered, each time using the final A and B at the previous frequency as the initial values for the iterative procedure at the next frequency. In this manner the frequency dependent parameters $A(\Omega_c)$ and $B(\Omega_c)$ have been determined for the amplitudes of forced motion in the range of $\hat{y}/D = 0.2$ to 1.2 with a step size of $d\hat{y} = 0.1 \cdot D$.

3.2 Challenges involved in determining the coefficients $A(\Omega_c)$ and $B(\Omega_c)$

It is instructive at this point to state explicitly what the difficulties are in trying to determine the frequency dependent coefficients on the basis of the forced vibration experiments. Firstly, the frequency dependent coefficients will be determined for a number of amplitudes of forced vibration. But when modeling the free vibration with the wake oscillator containing the convolution integral, *one* kernel K based on only *one* set of frequency dependent curves $A(\Omega_c)$ and $B(\Omega_c)$ should be able to describe the fluid force behavior for all amplitudes of cy-

linder motion. This implies that for all amplitudes of forced vibration the same set of curves for $A(\Omega_c)$ and $B(\Omega_c)$ should be found.

Secondly, it has been shown in Section 2.2 that $A(\Omega_c)$ and $B(\Omega_c)$ are related through the Kramers-Kronig relations. It is not possible to determine $A(\Omega_c)$ and $B(\Omega_c)$ on the basis of the forced vibration measurements over the entire frequency range from zero to infinity, as the measurements have obviously been performed over a finite frequency range. For a set of frequency dependent coefficient $A(\Omega_c)$ and $B(\Omega_c)$ that is self-consistent, it should however be possible to extend these coefficient over the entire frequency range, such that the Kramers-Kronig relations are satisfied.

If we fail to find one set of coefficients $A(\Omega_c)$ and $B(\Omega_c)$ that are valid over a range of forced vibration amplitudes, or if the set of coefficients cannot be extended over the entire frequency range to satisfy the Kramers-Kronig relation, this will be an indication that the wake oscillator model does not contain the correct non-linearities.

3.3 Results of determining the coefficients $A(\Omega_c)$ and $B(\Omega_c)$ on the basis of forced vibration measurements

The frequency dependent curves that have been found for $A(\Omega_c)$ and $B(\Omega_c)$ with the method described in Section 3.1 are depicted in Fig. 8 and 9 for *Case U* and in Fig. 10 and 11 for *Case L*. It is clear from these figures that in both cases different curves for A and B are found at different amplitudes of forcing, implying that with the current model the results of Gopal-krishnan cannot be reproduced with a single set of frequency dependent parameters. It appears that the wake oscillator as tuned in *Case U* gives better results than as tuned in *Case L*, since in Fig. 8 and 9 the spread in the curves of $A(\Omega_c)$ and $B(\Omega_c)$ for different amplitudes is one order of magnitude smaller than in Fig. 10 and 11.

In [6], we have attempted to reduce the spread in the curves of $A(\Omega_c)$ and $B(\Omega_c)$ at different amplitudes of forcing in a number of ways. This included redefining the error function that has been used in the determination procedure, retuning the model by changing the parameter values given by eq. (10) and by replacing the Van der Pol-type non-linearity in eq. (20) with a Rayleigh-type non-linearity. None of these approaches reduced the spread in the curves of $A(\Omega_c)$ and $B(\Omega_c)$ to a significant degree.

Subsequently in [6], we have described a method based on complex curve fitting with a complex polynomial that should be able to, starting with a set of frequency dependent curves that are known over only a limited range of the frequency spectrum, expand this set over the entire spectrum such that the Kramers-Kronig relations are satisfied and the inverse transform of the coefficients $A(\Omega_c)$ and $B(\Omega_c)$ can be taken to determine the convolution kernel $K(\tau)$. We found that with this method we were not able to extend the curves for the amplitudes higher than $0.6 \cdot D$ over the entire spectrum and therefore we were not able to determine a convolution kernel on the basis of these curves. For the curves plotted in Figs. 8, 9, 10 and 11 at amplitudes of $0.6 \cdot D$ and lower, we were able to extend the curves over the entire spectrum, but this could only be done with a low order polynomial and therefore a poor fit to the curves used. After determining the convolution kernel $K(\tau)$ on the basis of one of these fits, the free vibration was modeled with inclusion of the convolution coupling. The results were very poor. See Fig. 10 in [6].

We therefore came to the conclusion that the wake oscillator model given by eq. (4), (6) and (9), with or without the convolution coupling, does not contain the correct non-linearities in either the damping term in eq. (9), the coupling term in eq. (9) or both. We also noted that the wake oscillator could possibly be improved by adding an additional oscillator, so that the fluid force is modeled with a combination of two wake oscillators.

Figure 8: Curves found through a minimization procedure for the coefficient A for *Case U*.

Figure 9: Curves found through a minimization procedure for the coefficient B for *Case U*.

Figure 11: Curves found through a minimization procedure for the coefficient B for *Case L*.

3.4 Effect of removing the non-linearity in the damping term of the wake oscillator

It is remarkable that the spread in the curves for the frequency dependent coefficient at different amplitudes of forced vibration is an order of magnitude smaller for *Case U* compared to *Case L*. For *Case U*, the parameter ε , given by eq. (10), that multiplies the Van der Pol-type non-linearity in eq. (20) is on order of magnitude smaller compared to *Case L*. It seems, therefore, that the Van der Pol-type non-linearity in eq. (20) has a large influence on the spread of the frequency dependent curves found at different amplitudes of forced vibration. To explore whether this is indeed the case, the minimization procedure from Section 3.1 is repeated and the frequency dependent coefficients are determined anew, but in this case the non-linearity in the damping term in eq. (20) is replaced by a linear damping term:

$$\frac{d^2 C_{VL}}{d\tau^2} + 2\varepsilon \frac{dC_{VL}}{d\tau} + C_{VL} = \left(-\Omega_c A \frac{\hat{y}}{D} \sin(\Omega_c \tau) + \Omega_c B \frac{\hat{y}}{D} \cos(\Omega_c \tau) \right) \cos \beta \quad (22)$$

We are fully aware that it is not possible to model the free vibration with eq. (22), as this equation does not contain a limit cycle and therefore cannot model the energy input from the fluid into the structural system at low amplitudes of motion, but we only wish to investigate the effects of the presence/non-presence of this non-linear damping term on the spread of the frequency dependent coefficient at different amplitudes of forced vibration.

The frequency dependent curves that have been found for $A(\Omega_c)$ and $B(\Omega_c)$ with the help of eq. (22) are depicted in Fig. 12 to 17 for three different values of the non-dimensional damping ratio ε , namely $\varepsilon = 0.5$, $\varepsilon = 0.3$ and $\varepsilon = 0.1$. It is immediately clear from Fig. 12 to 17, that the spread in the curves for $A(\Omega_c)$ and $B(\Omega_c)$ at different amplitudes of forced vibration is of the same order of magnitude as has been found for *Case U* in Section 3.3. For decreasing damping ratio ε , the spread in the curves reduces unmistakably. Only the curves for the highest amplitude of forced vibration $\hat{y}/D = 1.2$ does not collapse onto the other curves. But additional non-linearities in the coupled structure-fluid system that are not modeled with the equations used, will certainly be present in reality. These additional non-linearities will be most visible at the higher amplitudes of cylinder motion.

The fact that a much better correspondence of the frequency dependent curves at different amplitudes of forced vibration is found when the non-linearity in the damping term in the oscillator that describes C_{VL} is removed, leads to the conclusion that this non-linearity should most likely not be included at this place. The behavior of the oscillator that describes C_{VL} appears to be linear at low amplitudes of vibration. This means that the negative damping term that models the energy input from the fluid into the structural system should be placed at a different position in the coupled fluid-structure system.

4 A FIRST ATTEMPT AT A NEW WAKE MODEL CONTAINING MULTIPLE OSCILLATORS

Based on the findings of the previous section, a first attempt is made to develop a wake oscillator model in which the oscillator that describes C_{VL} is linear in first order approximation at low amplitudes of cylinder motion. We do not wish to derive a full model at this point that is able to describe both the free and forced vibration. It is only our objective here to investigate whether focusing our attention into this direction could be worthwhile. We start with the same basic equations as before and return to the usage of dimensional time t . The equations for the structural oscillator and the cross-flow fluid force do not change and are given by:

$$(m + m_a) \ddot{y} + b \dot{y} + ky = \frac{1}{2} \rho D V^2 L C_{VY} \quad (23)$$

$$C_{VY} = (C_{VD} \sin \beta + C_{VL} \cos \beta) \frac{U^2}{V^2} \quad (6)$$

It will still be assumed that: $C_{VD} = \hat{C}_{x0}^0$. For the force component C_{VL} the following equation is proposed of which the left-hand side is linear as discussed in Section 3.4:

$$\ddot{C}_{VL} + 2\varepsilon_L \omega_s \dot{C}_{VL} + \omega_s^2 C_{VL} = P_L \omega_s \dot{q} + \left(\frac{A_L}{D} \ddot{y} + \frac{B_L}{D} \omega_s \dot{y} + \frac{G_L}{D} \omega_s^2 y \right) \cos \beta, \quad (24)$$

Figure 12: Curves found for the coefficient A for the linear case with $\varepsilon = 0.5$.

Figure 13: Curves found for the coefficient B for the linear case with $\varepsilon = 0.5$.

Figure 14: Curves found for the coefficient A for the linear case with $\varepsilon = 0.3$.

Figure 15: Curves found for the coefficient B for the linear case with $\varepsilon = 0.3$.

Figure 16: Curves found for the coefficient A for the linear case with $\varepsilon = 0.1$.

Figure 17: Curves found for the coefficient B for the linear case with $\varepsilon = 0.1$.

in which A_L , B_L , G_L and P_L are constant non-dimensional coupling coefficients and ε_L is the non-dimensional damping ratio. The non-linear damping term that is present in eq. (9) and that models the limit cycle of the cross-flow fluid force and hence the energy input from the fluid into the structural system, has been removed from eq. (24). Therefore a second oscillator is needed that reintroduces the limit cycle and thereby acts as forcing on eq. (24). The following form for this second oscillator is proposed:

$$\ddot{q} + \varepsilon_Q \omega_s (q^2 - 1) \dot{q} + \omega_s^2 q = \left(\frac{A_Q}{D} \ddot{y} + \frac{B_Q}{D} \omega_s \dot{y} + \frac{G_Q}{D} \omega_s^2 y \right) \cos \beta, \quad (25)$$

in which q is a wake variable that will be left undefined. A_Q , B_Q , and G_Q are constant non-dimensional coupling coefficients and ε_Q is a non-dimensional tuning parameter. To ensure that the cross-flow fluid force on a stationary cylinder as predicted by eq. (6), (24) and (25) is equal to \hat{C}_{y1}^0 , P_L should be equal to: $P_L = 2\varepsilon_L \hat{C}_{y1}^0 / 2 = \varepsilon_L \hat{C}_{y1}^0$.

The coupled system consisting of eq. (6), (23), (24) and (25) has been solved in the time domain and it has been tried to find values for the tuning coefficients A_L , B_L , G_L , ε_L , A_Q , B_Q , G_Q and ε_Q , such that results of the model would compare favorably with the free vibration measurements of Khalak et al. It has however been found that for the free vibration modeling this system of equations always overpredicted the amplitude of free vibration. This is likely caused by the removal of the Van der Pol-type nonlinearity from eq. (24). The presence of this term resulted in a strong damping at higher amplitudes of cylinder motion and it limited thereby the amplitude of cylinder motion that could be attained. This can be corrected by letting go of the assumption that: $C_{VD} = \hat{C}_{x0}^0$ and introducing an additional oscillator equation to describe C_{VD} . The presence of this additional oscillator will limit the amplitude of the cylinder motion. A suitable form for this oscillator is given by:

$$\ddot{C}_{VD} + 4\varepsilon_D \omega_s \dot{C}_{VD} + 4\omega_s^2 (C_{VD} - \hat{C}_{x0}^0) = P_D \omega_s q \dot{q} + \left(\frac{A_D}{D} \ddot{y} + \frac{B_D}{D} \omega_s \dot{y} + \frac{G_D}{D} \omega_s^2 y \right) \sin \beta, \quad (26)$$

in which A_D , B_D , G_D and P_D are constant non-dimensional coupling coefficients and ε_D is the non-dimensional damping ratio. The inclusion of eq. (26) into the model has the added advantage that it creates the possibility to also model the oscillating components of the drag force, which are known to oscillate at even multiples of the Strouhal frequency [1, 2]. To ensure that the oscillating component of the in-line fluid force on a stationary cylinder as predicted by the present system of equations is equal to the force component \hat{C}_{x2}^0 from the measurements of Gopalkrishnan, P_D should be equal to: $P_D = -16 \varepsilon_D \hat{C}_{x2}^0 / 4 = -4 \varepsilon_D \hat{C}_{x2}^0$.

Again, it has been tried to tune the system of equations, now given by eq. (6), (23), (24), (25) and (26) to the free vibration experiments of Khalak et al. The results of this attempt are depicted in Fig. 18 and 19. The following values for the tuning parameters have been used:

$$\begin{aligned} St &= 0.1932, \quad \hat{C}_{x0}^0 = 1.1856, \quad \hat{C}_{y1}^0 = 0.3842, \quad \hat{C}_{x2}^0 = -0.0215, \\ A_Q &= 1.10, \quad B_Q = -0.50, \quad G_Q = 0.0, \quad \varepsilon_Q = 0.10, \\ A_L &= 0.70, \quad B_L = 0.00, \quad G_L = -1.15, \quad \varepsilon_L = 0.30, \\ A_D &= -8.00, \quad B_D = -8.00, \quad G_D = 5.00, \quad \varepsilon_D = 0.30 \end{aligned}$$

It can be seen in Figs. 18 and 19 that the first results of the new wake model consisting of multiple oscillators seem to be very promising. It appears that with the help of multiple wake oscillators it is possible to describe the upper and lower branch of free vibration.

Figure 18: Comparison of the amplitude and frequency of oscillation of the multiple oscillator model with the measurements of Khalak et al. [3] for $m^* = 2.4$.

Figure 19: Comparison of the amplitude and frequency of oscillation of the multiple oscillator model with the measurements of Khalak et al. [3] for $m^* = 20.6$.

5 CONCLUSIONS

Starting with a wake oscillator model that has been developed earlier in [6] and [7] for the description of vortex-induced vibration, an attempt has been made to improve this model by making the coupling term between the structural and fluid oscillator frequency dependent. A set of consistent frequency dependent coupling coefficients is valid at all amplitudes of cylinder motion and satisfies the Kramers-Kronig relations. The frequency dependent coefficients have been determined on the basis of the results of a forced vibration experiment.

As reported earlier in [6], the sets of frequency dependent coefficients found at different amplitudes of forced cylinder motion do not correspond with each other and therefore fail the requirements mentioned above.

In this paper the influence of the presence of the dominant non-linearity in the wake oscillator on the discrepancy between the various sets of frequency dependent coefficients found at different amplitudes of cylinder motion has been examined. It has been found that removal of the dominant non-linearity reduced the discrepancy between the sets of frequency dependent coefficient.

Based on this result a new model is proposed consisting of linear oscillators for the components of the fluid forces due to vortex shedding. These oscillators are forced by the cylinder motion and a wake variable q , which is described by a Van der Pol equation. Preliminary results of this model seem to be promising.

Abstract. *Finite element and finite difference methods have been widely used, among other methods, to numerically solve the Fokker-Planck equation for investigating the time history of the probability density function of linear and nonlinear 2d and 3d problems, and also the application to 4d problems has been addressed. However, due to the enormous increase of the computational costs, different strategies are required for an efficient application to problems of dimension ≥ 3 . Recently, a stabilized multi-scale finite element method has been effectively applied to the Fokker-Planck equation effectively by means of a considerably reduction of the required number of elements. Also, the alternating directions implicit method shows good performance in terms of efficiency and accuracy. In this paper various finite difference and finite element methods are discussed and the results are compared using various numerical examples.*

1 INTRODUCTION

The response of linear systems subjected to additive Gaussian white noise or linearly filtered Gaussian white noise is Gaussian. The derivation for an N-dimensional system can be found, e.g. in [1]. For the case of nonlinear systems subjected to additive Gaussian white noise, analytical solutions are restricted to certain scalar systems. It has been shown (see [2]), that the response of a multi-dimensional memoryless nonlinear system subjected to additive Gaussian white noise forms a vector Markov process, with transition probability density function satisfying both the forward (Fokker-Planck) and backward Kolmogorov equations for which numerical approximations in terms of finite element and finite difference methods can be pursued.

1.1 Scope of this work

A number of numerical methods have been introduced over the past five decades to obtain approximate results for the solution of the Fokker-Planck equation (FPE). Many of these approximations can be shown to be accurate. This work deals with a review of several finite element and finite difference methods. A comparison and assessment of different methods is carried out by means of various numerical examples including a 2d linear, 2d unimodal and bimodal Duffing oscillators, 3d linear and 3d Duffing oscillators.

The goal is to evaluate the transient solution for the probability density function (PDF) of the oscillator due to stochastic (white noise) excitation. Thus, the forward Kolmogorov or Fokker Planck equation is of interest and will be approximated within the numerical methods.

1.2 Background

The finite element method was first applied by [3] to determine the reliability of the linear, single degree-of-freedom oscillator subjected to stationary Gaussian white noise. The initial boundary problem associated with the backward Kolmogorov equation was solved numerically using a Petrov-Galerkin finite element method.

[4] has solved the stationary form of the FPE adopting the finite element method (FEM) in order to calculate the stationary probability density function of response. The weighted residual statement for the Fokker-Planck equation was first integrated by parts to yield the weak form of the equations.

The transient form of the FPE has been analyzed by [5] using a Bubnov-Galerkin FEM. It is shown that the initial boundary value problem can be modified in order to evaluate the first passage problem. A comparison for the reliability was carried out with the results obtained from the backward Kolmogorov equation.

The drawback of the FEM is the quickly increasing computational cost with increasing dimension. Thus while 2 and 3 dimensional systems have been analyzed in the literature, the analysis of 4d or 5d problems touches the limits of today's computational capabilities and are not yet feasible.

Computationally more economical - in terms of memory requirements, and when considering the effort spent for the assembly of the mass and stiffness matrices - are finite difference methods. The application of central differences is, as expected, only feasible for the case of 2d linear systems, because of stability issues. The stability is a function of the nonlinearity and the dimension (ratio Δt and $\prod_{i=1}^n \Delta x_i$), thus being unfavorable to the use of this simple method.

A successful approach to overcome the limitations of simple finite differences was achieved by [6] in terms of higher order finite differences. The solution of a 4d system using higher order finite differences is reported in [6]. A comparison of various higher order FD formulations is

presented in [7].

A viable approach to achieve higher accuracy is the application of operator splitting methods. Their capabilities with respect to the numerical solution of the FPE has so far received little attention. Operator splitting methods provide a tool to reduce the computational costs by the reduction of the solution to a series of problems of dimension of one order less than the original problem. Thus, more efficiency, required for the solution of problems of larger dimension (≥ 3), can be achieved. An operator splitting method for the solution of the 2d Duffing oscillator is presented in [8]. An operator splitting scheme for 3d oscillators subjected to additive and multiplicative white noise is given by [9]. The method consists in a series of consecutive difference equations for the three fluxes and is numerically stable. The ADI [10] is adopted in this paper for a series of problems and acceptably accurate results are achieved at low costs. The implementation of the method is straightforward and can be readily extended to higher dimensions.

Recent work by Masud et al. introduced a stabilized multi-scale finite element method which allows for a reduction of the number of elements for given accuracy and, thus, the efficiency of the computation can be increased by an order of magnitude when solving a 3d problem.

Several four-state dynamical systems were studied by [11, 12] in which the Fokker-Planck equation was solved using a global weighted residual method and extended orthogonal functions.

Meshless methods were proposed by [13, 14] to solve the transient FPE and [15] for the stationary FPE. Considerable reduction of the memory storage requirements could be expected due to coarse meshes employed and thus a standard desktop PC suffices to carry out the numerical analysis.

In addition, many numerical packages now provide the capability to solve partial differential equations by means of finite element and finite difference methods. However, in most cases these tools are limited to 2d and can only solve special forms of elliptic, parabolic or hyperbolic partial differential equations (PDE). The implementation of FD and FEM into computational software is shown for the cases of COMSOL (2d linear) and FEAP (general 3d).

2 THE FOKKER-PLANCK EQUATION

The Fokker-Planck equation for a n -dimensional system subjected to external Gaussian white noise excitation is given by

$$\frac{\partial p}{\partial t} = - \sum_{j=1}^n \frac{\partial}{\partial x_j} (z_j p) + \frac{1}{2} \left(\sum_{i=1}^n \sum_{j=1}^n \frac{\partial^2}{\partial x_i \partial x_j} (H_{ij} p) \right) \quad (1)$$

where p denotes the transition probability density function, \mathbf{x} the n -dimensional state space vector and $\mathbf{z}(\mathbf{x})$ and $\mathbf{H}(\mathbf{x})$ denote the drift vector and diffusion matrix, respectively.

The normalization condition for the probability density function is given by:

$$\int p_X(\mathbf{x}) d\mathbf{x} = 1, \quad (2)$$

and the initial conditions are given by $p(\mathbf{x}_0, 0)$. Examples for initial conditions are, e.g., deterministic given by the Dirac delta function

$$p_X(\mathbf{x}_0, 0) = \prod_{i=1}^n \delta((x_i - x_{0i})) \quad (3)$$

or the n -dimensional Gaussian distribution

$$p_X(\mathbf{x}_0, 0) = \frac{1}{(2\pi)^{n/2} |\Sigma|^{1/2}} \exp\left(-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T \Sigma^{-1}(\mathbf{x} - \boldsymbol{\mu})\right) \quad (4)$$

in the random case.

At infinity, a zero-flux condition is imposed:

$$p(x_i, t) \rightarrow 0 \quad \text{as} \quad x_i \rightarrow \pm\infty \quad i = 1, 2, \dots, n \quad (5)$$

Without loss of generality, and for a better comparison, the various methods introduced in the following, will be presented for the 2d linear case,

$$\begin{Bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{Bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 - \omega^2 x_1 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w(t) \quad (6)$$

The corresponding FPE is

$$\frac{\partial p}{\partial t} = -\frac{\partial(x_2 p)}{\partial x_1} + \frac{\partial[(2\xi\omega x_2 + x_1)p]}{\partial x_2} + D \frac{\partial^2 p}{\partial x_2^2} \quad (7)$$

which, after application of the chain rule, becomes:

$$\frac{\partial p}{\partial t} = -x_2 \frac{\partial p}{\partial x_1} + (2\xi\omega x_2 + x_1) \frac{\partial p}{\partial x_2} + 2\xi\omega p + D \frac{\partial^2 p}{\partial x_2^2} \quad (8)$$

3 FINITE DIFFERENCE AND FINITE ELEMENT METHODS

Many references deal with the application of FE and FE methods to the numerical solution of the Fokker-Planck equation (see e.g. [7, 16]).

3.1 Central finite differences

In terms of central finite differences, Eq. (8) becomes:

$$\frac{p_{i,j}^{m+1} - p_{i,j}^m}{\Delta t} = -x_2 \frac{p_{i+1,j}^m - p_{i-1,j}^m}{2\Delta x_1} + 2\xi\omega p_{i,j}^m + (2\xi\omega x_2) \frac{p_{i,j+1}^m - p_{i,j-1}^m}{2\Delta x_2} + D \frac{p_{i,j+1}^m - 2p_{i,j}^m + p_{i,j-1}^m}{\Delta x_2^2} \quad (9)$$

and an explicit formulation is obtained for the probability density function

$$\begin{aligned} p_{i,j}^{m+1} = & p_{i,j}^m + \Delta t \left(-x_2 \frac{p_{i+1,j}^m - p_{i-1,j}^m}{2\Delta x_1} + 2\xi\omega p_{i,j}^m + (2\xi\omega x_2) \frac{p_{i,j+1}^m - p_{i,j-1}^m}{2\Delta x_2} \right. \\ & \left. + D \frac{p_{i,j+1}^m - 2p_{i,j}^m + p_{i,j-1}^m}{\Delta x_2^2} \right) \end{aligned} \quad (10)$$

The boundary conditions are given by $p_{i,j} = 0$ for $i, j = 1, N$. The discretization using central finite differences leads to an explicit scheme, which means that the values $p_{i,j}^{m+1}$ can be calculated directly from values $p_{i,j}^m$. Thus, the linear system of equations can be solved directly, and no inversion of the matrix relating $p_{i,j}^m$ to $p_{i,j}^{m+1}$ is required.

Explicit finite difference represents the simplest approximation; however, due to stability issues, implicit FD formulations are generally required.

Implicit, higher order finite difference schemes to solve Fokker-Planck equations have been developed by [6]. Higher order FD lead to more accurate results, but they are not used for comparison herein.

3.2 Alternating directions implicit method

The alternating directions implicit method (ADI) is a finite difference scheme, for which the finite difference steps in each direction are resolved separately and in each step implicitly for one dimension and explicitly for the others, leading to a stable finite difference formulation. The main advantages are that the resulting operational matrix is tridiagonal and, thus, its inverse can be computed efficiently. Moreover, the dimensionality of the problem is reduced by one and the problem is reduced to a series of problems of dimension of one order less.

In Eq. (8), finite differences are first applied implicitly to the x_1 -direction

$$\frac{p_{i,j}^{m+\frac{1}{2}} - p_{i,j}^m}{\Delta \frac{t}{2}} = -x_2 \frac{p_{i+1,j}^{m+\frac{1}{2}} - p_{i-1,j}^{m+\frac{1}{2}}}{2\Delta x_1} + 2\xi\omega p_{i,j}^m + (2\xi\omega x_2) \frac{p_{i,j+1}^m - p_{i,j-1}^m}{2\Delta x_2} + D \frac{p_{i,j+1}^m - 2p_{i,j}^m + p_{i,j-1}^m}{\Delta x_2^2} \quad (11)$$

and then to the x_2 -direction.

$$\frac{p_{i,j}^{m+1} - p_{i,j}^{m+\frac{1}{2}}}{\Delta \frac{t}{2}} = -x_2 \frac{p_{i+1,j}^{m+\frac{1}{2}} - p_{i-1,j}^{m+\frac{1}{2}}}{2\Delta x_1} + 2\xi\omega p_{i,j}^{m+\frac{1}{2}} + (2\xi\omega x_2) \frac{p_{i,j+1}^{m+1} - p_{i,j-1}^{m+1}}{2\Delta x_2} + D \frac{p_{i,j+1}^{m+1} - 2p_{i,j}^{m+1} + p_{i,j-1}^{m+1}}{\Delta x_2^2} \quad (12)$$

Both Eq. (11) and Eq. (12) give $M - 2$ tridiagonal linear systems of equations in x_1 for the $j = 2, \dots, M - 1$ values of x_2 and in case of Eq. (11) to $M - 2$ tridiagonal linear systems of equations in x_2 for the $i = 2, \dots, M - 1$ values of x_1 and in case of Eq. (12).

The computational cost is mainly due to the n times N matrix inversions which are encountered in the n -loops solution for a full time step. n denotes the dimension of the problem and N the number of nodes per dimension.

3.3 Finite element method

Reduction of Eq. (1) to the weak form and the introduction of shape functions of C^0 continuity lead to

$$\mathbf{C}\dot{\mathbf{p}} + \mathbf{K}\mathbf{p} = 0 \quad (13)$$

where

$$C_{rs}^e = \int_{\Omega^e} N_r(\mathbf{x}) N_s(\mathbf{x}) d\mathbf{x} \quad (14)$$

and

$$K_{rs}^e = \int_{\Omega^e} \left(\sum_{i=1}^n z_i(\mathbf{x}) N_s \frac{\partial}{\partial x_i} N_r d\mathbf{x} - \sum_{i=1}^n \sum_{j=1}^n \frac{\partial}{\partial x_i} N_r \frac{\partial}{\partial x_i} [H_{ij} N_s] d\mathbf{x} \right) N_r(\mathbf{x}) N_s(\mathbf{x}) d\mathbf{x} \quad (15)$$

The integration over time can be performed in a suitable way using the Crank-Nicholson scheme ($\theta = 0.5$).

3.4 Multi-scale finite element method

The multi-scale FEM used herein was introduced by [17] for the numerical treatment of advection-diffusion equations in fluid dynamics. Then, the methodology was extended by [18]

to the special case of the Fokker-Planck equation. Finally, the method was applied for the numerical solution of the Fokker-Planck equation of a 3d linear system [19]. [20] provide an overview of stabilized finite element methods and recent developments of their application to the advection-diffusion equation.

For a description of the method the reader is referred to the aforementioned references. Basically, a multi-scale FEM means that an approximation of the error term from the traditional FE formulation is included as a fine scales into the formulation, the probability density function is then given by

$$p = \hat{p} + p' \quad (16)$$

where \hat{p} represents the contribution of the coarse scale and p' the contribution of the fine scale.

3.5 Implementation within COMSOL / FEAP

The FE code COMSOL provides the possibility to solve partial differential equations in terms of finite differences. For an extensive discussion, refer to the COMSOL documentation, [21]. Fig. 1 shows the results obtained for the FPE for the 2d linear oscillator with parameters discussed later.

Figure 1: Probability density function $p(0, 0, t)$ at central node over time.

The multiscale finite element method was implemented by Masud and coworkers into the finite element code FEAP and is used herein for comparison of the 3d examples.

4 NUMERICAL EXAMPLES

The numerical methods used in this comparison are:

1. central finite differences (FD)
2. alternating directions implicit method (ADI)
3. Bubnov Galerkin finite element method (FEM)
4. stabilized multiscale finite element method (MSFEM)

The methods 1-3 are coded in MATLAB and the analysis was carried out on a 64-bit Windows server (32GB). The results for method 4 are obtained on 32 bit Linux or Windows machines with 2GB memory using an implementation within FEAP, [18].

4.1 2-d linear oscillator

The different methods are applied to solve the FPE for the linear oscillator

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 - \omega^2 x_1 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w(t) \quad (17)$$

The parameters of the oscillator are chosen according to [5] and are given by:

μ	σ	ξ	ω	D
$[5, 5]$	$\frac{1}{9}\mathbf{I}(2)$	0.05	1	0.1

Table 1: Parameter for the linear oscillator

Finite element results obtained using a 61×61 mesh are shown in Fig. 2 and Fig. 3. All results are calculated with a time increment of $\Delta t = 0.001$ and a total time of $\tau = 20$ natural periods. The state space is discretized on the domain $[-10, 10] \times [-10, 10]$;

Fig. 2 shows the evolution of the probability density function over time. In Fig. 3 the transient solution for the PDF at the origin is given. The exact stationary value at the origin is $p(0, 0)_{stat} = 1.5915e-1$.

Figure 2: FEM: 61×61 - Probability density function $p(t)$ over time.

The accuracy of the numerical solutions are compared at stationarity (i.e. after $t = 20$ cycles) using two error measures. The first, the maximum norm

$$\|e\|_{\infty} = \|p^{ex} - p^{num}\|_{\infty} \quad (18)$$

Figure 3: FEM: 61×61 - Probability density function at central node $p(0, 0, t)$ over time.

is a measure of the maximum error across the entire mesh. The second,

$$\|e\|_2 = \|p^{ex} - p^{num}\|_2 \quad (19)$$

can be used to describe the average nodal error $\bar{e} = \|e\|_2/n_{nodes}$, where n_{nodes} is the total number of nodes.

mesh method	61×61		81×81		101×101		121×121	
	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$
FD	7.05e-3	2.99e-2	4.169e-3	2.405e-2	2.983e-3	2.201e-2	2.371e-3	2.199e-2
ADI	1.66e-2	4.61e-2	4.144e-3	2.375e-2	2.931e-3	2.149e-2	2.305e-3	2.124e-2
FEM	2.04e-3	1.00e-2	1.712e-3	1.152e-2	1.550e-3	1.370e-2	1.464e-3	1.613e-2

Table 2: Comparison of the accuracy for the linear oscillator

Table 2 correctly visualizes the increasing accuracy for all methods when the mesh is refined. It can also be seen that the FD and ADI deliver similar results. The advantage of the ADI over FD consists in the fact that the stability of the method allows one to use larger time steps. The FEM provides more accurate results for the same mesh refinement as the finite difference methods. The FEM is the preferable method to investigate the first passage problem, in case small probabilities of failure are involved and a highly accurate method is required.

Alternatively, the accuracy of the solution at stationarity can also be represented by comparison of the exact and numerical covariance matrices K_{xx} , the latter computed from FE/FD results for the PDF.

The transient solution for the probability density at the center node can be obtained with all three methods as listed in Table 2. Fig. 4 shows a comparison for the PDF at the origin using finite difference method and different mesh sizes.

 Figure 4: FD - Comparison for probability density function at central node $p(0, 0, t)$ over time.

4.2 2-d Duffing oscillator

4.2.1 Unimodal

The unimodal Duffing oscillator is considered next:

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 - \omega^2 x_1 - \omega^2 \gamma x_1^3 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w(t) \quad (20)$$

The parameters of the oscillator are chosen as:

μ	σ	ξ	ω	D	γ
$[0, 10]$	$\frac{1}{2}\mathbf{I}(2)$	0.2	1	0.4	0.1

Table 3: Parameters for the unimodal Duffing oscillator

The state space is discretized on the domain $[-15, 15] \times [-15, 15]$.

It is known that central finite differences are not suited in case of nonlinearities, but ADI can be utilized nonetheless. In case the Duffing-oscillator is analyzed, it is found that the ADI can be used due to its implicit formulation with the largest time step Δt , thus providing a good compromise between accuracy and efficiency as can be seen from Table 4. The time steps used are $\Delta t = 1e - 2$ (ADI), $\Delta t = 1e - 3$ (FEM) and $\Delta t = 5e - 4$ (FEM: mesh 101).

The exact analytical expression for the stationary PDF of the unimodal Duffing oscillator of Eq. (20) is given as:

$$\begin{aligned} \sigma_{x_0}^2 &= \frac{\pi G_0}{4\xi\omega_0^3} \\ \sigma_{v_0}^2 &= \omega_0^2 \sigma_{x_0}^2 \\ p_X(\mathbf{x}) &= C \exp \left(-\frac{1}{2\sigma_{x_0}^2} \left(x^2 + \frac{\gamma}{2} x^4 \right) - \frac{1}{2} \sigma_{v_0}^2 v^2 \right) \end{aligned} \quad (21)$$

The value of the stationary PDF at the central node is $p_{stat}(0, 0) = 1.6851e - 1$.

Figure 5: FEM: 101×101 - Probability density function at central node $p(0, 0, t)$ over time.

method / mesh	61×61		81×81		101×101	
	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$
ADI	1.7832e-2	4.9323e-2	9.6731e-3	3.5553e-2	6.1694e-3	2.8444e-2
FEM	2.6002e-3	1.1587e-2	1.3999e-3	8.5297e-3	9.3290e-4	6.8215e-3

Table 4: Comparison of the accuracy for the unimodal Duffing oscillator

4.2.2 Bimodal

The equations for the bimodal Duffing oscillator are characterized by the changed sign of the term $\omega^2 x_1$.

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 + \omega^2 x_1 - \omega^2 \gamma x_1^3 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w(t) \quad (22)$$

The parameters of the oscillator are chosen according to [5] and are given by:

μ	σ	ξ	ω	D	γ
$[0, 10]$	$\frac{1}{2}\mathbf{I}(2)$	0.2	1	0.4	0.1

Table 5: Parameter for the bimodal Duffing oscillator

The state space is discretized on the domain $[-15, 15] \times [-15, 15]$. Again, the ADI provides a tool for obtaining accurate results rather quickly.

In Fig. 6 the PDF is depicted for stationary conditions and a 61×61 mesh. A comparison of the evolution of the probability density function at the origin is shown in Fig. 7 for FEM and different meshes.

To compare the solution, the analytical expression according to [22] should be used. The exact analytical expression for the bimodal Duffing oscillator of Eq. (22) is given as:

$$p_X(\mathbf{x}) = C \exp \left(-\frac{1}{2\sigma_{x_0}^2} \left(-x^2 + \frac{\gamma}{2}x^4 \right) - \frac{1}{2}\sigma_{v_0}^2 v^2 \right)$$

The value of the stationary PDF at the central node is $p_{stat}(0, 0) = 8.3161e - 3$. The maximum value of the stationary PDF of the bimodal oscillator at $x_{1,2} = \pm\sqrt{1/\gamma} = \pm 3.1623$ and $y_{1,2} = 0$ is $p_{stat}(x_{1,2}, 0) = 0.1013$. A comparison of the evolution of the probability density function at the mesh point $(x = 3, y = 0)$ which is closest to the maximum of the PDF is shown in Fig. 8 for FEM and different meshes; $p_{stat}(3, 0) = 0.0988$.

method / mesh	61 × 61		81 × 81		101 × 101	
	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$
ADI	4.7186e-2	1.8229e-1	1.1899e-2	4.2491e-2	7.5077e-3	3.0640e-2

4.3 3-d linear oscillator

A 3-rd state variable is introduced in terms of a low pass filter for the white noise excitation which is applied to the linear 2d system.

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 - \omega^2 x_1 + x_3 \\ -\alpha x_3 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} w(t) \quad (23)$$

The parameters of the 3d linear oscillator are:

μ	σ	ξ	ω	D	α
$[0, 0, 0]$	$0.2\mathbf{I}(3)$	0.2	1	0.4	1

Table 7: Parameter for the 3d linear oscillator

Tables 8 and 9 shows a comparison of the accuracy of the results for the linear oscillator. The time step is chosen to be $\Delta t = 0.01$, and only for FEM (net 81^3) $\Delta t = 0.001$ is required. The exact stationary value of the PDF at the origin is $p(0, 0, 0) = 0.2409$.

method / mesh	25^3		41^3	
	$\ e\ _\infty$	$\ e\ _2$	$\ e\ _\infty$	$\ e\ _2$
ADI	1.8009e-1	3.6649e+0	4.8336e-2	4.8748e-1

ADI	1.2542e-2	2.1170e-1	6.9165e-3	1.8067e-1	4.3899e-3	1.6063e-1
FEM	1.4081e-3	3.4554e-2	3.9016e-4	2.4920e-2		

Table 9: Comparison of the accuracy for the linear oscillator

4.4 3-d Duffing oscillator

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{bmatrix} x_2 \\ -2\xi\omega x_2 - \omega^2 x_1 - \omega^2 \gamma x_1^3 + x_3 \\ -\alpha x_3 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} w(t) \quad (24)$$

The parameters of the 3d Duffing oscillator are:

μ	σ	ξ	ω	D	α	γ
$[0, 0, 0]$	$0.2\mathbf{I}(3)$	0.2	1	0.4	1	0.1

Table 10: Parameters for the 3d Duffing oscillator

Fig. 10 shows converged results for the evolution of the PDF at the origin over time using ADI for two different degrees of nonlinearity and for the corresponding linear system ($\gamma = 0$).

Figure 10: Probability density function at the central node $p(0, 0, 0, t)$ over time.

5 DISCUSSION

Despite of the greater numerical effort, the FEM is preferable over FD, because it yields more accurate results. However, at this time the FEM is only suitable for dimension ≤ 3 . In the case of 3d and 4d problems, the stabilized multi-scale FEM provides a tool with a high order of accuracy, preserving numerical efficiency due to the fact that a coarser mesh size can be used.

The first effective numerical solution for 4d problems was reported by [23] in terms of high-order finite differences. The advantage of operator splitting methods including the ADI is the stability of the method, meaning that larger time steps (when compared to FEM) can be used, thus speeding up the analysis as the dimensionality of the problem is reduced by one.

The recently introduced PUFEM (see Kumar et al.) represents a possibility to obtain good results with coarse mesh sizes. The price paid is the computational overhead required in order to allow for the proposed coarse mesh size.

From the above discussion it is clear that future developments will be bounded by the so-called curse of dimensionality for some time.

Keywords: Uncertain rigid body, Random mass, Random center of mass, Random tensor of inertia.

Abstract. *This research is devoted to the construction of the random dynamical response of a multibody system with uncertain rigid bodies. We first construct a stochastic model of an uncertain rigid body by replacing the mass, the center of mass and the tensor of inertia by random variables. The prior probability distributions of the stochastic model are constructed using the maximum entropy principle under the constraints defined by the available information. The generator of independent realizations corresponding to the prior probability distribution of these random quantities are developed. Then, several uncertain rigid bodies can be linked each others in order to calculate the random response of a multibody dynamical system. An application is proposed to illustrate the theoretical development.*

1 INTRODUCTION

This study is devoted to the construction of a probabilistic model of uncertainties for a rigid multibody dynamical system made up of uncertain rigid bodies. In some cases, the mass distribution inside a rigid body is not perfectly known and must be considered as random (for example, the distribution of passengers inside a vehicle) and therefore, this unknown mass distribution inside the rigid body induces uncertainties in the model of this rigid body. Here, we propose a new probabilistic modeling for uncertain rigid bodies in the context of the multibody dynamics. Concerning the modeling of uncertainties in multibody dynamical system, a very few previous researches have been carried out. These researches concerned parameters which describe the joints linking each rigid body to the others and the external sources (see [7], [16], [3]), [12], [13]), but not rigid bodies themselves. In the field of uncertain rigid bodies, a first work has been proposed in [9, 10], in which the authors take into account uncertain rigid bodies for rotor dynamical systems using the nonparametric probabilistic approach [18, 19] consisting in replacing the mass and gyroscopic matrices by random matrices.

In this paper, a general and complete stochastic model is constructed for an uncertain rigid body. The mass, the center of mass and the tensor of inertia which describe the rigid body are modeled by random variables. The prior probability distributions of the random variables are constructed using the maximum entropy principle [6] from Information Theory [17]. The generator of independent realizations corresponding to the prior probability distributions of these random quantities are developed and presented. Then, several uncertain rigid bodies can be linked each others in order to calculate the random response of an uncertain multibody dynamical system. The stochastic multibody dynamical equations are solved using the Monte Carlo simulation method.

Section 2 is devoted to the construction of the mean model for the rigid multibody dynamical system by using the classical method. In Section 3, firstly, we propose a general probability model for an unconstrained uncertain rigid body and secondly, the uncertain rigid multibody dynamical system is obtained by joining this unconstrained uncertain rigid body to the other rigid bodies. The last section is devoted to an application which illustrates the proposed theory.

2 MEAN MODEL FOR THE RIGID MULTIBODY DYNAMICAL SYSTEM

In this paper, the usual model of a rigid multibody dynamical system for which all the mechanical properties are known will be called the mean model (or the nominal model). This section is devoted to the construction of the mean model for a rigid multibody dynamical system. This mean model is constructed as in ([14, 15]) and is summarized below.

2.1 Dynamical equations for a rigid body of the multibody system

Let RB_i be the rigid body occupying a bounded domain Ω_i with a given geometry. Let ξ be the generic point of the three dimensional space. Let $\mathbf{x} = (x_1, x_2, x_3)$ be the position vector of point ξ defined in a fixed inertial frame $(O, x_{0,1}, x_{0,2}, x_{0,3})$, such that $\mathbf{x} = \overrightarrow{O\xi}$. The rigid body class is then defined by three quantities.

- (1) The first one is the mass m_i of RB_i which is such that

$$m_i = \int_{\Omega_i} \rho(\mathbf{x}) d\mathbf{x} \quad , \quad (1)$$

where $\rho(\mathbf{x})$ is the mass density.

(2) The second quantity is the position vector \mathbf{r}_i of the center of mass G_i , defined in the fixed inertial frame, by

$$\mathbf{r}_i = \frac{1}{m_i} \int_{\Omega_i} \mathbf{x} \rho(\mathbf{x}) d\mathbf{x} \quad . \quad (2)$$

(3) Let $(G_i, x'_{i,1}, x'_{i,2}, x'_{i,3})$ be the local frame for which the origin is G_i and which is deduced from the fixed frame $(O, x_{0,1}, x_{0,2}, x_{0,3})$ by the translation $\overrightarrow{OG_i}$ and a rotation defined by the three Euler angles α_i, β_i and γ_i . The third quantity is the positive-definite matrix $[J_i]$ of the tensor of inertia in the local frame such that

$$[J_i] \mathbf{u} = - \int_{\Omega_i} \mathbf{x}' \times \mathbf{x}' \times \mathbf{u} \rho(\mathbf{x}') d\mathbf{x}' \quad , \quad \forall \mathbf{u} \in \mathbb{R}^3 \quad , \quad (3)$$

in which the vector $\mathbf{x}' = (x'_1, x'_2, x'_3)$ of the components of vector $\overrightarrow{G_i \xi}$ are given in $(G_i, x'_{i,1}, x'_{i,2}, x'_{i,3})$. In the above equation, $\mathbf{u} \times \mathbf{v}$ denotes the cross product between the vectors \mathbf{u} and \mathbf{v} .

2.2 Matrix model for the rigid multibody dynamical system

The rigid multibody dynamical system is made up of n_b rigid bodies and ideal joints including rigid joints, joints with given motion (rheonomic constraints) and vanishing joints (free motion). The interactions between the rigid bodies are realized by these ideal joints but also by springs, dampers or actuators which produce forces between the bodies. In this paper, only n_c holonomic constraints are considered. Let \mathbf{u} be the vector in \mathbb{R}^{6n_b} such that $\mathbf{u} = (\mathbf{r}_1, \dots, \mathbf{r}_{n_b}, \mathbf{s}_1, \dots, \mathbf{s}_{n_b})$ in which $\mathbf{s}_i = (\alpha_i, \beta_i, \gamma_i)$ is the rotation vector. The n_c constraints are given by n_c implicit equations which are globally written as $\varphi(\mathbf{u}, t) = 0$. The $(6n_b \times 6n_b)$ mass matrix $[M]$ is defined by

$$[M] = \begin{bmatrix} [M^r] & 0 \\ 0 & [M^s] \end{bmatrix} \quad , \quad (4)$$

where the $(3n_b \times 3n_b)$ matrices $[M^r]$ and $[M^s]$ are defined by

$$[M^r] = \begin{bmatrix} m_1 [I_3] & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & m_{n_b} [I_3] \end{bmatrix} \quad , \quad [M^s] = \begin{bmatrix} [J_1] & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & [J_{n_b}] \end{bmatrix} \quad , \quad (5)$$

in which $[I_3]$ is the (3×3) identity matrix. The function $\{\mathbf{u}(t), t \in [0, T]\}$ is then the solution of the following differential equation (see [15])

$$\begin{bmatrix} [M] & [\varphi_{\mathbf{u}}]^T \\ [\varphi_{\mathbf{u}}] & [0] \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{q} - \mathbf{k} \\ -\frac{d}{dt} \varphi_t - [\frac{d}{dt} \varphi_{\mathbf{u}}] \dot{\mathbf{u}} \end{bmatrix} \quad , \quad (6)$$

with the initial conditions

$$\mathbf{u}(0) = \mathbf{u}_0 \quad , \quad \dot{\mathbf{u}}(0) = \mathbf{v}_0 \quad , \quad (7)$$

in which $\mathbf{k}(\dot{\mathbf{u}})$ is the vector of the Coriolis forces and where $[\varphi_{\mathbf{u}}(\mathbf{u}(t), t)]_{ij} = \partial \varphi_i(\mathbf{u}(t), t) / \partial u_j(t)$ and $\varphi_t = \partial \varphi / \partial t$. The vector $\mathbf{q}(\mathbf{u}, \dot{\mathbf{u}}, t)$ is constituted of the applied forces and torques induced by springs, dampers and actuators. The vector $\boldsymbol{\lambda}(t)$ is the vector of the Lagrange multipliers. Equation (6) can be solved using an adapted integration algorithm (see for instance [2]).

3 STOCHASTIC MODEL FOR A MULTIBODY DYNAMICAL SYSTEM WITH UNCERTAIN RIGID BODIES

Firstly, a stochastic model for an uncertain rigid body of the multibody dynamical system is proposed and secondly, the stochastic model for the multibody dynamical system with uncertain rigid bodies is constructed joining the stochastic model of the uncertain rigid bodies.

3.1 Stochastic model for an uncertain rigid body of the multibody dynamical system

The properties of the mean model (or the nominal model) of the rigid body RB_i are defined by its mass \underline{m}_i , the position vector $\underline{\mathbf{r}}_{0,i}$ of its center of mass \underline{G}_i at initial time $t = 0$ and the matrix $[\underline{J}_i]$ of its tensor of inertia with respect to the local frame $(\underline{G}_i, \underline{x}'_{i,1}, \underline{x}'_{i,2}, \underline{x}'_{i,3})$. The probabilistic model of uncertainties for this rigid body is constructed by replacing these three parameters by the following three random variables: the random mass M_i , the random position vector $\mathbf{R}_{0,i}$ of its random center of mass \mathbf{G}_i at initial time $t = 0$ and the random matrix $[\mathbf{J}_i]$ of its random tensor of inertia with respect to the random local frame $(\mathbf{G}_i, \underline{x}'_{i,1}, \underline{x}'_{i,2}, \underline{x}'_{i,3})$. The probability density functions (PDF) of these three random variables are constructed using the maximum entropy principle (see [17], [6]), that is to say, in maximizing the uncertainties in the model under the constraints defined by the available information.

3.1.1 Construction of the PDF for the random mass

(i) Available information

Let $E\{\cdot\}$ be the mathematical expectation. The available information for the random mass M_i is defined as follows. Firstly, the random variable M_i must be positive almost surely. Secondly, the mean value of the random mass M_i must be equal to the value \underline{m}_i of the mean (or nominal) model. Thirdly, as it is proven in [19], the random mass must verify the inequality $E\{M_i^{-2}\} < +\infty$ in order that a second-order solution exists for the stochastic dynamical system. In addition, it is also proven that this constraint can be replaced by $|E\{\log M_i\}| < +\infty$.

(ii) Maximum entropy principle

The probability density function $\mu \mapsto p_{M_i}(\mu)$ of the random variable M_i is constructed by maximizing the entropy under the constraints defined above. The solution of this optimization problem is the PDF of a gamma random variable defined on $]0, +\infty[$. This PDF depends on two parameters which are \underline{m}_i and C_{M_i} . Since parameter C_{M_i} has no physical meaning, it is eliminated in introducing the coefficient of variation δ_{M_i} of the random variable M_i such that $\delta_{M_i} = \sigma_{M_i}/\underline{m}_i$ where σ_{M_i} is the standard deviation of the random variable M_i . Therefore, the PDF of the random mass is completely defined by the mean value \underline{m}_i and by the dispersion parameter δ_{M_i} .

3.1.2 Construction of the PDF for the random position vector $\mathbf{R}_{0,i}$

In this subsection, the PDF of the random initial position vector $\mathbf{R}_{0,i}$ of the center of mass of RB_i at initial time $t = 0$ is constructed.

(i) Available information

The position vector $\underline{\mathbf{r}}_{0,i}$ of the center of mass \underline{G}_i at initial time $t = 0$ of the mean (or nominal) model is given. However, the real position is not exactly known and $\underline{\mathbf{r}}_{0,i}$ only corresponds to a mean position. Consequently, there is an uncertainty about the real position and this is the

reason why this position is modeled by the random vector $\mathbf{R}_{0,i}$. Some geometrical and mechanical considerations lead us to introduce an admissible domain D_i of random vector $\mathbf{R}_{0,i}$. We introduce the vector \mathbf{h} of the parameters describing the geometry of domain D_i . In addition, the mean value of the random vector $\mathbf{R}_{0,i}$ must be equal to the value $\mathbf{r}_{0,i}$ of the mean (or nominal) model. Therefore, the available information for random variable $\mathbf{R}_{0,i}$ can be written as

$$\begin{aligned} \mathbf{R}_{0,i} &\in D_i(\mathbf{h}) \quad \text{a.s.} \quad , & (a) \\ E\{\mathbf{R}_{0,i}\} &= \mathbf{r}_{0,i} \in D_i(\mathbf{h}) \quad . & (b) \end{aligned} \quad (8)$$

(ii) Maximum entropy principle

The probability density function $\mathbf{a} \mapsto p_{\mathbf{R}_{0,i}}(\mathbf{a})$ of random variable $\mathbf{R}_{0,i}$ is then constructed by maximizing the entropy with the constraints defined by the available information in Eq. (8). The solution of this optimization problem depends on two parameters which are $\mathbf{r}_{0,i}$ and vector-valued parameter \mathbf{h} , and is such that

$$p_{\mathbf{R}_{0,i}}(\mathbf{a}; \mathbf{h}) = \mathbb{1}_{D_i(\mathbf{h})}(\mathbf{a}) C_0 e^{-\langle \boldsymbol{\lambda}, \mathbf{a} \rangle} \quad . \quad (9)$$

The positive valued parameter C_0 and vector $\boldsymbol{\lambda}$ are the unique solution of the equations

$$\begin{aligned} C_0 \int_{D_i(\mathbf{h})} e^{-\langle \boldsymbol{\lambda}, \mathbf{a} \rangle} d\mathbf{a} &= 1 \quad , & (a) \\ C_0 \int_{D_i(\mathbf{h})} \mathbf{a} e^{-\langle \boldsymbol{\lambda}, \mathbf{a} \rangle} d\mathbf{a} &= \mathbf{r}_{0,i} \quad . & (b) \end{aligned} \quad (10)$$

(iii) Generator of independent realizations

The independent realizations of random variable $\mathbf{R}_{0,i}$ must be generated using the constructed PDF $p_{\mathbf{R}_{0,i}}$. Such a generator can be obtained using the Monte Carlo Markov Chain (MCMC) method (Metropolis-Hastings algorithm [5]).

3.1.3 Random matrix $[\mathbf{J}_i]$ of the random tensor of inertia.

In this subsection, the random matrix $[\mathbf{J}_i]$ of the random tensor of inertia with respect to $(\mathbf{G}_i, \underline{x}'_{i,1}, \underline{x}'_{i,2}, \underline{x}'_{i,3})$ is defined and an algebraic representation of this random matrix is constructed. The mass distribution around the random center of mass \mathbf{G}_i is uncertain and consequently, the tensor of inertia is also uncertain. This is the reason why the matrix $[\underline{J}_i]$ of the tensor of inertia of the mean (or nominal) model with respect to $(\underline{G}_i, \underline{x}'_{i,1}, \underline{x}'_{i,2}, \underline{x}'_{i,3})$ is replaced by a random matrix $[\mathbf{J}_i]$ which is constructed by using the maximum entropy principle.

We introduce the positive-definite matrix $[Z_i]$ independent of m_i such that

$$[Z_i] = \frac{1}{m_i} \left\{ \frac{\text{tr}([J_i])}{2} [I_3] - [J_i] \right\} \quad . \quad (11)$$

Then $[J_i]$ can be calculated as a function of $[Z_i]$,

$$[J_i] = m_i \{ \text{tr}([Z_i]) [I_3] - [Z_i] \} \quad . \quad (12)$$

It can be proven that $[Z_i]$ is positive definite and that each positive definite matrix $[J_i]$ constructed using Eq. (12), where $[Z_i]$ is a given positive definite matrix, can be interpreted as the matrix of a tensor of inertia of a physical rigid body for which the mass is 1 (see [1]).

The probabilistic modeling $[\mathbf{J}_i]$ of $[J_i]$ consists in introducing the random matrix $[\mathbf{Z}_i]$ and in using Eq. (12) in which m_i is replaced by the random variable M_i and where $[Z_i]$ is replaced by $[\mathbf{Z}_i]$. We then obtain

$$[\mathbf{Z}_i] = \frac{1}{M_i} \left\{ \frac{\text{tr}([\mathbf{J}_i])}{2} [I_3] - [\mathbf{J}_i] \right\}, \quad (13)$$

$$[\mathbf{J}_i] = M_i \{ \text{tr}([\mathbf{Z}_i]) [I_3] - [\mathbf{Z}_i] \} \quad . \quad (14)$$

(i) *Available information concerning random matrix $[\mathbf{Z}_i]$*

Let us introduce (1) the nominal value $[\underline{Z}_i]$ of deterministic matrix $[Z_i]$ such that $[\underline{Z}_i] = (1/m_i) \{ \text{tr}([\underline{J}_i])/2 [I_3] - [\underline{J}_i] \}$ and (2) the upper bound $[Z_i^{\max}]$ of random matrix $[\mathbf{Z}_i]$. Then, the available information for $[\mathbf{Z}_i]$ can be summarized as follows,

$$\begin{aligned} [\mathbf{Z}_i] &\in \mathbb{M}_3^+(\mathbb{R}) \quad \text{a.s.} \quad , \\ \{[Z_i^{\max}] - [\mathbf{Z}_i]\} &\in \mathbb{M}_3^+(\mathbb{R}) \quad \text{a.s.} \quad , \\ E\{[\mathbf{Z}_i]\} &= [\underline{Z}_i] \quad , \\ E\{\log(\det[\mathbf{Z}_i])\} &= C_i^l \quad , \quad |C_i^l| < +\infty \quad , \\ E\{\log(\det([Z_i^{\max}] - [\mathbf{Z}_i]))\} &= C_i^u \quad , \quad |C_i^u| < +\infty \quad .(e) \end{aligned} \quad (15)$$

For more convenience, random matrix $[\mathbf{Z}_i]$ is normalized as follow. Matrix $[\underline{Z}_i]$ being positive definite, its Cholesky decomposition yields $[\underline{Z}_i] = [\underline{L}_{Z_i}]^T [\underline{L}_{Z_i}]$ in which $[\underline{L}_{Z_i}]$ is an upper triangular matrix in the set $\mathbb{M}_3(\mathbb{R})$ of all the (3×3) real matrices. Then, random matrix $[\mathbf{Z}_i]$ can be rewritten as

$$[\mathbf{Z}_i] = [\underline{L}_{Z_i}]^T [\mathbf{G}_i] [\underline{L}_{Z_i}] \quad , \quad (16)$$

in which the matrix $[\mathbf{G}_i]$ is a random matrix for which the available information is

$$\begin{aligned} [\mathbf{G}_i] &\in \mathbb{M}_3^+(\mathbb{R}) \quad \text{a.s.} \quad , \\ \{[G_i^{\max}] - [\mathbf{G}_i]\} &\in \mathbb{M}_3^+(\mathbb{R}) \quad \text{a.s.} \quad , \\ E\{[\mathbf{G}_i]\} &= [I_3] \quad , \\ E\{\log(\det[\mathbf{G}_i])\} &= C_i^{l'} \quad , \quad |C_i^{l'}| < +\infty \quad , \\ E\{\log(\det([G_i^{\max}] - [\mathbf{G}_i]))\} &= C_i^{u'} \quad , \quad |C_i^{u'}| < +\infty \quad , \end{aligned} \quad (17)$$

in which $C_i^{l'} = C_i^l - \log(\det[\underline{Z}_i])$, $C_i^{u'} = C_i^u - \log(\det[\underline{Z}_i])$ and where the matrix $[G_i^{\max}]$ is an upper bound for random matrix $[\mathbf{G}_i]$ and is defined by $[G_i^{\max}] = ([\underline{L}_{Z_i}]^T)^{-1} [Z_i^{\max}] [\underline{L}_{Z_i}]^{-1}$.

(ii) *Maximum entropy principle*

The probability distribution of random matrix $[\mathbf{G}_i]$ is constructed using the maximum entropy principle under the constraints defined by the available information given by Eq. (17). The probability density function $p_{[\mathbf{G}_i]}([G])$ with respect to the volume element dG of random matrix $[\mathbf{G}_i]$ is then written as

$$\begin{aligned} p_{[\mathbf{G}_i]}([G]) &= \mathbf{1}_{\mathbb{M}_3^+(\mathbb{R})}([G]) \times \mathbf{1}_{\mathbb{M}_3^+(\mathbb{R})}([G_i^{\max}] - [G]) \times C_{G_i} \\ &\times (\det [G])^{-\lambda_l} \times (\det ([G_i^{\max}] - [G]))^{-\lambda_u} \times e^{-\text{tr}([\mu][G])} \quad , \end{aligned} \quad (18)$$

in which the positive valued parameter C_{G_i} is a normalization constant, the real parameters $\lambda_l < 1$ and $\lambda_u < 1$ are Lagrange multipliers relative to the two last constraints defined by Eq. (17) and the symmetric real matrix $[\mu]$ is a Lagrange multiplier relative to the third constraint defined by Eq. (17). This probability density function is a particular case the Kummer-Beta matrix variate distribution (see [11], [4]) for which the lower bound is a zero matrix.

Parameters C_{G_i} , λ_l , λ_u and matrix $[\mu]$ are the unique solution of the equations

$$\begin{aligned} E\{\mathbf{1}_{\mathbb{M}_3^S(\mathbb{R})}([\mathbf{G}_i])\} &= 1 \quad , \\ E\{[\mathbf{G}_i]\} &= [I_3] \quad , \\ E\{\log(\det[\mathbf{G}_i])\} &= C_i^{l'} \quad , \\ E\{\log(\det([G_i^{max}] - [\mathbf{G}_i]))\} &= C_i^{u'} \quad . \end{aligned} \quad (19)$$

For fixed values of λ_l and λ_u , parameters C_{G_i} and $[\mu]$ can be estimated using Eq. (19). In Eq. (19), since the parameters $C_i^{l'}$ and $C_i^{u'}$ have no real physical meaning, the parameters λ_l and λ_u are kept as parameters which then allows the "shape" of the PDF to be controlled. If experimental data are available for the responses of the dynamical system, then the two parameters λ_l and λ_u can be identified solving an inverse problem. If experimental data are not available, these two parameters allow a sensitivity analysis of the solution to be carried out with respect to the level of uncertainties.

(iii) Properties for random matrix $[\mathbf{J}_i]$

It is proven in [1] that using Eq. (14) and the available information defined by Eq. (15), the following important properties for random matrix $[\mathbf{J}_i]$ can be deduced,

$$\begin{aligned} \{\tfrac{1}{2}tr([\mathbf{J}_i]) [I_3] - [\mathbf{J}_i]\} &\in \mathbb{M}_3^+(\mathbb{R}) \quad a.s \quad , \quad (a) \\ \{[\mathbf{J}_i^{max}] - [\mathbf{J}_i]\} &\in \mathbb{M}_3^+(\mathbb{R}) \quad a.s \quad , \quad (b) \\ E\{[\mathbf{J}_i]\} &= [\underline{J}_i] \quad , \quad (c) \\ \{\lambda_l < -2, \lambda_u < 0\} &\Rightarrow E\{\|[\mathbf{J}_i]^{-1}\|^2\} < +\infty \quad , \quad (d) \end{aligned} \quad (20)$$

in which the random matrix $[\mathbf{J}_i^{max}]$, which represents a random upper bound for random matrix $[\mathbf{J}_i]$, is defined by

$$[\mathbf{J}_i^{max}] = M_i\{tr([Z_i^{max}]) [I_3] - [Z_i^{max}]\} \quad . \quad (21)$$

It should be noted that Eq. (20-a) implies that each realization of random matrix $[\mathbf{J}_i]$ corresponds to the matrix of a tensor of inertia of a physical rigid body. In addition, this equation implies that random matrix $[\mathbf{J}_i]$ is almost surely positive definite. Eq. (20-b) provides a random upper bound for random matrix $[\mathbf{J}_i]$. Eq. (20-c) corresponds to a construction for which the mean value of random matrix $[\mathbf{J}_i]$ is equal to the nominal value $[\underline{J}_i]$. Finally, Eq. (20-d) is necessary for that the random solution of the nonlinear dynamical system be a second-order stochastic process.

(iv) Generator of independent realizations for random matrix $[\mathbf{J}_i]$

The generator of independent realizations of random matrix $[\mathbf{G}_i]$ is based on the Monte Carlo Markov Chain (MCMC) (Metropolis-Hastings algorithm [5] with the PDF defined by Eq. (18). Then, independent realizations of random matrix $[\mathbf{Z}_i]$ are obtained using Eq. (16). Finally, independent realizations of random matrix $[\mathbf{J}_i]$ are obtained using Eq. (14) and independent realizations of random mass M_i .

3.2 Stochastic matrix model for a multibody dynamical system with uncertain rigid bodies and its random response

In order to limit the developments, it is assumed that only one of the n_b rigid bodies denoted by RB_i of the rigid multibody system is uncertain. The extension to several uncertain rigid bodies is straightforward. Let the $6n_b$ random coordinates be represented by the \mathbb{R}^{6n_b} -valued stochastic process $\mathbf{U} = (\mathbf{R}_1, \dots, \mathbf{R}_{n_b}, \mathbf{S}_1, \dots, \mathbf{S}_{n_b})$ indexed by $[0, T]$ and let the n_c random Lagrange multipliers be represented by the \mathbb{R}^{n_c} -valued stochastic process $\mathbf{\Lambda}$ indexed by $[0, T]$. The deterministic Eq. (6) becomes the following stochastic equation

$$\begin{bmatrix} [\mathbf{M}] & [\varphi_u]^T \\ [\varphi_u] & [0] \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{U}} \\ \mathbf{\Lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{q} - \mathbf{K} \\ -\frac{d}{dt}\varphi_t - [\frac{d}{dt}\varphi_u] \dot{\mathbf{U}} \end{bmatrix}, \quad (22)$$

$$\mathbf{U}(0) = \mathbf{U}_0, \quad \dot{\mathbf{U}}(0) = \mathbf{v}_0, \quad a.s. \quad (23)$$

in which the vector $\mathbf{U}_0 = (\mathbf{r}_{0,1}, \dots, \mathbf{R}_{0,i}, \dots, \mathbf{r}_{0,n_b}, \mathbf{s}_{0,1}, \dots, \mathbf{s}_{0,n_b})$ is random due to the random vector $\mathbf{R}_{0,i}$. For all given real vector $\dot{\mathbf{u}}$, the vector $\mathbf{K}(\dot{\mathbf{u}})$ of the Coriolis forces is random due to the random matrix $[\mathbf{J}_i]$. The random mass matrix $[\mathbf{M}]$ is defined by

$$[\mathbf{M}] = \begin{bmatrix} [\mathbf{M}^r] & 0 \\ 0 & [\mathbf{M}^s] \end{bmatrix}, \quad (24)$$

in which the $(3n_b \times 3n_b)$ random matrices $[\mathbf{M}^r]$ and $[\mathbf{M}^s]$ are defined by

$$[\mathbf{M}^r] = \begin{bmatrix} m_1[I_3] & \dots & 0 \\ \vdots & M_i[I_3] & \vdots \\ 0 & \dots & m_{n_b}[I_3] \end{bmatrix}, \quad (25)$$

$$[\mathbf{M}^s] = \begin{bmatrix} [J_1] & \dots & 0 \\ \vdots & [\mathbf{J}_i] & \vdots \\ 0 & \dots & [J_{n_b}] \end{bmatrix}. \quad (26)$$

Random Eqs. (22) and (23) are solved using the Monte Carlo simulation method.

4 APPLICATION

In this section, we present a numerical application which validates the methodology presented in this paper.

4.1 Description of the mean model

The rigid multibody model is made up of five rigid bodies and six joints which are described in the fixed frame $(O, x_{0,1}, x_{0,2}, x_{0,3})$ (see Fig. 1). The plan defined by $(O, x_{0,1}, x_{0,2})$ is identified below as the "ground". The gravity forces in the $x_{0,3}$ -direction are taken into account.

(i) *Rigid bodies*

In the initial configuration, the rigid bodies $Rb1$, $Rb2$, $Rb3$ and $Rb4$ are cylinders for which the

Figure 1: Rigid multibody system.

Figure 2: Imposed displacement $u1(t)$ (left figure) and $u2(t)$ (right figure).

axes follow the $x_{0,3}$ -direction. In the initial configuration, the rigid body $Rb5$ is supposed to be symmetric with respect to the planes $(G5, x_{0,1}, x_{0,2})$ and $(G5, x_{0,1}, x_{0,3})$ in which $G5$ is the center of mass of $Rb5$.

(ii) Joints

- The joint *Ground-Rb1* is made up of a prismatic joint following $x_{0,3}$ -direction. The displacement following $x_{0,3}$ -direction (see Fig. 1), denoted by $u1(t)$, is imposed. The joint *Ground-Rb2* is a prismatic joint following $x_{0,3}$ -direction. The displacement following $x_{0,3}$ -direction (see Fig. 1), denoted by $u2(t)$, is imposed. The displacement following $x_{0,1}$ -direction is unconstrained. Imposed displacements $u1(t)$ and $u2(t)$ are plotted in Fig. 2 for t in $[0, 0.03]$ s.
- The joints *Rb1-Rb3* and *Rb2-Rb4* are constituted of 6D spring-dampers..
- Finally, the joints *Rb3-Rb5* and *Rb4-Rb5* are $x_{0,2}$ -direction revolute joints.

4.2 Random response of the stochastic model

Rigid body $Rb5a$ is considered as uncertain and is therefore modeled by a random rigid body. As explained in Section 3, the elements of inertia of the uncertain rigid Body $Rb5$ are replaced by random quantities. The fluctuation of the response is controlled by four parameters δ_{M_5} , \mathbf{h} , λ_l and λ_u . A sensitivity analysis is carried out with respect to these four parameters. Statistics on the transient response are estimated using the Monte Carlo simulation method with 500 independent realizations. The initial velocities and angular velocities are zero. The observation point P_{obs} belongs to $Rb5$.

(i) Case 1: M_5 is random, $\mathbf{R}_{0,5}$ is deterministic and $[\mathbf{J}_5]$ is deterministic.

We choose $\delta_{M_5} = 0.5$. The confidence region, with a probability level $P_c = 0.90$, of the random

Figure 3: Random transient acceleration of point P_{obs} , Case 1: confidence region (upper and lower thin solid lines), mean response (thick solid line) and response of the mean model (dashed line); $x_{0,3}$ -acceleration (left figure) and $x_{0,1}$ -angular acceleration (right figure).

Figure 4: Random transient acceleration of point P_{obs} , Case 2: confidence region (upper and lower envelopes), mean response and response of the mean model are superimposed; $x_{0,3}$ -acceleration (left figure) and $x_{0,1}$ -angular acceleration (right figure).

acceleration of point P_{obs} is plotted in Fig. 3. It can be noted that the acceleration is sensitive to the mass uncertainties.

(ii) Case 2: M_i is deterministic, $\mathbf{R}_{0,5}$ is deterministic and $[\mathbf{J}_5]$ is random.

We choose $\lambda_l = -5$ and $\lambda_u = -5$ for random matrix $[\mathbf{J}_5]$. The confidence region, with a probability level $P_c = 0.90$, of the random acceleration of point P_{obs} is plotted in Fig. 4. We can remark, as it was expected, that the angular acceleration is sensitive to uncertainties on the tensor of inertia.

(iii) Case 3: M_5 is deterministic, $\mathbf{R}_{0,5}$ is random and $[\mathbf{J}_5]$ is deterministic.

The domain of $\mathbf{R}_{0,5}$ is supposed to be a parallelepiped which is centered at point $(0, 0, 0.55)$ for which its edges are parallel to the directions $x_{0,1}$, $x_{0,2}$ and $x_{0,3}$ and for which the lengths following these three directions are respectively 0.5, 0.2 and 0.02. The confidence region, with a probability level $P_c = 0.90$, of the random acceleration of point P_{obs} is plotted in Fig. 5. We can remark that the angular acceleration is sensitive to uncertainties on initial center of mass of $Rb5$.

(iv) Case 4: M_5 , $\mathbf{R}_{0,5}$ and $[\mathbf{J}_5]$ are random.

The values of the parameters of the PDF are those fixed in the three previous cases. The confidence region, with a probability level $P_c = 0.90$, of the random acceleration of point P_{obs} is plotted in Fig. 6. It can be viewed that (1) the randomness on the acceleration is mainly due to the randomness of mass M_5 , (2) the randomness on the angular acceleration is mainly due to the randomness of the initial position $\mathbf{R}_{0,5}$ of the center of mass and the random tensor of inertia $[\mathbf{J}_5]$.

Figure 5: Random transient acceleration of point P_{obs} , Case 3: confidence region (upper and lower envelopes), mean response and response of the mean model are superimposed; $x_{0,3}$ -acceleration (left figure) and $x_{0,1}$ -angular acceleration (right figure).

Figure 6: Random transient acceleration of point P_{obs} , Case 4: confidence region (upper and lower thin solid lines), mean response (thick solid line) and response of the mean model (dashed line); $x_{0,3}$ -acceleration (left figure) and $x_{0,1}$ -angular acceleration (right figure).

5 CONCLUSION

We have presented a complete and general probabilistic modeling of uncertain rigid bodies taking into account all the known mechanical and mathematical properties. This probabilistic model of uncertainties is used to construct the stochastic equations of uncertain multibody dynamical systems. The random dynamical responses can then be calculated. In the proposed probabilistic model, the mass, the center of mass and the tensor of inertia are modeled by random variables for which the prior probability density functions are constructed using the maximum entropy principle under the constraints defined by all the available mathematical, mechanical and design properties. Several uncertain rigid bodies can be linked each others in order to obtain the stochastic dynamical model of the uncertain multibody dynamical system. The theory proposed has been illustrated analyzing a simple example. The results obtained clearly show the role played by uncertainties and the sensitivity of the responses due to uncertainties on (1) the mass (2) the center of mass and (3) the tensor of inertia. Such a prior stochastic model allows the robustness of the responses to be analyzed with respect to uncertainties. If experimental data were available on the responses, then the parameters which control the level of uncertainties could be estimated by solving an inverse stochastic problem.

Keywords: SFR, Random Eigenvalue Problem, HPCEM, DSBM, Modal Intermixing.

Abstract. *The frequency response shows a big significance in estimating the structural response of linear systems subjected to dynamic loads. Its quantification is decided by the modal properties (e.g. natural frequencies and mode shapes), which are always involved in the random eigenvalue problem regarding uncertain structures. The conventional way to determine the associated stochastic frequency response (SFR) is the directly sample-based method (DSBM), which relays on Monte Carlo sampling technique and deterministic modal analysis by FEA. However, the accuracy of the DSBM is at the cost of efficiency since a large number of modal analyses are required. In this work, the Hermite polynomial chaos expansion method (HPCEM) is implemented to solve the random eigenvalue problem. The coefficients are estimated by the least square method (LSM) considering its robustness and facility. Furthermore, the modal intermixing problem is particularly considered whereby the mathematical limitation and physical validity of the HPCEM are specified. In order to fulfill the practical requirements, a univariable based strategy is proposed to avoid this issue. This strategy in conjunction with the modal assurance criterion (MAC) provides a quantitative way to define the modal intermixing. The fast modal solutions by the HPCEM will be helpful to control the dynamic response within certain frequency interval of interest during the design phase, on one hand; on the other hand, the HPCEM can also be used to evaluate the dynamic response and thereafter to improve efficiency of reliability analysis. Numerical investigations of the SFR provide the comparisons between the results obtained by the HPCEM and DSBM, which demonstrate the efficiency and accuracy.*

1 INTRODUCTION

Uncertainties are always taken into account for modern systems since there is no adequate information to precisely specify the structural parameters, boundary conditions and excitations, the randomness of which can be described by random variables or stochastic processes. Furthermore, the model uncertainties induced from the mathematical-mechanical modeling process has to be dealt with an alternative developed by Soize [17, 18] in the light of the random matrix theory. In the context of design or maintenance, how to determine the effects of uncertainties has been paid close attention to for decades.

In practical applications, complex structures or systems are always concerned. The procedure to obtain the structural response (other quantities such as the stress and deformation are also included) relies exclusively on the finite element analysis (FEA). One of the most attractive structural response of dynamical systems is the frequency response, which can provide the information of the response within certain excitation frequency interval of interest. It will be helpful to control the amplitude of the response in the design phase [19–22], regardless of deterministic systems or random systems. In cases where the uncertainties are considered, in conjunction with Monte Carlo sampling technique, huge amounts of deterministic FE analyses have to be executed so as to quantify the statistics of the structural response. The way mentioned above to determine the associated SFR is the DSBM, which is related to MCS. However, this method will not be tractable in engineering due to computationally intensive numerical simulation.

For linear structures, the frequency response is the function of the modal properties, i.e. natural frequencies, mode shapes and modal damping. As long as the statistics of the modal properties can be decided, the randomness of the SFR are readily characterized. To gain the statistics of the modal properties, the random eigenvalue problem is usually involved. From the literatures, the perturbation method [15, 23] is a classic method to solve this problem. Nevertheless, the achieved accuracy will only be satisfied for random inputs (e.g. material properties) with small coefficients of variation (COV), say less than 5% [23]. To this end, an alternative named the HPCEM [4, 5, 15] is developed to solve the random eigenvalue problem.

In current work, the HPCEM is implemented to calculate the eigenvalues and eigenvectors defined in [11]. The LSM is implemented to determine the associated coefficients. The DSBM based on Matlab in conjunction with FE-software is applied to prepare the small number of samples for the LSM. Moreover, the modal intermixing [14] or modal interaction [15, 16] problem is particularly considered whereby the mathematical limitation and physical validity of the HPCEM are specified. Regarding the practical applications, it is dispensable to be avoided. However, none of the above works provide an effective way to remove this issue. In this case, a univariable based strategy is proposed, the kernel of which is to keep the random eigenvalues and eigenvectors with small variability comparing to the mean model. The consistency is delineated by the MAC (modal assurance criterion) factor. In this strategy, we can check which random variable can cause modal intermixing and then avert the modal intermixing by reducing the associated variance.

In section 2, the SFR representation of multi-degree structures is addressed. Section 3 specifies the DSBM and HPCEM to solve the random eigenvalue problem and discusses the approaches to calculate the associated coefficients. In Section 4, we state the strategy to avoid the modal intermixing problem. To show the efficiency and accuracy, in Section 5, two numerical examples are investigated, which are demonstrated by comparing the results obtained by the DSBM. At last, we summarize the main findings of this work in Section 6.

2 SFR REPRESENTATION

The SFR of a linear multi-degree structure can be calculated by the modal superposition principle which is written as:

$$d_{rk}(\boldsymbol{\theta}, \omega) = \sum_j^{N \ll n} \frac{\phi_{rj}(\boldsymbol{\theta}) \phi_{kj}(\boldsymbol{\theta}) \omega^l}{\omega_j^2(\boldsymbol{\theta}) + i \cdot 2\zeta_j(\boldsymbol{\theta}) \omega_j(\boldsymbol{\theta}) \omega - \omega^2}, \quad (1)$$

where $d_{rk}(\boldsymbol{\theta}, \omega)$ denotes the SFR at the r th degree of freedom (DOF) under the excitation at the k th DOF; $\boldsymbol{\theta}$ indicates the set of random structural parameters; ω is the excitation frequency; $\omega_j(\boldsymbol{\theta})$ is associated with the j th random natural frequency, i.e. $\lambda_j = \omega_j^2(\boldsymbol{\theta})$ is the associated random eigenvalue; $\phi_{kj}(\boldsymbol{\theta})$ represents the j th random eigenvector (mode shape) at the k th DOF; $l = 0, 1, 2$ represent the displacement, velocity and acceleration SFR, respectively; n is the number of the DOF, while N is the number of the modes of interest.

High non-linearity has been observed in Eq. (1) so that no simple linearly approximate relation between the SFR and random parameters can be found. To this end, more attempts to solve the random eigenvalue problem have been made since the SFR is expressed explicitly by the natural frequencies and mode shapes.

3 RANDOM EIGENVALUE PROBLEM

3.1 DSBM

Regarding the random eigenvalue problem, the simply numerical method is the DSBM. In this work, the general process is realized by Matlab and FE softwares shown in Fig.1. Matlab takes charge of generating random variables (random inputs) and FE softwares provide modal solutions. The advantages of this method are those:

- Matlab can offer commonly used random variables based on Monte Carlo sampling technique. That means we can get almost any unimodal distributed random variable of interest efficiently and accurately.
- The modal analysis is the basic module of most FE softwares. No matter how complex and large the structure is, modal solutions of FE softwares could be reasonably precise.
- There is no assumption during the whole process. Hence, all the results are accurate which can be treated as calibrations.

Because FE softwares are usually the deterministic solvers, each time they can only carry out one modal analysis associated with one set of random variables. It is obvious that, in order to gain a large number of modal solutions, the process must be repeated for many times shown in Fig. 1. As a result, this method is computationally expensive, which is not practical in engineering.

3.2 Approximate sample-based method

3.2.1 HPCEM

The generalized random eigenvalue problem of undamped multi-degree structures is given by:

$$[K(\boldsymbol{\theta})]\{\phi(\boldsymbol{\theta})\} = \lambda(\boldsymbol{\theta})[M(\boldsymbol{\theta})]\{\phi(\boldsymbol{\theta})\}, \quad (2)$$

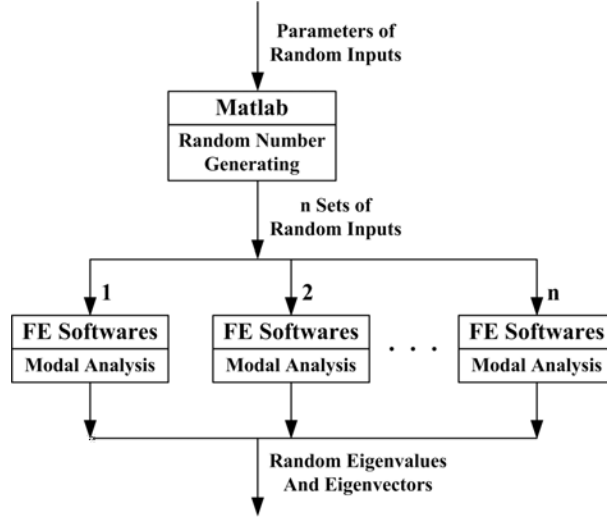

Figure 1: DSBM

where $[K(\theta)]$ and $[M(\theta)]$ are random stiffness and mass matrices; $\lambda(\theta)$ and $\{\phi(\theta)\}$ represent random eigenvalue and eigenvector respectively. Solving a random eigenvalue problem, the statistics of the eigenvalue and eigenvector must be characterized by the randomness of the structures, i.e the random inputs θ . Based on the theorem of Gameron-Martin [6], a square integrable random variable can be represented by HPC with an acceptable convergence. In case that the convergence rate is substantially slow, extensions to other orthogonal polynomials (named Wiener-Askey polynomial chaos) representation could be used according to the work [1,4,5]. Furthermore, Roger Ghanem et al [2] used HPC to express the stiffness matrix, random eigenvalues and eigenvectors to solve the random eigenvalue problem (see Eq. (2)). Inspired by these works, the j th random eigenvalue and eigenvector can reasonably be formed as:

$$\lambda_j = \sum_{p=0}^{\infty} a_p H_p(\xi), \quad \{\phi\}_j = \sum_{p=0}^{\infty} b_p H_p(\xi), \quad (3)$$

where $H_p(\xi)$ is the multidimensional HPC of order p in standard normal space in which ξ represents the standard normal variables, a_p and b_p are the constant coefficients. HPC has the properties:

$$H_0 \equiv 1, \quad \langle H_p = 0 \rangle, \quad p > 0, \quad \langle H_p H_q \rangle = \delta_{pq} \langle H_p^2 \rangle, \quad (4)$$

where δ_{pq} is the Kronecker delta and $\langle \cdot, \cdot \rangle$ denotes the ensemble average. This is the inner product in the Hilbert space of Gaussian random variables defined by:

$$\langle f(\xi)g(\xi) \rangle = \int f(\xi)g(\xi)W(\xi)d\xi, \quad (5)$$

The weight $W(\xi)$ function is multidimensional Gaussian joint probability density function. Notice that Hermite polynomials are functions of standard normal random variables ξ . In the original random eigenvalue problem (see Eq. (2)), random solutions are determined by random variables θ . θ and ξ are usually not the same. Nonetheless, implementation of transformation techniques, such as Rossenblatt transformation [7] and Nataf model in [8], the random variables θ can be transformed to standard normal random variables ξ with one to one mapping: $\theta_i \rightarrow \xi_i$. Then the Eq. (2) will be rewritten as:

$$[K(\xi)]\{\phi(\xi)\} = \lambda(\xi)[M(\xi)]\{\phi(\xi)\}, \quad (6)$$

Some analytical transformations between random variables of common univariate distributions and standard normal variables have been listed in [9, 10]. From Eq. (1), the SFR is the function of natural frequencies ω_j , and the eigenfactor defined as $\phi_{rj}\phi_{kj}$ [11]. Debusschere et al [12] indicated that multiplication of two random variables expanded by polynomial chaos can also be expanded by the same polynomial chaos. This proposition can save the CPU time. Moreover, the elements ϕ_{rj} and ϕ_{kj} from the same eigenvector which insinuates that they have the same converged rate. Consequently, we can use the HPC expansion to represent the eigenfactor directly:

$$\phi_{rj}\phi_{kj} = \sum_{p=0}^{\infty} c_p H_p(\boldsymbol{\xi}), \quad (7)$$

3.2.2 Coefficients calculation

When implementing HPC, one of the critical issues is to accurately estimate the coefficients. In the expressions of random eigenvalues and eigenfactors (See Eq. (3) and Eq. (7)), the number of the coefficients is infinite. This formula is not tractable in practice. Generally, the truncation formula is usually used. The representations of eigenvalues and eigenvectors are rewritten as:

$$\lambda_j = \sum_{p=0}^P a_p H_p(\boldsymbol{\xi}), \quad \phi_{rj}\phi_{kj} = \sum_{p=0}^P c_p H_p(\boldsymbol{\xi}), \quad (8)$$

The total number of polynomial chaos is $N_{pc} = P + 1$ which is determined by the dimension N_{rv} of random variables $\boldsymbol{\xi}$ and the highest order N_{ho} of the HPC.

$$N_{pc} = \frac{(N_{rv} + N_{ho})!}{N_{rv}! N_{ho}!}, \quad (9)$$

Several methods can be exploited to compute the coefficients:

- Orthogonalized method [2]. This method makes use of the orthogonality of the polynomial chaos basis. Taking the inner product in Eq. (8) with H_p , we have

$$a_p = \frac{\langle \lambda_j H_p \rangle}{\langle H_p^2 \rangle}, \quad c_p = \frac{\langle \phi_{rj}\phi_{kj} H_p \rangle}{\langle H_p^2 \rangle}, \quad (10)$$

The denominators in the above expressions have been calculated in [3]. However, the numerators are usually evaluated by MCS. To keep the coefficients accurate, a large quantity of samples are needed. In that case, we prefer the DSBM since the orthogonalized method takes no advantage of economy.

- Probabilistic collocation method [9, 13]. As the name defined, the collocation points are specially selected which correspond to the roots of the Hermite polynomial of one degree higher than the maximum order of current HPC expansion. With the increase of the number of random inputs and the order of the expansion, the number of available collocation points increasing exponentially. For example, in Eq. (9), for the case $N_{rv} = 5, 6$ and $N_{ho} = 2, 3$, the number of the collocation is $(N_{ho} + 1)^{N_{rv}} = 243, 4096$, whereas $N_{pc} = 21, 84$ respectively. As long as the selected number of the collocation points is equal to the number of HPC expansion terms, we could obtain the coefficients by solving a set of equations. However, different combination of collocation points may result in different coefficients. This imposes the instability of the collocation method.

- Least square method (LSM). This method belongs to parametric data fitting methods which will be representative for the whole sample population rather than precisely fitting each sample point. From this point of view, as long as the HPC expansion model can contain all information of random outputs, least square method is the first choice thanks to its facilities and efficiency. Let $\{a\} = [a_1, \dots, a_p, \dots, a_{N_{pc}}]^T$, $\{c\} = [c_1, \dots, c_p, \dots, c_{N_{pc}}]^T$ and $[H] = \{H_1, \dots, H_p, \dots, H_{N_{pc}}\}$. Consequently, the least square solutions of the coefficients with respect to the j^{th} set of random eigenvalues and eigenfactors are

$$\{a\} = ([H]^T[H])^{-1}[H]^T\{\lambda_j\}, \quad \{c\} = ([H]^T[H])^{-1}[H]^T\{\phi_{rj}\phi_{kj}\} \quad (11)$$

Here $\{\lambda_j\}$ and $\{\phi_{rj}\phi_{kj}\}$ are the m -dimension vectors, in which m denotes the number of random input samples; $[H]$ is the matrix of dimension of $m \times N_{pc}$. **For this work, LSM is utilized.** That signifies when we need M random eigenpairs, only $m \ll M$ are needed to determine the HPC representation, with which the M random eigenpairs are readily gained.

Practically, no matter what method is applied to calculate the coefficients, another critical issue is that HPC expansion can represent the random eigenvalue reasonably. In the next section, the mathematical limitation and physical validity of the HPCEM will be discussed.

4 MODAL INTERMIXING

4.1 Problem description

In random structures, the modal intermixing [14] or modal interaction [15, 16] phenomenon is usually observed when using MCS to model the uncertainties. That means, from one simulation to next, the adjacent modes may exchange whereby the random eigenvectors associated with the same order, actually, contain more than one mode. Generally, different modes behave physically different. This is exacerbated for those structures with closed space eigenvalues as the variances of random inputs increase. That is, mathematically, because the area of probability overlapping of adjacent modes become larger and larger.

Modal intermixing can strongly affect the accuracy of the HPCEM. In fact, the HPC expansion is originated to represent the solutions of random differential equations. That signifies one deterministic HPC expansion just refers to the random solutions of one family. Accordingly, for random eigenvalue problem, the accuracy of HPCEM is guaranteed by averting the modal intermixing problem. Such mathematical limitation seems to restrict wide applications of the HPCEM for random eigenvalue problem. However, this limitation has great significance in practice.

In engineering, when concerning the randomness in structures, the mean model is usually treated as a benchmark or reference. The modal behaviors of uncertain structures should be consistent with the benchmark. In that case, the modal intermixing is indispensable to avoid, the interpretation of which is that the variabilities of random eigenvalues and eigenvector should be limited in a reasonably acceptable bounds.

4.2 MAC factor

As indicated above, the variabilities of random eigenvalues and eigenvectors around the ones of mean model ought to be small in order to remove the modal intermixing issue. If this property holds, the random mode shape can be described as a linear combination [15, 19] of N mode shapes of mean model. The j th eigenvector of simulation k is formulated as:

$$\{\phi\}_j^{(k)} = \sum_{i=1}^N A_i^{(k)} \{\phi\}_i^{(0)}, \quad 1 \leq j \leq N, \quad (12)$$

where N is the number of modes considered in Eq. (1); $A_i^{(k)}$ denotes the constant weight coefficient; $\{\phi\}_i^{(0)}$ represents the i th eigenvector of the mean model. When the behaviors of random models are identical with the ones of mean model, the effects of the other modes can be ignored, which is interpreted as the most contribution to the sample $\{\phi\}_j^{(k)}$ is from the j th mode of the mean model. In this situation, the last equation in the approximate formula is:

$$\{\phi\}_j^{(k)} \approx A_j^{(k)} \{\phi\}_j^{(0)}, \quad A_j^{(k)} > 0, \quad (13)$$

Obviously, the angle between eigenvector $\{\phi\}_j^{(k)}$ and $\{\phi\}_j^{(0)}$ will meet $\alpha_j^{(k)} \approx 0$. In conjunction with Eq. (13), the direction cosine of these two eigenvectors has the property:

$$\cos(\alpha_{jj}^{(k)}) = \frac{\{\phi\}_j^{(k)} \cdot \{\phi\}_j^{(0)}}{\|\{\phi\}_j^{(k)}\| \|\{\phi\}_j^{(0)}\|} \approx 1, \quad (14)$$

Here, $\{\phi\}_j^{(k)} \cdot \{\phi\}_j^{(0)}$ denotes the dot product and $\|\{\phi\}_j^{(0)}\|$ is the Euclidean norm. Eq. (14) is the condition to prevent the random models from the modal intermixing. It is actually a variant of the Modal Assurance Criterion (MAC) [24]. The corresponding MAC factor is defined by:

$$f_{MAC_{jj}}^{(k)} = \frac{(\{\phi\}_j^{(k)} \cdot \{\phi\}_j^{(0)})^2}{\|\{\phi\}_j^{(k)}\|^2 \|\{\phi\}_j^{(0)}\|^2} = \cos^2(\alpha_{jj}^{(k)}) \approx 1 \quad (15)$$

The MAC is the criterion to check the consistency between two modes. When the value approaches unity, the consistency is well observed; on the contrary, the value is smaller than 1, the behaviors show the violation. The modal intermixing is the right phenomenon from one simulation to another that reflects the violated modes against the mean modes. Therefore, based on Eq. (15), the MAC factor is an indicator of the modal intermixing:

$$\begin{aligned} f_{MAC_{jj}}^{(k)} &\approx 1, & \text{no modal intermixing} \\ f_{MAC_{jj}}^{(k)} &< 1, & \text{modal intermixing} \end{aligned} \quad (16)$$

4.3 Univariable based strategy

The randomness in modal properties is induced from the random inputs. We have to note that the information of underlying physical models is usually insufficient so that uncertainties are always assumed to follow certain distribution. Mean values can be obtained readily according to the knowledge of the problems right in hand. On the contrary, it is difficult to get the precise variance since the number of sampling tests is practically small. For that reason, by means of simulation techniques, we need to carefully select the proper variance to fulfill the practical requirements, i.e. no modal intermixing.

So as to select the proper variance, a univariable based strategy is proposed to check which random input can cause the modal intermixing and determine what variance should be used. In this strategy, only one parameter is treated as random variable; others are deterministic. Special random inputs around the mean value are picked out to capture the associated modal solutions.

Let μ_θ and σ_θ be the mean and standard deviation (SD) of random variable θ . Then, the random inputs are written as:

$$\{\tilde{\theta}\} = [\mu_\theta \pm 2\sigma_\theta \quad \mu_\theta \pm 3\sigma_\theta \quad \mu_\theta \pm 4\sigma_\theta \quad \mu_\theta \pm 5\sigma_\theta]^T; \quad (17)$$

where $\{\tilde{\theta}\}$ are the selected random inputs of dimension 8. The last four elements of $\{\tilde{\theta}\}$ suggest the very rare realizations. If all the associated eigenvectors especially the ones corresponding the rare random inputs can meet the condition in Eq. (15), σ_θ is the proper SD; otherwise, a smaller SD will be used to check until the condition is satisfied. An infeasible variance is always chosen as the initial one so that the final choice will be as large as possible. Because only 8 modal analyses are required for each candidate variance, regardless of simple systems or complex systems, this strategy will be computationally efficient. Furthermore, this strategy is insensitive with distributions of random inputs since the special random inputs are determined by the mean and SD but the types of distributions. For those reasons, this strategy is very powerful to avoid the modal intermixing.

5 NUMERICAL EXAMPLES

In the following, two models are investigated to demonstrate the efficiency and accuracy of this procedure to determine the statistics of the SFR. Random structural parameters are modeled by normal, lognormal and Gamma distribution respectively for both examples.

Due to the similarity of the results, only the cases associated with normal distribution are specified. In Section 5.1, a 2-D bridge-like structure: simply supported beam is regarded. For this model, no modal intermixing problem is taken into consideration as it belongs to the structure with largely-spaced frequencies. A building-like structure: fixed support plate-beam is investigated in Section 5.2. The modal intermixing problem must be considered due to its high symmetry.

5.1 Bridge-like structure: simply supported beam

Figure 2: Beam model

A 2-D simply supported beam shown in Fig. 2. The first three modes have been used to estimate the SFR. The corresponding natural frequencies of the mean model are $\omega_1 = 321.0$ rad/s, $\omega_2 = 921.9$ rad/s and $\omega_3 = 2065.9$ rad/s. Two deterministic parameters are: Poisson's ratio $\nu = 0.3$, modal damping ratio coefficient $\zeta = 0.05$; the other parameters are independent random variables, the mean values of which are $\rho = 7.8 \times 10^3$ kg/m³, $E = 2.0 \times 10^{11}$ Pa, $L = 2.5$ m, $H = 0.1$ m, $W = 0.08$ m for density, Young's modulus, length, height and width respectively. Two levels of coefficients of variance (COV), $COV = 5\%$ and $COV = 10\%$, are considered associated with each distribution. All following results are related to the node in the middle.

5.1.1 PDFs investigations

Consider normal distribution. Fig. 3(a) and Fig. 3(b) show the probability density functions (PDFs) of eigenvalues and eigenfactors for the first three modes. The perfect consistence be-

tween the distributions obtained by HPCEM and DSBM implies that HPCEM can reflect the statistics characteristics correctly. The largest error of the PDF estimation occurs for the second eigenfactor. However, it is emphasized that the magnitude is very small which contributes almost zero to the SFR. Therefore, such bad approximation of Mode 2 can be ignored. Moreover, larger COVs of eigenvalues and eigenfactors are observed as to the random inputs with large COVs. The approximate method such as perturbation method always has difficulty in dealing with larger COV problems, while the HPCEM can provide the acceptable results. Therefore, the HPCEM is a powerful tool to solve such problems.

It is revealed that the choice of the current order of HPC seems not sufficient since differences exist. Note that increasing the order of HPC is profitable in improving the accuracy. But we have to pay attention that higher order HPC signifies the more computational expense. Accordingly, there should be a trade-off between the efficiency and accuracy. The similar results of PDFs can be seen from the rest four figures in Fig. 3 corresponding the other two distributions.

(a) Normal: $COV = 5\%$ (b) Normal: $COV = 10\%$ (c) Lognormal: $COV = 5\%$ (d) Lognormal: $COV = 10\%$ (e) Gamma: $COV = 5\%$ (f) Gamma: $COV = 10\%$

Figure 3: PDF of eigenvalues and eigenfactors based on 10000 samples

5.1.2 SFR investigations

Fig. 4 shows a comparison of the statistics of the SFR between the DSBM and HPCEM, in which the maximum, minimum, mean value of the SFR are very close to each other, respectively. The differences are observed for larger COV (see Fig. 4(b), 4(d) and 4(f)). However, the mean value comparisons represent little difference, which is very significant for reliability analysis. For smaller COV, the maximum is smaller.

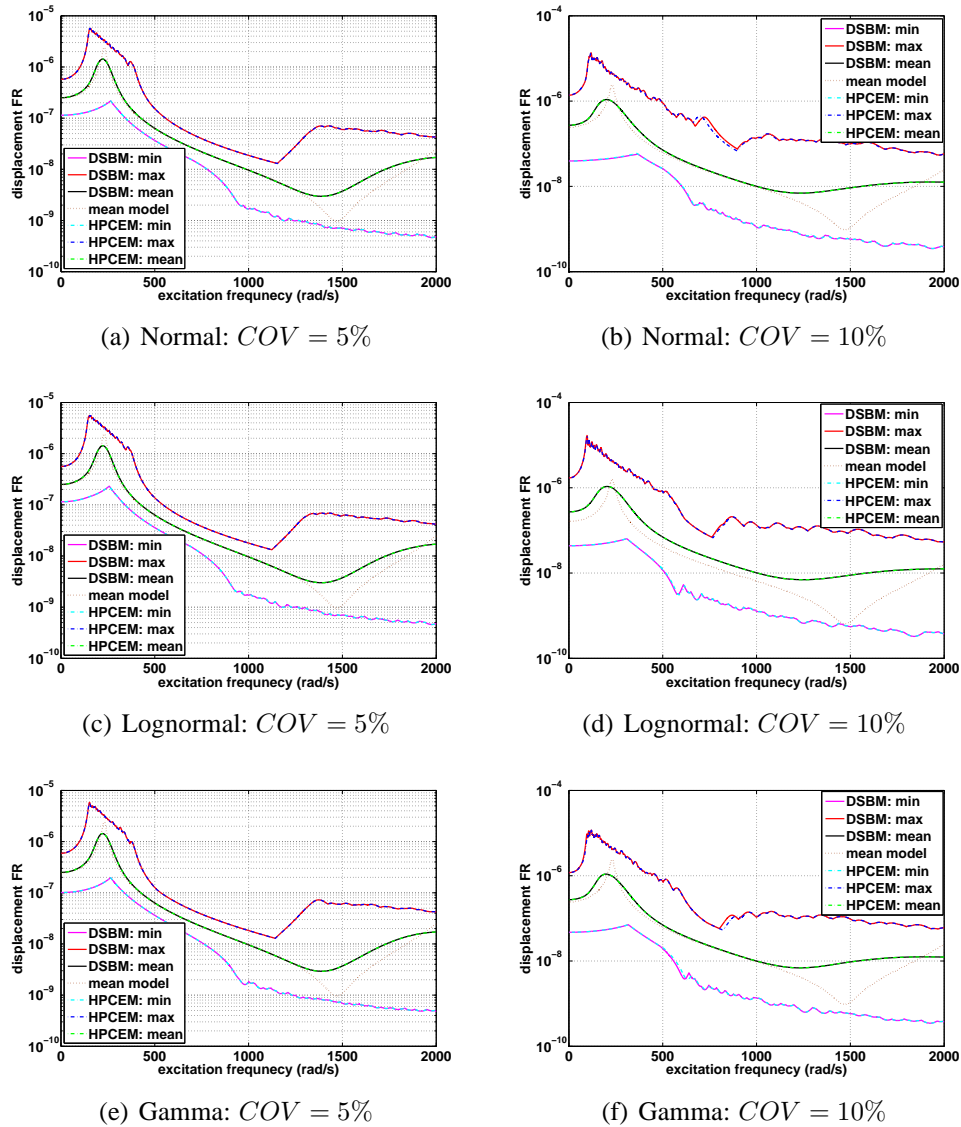

Figure 4: SFR based on 10000 samples for beam

The fourth-order HPC expansion are utilized to represent the eigenvalues and eigenfactors for all considered distributions with both COV levels. According to Eq. (9), the number of coefficients is 126. After numerical examinations, 400 samples are chosen to calculate these coefficients, which is more or less 3 times the coefficients.

In the following, a comparison of average computational time will be specified. So as to obtain the results in Fig. 4, 10^4 modal analyses are executed in the context of DSBM. Yet, for the HPCEM, only 400 modal analyses are carried out by DSBM and plus 10s to determine the

coefficients and approximate 10^4 sets of eigenpairs. In conclusion, HPCEM only needs about 4% CPU time of the one needed by DSBM. Efficiency is strongly improved.

It is evident that the HPCEM could be a general method to deal with eigenvalue problem since good results are obtained for the normal, lognormal and Gamma distribution respectively. From the above, HPCEM has the capacities to estimate the SFR effectively, which is of big value concerning reliability analysis since it can save a lot of time from generating a large quantity of samples. Moreover, for structures with larger COV, it turns out that HPCEM is a powerful tool. We also find that the LSM works well in estimating the coefficients of HPC model.

5.2 Building-like structure: plate-beam

In this example, four parameters are selected as random inputs. They are: density, mean value $\mu_\rho = 7.8 \times 10^3$, $COV = 10\%$; Young's modulus, mean value $\mu_E = 2.0 \times 10^{11}$, $COV = 10\%$; beam length, mean value $\mu_{BL} = 3$, $COV = 1.75\%$; plate thickness, mean value $\mu_{PT} = 0.02$, $COV = 2\%$. The cases with random inputs following lognormal, normal and Gamma distribution are studied respectively. More information about this model are as followed: Poisson's ratio $\nu = 0.3$, modal damping ratio coefficient $\zeta = 0.01$, the height of beam is 0.04, the width of beam is 0.04 and the length of plate (square) is 5. All the unites belong to SI. Ten modes are used to calculated the displacement response. The natural frequencies of the mean model are $\omega_1 = 1.30$ rad/s, $\omega_2 = 1.31$, $\omega_3 = 1.87$, $\omega_4 = 3.99$ rad/s, $\omega_5 = 4.01$ rad/s, $\omega_6 = 5.78$ rad/s, $\omega_7 = 6.48$ rad/s, $\omega_8 = 6.50$ rad/s, $\omega_9 = 9.56$ rad/s and $\omega_{10} = 10.86$ rad/s. 294 nodes are in the FE model which is shown in Fig. 5. The results are related to node 14 in direction X. Because of high symmetry in this model, modal intermixing must be considered. The COVs mentioned above are the proper ones selected by the univariable based strategy.

Figure 5: Plate-Beam model

5.2.1 Modal intermixing

Take the random parameter plate thickness as the example. Fig. 6 schematically describes the MAC factors with respect to 8 special random inputs. It is found that the modal intermixing always concerns the random model whose plate thickness is less than the mean value. The

explanation is that as the thickness decreases, the flexibility increases since the plate belongs to thin walled structures. The associated structural behaviors can be different from the reference (mean model) more easily. Yet, as to thicker plates, the modes have a large probability to agree with the ones of the mean model.

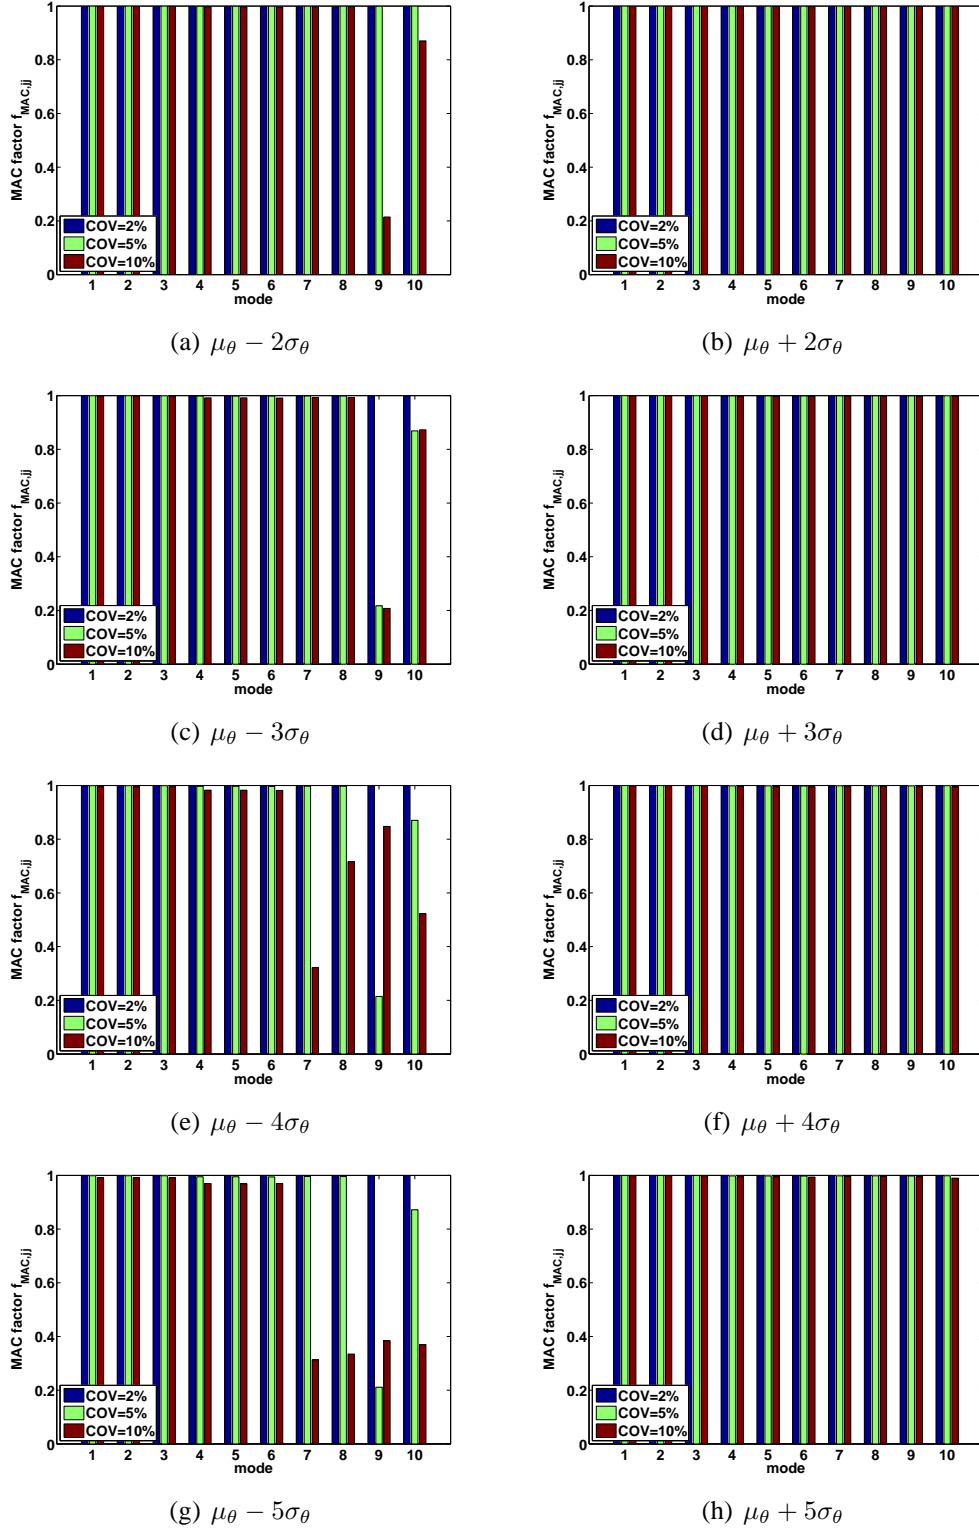

Figure 6: MAC factor comparison for 8 special random inputs

From Fig. 6, it is observed that the modal intermixing always occurs with respect to higher modes, i.e. mode 7, 8, 9 and 10. Moreover, the larger the variance is, the more probable the modal intermixing is induced. To that end, it is reasonable to avert the modal intermixing by reducing the variance.

It is also discovered that when we increase the COVs of density and Young's modulus to 30%, no modal intermixing occurs, the MAC factors of which is always similar to Fig. 6(b). In that case, the random inputs like them can be seen as the insensitive parameters; On the contrary, in cases where random inputs with large COV causing the modal intermixing can be defined as the sensitive parameters, e.g. plate thickness.

5.2.2 Cases study with different distributions

As the probabilistic information of the random inputs are priory unknown, one can choose any distribution to describe the randomness as long as the engineering requirements are fulfilled. From this point of view, like what we have done in Section 5.1, different distribution assumptions are applied so that the universality of the HPCEM is revealed again.

The accuracy investigation is shown by the comparison of the frequency response in Fig. 7 for all the three distributions. Probabilistic results (mean) obtained by HPCEM and DSBM agree with each other well. It is observed that only 6 peaks of the mean model can be told off. That implies there exists very close frequencies.

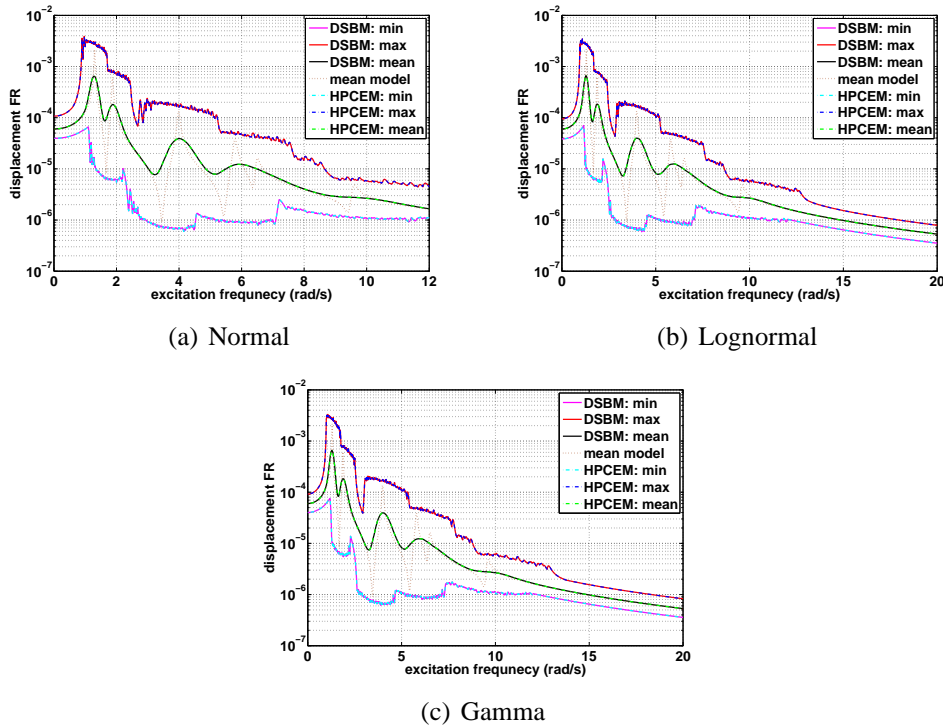

Figure 7: SFR based on 10000 samples of Plate-Beam

For this model, the fourth-order HPC expansion is utilized. Only 200 samples are needed to calculate the 70 coefficients by LSM. We have to note that the number of samples is again about 3 times of that of the coefficients. Considering the situations in Section 5.1, we recommend that the number of the samples equals more or less 3 times the number of the coefficients in order to determine the HPC model. The efficiency is still shown by the average CPU time. The DSBM

needs 10^4 modal analyses, while the HPCEM only requires 200 modal analyses plus 10s to gain 10^4 sets of eigenvalues and eigenfactors. Almost 98% CPU time is saved.

6 CONCLUSIONS

This work concentrates on estimating the statistics of the SFR. The HPCEM is applied to solve the involved random eigenvalue problem, the coefficients are evaluated by the LSM. The mathematical limitation and physical validity are specially discussed by considering the modal intermixing problem, which is always encountered when using Monte Carlo sampling technique. The univariable based strategy with conjunction with the MAC is proposed to avoid the modal intermixing problem by reducing the variances of the random inputs. It is helpful to select the proper variances since no adequate information is a priori in the physical models. Comparing with the DSBM, the HPCEM is an efficient method to obtain random eigen-solutions. Several factors have significant influences on the accuracy and efficiency of HPCEM:

- The modal intermixing problem should be avoided. In cases where this problem exists, the physical behaviors associated with individual random model may differ from the mean model (benchmark) and the HPCEM is not acceptable to solve the random eigenvalue problem.
- The proper number of samples used for LSM for the HPC coefficients estimation ought to be proper. In this work, according to the simulation examinations, the number of the samples is recommended as about 3 times the number of the coefficients.
- The dimension of the underlying physical (the number of DOF) systems has a large influence of the efficiency. The larger a structure is, the more time the modal analysis needs.
- The efficiency is highly improved compared with the DSBM. However, as the number of random inputs increase,
 - the dimension of the HPC expansion increase. It signifies more time are needed to construct the HPC model which is always obtained by the expensive symbolic calculation.
 - more coefficients have to be evaluated by the LSM. In that case, more samples have to be prepared for the least square solution.

Note that the HPCEM can effectively obtain the variability of the random eigenvalues and eigenfactors, and thereafter the SFR. This achievement is very valuable for reliability analysis as well as reliability based design optimization since reliability analysis has to be carried out during each function evaluation of the optimization procedure.

Abstract. *This paper reports on an experiment carried out in the laboratory of Civil and Environmental Engineering of the University of Florence, where a reduced scale (approximately 2.5 m width \times 2.5 m depth \times 4.8 m height), three storey steel spatial frame was instrumented and progressively damaged by cutting one of its pillars just above the foundation; the depth of the cut could be measured and was taken as the entity of the damage. A series of 12 accelerometers was installed on the frame and 3 more accelerometers were installed on the ground; acceleration measurements induced by ambient vibrations were recorded as the frame was progressively damaged. Acceleration signals were subsequently analyzed in both time and frequency domain (SSI, EFDD, neural networks): a frequency shift and a change in the corresponding modal shapes were observed as the damage increased. The damaged truss was also modelled by means of a FEM code and the frequency shift and the change in the modal shapes were reproduced. A genetic algorithm approach is currently being tested to try and indentify the location and entity of the damage, and is reported on.*

1 INTRODUCTION

Safety evaluation and damage assessment of existing engineering structures asks for a deeper structural analysis; usually this investigation is carried out through the finite element method techniques: a numerical model of the structure simulates the behavior of the structure (both in static and dynamic field) and it is used to predict the building response to service and exceptional loads (such as earthquakes). The correct identification of the numerical model is then a fundamental task as the modeling, even if refined from a geometrical point of view, could differ from the real structural behavior if assumptions on material, constraints, masses and stiffness are not properly evaluated. Variability of these elements can produce results that could be substantially different from the actual behavior of the structure.

To properly identify the numerical model several strategies, or methodologies, are available in the inherent literature. An effective approach to assess the structural behavior is to evaluate, by performing dynamic experimental tests, actual modal frequencies and corresponding mode shapes. Dynamic tests could be made assuming both forced (vibroline) and/or environmental (wind or traffic) loads. This step is interesting also with respect to the so-called Structural Health Monitoring (SHM) [1] [2]. The evaluation of these quantities becomes a classical “output-only identification” problem. The identification of the FE model can thus be seen as an optimization strategy where the cost function could be assumed, f.i., the distance between the modal frequencies and mode shape obtained by experimental dynamic tests and those obtained by the numerical model. To address this optimization several approaches have been proposed in literature; among the others quite recently Facchini *et al.* [3] [4] propose a neural network approach. The “output-only” procedure could be framed as an emerging topic of both the scientific and technical community as it covers a wide range of practical problems. Effective examples can be considered, for instance, any situation where the need is felt to maintain the structure at hand operative during structural health monitoring investigation: this is the case of bridges which have to remain open to traffic during the test, as well as offshore structures (both small and medium size) ([4]) where the transport of the equipment needed for the monitoring can be extremely difficult.

In structural engineering field the most expeditive (but also, in some respects, the most “brutal”) method to approach the identification problems in case of “output only” systems is the Peak – Picking method (see e.g. Bendat & Piersol 1993 [5]). After the evaluation of the Fourier transform of the recorded signals, the eigen-frequencies of the investigated structure are assessed searching the peaks in the spectrum plot. The eigen-modes can then be determined by comparing the transfer functions of the various recordings with a reference one. The method has the advantage of being relatively simple, however in the case of complex structures it might not be able to provide significant results due to the fact that, of course, it depends on the sensitivity of the operator who has to recognize the peak of auto-spectral density. Despite its disadvantages the popularity of the method is mainly due to its simplicity as the only algorithm that is needed to convert time data to spectra is the Fast Fourier Transform (FFT).

In the last decade more advanced methods, even if more computational demanding, have been proposed. Among them it is noteworthy to remember the so-called SSI (Stochastic Subspace Identification) (see e.g. Peeters & De Roeck 1996 [6]). Starting from the consideration that in many cases of engineering interest is extremely difficult, if not impossible, to have a deterministic knowledge of the forcing process (environmental loads) the method assume a stochastic loading (often a white noise). Many applications of SSI were presented in the scientific literature showing the attractiveness of the method.

Figure 1: Three-storey investigated steel building.

The paper, discussing these problems, presents a technique for the identification of “output only” systems by means of neural networks. In a first part of the paper the experimental campaign conducted in a benchmark three-storey steel structure built at the Civil Engineering Laboratory of the University of Florence (Italy). The structure has been tested under ambient loading starting from the undamaged configuration and imposing steps of increasing damage level by incremental cuts on a steel column: the tests have been performed assuming the building being initially undamaged; successively, incremental damage states have been imposed by partially cutting one of the columns and test have been repeated. Then, a neural network based procedure has been developed to analyze accelerometer signals recorded during the experimental campaign. Results are discussed and the dynamic properties of the building are evaluated at each damage level. At the end, the ongoing research aimed to employ genetic algorithms to the structural system identification is discussed.

2 EXPERIMENTAL LAYOUT

2.1 The specimen

The case study is a three-storey steel structure (Figure 1) with profiled steel elements; this specimen has been analysed starting from an undamaged configuration and imposing increasing damage level (by progressive cutting of a column flanges).

The plane dimension of the steel frame is $2.5 \text{ m} \times 2.5 \text{ m}$. The height of the first storey is 1.64 m, while is 1.6 m for 2nd story and 1.54 for 3rd storey. The total height of the structure is 4.87 m. The layout of the specimen is shown in Figure 7. The material of steel elements was grade S235 steel with a nominal yield stress of 235 MPa. At each level a mass of about 22 kN was applied by means of concrete slabs (Figure 1) which have no structural function. The beam-to-column connections were fully welded to ensure rigidity. Column base connec-

tions were made as rigid as possible. The cross section of steel members is as follows: a) column HEB140; b) beam IPE 140; geometrical properties of member are reported in Table 1.

Properties	Columns	Beam
Section type	HEB140	IPE 140
Cross sectional area (cm ²)	42.96	16.43
	<i>Moments of inertia (cm⁴)</i>	
Strong direction	1509	541.2
Weak direction	549.7	44.92

Table 1: Sectional properties of the structural members.

2.2 Ambient vibration test

To determine the vibration characteristics (natural frequencies and mode shapes) of the steel building model a series of ambient vibration tests were conducted.

A total of 12 uniaxial seismic accelerometers were installed on the frame (Figure 2); in particular at each level of the specimen 4 sensors have been placed to collect acceleration along the two main horizontal dimensions). The accelerometers are characterized by a 10 V/g sensitivity and a 0.1–1500 Hz frequency range.

Figure 2: Accelerometers disposition (level #1).

Test	Type of test	Load
Test # 1÷ 5	Without damage	Environmental
Test # 11÷13	Damage Level #1	Environmental
Test # 21÷23	Damage Level #2	Environmental
Test # 31÷33	Damage Level #3	Environmental
Test # 41÷43	Damage Level #4	Environmental

Table 2: Experimental campaign.

The sampling frequency during the experiment was 400 Hz and the measurement duration was selected as about 4 min for each test considering the vibration source. Table 2 reports a summary of the tests executed during the experimental campaign. The tests were performed starting from the specimen in its undamaged configuration and were repeated at four different levels of increasing damage (Figure 3÷Figure 4). The damage consisted in a progressive cut of the column flanges, as shown in Figure 3 to Figure 6.

Figure 3: Damage Level #1 (left) and Damage Level #3 (right).

3 NETWORK TRAINING AND SIGNAL ANALYSIS

The recognition of the structural eigenfrequencies was assisted by a neural network (described later) fed with four frequency-dependent indexes which summarize the behavior of the spectral tensor at each frequency of interest.

As a matter of fact, the response of structures with well separated eigenfrequencies and relatively low damping, when excited by random forcing processes, exhibit a spectral tensor characterized, in correspondence with the structural eigenfrequencies, by:

- the possibility to be decomposed in the tensor product of the corresponding modal shape by itself;
- a high coherence between any couple of degrees of freedom;
- a phase close to zero or to a multiple of π between any couple of degrees of freedom;
- the presence of peaks in the auto-spectral densities.

These four conditions enable to define four indexes which describe a kind of “degree of fulfillment” for each condition; the indexes were defined as follows.

The possibility to decompose the spectral tensor in the tensor product of a vector by itself can be readily checked by means of a singular value decomposition; the spectral theorem ensures that, at each frequency f of interest, the spectral tensor of the degrees of freedom can be decomposed as:

$$S(f) = \sum_{h=1}^N \lambda_h(f) \boldsymbol{\varphi}^{(h)}(f) \otimes \boldsymbol{\varphi}^{(h)}(f) \quad (1)$$

where $\lambda_h(f)$ are the eigenvalues and $\boldsymbol{\varphi}^{(h)}(f)$ the corresponding eigenvectors. When an eigenvalue is much greater than the others the spectral tensor reduces to:

$$S(f) \approx \lambda_1(f) \boldsymbol{\varphi}^{(1)}(f) \otimes \boldsymbol{\varphi}^{(1)}(f) \quad (2)$$

where, without loss in generality, the eigenvalues are considered to be sorted in descending order. The first index can therefore be defined as:

$$i_1(f) = \max \left\{ 0, 1 - \frac{\|S(f) - \lambda_1(f) \boldsymbol{\varphi}^{(1)}(f) \otimes \boldsymbol{\varphi}^{(1)}(f)\|}{\|S(f)\|} \right\} \quad (3)$$

The degree of coherence between the various couples of signals can be checked by computing the norm of the coherence tensor; therefore the second index is defined as

$$i_2(f) = \frac{\|\mathbf{C}(f)\|}{N_{dof}} \quad (4)$$

where $\mathbf{C}(f)$ is the coherence tensor at each frequency of interest and N_{dof} the number of degrees of freedom of the structure.

The third index is a measure of the norm of the phase angle tensor, modulus π :

$$i_3(f) = \max \left\{ 0, 1 - \frac{\|\Phi(f) \bmod \pi\|}{N_{dof}} \right\} \quad (5)$$

The fourth index is derived from an index reported in Deraemaeker *et al.* (2008) [1], and is the peak index. Denoting with $S_i(f)$ the auto-spectral density to be analyzed to evaluate the peaks it is possible to define the following quantities:

$$K(f_c) = \left[\int_{f_c - \Delta f}^{f_c + \Delta f} S_i(f) df \right]^{-1} ; \tilde{S}_i(f_c, f) = K(f_c) S_i(f)$$

$$\mu(f_c) = \int_{f_c - \Delta f}^{f_c + \Delta f} f \tilde{S}_i(f_c, f) df ; \sigma^2(f_c) = \int_{f_c - \Delta f}^{f_c + \Delta f} [f - \mu(f_c)]^2 \tilde{S}_i(f_c, f) df$$

The peak index is eventually defined by:

$$\lambda_4(f) = 1 - \frac{f_c \sqrt{3} \sigma(f)}{\Delta f \mu(f)} \quad (6)$$

Since as many peak indexes can be evaluated as the number of degrees of freedom, the maximum of the various indexes is taken at each frequency.

3.1 Network definition and training

The utilized network was a feed-forward back-propagation network characterized by two-hidden layers with variable number of neurons: in particular, the behavior of networks with 5, 10 or 15 neurons in both hidden layers was inspected. Hidden neurons were characterised by sigmoid activation functions.

The input layer was always composed by 4 neurons, each accepting one of the indexes i_1 to i_4 . The output layer computed a linear combination of the outputs of the second layer of neurons and gave the network output, i.e. an estimate $L(f)$ of the likelihood of finding a structural resonance at frequency f .

Figure 8: Example of neural architecture; here a 4-5-5-1 network is shown.

One of the major advantages of feeding the network with the four above-mentioned indexes is that training of neural network can be performed on a completely different structure,

as the indexes characteristics are widely general. The possibility of training the network on a generic structure overcomes the problem that the examined structure is still widely unknown, and moreover the training structure can be built numerically, thus perfectly knowing its dynamical characteristics.

Nevertheless, the network was trained on the results obtained for the FEM model of the investigated frame *prior* to identification. In other words, a FEM model was first built on the basis of the available information for the geometry and material. Once defined the stiffness and mass matrices of the model, the frequency response functions could be evaluated, together with the first eigenfrequencies and associated modal shapes (see Figure 9).

Figure 9: the response function of the structural degrees of freedom evaluated for a damping of $\nu=10^{-4}$

From the frequency response functions of the model, the four indexes $i_h(f)$ were computed, while a target function $T(f)$ for the neural network was defined as

$$T(f) = \frac{10^{t(f)} - 1}{9}, \quad t(f) = \sum_{h=1}^{N_r} \exp\left[-(f - f_{r,h})^2 / \sigma^2\right] \quad (7)$$

where N_r is the number of eigenfrequencies $f_{r,h}$ considered (in the case at hand, the first 10 eigenfrequencies were considered); f is the frequency and σ a proper decay parameter.

The choice of the decay parameter σ was made on the basis of some considerations on the shape of the structural FRFs; since this parameter affects the width of the peaks that indicate the resonance frequencies, σ was determined to keep as separated as possible the pairs of close resonances around 10, 14 and 19 Hz in the target function (Figure 10). Correspondingly, the target function should exhibit pairs of close peaks, which can only be possible for $\sigma^2 \leq 0.001$.

Figure 10: the four indexes obtained for the FEM model and the target function

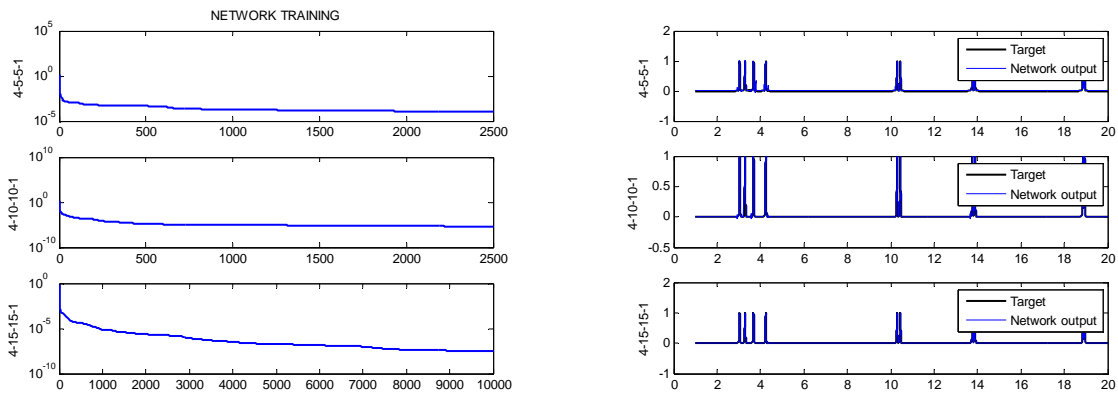

Figure 11: on the left, the performance of different networks during the training phase; on the right, the network output after the training phase (blue line) compared to the target function (thick black line)

Training was based on the Levenberg-Marquardt algorithm and employed as long as 10000 epochs in the most difficult cases.

Network validation was carried out on another structure (the shear type frame shown in Figure 12) and showed that two kinds of errors can arise: the presence of a natural frequency where there is no actual eigenfrequency, and the absence of a natural frequency where it should be present.

Figure 12: The validation structure with its first modal shape.

Figure 13: Example of validation of the 4-15-15-1 NN. Structural resonances are denoted by dashed vertical lines.

Figure 13 shows an example of both types of error: at a frequency of about 3 Hz a false eigenfrequency is detected, and the last eigenfrequency is not detected at about 12 Hz. It must be noted that network validation was performed on 3 different data sets, and the other two gave good results.

The validation results show that the network output must be considered (when properly normalized) as an estimation of the probability of finding a structural resonance at a given frequency, rather than the certain presence or absence of eigenfrequencies.

In this light, it is useful to perform more than one test on the investigated structure: the analysis of the time histories of each test will give as many likelihood functions for the presence of structural resonances.

4 OUTPUT-ONLY IDENTIFICATION PROCEDURE

4.1 Signal analysis

The analysis of accelerometer signals is the first of two steps that constitute the identification procedure.

The recorded signals were transferred into a portable computer via a cross-cable. Then, the signals were digitally low-pass filtered at 12.5 Hz and resampled at 25 Hz. Spectral densities were evaluated by means of nonparametric estimation using different windows (Hanning, Hamming, DPSS and Blackman) and successively applying Fast Fourier Transform (FFT) to windowed data; with the exception of the periodogram (which is more sensitive to bias), no significant difference could be noticed in the evaluated spectral densities (Percival and Walden 1993 [8]), see Figure 14.

Figure 14. Comparison of the estimates of the spectral density of signal #2 with different data tapers.

The results obtained in the following analyses were also similar, so the data taper given by discrete prolate spheroidal sequences (4096,2) (Percival and Walden 1993 [8]) was adopted. The spectral densities were divided by a factor of $(2\pi)^4$ in order to evaluate the displacement spectra and the indicators previously described, $i_1(f)$ to $i_4(f)$, were estimated.

Figure 15 shows that the fourth index is capable of detecting resonances (one of the first identification methods, the peak picking, was based on this criterion), but shows also a certain width of its peaks, thus affecting the reliability of the estimate. The first index is close to 1 very often, but in proximity of structural resonances decreases rapidly when the frequency differs from the eigenfrequency; further useful indications come from the second and third indexes.

4.2 Combination of network output for different tests with same level of damage.

Since the neural network can undergo different kinds of errors, as pointed out before, for each level of damage several recordings of environmentally induced accelerations were taken.

Figure 15: The four indexes as evaluated from the analysis of the signals recorded during the third test.

Figure 16: Pdf of structural resonance: first set of tests (undamaged structure)

Figure 17: *Pdf* of structural resonance: third set of tests (third level of damage)

The results given by the network for each recording were therefore combined from a Bayesian point of view. Before the first recording was taken (for each level of damage), no assumptions about the distribution of structural eigenfrequencies were made, and therefore a uniform probability density for the eigenfrequency positions was considered.

The output of the neural network after each test brings information about the location of structural eigenfrequencies, but can be affected by errors. Therefore, it can be considered as an estimate of the likelihood to find a structural eigenfrequency at each frequency of interest.

The result is the final probability density function for the presence of eigenfrequencies. Figure 16 and Figure 17 show the likelihood functions coming out of each test of a given set (blue lines) and the final pdf for the structural resonances (thick black line).

It is worth spending some words on the results shown in Figure 18, where the evolution of the probability density of the first two structural eigenfrequencies is plotted.

Set #	f^1 (Hz)	f_2 (Hz)	f_3 (Hz)	f_4 (Hz)
Set #0	3.14	3.76	6.18	10.06
Set #1	3.08	3.75	6.24	9.98
Set #2	3.09	3.71	6.20	9.96
Set #3	3.05	3.74	6.11	9.94
Set #4	3.03	3.72	6.13	9.91

Table 3. Main identified frequencies.

The probability density in the undamaged state is represented by the blue line, and shows peaks located at the highest values of the two resonances; they are also more narrow than the other ones, implying a higher reliability of the estimate.

Figure 18: Evolution of probability density of the first two resonances with increasing damage

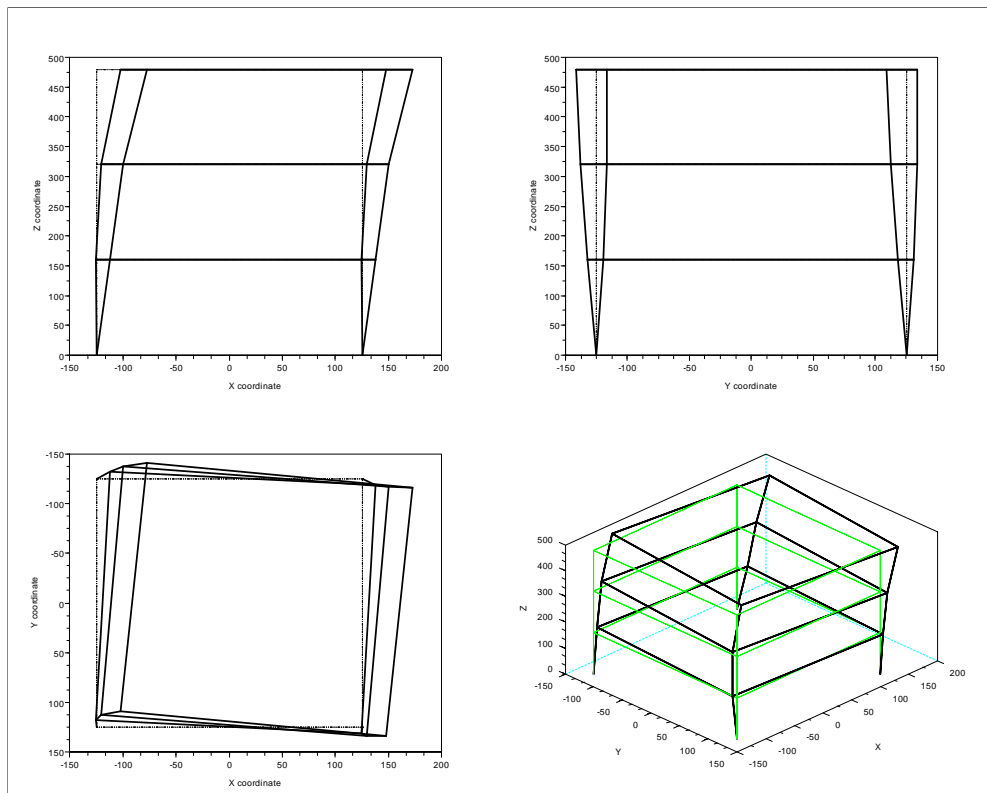

Figure 19: First bending mode (x-direction) - $f_1=3.14$ Hz

As it is clear also from Table 3, it is interesting to note that the second eigenfrequency estimate does not always decrease with increasing damage: as a matter of fact, it shows a minimum for set # 2 (2nd level of damage). But if we look at Figure 18, it can be noticed that the peaks relative to set #1 and set #2 estimate of the second eigenfrequency are a bit wider than the others, meaning a less reliable estimate.

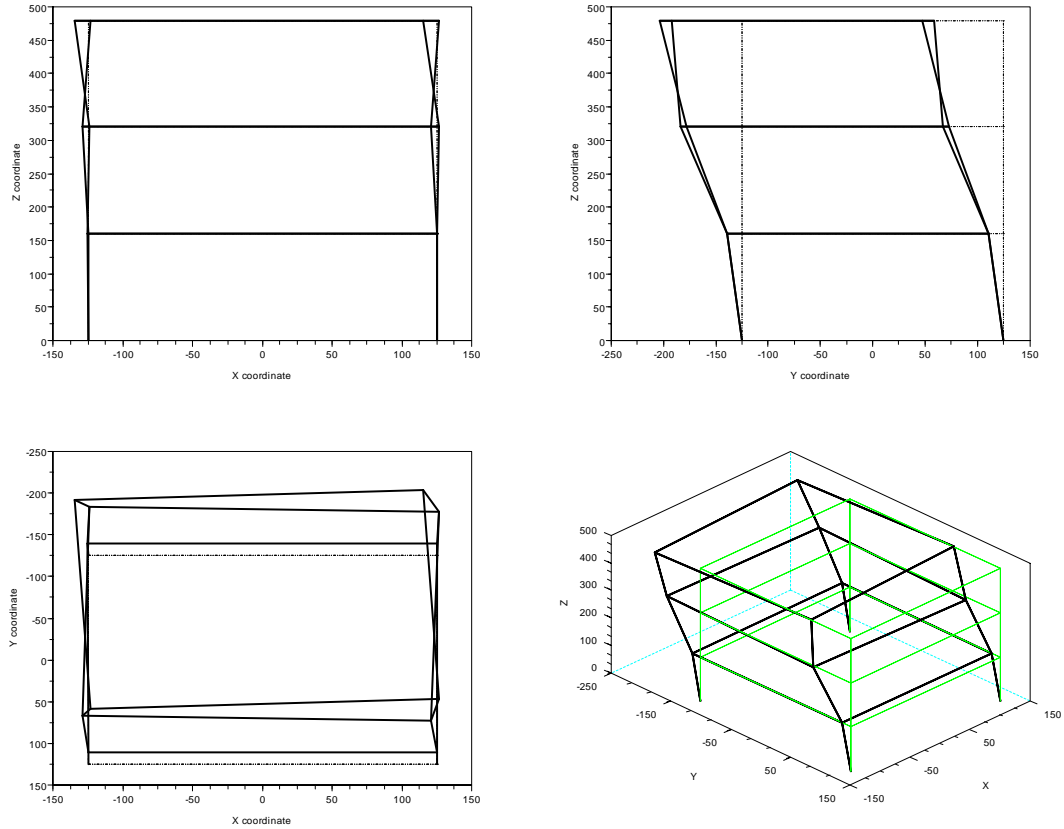

Figure 20: First bending mode (y-direction) - $f_2=3.76$ Hz

The same considerations hold also for the variation of the torsional frequency, f_3 . The exact relation between the width of the peaks and the estimate reliability is currently under examination. Once the eigenfrequencies were estimated, the corresponding modal shapes could be retrieved by means of the spectral SVD. The first three estimated modal shapes for the undamaged state of the frame are reported in Figure 19, Figure 20 and Figure 21.

The obtained results have been compared with those given by SSI in the output-only, covariance-driven form. Even in the case of SSI the stabilization diagram can be used to define the probability density of structural resonance. The *pdf* could be built by means of a Gaussian base according to Eq. (8) where O_{min} and O_{max} represent the minimum and maximum order of the SSI model and N_f is the number of identified main frequencies.

Figure 22 is an example of the stabilization diagram and the *pdf* of structural resonance as calculated for the specimen in its initial configuration (i.e. without damage).

$$p(f) = K \sum_{h=O_{\min}}^{O_{\max}} \sum_{k=1}^{N_f} \exp \left(-\frac{(f - f_{hk})^2}{2\sigma_h^2} \right)$$

$$K = \left[\int_{-\infty}^{\infty} \sum_{h=O_{\min}}^{O_{\max}} \sum_{k=1}^{N_f} \exp \left(-\frac{(f - f_{hk})^2}{2\sigma_h^2} \right) df \right]^{-1}$$
(8)

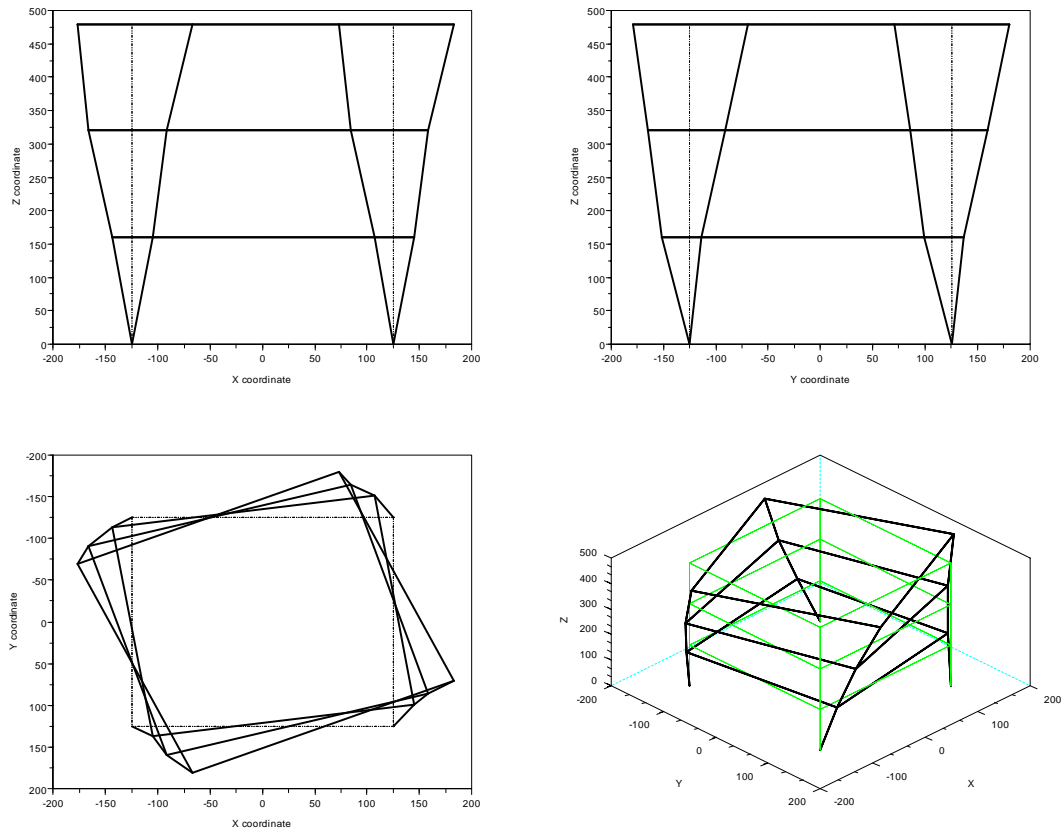

Figure 21: First torsional mode (x-y plane) - $f_3 = 6.18$ Hz

Table 4 reports the first three identified frequencies for representative tests of each damage level. The increasing level of damage (being the column's flange cut) interests mainly the frequency in the x-direction (Figure 18) and the torsional one.

Test #	f_1 (Hz)	f_2 (Hz)	f_3 (Hz)
Test # 1	3.12	3.75	6.28
Test #32	3.08	3.72	6.16
Test #41	3.04	3.72	6.14

Table 4: Main identified frequencies (SSI).

Figure 23: Pdf of the first two structural resonances: test #1, 32, 41

Figure 23 reports the *pdf* of the two first structural resonances in case of damage (test #32 &41) compared with the case without damage (test #1).

5 NEXT RESEARCH STEP: GENETIC ALGORITHM

Next steps of the research aim to propose the employment of genetic algorithms (GA) techniques for the identification of a finite element model of the specimen, as GA has been shown to be able to overcome the limitations of traditional methods (see e.g. Faravelli *et al.*[7]).

Genetic algorithms are based on ideas from the science of genetics and the process of natural selection. They work with an initial population (strings of zeros and ones i.e. binary strings) which may correspond to certain numerical values of a particular variable whose size is depending on the problem under consideration. The initial population is generated randomly; each string in the population corresponds to a chromosome and each binary element of the string to a gene. A new population is developed starting from the initial population according to the processed that are analogue to the fundamental genetic processes: a) reproduction based on fitness, b) crossover and c) mutation.

A set of chromosomes is selected at the reproduction stage and members of the population are chosen for reproduction on the basis of their fitness: the fittest have a greater probability of reproducing in proportion to the value of their fitness. The process of reproduction is implemented by using the crossover. Many crossover techniques are available using different data structures (single crossover point or many cross-over points). The mutation is a process where randomly a particular gene in a particular chromosome is changed. The process of mutation in a genetic algorithm occurs very rarely and hence this probability of a change in a string is normally kept very low. Nevertheless the purpose of mutation is to preserve and introducing diversity. From a computational point of view mutation should allow the algorithm to avoid local minima by preventing the population of chromosomes from becoming too similar to each other, thus slowing or even stopping evolution. Crossover and mutation represent the two special features that make different a genetic algorithm with respect to a traditional direct search procedure and make it interesting for optimization and search problems.

$$F = \sum_{i=1}^k \left[p_{\lambda,i} \cdot \left(\frac{\lambda_{F,i} - \lambda_{Exp,i}}{\lambda_{F,i}} \right)^2 + p_{\phi,i} \cdot (1 - MAC(i,i))^2 \right] \quad (9)$$

$$MAC(i,i) = \frac{(\phi_{Fi}^t \cdot \phi_{Exp,i})^2}{(\phi_{Fi}^t \cdot \phi_{Fi}) \cdot (\phi_{Exp,i}^t \cdot \phi_{Exp,i})}$$

CONCLUSIVE REMARKS

The paper has discussed some recent advances in case of “output-only” systems aimed at the damage identification of structural systems. To this aim the experimental campaign conducted in a benchmark three-story steel structure at the Civil Engineering Laboratory of the University of Florence (Italy) laboratory is currently carried out and has been reported on. The benchmark structure has been tested (under ambient loading) starting from the actual configuration and imposing steps of increasingly damage level by partial cuts of flanges on some steel elements (columns). Successively a neural network based procedure has been proposed

and employed to analyse accelerometer signals recorded during the experimental campaign. Results are discussed and the dynamic properties of the building are evaluated at each damage level. At the end, the ongoing research step aimed to employ genetic algorithms to finite element model identification has been discussed.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Saverio Giordano (Civil Engineering Laboratory of the Department of Civil and Environmental Engineering) for his precious assistance and cooperation during the whole experimental campaign.

Keywords: building, vulnerability, constitutive equations, earthquake engineering

Abstract. Nowadays sustainable constructions imply an objective of energetic performances by reducing the level of thermal conduction. The thermal-bridge shunt elements, an innovative technological element is under study in several countries in Europe. If the thermal benefits have already been proved, the mechanical effects of such a wall-slab connection in a building for the seismic risk have not been assessed. To evaluate the building seismic vulnerability modifications due to these thermal bridges shunt, experimental and numerical developments have to be performed. An experimental campaign is proposed to evaluate the seismic ability of such structural elements and a simplified modelling is proposed aiming at developing numerical framework able to handle parametrical and probabilistic approaches for structural analysis.

1 INTRODUCTION

Nowadays sustainable constructions imply an objective of energetic performances by reducing the level of thermal conduction. The thermal-bridge shunt elements, an innovative technological element is under study in several countries around Europe. If the thermal benefits have already been proved, the mechanical effects of such as wall-slab connection in a building under seismic risk have not been assessed. To evaluate the building seismic vulnerability modifications due to these thermal bridges shunt, experimental and numerical developments have to be performed.

A two steps analysis is adopted in this work. In order to assess the seismic vulnerability of a building, one has to be able to perform statistic and sensitivity analysis. The numerical models to be developed should be as simple and robust as possible. Firstly the experimental analysis of reduced scale elements in comparison with 3D numerical investigations allow to determine failure mechanisms of thermal shunt elements (made of concrete and steel combinations) subject to earthquake loadings. The thermodynamic internal variables are determined in this stage. Secondly, a macro-scale model for slab-wall connection is derived following the previous analysis and based on irreversible processes thermodynamic assumptions [1]. This model accounts for damage due to shear and flexural combinations, frictional sliding and hysteresis, steel plasticity and stiffness recovery in case of alternate loadings. The finite element numerical implementation has been carried out using an implicit scheme. The model is validated thanks to experimental campaigns achieved under quasi-static loading and seismic.

2 NONLINEAR MECHANISMS IDENTIFICATION

2.1 Thermal bridge shunt elements

This new technique for buildings allows for reducing the thermal conductivity from the inside of the construction to the outside. The thermal bridges are taking place at the wall-slab connection. The role of the thermal bridges shunt elements is to break the thermal connectivity by eliminating any concrete liaison by thermal insulation passive material devices. Different solutions may be adopted, for example in figure 1 two technological solutions allowing breaking the energetic loss.

Figure 1: Thermal bridge shunt elements from Lafarge (Ruptal) (left) and Schöck (Rurtherma) (right)

2.2 Experimental investigation

The experimental set-up has to be able to reproduce the load transmission mechanism between the wall and the slab when subject to lateral and horizontal acceleration motion due to earthquake loadings. A double shear test as shown in figure 2, preventing any flexion occurrence has been performed on the thermal bridge shunts elements. Four ends steel plates allows to recover the anchored boundary conditions as in the real situation.

Figure 2: Experimental set-up for a double shear test

The uniaxial load is imposed by a centered hydraulic actuator. Two parallel thermal bridge shunt elements (60 cm long each) allow the load transmission to the two parallel walls. The maximum load capacity for the actuator is 25 tons. LVDT gages have been used to measure the displacements between the walls and the slab as well as digital images for numerical correlation. In the figure 3, one can appreciate an example of a global response, using normalized axis for confidentiality requirements.

Figure 3: Experimental global response. Normalized axis

Coupling steel plasticity and concrete cracking, the main nonlinear mechanisms can be observed as: stiffness decrease, permanent displacements in unloading, hysteresis loops, nonlinear hardening and softening. This kind of experimental results can be used to develop some modeling allowing the numerical prediction of seismic behavior of building made of such innovative technological elements.

2.3 3D modeling and understanding

The objectives of this section are to proceed to 3D numerical computations on the previous case-study to be able to discriminate the different sources of nonlinearity allowing expressing a constitutive behavior for the connection.

A Finite element model has been established, thanks to the 2 axis of symmetry of the problem. Both steel and concrete have been modeled using 3D cubic elements. A plastic perfectly plastic constitutive equation has been introduced for steel and a continuum damage mechanics based model is used for concrete (wall and slab) and Ductal (connection). The different parameters introduced in the computation are given in table 1.

	Materials parameters			
	Young's modulus (GPa)	Poisson's ratio	σ compression (MPa)	σ traction (MPa)
Concrete	25	0,2	25-35	3
Ductal	45-50	0,2	100-150	8
Steel	210	0,3	$\sigma_y = 500$ MPa	

Table 1: Material features for the 3D nonlinear computations

Figure 4: finite element model and results (damage map) of a shear type loading on the connection

The figure 4 presents the finite element model used in the computation as well as a damage map obtained at the end of the analysis. The damage is entirely localized in the Ductal connection zone, inducing flexion of the Ductal block. A good approximation of the experimental response can be fitted as emphasized in figure 5.

Figure 5: Correlation between 3D numerical analysis and experimental response.

These numerical results will be used in the following section to help one to identify the different evolutions laws for the constitutive equations which has to be expressed.

2.4 Micromechanical analysis

The aim of this section is to analyze the previous numerical/experimental comparisons to be able to define the number of thermodynamic variables which should be introduced in the future modeling, and to calibrate the corresponding evolution laws in case of irreversible processes. For that purpose, the nonlinear behavior of the Ductal square block is analyzed using nonlinear micromechanical models. For example, the stiffness evolution and decrease is computed in different directions according to the increase of a crack in the body. The figure 6 presents the crack propagation in the vertical direction for a vertical load applied on the block.

Figure 6: Crack propagation in the ductal block subject to vertical loading

The stiffness decrease is evaluated in the vertical and horizontal directions in the figures 7. Two computations are plotted in the figure 7: the results of the full 3D computation using the modeling of figure 6 and the analytical computations based on the Timoshenko's beam theory. The main conclusion is that a kind of anisotropy appears in the behavior and should be ac-

counted for in the future modeling. The same analysis may be carried out for a cyclic loading. The reverse loading leads to crack openings and closing in different zones of the Ductal block.

Figure 7: Stiffness reduction in different directions for a vertical crack propagation

The conclusions which could be assessed leads to the definition of two different damage variables for the two major directions of solicitations (horizontal and vertical) allowing accounting for the damage decrease in these directions. Regarding the different zones affected by crack openings and closings, two different damage variables could be introduced to account for unilateral effects and damage deactivation.

2.5 Damage evolutions

After defining the type of variables (damage ones), this section has to be able to calibrate the evolution laws of these thermodynamic quantities. Two more complete 3D computations, based on the model of figure 4, are performed to point out the effect of the steel and the Ductal block. In figure 8, the numerical results are presented by comparing the global force/displacements responses using the 3 different configurations. These comparisons allow to identify in the linear regime, the contribution of each one of the materials to the global stiffness and in the nonlinear regime to express the stiffness reduction only due to crack propagation allowing to evaluate damage variable evolution law.

Figure 8: Contribution of the different materials to the global response (left). Damage law identification based on the numerical simulations

3 MODELLING

Regarding the ability of a model to proceed to the seismic vulnerability evaluation of a structure, the model should be, at the structural level, as simple as possible allowing performing probabilistic analysis and parametrical approaches. The choice made is to introduce the nonlinear behavior in the connection thanks global modeling based on the generalized strains and stresses concept (beam theory). The Finite Element supports are Timoshenko beams using a unique Gauss point for the numerical integration. This feature guarantees a uniform state of stresses and strains in the element.

The following sections present the thermodynamic framework detailing the developments concerning the structural element constitutive equation.

3.1 Free energy and state laws

The framework of irreversible processes thermodynamic is chosen to express the model. The previous experimental and numerical investigations allows for defining the number of thermodynamic variables, their couplings and evolutions. A choice is made concerning the thermodynamic potential from which the state laws will be derived. Expressed in different terms due to the contribution of concrete cracking, frictional sliding, steel plasticity and hardening, the potential takes the following form,

$$\rho\Psi = \frac{1}{2}K_b(1-d)D^2 + \frac{1}{2}K_b g(d).(D-D^\pi)^2 + \frac{1}{2}K_a(D-D^p)^2 + f(V_k) \quad (1)$$

Where ρ is the density, ψ the Helmholtz free energy, K_b et K_a are the concrete stiffness and steel stiffness respectively, D is the total displacement, D^π is the displacement associated to frictional sliding, D^p is the steel plastic displacement, $g(d)$ is a function insuring the coupling between the level of damage and the friction, in a first approximation it is chosen as $g(d)=d$, V_k are the other internal variable linked to hardening.

From this free energy, one can obtain the expressions of the state equations by simple derivatives. The total forces vectors are expressed below:

$$F = \rho \frac{\partial \Psi}{\partial D} = \underbrace{K_b(1-d)D + K_b d(D - D_\pi)}_{\text{Béton}} + \underbrace{K_a(D - D_p)}_{\text{Acier}} \quad (2)$$

$$F_\pi = -\rho \frac{\partial \Psi}{\partial D_\pi} = dK_b(D - D_\pi) \quad (3)$$

$$F_a = -\rho \frac{\partial \Psi}{\partial D_p} = K_a(D - D_p) \quad (4)$$

And the damage energy release rate,

$$Y = \rho \frac{\partial \Psi}{\partial d} = -\frac{1}{2}K_b D^2 + \frac{1}{2}K_b(D - D_\pi)^2 \quad (5)$$

3.2 Thresholds functions and evolution laws

To define the nonlinear evolutions, one has to define thresholds function. The model is based on damage mechanics, the first and major irreversible mechanisms to be checked is

damage evolution. A simple law, based on the original work of [2] allows a simple damage threshold implying associated flow rule,

$$f_{di} = Y_{di} - (Z_i + Y_0) \quad (6)$$

Z_i is the thermodynamic variable associated to isotropic hardening and Y_0 is the initial threshold.

According to associated flow rule, the damage evolution for concrete may be simply and analytically integrated to obtain a direct computation of the damage variable,

$$d_i = 1 - \frac{1}{1 + pY_{di}^q} \quad (7)$$

Where q and p are material parameters to be identified.

Concerning permanent displacements and frictional sliding, a non associated flow rule based on the works of [3] introducing nonlinear evolutions for kinematic hardening has been adopted for this study. The friction threshold stands as,

$$f_\pi = |F_\pi - X_b| \quad (8)$$

With X_b the backstress for nonlinear kinematic hardening. The plastic potential is non associated and is classically expressed as,

$$\phi_\pi = |F_\pi - X_b| + \frac{a_b}{2} X_b^2 \quad (9)$$

The evolution laws are obtained thanks to normality rules applied to the plastic potential,

$$\dot{D}_\pi = \dot{\lambda}_\pi \frac{\partial \phi_\pi}{\partial F_\pi}, \quad \dot{\alpha}_b = -\dot{\lambda}_\pi \frac{\partial \phi_\pi}{\partial X_b} \quad (10)$$

The plastic multiplier is computed using iterative procedure based on return-mapping or Newton procedures.

3.3 Cyclic response

Standing as a first validation case-study, an experimental investigation has been performed on a slab-wall connection made of Shöck thermal bridge shunt elements. A double shear tests has been performed on a mock-up. To emphasize the seismic effect, a cyclic loading has been imposed to the sample (2.5 m long and 1.6 m large). The previous model has been used to simulate the global response and the load-displacement diagram is plotted in figure 9.

Figure 9: Cyclic loading on a Schöck thermal bridge shunt element. Comparisons between numerical simulations and experimental results.

4 CONCLUSIONS

Considering the nonlinear behavior of innovative wall-slab connection in buildings, an experimental and numerical analysis of the mechanical response of thermal bridge shunt elements is proposed in this work. The experimental part allowed assessing the ability for such structural elements to bear horizontal seismic loadings. Finite elements analysis based 3D nonlinear behaviors help one to discriminate the fundamental thermodynamic variables to be introduced and to evaluate their respective evolution laws linked to the global displacement. At last, a simplified model, based on the beam theory assumption is proposed to predict the nonlinear response of building connections subject to cyclic loading. The next step to achieve will be the assessment of building seismic vulnerability performing probabilistic and parametrical analysis.

Keywords: Randomness, Non-linear Structural Dynamics, Invariant manifold.

Abstract. *Structural response can be affected by randomness under two different points of view – either in the forcing process and/or in the structural behaviour. Various approaches can be employed to investigate the structural response, among which polynomial chaos (Ghanem, Spanos [1]) and perturbation approaches (Liu et al. [2], Chiostrini and Facchini [3]) can be found.*

Both kinds of approaches require the investigation of the response variation in dependence on the (random) structural parameters, thus – often dramatically – increasing the number of degrees of freedom of the examined system.

In case of linearity of the system response, a modal reduction approach can be effectively employed together with perturbation techniques; on the other hand, for some kind of nonlinear systems, such reduction approach (Bucher [4], Geschwindner [5]) might fail to give satisfactory results unless a very large number of modes is employed in the analysis (Betti et al. [6]).

The task of reducing the number of degrees of freedom of nonlinear systems has therefore to be accomplished by means of alternative procedures, such as the introduction of nonlinear normal modes.

1 INTRODUCTION

Randomness can affect structural systems by several points of view; in particular, randomness can affect the forcing process that a system undergoes, or might as well influence the structural parameters.

The study of disordered systems, as such structures are usually referred to, is a point of concern in specialized literature: a fair amount of methods to investigate the dynamics of disordered structures can in fact be found.

One of the most common methods is taken into consideration in the present work: the first application is described in Liu et al. (1986), and subsequently enhanced in Chiostrini and Facchini (1999); it can be classified as a perturbation method and makes use of sensitivity vectors to evaluate the first two moments of the response.

Unfortunately, a severe drawback of the method is that the number of degrees of freedom of the examined structure grows rapidly for increasing number of random parameters, thus leading to the solution of very large (non) linear systems.

The idea that is introduced in the present work is to investigate the possibility to compute and apply the concept of nonlinear normal modes in order to reduce the number of degrees of freedom of the resulting system, as it has recently been examined by Rizzo (2007).

It is well known that the normal modes are of fundamental importance in the theory of linear dynamic conservative and non conservative systems, as the linear normal modes can be used to decouple the equations governing the motion and analytically evaluate the dynamic response of the examined system.

Such procedure is performed making use of modal analyses and the principle of superposition to express the response of the system as a time-dependent superposition of its modal shapes.

Clearly, such an approach is generally inapplicable in the nonlinear theory. Nevertheless, it is possible to define nonlinear normal modes (NNMs) as particular synchronous periodic solutions of the non-linear motion equations, but no link of such motions to the principle of superposition can be considered.

Several techniques can be found in specialized literature for determining the response of nonlinear systems; for free vibration problems system modes can be usefully employed to construct reduced order models: such procedures have been well developed for both linear and nonlinear systems by Vakakis (1997) and by Vakakis et al. (1996).

One such technique, introduced by Shaw and Pierre (1991, 1993, 1993), defines the normal mode of a nonlinear oscillatory system in terms of invariant manifolds in the phase space that are tangent to the linear eigenmodes at the equilibrium point. In such a formulation, a master mode is selected, and the normal mode is constructed by a formulation in which the remaining linear modes of the system, i.e., the slave modes, depend on the master mode in a manner consistent with the system dynamics. This dependence defines the invariant manifold for the nonlinear normal mode (NNM).

The construction of the NNM invariant manifold is equivalent to the determination of the constraint relationships for all of the slave coordinates with the master coordinate; once these constraint relationships are obtained, the system dynamics can be restricted to the invariant manifold, resulting in a minimal sized model that depends only on the master coordinates. By studying the dynamics of the reduced-order model, it is possible to recover the associated modal dynamics of the original nonlinear system.

Pesheck et al. (2002) used numerical solutions of the invariant manifold equations to extend the invariant manifold approach to more general systems, including strongly nonlinear

ones. In this approach, the master coordinates were expressed in polar coordinate form, and a Galerkin-based solution technique was introduced to solve the invariant manifold equations.

The present method differs from the work by present authors (2009), because the modal forms are only generated regarding the lagrangian coordinates and not regarding the total coordinate, including the derived to the first one and second order.

2 FORMULATION

A system endowed with a displacement dependent nonlinear restoring force which can be expressed by means of a nonlinear stiffness matrix is taken into consideration. The stiffness is affected by randomness in one or more of the defining parameters; such random parameters will be grouped together in the vector \mathbf{b} .

In specialised literature a common approach for the study of the dynamic response of nonlinear systems is to express the dependence of the system response on the random parameters at each instant of the motion, and eventually combine such dependence with the probability distribution function of the random parameters themselves.

Several examples can be found of this approach. In the following, the method proposed by Liu *et al.* (1986) and successively modified and enhanced by Chiostrini and Facchini (1999) is considered.

Let the equation of motion of a N DOF disordered nonlinear system, where the nonlinear restoring forces depend on both the system response and the uncertain parameters grouped in the vector \mathbf{b} , be given in the form:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{g}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{b}) = \mathbf{f}(t) \quad (1)$$

The system velocity and displacement vectors are expressed by means of a second order expansion with respect to the mean value of the random parameter vector \mathbf{b} :

$$x_h(t, \mathbf{b}) \cong \bar{x}_h(t) + \frac{\partial \bar{x}_h}{\partial b_i} (b_i - \bar{b}_i) + \frac{1}{2} \frac{\partial^2 \bar{x}_h}{\partial b_i \partial b_j} (b_i - \bar{b}_i)(b_j - \bar{b}_j) \quad (2)$$

where the overbar denotes that the quantity is evaluated in correspondence of the expected value of the random parameters \mathbf{b} . A completely analogous equation holds for the system velocity.

The response and its derivatives up to the second order can be evaluated by means of their respective equations of motion, obtained by differentiation of the system equation of motion, evaluated in correspondence of the expected values of the random vector \mathbf{b} . Thus, the first group of equations is given by

$$\mathbf{M}\ddot{\bar{\mathbf{x}}} + \mathbf{g}(\dot{\bar{\mathbf{x}}}, \bar{\mathbf{x}}, \bar{\mathbf{b}}) = \mathbf{f}(t) \quad (3)$$

while the second and third groups of equations can be obtained deriving equation (1) with respect to each component of vector \mathbf{b} and considering again the expected value of the random vector:

$$\begin{aligned} \mathbf{M}\ddot{\bar{\mathbf{x}}}_l + \mathbf{C}_T \dot{\bar{\mathbf{x}}}_l + \mathbf{K}_T \bar{\mathbf{x}}_l &= \mathbf{f}_1(t) \\ \mathbf{M}\ddot{\bar{\mathbf{x}}}_{lm} + \mathbf{C}_T \dot{\bar{\mathbf{x}}}_{lm} + \mathbf{K}_T \bar{\mathbf{x}}_{lm} &= \mathbf{f}_2(t) \end{aligned} \quad (4)$$

where

$$\mathbf{f}_1(t) = -\frac{\partial \mathbf{g}}{\partial b_l} \quad (5)$$

$$\mathbf{f}_2(t) = -\frac{\partial \mathbf{C}_T}{\partial b_m} \dot{\bar{\mathbf{x}}}_l - \frac{\partial \mathbf{K}_T}{\partial b_m} \bar{\mathbf{x}}_l - \frac{\partial \mathbf{C}_T}{\partial b_l} \dot{\bar{\mathbf{x}}}_m - \frac{\partial \mathbf{K}_T}{\partial b_l} \bar{\mathbf{x}}_m - \frac{\partial^2 \mathbf{g}}{\partial b_l \partial b_m}$$

The symbols \mathbf{C}_T and \mathbf{K}_T respectively denote the tangent damping and stiffness matrices, obtained by derivation of the nonlinear restoring function:

$$\mathbf{C}_T = \frac{\partial \mathbf{g}}{\partial \dot{\mathbf{x}}}; \quad \mathbf{K}_T = \frac{\partial \mathbf{g}}{\partial \mathbf{x}} \quad (6)$$

When the nonlinear restoring function can be expressed by only means of a response-dependent matrix times the displacement, as in:

$$\mathbf{g}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{b}) = \mathbf{g}(\mathbf{x}, \mathbf{b}) = \mathbf{K}(\mathbf{x}, \mathbf{b}) \mathbf{x} \quad (7)$$

then the components of the tangent stiffness matrix and its derivatives can be obtained as:

$$\begin{aligned} K_{Tij} &= \frac{\partial g_i}{\partial x_j} = \frac{\partial K_{ih}}{\partial x_j} x_h + K_{ij} \\ \frac{\partial g_i}{\partial b_l} &= \frac{\partial K_{ij}}{\partial b_l} x_j; \quad \frac{\partial^2 g_i}{\partial b_l \partial b_m} = \frac{\partial^2 K_{ij}}{\partial b_l \partial b_m} x_j \\ \frac{\partial K_{Tij}}{\partial b_l} &= \frac{\partial^2 K_{ih}}{\partial b_l \partial x_j} x_h + \frac{\partial^2 K_{ih}}{\partial x_m \partial x_j} \frac{\partial x_m}{\partial b_l} x_h + \\ &\quad + \frac{\partial K_{ih}}{\partial x_j} \frac{\partial x_h}{\partial b_l} + \frac{\partial K_{ij}}{\partial b_l} + \frac{\partial K_{ij}}{\partial x_m} \frac{\partial x_m}{\partial b_l} \end{aligned} \quad (8)$$

and equation (4) can be simplified in the following form:

$$\begin{aligned} \mathbf{M} \ddot{\bar{\mathbf{x}}}_l + \mathbf{K}_T \bar{\mathbf{x}}_l &= -\frac{\partial \mathbf{g}}{\partial b_l} \\ \mathbf{M} \ddot{\bar{\mathbf{x}}}_{lm} + \mathbf{K}_T \bar{\mathbf{x}}_{lm} &= -\frac{\partial \mathbf{K}_T}{\partial b_m} \bar{\mathbf{x}}_l - \frac{\partial \mathbf{K}_T}{\partial b_l} \bar{\mathbf{x}}_m - \frac{\partial^2 \mathbf{g}}{\partial b_l \partial b_m} \end{aligned} \quad (9)$$

Equation (3) together with (4) or (8) define a set of a total of $N(1 + N_b + N_b^2)$ scalar equations which give the evolution in time of the system response and its derivatives with respect to the random parameters. N_b is in fact the number of the random parameters of the system, which correspond to the dimension of vector \mathbf{b} .

For systems with many degrees of freedom, affected by randomness in one or more parameters, the number of equations grows in a way that can be hardly manageable by current computers. In order to reduce the number of equations, the non-linear normal modes of the system can be introduced.

The approach followed in the application was introduced by a series of works by Shaw and Pierre (1991, 1993, 1993).

The new formulation, regarding the work by present authors (2009), regards the resolution of the equations (7) and (7). This equations can be resolved separately. Only the equations (7) can be resolved with the use of non-linear normal mode instead the equations (7), which are decoupled from the (7), with a non linear dynamic analysis.

The first group of equations can be resolved by a non-linear normal mode approach by means of the explicitation of the linear part of the equations of motion. The modal shapes and associated eigenfrequencies of the linearized system can be calculated, and the LHS term of system **Errore. L'origine riferimento non è stata trovata.** can be diagonalized, obtaining

$$\ddot{\boldsymbol{\eta}} + \boldsymbol{\Omega}\boldsymbol{\eta} = \mathbf{f}(\boldsymbol{\eta}) \quad (10)$$

where $\boldsymbol{\eta} = \boldsymbol{\Phi}\mathbf{y}$ is the vector of the principal coordinates, $\boldsymbol{\Phi}$ is the matrix containing the linearized modal shapes of the system **Errore. L'origine riferimento non è stata trovata.** and $\boldsymbol{\Omega}$ is a diagonal matrix whose elements are ω_k^2 .

If η_m denotes the master degree of freedom, its evolution in time is described by the expression:

$$\begin{aligned} \eta_m &= a \cos \phi \\ \dot{\eta}_m &= -a\omega_m \sin \phi \end{aligned} \quad (11)$$

and the remaining “slave” degrees of freedom are expressed in terms of the master amplitude and phase as

$$\begin{aligned} \eta_i &= P_i(a, \phi) \\ \dot{\eta}_i &= Q_i(a, \phi) \end{aligned} \quad (12)$$

The time evolution of the master amplitude and phase can be expressed by the relations

$$\begin{aligned} \dot{a} &= -\frac{f_m(\boldsymbol{\eta})}{\omega_m} \sin \phi \\ \dot{\phi} &= \omega_m - \frac{f_m(\boldsymbol{\eta})}{a\omega_m} \cos \phi \end{aligned} \quad (13)$$

and also the evolution of functions P_i and Q_i in equations (12) can be obtained by the diagonalized system (10) in the form

$$\begin{aligned} \dot{P}_i(a, \phi) &= Q_i(a, \phi) \\ \dot{Q}_i(a, \phi) &= f_i(\boldsymbol{\eta}) - \omega_i^2 P_i(a, \phi) \end{aligned} \quad (14)$$

Functions P_i and Q_i in equations (12) can be expressed in incremental terms, obtaining first order differential equations where the independent variable is time:

$$\begin{aligned} \dot{P}_i(a, \phi) &= \frac{\partial P_i}{\partial a} \dot{a} + \frac{\partial P_i}{\partial \phi} \dot{\phi} \\ \dot{Q}_i(a, \phi) &= \frac{\partial Q_i}{\partial a} \dot{a} + \frac{\partial Q_i}{\partial \phi} \dot{\phi} \end{aligned} \quad (15)$$

When the system is subject to free oscillations and therefore $\mathbf{f}(t) = \mathbf{0}$ in equations (1) and **Errore. L'origine riferimento non è stata trovata.**, by means of the substitution of equations (13) and (14) into (15), first order differential equations are obtained for the first derivatives of functions P_i and Q_i , which are independent of time. Such equations describe the geometry of the considered non normal mode (see Pesheck *et al.* (2002) for details):

$$Q_i(a, \phi) = -\frac{\partial P_i}{\partial a} \frac{f_m(\boldsymbol{\eta})}{\omega_m} \sin \phi + \frac{\partial P_i}{\partial \phi} \left[\omega_m - \frac{f_m(\boldsymbol{\eta})}{a \omega_m} \cos \phi \right] \quad (16)$$

$$f_i(\boldsymbol{\eta}) - \omega_i^2 P_i(a, \phi) = -\frac{\partial Q_i}{\partial a} \frac{f_m(\boldsymbol{\eta})}{\omega_m} \sin \phi + \frac{\partial Q_i}{\partial \phi} \left[\omega_m - \frac{f_m(\boldsymbol{\eta})}{a \omega_m} \cos \phi \right]$$

When the evaluation of the non normal mode is completely performed, the corresponding vector \mathbf{y} can be evaluated by means of

$$\mathbf{y} = \boldsymbol{\Phi}^t \boldsymbol{\eta} = \boldsymbol{\Phi}^t \begin{bmatrix} P_1 & \dots & P_{m-1} & a \cos \phi & P_{m+1} & P_{N_{tot}} \end{bmatrix} \quad (17)$$

The projection in the lagrangian coordinates $\bar{\mathbf{x}}$ and the resolution of the second group of equations (13) gives the desired approximation for the dependence of the system response \mathbf{x} on the random parameters vector \mathbf{b} .

As outlined in the works of Liu *et al.* (1986) and Chiostrini and Facchini (1999), the response statistics can be obtained by

$$\mu_{x_h} \cong \bar{x}_h(t) + \frac{1}{2} \frac{\partial^2 \bar{x}_h}{\partial b_i \partial b_j} E[(b_i - \bar{b}_i)(b_j - \bar{b}_j)] \quad (18)$$

$$\sigma_{x_h}^2 \cong \frac{\partial \bar{x}_h}{\partial b_i} \frac{\partial \bar{x}_h}{\partial b_j} E[(b_i - \bar{b}_i)(b_j - \bar{b}_j)]$$

3 APPLICATION

The method's application in the present work is made with the use of a multidimensional Duffing equation:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}\mathbf{x} + \lambda(\mathbf{x}^t \mathbf{C}\mathbf{x})\mathbf{K}\mathbf{x} = \mathbf{0} \quad (19)$$

In the 2DOF system used $\mathbf{M}=[1 \ 0; 0 \ 2]$, $\mathbf{K}=[10 \ -5; -5 \ 5]$, $\mathbf{C}=[1 \ -0.5; -0.5 \ 1]$ and $\lambda_m=0.001$ and 0.01.

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{K}(1 + \lambda_m \mathbf{x}^t \mathbf{C}\mathbf{x})\mathbf{x} = \mathbf{0} \quad (20)$$

$$\mathbf{M}\ddot{\mathbf{x}}_{,\lambda} + \mathbf{K}[\mathbf{x}^t \mathbf{C}\mathbf{x} + \lambda_m (\mathbf{x}_{,\lambda}^t \mathbf{C}\mathbf{x} + \mathbf{x}^t \mathbf{C}\mathbf{x}_{,\lambda})]\mathbf{x} + \mathbf{K}(1 + \lambda_m \mathbf{x}^t \mathbf{C}\mathbf{x})\mathbf{x}_{,\lambda} = \mathbf{0} \quad (21)$$

$$\mathbf{M}\ddot{\mathbf{x}}_{,\lambda\lambda} + \mathbf{K}[2\mathbf{x}_{,\lambda}^t \mathbf{C}\mathbf{x} + 2\mathbf{x}^t \mathbf{C}\mathbf{x}_{,\lambda} + \lambda_m (\mathbf{x}_{,\lambda\lambda}^t \mathbf{C}\mathbf{x} + 2\mathbf{x}_{,\lambda}^t \mathbf{C}\mathbf{x}_{,\lambda} + \mathbf{x}^t \mathbf{C}\mathbf{x}_{,\lambda\lambda})]\mathbf{x} + 2\mathbf{K}[\mathbf{x}^t \mathbf{C}\mathbf{x} + \lambda_m (\mathbf{x}_{,\lambda}^t \mathbf{C}\mathbf{x} + \mathbf{x}^t \mathbf{C}\mathbf{x}_{,\lambda})]\mathbf{x}_{,\lambda} + \mathbf{K}(1 + \lambda_m \mathbf{x}^t \mathbf{C}\mathbf{x})\mathbf{x}_{,\lambda\lambda} = \mathbf{0} \quad (22)$$

The groups of equations (13), (13) and (13) are solved separately; in the first is solved the system (13) and the linear system associated gives $\omega_1=1.047$ rad/s, $\omega_2=3.377$ rad/s and $\boldsymbol{\Phi}=[0.369 \ -0.929; 0.657 \ 0.261]$.

The non-linear mode shapes are generated for the first group of equation while the second and third group of equations are solved directly integrating the differential equations. this is possible because the first group of equations does not depend from the derivate ones of x . A possible future development of the method is to resolve also according to group and the third by means of use of the NNMs.

The application is made with $\lambda_m=0.001$ and are showed in figure 1, while the application with $\lambda_m=0.01$ in figure 2. The numeric simulation for the free oscillation are showed in figure 3 and 4 for $\lambda_m=0.001$ and for $\lambda_m=0.01$.

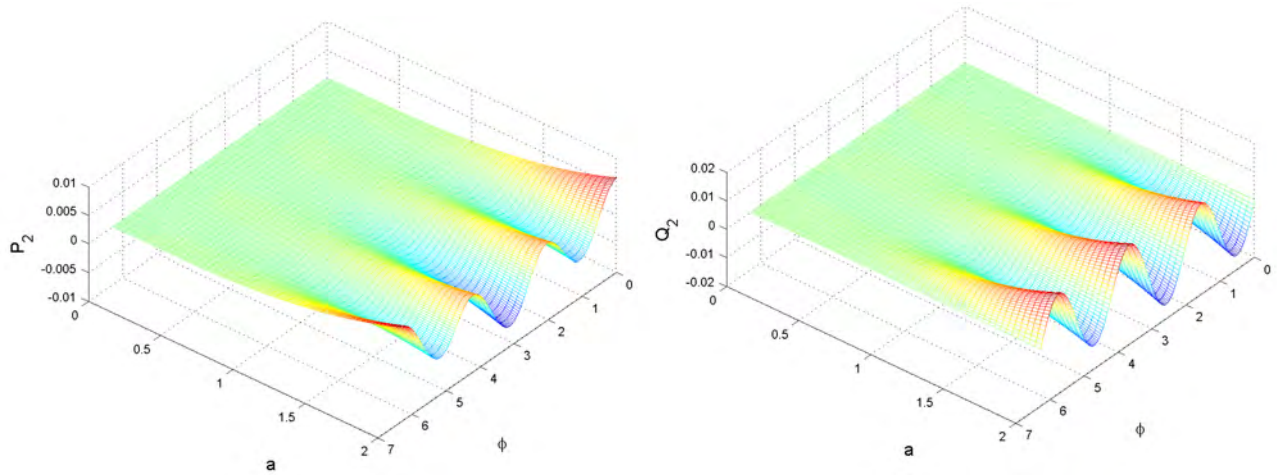

Figure 1. Non linear modal shape P_2 Q_2 for $\lambda_m=0.001$ and $N_a=2$, $N_\phi=4$.

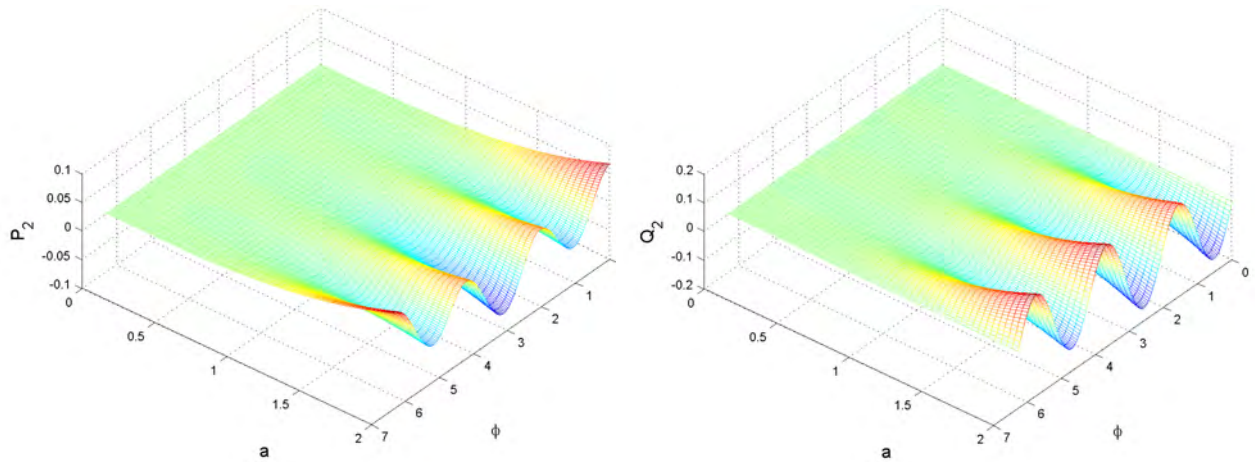

Figure 2. Non linear modal shape P_2 Q_2 for $\lambda_m=0.01$ and $N_a=2$, $N_\phi=4$.

Figure 3. Numerical simulation of the amplitude a and ϕ and the system response $\mathbf{x}(t)$ obtained imposing $\lambda_m=0.001$.

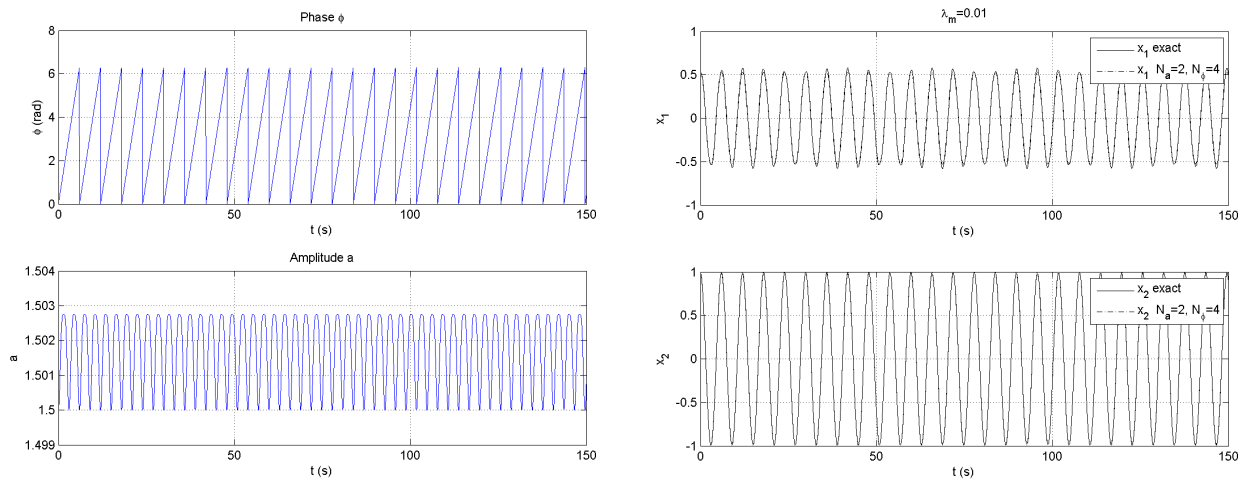

Figure 4. Numerical simulation of the amplitude a and ϕ and the system response $\mathbf{x}(t)$ obtained imposing $\lambda_m=0.01$.

The method that uses the NNM's and the exact simulations in figure 3 and 4 gives results indistinguishable. In order to gain the expected value and the standard deviation of the variable ones x_1 and x_2 the following approximations in the works of Liu *et al.* (1986) and Chiostrini and Facchini (1999) are used:

$$E[x] = x(\varepsilon_m) + \frac{1}{2} x_{,\varepsilon\varepsilon} \cdot \sigma_\varepsilon^2; \quad (23)$$

$$\sigma_x^2 \cong x_{,\varepsilon}^2 \cdot \sigma_\varepsilon^2; \quad (24)$$

$$x \cong x(\varepsilon_m) + (\varepsilon - \varepsilon_m) \cdot x_{,\varepsilon} + \frac{1}{2} x_{,\varepsilon\varepsilon} \cdot (\varepsilon - \varepsilon_m)^2. \quad (25)$$

In the following figures the variations of x_1 are brought back and x_2 regarding λ and variable t . The variation coefficient used in the numerical simulations is 50%.

Figure 5. Numerical simulation of the system response $x_1(t, \lambda)$ and $x_2(t, \lambda)$ obtained with $\lambda_m=0.01$.

In order to confront the method we have been simulated 1000 dynamic analyses with $\lambda_m=0.01$ and coefficient of variation 50%. In figure 6 the corresponding probability distribution is brought back.

Figure 6. Normal probability distribution for the numerical simulation with $\lambda_m=0.01$ and CV 50%.

The comparison between the adopted method and the simulations random is shown in the following figures. The method that uses the NNM's and the simulations random gives results indistinguishable.

Figure 7. Numerical simulation of the expected value system response $E\mathbf{x}_1$ and $E\mathbf{x}_2$ obtained with $\lambda_m=0.01$.

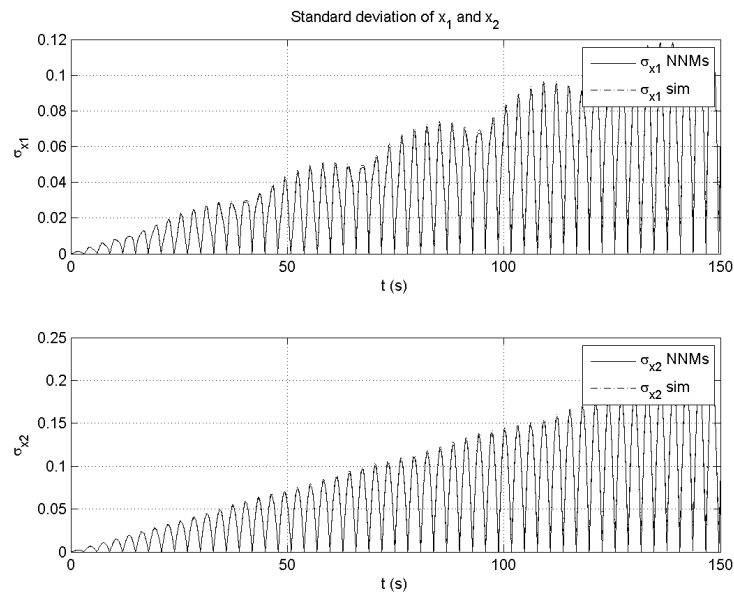

Figure 8. Numerical simulation of the standard deviation of the system response $\sigma\mathbf{x}_1$ and $\sigma\mathbf{x}_2$ obtained with $\lambda_m=0.01$.

4 CONCLUSIONS

In the present formulation is developed a new approach that can be effectively used for the solution of the non linear dynamics of large disordered structures, when the number of degrees of freedom considerably increase owing to the presence of randomness.

The most severe problem in the present formulation is to obtain numerically the non linear modal shapes, therefore future developments of the present method will be devoted to finding a more efficient numerical method to obtain the NNM's.

Keywords: Uncertainty Propagation, Epistemic Uncertainty, Aleatory uncertainty, UDR, PCE, FOSM, Evidence theory.

Abstract. Several uncertainty propagation algorithms are available in literature: (i) Monte-Carlo simulations based on response surfaces, (ii) approximate uncertainty propagation algorithms and (iii) non probabilistic algorithms. All of these approaches are based on some a priori assumptions about the nature of design variables uncertainty and on the models and systems behavior. Some of these assumptions could misrepresent the original problem and, consequently, could yield to erroneous design solutions, in particular where the prior information is poor or inexistent (complete ignorance). Therefore, when selecting a method to solve an uncertainty based design problem, several aspects should be considered: prior assumptions, non-linearity of the performance function, number of input random variables and required accuracy. It could be useful to develop some guidelines to choose an appropriate method for a specific situation.

In the present work some classical structural problems will be studied in order to investigate which probabilistic approach, in terms of accuracy and computational cost, better propagates the uncertainty from input to output data. The methods under analysis will be: Univariate Dimension Reduction methods, Polynomial Chaos Expansion, First-Order Second Moment method, and algorithms based on the Evidence theory for epistemic uncertainty. The performances of these methods will be compared in terms of moment estimations and probability density function construction corresponding to several scenarios of reliability based design and robust design. The structural problems presented will be: (1) the static, dynamic and buckling behavior of a composite plate, (2) the reconstruction of the deformed shape of a structure from measured surface strains.

1 INTRODUCTION

The design for reliability, as well as robust design, is phased in over last decades in the structural design. Although these concepts are well-known in many engineering fields, the high computational cost of the mathematical approaches needed to perform these kinds of analysis, have set back their application in the aerospace structural design. Although in this last field, the problems that deal with the input variable uncertainties are known since the beginning of the aviation history, they are coped with deterministic methods based on the safety factor approach. The diffusion of components based on composite materials, in secondary and primary aerospace structures, and the dropping of aerospace and aviation companies' profit have reawaken the interest in design philosophies that deal with the uncertainty in a more effective way. For this reason, mathematicians and researchers have been urged on the study of new numerical approaches for an accurate Uncertainty Propagation (UP) from input to output data. Traditionally, both the reliability and the robustness of a design configuration have been studied using the Montecarlo simulation; although it is the most accurate method, its computational cost could be prohibitive. For this reason several alternative approaches have been developed to face UP.

Most of the available UP algorithms have particular characteristics that make them appropriate for some specific problems but their capabilities are not fully exploited in all kinds of applications. First of all it is possible to distinguish between algorithms for the study of aleatory uncertainty and approaches that deal with the epistemic uncertainty. This classification can be based on the prior hypotheses needed to simulate the prior uncertainty. In order to model the epistemic uncertainty by means of probabilistic (aleatory) algorithms, some prior hypotheses should be adopted to transform the epistemic information into a probability distribution function (epistemic algorithms do not need such assumptions). On the other hand, a probabilistic problem may be studied by means of an epistemic algorithm if the prior probability density functions are transformed into set-based information.

The UP algorithms based on the probability theory are usually classified into five categories [1]: 1) Simulation based methods: these techniques are based on the simulation of the problem in proper trial points, selected according to the stochastic characteristics of the input variables. MonteCarlo Simulation (MCS) is certainly the most known and used of these methods. 2) Local expansion based methods: these algorithms, also known as perturbation methods, are based on the local series expansion of output functions in terms of input random parameters. The methods based on Taylor expansion, such as the FOSM (First Order Second Moment) or the SOSM (Second Order Second Moment) methods, belong to this class. 3) Most Probable Points (MPP) based methods: this class includes the First and Second Order Reliability Methods (FORM and SORM, respectively). 4) Functional expansion based methods: they rely on a stochastic expansion of the performance function. The most known method of this class is the Polynomial Chaos Expansion (PCE). 5) Numerical integration based methods: these techniques are based on the numerical solving of integral equations for the statistical moments. These methods don't yield directly the performance joint probability function, but the corresponding statistical moments; by using the Pearson System and knowing the first four statistical moments, the probability distribution function can be obtained.

Several factors affect the choice of a suitable UP approach: (i) the identification and the classification of the input uncertainty, (ii) the definition of the required outputs (the first two statistical moments in robust design and the probability density function or the most probable points in a reliability based analysis), (iii) and the mathematical characteristics of the studied model (if the first order interactions cannot be neglected the Univariate Dimension Reduction method does not yield accurate prediction while the performance function is non linear the

methods based in Taylor local expansion are not accurate). This last information can be obtained using some numerical tools, such as the sensitivity analysis.

The main objective of this work is a comparative study of some of the most common and newest UP algorithms for both aleatory and epistemic uncertainties. As far as the first ones, the limits and merits of the Univariate Dimension Reduction method (UDR), of the Polynomial Chaos Expansion (PCE), and of the First Order Second Moments algorithm (FOSM) will be analyzed and discussed. These methods will be tested and compared on some numerical test functions and a classical structural problem: the probabilistic study of static, dynamic and buckling behavior of a composite plate. The sensitivity analysis has been performed in order to study the mathematical characteristics of the model. In the second part of the present work a probabilistic approach based on the UDR is compared with an epistemic approach based on the evidence theory. The structural application used as a test case for the comparison is an inverse problem: reconstruction of the deformed shape of a beam from measured surface strains using the inverse Finite elements Method (iFEM) [2][3].

2 UNCERTAINTY PROPAGATION ALGORITHMS

In this section, a review of some uncertainty propagation algorithms will be presented in order to set the framework for the assessment and comparison, through some structural applications, discussed in Sec. 3.

2.1 The Univariate Dimension Reduction method (UDR)

This method involves an additive decomposition of a multidimensional integral function to multiple one-dimensional integral functions. The technique is suitable for calculating the stochastic moments of a system response function, as Rahman and Xu have shown [4]-[6]. The stochastic moments of a probability distribution may be calculated as follows

$$m_l = \zeta[Y^l(X)] = \int_{-\infty}^{+\infty} \dots \int_{-\infty}^{+\infty} y^l(X) f_X(X) dx \quad l = 0, 1, \dots, m \quad (1)$$

where m_l is the l^{th} -order statistical moment (i.e., $m=1$ is the mean value, $m=2$ is the variance, etc.), $f_X(X)$ is the system response joint probability density function, $y(X)$ is the deterministic response when the input variables assume the values collected in the vector $X = \{x_1, \dots, x_n\}^T$, and $Y(X) = y^l(X) f_X(X)$ is the performance function. The latter can be approximated as the sum of univariate functions, each one depending on only one random variable at a time and the other variables being fixed to nominal values

$$Y(x_1, \dots, x_n) \cong \tilde{Y}(X) \equiv \sum_{j=1}^N Y(\mu_1, \dots, \mu_{j-1}, x_j, \mu_{j+1}, \dots, \mu_N) - (N-1) \cdot y(\mu_1, \dots, \mu_N) \quad (2)$$

where μ_j is the first moment of the stochastic variable x_j , $Y(\mu_1, \dots, \mu_{j-1}, x_j, \mu_{j+1}, \dots, \mu_N)$ is the stochastic response of the system only depending on the x_j random variable, and $y(\mu_1, \dots, \mu_N)$ is the deterministic response of the system depending on the nominal value of the N input variables. Adopting the dimension-reduction procedure, the expression of statistical moments (1) can be rewritten as:

$$m_l = \int_{-\infty}^{+\infty} \dots \int_{-\infty}^{+\infty} \sum_{j=1}^N \left(Y(\mu_1, \dots, \mu_{j-1}, x_j, \mu_{j+1}, \dots, \mu_N) - (N-1) \cdot y(\mu_1, \dots, \mu_N) \right) dx \quad (3)$$

To solve the univariate integration in the context of the UDR method, Xu and Rahman [4] suggest the use of the moment based quadrature rule. The evaluation of integration points x_j involves the solution of the following equation

$$x_j^n - r_{j,1} x_j^{n-1} + r_{j,2} x_j^{n-2} - \dots + (-1)^n r_{j,n} = 0 \quad (5)$$

where the coefficients r_j are solution of the following linear system of equations

$$\begin{bmatrix} \mu_{j,n-1} & -\mu_{j,n-2} & \mu_{j,n-3} & \dots & (-1)^{n-1} \mu_{j,0} \\ \mu_{j,n} & -\mu_{j,n-1} & \mu_{j,n-2} & \dots & (-1)^{n-1} \mu_{j,1} \\ \mu_{j,n+1} & -\mu_{j,n} & \mu_{j,n-1} & \dots & (-1)^{n-1} \mu_{j,2} \\ \dots & \dots & \dots & \dots & \dots \\ \mu_{j,2n-2} & -\mu_{j,2n-3} & \mu_{j,2n-4} & \dots & (-1)^{n-1} \mu_{j,n-1} \end{bmatrix} \begin{bmatrix} r_{j,1} \\ r_{j,2} \\ r_{j,3} \\ \dots \\ r_{j,n} \end{bmatrix} = \begin{bmatrix} \mu_{j,n} \\ \mu_{j,n+1} \\ \mu_{j,n+2} \\ \dots \\ \mu_{j,2n-1} \end{bmatrix} \quad (6)$$

$\mu_{j,i}$ ($i=1, \dots, n$) represents the i^{th} stochastic moment of the j^{th} input variable. Thus, the univariate integral can be numerically solved as

$$\int_{-\infty}^{+\infty} y'(\mu_1, \dots, x_j, \dots, \mu_N) f_{x_j}(x_j) \cdot dx_j \cong \sum_{i=1}^n w_{j,i} y'(\mu_1, \dots, x_j, \dots, \mu_N) \quad (7)$$

where f_{x_j} is the probability density function of input variable x_j . The weight $w_{j,i}$ appearing in Eq. (7) are evaluated using the following expression:

$$w_{i,j} = \frac{\sum_{k=0}^{n-1} (-1)^k \mu_{j,(n-k-1)} \cdot q_{j,(ik)}}{\prod_{k=1, k \neq i}^n (x_{j,i} - x_{j,k})} \quad q_{j,i_0} = 1; \quad q_{j,ik} = r_{j,k} - x_{j,i} \cdot q_{j,i(k-1)} \quad (8)$$

2.2 The Polynomial Chaos Expansion (PCE)

The Polynomial Chaos Expansion was introduced by Wiener [7] and is based on the approximation of each random variable by means of a suitable polynomial expansion about centered normalized Gaussian variables.

Any set $X = \{x_1, \dots, x_n\}^T$ of independent Gaussian variables can be expressed as function of a set $\xi = \{\xi_1, \dots, \xi_n\}$ of independent normal variables

$$X = f(\xi) \quad (9)$$

Hence, a performance function $y = Y(X)$ could be transformed into a function expressed in terms of ξ and, afterwards, approximated by means of the Polynomial Chaos Expansion (PCE) on the vector space

$$Y(X) = a_0 \Gamma_0 + \sum_{i_1=1}^{\infty} a_{i_1} \Gamma_1(\xi_{i_1}) + \sum_{i_1=1}^{\infty} \sum_{i_2=1}^{i_1} a_{i_1 i_2} \Gamma_2(\xi_{i_1}, \xi_{i_2}) + \sum_{i_1=1}^{\infty} \sum_{i_2=1}^{i_1} \sum_{i_3=1}^{i_2} a_{i_1 i_2 i_3} \Gamma_3(\xi_{i_1}, \xi_{i_2}, \xi_{i_3}) + \dots \quad (10)$$

where $a = [a_0, \dots, a_n]$ is the vector of the expansion unknown terms and $\Gamma_p(\xi_1, \dots, \xi_n)$ are the multidimensional Hermite polynomials (only if the input random variables are defined by a normal probability distribution) of order p .

Cameron and Martin have shown that this kind of series is convergent in the L_2 -sense [8]. In order to simplify the notation a univocal relation between the functional Γ and a new functional Ψ is defined. Hence, the PCE expansion, expressed by Eq. (10), can be rewritten as follows

$$Y(X) = \sum_{k=0}^{\infty} \beta_k \Psi_k(\xi(X)) \quad (11)$$

In the present work the classical convention is adopted:

- $\Psi_0 = 1$: is the 0th-order polynomial
- β_k are the constant coefficients of the expansion
- Ψ_k are multivariate Hermite polynomials, orthogonal in the L_2 -space. These polynomials are the product of the proper set of univariate Hermite polynomials [9].

The expansion is normally truncated at a selected order P

$$Y(X) \approx \hat{Y}(X) = \sum_{k=0}^P \beta_k \Psi_k(\xi) \quad (12)$$

The number of unknown coefficients β_k (13) can be evaluated using the following expression

$$P+1 = \frac{(p+n)!}{p!n!} \quad (13)$$

The procedure described above is general, but the Hermite polynomials can be used only in the cases of input variables with Gaussian probability distribution function. Xiu and Karniadakis [9] have extended the PCE applicability to all kinds of input distribution function, adopting the Wiener-Askey scheme for non Gaussian input distribution. They have proposed to use the Askey scheme to combine the non Gaussian input distribution with orthogonal polynomial family; in this way the expansion convergence for all kind of input PDF. As well as the Hermite polynomials are orthogonal in the Hilbert space, in the same way all polynomials, adopted in the Wiener-Askey [9] scheme are orthogonal in the Hilbert space and form an Hilbert basis of the corresponding space.

The set $\beta = \{\beta_0, \dots, \beta_n\}^T$ of the PCE unknown coefficients, can be approximated by a new vector $\hat{\beta}$, obtained solving the following least squares problem

$$\hat{\beta} = \arg \min_{\beta} \sum_{i=1}^N \left(Y(X_i) - \sum_{k=0}^p \beta_k \psi_k(\xi_i) \right)^2 \quad (12)$$

where N is the training points set size; generally, it is convenient that $N > p + 1$.

2.3 The First Order Second Moment algorithm (FOSM)

In this approach a performance function $Y(X)$ is approximated by means of a first order Taylor-series expansion around the design point [10]

$$Y(X) \cong Y(\bar{X}) + \sum_{i=1}^n \frac{\partial Y}{\partial x_i} \bigg|_{\bar{X}} (x_i - \bar{x}_i) \quad (13)$$

Substituting Eq. (13) in the expectation definition (mean)

$$E[Y(X)] = E[Y(\bar{X})] + E \left[\sum_{i=1}^n \frac{\partial Y}{\partial x_i} \bigg|_{\bar{X}} (x_i - \bar{x}_i) \right] \quad (14)$$

and considering that:

$$E \left[\sum_{i=1}^n \frac{\partial Y}{\partial x_i} \bigg|_{\bar{X}} (x_i - \bar{x}_i) \right] = \sum_{i=1}^n \frac{\partial Y}{\partial x_i} \bigg|_{\bar{X}} E[(x_i - \bar{x}_i)] = 0 \quad (15)$$

$$E[(x_i - \bar{x}_i)] = E(x_i) - \bar{x}_i = \bar{x}_i - \bar{x}_i = 0 \quad (16)$$

the performance function mean value, estimated by means of FOSM, assumes the following expression

$$E[Y(X)] = Y(\bar{X}) \quad (17)$$

Now, given the variance definition

$$Var[Y(X)] = E[(Y(X) - E(Y(X)))^2] \equiv \sigma^2[Y(X)] \quad (18)$$

and substituting in it Eq. (13), the variance assumes the following expression

$$\sigma^2[Y(X)] = \sum_{i=1}^n \sum_{j=1}^m \frac{\partial Y}{\partial x_i} \bigg|_{\bar{x}_i} \frac{\partial Y}{\partial x_j} \bigg|_{x_j} \cdot COV(x_i, x_j) \quad (19)$$

where $COV(x_i, x_j)$ is the covariance matrix.

2.4 The Evidence Theory

The Evidence Theory is a non probabilistic approach, used to characterize the effect of epistemic uncertainty on a system.

Given a design variable x_1 , the prior information, or evidence, consists of n intervals, obtained from s sources $[x_{1,i}^l, x_{1,i}^u]$ (with $i = 1, \dots, s$) that enclose the supposed true value. Clearly, the traditional probability theory cannot handle this type of evidence, without making some assumptions that can pervert the nature of the information. Several combination rules have been formulated to handle this kind of prior information [11],[12]; in this work, the Dempster-Shafer combination rule is adopted.

When a source provides a set information, this means that the variable can assume any value inside the interval. The probability that a variable x_1 assumes the value \bar{x}_1 is not defined by a probability distribution function but is included between a maximum probability (plausibility), and a minimum probability (belief). In order to define the plausibility and the belief, the basic probability assignment (m) must be introduced; m defines a mapping of the variable prior information. Formally the basic probability assignment function is defined by means of the following expressions

$$m : P(x_1) \rightarrow [0,1] \quad (20)$$

$$m(\emptyset) = 0 \quad (21)$$

$$m = 1 \text{ if } \bar{x}_1 \in S_i \text{ with } i = 1, \dots, s \quad (22)$$

where $P(x_1)$ represents the power set of x_1 (defined, according to the axiomatic set theory [12] as the set of all subset of S), while \emptyset is the null set and S_i is the i -th evidence set. According to the previous equations, the basic probability assignment assumes any value included between 0 and 1; if \bar{x}_1 does not belong to any subset, the basic probability assignment assumes value 0, while if \bar{x}_1 belongs to every subset, it assumes the value 1. Once defined the basic probability assignment m , the plausibility and belief probability measures can be introduced. Given a set $C = [D(x_1)^-, \bar{x}_1]$, where \bar{x}_1 is a generic value of the variable x_1 on its domain $D(x_1)$, while $D(x_1)^-$ represents the lower domain boundary, the plausibility can be expressed by

$$Pl(C_1) = \sum_{C_1 \cap S_{x_1}^i \neq \emptyset} m_{x_1}(S_{x_1}^i) \quad (24)$$

while the belief is defined as:

$$Bel(C_1) = \sum_{S_{x_1}^i \subseteq C_1} m_{x_1}(S_{x_1}^i) \quad (25)$$

In other words, the plausibility is the sum of all basic probability assignments of the sets $S_{x_1}^i$ which intersect the set of interest C_1 , hence it represents the maximum probability that a variable x_1 assumes a given value \bar{x}_1 . On the other hand, the belief is defined as the sum of all

basic probability assignments of the sets $S_{x_1}^i$ that $S_{x_1}^i \subseteq C_1$ hence it is a measure of the minimum probability that a variable x_1 assumes a given value \bar{x}_1 .

The probability lies between the plausibility and the belief

$$Bel(C_1) \leq P(C_1) \leq Pl(C_1) \quad (26)$$

and, only when plausibility and belief are overlapped, it can be univocally defined.

In a problem with n input variables there is the need to transfer the basic probability assignment values m_{x_j} , evaluated for each variable, into an equivalent information in the n -dimensional design variables space. Assuming that all the variables are uncorrelated, the probability of each elementary set in the design variables space is defined by

$$m_{x_1, x_2, \dots, x_n}([S_{x_1}^j], \dots, [S_{x_n}^j]) = m_{x_1}([S_{x_1}^j]) \cdot \dots \cdot m_{x_n}([S_{x_n}^j]) \quad (27)$$

Once defined the uncertainty acting on the design variables, its effects on the performance function can be evaluated. Given a generic function $y = Y(X)$, linking the output with the input variables $X = \{x_1, \dots, x_n\}$, the evidence about y must be estimated from the joint body of evidence previously described in Eq. (27). By means of two optimization problems, for each evidence-set of the input variables space, the lower and upper boundary of the corresponding set into the output space are evaluated

$$\begin{aligned} \text{find } \bar{X} &= \{\bar{x}_1, \dots, \bar{x}_n\} \in \Sigma_j ([S_{x_1}^j], [S_{x_2}^j], \dots, [S_{x_n}^j]) \\ \text{t.c. } \max / \min y &= f(X) \quad \square \\ &\Downarrow \\ S_y^j &= [y_l^j, y_u^j] \end{aligned} \quad (28)$$

The above optimization problems yield an evidence set on output-space S_y^j for each set Σ_j of the joint body of evidence (Fig 4.5). Hence, in order to propagate the uncertainty from input to output two optimizations for each set Σ_j have to be performed.

3 NUMERICAL EXAMPLES

In this section some numerical examples will be presented in order to verify the accuracy of the UP methods described above. Some test functions and a structural problem (static, dynamic and buckling behavior of a composite plate) will be the test cases considered for assessing the methods for stochastic uncertainty. A comparison between stochastic and epistemic approaches when applied to a structural shape sensing problem will be then discussed.

3.1 Test functions

Two test functions are used to compare the performance of the UP methods introduced in the previous paragraphs (Table 1).

Function	PDF	PDF Parameters
$y = x_1^k x_2^k + 2x_3^4 \quad k = 2, 3, 5$	Gaussian	$\mu = [1, 1, 1]$ $\sigma = 0.1, 0.2, 0.4, 0.8$
$y = \sin x_1 + a \sin^2 x_2 + b x_3^4 \sin x_1$	Gaussian	$\mu = [\pi/4, \pi/4, \pi/4]$ $\sigma = 0.05, 0.1, 0.2, 0.5$

Table 1: Test functions used to test the UP methods

The first example is a three-variate function, chosen to compare the performance of the UP algorithms against the first order interaction of the input variables. The input variables follow a Gaussian distribution centered in $X = [1, 1, 1]$ and four values of standard deviation are tested ($\sigma = 0.1, 0.2, 0.4, 0.8$). In addition, the effect of the interactions among the variables is studied changing the value of k . The analysis of the accuracy of each method is performed comparing the predicted values of the statistical moments with those evaluated using a MonteCarlo Simulation, based on 10^6 observations. In this example the effect of an increasing input variability is combined with that of an increasing interaction effect.

In Table 2 the main effects and the interactions are listed for each value of k . These indices are evaluated by means of the Polynomial Chaos Expansion [13]. We can observe that changing the value of k the interaction $x_1 x_2$ increases its effect on the output, becoming gradually the most important factor.

	<i>Main Effects and Interactions</i>		
	k=2	k=3	k=5
X_1	0,011	0,0838	0,0575
X_2	0,011	0,0838	0,0572
X_3	0,9587	0,4734	0,0006
$X_1 X_2$	0,01927	0,359	0,8808
$X_1 X_3$	9,60E-25	8,78E-25	5,82E-04
$X_2 X_3$	4,84E-26	8,34E-25	1,22E-03

Table 2: Main effects and interaction

In Fig (1) the errors in the estimation of the mean value are plotted in function of the input variables standard deviation and against different values of k . As a general rule, when the input variability increases, all the UP methods here discussed become less accurate. This phenomenon is negligible if the first order interactions are marginal; on the contrary, in problems

where the interaction effects are more important ($k = 3$ or $k = 5$) the results become more sensitive to the input variability.

As shown in Fig (1A) the UDR yields a good estimation of the mean values when the interaction between the variables is low ($k = 2$), also in the case of high input variability ($\sigma = 0.8$). Increasing the effect of interaction, the accuracy of this method greatly decays, in particular for higher values of input variability.

Similar behaviors are shown in Fig (1B-D); the output function is approximated with the Polynomial Chaos Expansion, truncated at different orders. Also in this case, for higher values of k and for a higher input uncertainty, the mean value is poorly approximated. When using the PCE, however, the reduced accuracy is not due to the interaction effects, but it is caused by the non-linearity of the output function: for example, if $k = 2$ we have a 4th order function, while if $k = 3$ we have a 6th order function. Hence, it is clear that a Polynomial Chaos Expansion truncated at the 5th order better describes the problem than an expansion truncated at the 2nd order, but, for $k = 5$, it does not guarantee adequate accuracy. Increasing the order of the expansion, the error in the prediction gradually vanishes.

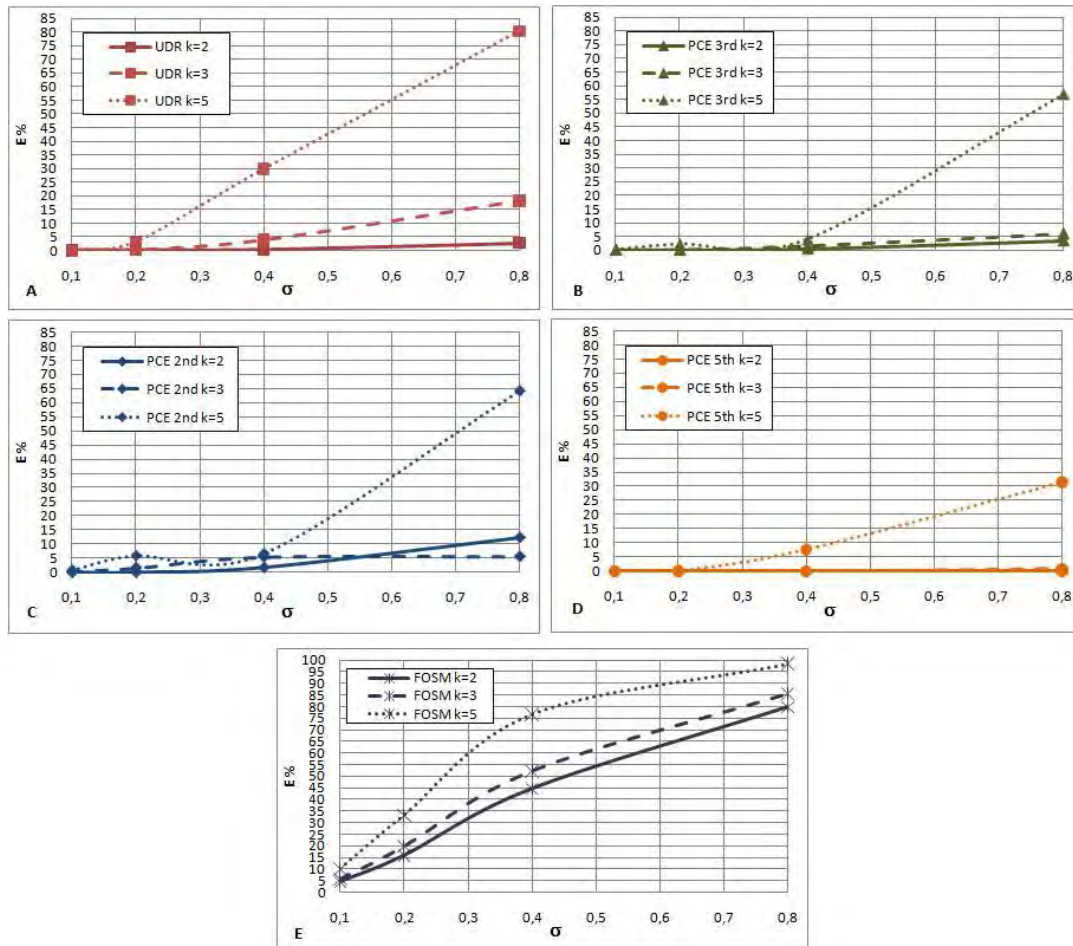

Fig 1 Error in the estimation of the output mean value: A) Error due to the Univariate dimension reduction method (UDR) B-D) Error due to the Polynomial Chaos Expansion (PCE) respectively of 2nd, 3rd and 5th order. E) Error due to the FOSM algorithm

Therefore, there is a substantial difference between the UDR and the PCE. In the UDR the lack of accuracy, is inherent to its mathematical formulation and cannot be reduced. On the

other hand, the accuracy of the PCE results can be improved increasing the order of the expansion.

In Fig (1E) the errors are shown on the output function mean value when computed using the FOSM algorithm. In this case the approximation is based on the hypothesis that the output function has a linear behavior in the studied domain; the errors are quite high also for small input variability levels.

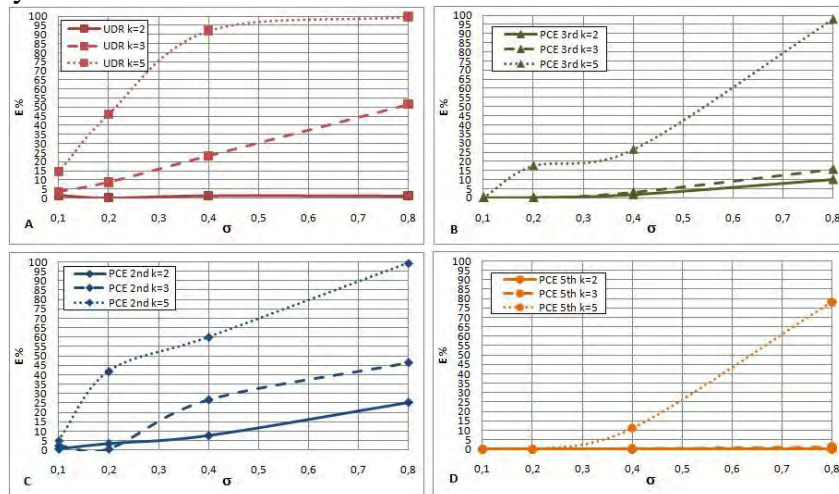

Fig 2 Error in the estimation of the output variance: A) Error due to the Univariate dimension reduction method (UDR) B-D) Error due to the Polynomial Chaos Expansion (PCE) respectively of 2nd, 3rd and 5th order.

The decay of UDR accuracy in the prediction of the statistical moments (due mainly to the first order effects) is more evident in the evaluation of the variance Fig (2-A) and of the higher order moments: Skewness (Fig 3-A) and Kurtosis (Fig 4-A). As already observed in the evaluation of mean value, for quite small interaction effects ($k=2$), the UDR approximation does not affect the accuracy of the results. This is not true for the higher order moments.

Results regarding higher order statistical moments (Figs. 6.4B-D, 6.5B-D, 6.6B-D) confirm that the interaction between the variables does not affect the accuracy of the Polynomial Chaos Expansion; anyhow, a higher order expansion is required in order to have a good estimation of the variance, skewness and kurtosis.

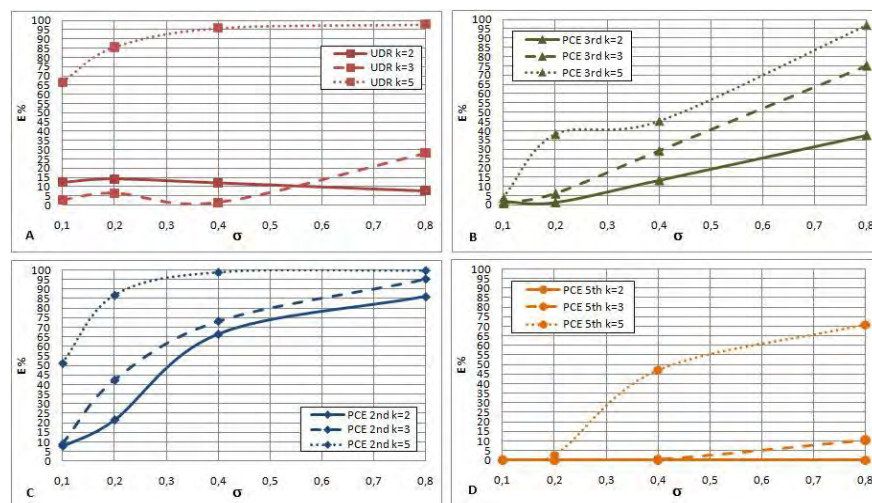

Fig 3: Error in the estimation of the output skewness: A) Error due to the Univariate dimension reduction method (UDR) B-D) Error due to the Polynomial Chaos Expansion (PCE) respectively of 2nd, 3rd and 5th order.

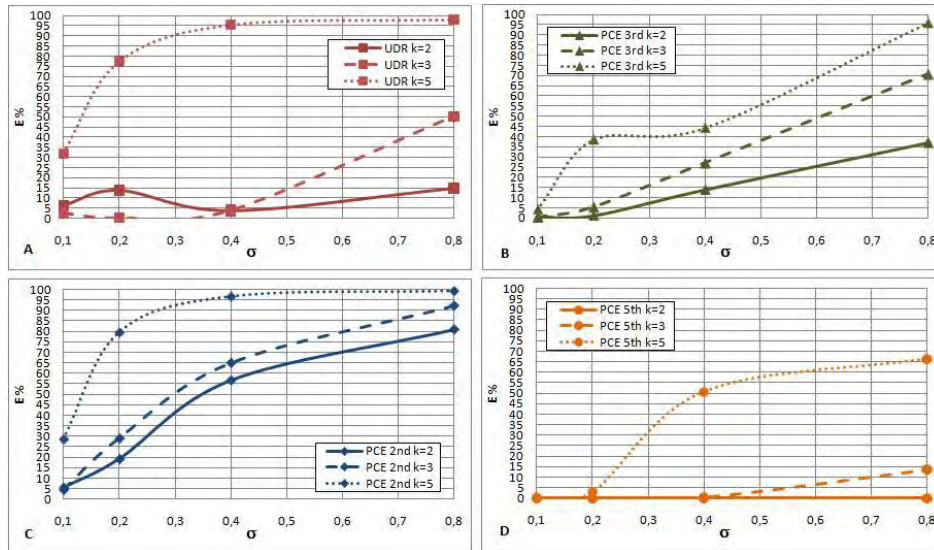

Fig 4: Error in the estimation of the output kurtosis: A) Error due to the Univariate dimension reduction method (UDR) B-D) Error due to the Polinomial Chaos Expansion (PCE) respectively of 2nd, 3rd and 5th order.

In Table 3 the number of observation points needed to perform each analysis are listed. The UDR methods needs only 16 observed data (it requires only $5n + 1$, where n are the stocastic input variables).

FOSM	UDR	PCE 2nd	PCE 3rd	PCE 5th
49	16	31	61	168

Tab 3: Number of observations for each methods

The UDR method is the cheapest one and, as seen in the present example, if there is a negligible interaction between the input variables it yields a good estimation of the statistical moments. The computational cost of the PCE grows considerably increasing the order of expansion and the problem dimension.

The second function here considered (see Tab (1)) is the Ishigami function, commonly used to test the uncertainty propagation algorithms and the sensitivity in order to understand their behavior with non-linear and non-monotonic functions. The three variables follow a Gaussian distribution, centered in $X = [\pi/4, \pi/4, \pi/4]$; the standard deviation ranges from 0.05 to 0.5. The accuracy of each method is assessed comparing the predicted values of the statistical moments with those evaluated using a MonteCarlo Simulation, based on 10^6 observations.

In Table 6.5 the percentage errors on the estimation of the mean value and variance are listed for different values of the input standard deviation. All methods yield a good estimation of the mean value (the error is always less than 1%). The differences between the methods are more evident when considering the variance evaluation. The FOSM method yields a very poor estimation in particular for high values of input variability: for example, the error with an input standard deviation of $\sigma = 0.2$ is around 12.3%, while with $\sigma = 0.5$ is around 56%. The UDR method leads to a good estimation of the variance (error around 2%); there is no evident correlation between the input variability and the estimation error. The PCE is very accurate, if the order of the expansion is sufficient to describe the problem; we can observe that a 5th order expansion is very accurate in the prediction of variance, and that the 7th order expansion yields the exact solution.

Tab 4: Mean values and variance estimation errors

Fig 5: Probability density function in the case that all input variables have a standard deviation of 0.2

Fig 6: Probability density function in the case that all input variables have a standard deviation of 0.5.

In a robust design framework it is important the accurate evaluation of the first two statistical moments (mean and variance), but for the evaluation of the reliability degree this information

is not enough. Hence, the knowledge of the probability distribution function is needed. One of the main problems of the UDR approach is that it does not yield directly the probability distribution, but only the statistical moments. Anyway, it is possible to obtain the PDF, knowing the first four statistical moments, by means of the Pearson System. In fig (5) and fig (6) the probability distribution function, evaluated with the UDR and the Pearson System, is compared with the PDF obtained using the PCE with different expansion orders and the one obtained by means of MCS (10^6 training points). The curves plotted in Fig (5) and in Fig (6) are referred, respectively, to the case of an input standard deviation of $\sigma = 0.2$ and of $\sigma = 0.5$. In the first case (fig 5) a good agreement among all plotted curves can be observed. The UDR method coupled with the Pearson System yields a very good approximation of the probability density function. There is only a small discrepancy in the description of the tails: the tails of PDFs, obtained with the UDR method and the 2nd order PCE, end with an asymptotic behavior, while in the one obtained with MCS the tails are limited. On the contrary there is a perfect correspondence between the probability function obtained with a 3rd order PCE and the one obtained with the MonteCarlo Simulation.

In the second case ($\sigma = 0.5$) it is possible to appreciate a bigger discrepancy among the methods (fig 5-A). Although the UDR method is able to predict with a good accuracy the mean and the variance of the output, it fails in the estimation of the PDF. This is mainly due to the fact that the higher order moments are predicted with low-accuracy and, as well known, the Pearson System is based on the relation between skewness and kurtosis. Also the 3rd order PCE gives not an accurate probability distribution. Only by means of a 5th order PCE a good PDF approximation can be obtained.

In this example we have seen that, although the UDR approach is adequately accurate to be used in a robust design problem, it cannot be used in a reliability based problem.

3.2 Composite plate mechanical behavior

In this example the performances of UDR and PCE are tested on the static and dynamic response analysis of a symmetric composite plate ($0^\circ/90^\circ/90^\circ/0^\circ$) with all edges clamped. The material properties, the fiber angles, and the plies thickness are considered affected by uncertainty and are described by means of Gaussian distributions. In tab (5) all plate properties are reported in terms of mean value and standard deviation. The stochastic moments of the maximum deflection (w), the first natural frequency (f), the maximum Von Misses stress (σ_{VM}), the maximum τ_{xz} and the maximum τ_{yz} are evaluated by means of the UDR and of the PCE. The static and dynamic responses of the plate have been obtained using the Refined Zigzag plate Theory (RZT) [14]-[18]; a Rayleigh-Ritz solution procedure has been adopted to find maximum deflection, first natural frequency and stresses distribution. The results are compared with those obtained using a MCS based on 10^5 observations.

Finally, the first four statistical moments, evaluated using the UDR and PCE, are compared with those obtained by a MonteCarlo Simulation (Tab 6). In Tab (6) one can observe that approximately all approaches give the same results, the main difference between the UDR and the 2nd order PCE is in the computational cost needed to perform the analysis, indeed are needed 71 observations and 360 training points, respectively.

3.3 Structural shape sensing

The inverse Finite Element Method (iFEM), developed by Tessler for plate and shell structures [18] and specialized by Gherlone for beams and frames [19], is aimed at the reconstruction of the displacement field of a structure starting from in situ measurements of surface strains [19]; this represents an inverse problem [20].

In the present work a cantilevered aluminum beam with a circular thin-walled cross-section, subjected to different load conditions, has been studied. In lieu of the experimental measures

of surface strains, high-fidelity forward FE analyses (MSC/NASTRAN) have been carried out for the example problem (Table 7). These results have also been used to verify the accuracy of the nodal displacements and rotations obtained by iFEM.

Element type (name)	N° of elements along the external circumference	N° of elements along the beam length ($L = 20$) [dm]	N° of ele- ments	N° of nodes
Shell ele- ment (QUAD4)	114	360	41,040	41,156

Tab 7: Sensor configuration: 1

The position of a strain gauge, used to measure surface strains, is defined by three coordinates: the first one, x , indicates the position along the longitudinal beam axis, the second one, θ , is an angle representing the circumferential position on the beam and the coordinate β indicates the strain gauge orientation (i.e., it represents the rotation of the strain gauge with respect to the beam axis (Fig 7). For the current application, six strain gauges are used; their nominal positions are reported in Table 8 and their location is also represented in Figure 8.

Fig 7. Location of a strain gauge on the beam external surface. [20]

Strain gauges	x	θ	β
1	10	-120	0
2	10	-120	45
3	10	0	0
4	10	0	45
5	10	120	0
6	10	120	45

Tab 8 Strain gauge nominal positions

Fig 8 Sensors position [20]

In this example three different load conditions are considered (Fig (9-A)): 1) a shear force applied along y-axis, 2) the torque moment and 3) the bending moment around the z-axis. The free end displacements and rotations (Fig (9-B)) are computed by means of the iFEM and are compared with the ones obtained using the forward FEM solution. Hence, the iFEM accuracy is evaluated by means of the following error:

$$E \equiv \frac{\text{Value}(FEM) - \text{Value}(iFEM)}{\text{Value}(FEM)} \quad (29)$$

Fig 9 (A)Applied load, (B) Studied degrees of freedom.

The aim of the present application is to verify the robustness of the iFEM in evaluating the displacement field when the sensor positions are considered affected by uncertainty. For this purpose a probabilistic approach is compared with a non-probabilistic method based on the evidence theory. The main issue is the definition of the uncertainty that affects the coordinate values describing the sensors position. In order to obtain this kind of information, three technicians have been interviewed. They have given three different estimations of the error in the strain gauge location; all these experts are equally trusted. The second expert (see Tab 9) defined the errors using disjoint sets.

Expert	x [mm]		θ [°]		β [°]	
	LOWER	UPPER	LOWER	UPPER	LOWER	UPPER
1	-5	5	-5	5	-4	4
2	-5	-1	-5	5	-4	-1,5
	1	5	-5	5	1,5	4
3	-1	1	-5	5	-1,5	1,5

Tab 9: Sensor coordinates defined by means of interval sets

In order to use a probabilistic approach to propagate the uncertainty from input to output, there is the need to transform the input epistemic uncertainty into probabilistic information. Several hypotheses are then needed about the shape of the probability distribution and its standard deviation. In the present example we have assumed that the uncertainty in the sensor position is described by means of a Gaussian distribution, having the standard deviations listed in Tab (10).

Input variables	PDF	Standard Deviation
x	Gaussian	0,0233
θ	Gaussian	1,1666
β	Gaussian	1,3333

Tab 10: Probabilistic assumptions of sensor position

The information obtained by the sensitivity analysis [21] are used to select which input variables should be considered and which could be neglected during the uncertainty propagation process, performed both using the evidence theory and a probabilistic approach (the UDR method, having verified that there are not significant interactions between variables).. Then, once the first four statistical moments are known, the corresponding probability distribution function is evaluated by means of the Pearson System.

The probability that the iFEM error on the FEM reference displacements and rotations is greater than a given threshold value, is finally evaluated.

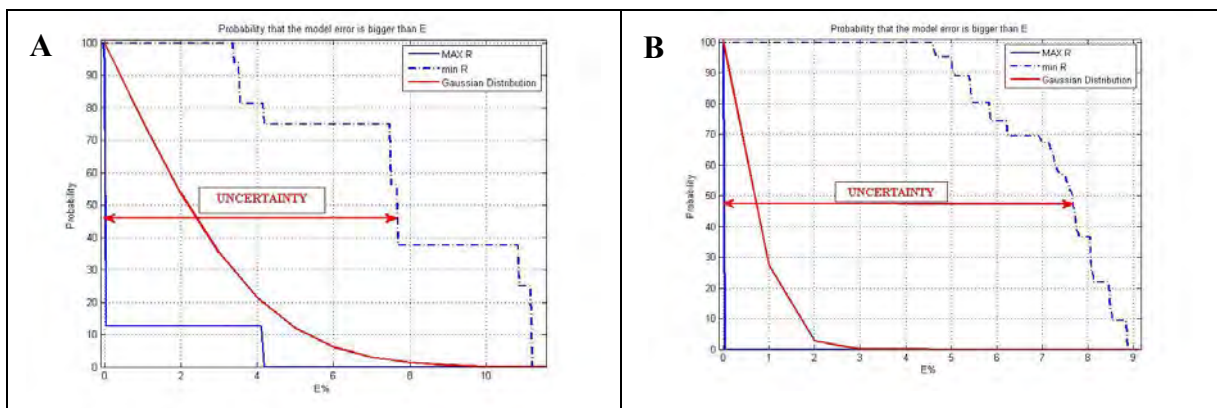

Fig 10 Shear load (F_y): Probability that the error E about U_y (A) and θ_z (B) is bigger than a given threshold value. Three curves are plotted: the first one represents the maximum model reliability (labeled with MAX R), the second one represents the minimum reliability of the model (labeled with min R), the red one represents the curve obtained using the assumption of the Gaussian distribution.

Fig 11 Torque Moment Probability that the error E about θ_x (B) is bigger than a given threshold value. Three curves are plotted: the first one represents the maximum model reliability (labeled with MAX R), the second one represents the minimum reliability of the model (labeled with min R), the red one represents the curve obtained using the assumption of the Gaussian distribution.

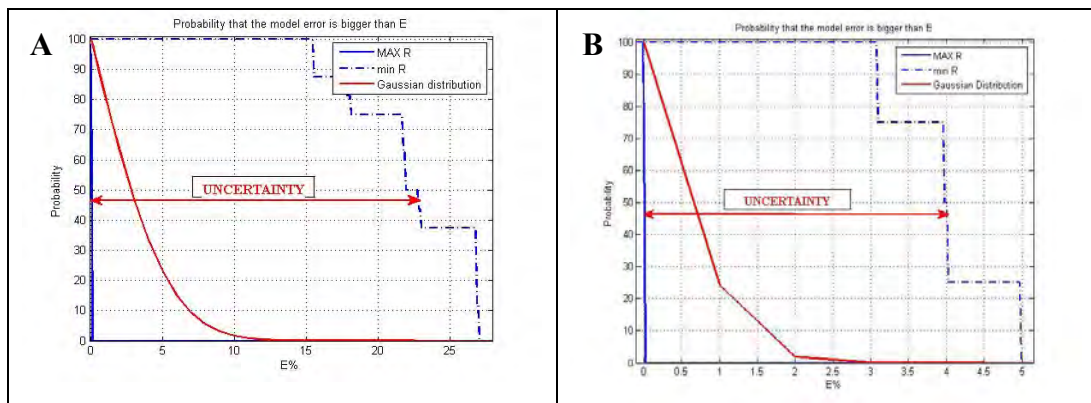

Fig 12 Bending Moment (z): Probability that the error E about U_y (A) and θ_z (B) is bigger than a given threshold value. Three curves are plotted: the first one represents the maximum model reliability (labeled with MAX R), the second one represents the minimum reliability of the model (labeled with min R), the red one represents the curve obtained using the assumption of the Gaussian distribution.

The evidence theory does not furnish a unique measure of the probability, but it gives two different probability curves: the plausibility, that describes the curve of the maximum reliability of the system and the belief, that describes the minimum reliability of the system (fig 10-12). According to what it was said in Section 2.4, the true reliability curve is included between the plausibility and the belief. Actually, the area included between the maximum reliability curve and the minimum one represents a region of uncertainty; this means that, without further information, no prediction about the actual behavior of the model can be made (we only know that the true error is included between the two probability curves). For this reason, the belief curve, that represents a conservative estimation of the model behavior, is used during the design phase. In this study we have compared the results obtained assuming that the position error is described by means of Gaussian distributions with those obtained assuming that each sensor is located inside an interval. In this last case no hypothesis has been made about the probability that a sensor is in a given point (inside the region). As shown in Fig (10-12) the maximum reliability curves give almost null prediction errors, otherwise the minimum

reliability curves indicate bigger probability to have large errors; in particular the evaluation of the y-displacement and z-rotation is quite sensible to the sensor position uncertainty Fig (10) and Fig (12). In most cases the reliability curves, based on the Gaussian distribution hypothesis, underestimate considerably the prediction errors. In particular the Gaussian hypothesis furnishes probability values close to those given by the maximum reliability curves.

4. Conclusion

In the present work a comparative study of some uncertainty propagation algorithms is performed and discussed.

Methods for both aleatory and epistemic uncertainty are considered; in particular, a brief review of Univariate Dimension Reduction method (UDR), Polynomial Chaos Expansion (PCE), and First Order Second Moments algorithm (FOSM) - for aleatory uncertainty - and of Evidence Theory – for epistemic uncertainty - is presented.

Then, selected example problems are considered to assess and compare the available methods; some test functions are used as preliminary test cases, then structural applications are studied, ranging from the mechanical behavior of a composite plate to the shape sensing of a beam starting from measured surface strains. As for the latter application, an epistemic uncertainty propagation approach (Evidence Theory) has been compared with a probabilistic uncertainty propagation algorithm (UDR); the considered problem is a classical example of epistemic uncertainty, therefore probabilistic approaches may be applied after introducing some prior assumptions whose correctness may not be guaranteed.

Although this study is limited to some particular examples, interesting general conclusions can be drawn.

If there is no significant interaction between variables, the UDR is the most efficient method for statistical moments estimation. Its accuracy decreases when the interactions cannot be neglected; in particular, the evaluation of the 3rd and 4th statistical moments is more sensitive to the interaction effects and, therefore, also the evaluation of the corresponding Probability Distribution Function (PDF), by means of the Pearson System, can be compromised. The accuracy and the computational cost of the PCE depend on the truncation order of the expansion. However, the PCE is a useful approach when the knowledge of the PDF is desired. Moreover, the UDR method leads to the best compromise between accuracy and computational cost when performing a probabilistic study of the mechanical behavior of a composite plate.

The transformation of the epistemic knowledge into a probabilistic knowledge could often cause a loss of information and consequently the underestimation of the uncertainty effects. The evidence theory, in the particular case of the shape sensing problem, seems to be the more robust and conservative approach. The use of a probabilistic approach is not wrong but it requires too strong prior assumptions. In other words, the correct use of the probabilistic approach would require the experimental probabilistic characterization of the sensors position.

Keywords: intra-event, inter-event, ground motion correlation, spatial correlation, response spectra.

Abstract. *The intensities of ground motions and structural responses at two sites are correlated. The magnitude of the correlation depends on the distance between the sites and the natural vibration period of the structures. Spatial correlation of intra-event peak ground motion amplitudes at different sites is an important issue for seismic hazard and risk assessment of spatially distributed buildings and infrastructures. Correlated seismic effects cause acute concentration and accumulation of seismic losses, potentially resulting in a catastrophic event. The adequacy of the existing spatial correlation model has been checked using the L'Aquila earthquake ground motion data. Spatial correlations based on the L'Aquila earthquake data decrease gradually with increasing inter-station separation distance. At short separation distances, the estimated spatial correlation data points show large variability around the average trend. At short separation distances such as 1 km, where empirical data are limited and estimates are uncertain, discretion is required in adopting such models for seismic hazard and risk assessment of spatially distributed structures.*

1 INTRODUCTION

Traditional probabilistic seismic hazard analysis (PSHA) is often focused on a single site, however often the seismic hazard analysis for multiple sites is of interest (e.g. for regionally located building assets (portfolio) and spatially distributed systems (lifelines)) therefore correlation of ground motion intensity measures (e.g. peak ground motion, response spectra, etc.) at different location for the same seismic event need to be evaluated. Correlated seismic effects cause acute concentration and accumulation of seismic losses, and increased correlation of ground motion parameters affects the probability distribution of seismic risk for multiple structures due to the simultaneous occurrence of structural damage and collapse. The spatial intra-event correlation can be analyzed empirically for a given area, but a dense observation of records from numerous earthquakes is necessary and it has not been extensively investigated so far. The spatial intra-event correlation of ground motion parameters such as PGA have already been investigated in previous studies by Boore et al. [1] that considered particular earthquakes in California; Wang and Takada [2] considered 5 earthquakes in Japan and the Chi-Chi earthquake in Taiwan; Goda and Atkinson [3] used the K_NET and the KiK-net records collected in Japan to study spatial correlation for peak ground acceleration and pseudo-spectra acceleration. However, not many studies can be found on the correlation of the PSA at different periods and sites using a European database. Therefore this study focuses on estimating the correlation PSAs responses developing empirical equations that are able to predict the correlation coefficient considering both spatial separation distance and natural vibration periods of SDOF systems using a European earthquake set. In the paper intra-event and inter-event spatial correlation models have been proposed and calibrated using the records from the 2009 L'Aquila earthquake in Central Italy. The inter-event correlation is function of the considered ground-motion parameters, whereas the intra-event correlation is a function of the considered ground-motion parameters and the separation distance between two sites of interest. Sensitivity of the observed spatial correlation to the uncertainty in the magnitude and distance is also investigated.

2 CLASSIFICATION OF UNCERTAINTIES

Uncertainties in an attenuation relationship model (AR) can be distinguished between epistemic and aleatory uncertainty. Epistemic uncertainty results from the limited amount of observed data, while aleatory uncertainty describes the disagreement between observations and predictive models which is due to the absence of a physical explanation or due to the parameters that are not included in the predictive equations. Furthermore, the total aleatory variability [4][5] is separated in three independent components:

1. Inter-event variability (*earthquake to earthquake*);
2. Intra-event variability (*site-to-site*);
3. Variability remaining after accounting for the inter-event and the intra-event variability;

Usually the last two components are joined in a single one.

2.1 Inter-event correlation $\eta(T)$

The inter-event correlation describes the correlation among different seismic events (*earthquake to earthquake*) at the same site. In other words, earthquake ground motions at different sites caused by the same earthquake have something in common that depends on variation of earthquake source characteristics. So the inter-event residual $\eta(T)$ is a constant across all the sites during a given earthquake.

2.2 Intra-event correlation $\varepsilon'(T)$

The intra-event correlation describes the correlation among different sites (*site-to-site*) regarding the same seismic event. In other words, the intra-event variability considers the proposition that earthquake ground motion for a given event at different sites varies to some extent because of peculiarities of propagation path and local site conditions. Therefore, Tsai et al. [6] separated intra-event variability into path-to-path and site-to-site components. The site-to-site correlation depends on the ground conditions of the sites and it will decrease for sites that do not share the same geology, however a systematic research on quantifying the dependence has not been performed so far. Both inter-event and intra-event correlations can be incorporated in probabilistic seismic hazard analysis and risk assessments, because the ratio between joint probabilities and the probabilities at individual sites can vary depending on (i) inter-event correlation or ratio of inter-event and total components of variability, and on (ii) whether or not the hazard is dominated by one source or many sources.

3 DEVELOPMENT OF CORRELATION EQUATIONS

Attenuation relationships (ARs) describe the probability distribution of spectral acceleration at an individual period. A typical empirical AR at m locations during n seismic events is typically modeled explicitly as a lognormal function as follow

$$\log_{10} S_{a,ij}(T_n) = f(M_j, R_{ij}, \lambda, T_n) + \eta_j(T_n) + \varepsilon_{ij}(T_n) \quad (1)$$

$$i = 1, 2, \dots, m; \quad j = 1, 2, \dots, n$$

where $f(M_j, R_{ij}, \lambda, T_n) = \mu_{\log_{10}(S_a(T_n))}(M_j, R_{ij}, \lambda, T_n)$ is the predicted geometric mean of the logarithm in base 10 of the spectral acceleration S_a provided by the AR for the i th site in the j th seismic event. Equation (1) stands also if instead of S_a is considered PGA or PGV, but in these cases the equation is no longer function of T_n and it is function of the earthquake magnitude M , distance R , and a set of other explanatory variables λ such as local site conditions and faulting mechanism; $\eta_j(T_n)$ is the inter-event variability with zero mean and standard deviation $\sigma_{\eta}(T_n)$; $\varepsilon_{ij}(T_n)$ is the intra-event variability with zero mean and standard deviation $\sigma_{\varepsilon}(T_n)$. Usually the standard deviation of $\varepsilon_{ij}(T_n)$ is significantly larger than the standard deviation of $\eta_j(T_n)$, so $\varepsilon_{ij}(T_n)$ is the dominant contributor to the total $\varepsilon_T(T_n) = \eta_j(T_n) + \varepsilon_{ij}(T_n)$ that is computed for each record of the dataset at a range of periods using a given AR as follow

$$\varepsilon_T(T_n) = \frac{\log_{10}(S_a(T_n)) - \mu_{\log_{10}(S_a(T_n))}(M, R, T_n)}{\sigma_{\log_{10}(S_a(T_n))}(M, T_n)} \quad (2)$$

where $\log_{10}(S_a(T_n))$ is the logarithm in base 10 of the observed spectral acceleration value, while $\mu_{\log_{10}(S_a(T_n))}$ and $\sigma_{\log_{10}(S_a(T_n))}$ are evaluated from the AR. The uncertainty $\varepsilon_T(T_n)$ comprises the inter-event $\eta(T_n)$ and the intra-event $\varepsilon_{ij}(T_n)$ uncertainty. The inter-event residual $\eta(T_n)$ is a constant across all the sites during a given earthquake. Therefore, when using records from a single earthquake, estimation of the intra-event (*site-to-site*) correlation

$\rho_\varepsilon(\Delta, T_n)$ does not require the knowledge of the inter-event residual for the earthquake. However, when the used database contains records from several earthquakes, using the same procedure the total correlation coefficient $\rho_T(\Delta, T_{n1}, T_{n2})$ between $\eta_j(T_{n1}) + \varepsilon_{ij}(T_{n1})$ and $\eta_j(T_{n2}) + \varepsilon_{kj}(T_{n2})$ for a randomly selected seismic event at two recording stations separated by the distance (km) is given by the approximated expression [7][8]

$$\rho_T(\Delta, T_{n1}, T_{n2}) = \frac{\rho_\eta(T_{n1}, T_{n2}) [\sigma_\eta(T_{n1})\sigma_\eta(T_{n2}) + \rho_\varepsilon(\Delta, T_{MAX})\sigma_\varepsilon(T_{n1})\sigma_\varepsilon(T_{n2})]}{\sigma_T(T_{n1})\sigma_T(T_{n2})} \quad (3)$$

where $\rho_\eta(T_{n1}, T_{n2})$ represents the correlation between $\eta_j(T_{n1})$ and $\eta_j(T_{n2})$; $\rho_\varepsilon(\Delta, T_{MAX})$ is the intra-event spatial correlation focusing on a single vibration period T_n , and T_{MAX} is the larger between T_{n1} and T_{n2} ; $\sigma_\eta(T_n)$ is the standard deviation of the inter-event residuals $\eta_j(T_n)$; $\sigma_\varepsilon(T_n)$ is the standard deviation of the intra-event residuals $\varepsilon_{ij}(T_n)$ and $\sigma_T(T_n)$ is the standard deviation of the total residuals given in equation (2). The total correlation $\rho_T(\Delta, T_{n1}, T_{n2})$ and the intra-event correlation $\rho_\varepsilon(\Delta, T_n)$ are related through Equation (3), while the inter-event component can be removed from the residuals of earthquake j using the estimation of $\hat{\eta}_j$ [9]

$$\hat{\eta}_j = \frac{\sigma_\eta^2 \sum_{i=1}^{n_j} [\log_{10}(S_{a,i,j}(T_n)) - \mu_{\log_{10}(S_a(T_n)),i,j}(M, R, T_n)]}{n_j \sigma_\eta^2 + \sigma_\varepsilon^2} \quad (4)$$

3.1 Evaluation of inter-event spatial correlation

The inter-event correlation is evaluated by using the regression residuals $\eta(T_n)$ based on the selected ground motion data. For a given pair of two natural vibration periods T_{n1} and T_{n2} , $\rho_\eta(T_{n1}, T_{n2})$ is evaluated using the Pearson's linear correlation coefficient. In details, the observed values of $\rho_\eta(T_{n1}, T_{n2})$ are determined using the following step-by-step procedure:

1. Select the sites for a given earthquake;
2. Given the $S_a(T_n)$ values at several sites for one earthquake, and given the predicted value at each site using the AR, the residuals values can be determined;
3. The inter-event residual $\eta(T_n)$ is the mean of the residual values and it is associated to a given earthquake, so it will not change from site to site;
4. The inter-event residual $\eta(T_n)$ for different earthquakes is evaluated using step 2 and 3, so if n earthquakes are provided n inter-event residuals $\eta(T_n)$ are determined;
5. Repeating step 1, 2 and 3 for m vibration periods until a $m \times n$ matrix is determined that can be used to determine the inter-event correlation coefficient $\rho_\eta(T_{n1}, T_{n2})$ as shown in the example below.

3.2 Evaluation of intra-event spatial correlation

The intra-event correlation is evaluated by using the regression residuals $\varepsilon_{ij}(T_n)$ based on the selected ground motion data. The observed intra-event spatial correlation at a single vibration period $\rho_\varepsilon(\Delta, T_n)$ (i.e., $\rho_\varepsilon(\Delta, T_{n1}, T_{n2})$ with $T_{n1}=T_{n2}$), can be determined using the following step-by-step procedure:

1. Select the sites for a given earthquake;
2. Compute the separation distance Δ for all pairs of sites (or stations);
3. Compute the differences ε using equation (2);
4. Divide the range of Δ into bins so that the separation distance in the same bin is $\Delta \pm \delta/2$;
5. All pairs of sites that fall in the bin centered at Δ are used to compute the correlation function $\rho_\varepsilon(\Delta, T_n)$ that will be function of the period and the sites distance Δ ;

In detail, the observed intra-event correlation $\rho_\varepsilon(\Delta, T_n)$ at a given vibration period is carried out by analyzing regression residuals from the AR using the following equation

$$\rho_\varepsilon(\Delta, T_n) = 1 - \frac{[\sigma_d(\Delta, T_n)]^2}{2[\sigma_\varepsilon(T_n)]^2} \quad (5)$$

where $\sigma_d(\Delta, T_n)$ represents the variance of the difference $\varepsilon_{ij}(T_n) - \varepsilon_{kj}(T_n)$ calculated at discrete intervals Δ ; $\sigma_\varepsilon(T_n)$ represents the variance of the difference $\varepsilon_{ij}(T_n) - \varepsilon_{kj}(T_n)$ calculated over the entire sample. The observed values of $\rho_\varepsilon(\Delta, T_n)$ given by equation (5) can be compared with the predicted values of the proposed model given by the following equation

$$\rho_\varepsilon(\Delta, T_n) = e^{-\alpha(T_n)\Delta} \quad (6)$$

where $\alpha(T_n)$ is the parameter that needs to be calibrated according to the earthquake data used.

Figure 1: (Moment magnitude-focal depth) distributions of L'Aquila aftershocks.

4 L'AQUILA EARTHQUAKE DATA

All the ground motions used for the calibration of the predictive correlation models in the paper are extracted from the ITACA Database [10], <http://itaca.mi.ingv.it/ItacaNet/> (last accessed January 31, 2011). The goal of the work is to investigate the intra-event and inter-event spatial correlation; therefore it is better to focus on well-recorded events that produced numerous observations at different locations such as L'Aquila 2009 earthquake. The selected ground motion set includes L'Aquila main shock and the following 12 main aftershocks and the main seismic characteristics are summarized in Table 1. All events are shallow events with a focal depth between 7 and 18 km and a moment magnitude between 4 and 6.3 as shown in Figure 1. The fault mechanism of all events is normal type. The geographical location of the aftershocks is shown in Figure 2b, while the spatial distribution of the INGV network station is shown in Figure 2a. Totally 4725 records from the 13 earthquakes have been considered for the analysis. The use of this set of record is to assess whether the observed differences in the decaying rate of the spatial correlation of the PGAs persist also for the spatial correlation of the PSAs and to calibrate the predictive correlation models for the region.

	Event (Date - Time)	Event Name	Latitude	Longitude	M_L	M_W	Depth (km)

5 NUMERICAL RESULTS

To investigate the variation of the empirical spatial correlation based on the residuals, statistical analysis is conducted individually for a selected major earthquake (L'Aquila Earthquake, 2009) that have a large number of records. The investigation on a single earthquake it is useful because it can provide valuable insights on the variability of spatial correlation among different sites and the dependence of spatial correlation on the vibration period for a given earthquake. To investigate the spatial correlation and carry out sensitivity analysis, a complete set of PSA responses are calculated, and the regression analysis is carried out for PSA for values of T_n ranging from 0.01 to 2 sec. The ε values were computed for each record of the dataset at a range of periods using Ambraseys AR [11]. For each record and period of the dataset, ε values were computed using Equation(2). An analysis of correlations of epsilon values has been carried out using the earthquake records in Table 1 following the procedure described above. In Figure 3 are shown the observed intra-event correlation coefficient $\rho_\varepsilon(\Delta, T_n)$ evaluated using equation (5), when considering only L'Aquila earthquake main shock.

Figure 3: (a) Intra-event spatial correlation for PSA at 0.2, 0.5, 1.0 and 2 sec based on Equation (5); (b) Intra-event spatial correlation for PSA at 0.2 sec and different size bins at 5, 10, 15 and 30 km.

It can be observed that there is more correlation at high frequencies ($T_n=0.2s$), while at low frequencies and for separation distances more than 20 km, there is almost no correlation (Figure 3a). When considering the PSA at $T_n=0.2s$ the correlation values are stable for bin size resolutions between 10 and 30 km (Figure 3b).

When considering all earthquake set in Table 1, there is no correlation at low frequencies for distances Δ higher than 20km (Figure 4a). The correlation remains stable for values of bin size between 10 and 15 km, while it is not reliable for bin sizes higher than 30 km at high frequencies (Figure 4b).

An analysis of intra-event correlations of epsilon values at different periods has been carried out using 4725 records from the 13 earthquakes of L'Aquila region. For a given pair of two natural vibration periods T_{n1} and T_{n2} , the observed correlation coefficient $\rho_\varepsilon(\Delta, T_{n1}, T_{n2})$ between $\varepsilon_{ij}(T_{n1})$ and $\varepsilon_{ij}(T_{n2})$ is evaluated using equation (5).

Figure 4: Intra-event spatial correlation for L'Aquila earthquake (a) for different PSAs at different periods; (b) for PSA at 0.2 sec and different size bins.

In Figure 5 are shown the observed intra-event spatial correlation $\rho_e(\Delta, T_{n1}, T_{n2})$ for different periods and for bins separation distance of 0-20, 20-40, 40-60 and 60-80 km when all events are included. The shape of the intra-event spatial correlation is not affected significantly by the bin size resolution when all events in Table 1 are considered, while when only L'Aquila earthquake main shock is considered (Figure 6) the observed intra-event spatial correlation is affected by the bin size resolution.

Δ	A0	A1	A2	R^2
0 - 15 km	-0.0859	0.7095	1.0683	0.8613
15 - 30 km	0.8184	0.0912	0.1639	0.7443
30 - 60 km	0.6946	0.2014	0.3008	0.8738
60 - 100 km	0.6137	0.2169	0.3842	0.8823

5.1 Proposed predictive intra-event correlation equations for $\rho_e(\Delta, T_{n1}, T_{n2})$

A correlation model of $\rho_e(\Delta, T_{n1}, T_{n2})$ is proposed and validated by comparison with the observed values of $\rho_e(\Delta, T_{n1}, T_{n2})$ obtained by Equation (5). Several linear and nonlinear equations were fitted to the observed data of the intra-event correlation coefficients and results were sorted using the r^2 value as goodness of fit measure. Finally, the predictive equation was selected based on the number of parameters adopted, the simplicity and the goodness of fit. The proposed predictive intra-event correlation coefficient model between the residual values of a single horizontal component at two differing periods for L'Aquila main event is given by

$$\rho_e(\Delta, T_{n1}, T_{n2}) = A0 + A1 \cdot e^{-T_{\min}} + A2 \cdot e^{-T_{\max}} \quad (7)$$

where $T_{\min} = \min(T_1, T_2)$ and $T_{\max} = \max(T_1, T_2)$. The parameters of the model in Equation (7) for different distance range Δ are listed in Table 2, while results of the model for different

range distances are shown in Figure 7. The r^2 value that describes the goodness of fit oscillates between 0.7443 and 0.8823 (Figure 7). The uncertainties are probably due to the fact that only the main shock is used and therefore results are sensitive to the separation distance and it is difficult to find a simple predictive model that can be adopted for different distance ranges.

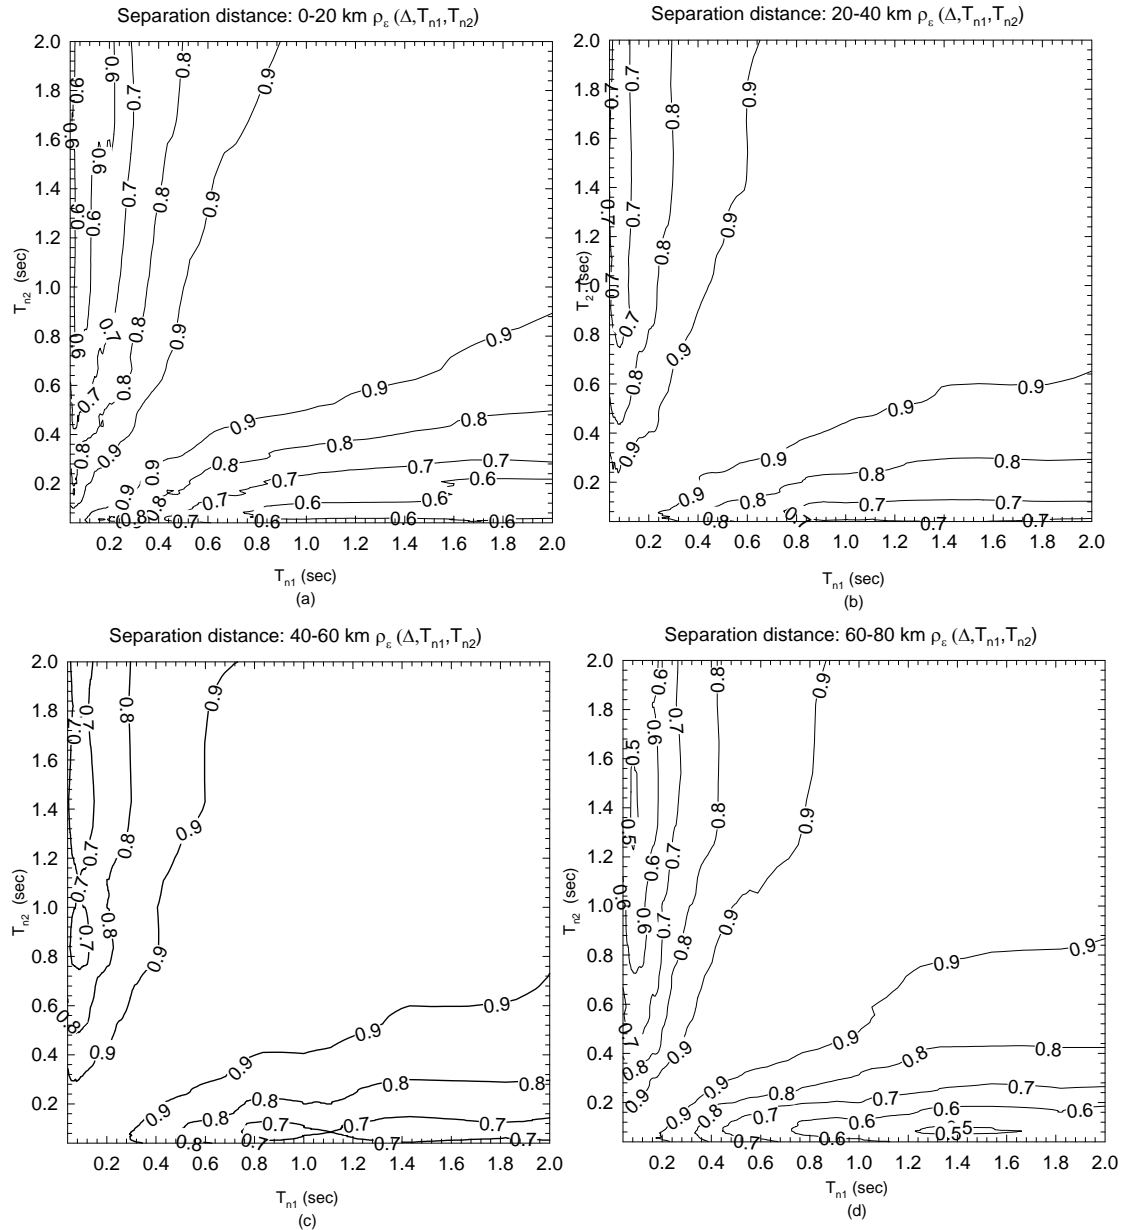

Figure 5: Observed intra-event spatial correlation $\rho_e(\Delta, T_{n1}, T_{n2})$ for separation distance bins of 0-20, 20-40, 40-60 and 60-80 km for all events.

Another analytical predictive equation has been proposed by the author when all earthquakes in Table 1 area are considered.

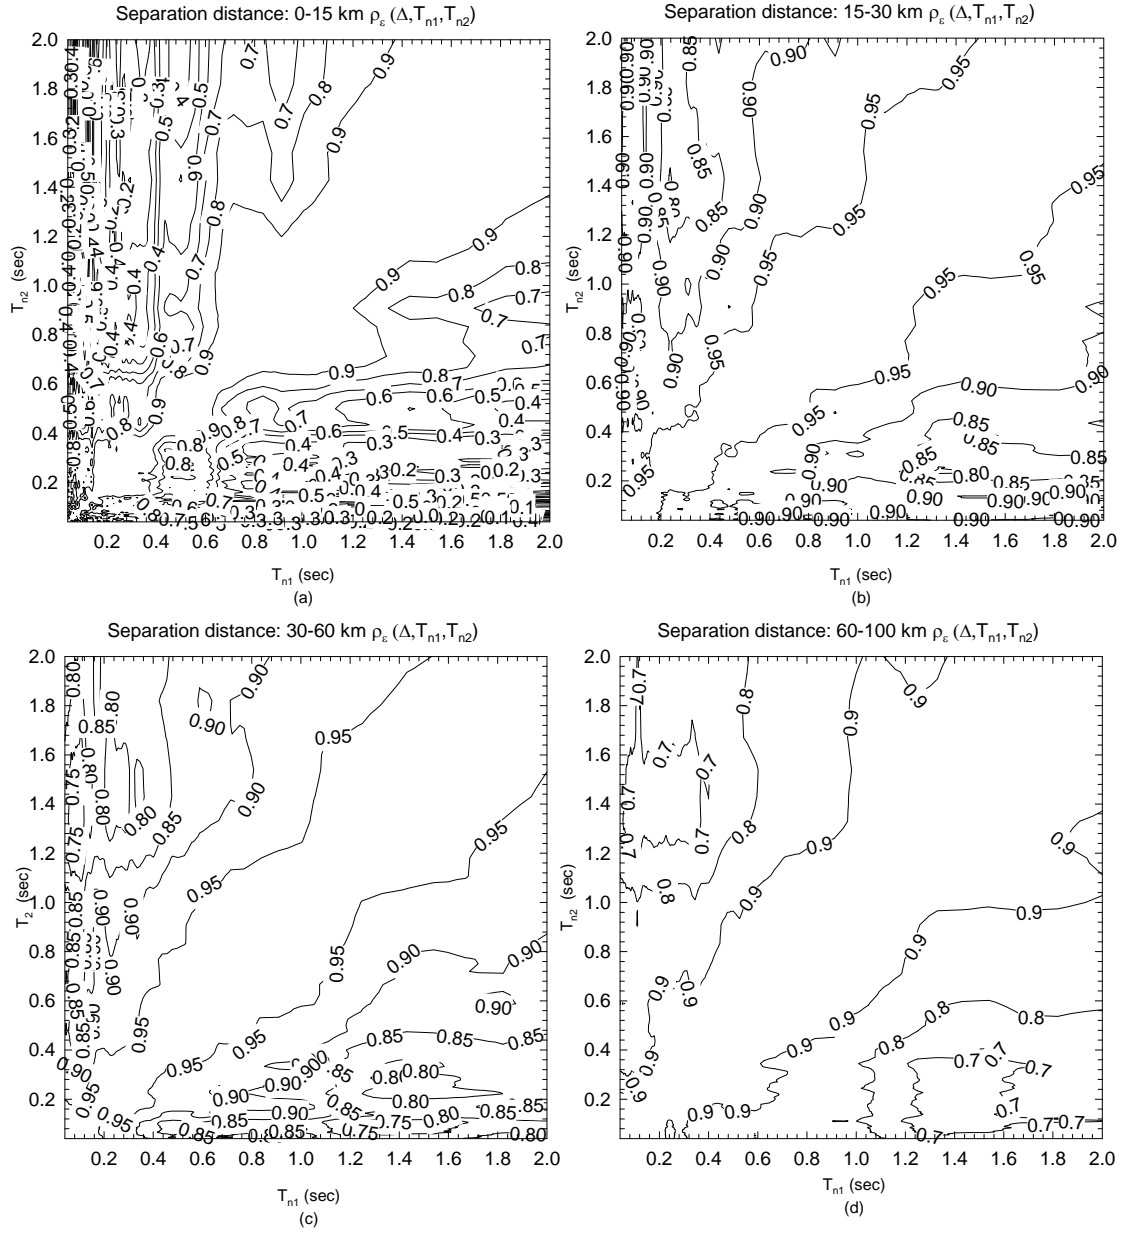

Figure 6: Observed intra-event spatial correlation $\rho_e(\Delta, T_{n1}, T_{n2})$ for separation distance bins of 0-15, 15-30, 30-60 and 60-100 km for L'Aquila main shock event.

The predictive intra-event correlation coefficient model is given by

$$\rho_e(\Delta, T_{n1}, T_{n2}) = \left(A0 + A1 \cdot e^{-T_{\min}} + A2 \cdot e^{-T_{\max}} \right)^{-1} \quad (8)$$

where the parameters of the model in Equation (8) for different distance range Δ are listed in Table 3, while the predicted values are shown in Figure 8 for different distance ranges. The r^2 value that describes the goodness of fit oscillates between 0.9289 and 0.9496 (Figure 8), showing the robustness of the model for different distance ranges.

Δ	A0	A1	A2	R^2
----------	----	----	----	-------

0 - 20 km	0.7941	1.2669	-0.9924	0.9289
20 - 40 km	0.9180	0.7203	-0.6322	0.9496
40 - 60 km	0.9014	0.7684	-0.6587	0.9420
60 - 80 km	0.8480	1.2394	-1.0756	0.8823

Table 3: Parameters of the correlation coefficient model for equation (8).

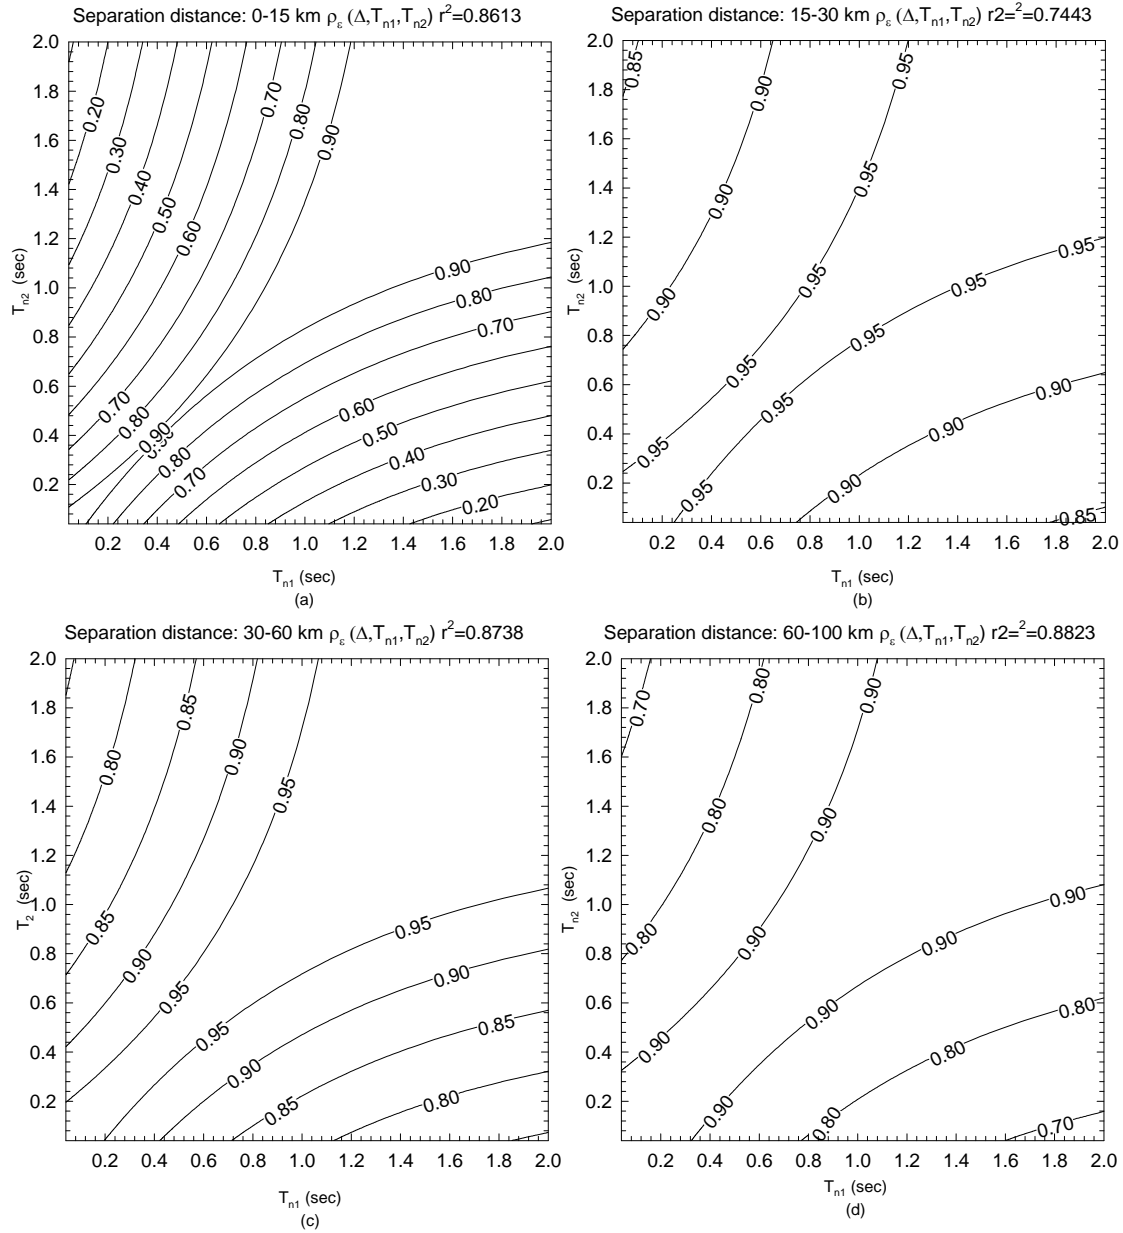

Figure 7: Intra-event spatial correlation model $p_e(\Delta, T_{n1}, T_{n2})$ for separation distance bins of 0-15, 15-30, 30-60 and 60-100 km for L'Aquila main shock event.

5.2 Proposed predictive inter-event correlation equations for $\rho_\eta(T_{n1}, T_{n2})$

The inter-event correlation of pseudo spectra acceleration is evaluated by using regression residuals $\eta(T_n)$, based on the records from the earthquakes in Table 1 using the procedure de-

scribed above. For a given pair of two natural vibration periods T_{n1} and T_{n2} , $\rho_\eta(T_{n1}, T_{n2})$ is evaluated by using the Pearson's linear correlation coefficient. The observed values of $\rho_\eta(T_{n1}, T_{n2})$ are shown in Figure 9a showing that the inter-event correlation decreases monotonically as the inter period separation distance increases. The correlation has been evaluated using the stations that were recording the seismic series of 2009 L'Aquila earthquake. To characterize $\rho_\eta(T_{n1}, T_{n2})$ the following predictive model is proposed

$$\rho_\eta(T_{n1}, T_{n2}) = e^{(A0 + A1/T_{\min} + A2/T_{\min}^{1.5} + A3/T_{\max} + A4/T_{\max}^2)} \quad (9)$$

where the parameters of the model are respectively, $A0=-0.0045$; $A1=-0.02256$; $A2=0.0036$; $A3=0.0165$ and $A4=-0.0005$.

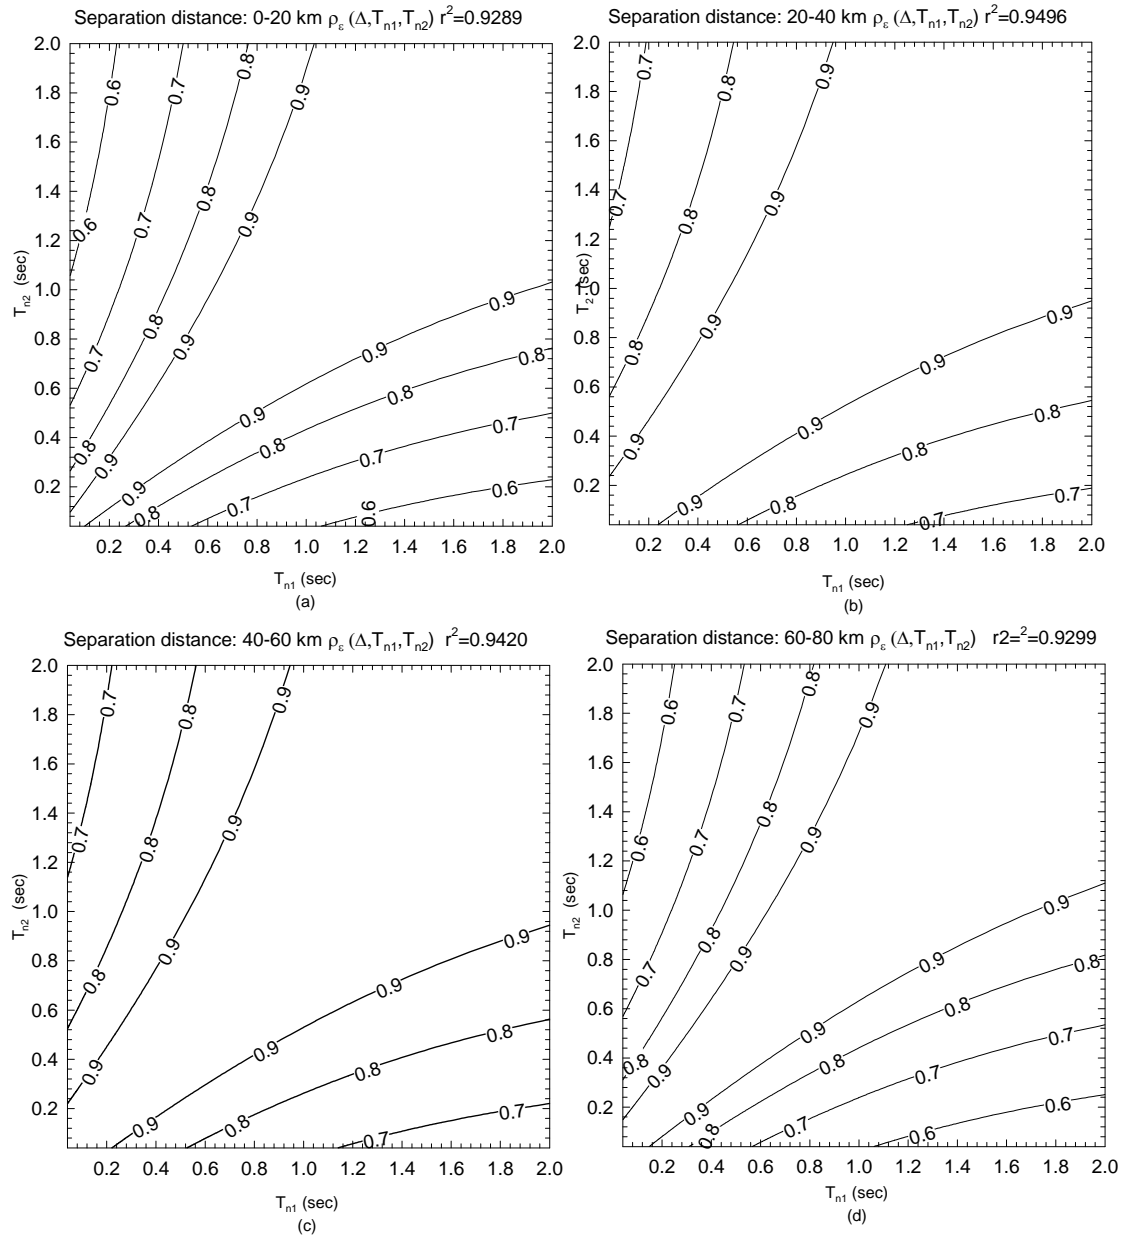

Figure 8: Intra-event spatial correlation model $\rho_{\varepsilon}(\Delta, T_{n1}, T_{n2})$ for separation distance bins of 0-20, 20-40, 40-60 and 60-80 km for all events.

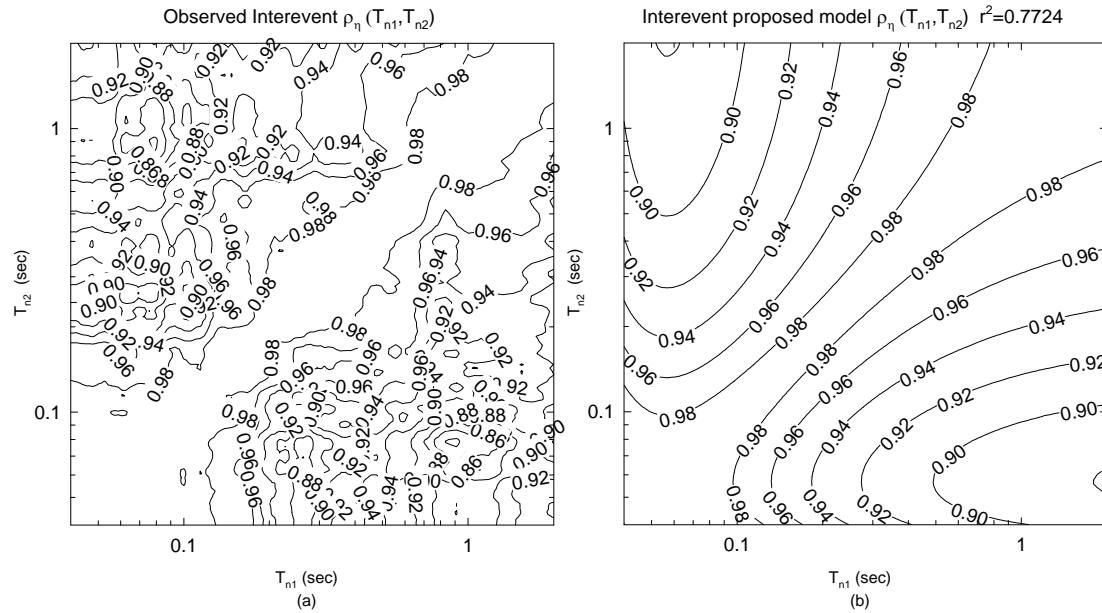

Figure 9: Inter-event correlation model $\rho_{\eta}(T_{n1}, T_{n2})$.

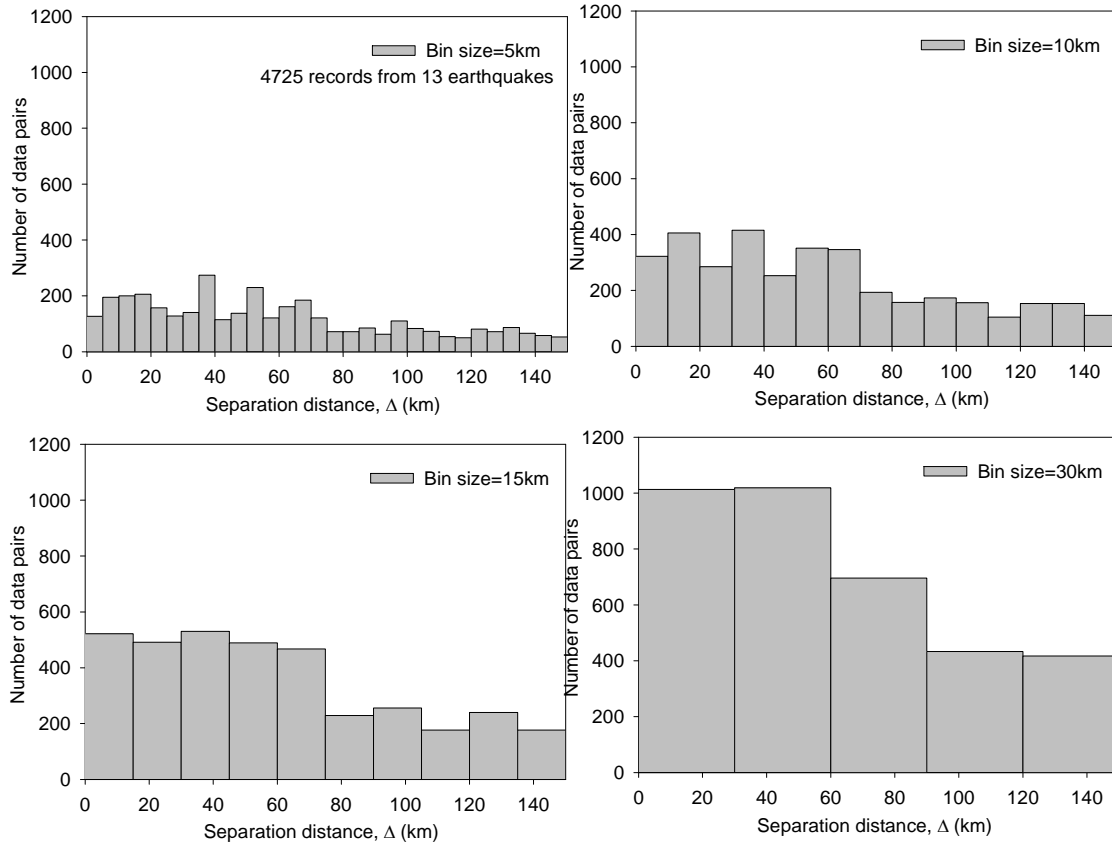

Figure 10: Histogram of the number of strong ground motion data pairs by different size bins.

The predictive values of $\rho_{\eta}(T_{n1}, T_{n2})$ based on equation (9) are shown in Figure 9b. The comparison of the observed and predictive values shows a good fit ($r^2=0.77$) by capturing the observed values of $\rho_{\eta}(T_{n1}, T_{n2})$ for shallow earthquakes and for the central region of Italy however it is important to mention that results may not be stable due to the limited number of available samples.

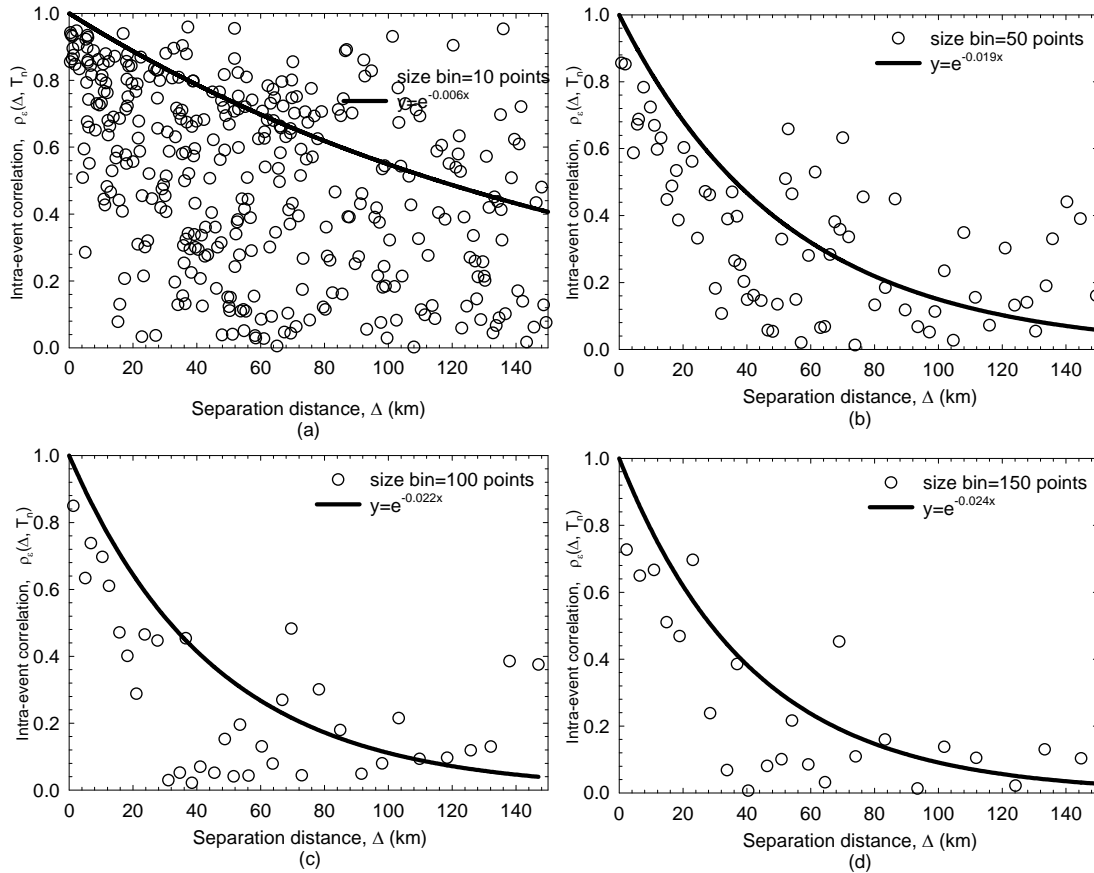

Figure 11: Overall intra-event spatial correlation for PSA at 0.2 sec using all shallow events (13 L'Aquila aftershocks) for different size bins.

5.3 Sensitivity to the size bin resolution

One of the goals of this research is to investigate the intra-event spatial correlation of L'Aquila earthquake ground motions with short separation distances; therefore it is of particular interest to inspect how many data pairs can be selected from the records using different bin size resolutions as shown in the histogram in Figure 10. In order to achieve a good estimate of the correlation coefficient at the short separation distances it is necessary at least 300 data pairs that can be obtained using a bin size resolution of 10 km. At large separation distances above 80 km the number of data pairs from the selected records reduce to half with respect to the short separation distances, regardless the bin size resolution. This brings to the conclusion that the estimation of the correlation coefficient at large separation distances is less accurate with respect to the short separation distances especially when the bin size resolution reduces

to 5 km as shown in Figure 10a. This observation should be taken in account when considering results in the figures shown in the paper.

Figure 12: Comparison of fitted curves for intra-event spatial correlation at PSA of 0.2 sec and different size bins.

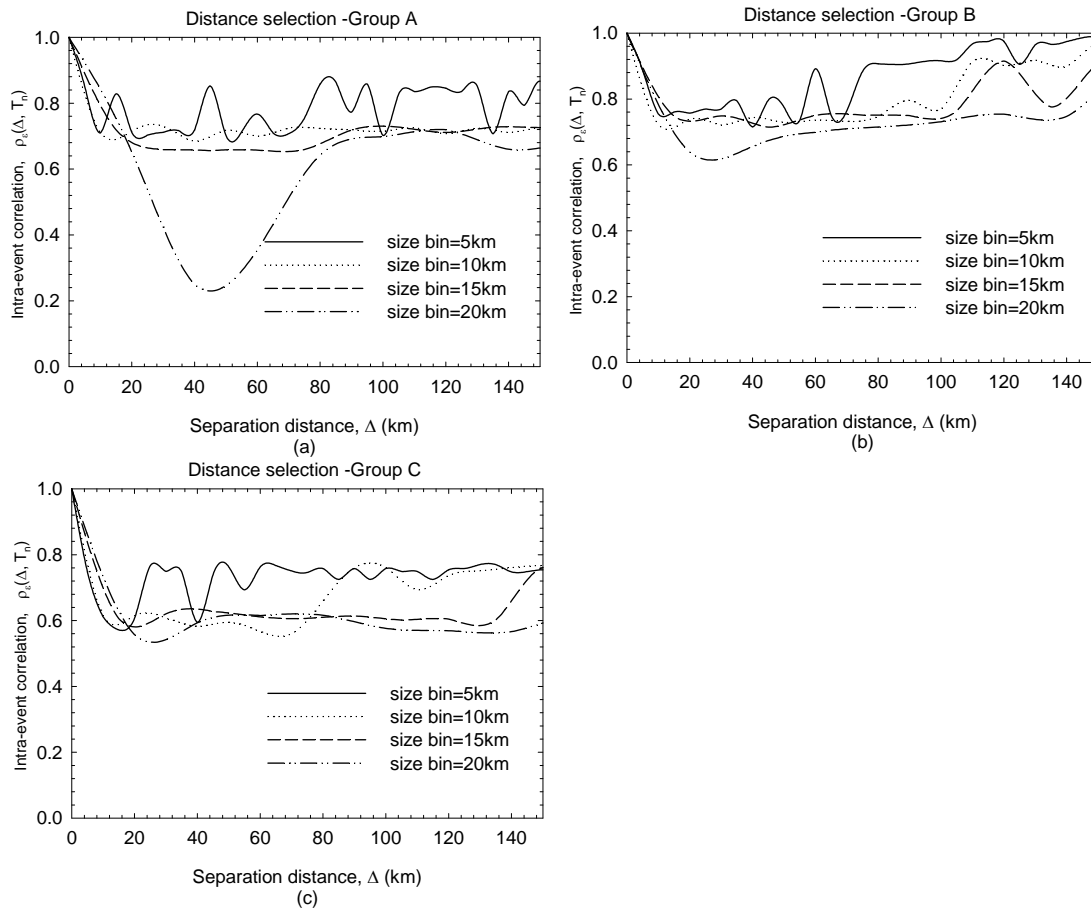

Figure 13: Intra-event spatial correlation for different size bins and PSA of 0.2 sec divided by distance selection.

Observing Figure 11 and Figure 12 it is shown that the intra-event spatial correlations based on the L'Aquila earthquakes aftershocks decrease gradually with increasing inter-station separation distance when the vibration period is 0.2 sec.

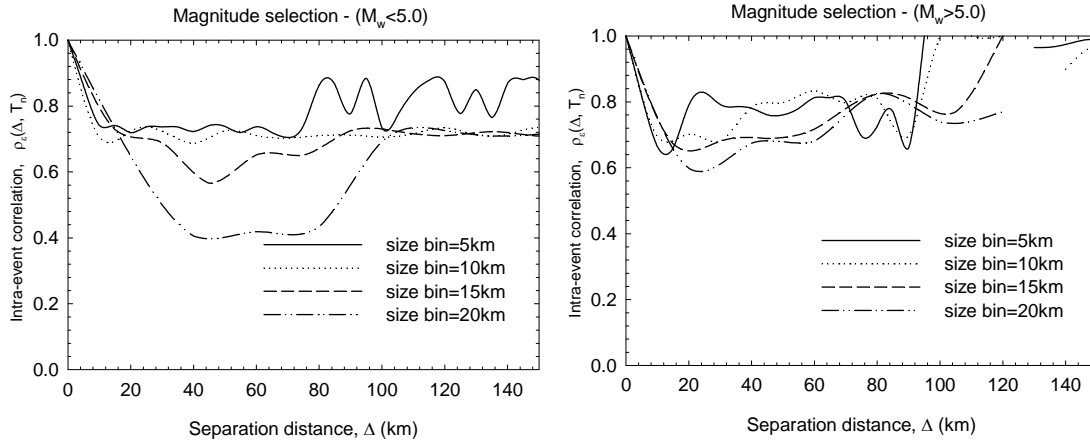

Figure 14: Intra-event spatial correlation for different size bins and PSA of 0.2 sec divided by magnitude selection.

With low resolution of the bin size (Figure 11a) the spatial correlation data points show large variability, so results due to the smaller number of available samples are not stable, therefore the parameters of the model in equation (6) given in Table 4 are uncertain, and discretion is required in adopting such models for seismic hazard and risk assessment of spatially distributed structures.

points	10	50	100	150
$\alpha(T_n=0.2s)$	0.006	0.019	0.022	0.024

Table 4: Parameters of the model for equation (6).

By increasing the bin size resolution to at least 50 points (corresponding to a bin size of about 10 km) the estimation of the parameters of the model in equation (6) is more stable, because a larger database is used and the decaying rate of the intra-event spatial correlation is more reliable as shown in Figure 12. In summary, the results reported by these research efforts reveal different rates of decay of correlation with separation distance that may be caused by regional peculiarities [3], because the site-to-site correlation depends on ground conditions of the sites and it will decrease for sites that do not share the same geology. It is also noted that the decay rate of the spatial correlation of the PSA responses depends on the natural vibration period and it is more gradual for longer natural vibration periods.

5.4 Sensitivity of observed intra-event spatial correlation to magnitude and distance

By grouping the earthquake sets according to the scheme in Figure 2b using the epicentral distance, it seems that the intra-event spatial correlation does not change with the distance when the size of the bin resolution is between 10 and 20 km as shown in Figure 13. This behavior is clear and it explained by the fact that the intra-event spatial correlation depends on the soil type and geological setting. This trend is not followed by the group A when the reso-

lution of the bin size is 20 km that is probably too large, generating numerical errors. In Figure 14 is shown the intra-event spatial correlation coefficient is not affected by the magnitude selection. For large intensity earthquakes (with Magnitude $M > 5.0$) the correlation increases for distances more than 100km, however, as shown before in Figure 10, the estimation of the observed intra-event correlation coefficient at large separation distances is not reliable.

6 CONCLUDING REMARKS

The paper, based on the statistical analysis of the L'Aquila earthquake records in Italy, proposes empirical intra-event and inter-event spatial correlation relations to predict the spatial correlation of the PSA responses to be used for shallow earthquakes in Central Italy.

Results of this paper show that the ground motion correlation structure is highly dependent on local geology and on peculiarities of the propagation path, however the spatial correlation coefficient decreases as the separation distance increases. The analysis results also indicate that the intra-event spatial correlation is not affected by the magnitude. A single generalized spatial correlation model may not be adequate for all European territory or similar larger areas, but it can provide a first preliminary estimation of the correlation. The characteristics are very important for assessment of seismic hazard analysis and spatially distributed systems (lifelines) and Shake Map generation. Due to the limited amount of observed data, the proposed models are affected by epistemic uncertainties. Applicability of the model to other regions remains to be tested. As future earthquakes at closely-spaced locations are recorded, these aspects of intra-event spatial correlation should be further investigated.

Keywords: Structural Dynamics, Meta-modeling, Uncertainty Analysis, Mode Veering, Characteristic Polynomial

Abstract. *The variability and uncertainty of structural parameters have a large impact on the modal properties and need to be considered for an adequate assessment of the dynamic response. Recently, so-called modal meta-models were used to approximate the natural frequencies of structures modeled with finite elements when structural modifications are present. The present paper proposes a viable meta-modeling approach which, based on the approximation of the coefficients of the characteristic polynomial, succeeds in accurately predicting the natural frequencies of the system in presence of veering assuming stiffness variability. The meta-model is based on $m^p + p$ finite element analyses, where m denotes the number of analyzed modes and p the number of parameters. The number of required analyses is independent of the model or of the complexity of the evolution of the modal parameters. Furthermore, the obtained modal meta-model is used in combination with a procedure for efficient detection of veering and crossing phenomena without resorting to time-consuming mode tracking procedures.*

1 INTRODUCTION

The evolution of the modal parameters (e.g., eigenfrequencies) as a function of changing structural parameters provides important information required for the response assessment of a structure. In many cases, the studied modal parameters show fairly smooth evolutions which suggest the utilization of direct approximations of these modal quantities as functions of the varying structural parameters, requiring only few finite element analyses. This fact proves to be especially advantageous in the case of optimization or uncertainty analysis, where many analyses with different parameter combinations need to be carried out. The utilization of approximations based on the results of several finite element runs, which are carried out according to a planned design, provides a means for reducing the computational costs. The dependence on a large number of full finite element simulations can thus be eliminated by employing fast surrogate or meta-models [1]. Relatively simple approximations based on linear regression, polynomial interpolation, kriging, radial basis functions, etc. are generally used for meta-modeling. In structural dynamics, so-called modal meta-models are introduced and refer to the case when these techniques are used to approximate modal quantities, i.e., eigenfrequencies, eigenvectors, mode shapes, modal mass, etc. Examples are the approximation of the modal parameters of a structure using linear regression with polynomial functions [2], the approximation of the eigenvalues of civil structures using polynomial functions [3] or the kriging approximation of the modal mass and stiffness as utilized in [4]. In recent investigations concerning reliability and uncertainty analysis, the linear combination of the modal parameters of a reference system is used to represent the varying modal parameters [5].

Despite the versatility and simplicity to use direct modal meta-modeling - direct refers to *direct approximation* of the response quantities of interest - recent investigations [2] have pointed out its limitations which arise when the dynamic behavior of undamped structures exhibits mode degeneration. In the presence of degenerate phenomena such as mode crossing, mode veering [6] or mode coalescence [7], the evolution of the modal parameters generally strongly varies from a smooth evolution. Consequently, the direct approximation of the modal properties gets more involved under these conditions, because only a considerably increasing number of design points can improve the quality of the approximation.

The issue of inaccurate or erroneous approximations arising from the utilization of direct meta-modeling was discussed in [8] and indirect modal meta-modeling is proposed. The idea of the indirect approach is that quantities involved in the structural eigenvalue problem are approximated before proceeding with the solution of the eigenvalue problem (see Fig. 1). As an example, in the simplest case the structural matrices (i.e., the mass and stiffness matrices) can be approximated; such approaches based on the interpolation of the structural matrices evaluated at some supporting points are used for the eigenfrequency and eigenvector approximation and are introduced in, e.g. [8, 9].

When the evolution of the eigenfrequencies is of interest, the approximation of the coefficients of a reduced characteristic polynomial can be used to analyze the influence of structural parameter changes to the eigenfrequencies. Such an approach was first introduced in [10] and a clear theoretical description of the approach in the presence of stiffness variations was presented in [11]. The proposed procedure yields very accurate predictions of the natural frequencies. It can be shown that the coefficients of the reduced characteristic polynomial demonstrate smooth behavior when linear changes are introduced for the elements of the *stiffness matrix*. Independent of the model and the complexity of the modal behavior, the procedure always requires $m^p + p$ finite element runs, where m and p are the number of analyzed modes and input pa-

rameters, respectively. Differently from a direct modal meta-modeling approach, in the indirect

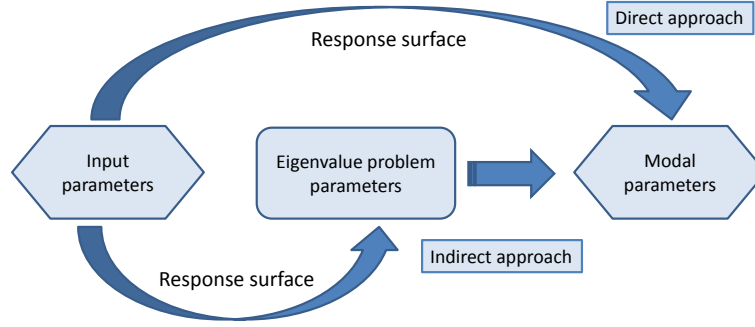

Figure 1: Modal meta-modeling: direct and indirect approaches.

approach based on the approximation of the chareacteristic polynomial, no mode tracking procedure is required to account for mode switching. This means that the method does not provide any information about the physical evolution of the modes. To obtain nonetheless a continuous (physical) evolution of the eigenfrequencies a step-wise procedure is applied. The procedure uses the fast predictions of the modal meta-model to identify and quantify crossing or veering phenomena. A major advantage of this approach is that the presence of the veering regions can be determined. This further allows the design of a system which is not prone to unexpected dynamic behavior associated with mode degeneration.

In this paper, first the procedure as described in more detail in [11] is presented in Section 2 and is then combined with an algorithm for eigenfrequency loci reconstruction. This step-wise procedure (Section 3, see also [10]) allows us to detect mode degeneration within the analyzed parameter space. Finally, the effectiveness of the proposed approach is demonstrated in Section 4 for a system affected by crossing and veering.

2 THE q -METHOD

The q -method is a meta-modeling strategy for eigenfrequency approximation of the a structure subjected to stiffness variability. The procedure consists of directly approximating the coefficients of the system's characteristic polynomial. In the following it is shown that $m^p + p$ finite element runs provide a sufficient base for achieving a correct description of the characteristic polynomial coefficients and consequently of the eigenfrequencies evoltion, with m the number of analyzed modes and p input parameters. Moreover, a viable approach for the approximation of the coefficients is proposed.

The eigenvalue problem for a system at its nominal configuration can be written as

$$(\mathbf{K}_0 - \lambda_0 \mathbf{M}_0) \phi_0 = 0, \quad (1)$$

with \mathbf{K}_0 , \mathbf{M}_0 , λ_0 and ϕ_0 denoting the stiffness matrix, mass matrix, eigenvalue and eigenvector of the nominal system, respectively. A possible approximation of the modal parameters at a perturbed system configuration is obtained by applying modal reduction [12]. Modal reduction implies the definition of a eigenvector modal basis Φ_0 that allows one to approximate the perturbed eigenvector ϕ^* as a linear combination of the assumed modal basis

$$\phi^* = \Phi_0 \alpha. \quad (2)$$

Under this assumption and for constant mass matrix, it is possible to write a reduced eigenvalue problem of the perturbed system as

$$(\Phi_0^T \mathbf{K} \Phi_0 - \lambda^* \Phi_0^T \mathbf{M}_0 \Phi_0) \alpha = 0, \quad (3)$$

with \mathbf{K} and λ^* representing the stiffness matrix and the approximated eigenvalue of the perturbed system. The reduced eigenvalue problem yields very accurate modal parameters approximation as long as the analyzed eigenvectors of the perturbed system remains within the same eigenvector subspace spanned by the truncated set of nominal modes Φ_0 . This is the case for mode veering where the eigenvectors, even though undergoing large variations within the veering region, stay and rigidly rotate within the same eigenvector subspace. Therefore, modal reduction is effective in the presence of mode veering provided that the assumed modal basis includes all pairs of eigenvectors involved in the veering phenomenon. Under this condition and using a truncated modal basis of m eigenvectors, the m modes of the system with perturbed stiffness will be studied in the following. Mass-normalizing the eigenvectors of Φ_0 Eq. (3) becomes

$$(\mathbf{K}^* - \lambda^* \mathbf{I}) \alpha = 0, \quad (4)$$

with

$$\mathbf{K}^* = \Phi_0^T \mathbf{K} \Phi_0. \quad (5)$$

Each element k_{uv}^* of \mathbf{K}^* can be written as a sum of all terms of the perturbed stiffness matrix

$$k_{uv}^* = \sum_{i=1}^n \phi_{0ui} \sum_{j=1}^n \phi_{0vj} k_{ij}, \quad (6)$$

with n the number of degrees of freedom of the model and ϕ_{0ui} meaning the u -th degree of freedom of the i -th mode of the modal basis. Eq. (6) shows that the k_{uv}^* are linear functions of k_{ij} . When the elements k_{ij} undergo linear changes with respect to an assumed input parameter, the elements k_{uv}^* also represent a linear behavior with respect to the same input parameter.

The characteristic polynomial associated with the reduced eigenvalue problem of Eq. (4) is given by

$$\lambda^{*m} + q_{m-1} \lambda^{*m-1} + \dots + q_1 \lambda^* + q_0 = 0. \quad (7)$$

The q coefficients (thus the name q -method) of the Eq. (10) can be expressed in terms of the elements k_{uv}^* through the relations

$$\begin{aligned} q_{m-1} &= (-1)^1 \sum_{r=1}^m |\mathbf{K}_{r,r}^*| = (-1)^1 \sum_{r=1}^m k_{rr}^* \\ q_{m-2} &= (-1)^2 \sum_{r=1}^{m-1} \sum_{s=r+1}^m |\mathbf{K}_{\{r,s\},\{r,s\}}^*| \\ q_{m-3} &= (-1)^3 \sum_{r=1}^{m-2} \sum_{s=r+1}^{m-1} \sum_{t=s+1}^m |\mathbf{K}_{\{r,s,t\},\{r,s,t\}}^*| \\ &\dots \\ q_0 &= (-1)^m |\mathbf{K}^*|, \end{aligned} \quad (8)$$

with $|\mathbf{K}_{\{r,s,t\},\{r,s,t\}}^*|$ denoting the determinant of a principal minor of \mathbf{K}^*

$$|\mathbf{K}_{\{r,s,t\},\{r,s,t\}}^*| = \begin{vmatrix} k_{rr}^* & k_{rs}^* & k_{rt}^* \\ k_{sr}^* & k_{ss}^* & k_{st}^* \\ k_{tr}^* & k_{ts}^* & k_{tt}^* \end{vmatrix}. \quad (9)$$

According to Eq. (6) and 8, it is seen that q_{m-1} is a linear function of the factors k_{ij} , q_{m-2} a second order polynomial with interactions, q_{m-3} a third order polynomial with second order interactions, and so forth. The highest order function is due to q_0 which is a m -th order polynomial with $m - 1$ order interactions. Any variation of the structural parameters which is linear with k_{ij} is related to the q coefficients by the same kind of relationship. Thus, when a number p of structural parameters are analyzed simultaneously, a correct approximation of the m coefficients q can be obtained through a set of m -th order polynomial functions with $(m - 1)$ th order interactions. Polynomial regression can efficiently interpolate these functions using $m^p + p$ observations.

The approximation of the q coefficients by using Eq. (8) is not handy as it involves operations with the stiffness matrix which is usually very large. A more viable approach exploits the exiting relation between the coefficients of a polynomial equation and its roots, that is between the characteristic polynomial coefficients and the eigenfrequencies associated to the reduced eigenvalue problem Eq. (4). Indeed, rewriting Eq. (10) as

$$(\lambda^* - \lambda_{*1}^*)(\lambda^* - \lambda_{*2}^*) \dots (\lambda^* - \lambda_{*m}^*) = 0, \quad (10)$$

and solving the multiplication by binomials, it is possible to express the q in terms of the roots of λ^* . This allows one to calculate the q coefficient at the $m^p + p$ design sites directly from the results of FE analyses. Then, the q coefficients are approximated within the design space via polynomial regression and the eigenvalues at untried points are calculated by solving the approximated m th-order characteristic polynomial.

The big advantage of the proposed methodology with respect to a direct modal meta-modeling consists of being insensitive to the complexity of the modal behavior. However, it is important to bear in mind that the method is effective as long as all analyzed modes move within the subspace spanned by the same modal basis within the whole domain of interest. As mentioned above, this means also that in the presence of veering phenomena, the assumed modal basis has to accommodate always both modes involved in the veering. The detection of coupled modes resulting from veering phenomena can be accomplished by the modal assurance criterion (MAC) matrix histogram.

From the calculation of the MAC values between every possible pair of eigenvectors and design points it is possible to assemble the MAC matrix histogram. In this matrix, each element (i.e., each histogram) shows the frequency of occurrence of a certain MAC value (see Fig. 2). The y-axis shows the number of occurrences and the x-axis labels the range of the MAC value from 0 to 1 which for convenience is subdivided into 10 parts. A dispersion on the diagonal of this matrix clearly indicates mode veering. Fig. 2 shows that the modes j and k are coupled with each other but decoupled from mode i .

3 MODE VEERING DETECTION

The q -method approximates the coefficients of the characteristic polynomial and can be used as an efficient tool to investigate mode degeneration phenomena. This is accomplished in the

Figure 2: MAC matrix histogram. The modes j and k are coupled with each other but decoupled from i .

following way. The meta-model of the q -coefficients is used to evaluate the eigenfrequencies by the solution of Eq. (10). Due to the fact that no eigenvectors are calculated, no information about the presence of veering or crossing can be extracted from MAC analysis. However, the capability of the modal meta-model to correctly predicting the eigenfrequencies can be utilized for developing an efficient iterative procedure that detects possible mode degeneration within the parameter space. The step-wise algorithm is based on tangential approximations and at each step it is checked whether a change in the mode order is occurring within the range of Δ . In the sample graph of Fig. 3 this would be the case for the step ② – ③. The eigenfrequencies

Figure 3: Step-wise algorithm.

cies obtained from the q -method are denoted as f (blue: \overline{acb}) and g (green: \overline{dce}) as shown in Fig. 3 and 4; the eigenfrequencies given after the construction of the eigenfrequency locus are denoted as F (\overline{ace}) and G (\overline{dcb}). The correct representation of the evolution of the modes is accomplished in the following way. First, initial values are calculated using the meta-model; they are denoted with the superscript (0) , i.e., $F^{(0)} = f^{(0)}$ and $G^{(0)} = g^{(0)}$. Then, the new values of the eigenfrequencies at position (1) are calculated using finite tangential approximations

$$F^{(1)} = \begin{cases} f^{(1)}, & \text{if } \|F^{(0)} + \frac{\partial f^{(0)}}{\partial q} \Delta - f^{(1)}\| < \|F^{(0)} + \frac{\partial f^{(0)}}{\partial q} \Delta - g^{(1)}\| \\ g^{(1)}, & \text{if } \|F^{(0)} + \frac{\partial f^{(0)}}{\partial q} \Delta - f^{(1)}\| > \|F^{(0)} + \frac{\partial f^{(0)}}{\partial q} \Delta - g^{(1)}\| \end{cases} \quad (11)$$

and

$$G^{(1)} = \begin{cases} g^{(1)}, & \text{if } \|G^{(0)} + \frac{\partial g^{(0)}}{\partial q} \Delta - g^{(1)}\| < \|G^{(0)} + \frac{\partial g^{(0)}}{\partial q} \Delta - f^{(1)}\| \\ f^{(1)}, & \text{if } \|G^{(0)} + \frac{\partial g^{(0)}}{\partial q} \Delta - g^{(1)}\| > \|G^{(0)} + \frac{\partial g^{(0)}}{\partial q} \Delta - f^{(1)}\| \end{cases} \quad (12)$$

In Eq. (11) $\frac{\partial f^{(0)}}{\partial q}$ denotes the derivative at $f^{(0)}$ and in Eq. (12) $\frac{\partial g^{(0)}}{\partial q}$ denotes the derivative at $g^{(0)}$ which are calculated numerically using a small increment ∂q ; $\partial q \ll \Delta$. If the second lines of Eq. (11) and (12) appear to be correct, this is an indication of a crossing or veering occurrence within the interval Δ as shown in Fig. 4 for ② – ③.

Figure 4: Bisection algorithm.

At every subsequent step, the interval is halved, until either the initial crossing is revealed to be a veering, or an established Δ_{min} is reached. In the former case, the smallest Δ_{out} is stored, and the veering point P_v is determined. Then the domain Ω_v of mode degeneration is assumed to be within the interval $[P_v - I_v, P_v + I_v]$ with $I_v = \Delta_{out}$ providing a metric for the veering intensity. In the latter case, this means that either the modes are crossing, or the modes are sharply veering within the current Δ_{min} . In both cases, the crossing/veering point P_v is determined and the domain Ω_v within which mode degeneration occurs $[P_v - I_v, P_v + I_v]$ with $I_v = \Delta_{min}$ calculated. In case of abrupt veering or crossing, a so-called veering/crossing line can be drawn by connecting the points P_v ; otherwise the evaluation of the region Ω_v is more meaningful. In general, the procedure will never distinguish between mode switching and mode veering with veering region smaller than Δ_{min} , however, by reducing the value of Δ_{min} it is possible to recognize sharper and sharper veering phenomena.

4 NUMERICAL EXAMPLE

4.1 Model description

An assessment of the presented procedure and its capability to predict a physically meaningful evolution of the eigenvalue loci in the presence of veering is completed via a numerical example. A two-bay frame, modeled with finite elements provides a test case therefore; despite the simplicity of the structure, the model shows complex behavior of its modal parameters. The frame model consists of three vertical plates which are connected through a horizontal plate. Two horizontal bars, linking the vertical plates, produce an additional weak coupling between the vertical plates. The frame is unconstrained. The underlying FE model consists of 320 shell elements and 423 nodes leading to 2538 degrees of freedom. Fig. 5 shows the FE model and Table 1 lists its properties at the nominal configuration.

The eigenfrequency loci evolution is approximated when the Young's moduli E_1 and E_2 of the plates 1 and 2 are changed. Both Young's moduli vary $\pm 30\%$ with respect to their nominal values, resulting in a range of $0.7 \cdot E_{1,2} - 1.3 \cdot E_{1,2}$.

Element	Young's modulus [Pa]	mass density ρ [kg/m ³]	ν	thickness[m] a,b	L[m]	H[m]
plates 1 – 4	2.1×10^{11}	7860	0.3	0.002	0.2	1
bars	2.1×10^{11}	7860	0.3	0.002, 0.0002	0.5	-

Table 1: Nominal configuration of the frame.

Figure 5: M-shaped frame structure.

4.2 Response surface approximation

First the MAC matrix histograms (Fig. 6) was calculated from a small number of FE runs for detecting coupled modes. The MAC matrix histogram shows a clear coupling for the modes 2 to 4. Thus, these 4 modes are selected for the further analysis.

Figure 6: MAC histogram.

According to the law proposed in Section 2, $4^2 + 2 = 18$ numerical runs should suffice to accurately describe the natural frequency evolution of the analyzed modes. Thus, a 18-sample Latin hypercube sampling was carried out and 4th order polynomials (with interactions) fitted to the observations at the 18 design points via polynomial regression. The results from the q -method has been compared with the results from a direct meta-modeling approach and with the exact numerical solution calculated on a 21×21 regular grid. In particular, both meta-modeling techniques evidence high accuracy for modes 4 and 5, those not affected by degeneration (Fig. 7(a)). However, the q -method performs much better than the direct approach

for modes 2 and 3, that coalesce within the parameter space as presented in Fig. 7(b). In order to assess the quality of meta-models prediction, the relative error with respect to the reference solution has been calculated at modes 2 and 3. The q -method reveals to be much more accurate than the direct method, as shown in the plots of Fig. 8.

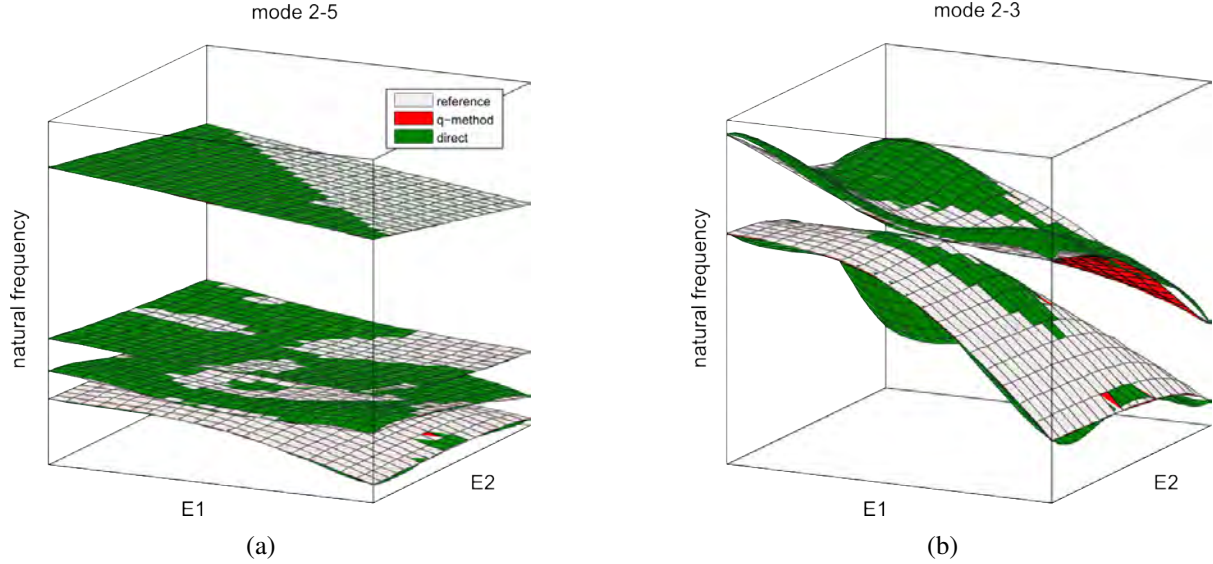

Figure 7: Comparison of the eigenfrequency variation: exact solution vs. q -method and direct approximation.

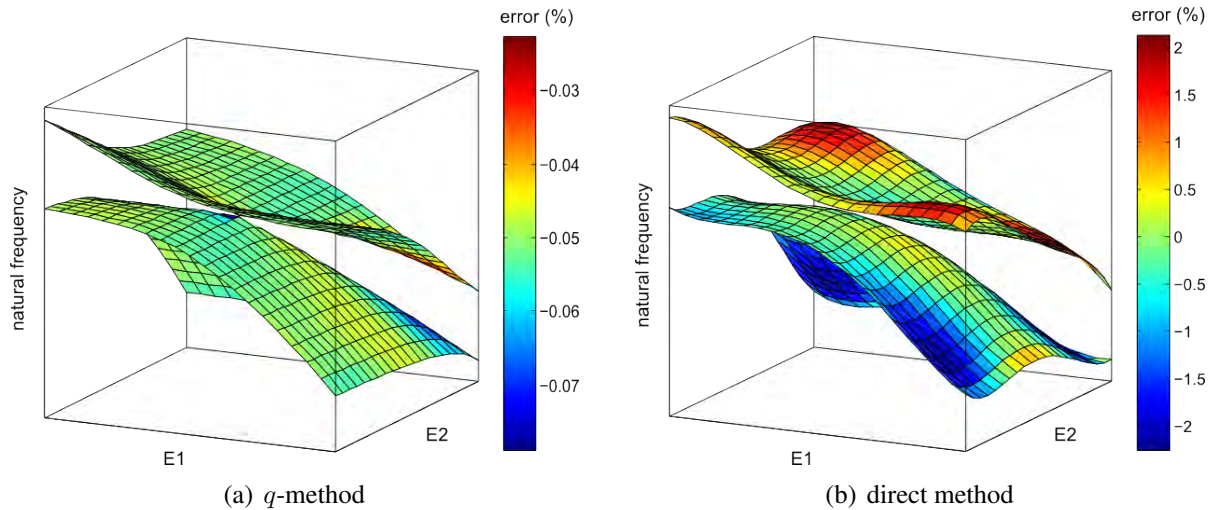

Figure 8: Measured per cent error of the approximated responses with respect to the reference solution.

4.3 Detection of mode coalescence

The step-wise procedure was applied to a 4×20 grid which was imposed on the input parameter space. The procedure succeeded in detecting the region of mode degeneration, as presented in Section 3. The solid lines in Fig. 9 show the veering region, and the extension of the domain is given by the veering intensity $I_v = \Delta_{out}$. Close to the occurrence of mode coalescence, the veering intensity factor assumes a small value which also suggests the occurrence of abrupt

veering or crossing.

Figure 9: Spatial occurrence of coalescence.

5 CONCLUSIONS

The utilization of indirect meta-modeling for the investigation of the eigenfrequency loci evolution has been discussed in this work. A sufficient number of design sites for constructing accurate meta-models of the natural frequencies has been assessed independently of the presence of mode degeneration phenomena within the analyzed parameter space. Combined with a step-wise mode tracking procedure based on the natural frequency analysis, the modal meta-model is able to provide meaningful information about the physical mode evolution. This is an advantage with respect to direct modal meta-modeling that has difficulty in dealing with systems affected by mode veering, crossing and coalescence. A numerical example discussed the application of the methodology on a structure affected by mode coalescence. The combination of the surrogate model with the step-wise procedure provides a tool to improve the design through the identification of regions where the system dynamic behavior undergoes large modal parameter variations. In addition, it has been shown that for the examined structure, the proposed indirect meta-model is clearly outperforming a direct approximation. At present the procedure is able to only deal with systems subjected to stiffness variability. Future works will concern with the extension of the procedure to also account for mass modifications.

Keywords: Masonry Structures, Earthquake Engineering, Shaking table tests, Dynamic Damage Identification

Abstract. *In the present paper, the seismic behavior of a physical 1:5.5 scaled model of the church of the Fossanova Abbey is investigated by means of numerical and experimental analyses. Aiming at defining the seismic vulnerability of such a structural typology a wide experimental campaign was carried out. The achieved experimental results lead to the definition of a refined FE model reproducing the dynamic behavior of the whole structural complex. Then, the central transversal three-central bays of the church, as it mostly influences the seismic vulnerability of the Abbey, was investigated in a more detail by means of a shaking table test on a 1:5.5 scaled physical model in the Laboratory of the Institute for Earthquake Engineering and Engineering Seismology in Skopje. In the present paper a brief review of the numerical activity related to the prediction of the shaking table test response of the model is first proposed. Then, the identification of frequency decay during collapse is performed through decomposition of the measured power spectral density matrix. Finally, the localization and evolution of damage in the structure is analyzed. The obtained results shown that a very good agreement is achieved between the experimental data and the predictive/interpretative numerical analyses.*

1 INTRODUCTION

Gothic architecture spread as from the 12th Century and broke out during the Middle Ages in the cultural and religious area of the Christianity of Western Europe, with some trespasses in the Middle East and in the Slavic-Byzantine Europe. Many important abbeys were built in those areas, providing a key impulse to the regional economy and contributing to a general social, economic and cultural development. The most interested areas sprawl from the northern Countries (England) to those facing the Mediterranean Basin (Italy), but also spread out from the Western (Portugal) to the Eastern Countries, as Poland and Hungary. Monastic orders and in particular the Cistercian one, with its monasteries, had an important role for broaden the new architectonic message, adapting to the local traditions the technical and formal heritage received by the Gothic style [1], [2] and [3] .

Gothic cathedrals may result particularly sensitive to earthquake loading. Therefore, within the European research project “Earthquake Protection of Historical Buildings by Reversible Mixed Technologies” (PROHITECH), this structural typology has been investigated by means of shaking table tests on large scale models [4]. Based on a preliminary study devoted to define typological schemes and geometry which could be assumed as representative of many cases largely present in the seismic prone Mediterranean Countries, the Fossanova cathedral, which belongs to the Cistercian abbatial complex built in a small village in the central part of Italy, close to the city of Priverno (LT), has been selected as an interesting and reference example of pre-Gothic style church [5]. In order to assess the vulnerability of the church against seismic actions a wide numerical and experimental activity was developed. Firstly, the identification of the geometry of the main constructional parts as well as of the mechanical features of the constituting materials of the cathedral was carried out. Then, Ambient Vibration Tests were performed in order to characterize the dynamic behavior of the church and to calibrate refined FE models developed by the ABAQUS code [6]. At this purpose elastic FEM analyses were performed to predict the behavior of the three-central bays of the church, which were detected as the key-part of the structural complex [7], [8]. The recognized resistant unit about transversal direction was designed in length scale 1:5.5 according to “true replica” modeling principles and tested on the shaking table in the IZIIS Laboratory in Skopje [9]. The physical model was tested and the as-built model was loaded until heavy damage occurred. The structural response of the tested physical model has been deeply investigated by means of non-linear numerical analyses that has shown good agreements with experimental measurements [10].

In this paper, the identification of frequency decay during collapse is performed through decomposition of the measured power spectral density matrix. Finally, the localization and evolution of damage in the structure is analyzed. The obtained results has shown that a very good agreement is achieved between the experimental data and the predictive/interpretative numerical analyses.

2 THE FOSSANOVA ABBEY: MODEL AND EXPERIMENTAL TEST

The Fossanova Abbey (Fig. 1) was built in the XII century and opened in 1208. The architectural complex presents three rectangular aisles with seven bays, a transept and a rectangular apse. Between the main bay and the transept raises the skylight turret with a bell tower. The main dimensions are 69.85 m (length), 20.05 m (height), and 23.20 m (width). The nave, the aisles, the transept and the apse are covered by ogival cross vaults. Detailed information on the main dimensions of the bays are provided in De Matteis et al. [6].

Figure 1. The Fossanova church.

The previously mentioned vaulted system does not present ribs, but only ogival arches transversally oriented respect to the span and ogival arches placed on the confining walls (Fig. 2). The ridge-poles of the covering wood structure is supported by masonry columns placed on the boss of the transversal arches of the nave and apse. The crossing between the main bay and the transept is covered by a wide ogival cross vault with diagonal ribs sustained by four cross shaped columns delimiting a span with the dimensions of 9.15x8.85m.

Figure 2. The vaulted system of the Fossanova church.

The main structural elements constituting the central nave and the aisles are four longitudinal walls (west-east direction). The walls delimiting the nave are sustained by seven couples of cross-shaped piers (with dimensions of 1.80x1.80 m) with small columns laying on them and linked to the arches. The bays are delimited inside the church by columns with adjacent elements having a capital at the top. The columns-capital system supports the transversal arches of the nave. The external of the clearstory walls are delimited by the presence of buttresses with a hat on the top that reaches the height of 17.90 m. The walls of the clearstory present large splayed windows and oval openings that give access to the garret of the aisles. Also the walls that close the aisles present seven coupled column-buttresses systems reaching the height of 6.87 m and further splayed windows.

During the centuries, the complex suffered some esthetical modifications: the main prospect was modified since the narthex was eliminated installing an elaborate portal with a large rose-window; a part of the roof and of the lantern were rebuilt, introducing a Baroque style skylight turret; additional modifications on the roofing of the church were applied, with the reduction of the slope of pitches and with the restoration of the same slope as in the original form.

In order to determine the actual geometry and the mechanical features of the main constructional elements, an accurate experimental activity has been developed. In particular, both in situ inspection and laboratory tests have been carried out [6, 7].

It has been determined that the basic material constituting the constructional elements of the church is a very compact sedimentary limestone. In particular, columns and buttresses are made of plain stones with fine mortar joints (thickness less than 1 cm). The lateral walls (total thickness 120 cm) consist of two outer skins of good coursed ashlar (the skins being 30 cm thick) with an internal cavity with random rubble and mortar mixture fill.

In order to inspect the hidden parts of the constituting structural elements, endoscope tests have been executed on the right and left columns of the first bay, on the third buttress of the right aisle, on the wall of the main prospect and at the end on the filling of the vault covering the fourth bay of the nave. The test on the columns (Fig. 3a) allowed the exploration of the internal nucleus of the pier, relieving a total lack of internal vacuum, with the predominant presence of limestone connected with continuum joints of mortar (Fig. 3b). The test on the buttress was performed at the level of 143 cm, reaching the centre of the internal wall. The presence of regular stone blocks having different dimensions and connected to each other with mortar joints without any significant vacuum was detected. The tests on the wall put into evidence the presence of a two skins and rubble fill. The test made on the extrados of the vault, with a drilling depth of 100 cm, allowed a first layer of 7 cm made of light concrete and then a filling layer of irregular stones and mortar with the average thickness of 10 cm to be identified. In order to define the mechanical features of the material, original blocks of stone were taken from the cathedral and submitted to compression tests (Fig. 4a). In total, 10 different specimens having different sizes have been tested, giving rise to an average ultimate strength of about 140 MPa and an average density $\gamma = 1700 \text{ kg/m}^3$. Besides, based on the results obtained for three different specimens, a Young's modulus equal to 42.600 MPa has been assessed, while a Poisson's ratio equal to 0.35 has been estimated.

Figure 3: Endoscope tests.

Also, mortar specimens were extracted from the first column placed on the left of the first bay, from the wall of the aisle on the right and from the wall on the northern side of the transept. The specimens were catalogued as belonging to either the external joints (external mortar) or to the filling material (internal mortar). Compression tests have been carried out according to the Italian provisions (UNI EN 1926:2001), relieving a noticeable reduction of the average compressive strength for the specimens belonging to the external mortar (3.33 MPa) with respect to the internal ones (10.30 MPa). Besides, the Young's modulus has been determined on three different mortar specimens, according to the UNI EN 1015-11:2001 provisions, providing values ranging from 8.33 MPa to 12.16 MPa.

Figure 4: Compression tests on limestone (a) and microscope analysis on mortar (b).

Chemical and petrography analyses have been also performed on the mortar specimens. In particular, chemical tests were made by X rays diffractometer analysis, according to the UNI 11088:2003 provisions. The prevalence of three material, namely, quartz crystal SiO_2 , crystallized calcium carbonate CaCO_3 and some traces of feldspate, was noticed. Also, a petrography study on thin sections of mortar specimens have been done by using two electronic microscopes, according to the UNI EN 932-3:1998 provisions (Fig. 4b). The analysis relieved the presence of quartz crystal sand and feldspate, without any significant presence of crystallized calcium carbonate. The binding was quantified with a percentage of 60% of the total volume.

A FE model of the entire Abbey was calibrated on the basis of the in-situ experimental activity. The seismic analyses on such a model revealed that the more important structural part of the structural complex was to be recognized in the three-central bays of the main nave shown in Figure 5 [8]. For the above reason a physical model of the key-structural part was designed and constructed in the IZIIS Laboratory in Skopje (Fig. 6). The model was executed in a 1:5.5 scale ratio (length) which was the maximum value compatible with the capacity of the shaking table.

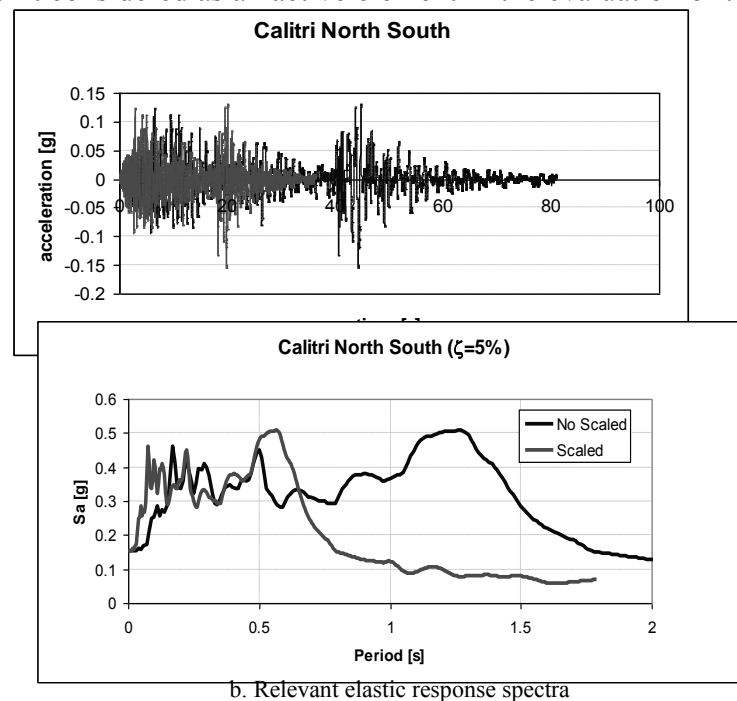

Figure 5. Recognized seismic resistant unit in transversal direction.

The Buckingham's theorem was followed to define all the physical parameters needed to the construction of the model, according to the "true replica" modeling principles. All the involved quantities was scaled on the base of the three main parameters Length ($L_r=1/5.5$), Mass Density ($\rho_r=1$) and Acceleration ($a_r=1$) so that for the stresses a scaling ratio $\sigma_r=0.18$ is obtained. The dimensions of the model were 3.97x4.44 m at the base, 3.67 m was the maximum height.

Fig. 6. Fossanova physical model (UPM) in scale 1:5.5 tested on shaking table.

Some simplifications were adopted in the construction of the prototype: free edges were left in longitudinal direction, in fact no boundary restraints were applied on the fronts, neglecting the longitudinal continuity as it is in the reality. Then, the wooden roof structure wasn't realized because it wasn't considered as an active element in the evaluation of the seismic vulnerability [9].

b. Relevant elastic response spectra

Figure 7. The accelerometric record (Irpinia, 1980).

The input signal of the test was assumed to be the scaled natural Calitri record (North-South direction) of Irpinia (Italy) 1980 earthquake record. The main features of the selected earthquake are a maximum acceleration of 0.155g (compatible with seismic hazard of the site), a quite long duration time (80 sec), a high input energy for the relevant frequency (0.5Hz-10Hz) and typical two peak accelerations (or two strong motions). The record and the derived elastic spectra (with damping ratio $\zeta=5\%$) are shown in Figure 7a,b. The shaking table test was performed by considering three phases: phase 1, phase 2A and phase 2B. In the first phase the as-built unreinforced physical model (UPM) was tested and heavily damaged at the end. In the second phase (2A) the model was repaired and reinforced with carbon fiber ties. Finally, in the phase 2B, the reinforcing system was modified and the model was loaded until failure. Even though the examination of the reinforced systems is not the object of the present paper, in the following the level of input intensity which provoked serious damage to the model for every phase is listed:

- 0.14g for the original model (phase 1);
- 0.28g for the strengthened model (phase 2A);
- 0.40g for the strengthened model (phase 2B);

In particular, the maximum acceleration measured at the base of the shaking table, by means of the accelerometer “CH1” [11], versus the maximum absolute displacement measured at the top of the buttresses at each step of the phase 1 (unreinforced physical model) is shown in Figure 8. The curve can be assumed as an equivalent capacity curve for the tested UPM [10].

Figure 8. Equivalent capacity curve of the tested model.

3 DYNAMIC DAMAGE IDENTIFICATION

A more suitable representation of the structural response may be achieved by means of the decomposition in fully coherent independent vectors. Although the non gaussianity of the structural response vector $\mathbf{X}(t) = [X_i(t)]$ ($i=1, \dots, n$), collecting the nodal response processes, its main characteristics can be represented by the knowledge of the second order spectral properties. To this end, let us consider the PSD matrix of $\mathbf{X}(t)$

$$\mathbf{S}_X(\omega) = \begin{bmatrix} S_{X_1}(\omega) & S_{X_1 X_2}(\omega) & \cdots & S_{X_1 X_n}(\omega) \\ S_{X_2 X_1}(\omega) & S_{X_2}(\omega) & \cdots & S_{X_2 X_n}(\omega) \\ \vdots & \vdots & \ddots & \vdots \\ S_{X_n X_1}(\omega) & \cdots & \cdots & S_{X_n}(\omega) \end{bmatrix} \quad (1)$$

The elements of $\mathbf{S}_X(\omega)$ are the direct and cross power spectral densities, defined as the Fourier transform of the correlation components

$$S_{X_i X_j}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} R_{X_i X_j}(\tau) e^{-j\omega\tau} d\tau \quad (2)$$

or equivalently, starting from measurements of the process $\mathbf{X}(t)$:

$$S_{X_i X_j}(\omega) = \frac{1}{2\pi} \lim_{T \rightarrow \infty} \frac{E[X_i(\omega, T) X_j^*(\omega, T)]}{T} \quad (3)$$

where $X_i(\omega, T)$ denotes the Fourier transform of $X_i(t)$ over the observation time T

$$X_i(\omega, T) = \int_0^T X_i(t) e^{-j\omega t} dt \quad (4)$$

The psd matrix is Hermitian and non-negative definite, thus its eigenvalues $\Gamma(\omega) = \text{diag}(\gamma_1(\omega) \gamma_2(\omega) \dots \gamma_n(\omega))$ are real and non-negative, with orthonormal complex eigenvectors $\Psi(\omega) = [\psi_1(\omega) \psi_2(\omega) \dots \psi_n(\omega)]$

$$\Psi(\omega)^* \Psi(\omega) = \mathbf{I}, \quad \Psi(\omega)^* \mathbf{S}_X(\omega) \Psi(\omega) = \Gamma(\omega) \quad (5)$$

$$\mathbf{S}_X(\omega) \Psi(\omega) = \Psi(\omega) \Gamma(\omega) \quad (6)$$

If the eigenvalues are sorted in decreasing order, then the summation in Eq.(9) can be truncated considering only a limited number of principal components.

Fig.9 Response spectral eigenvalues for different values of ground peak acceleration: $a_g=0.14g$, $a_g=0.28g$ and $a_g=0.4g$

Fig.10 Comparison between experimental and identified frequency decay for different values of ground peak acceleration

Figures 9 show the response spectral eigenvalues for different values of ground peak acceleration, leading to the identification of the frequency decay, Fig. 10

Damage localization has been performed using the Parameter Method (PM) proposed by Dong et al. [14], [15] using a combination of frequency and mode shapes. The expression for the PM method is

$$\Delta\varphi = \sum_{j=1}^n \left[\phi_j^d \left(\frac{\omega_j^u}{\omega_j^d} \right) - \phi_j^u \right] \quad (10)$$

where ϕ is the structural mode, n the mode number while upper script u,d stands for undamaged and damage state respectively.

Figure 11 show the FEM prediction of the progressive damage of the model with increasing PGA. In Figures 12, based on a 2D finite element model, it is shown the identification of damage location by the PM method.

CONCLUSIONS

The seismic behavior of a physical 1:5.5 scaled model of the church of the Fossanova Abbey has been investigated by means of numerical and experimental analyses. The achieved experimental results lead to the definition of a refined FE model reproducing the dynamic behavior of the whole structural complex. Then, the central transversal three-central bays of the church, as it mostly influences the seismic vulnerability of the Abbey, was investigated in a more de-

tail by means of a shaking table test on a 1:5.5 scaled physical model in the Laboratory of the Institute for Earthquake Engineering and Engineering Seismology in Skopje. In the present paper a brief review of the numerical activity related to the prediction of the shaking table test response of the model is first proposed. Then, the identification of frequency decay during collapse is performed through decomposition of the measured power spectral density matrix. Finally, the localization and evolution of damage in the structure is analyzed. The obtained results shown that a very good agreement is achieved between the experimental data and the predictive/interpretative numerical analyses.

Abstract. *A high-order Absorbing Boundary Condition (ABC) is devised on an artificial boundary for time-dependent elastic waves in unbounded domains. The configuration considered is that of a two-dimensional elastic waveguide. The proposed ABC is an extension of the Hagstrom-Warburton ABC which was originally designed for acoustic waves, and is applied directly to the displacement field. The order of the ABC determines its accuracy and can be chosen to be arbitrarily high. A special variational formulation is constructed which incorporates the ABC. A standard FE discretization is used in space, and a Newmark-type scheme is used for time-stepping. A long-time instability is observed, but simple means are shown to dramatically postpone its onset so as to make it harmless during the simulation time of interest.*

1 INTRODUCTION

A well-known computational technique for treating wave problems in unbounded domains is the use of Absorbing Boundary Conditions (ABCs), also known by other names such as Radiating Boundary Conditions and Non-reflecting Boundary Conditions; see the review papers [1–3]. An ABC is a condition imposed on an artificial boundary which truncates the unbounded domain, thus allowing the replacement of the original problem by another problem defined in a finite domain. The latter can then be solved using standard numerical techniques like finite element (FE) or finite difference schemes. Application areas include acoustics, oceanography, electromagnetic waves and Solid-Earth Geophysics (SEG).

In 1993, Collino [4] proposed the first genuinely *high-order* local ABC for the wave equation, which does not involve high derivatives and can be implemented up to any desired order. The key here is the use of *auxiliary variables*, which are introduced on the artificial boundary and enable the elimination of the high derivatives from the ABC equations. Various authors followed Collino in proposing different high-order ABCs; see the review in [5]. Here we concentrate on the Hagstrom-Warburton [6] high-order ABC.

The use of ABCs in SEG, for the solution of direct or inverse elastic wave problems, goes back to the seminal 1969 paper of Lysmer and Kuhlemeyer [7], who proposed a dashpot-type ABC. Despite its crude accuracy, the dashpot ABC is still used today, along with various improved ABCs and absorbing layers which have been proposed in the last four decades; see, e.g., [8–10].

In contrast to the situation with PML, the only high-order ABC developed for elastic waves to date, to the best of our knowledge, is that of Tsogka and Joly [11, 12]. Their ABC is an extension of the Collino ABC [4] to elastodynamics, and is based on using special potential functions. The ABC was incorporated in a mixed FE formulation. Very recently [13], a long-time instability has been observed in solutions generated by this scheme. We shall see that the scheme proposed here suffers from the same malady, although the onset of the instability can be postponed dramatically by using various means.

In the present paper, we propose another high-order ABC for elastodynamics, which is an extension of the Hagstrom-Warburton ABC [6]. The latter is, in turn, a high-order form of the Higdon ABC [14], and a symmetrized modification of the Givoli-Neta high-order formulation [15, 16]. This ABC, developed originally for scalar time-dependent problems and hyperbolic conservation systems, has been shown to be extremely effective in a variety of situations [6, 17–21]. Here we extend the ABC for use in elastodynamics, basing it directly on the displacement field.

2 PROBLEM STATEMENT

We consider a two-dimensional semi-infinite elastic waveguide of width b , as shown in Fig. 1(a).

In the waveguide we consider the two-dimensional (plane strain) linear equations of elastodynamics. Some boundary conditions are specified on all three boundaries. Initial conditions are also prescribed. We assume that outside a compact region, denoted Ω_0 , the following simplified conditions hold: (a) the medium is *homogeneous*, namely the material properties are constant; (b) the material is *isotropic*; (c) body forces are absent; and (d) the initial values vanish. As a result of these assumptions, in the semi-infinite region outside Ω_0 the governing equations are reduced to the Navier equations.

We now truncate the semi-infinite domain by introducing the artificial boundary Γ_E , located

Figure 1: A semi-infinite waveguide: (a) the original setup, (b) the setup of the problem with truncated domain.

at $x = x_E$, $0 \leq y \leq b$; see Fig. 1(b). This boundary divides the original semi-infinite domain into two subdomains: the exterior domain D , and a finite computational domain Ω , which is bounded by Γ_W , Γ_S , Γ_N and Γ_E . We choose the location of Γ_E such that Ω_0 is strictly contained in Ω .

The initial boundary value problem in Ω consists of the elastic equations in Ω , the given initial conditions, the boundary conditions on Γ_W , Γ_N and Γ_S , and an ABC imposed on Γ_E . We shall consider this ABC in the next sections.

3 THE HIGH-ORDER ABC: GENERAL APPROACH

The general approach devised in [15] and adopted in [6] to construct a high-order ABC consists of the following four steps (presented here in the context of a scalar problem, for simplicity):

Step 1. We start with a basic, low-order, ABC, $B_0 u = 0$ on Γ_E . The only essential requirement from this ABC is that it be associated with a reflection coefficient smaller than 1.

Step 2. Taking a product of operators B_j , each one of which has the same form as B_0 , possibly with different coefficients, we obtain a P th-order ABC,

$$\mathcal{B}^P u \equiv \left(\prod_{j=0}^P B_j \right) u = 0.$$

Its reflection coefficient is the product of the reflection coefficients R_j associated with each B_j , and hence becomes exponentially small as P is increased.

Step 3. This high-order ABC is not computationally practical because it involves high-order derivatives. We introduce the auxiliary variables ϕ_j which are defined recursively; using them we eliminate all the high derivatives, and thus obtain a high-order ABC that involves only low derivatives.

Step 4. The latter high-order ABC is still not computationally practical, since it involves (in general) normal derivatives of the auxiliary variables ϕ_j on the boundary Γ_E . These

derivatives do not allow us to discretize the ϕ_j on Γ_E alone. We therefore use the wave equation itself (which we prove to be satisfied by each ϕ_j) to eliminate all normal derivatives of all auxiliary variables. This finally results in a practical high-order ABC.

For details on the development of the elastic ABC based on this approach, see [22].

4 THE HIGH-ORDER ABC: FINAL FORM

The final form of the high-order ABC is as follows.

For $j = 2, \dots, P$:

$$\begin{aligned} & [(a_{j-1}a_j^2 + a_ja_{j-1}^2)(\lambda + 2\mu) + (a_{j-1} + a_j)c^2\rho] \partial_{tt}\phi_j^x - (a_{j-1} + a_j)c^2\mu\partial_{yy}\phi_j^x \\ & = [a_{j-1}a_j^2(\lambda + 2\mu) - a_{j-1}c^2\rho] \partial_{tt}\phi_{j+1}^x + a_{j-1}a_jc(\lambda + \mu)\partial_{yt}\phi_{j+1}^y + a_{j-1}c^2\mu\partial_{yy}\phi_{j+1}^x \\ & + [a_ja_{j-1}^2(\lambda + 2\mu) - a_jc^2\rho] \partial_{tt}\phi_{j-1}^x - a_ja_{j-1}c(\lambda + \mu)\partial_{yt}\phi_{j-1}^y + a_jc^2\mu\partial_{yy}\phi_{j-1}^x, \end{aligned} \quad (1)$$

$$\begin{aligned} & [(a_{j-1}a_j^2 + a_ja_{j-1}^2)\mu + (a_{j-1} + a_j)c^2\rho] \partial_{tt}\phi_j^y - (a_{j-1} + a_j)c^2(\lambda + 2\mu)\partial_{yy}\phi_j^y \\ & = [a_{j-1}a_j^2\mu - a_{j-1}c^2\rho] \partial_{tt}\phi_{j+1}^y + a_{j-1}a_jc(\lambda + \mu)\partial_{yt}\phi_{j+1}^x + a_{j-1}c^2(\lambda + 2\mu)\partial_{yy}\phi_{j+1}^y \\ & + [a_ja_{j-1}^2\mu - a_jc^2\rho] \partial_{tt}\phi_{j-1}^y - a_ja_{j-1}c(\lambda + \mu)\partial_{yt}\phi_{j-1}^x + a_jc^2(\lambda + 2\mu)\partial_{yy}\phi_{j-1}^y, \end{aligned} \quad (2)$$

For $j = 1$:

$$\begin{aligned} & [(a_0a_1^2 + 2a_1a_0^2)(\lambda + 2\mu) + a_0c^2\rho] \partial_{tt}\phi_1^x - a_0a_1c(\lambda + \mu)\partial_{yt}\phi_1^y - a_0c^2\mu\partial_{yy}\phi_1^x \\ & = [a_0a_1^2(\lambda + 2\mu) - a_0c^2\rho] \partial_{tt}\phi_2^x + a_0a_1c(\lambda + \mu)\partial_{yt}\phi_2^y + a_0c^2\mu\partial_{yy}\phi_2^x \\ & + [2a_1a_0^2(\lambda + 2\mu) - 2a_1c^2\rho] \partial_{tt}\phi_0^x - 2a_1a_0c(\lambda + \mu)\partial_{yt}\phi_0^y + 2a_1c^2\mu\partial_{yy}\phi_0^x, \end{aligned} \quad (3)$$

$$\begin{aligned} & [(a_0a_1^2 + 2a_1a_0^2)\mu + a_0c^2\rho] \partial_{tt}\phi_1^y - a_0a_1c(\lambda + \mu)\partial_{yt}\phi_1^x - a_0c^2(\lambda + 2\mu)\partial_{yy}\phi_1^y \\ & = [a_0a_1^2\mu - a_0c^2\rho] \partial_{tt}\phi_2^y + a_0a_1c(\lambda + \mu)\partial_{yt}\phi_2^x + a_0c^2(\lambda + 2\mu)\partial_{yy}\phi_2^y \\ & + [2a_1a_0^2\mu - 2a_1c^2\rho] \partial_{tt}\phi_0^y - 2a_1a_0c(\lambda + \mu)\partial_{yt}\phi_0^x + 2a_1c^2(\lambda + 2\mu)\partial_{yy}\phi_0^y, \end{aligned} \quad (4)$$

These equations are accompanied by (6) and (9) which correspond to $j = 0$; namely, they connect u_i and ϕ_1^i :

$$(a_0\partial_t + c\partial_x)u_x = a_0\partial_t\phi_1^x, \quad (a_0\partial_t + c\partial_x)u_y = a_0\partial_t\phi_1^y. \quad (5)$$

In addition we have the ‘closure’ conditions

$$(a_0\partial_t + c\partial_x)u_x = a_0\partial_t\phi_1^x, \quad (6)$$

$$(a_j\partial_t + c\partial_x)\phi_j^x = (a_j\partial_t - c\partial_x)\phi_{j+1}^x, \quad j = 1, \dots, P, \quad (7)$$

$$\phi_{P+1}^x = 0 \quad \text{on} \quad \Gamma_E, \quad (8)$$

$$(a_0\partial_t + c\partial_x)u_y = a_0\partial_t\phi_1^y, \quad (9)$$

$$(a_j\partial_t + c\partial_x)\phi_j^y = (a_j\partial_t - c\partial_x)\phi_{j+1}^y, \quad j = 1, \dots, P, \quad (10)$$

$$\phi_{P+1}^y = 0 \quad \text{on} \quad \Gamma_E, \quad (11)$$

as well as

$$\phi_0^x = u_x, \quad \phi_0^y = u_y. \quad (12)$$

Eqs. (1)–(12) constitute together the desired ABC on Γ_E .

5 NUMERICAL EXAMPLE

We take zero initial conditions, and we ‘drive’ the problem through a persistent surface force applied on the north boundary Γ_N . On this boundary we take $u_y = 0$ and the nonzero tangential traction $T_x = \sigma_{xy} = T_x^N$, where

$$T_x^N(x, t) = \begin{cases} 1 & \text{for } 0 \leq x \leq 8 \\ 0 & \text{for } x > 8 \end{cases}, \quad t > 0. \quad (13)$$

Snapshots of the reference solution (obtained in a long domain) and the truncated-domain solution using the ABC with $P = 20$ are shown in Fig. 2. Steady state is rapidly reached due to the persistence of the applied force. In later times the solution does not change significantly, and hence no snapshots are shown after $t = 3$. It is apparent that the agreement between the two solutions is excellent.

6 LONG-TIME INSTABILITY

Numerical experiments show that our scheme exhibits a long-time instability, which causes the solution to grow exponentially after a sufficiently long amount of time. A similar phenomenon was observed with the potential-based high-order ABC of Tsogka and Joly [11, 12]. The origin of this instability is not clear yet. Nevertheless, we have found that the onset of the instability can be dramatically *postponed* by injecting small *numerical damping* into the time-stepping scheme on the boundary Γ_E . See [22] for more details.

Keywords: Seismology, Elastic waves, homogenization, non periodic, spectral elements

Abstract. *When considering numerical acoustic or elastic wave propagation in media containing small heterogeneities with respect to the minimum wavelength of the wavefield, being able to upscale physical properties (or homogenize them) is valuable, for mainly two reasons: first, replacing the original discontinuous and very heterogeneous media by a smooth and more simple one, is a judicious alternative to the necessary fine and difficult meshing of the original media required by many wave equation solvers; second, it helps to understand what properties of a medium are really “seen” by the wavefield propagating through it, which is an important aspect in an inverse problem approach. We present here a solution to solve this up-scaling problem for non-periodic complex media with rapid variations in all directions based on a non-periodic homogenization procedure. We first present a pedagogical introduction to non-periodic homogenization in 1-D, allowing to find the effective wave equation and effective physical properties of the wave equation in a highly heterogeneous medium. It can be extended from 1D to a higher space dimension and a special care of boundary conditions is required. This development can be seen as an extension of the classical two-scale periodic homogenization theory applied to the wave equation for non-periodic media. To validate this development, we then present two examples of wave propagation in 2D complex elastic models: a geometrically square model with random heterogeneities, and the Marmousi2 model. A reference solution is computed with the Spectral Element Method with meshes honoring all interfaces. Furthermore, we compare the results obtained in the homogenized model and in a low-pass filtered model with respect to the reference solution.*

1 Introduction

Being able to model and understand wave propagation in complex media is a constant concern for seismologist and the exploration community. In the recent years, advances in numerical methods have allowed to model full seismic waveform in complex media. Among these advances in numerical modeling, the introduction of the Spectral Element Method (SEM) in seismology has been particularly interesting [1]. This method has the advantage to be accurate for all type of waves and all type of media, as long as an hexahedral mesh, on which the method relies, can be designed such that all physical discontinuities are honored. In realistic media, the design of such a mesh is often impossible. For such a case, a smooth effective elastic media would solve the problem by removing the discontinuities of the elastic model while keeping the waveforms intact. Actually this problem is not limited to SEM and can be seen as a particular case of a more general problem in seismology: when an elastic model contains details much smaller than the wavelength, the model can be up-scaled consistently with the wave equation in some specific cases only: the layered media, and the periodic ones. In other words, the effective medium of a given general elastic model for a given minimum wavelength is unknown. For layered media, the up-scaling solution is known since the early work of Backus [2]. More recently, this order 0 (when referred to the homogenization theory) pioneer work has been extended to higher order, but still in the layered media case [3]. For elastic models with fast variations in several directions, the problem has been addressed for long with the two scale homogenization [4,] but is limited to the periodic media case.

In this work, we go beyond the non-periodic layered case and the high dimension periodic case with an up-scaling tool based on non-periodic homogenization.

2 Theory

We first present the homogenization method in a simple 1D periodic case and in a simplified manner. We consider a scalar wave propagating in a infinite elastic bar with ℓ -periodic elastic property $E(x)$ and density $\rho(x)$. We assume the existence of a minimum wavelength λ_m for the propagating wavefield and that $\varepsilon := \frac{\ell}{\lambda_m} \ll 1$. The equation of motion, driving the displacement u^ε , and the constitutive relation in the bar are

$$\begin{aligned}\rho^\varepsilon \partial_{tt} u^\varepsilon - \partial_x \sigma^\varepsilon &= f^\varepsilon \\ \sigma^\varepsilon &= E^\varepsilon \partial_x u^\varepsilon\end{aligned}\tag{1}$$

The classical periodic homogenization procedure to solve the above problem is the following:

1. The fast variable $y = \frac{x}{\varepsilon}$ is introduced;
2. The cell property $\rho(y) := \rho^\varepsilon(\varepsilon y)$ and $E(y) := E^\varepsilon(\varepsilon y)$ are defined;
3. As $\varepsilon \rightarrow 0$, y and x are treated as independent variables implying $\frac{\partial}{\partial x} \rightarrow \frac{\partial}{\partial x} + \frac{1}{\varepsilon} \frac{\partial}{\partial y}$;
4. Solutions to (1) are sought as asymptotic expansions in ε :

$$\begin{aligned}u^\varepsilon(x, t) &= \sum_{i \geq 0} \varepsilon^i u^i(x, y = \frac{x}{\varepsilon}, t) \\ \sigma^\varepsilon(x, t) &= \sum_{i \geq -1} \varepsilon^i \sigma^i(x, y = \frac{x}{\varepsilon}, t)\end{aligned}$$

5. Finally, injecting the previous expansions in 1 the series of equation to be solved for each i are:

$$\begin{aligned}\rho \partial_{tt} u^i + \partial_x \sigma^i + \partial_y \sigma^{i+1} &= f^i \\ \sigma^i &= E(\partial_x u^i + \partial_y u^{i+1})\end{aligned}\quad (2)$$

Defining, for any function $h(x, y)$, λ_m -periodic in y , the cell average

$$\langle h \rangle(x) = \frac{1}{\lambda_m} \int_0^{\lambda_m} h(x, y) dy,$$

and solving the series of equations (2) up to the first order, we find that $u = \langle u^0 \rangle + \varepsilon \langle u^1 \rangle$ and $\sigma = \langle \sigma^0 \rangle + \varepsilon \langle \sigma^1 \rangle$ are solutions of the following effective wave equation:

$$\langle \rho \rangle \partial_{tt} u - \partial_x \sigma = f, \quad \sigma = E^* \partial_x u$$

where $E^* = \langle E(1 + \partial_y \chi^1) \rangle$ is the effective elastic parameter and where χ^1 is the first order periodic corrector. χ^1 is solution of the cell problem:

$$\partial [E(1 + \partial_y \chi^1)] = 0. \quad (3)$$

The final order 1 solution can be obtained with

$$u^\varepsilon = (1 + \varepsilon \chi^1 \partial_x) u + O(\varepsilon^2)$$

It appears that:

- in this simple 1D case, we can find an analytical solution to the cell problem leading to $1/E^* = \langle 1/E \rangle$. This result is similar to the Backus (1962)'s result. There is not such an analytical solution for higher spatial dimensions.
- at the order 0, the solutions do not depend on the microscopic scale (y). This is still true in 2D and 3D for u^0 but not for σ^0 ;
- at order > 0 : the boundary conditions change (e.g. Neumann condition becomes Dirichlet to Neumann);
- at order > 1 : the effective equation changes (it is not the classical wave equation anymore);

Moving to the non-periodic case

When dealing with non-periodic media, the classical periodic homogenization can still be applied for the whole bar, but, then obtaining a simple constant effective media, is not really interesting. To keep the ideas of periodic homogenization and allowing a more complete effective medium, we introduce an arbitrary scale separation around a given wavelength λ_0 . All scales smaller than λ_0 are considered as small scales and scales larger than λ_0 are considered as large scales. We define $\varepsilon_0 := \lambda_0/\lambda_m$. A spatial filter operator (a low-pass filter) is introduced:

$$\mathcal{F}^{\varepsilon_0}(h)(x) = \int h(x') w_{\varepsilon_0}(x - x') dx'$$

where w_{ε_0} is a low-pass filter wavelet with a wave-number cutoff around $1/\lambda_0$ (see Fig. 1). $\mathcal{F}^{\varepsilon_0}$

Figure 1: w wavelet example, in the space (left plot) and in the wave-number (right plot) domains, with a cutoff at $\simeq 1m^{-1}$.

allows to piratically define the slow (x part) from the fast (y part) variations. The difficulty is to define an $E^{\varepsilon_0}(x, y)$ allowing to separate the scales according to $\mathcal{F}^{\varepsilon_0}$. In the 1D case [3], this can be done using

$$\frac{1}{E^{\varepsilon_0}}(x, y) = \mathcal{F}^{\varepsilon_0} \left(\frac{1}{E} \right) (x) + \left(\frac{1}{E} - \mathcal{F}^{\varepsilon_0} \left(\frac{1}{E} \right) \right) (y) \quad (4)$$

In that case, we can readily show that

$$\frac{1}{E^{\varepsilon_0*}} = \left\langle \frac{1}{E^{\varepsilon_0}} \right\rangle = \mathcal{F}^{\varepsilon_0} \left(\frac{1}{E} \right)$$

This effective E^{ε_0*} is smooth but allows to capture the whole wavefield for small enough ε_0 . At this point, most of the periodic development is still valid and non-periodic correctors can be computed.

Going to higher dimensions

For the periodic case, 2D/3D homogenization technique exists and can be applied to the wave equation without specific difficulty. For non periodic media, the generalization of the 1D case previously presented is difficult because no analytical solution to the cell (3) problem does exist and a direct construction similar to (4) is not possible. We have nevertheless developed an un-direct construction of the elastic tensor $\mathbf{c}^{\varepsilon_0}(\mathbf{x}, \mathbf{y})$ allowing non-periodic homogenization in a spatial dimension higher than 1. In the next section are shown two examples of applications in the case of the P-SV wave propagation in 2D.

Two examples

2.1 Random square example

The first model is a randomly generated 2D elastic medium. It consists of a $30 \times 30 km^2$ square matrix of 300×300 elements of constant elastic properties surrounded by a $10 km$ thick strip of constant elastic properties corresponding to P and S wave velocities of $5 km^{-1}$ and

Figure 2: “Random square” model. Only V_s is presented in this plot.

3.2 km^{-1} respectively and a density of 3000 kg m^{-3} (see Fig. 2). In each element of the matrix, the constant elastic properties and density are generated independently and randomly within $\pm 50\%$ of the outer square elastic values. We wish to propagate waves induced by an explosion located at $\mathbf{x}_0 = {}^t(20 \text{ km}, 20 \text{ km})$ (center of the square), the source time dependence being described by a Ricker wavelet (i.e. second derivative of a Gaussian function) with a central frequency of 1.5 Hz (corresponding roughly to a corner frequency of 3.6 Hz). Ignoring the fluctuation of velocity in the inner square and far away enough from the source, we can estimate the minimum wavelength λ_m of the wavefield generated by the explosion, to be roughly equal to 800 m. To obtain the promised accuracy of the SEM, we must generate a mesh based on square elements that honors all physical discontinuities. In this case, the geometry is so simple that the mesh generation is trivial, nevertheless, it imposes $100 \times 100 \text{ m}^2$ elements in the random matrix. Knowing that a degree 4 spectral element (a tensorial product of degree 4 polynomial basis) can roughly handle one wavelength per element, the mesh is oversampling the wavefield by a factor 8 in each direction leading to a factor 512 in numerical cost (a factor 8 in each direction and a factor 8 in time to match the Newmark time marching scheme stability condition). For this simple 2-D case, this factor 512 can be handle and this allows to compute a reference solution. Nevertheless, one can imagine that for a 3-D case, meshing the original model can quickly be out of reach for a reasonable computing power and the temptation would be high to either use a mesh that doesn’t honor the physical interfaces or to simplify the model.

We choose an $\varepsilon_0 = 0.4$ for the homogenization procedure (which means we filter out all oscillations in the medium that are twice smaller than the wavelength). The V_s and the total anisotropy (we define the total anisotropy as $\max \{|\mathbf{c}^* - \mathbf{c}_{iso}^*|\} / \max \{|\mathbf{c}^*|\}$ where \mathbf{c}_{iso}^* is the closest isotope elastic tensor to \mathbf{c}^*) of the homogenized media are shown Fig. 3. In Fig. 4 are shown the reference solution, the result of a run in the homogenized model and in a naively “filtered model” (we defined the filtered model as $\mathbf{c}^f = \mathcal{F}^{\varepsilon_0}(\mathbf{c})$. The is a low-pass filtered version of the original model) for a receiver located in ${}^t(37 \text{ km}, 20 \text{ km})$. It can seen that the homogenized solution is very accurate compared to the “filtered” solution.

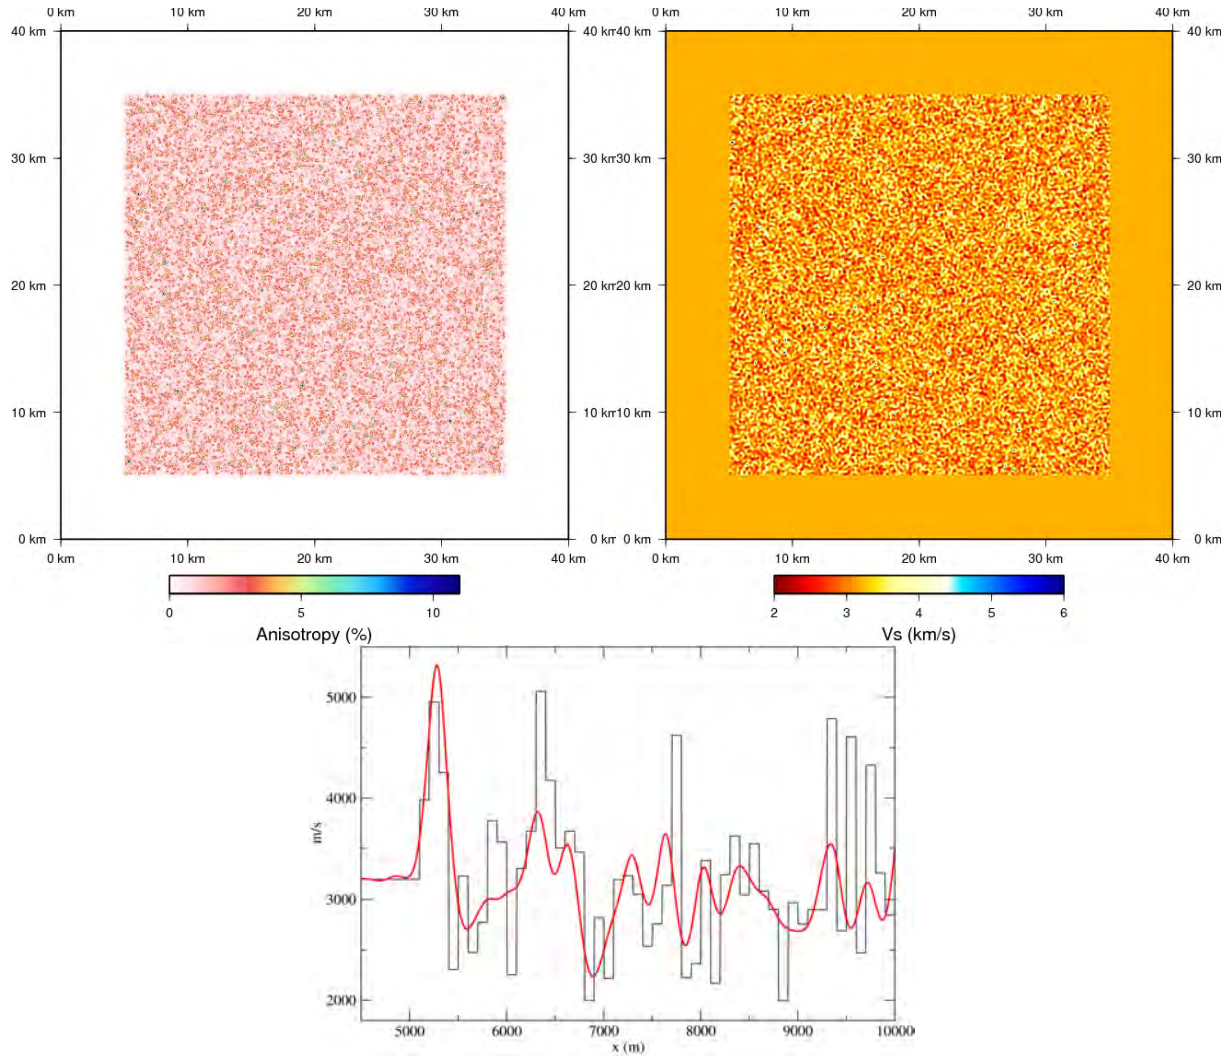

Figure 3: One of the V_s (top left plot) and total anisotropy (top right plot) of the homogenized model of the random square model. The bottom plot is a cut along $z = 32 \text{ km}$ in the original V_s (black line) and one of the V_s of the homogenized model (red line).

Marmousi2 model

Marmousi2 is a 2D elastic geological model derived by G.S. Martin from the original Marmousi model designed by the IFP (Fig. 5). The model contains thin (down to some meters) and complex structures. Even for a 2D model, the quadrangular mesh required for the Spectral Element Method is difficult to design and leads to a significant numerical cost (the reference solution computed here lasted for 7 days using 64 CPU). A sample of the mesh is shown Fig. 6, top plot. Here, the source is an explosion with, in time, a Ricker wavelet with central frequency of 6Hz (15Hz corner) leading to a minimum wavelength varying from 20m at the top of the model to 230m at the bottom. A snapshot of the propagating kinetic energy is shown in Fig. 8. The non-periodic homogenization is performed using a corner wavenumber of 0.017m^{-1} which implies a ε_0 varying from 3 at the top of the model to 0.25 at the bottom. One of the S velocity and the total anisotropy of the homogenized model are plotted in Fig. 7. For the homogenized model, the SEM mesh is a trivial regular mesh (see Fig. 6, bottom plot) leading to a lower numerical cost (1 hour using 64 CPU).

An example of traces is shown in Fig. 9. It appears that, even if the ε_0 is very poor at the

Figure 4: Traces (top: horizontal component, bottom: vertical component) for a receiver located in the middle of the model. The reference solution (black line), the homogenized solution (red line) and the “filtered” solution (green line, see text) are represented.

top of the medium, the seismograms obtained using the homogenization procedure are in very good agreement with the reference solution. The difference between those solutions and the “filtered” one is nevertheless less spectacular than for the random square example: this is due to the heterogeneities spectrum of the Marmousi2 model which has little power in the domain of the high wavenumbers.

3 Conclusions

We have presented a homogenization process for the wave equation allowing to up-scale 2D/3D non-periodic elastic models. This is a significant improvement of previous works which were limited to the layered non-periodic media case or to the 2D/3D periodic media case (more results can be found in [6, 7, 8]). To obtain a complete 2D/3D up-scaling tool, issues like boundary conditions in non-periodic 2-D/3-D cases (1-D case have been solved, [3, 5]) remain to be treated. This work should be useful for both forward and inverse problems.

4 Acknowledgments

This work was funded by the french ANR MUSE and the ANR mémé. Computations were done using the IPGP and the IDRIS clusters.

Keywords: wave reflection, dynamic coupling, discrete lattice, elastic continuum

Abstract. *Whereas the wave reflection and refraction at an interface of two continua has been studied in detail and has become a matter of text books, the wave reflection at an interface of a lattice and a continuum does not seem to have been systematically studied. The aim of this development is to close this gap. Two semi-infinite elastic media are considered in contact at a plane interface. One of these media is modelled using a rectangular network of identical masses and springs (hereafter called a lattice), whereas the other one is described by the equations of the classical elastic continuum. The wave reflection at the interface with the classical continuum is studied assuming that a plane harmonic wave falls from the lattice on the interface. The reflection coefficients for the reflected compressional and shear waves are found as functions of the wave frequency and of the incidence angle. It is shown that the reflection at low frequencies can be made very small by properly choosing the parameters of the continuum. However, the reflection coefficients inevitably grow with increase of the frequency and can reach the values close to one. This is to be expected as the classical continuum is capable of approximating a lattice only at relatively low frequencies.*

1 INTRODUCTION

The dynamic coupling of the discrete and continuum domains is widely used in concurrent multiscale simulations. The aim of such a coupling is to decrease the calculation time. This is achieved by breaking the computational domain into two parts. In the main part, where a detailed modeling is necessary, a discrete model is adopted. The rest of the domain is assumed to be occupied by a corresponding continuum. Often the role of this continuum is simply to serve as non-reflecting boundary or to pass the reflections from the outer boundaries of the computational domain. In either case the wave reflection from the fictitious boundary between the discrete and continuum domains should be minimized. This is the challenge researches are trying to cope with. A number of approaches have been introduced to couple discrete and continuum representations of materials. A coarse-grained molecular dynamics (CGMD) method has been proposed by Rudd and Broughton [3], an approach based on the Green's functions formalism has been proposed in [4] – [5] to derive the non-reflecting boundary conditions. E [6] and his co-workers contributed on the study of optimal matching conditions, Wagner and Liu introduced the bridging scale decomposition (BSL) method [7] which was developed further by Xiao and Belytschko [8]. However, most of the methods either have limitations in their application or are often too complicated to implement. Moreover, in most approaches the wave reflections either have not been yet properly studied in multidimensional cases or the non-reflecting boundary conditions have been introduced only for 1D case.

In this development a systematic investigation into the wave reflection at the interface of a square lattice composed of masses and springs and a classical isotropic continuum is presented. The parameters of the lattice are chosen such as to assure that in the long-wave approximation the lattice is reduced to the continuum, with which it is coupled. The main aim of this investigation is to demonstrate the poor ability of the classical continuum to absorb high-frequency waves in the lattice. Such demonstration is necessary to motivate the use of generalized continua at the discrete-continuum interfaces. The promising character of the latter approach has recently been demonstrated in [9], where it has been shown that the reflections from the boundary between the 1D chain of masses and springs and a gradient continuum of the second order can be eliminated at the entire frequency band.

Figure 1: Coupled discrete and continuum domains (left) and wave reflection and transmission at the interface (right).

Two elastic semi-infinite half-spaces in contact are considered in this paper (see Figure 1). One of the half-spaces is described by the equations of motion of the classical continuum and another one is modelled using the system of masses and translational springs that form a so-called square lattice. It is assumed that the plane harmonic wave, either longitudinal or transversal

one, propagates in the lattice towards the interface between two domains. The energy of the reflected longitudinal and transversal waves is studied as a function of the frequency and the angle of incidence θ_0 in terms of the energy reflection coefficient.

The paper is organized as follows. First, the governing equations for the lattice and the correspondence between the parameters of the lattice and of the continuum in the long-wave limit are introduced. Thereafter the propagation characteristics of the body waves in the lattice are derived. The following boundary conditions are introduced: the continuity of forces and displacements at the interface. Then the equations of motion of the continuum are solved with the certain boundary conditions and the displacements in the continuum in the form of integrals are derived. Then the integrals for the displacements at the interface are evaluated. The system of boundary conditions is applied to find the amplitudes of the reflected waves. Then the energy reflection coefficients are introduced. Finally, the results and conclusions are presented.

2 GOVERNING EQUATIONS FOR THE LATTICE

The inner cell of the square lattice consists of identical masses M and translational springs: axial κ_{axi} and diagonal κ_{dia} . The derivation of the equations of motion for the square lattice with translational and shear springs can be found in [1]. It is assumed that the dynamic behaviour of the lattice corresponds to that of the isotropic classical elastic continuum in the long-wave limit. This assumption requires the following relations between the parameters of the lattice and of the continuum [1]:

$$M = \rho d^2 h, \quad \kappa_{axi} = 2\kappa_{dia}, \quad \kappa_{dia} = h\mu, \quad 2\kappa_{dia} = h(\lambda + \mu), \quad (1)$$

where ρ is the mass density of the continuum, λ and μ are Lamé's constants of the elastic continuum, d is the inter-particle distance in the lattice along the axes, h is a parameter of length in the direction normal to the $[x, y]$ plane. The introduction of this parameter is required to couple the 2D-lattice with the 3D-continuum. It follows from the equalities (1) that $\lambda = \mu$ in the continuum that corresponds to such a lattice in the long-wave limit.

Figure 2: Inner (left) and boundary (right) cells of the lattice.

We denote $\kappa = \kappa_{axi} = 2\kappa_{dia}$. Then the equations of motion for the inner cell of the lattice (depicted in the left part of Figure 2) read

$$M d_{tt} u_x^{(m,n)} = \kappa/4 \left(-12u_x^{(m,n)} + 4u_x^{(m+1,n)} + 4u_x^{(m-1,n)} + u_x^{(m+1,n+1)} + u_x^{(m+1,n-1)} + \right. \quad (2) \\ \left. + u_x^{(m-1,n+1)} + u_x^{(m-1,n-1)} + u_y^{(m+1,n+1)} + u_y^{(m-1,n-1)} - u_y^{(m+1,n-1)} - u_y^{(m-1,n+1)} \right),$$

$$Md_{tt}u_y^{(m,n)} = \kappa/4 \left(-12u_y^{(m,n)} + 4u_y^{(m,n+1)} + 4u_y^{(m,n-1)} + u_y^{(m+1,n+1)} + u_y^{(m+1,n-1)} + u_y^{(m-1,n+1)} + u_y^{(m-1,n-1)} - u_x^{(m+1,n-1)} - u_x^{(m-1,n+1)} + u_x^{(m+1,n+1)} + u_x^{(m-1,n-1)} \right).$$

Here $u_x^{(m,n)}(t)$, $u_y^{(m,n)}(t)$ are the displacements of the cell with the coordinates (md, nd) .

The mass of the boundary element is taken as a half of the mass of the inner cell and the stiffness of the axial springs at a boundary is taken as $\kappa/2$ (see the right part of Figure 2). The forces F_x^m , F_y^m act on the masses at the interface from the continuum. The equations of motion for the boundary cell read

$$\begin{aligned} \frac{1}{2}Md_{tt}u_x^{(m,0)} &= -\kappa/4 \left(6u_x^{(m,0)} - 2u_x^{(m+1,0)} - 2u_x^{(m-1,0)} + u_y^{(m+1,-1)} - u_x^{(m+1,-1)} - \right. \\ &\quad \left. - u_x^{(m-1,-1)} - u_y^{(m-1,-1)} \right) - F_x^m, \\ \frac{1}{2}Md_{tt}u_y^{(m,0)} &= -\kappa/4 \left(6u_y^{(m,0)} - 4u_y^{(m,-1)} - u_y^{(m+1,-1)} + u_x^{(m+1,-1)} - u_y^{(m-1,-1)} - \right. \\ &\quad \left. - u_x^{(m-1,n-1)} \right) - F_y^m. \end{aligned} \quad (3)$$

We consider first a plane longitudinal incident wave that propagates towards the continuum domain with the angle of incidence $\theta = \theta_0$. Then we have two reflected waves, namely the longitudinal and transversal ones (see the right part of Figure 1). We introduce the indexes I , L and T for the incident, longitudinal and transversal waves. Then the displacements in the lattice read

$$\begin{aligned} u_x^{(m,n)} &= e^{i\omega t} \left(A_I e^{-i(mK_x^I + nK_y^I)} + A_L e^{-i(mK_x^L - nK_y^L)} + A_T e^{-i(mK_x^T - nK_y^T)} \right), \\ u_y^{(m,n)} &= e^{i\omega t} \left(B_I e^{-i(mK_x^I + nK_y^I)} - B_L e^{-i(mK_x^L - nK_y^L)} - B_T e^{-i(mK_x^T - nK_y^T)} \right), \end{aligned} \quad (4)$$

where $K_x^I = k_0 \sin \theta_0$, k_0 is a dimensionless wavenumber of the longitudinal waves (wavenumber multiplied by d , hereafter we will work with dimensionless wavenumbers), and according to the Snell's law $K_x^I = K_x^L = K_x^T = K_x$. The angle of reflection of longitudinal waves is then the same as the angle of incidence and $K_y^I = K_y^L = k_0 \cos \theta_0$. We denote the angle of reflection of transversal waves as $\theta = \theta_2$ and wavenumber $k = k_2$. Then $K_x^T = k_2 \sin \theta_2$, $K_y^T = k_2 \cos \theta_2$.

The wavenumber k_0 can be found numerically from the dispersion relation [1] for longitudinal waves:

$$4 \cos(k_0 \sin \theta_0) \cos(k_0 \cos \theta_0) + 2 \cos(k_0 \sin \theta_0) + 2 \cos(k_0 \cos \theta_0) - 8 + \Omega^2 = 0, \quad (5)$$

where the angle of incidence θ_0 and the dimensionless frequency $\Omega = \omega d/c_T$ are input data, $c_T = \sqrt{\mu/\rho}$ is the shear wave velocity in the elastic continuum. As follows from the equalities (1), $\Omega^2/2 = \omega^2 M/\kappa$.

The reflection angle θ_2 and wavenumber k_2 can be found from the dispersion equation for transversal waves

$$2 \cos(k_2 \sin \theta_2) + 2 \cos(k_2 \cos \theta_2) - 4 + \Omega^2 = 0, \quad (6)$$

with the aid of the relation $k_2 = k_0 \sin \theta_0 / \sin \theta_2$ that follows from the Snell's law.

The dependence of the wavenumbers k_0 and k_2 on the frequency Ω for different incidence angles is depicted in Figure 2.

Figure 3: Wavenumbers of the longitudinal and transversal waves versus frequency for different angles of incidence

Substitution of the incident longitudinal (transversal) wave into the equations of motion (2) allows to obtain the relation between the x - and y -components of the amplitudes of the displacements. This gives:

$$\begin{aligned} D_L &= \frac{B_I}{A_I} = \frac{B_L}{A_L} = \frac{-\Omega^2/2 + 3 - \cos(K_x)(2 + \cos(K_y^L))}{-\sin(K_x) \sin(K_y^L)}, \\ D_T &= \frac{B_T}{A_T} = \frac{-\Omega^2/2 + 3 - \cos(K_x)(2 + \cos(K_y^T))}{-\sin(K_x) \sin(K_y^T)}. \end{aligned} \quad (7)$$

In correspondence with the incident wave the forces F_x^m, F_y^m are expressed as follows:

$$F_x^m = F_x^0(\omega) \exp(-imK_x) \exp(i\omega t), \quad F_y^m = F_y^0(\omega) \exp(-imK_x) \exp(i\omega t). \quad (8)$$

Substitution of the displacements (4) in the equations of motion for the boundary element (3) leads to the system of two algebraic equations with four variables, namely A_L, A_T, F_x^0, F_y^0 . We need two more equations to solve the system. They come from the second set of the boundary conditions that provides the continuity of displacements at the interface $y = 0$. This will be discussed in Section 4.

3 GOVERNING EQUATIONS FOR THE CONTINUUM

Equations of motion of the elastic continuum read [2]

$$\begin{aligned} \tilde{\mu} (\partial_{xx} u_x + \partial_{yy} u_x) + (\tilde{\lambda} + \tilde{\mu}) (\partial_{xx} u_x + \partial_{yx} u_y) &= \rho \partial_{tt} u_x, \\ \tilde{\mu} (\partial_{xx} u_y + \partial_{yy} u_y) + (\tilde{\lambda} + \tilde{\mu}) (\partial_{xy} u_x + \partial_{yy} u_y) &= \rho \partial_{tt} u_y, \end{aligned} \quad (9)$$

where u_x and u_y are the x - and y - components of the vectorial displacement in the continuum. We introduce small dissipation χ : $\tilde{\lambda} = \lambda + \chi \partial_t$, $\tilde{\mu} = \mu + \chi \partial_t$. λ and μ are Lamé's coefficients and $\lambda = \mu$, as it has been discussed in the previous section (1). The need to introduce a small dissipation will become clear in the course of derivation of the response of the continuum.

There is an infinite number of the points of contact between the discrete lattice and the continuum at the interface $y = 0$ (see Figure 1). At each point the forces F_x^j, F_y^j (8) act on the continuum from the lattice. We assume that there is finite contact area between each mass of the lattice and the continuum in order to avoid singularities in the solution for the classical

continuum (if this were not done, the contact forces would turn to zero). For this reason we introduce parameter b — the half-width of the contact of the continuum and one particle of the lattice at the interface. We also choose the boundary conditions such as to assure that the contact force is independent of b :

$$\int_{-b}^b \sigma dx = \frac{F}{h}. \quad (10)$$

Then the natural boundary conditions at the interface can be formulated:

$$\sigma_{yy}(x, 0) = - \sum_{j=-\infty}^{\infty} \frac{F_y^j}{2bh} H(b - |x - jd|), \quad \sigma_{yx}(x, 0) = - \sum_{j=-\infty}^{\infty} \frac{F_x^j}{2bh} H(b - |x - jd|), \quad (11)$$

where $\sigma_{yy}(x, y, t)$ is the normal stress, $\sigma_{yx}(x, y, t)$ is the shear stress, $H(x)$ is the unit step function (chosen for the sake of simplicity), j is an integer.

We also impose the correspondence between the stresses σ_{yy} , σ_{yx} and the forces F_y^j , F_x^j in the long-wave limit. This can be achieved if we take $b = d/2$.

We consider the following displacement representation:

$$u_x(x, y, t) = \partial_x \Phi(x, y, t) + \partial_y \Psi(x, y, t), \quad u_y(x, y, t) = \partial_y \Phi(x, y, t) - \partial_x \Psi(x, y, t). \quad (12)$$

Then the stresses σ_{yy} and σ_{yx} are related to the displacement potentials Φ , Ψ in the following way:

$$\sigma_{yy} = \tilde{\lambda}(\partial_{xx} + \partial_{yy})\Phi + 2\tilde{\mu}(\partial_{yy}\Phi - \partial_{yx}\Psi), \quad \sigma_{xy} = \tilde{\mu}(2\partial_{xy}\Phi + \partial_{yy}\Psi - \partial_{xx}\Psi). \quad (13)$$

This representation satisfies the equations of motion (9) if

$$\partial_{tt}\Phi - (\tilde{\lambda} + 2\tilde{\mu})/\rho(\partial_{xx} + \partial_{yy})\Phi = 0, \quad \partial_{tt}\Psi - \tilde{\mu}/\rho(\partial_{xx} + \partial_{yy})\Psi = 0. \quad (14)$$

The solutions of the above equations can be found in the form

$$\Phi(x, y, t) = \phi(x, y)e^{i\omega t}, \quad \Psi(x, y, t) = \psi(x, y)e^{i\omega t}. \quad (15)$$

We substitute (15) in (14) and (13) in (11), then we apply the exponential Fourier transform over the spatial coordinate y defined as

$$\phi^*(k, y) = \int_{-\infty}^{\infty} e^{ikx} \phi(x, y) dx, \quad \psi^*(k, y) = \int_{-\infty}^{\infty} e^{ikx} \psi(x, y) dx \quad (16)$$

and obtain the equations

$$\partial_{yy}\phi^* - \zeta_L^2\phi^* = 0, \quad \partial_{yy}\psi^* - \zeta_T^2\psi^* = 0 \quad (17)$$

with the boundary conditions at the interface $y = 0$

$$\begin{aligned} (\tilde{\lambda} + 2\tilde{\mu})\partial_{yy}\phi^* - \tilde{\lambda}k^2\phi^* + 2\tilde{\mu}ik\partial_y\psi^* &= - \sum_{j=-\infty}^{\infty} F_y^0 e^{-ijdK_x} (e^{ik(jd+b)} - e^{ik(jd-b)}) / idhk, \\ \tilde{\mu}(\partial_{yy}\psi^* + k^2\psi^* - 2ik\partial_y\phi^*) &= - \sum_{j=-\infty}^{\infty} F_x^0 e^{-ijdK_x} (e^{ik(jd+b)} - e^{ik(jd-b)}) / idhk, \end{aligned} \quad (18)$$

where $\zeta_L = \sqrt{k^2 - \omega^2/\tilde{c}_L^2}$, $\zeta_T = \sqrt{k^2 - \omega^2/\tilde{c}_T^2}$, $\tilde{c}_L^2 = c_L^2(1 + i\chi^*)$, $\tilde{c}_T^2 = c_T^2(1 + i\chi^*)$, $\chi^* = \omega\chi/\mu$; $c_L = \sqrt{(\lambda + 2\mu)/\rho}$ and $c_T = \sqrt{\mu/\rho}$ are the compressional and shear wave velocities in the classical continuum, respectively.

The general solutions of the equations (17), taking into account that the functions ϕ^* , ψ^* should have finite values when y goes to ∞ , can be written in the form

$$\phi^*(k, y) = A(k, \omega) \exp(-\zeta_L y), \quad \psi^*(k, y) = B(k, \omega) \exp(-\zeta_T y), \quad (19)$$

provided that the real parts of the radicals ζ_L , ζ_T are assumed positive.

We find the functions $A(k, \omega)$ and $B(k, \omega)$ that satisfy the boundary conditions (18). Then we substitute (15) to (12) and apply the Fourier transform to the result in order to obtain the Fourier transforms of the displacements u_x , u_y :

$$\begin{aligned} u_x^* &= (-ik\phi^* + \partial_y \psi^*) = \left(F_x^0 \zeta_T (2k^2 e^{-\zeta_L y} - \gamma e^{-\zeta_T y}) + F_y^0 ik (2\zeta_T \zeta_L e^{-\zeta_T y} - \gamma e^{-\zeta_L y}) \right) S, \\ u_y^* &= (ik\psi^* + \partial_y \phi^*) = \left(F_x^0 ik (\gamma e^{-\zeta_L y} - 2\zeta_T \zeta_L e^{-\zeta_T y}) + F_y^0 \zeta_L (2k^2 e^{-\zeta_T y} - \gamma e^{-\zeta_L y}) \right) S, \end{aligned} \quad (20)$$

where

$$S = \frac{\sum_{j=-\infty}^{\infty} e^{ikjd} (e^{-ikb} - e^{ikb})}{idhk\mu(1 + i\chi^*)\Delta}, \quad \gamma = 2k^2 - \omega^2/\tilde{c}_T^2, \quad \Delta = \gamma^2 - 4k^2\zeta_T\zeta_L. \quad (21)$$

The inverse Fourier transform is applied to derive the displacements in the continuum according to the following relations:

$$u_x(x, y, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-ikx} u_x^*(x, y, t) dk, \quad u_y(x, y, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-ikx} u_y^*(x, y, t) dk. \quad (22)$$

4 COUPLING OF THE DOMAINS

The continuity of forces and displacements is required at the boundary $y = 0$. We have smeared the contact between the lattice and the continuum at the interface to avoid singularities in the solution for the continuum and this causes the ambiguity of the boundary problem statement.

We assume that the displacements of the masses at the boundary in the lattice are equal to the displacements of the continuum in the points of contact:

$$u_x^{(m,0,t)} = u_x(md, 0, t), \quad u_y^{(m,0,t)} = u_y(md, 0, t). \quad (23)$$

Note that one could also equate the displacements in the lattice $u_x^{(m,0,t)}$, $u_y^{(m,0,t)}$ to the displacements $u_x(md, 0, t)$, $u_y(md, 0, t)$ averaged over the width of the contact $2b$.

We substitute the displacements in the lattice (4) into (23) and apply the results of the previous section. Then the equations (23) transform to the following equations:

$$\begin{aligned} A(f) e^{-iK_x m} &= \int_{-\infty}^{\infty} F(f) e^{-ikmd} \sum_{j=-\infty}^{\infty} e^{ikjd} e^{-iK_x j} dk, \quad f = 1, 2, \\ A^1 &= A_I + A_L + A_T, \quad A^2 = A_I D_L - A_L D_L - A_T D_T, \\ F^1(k, \omega) &= \frac{(2k^2 - \gamma)\zeta_T F_x^0 + ik(2\zeta_T \zeta_L - \gamma) F_y^0}{2\pi ikdh\mu(1 + i\chi^*)\Delta} (e^{-ikb} - e^{ikb}), \\ F^2(k, \omega) &= \frac{-ik(2\zeta_T \zeta_L - \gamma) F_x^0 + (2k^2 - \gamma)\zeta_L F_y^0}{2\pi ikdh\mu(1 + i\chi^*)\Delta} (e^{-ikb} - e^{ikb}). \end{aligned} \quad (24)$$

Let us multiply the left and the right parts of the equations (24) by $e^{iK_x m}$ and introduce $l = j - m$. Then the equations (24) can be rewritten as follows:

$$A^{(f)} = \int_{-\infty}^{\infty} F^{(f)} \sum_{l=-\infty}^{\infty} e^{il(kd-K_x)} dk. \quad (25)$$

We divide this equations by h , apply the relation $\kappa = 2\mu h$ and introduce dimensionless variables $K = kd$, $\tilde{F} = F/\kappa/h$, $b_{dl} = b/d$. After that the equations (25) take the form

$$A^1/h = C_1 \tilde{F}_x^0 + C_2 \tilde{F}_y^0, \quad A^2/h = C_3 \tilde{F}_x^0 + C_4 \tilde{F}_y^0, \quad C_3 = -C_2. \quad (26)$$

The coefficients C_1, C_2, C_4 should be evaluated:

$$\begin{aligned} C_1 &= \frac{1}{\pi i(1+i\chi^*)} \sum_{l=-\infty}^{\infty} e^{-ilK_x} \int_{-\infty}^{\infty} \frac{F_1(K, \Omega)}{K\Delta} e^{ilK} \left(e^{-iKb_{dl}} - e^{iKb_{dl}} \right) dK, \\ C_2 &= \frac{1}{\pi i(1+i\chi^*)} \sum_{l=-\infty}^{\infty} e^{-ilK_x} \int_{-\infty}^{\infty} \frac{F_2(K, \Omega)}{\Delta} e^{ilK} \left(e^{-iKb_{dl}} - e^{iKb_{dl}} \right) dK, \\ C_4 &= \frac{1}{\pi i(1+i\chi^*)} \sum_{l=-\infty}^{\infty} e^{-ilK_x} \int_{-\infty}^{\infty} \frac{F_1(K, \Omega)}{K\Delta} e^{ilK} \left(e^{-iKb_{dl}} - e^{iKb_{dl}} \right) dK, \end{aligned} \quad (27)$$

where $F_1 = \beta_T^2 \sqrt{K^2 - \beta_T^2}$, $F_2 = i(2\sqrt{K^2 - \beta_T^2} \sqrt{K^2 - \beta_L^2} - 2K^2 + \beta_T^2)$, $F_4 = \beta_T^2 \sqrt{K^2 - \beta_L^2}$ are symmetric functions, $\beta_L^2 = \Omega^2 c_T^2 / c_L^2 / (1 + i\chi^*)$, $\beta_T^2 = \Omega^2 / (1 + i\chi^*)$, $\Delta = (2K^2 - \beta_T^2)^2 - 4K^2 \sqrt{K^2 - \beta_T^2} \sqrt{K^2 - \beta_L^2}$.

It has been checked that the direct numerical calculation of the sums of integrals (27) is very time-consuming because one has to take a large number of the members of summation till the sum converges. To avoid this we carry out the summation analytically. We rewrite (27) in the following way:

$$\begin{aligned} C_{1(4)} &= -\frac{1}{\pi i(1+i\chi^*)} \left(\sum_{l=1}^{\infty} \left(e^{ilK_x} + e^{-ilK_x} \right) \int_{-\infty}^{\infty} \frac{F_{1(4)}(K)}{K\Delta} \left(e^{iK(b_{dl}-l)} + e^{iK(b_{dl}+l)} \right) dK + C_{1(4)0} \right), \\ C_2 &= -\frac{1}{\pi i(1+i\chi^*)} \sum_{l=1}^{\infty} \left(e^{ilK_x} - e^{-ilK_x} \right) \int_{-\infty}^{\infty} \frac{F_2(K)}{\Delta} \left(e^{iK(b_{dl}+l)} - e^{iK(b_{dl}-l)} \right) dK, \\ C_{1(4)0} &= \int_{-\infty}^{\infty} \frac{F_{1(4)}(K)}{K\Delta} \left(e^{iKb_{dl}} - e^{-iKb_{dl}} \right) dK = 2 \int_{-\infty}^{\infty} F_{1(4)}(K) \frac{e^{iKb_{dl}-1}}{K\Delta} dK. \end{aligned} \quad (28)$$

The integrands in (28) are multiple-valued functions because of the presence of the radicals. They become infinite at so-called Rayleigh poles which are the simple zeros of the equation $\Delta(K) = 0$. This equation in the case of zero damping has been examined by Achenbach [2]. There are two real roots: $K = \pm \omega d / c_R = \Omega c_T / c_R$, where c_R is the velocity of the Rayleigh waves. With non-zero damping the roots move to the lower and upper half-planes of the complex plane: $K = \pm \beta_R$, $\beta_R = \Omega c_T / c_R / (1 + i\mu_{dl})$. The branch points are $K = \pm \beta_L$, $K = \pm \beta_T$. We apply the contour integration around the poles in order to evaluate the following integrals from (28):

$$\begin{aligned} J_{1(4)}^1 &= \int_{-\infty}^{\infty} \frac{F_{1(4)}(K)}{K\Delta} e^{iK(b_{dl}+l)} dK, \quad J_{1(4)}^2 = \int_{-\infty}^{\infty} \frac{F_{1(4)}(K)}{K\Delta} e^{iK(b_{dl}-l)} dK, \\ J_2^1 &= \int_{-\infty}^{\infty} \frac{F_2(K)}{\Delta} e^{iK(b_{dl}+l)} dK, \quad J_2^2 = \int_{-\infty}^{\infty} \frac{F_2(K)}{\Delta} e^{iK(b_{dl}-l)} dK, \quad J_0 = \int_{-\infty}^{\infty} F_{1(4)}(K) \frac{e^{iKb_{dl}-1}}{K\Delta} dK. \end{aligned} \quad (29)$$

Figure 4: Contour of integration in the upper half-plane

The contour of integration and location of singular points for $J_{1(4)}^1$ are depicted in Figure 4. The contour for J_2^1 and J_0 is quite the same with the only exception that these integrals do not have a pole at $K = 0$. We integrate $J_{1(4)}^2$ and J_2^2 along the contour in the lower half-plane. The integration along the circular contours $c1$, $c2$ around the branch points vanishes as their radius decreases, the integration along the circular contours $c3$, $c4$, $c5$ vanishes as $|K| \rightarrow \infty$. Thus,

$$\oint f(K) dK = \left(\int_{c0} + \int_1 + \int_2 + \int_3 + \int_4 + \int_{-\infty}^{\infty} \right) f(K) dK = 2\pi i \text{Res}[f(K), K = -\beta_R], \quad (30)$$

where $\int_{-\infty}^{\infty}$ is to be understood in the sense of Cauchy principal value. The pole $K = 0$ was artificially introduced as the original integrals $C_{1(4)}$ from (27) do not have this pole. In accordance with this fact the integrals around the circular contour $c0$ in the upper and in the lower half-planes have the same absolute value but are of the opposite sign and thus vanish in the sum $J_{1(4)}^1 + J_{1(4)}^2$.

$\text{Im}(\sqrt{K^2 - \beta_L^2}) = 0$ on the contours of integration 1–2 and $\text{Im}(\sqrt{K^2 - \beta_T^2}) = 0$ on the contours of integration 3–4. These equalities hold true if $2\text{Im}(K)\text{Re}K = \alpha_i$, $i = 1, 2$, where $\alpha_1 = \text{Im}(\beta_L^2) = -\Omega^2 \chi^* c_T^2 / c_L^2 (1 + \chi^{*2})$, $\alpha_2 = \text{Im}(\beta_T^2) = -\Omega^2 \chi^* / (1 + \chi^{*2})$. The general representation of K at the contours 1–4 is $K = a + i\alpha/2/a$, where $a = \text{Re}(K)$ and $\alpha = \alpha_1$ or α_2 are negative. Thus $|\exp(i l K)| = |\exp(-\alpha/2/a)| < 1$. Now we swap the order of summation and integration and evaluate the sums from (28) as the sums of geometric progression:

$$\sum_{l=1}^{\infty} (e^{ilKx} \pm e^{-ilKx}) e^{ilK} = \frac{e^{i(Kx+K)}}{1 - e^{i(Kx+K)}} \pm \frac{e^{i(K-Kx)}}{1 - e^{i(K-Kx)}}. \quad (31)$$

In the lower half-plane we have K with the opposite sign, $|\exp(-ilK)| < 1$ and we can apply the formulae of the sum of geometric progression as well.

The evaluation accomplished in Eq (31) would have been impossible if no damping were present in the continuum. that is why it has been introduced in Section 3.

5 THE REFLECTION COEFFICIENTS

The amplitude reflection coefficient is found as the absolute value of the ratio of the complex amplitudes of reflected and incident waves and is given as $R_L = |A_L/A_I|$ for longitudinal wave

and as $R_T = |A_T/A_I|$ for transversal wave. These coefficients can be found by solving the system of four linear equations that constitute the boundary conditions. We substitute (4) and (8) into (3) and divide the whole equations by κA_I . Then we take the equations (26) and divide them by A_I/h . Finally, we have the system of four equations:

$$\begin{cases} a_{11}\tilde{A}_L + a_{12}\tilde{A}_T + \tilde{F}_x = b_1, & a_{21}\tilde{A}_L + a_{22}\tilde{A}_T + \tilde{F}_y = b_2, \\ \tilde{A}_L + \tilde{A}_T - C_1\tilde{F}_x - C_2\tilde{F}_y = -1, & \tilde{A}_L D_L + \tilde{A}_T D_T + C_3\tilde{F}_x + C_4\tilde{F}_y = D_L, \end{cases} \quad (32)$$

where $\tilde{A}_{L(T)} = A_{L(T)}/A_I$, $\tilde{F}_{x(y)} = F_{x(y)}^0/\kappa/A_I$ are the unknowns and

$$\begin{aligned} a_{11} &= -\cos(K_x) - 0.25\Omega^2 + 1.5 + 0.5 \exp(iK_y^L)(iD_L \sin(K_x) - \cos(K_x)), \\ a_{12} &= -\cos(K_x) - 0.25\Omega^2 + 1.5 + 0.5 \exp(-iK_y^T)(iD_T \sin(K_x) - \cos(K_x)), \\ a_{21} &= D_L(0.25\Omega^2 - 1.5 + \exp(-iK_y^L)) + 0.5 \exp(-iK_y^L)(D_L \cos(K_x) - i \sin(K_x)), \\ a_{22} &= D_T(0.25\Omega^2 - 1.5 + \exp(-iK_y^L)) + 0.5 \exp(-iK_y^L)(D_T \cos(K_x) - i \sin(K_x)), \\ b_1 &= \cos(K_x) + 0.25\Omega^2 - 1.5 + 0.5 \exp(iK_y^L)(iD_L \sin(K_x) + \cos(K_x)), \\ b_2 &= D_L(0.25\Omega^2 - 1.5 \exp(iK_y^L)) + 0.5 \exp(iK_y^L)(D^L \cos(K_x) + i \sin(K_x)). \end{aligned} \quad (33)$$

The input data for the system (32) includes the angle of incidence θ_0 and the dimensionless frequency Ω . The admissible values of θ_0 are between 0 and $\pi/2$ and that of Ω are between 0 and the cut-off frequency Ω_c up to which the longitudinal waves propagate.

We consider the flux of energy through the remote area in the lattice parallel to the interface. The flux of the wave energy is proportional to the square of its amplitude. The energy reflection coefficient is found as the ratio of the energy fluxes of reflected and incident waves and is given as $P_L = R_L^2$ and $P_T = \xi R_T^2$, where

$$\xi = \frac{4D_T^2 \sin(K_y^T) + \sin(K_x + K_y^T)(2D_T + D_T^2 + 1) \sin(K_x - K_y^T)(2D_T - D_T^2 - 1)}{4D_L^2 \sin(K_y^L) \sin(K_x + K_y^L)(2D_L + D_L^2 + 1) + \sin(K_y^L - K_x)(1 + D_L^2 - 2D_L)}. \quad (34)$$

Figure 5: The energy reflection coefficients for different angles of incidence

To demonstrate the results the following parameters for the continuum are taken: $\rho = 2300 \text{ kg/m}^3$, $E = 230 \text{ GPa}$. As coefficient $\mu = 0.5E/(1+\nu)$ should be equal to $\lambda = \nu E/(1+\nu)(1-2\nu)$, the Poisson's ratio of the continuum is $\nu = 0.25$. The damping parameter $\mu^* = 1000 \text{ Pa}\cdot\text{sec}$. The period of the lattice $d = 0.05 \text{ m}$. The values of the parameter $\mu_{dl} = \omega\mu^*/\mu = \Omega c_T \mu^*/d/\mu$ lie between 0 and 0.02 depending on the frequency Ω .

The dependence of the energy reflection coefficient P (either P_L or P_T) on the dimensionless frequency Ω for three different angles of incidence is depicted in Figure 5. One can see that there is almost no reflection at low frequencies, where the continuum is capable of approximating the lattice, and at higher frequencies the reflection grows rapidly as the dispersion properties of the lattice and the continuum differ a lot. One can also note that the reflection of transversal wave is less than that of the longitudinal one. The graph of P_T stops at a lower frequency than that of P_L as the cut-off frequency of the transversal waves is lower than that of the longitudinal waves.

Figure 6: The energy reflection coefficient

For the angles of incidence that are larger than $\pi/4$ we have obtained non-physical results: the reflected energy exceeds the energy of the incident wave. This anomalous reflection is depicted in Figure 6. We do not yet know the genuine explanation of this result. Most likely, it is a consequence of the boundary conditions at the interface.

The case when transversal wave falls on the interface from the lattice has also been examined. The energy reflection coefficients for different angles of incidence are depicted in Figure 7.

Figure 7: The energy reflection coefficients for different angles of incidence

Figure 8: The energy reflection coefficient

The reflection of the longitudinal waves is negligible when $\theta_0 = 0.01$. In the cases $\theta_0 = \pi/4$ and $\theta_0 = 1.4$ the longitudinal waves do not reflect.

The anomalous reflection has also been observed in this case (see Figure 8).

6 CONCLUSIONS

The motivation for this study has been to facilitate the development of the multi-scale numerical approaches that are becoming increasingly popular in investigations into the details of dynamic deformations of various materials. Specifically, this paper is envisaged to be of interest for those researchers who employ the discrete-continuum models in order to minimize the huge computational costs associated with the detailed discrete modelling. The continuum domain in such models is introduced in order to minimize the size of the discrete domain as much as possible thereby significantly reducing the computation time. To achieve this, however, the continuum domain should not introduce spurious reflections at as broad as possible frequency range. In this paper, the capabilities of the classical continuum have been assessed to comply with this requirement. To this end, the reflection of plane harmonic waves at the interface of the square lattice and the classical continuum has been studied. A method has been proposed to couple the domains in such a manner that no singularities occur due to the point-like character of particles in the lattice. It has been shown that while the classical continuum can serve as a non-reflecting boundary for the lattice at low frequencies, it cannot absorb higher frequency waves. Moreover, it has been found that due to the ambiguity in the formulation of the boundary conditions at the discrete-continuum interface, the energy of the reflected waves can be mathematically predicted in some cases to be larger than that of the incident waves — a result that is physically unacceptable. Given the above-formulated results, it can be concluded that the classical continuum is not the most desirable model for assuring the non-reflective conditions at a wide frequency band. One of the attractive alternatives could be a gradient continuum that, according to a recent study carried out in the 1D framework [9], can be expected to match the lattice at a wide frequency band. Additionally, no singularities occur at the contact between a point load and a surface of a gradient continuum. The authors of this contribution are currently investigating whether gradient continua will be up to these expectations in the multidimensional case.

Keywords: Elastic waves, finite elements, plane wave basis, Lagrange multipliers, layered media, free surface, Rayleigh waves.

Abstract. *This work deals with the extension of the Partition of Unity Finite Element Method (PUFEM) to solve wave problems involving propagation, transmission and reflection in layered elastic media. Problems dealing with wave reflection at a free surface and propagation of pure Rayleigh waves are also considered. The proposed method consist to apply the plane wave basis decomposition to the elastic wave equation in each layer of the elastic medium and then enforce necessary continuity conditions at the interfaces through the use of Lagrange multipliers. The accuracy and effectiveness of the proposed technique is determined by comparing results for selected problems with known analytical solutions.*

1 INTRODUCTION

Plane wave basis finite elements capable of containing many wavelengths per nodal spacing were developed and implemented to solve wave scattering problems in homogeneous elastic media [1, 2, 3]. These elements allow us to relax the traditional requirement of around ten nodal points per wavelength and therefore lead to huge savings in computing effort. Many other techniques were developed for the same objective, such as the Discontinuous Enrichment Method [4], the Ultra Weak Variational Formulation [5] and the Partition of Unity Boundary Element Method [6], for example.

In this work, problems of practical interest such as those encountered in soil wave propagation and scattering are considered. For a layered elastic medium, the displacement field is expressed as a combination of propagating planar pressure and shear waves within each homogeneous layer. At the interface between two layers, necessary continuity conditions are enforced through the use of Lagrange multipliers, which are also approximated using the plane wave decomposition approach [7].

After presenting relevant theory, some preliminary numerical tests are carried out. The first problem deals with elastic waves propagating in a homogeneous medium and hitting a plane free surface, for angles of incidence above and below the critical angle. The second test problem concerns the propagation of pure Rayleigh waves, which are known to propagate with a specific wave number different from the pressure and shear wave numbers. Last, reflection and transmission of elastic waves at a plane interface between two elastic media will be considered. For the first two problems, there is no need to incorporate the Lagrange multipliers as no inhomogeneity is involved in the problems unlike in the third one where they are necessary to ensure compatibility conditions at the interface.

2 MATHEMATICAL FORMULATIONS

Let Ω be a space domain in \mathbb{R}^2 occupied by an elastic inhomogeneous medium whose elastic properties are piecewise constant such as, for example, a multilayered soil medium where each layer is homogenous. It is then adequate to assume that the domain Ω is composed of multiple homogeneous linear and isotropic subdomains Ω_j with the Lamé coefficients λ_j and μ_j , and density ρ_j . In this paper, for simplicity, the two-subdomain problem shown in Figure 1 is considered where $\Omega = \Omega_1 \cup \Omega_2$ bounded by $\Gamma = \Gamma_1 \cup \Gamma_2$ with the boundary Γ_{int} being the interface between Ω_1 and Ω_2 . We will denote by (\mathbf{i}, \mathbf{j}) the cartesian vector system and by $\mathbf{x} = x\mathbf{i} + y\mathbf{j}$ a generic point in \mathbb{R}^2 . We will also assume a harmonic steady state problem and hence the time variable is omitted in the formulation.

2.1 Problem formulation

Let us first consider the subdomain Ω_1 bounded by $\Gamma_1 \cup \Gamma_{int}$. The time independent displacement field \mathbf{u}_1 satisfies the Navier's equation

$$-\rho_1\omega^2\mathbf{u}_1 - \nabla \cdot \boldsymbol{\sigma}(\mathbf{u}_1) = \rho_1\mathbf{f}_1, \quad (1)$$

where ω is the circular frequency, ρ_1 is the density and \mathbf{f}_1 is the body force. The stress tensor $\boldsymbol{\sigma}$ is defined via the classical Hooke's law

$$\boldsymbol{\sigma}(\mathbf{u}_1) = \lambda_1 \nabla \cdot \mathbf{u}_1 \mathbf{I} + \mu_1 (\nabla \mathbf{u}_1 + \nabla \mathbf{u}_1^\top), \quad (2)$$

where \mathbf{I} denotes the identity matrix, λ_1 and μ_1 are the Lamé coefficients, and $\nabla \mathbf{u}_1 = (\nabla u_1, \nabla v_1)^\top$, with u_1 and v_1 being the horizontal and vertical components of the displacement field \mathbf{u}_1 . The

notation ‘ \top ’ stands for the transpose of a given vector or tensor. The dot product ‘ \cdot ’ of ∇ and the tensor field $\boldsymbol{\sigma} = (\boldsymbol{\sigma}_x, \boldsymbol{\sigma}_y)^\top$ in $\mathbb{C}^2 \times \mathbb{C}^2$ is defined by

$$\nabla \cdot \boldsymbol{\sigma} = \begin{pmatrix} \nabla \cdot \boldsymbol{\sigma}_x \\ \nabla \cdot \boldsymbol{\sigma}_y \end{pmatrix}, \quad (3)$$

with ∇ being the gradient operator. In addition to expressions (1) and (2), the formulation of the problem is completed by the boundary conditions imposed on Γ_1 . Here we consider a Robin type boundary conditions such that

$$\boldsymbol{\sigma}(\mathbf{u}_1)\mathbf{n}_1 = i [(\lambda_1 + 2\mu_1)k_1^P(\mathbf{u}_1 \cdot \mathbf{n}_1)\mathbf{n}_1 + \mu_1 k_1^S(\mathbf{u}_1 \cdot \mathbf{t}_1)\mathbf{t}_1] + \mathbf{g}_1. \quad (4)$$

In the above expression, i represents the imaginary number such that $i^2 = -1$, \mathbf{n}_1 and \mathbf{t}_1 are

Figure 1: A two-subdomain example.

the normal and tangential vectors to the boundary. The wave numbers k_1^P and k_1^S correspond to the pressure (P) and shear (S) waves, respectively. They are defined by

$$k_1^P = \frac{\omega}{c_1^P} \quad \text{and} \quad k_1^S = \frac{\omega}{c_1^S}. \quad (5)$$

The P-wave and S-wave speeds are given by

$$c_1^P = \left(\frac{\lambda_1 + 2\mu_1}{\rho_1} \right)^{\frac{1}{2}} \quad \text{and} \quad c_1^S = \left(\frac{\mu_1}{\rho_1} \right)^{\frac{1}{2}}. \quad (6)$$

In expression 4, the source term \mathbf{g}_1 will involve analytical solutions of elastic wave problems. This approach is adopted with the aim to validate the proposed method and assess its performance. But in practice absorbing boundary conditions would rather be used and would therefore involve extra numerical errors.

2.2 Weighted residual scheme

Let us multiply equation (1) by the complex conjugate of a test function $\bar{\mathbf{w}}_1$

$$\int_{\Omega_1} (-\rho_1 \omega^2 \mathbf{u}_1 - \nabla \cdot \boldsymbol{\sigma}(\mathbf{u}_1)) \cdot \bar{\mathbf{w}}_1 d\Omega = \int_{\Omega_1} \rho_1 \mathbf{f}_1 \cdot \bar{\mathbf{w}}_1 d\Omega. \quad (7)$$

Integrating by parts over Ω_1 , the following weak form is obtained

$$\begin{aligned} & -\omega^2 \rho_1 \int_{\Omega_1} \mathbf{u}_1 \cdot \bar{\mathbf{w}}_1 d\Omega - \int_{\Gamma_1} \boldsymbol{\sigma}(\mathbf{u}_1)\mathbf{n}_1 \cdot \bar{\mathbf{w}}_1 d\Gamma - \int_{\Gamma_{int}} \boldsymbol{\sigma}(\mathbf{u}_1)\mathbf{n}_1 \cdot \bar{\mathbf{w}}_1 d\Gamma + \int_{\Omega_1} \boldsymbol{\sigma}(\mathbf{u}_1) \cdot \nabla \bar{\mathbf{w}}_1 d\Omega \\ & = \rho_1 \int_{\Omega_1} \mathbf{f}_1 \cdot \bar{\mathbf{w}}_1 d\Omega. \end{aligned} \quad (8)$$

For practicality let us express the stress tensor in terms of the displacement field by using the following expression

$$\boldsymbol{\sigma}(\mathbf{u}_1) = \lambda_1 \nabla \cdot \mathbf{u}_1 \mathbf{I} + \mu_1 \nabla \times \mathbf{u}_1 \mathbf{J} + 2\mu_1 \nabla \mathbf{u}_1, \quad (9)$$

where the matrix \mathbf{J} is defined by

$$\mathbf{J} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad (10)$$

and also re-write $\boldsymbol{\sigma}(\mathbf{u}_1) \cdot \nabla \bar{\mathbf{w}}_1$ in expression (8) under the following form

$$\boldsymbol{\sigma}(\mathbf{u}_1) \cdot \nabla \bar{\mathbf{w}}_1 = \lambda_1 (\nabla \cdot \mathbf{u}_1) (\nabla \cdot \bar{\mathbf{w}}_1) + 2\mu_1 \nabla \mathbf{u}_1 \cdot \nabla \bar{\mathbf{w}}_1 - \mu_1 (\nabla \times \mathbf{u}_1) (\nabla \times \bar{\mathbf{w}}_1). \quad (11)$$

Now using the boundary condition (4), the above variational formulation becomes

$$\begin{aligned} & -\omega^2 \rho_1 \int_{\Omega_1} \mathbf{u}_1 \cdot \bar{\mathbf{w}}_1 d\Omega + 2\mu_1 \int_{\Omega_1} \nabla \mathbf{u}_1 \cdot \nabla \bar{\mathbf{w}}_1 d\Omega - \mu_1 \int_{\Omega_1} (\nabla \times \mathbf{u}_1) (\nabla \times \bar{\mathbf{w}}_1) d\Omega \\ & + \lambda_1 \int_{\Omega_1} (\nabla \cdot \mathbf{u}_1) (\nabla \cdot \bar{\mathbf{w}}_1) d\Omega - i \int_{\Gamma_1} [(\lambda_1 + 2\mu_1) k_1^P (\mathbf{u}_1 \cdot \mathbf{n}_1) (\bar{\mathbf{w}}_1 \cdot \mathbf{n}_1) + \mu_1 k_1^S (\mathbf{u}_1 \cdot \mathbf{t}_1) (\bar{\mathbf{w}}_1 \cdot \mathbf{t}_1)] d\Gamma \\ & - \int_{\Gamma_{int}} \boldsymbol{\sigma}(\mathbf{u}_1) \mathbf{n}_1 \cdot \bar{\mathbf{w}}_1 d\Gamma = \rho_1 \int_{\Omega_1} \mathbf{f} \cdot \bar{\mathbf{w}}_1 d\Omega + \int_{\Gamma_1} \mathbf{g}_1 \cdot \bar{\mathbf{w}}_1 d\Gamma. \end{aligned} \quad (12)$$

Following the same approach, a similar weak form is obtained for the subdomain Ω_2 bounded by $\Gamma_2 \cup \Gamma_{int}$ such that

$$\begin{aligned} & -\omega^2 \rho_2 \int_{\Omega_2} \mathbf{u}_2 \cdot \bar{\mathbf{w}}_2 d\Omega + 2\mu_2 \int_{\Omega_2} \nabla \mathbf{u}_2 \cdot \nabla \bar{\mathbf{w}}_2 d\Omega - \mu_2 \int_{\Omega_2} (\nabla \times \mathbf{u}_2) (\nabla \times \bar{\mathbf{w}}_2) d\Omega \\ & + \lambda \int_{\Omega_2} (\nabla \cdot \mathbf{u}_2) (\nabla \cdot \bar{\mathbf{w}}_2) d\Omega - i \int_{\Gamma_2} [(\lambda_2 + 2\mu_2) k_2^P (\mathbf{u}_2 \cdot \mathbf{n}_2) (\bar{\mathbf{w}}_2 \cdot \mathbf{n}_2) + \mu_2 k_2^S (\mathbf{u}_2 \cdot \mathbf{t}_2) (\bar{\mathbf{w}}_2 \cdot \mathbf{t}_2)] d\Gamma \\ & - \int_{\Gamma_{int}} \boldsymbol{\sigma}(\mathbf{u}_2) \mathbf{n}_2 \cdot \bar{\mathbf{w}}_2 d\Gamma = \rho_2 \int_{\Omega_2} \mathbf{f} \cdot \bar{\mathbf{w}}_2 d\Omega + \int_{\Gamma_2} \mathbf{g}_2 \cdot \bar{\mathbf{w}}_2 d\Gamma, \end{aligned} \quad (13)$$

where all functions and parameters are defined in a similar way as for the weak form (12) replacing the subscript 1 by 2.

2.3 Compatibility conditions

At the interface Γ_{int} , between Ω_1 and Ω_2 , continuity of displacements and stresses must be satisfied

$$\mathbf{u}_1 = \mathbf{u}_2, \quad (14)$$

$$\boldsymbol{\sigma}(\mathbf{u}_1) \mathbf{n}_1 = -\boldsymbol{\sigma}(\mathbf{u}_2) \mathbf{n}_2. \quad (15)$$

Let us introduce the Lagrange multiplier ν defined by

$$\nu = \boldsymbol{\sigma}(\mathbf{u}_1) \mathbf{n}_1 = -\boldsymbol{\sigma}(\mathbf{u}_2) \mathbf{n}_2. \quad (16)$$

The weak forms (12) and (13) become then

$$\begin{aligned}
& -\omega^2 \rho_1 \int_{\Omega_1} \mathbf{u}_1 \cdot \bar{\mathbf{w}}_1 d\Omega + 2\mu_1 \int_{\Omega_1} \nabla \mathbf{u}_1 \cdot \nabla \bar{\mathbf{w}}_1 d\Omega - \mu_1 \int_{\Omega_1} (\nabla \times \mathbf{u}_1) (\nabla \times \bar{\mathbf{w}}_1) d\Omega \\
& + \lambda_1 \int_{\Omega_1} (\nabla \cdot \mathbf{u}_1) (\nabla \cdot \bar{\mathbf{w}}_1) d\Omega - i \int_{\Gamma_1} [(\lambda_1 + 2\mu_1) k_1^P (\mathbf{u}_1 \cdot \mathbf{n}_1) (\bar{\mathbf{w}}_1 \cdot \mathbf{n}_1) + \mu_1 k_1^S (\mathbf{u}_1 \cdot \mathbf{t}_1) (\bar{\mathbf{w}}_1 \cdot \mathbf{t}_1)] d\Gamma \\
& - \int_{\Gamma_{int}} \boldsymbol{\nu} \cdot \bar{\mathbf{w}}_1 d\Gamma = \rho_1 \int_{\Omega_1} \mathbf{f} \cdot \bar{\mathbf{w}}_1 d\Omega + \int_{\Gamma_1} \mathbf{g}_1 \cdot \bar{\mathbf{w}}_1 d\Gamma,
\end{aligned} \tag{17}$$

and

$$\begin{aligned}
& -\omega^2 \rho_2 \int_{\Omega_2} \mathbf{u}_2 \cdot \bar{\mathbf{w}}_2 d\Omega + 2\mu_2 \int_{\Omega_2} \nabla \mathbf{u}_2 \cdot \nabla \bar{\mathbf{w}}_2 d\Omega - \mu_2 \int_{\Omega_2} (\nabla \times \mathbf{u}_2) (\nabla \times \bar{\mathbf{w}}_2) d\Omega \\
& + \lambda_2 \int_{\Omega_2} (\nabla \cdot \mathbf{u}_2) (\nabla \cdot \bar{\mathbf{w}}_2) d\Omega - i \int_{\Gamma_2} [(\lambda_2 + 2\mu_2) k_P (\mathbf{u}_2 \cdot \mathbf{n}_2) (\bar{\mathbf{w}}_2 \cdot \mathbf{n}_2) + \mu_2 k_S (\mathbf{u}_2 \cdot \mathbf{t}_2) (\bar{\mathbf{w}}_2 \cdot \mathbf{t}_2)] d\Gamma \\
& + \int_{\Gamma_{int}} \boldsymbol{\nu} \cdot \bar{\mathbf{w}}_2 d\Gamma = \rho_2 \int_{\Omega_2} \mathbf{f} \cdot \bar{\mathbf{w}}_2 d\Omega + \int_{\Gamma_2} \mathbf{g}_2 \cdot \bar{\mathbf{w}}_2 d\Gamma.
\end{aligned} \tag{18}$$

It is clear from the above weak forms, (17) and (18), that the problem is augmented as the Lagrange multiplier $\boldsymbol{\nu}$ is introduced as an extra unknown in the problem. The integration of the two weak forms leads to a rectangular system of equations, where the number of unknowns exceeds the number of equations. Extra equations are therefore added by ensuring the continuity of displacements such as in expression (14). This is done through the weak form

$$\int_{\Gamma_{int}} (\bar{\mathbf{u}}_1 - \bar{\mathbf{u}}_2) \cdot \boldsymbol{\delta} d\Gamma = 0, \tag{19}$$

where $\boldsymbol{\delta}$ is a test function in the space of the Lagrange multipliers.

In the following subsection both the displacement field and the Lagrange multiplier will be approximated via plane wave basis finite elements.

2.4 Plane wave approximation

The computational domain Ω is meshed into finite elements with n nodal points in total. We denote by N^z , $z = 1, n$, the partition of unity by polynomial finite element shape functions, and respectively by m_p and m_s the number of approximating P and S plane waves. The displacement \mathbf{u}_j in a subdomain Ω_j is approximated as follows [1, 2]

$$\mathbf{u}_j = \sum_{z=1}^n \sum_{l=1}^{m_P} N^z A_{z,l}^P \exp(ik_j^P \mathbf{x} \cdot \mathbf{d}_P^l) \mathbf{d}_P^l + \sum_{z=1}^n \sum_{l=1}^{m_S} N^z A_{z,l}^S \exp(ik_j^S \mathbf{x} \cdot \mathbf{d}_S^l) \mathbf{d}_{S,\perp}^l. \tag{20}$$

The amplitudes $A_{z,l}^P$ and $A_{z,l}^S$, at a given node z and corresponding to P and S plane waves travelling in the directions \mathbf{d}_P^l and \mathbf{d}_S^l , respectively, are now the unknowns of the problem. The orthogonal of a vector \mathbf{d} denoted by \mathbf{d}_\perp is defined by $\mathbf{d}_\perp = -\mathbf{J}\mathbf{d}$, where the rotation matrix \mathbf{J} , with the angle $\frac{\pi}{2}$, is given in expression (10). The directions \mathbf{d}_P^l and \mathbf{d}_S^l are taken uniformly distributed on the unit circle such that

$$\begin{aligned}
\mathbf{d}_P^l &= (\cos \theta_P^l, \sin \theta_P^l)^\top, \quad \theta_P^l = \frac{2\pi l}{m_P} \\
\mathbf{d}_S^l &= (\cos \theta_S^l, \sin \theta_S^l)^\top, \quad \theta_S^l = \frac{2\pi l}{m_S}.
\end{aligned} \tag{21}$$

It is obvious from the above expression (20) of the displacement field that the pair of wave numbers (k_j^P, k_j^S) will take different values depending to which subdomain, Ω_1 or Ω_2 , the considered finite element belongs to.

For the approximation of the Lagrange multiplier ν , the approach is inspired from previous work [7], which consists to write

$$\nu = \sum_{z=1}^n \sum_{l=1}^{m_P} N^z B_{z,l}^P \exp(ik^P \mathbf{x} \cdot \mathbf{d}_P^l) \mathbf{d}_P^l + \sum_{z=1}^n \sum_{l=1}^{m_S} N^z B_{z,l}^S \exp(ik^S \mathbf{x} \cdot \mathbf{d}_S^l) \mathbf{d}_{S,\perp}^l. \quad (22)$$

In other words, the lagrange multiplier is also approximated by sets of P and S plane waves, and the unknowns $B_{z,l}^P$ and $B_{z,l}^S$ are in a sense the amplitudes of the approximating plane waves. At the interface between Ω_1 and Ω_2 , the pair of wave numbers (k^P, k^S) is chosen, for example, such that

$$k^P = \max(k_1^P, k_2^P) \quad \text{and} \quad k^S = \max(k_1^S, k_2^S) \quad (23)$$

The numbers m_P and m_S of approximating plane waves may be constant or may vary depending whether the approximation is applied to the displacements fields \mathbf{u}_1 and \mathbf{u}_2 or to the Lagrange multiplier ν . Expressions (17), (18) and (19) lead to square system matrix, where the solution is obtained through a direct solver which uses a factorization of the form \mathbf{LDL}^H where \mathbf{D} is a real diagonal matrix, \mathbf{L} is a lower triangular matrix with diagonal entries equal to 1 and \mathbf{L}^H is the transpose conjugate of \mathbf{L} [8]. It is worth mentioning that the element matrices are obtained via an exact integration developed in reference [2] and hence the computations are significantly faster compared to past work [1] where high order Gauss-Legendre quadrature schemes were used involving thousands of integration points per finite element.

In the next section, some preliminary numerical results validating the proposed model are presented.

3 PRELIMINARY RESULTS

The model presented above is validated by solving typical problems of practical interest such as those encountered in soil wave propagation, which involve interfaces between the soil layers and a free surface. First, SV elastic waves propagating in a homogeneous medium and hitting a plane free surface is considered. Then, a problem with pure Rayleigh waves is dealt with, where the displacement field approximation involves P and S plane waves, rather than plane waves with the Rayleigh wave number. Last, a test problem involving reflection and transmission of elastic waves at a plane interface between two semi-infinite elastic media is carried out. All considered problems have analytical solutions presented in various textbooks, such as reference [9]. To assess the accuracy of the numerical solution in percentage the following L^2 error

$$\varepsilon_2 = \frac{\|\mathbf{u} - \tilde{\mathbf{u}}\|_{L_2(\Omega)}}{\|\tilde{\mathbf{u}}\|_{L_2(\Omega)}} \times 100\% \quad (24)$$

Figure 2: Mesh of the computational domain.

is used where \mathbf{u} is the numerical solution and $\tilde{\mathbf{u}}$ is the analytical solution of the considered problem. The chosen computational domain is a square of unit length. It is meshed into 3-node triangular finite elements with 32 elements and 25 nodes (Figure 2).

3.1 SV plane wave hitting a free surface

This is a common situation occurring at the soil free surface, for example. Let us consider a shear wave, SV, of unit amplitude incident with an angle β (Figure 3). In general, this leads to both reflected compression and shear waves. The compression wave potential is therefore given only by the reflected wave

$$\phi = R_P e^{ik(-x-y \tan \alpha)}, \quad (25)$$

and the shear wave potential is the sum of the incident and the reflected waves

$$\psi = 1 e^{ik(-x+y \tan \beta)} + R_S e^{ik(-x-y \tan \beta)}, \quad (26)$$

where k is the wave number such that $k = k_P \cos \alpha = k_S \cos \beta$, with α being the angle of the reflected P-wave. The reflection coefficients R_P and R_S are computed by ensuring zero-stress boundary conditions at the free surface [9]. The displacements are computed via the following derivatives of the potentials

$$u = \frac{\partial \phi}{\partial x} - \frac{\partial \psi}{\partial y} \quad \text{and} \quad v = \frac{\partial \phi}{\partial y} + \frac{\partial \psi}{\partial x}. \quad (27)$$

Snell's law states that $c_P / \cos \alpha = c_S / \cos \beta$ and hence $\tan \alpha = (1/3 \cos^2 \beta - 1)^{1/2}$ for this elastic medium, with $\lambda = \mu = \rho = 1$. Consequently, the reflected compression wave exists only if the angle of incidence β reaches the critical angle $\beta_c = \cos^{-1}(1/\sqrt{3})$ and that for all angles $0 < \beta < \cos^{-1}(1/\sqrt{3})$ there is no reflected compression wave. In this latter case, $\tan \alpha$ becomes a complex number and the motion corresponding to the P-wave potential propagates along the free surface, as an edge wave, and decreases exponentially with depth, an an evanescent mode.

Figure 3: SV-plane wave hitting a free surface of a semi-infinite elastic medium.

Figure 7 shows, for $\omega = 30$, contour plots of the real part of the displacement for two cases of incidence. In the first case (left), the angle of incidence $\beta < \beta_c$, which means both P and S waves are reflected. In the second one, $\beta > \beta_c$ and hence only an S wave is reflected while there is an edge P-wave wave decaying exponentially with depth. In both cases, a total of 32 plane waves are used in the approximation of the displacement field \mathbf{u} , with $m_P = m_S = 16$. The L_2 errors, in both cases $\varepsilon_2 = 0.6\%$, show that the numerical solution is in good agreement with the analytical solution of the problem.

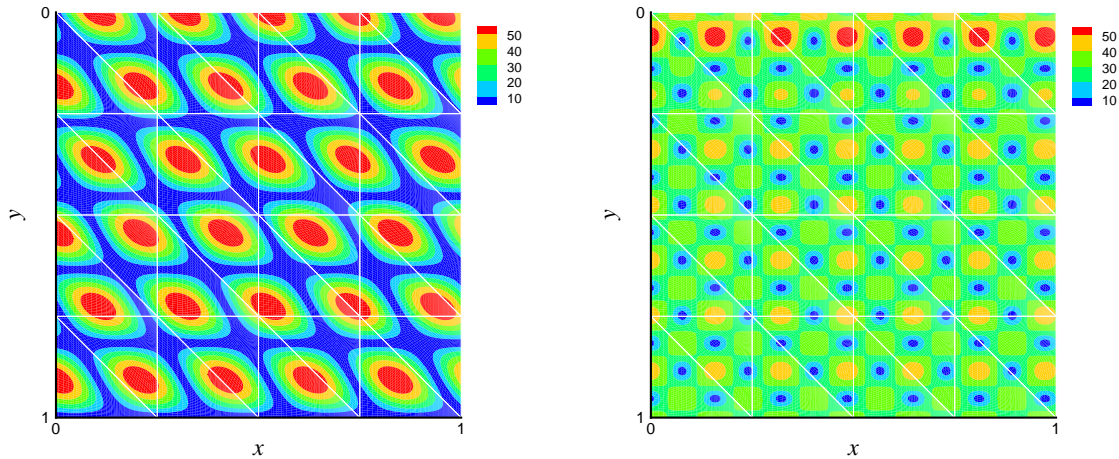

Figure 4: Real part of the displacement due to an SV-plane wave hitting a free surface of a semi-infinite elastic medium, $\omega = 30$, $m_P = m_S = 16$, (left) $\beta = 60^\circ$, $\varepsilon_2 = 0.6\%$, (right) $\beta = 50^\circ$, $\varepsilon_2 = 0.6\%$.

3.2 Pure Rayleigh waves

Rayleigh waves are present near the soil free surface and they decay exponentially with depth. They appear when body waves are reflected at the free surface. Part of their energy is converted into Rayleigh waves which propagate with their own wave number k_R given by the

approximate expression $k_R \approx k_S/0.9194$, for the same considered material ($\lambda = \mu = \rho = 1$). The horizontal and vertical components of the displacement field caused by the Rayleigh waves are given by the following expressions [10]

$$\begin{aligned} u &= \sqrt{k_R^2 - k_S^2} \left[e^{-\sqrt{k_R^2 - k_S^2} y} - \frac{2k_R^2}{2k_R^2 - k_S^2} e^{-\sqrt{k_R^2 - k_P^2} y} \right] e^{ik_R x}, \\ v &= ik_R \left[e^{-\sqrt{k_R^2 - k_S^2} y} - \frac{2\sqrt{(k_R^2 - k_P^2)(k_R^2 - k_S^2)}}{2k_R^2 - k_S^2} e^{-\sqrt{k_R^2 - k_P^2} y} \right] e^{ik_R x}. \end{aligned} \quad (28)$$

For the same computational domain of Figure 2, the Rayleigh induced displacements are imposed on its boundary and the model developed above is used to recover the displacement field inside the domain. It is worth pointing out again to the fact that Rayleigh waves propagate with the wave number k_R , while the plane wave approximation of expression (19) of the displacement field uses the pressure and shear wave numbers k_P and k_S , rather than k_R . Figure 5 shows two examples of numerical tests involving the Rayleigh wave problem for frequencies $\omega = 10$ and $\omega = 20$. Both figures show the displacement profile which displays ellipses with major axes normal to the free surface. Moreover, the displacements occur mainly near the free surface and decay rapidly with depth. For $\omega = 10$, only 16 plane waves are used to approximate the displacement field with $m_P = m_S = 8$, leading to an error of 0.5%. In the case of $\omega = 20$, 28 plane waves are used such that $m_P = m_S = 14$ and the L_2 -error remains low as well, $\varepsilon_2 = 0.8\%$. This clearly indicates the good performance of the proposed approximation and its ability to capture Rayleigh waves in spite of the model not explicitly including the wave number k_R in the plane wave approximation (20).

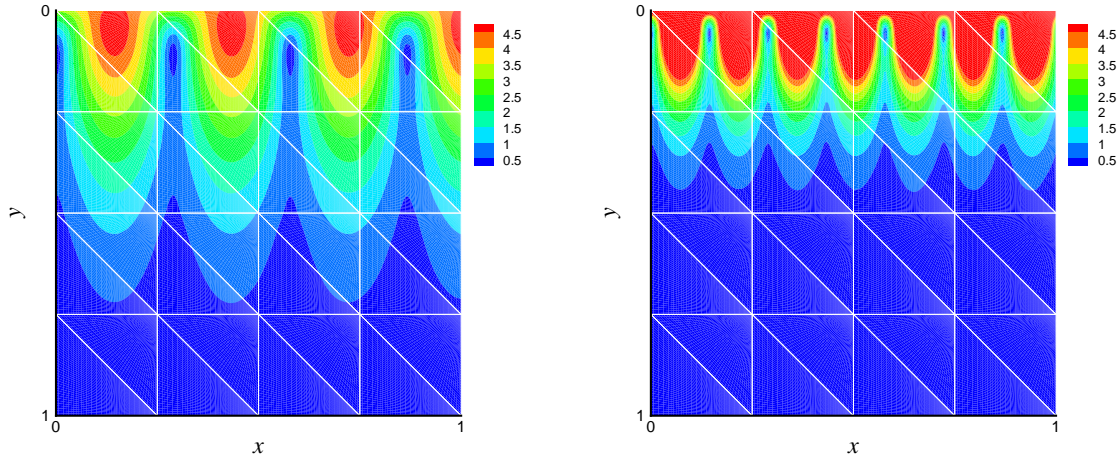

Figure 5: Real part of the displacement due to Rayleigh waves, (left) $\omega = 10$, $m_P = m_S = 8$, $\varepsilon_2 = 0.5\%$, (right) $\omega = 20$, $m_P = m_S = 14$, $\varepsilon_2 = 0.8\%$.

3.3 SV plane wave hitting a plane interface

In multilayered soils, for example, wave transmission and reflection occur at interfaces. In this sub-section, an incident elastic wave hitting a plane interface between two semi-infinite elastic media is considered. In general, this produces compression and shear waves in both media. Figure 6 shows a schematic diagram of an incident SV-plane wave hitting such interface.

For this case, the compression wave potential is therefore given by the reflected and transmitted waves

$$\phi = R_P e^{ik(-x-y \tan \alpha)} + T_P e^{ik(-x-y \tan \gamma)}, \quad (29)$$

while the shear wave potential is the sum of the incident, reflected and transmitted waves

$$\psi = 1 e^{ik(-x+y \tan \beta)} + R_S e^{ik(-x-y \tan \beta)} + T_S e^{ik(-x-y \tan \theta)}, \quad (30)$$

The wave number k is now given by $k = k_1^P \cos \alpha = k_1^S \cos \beta = k_2^P \cos \gamma = k_2^S \cos \theta$. The coefficients R_P , R_S , T_P and T_S are obtained by ensuring continuity of the displacement and stress fields at the interface [9]. The horizontal and vertical components of the displacement field, deduced from expressions (27), are imposed on the boundary of the computational domain of Figure 2 representing now two semi-infinite media in contact at the horizontal interface $y = 0.5$. Two cases are considered where a soft layer overlies a hard layer and *vice versa* with a ratio of densities of $1/3$. In both cases, the SV plane wave is incident in the lower layer with $\beta = 60^\circ$ and $\omega = 10$. A total of 24 plane waves are chosen such that $m_P = 10$ and $m_S = 14$. Figure 7 shows the numerical results of the real part of the displacement for both cases. The low L_2 errors, 0.8% and 0.7%, show the ability of the developed model to simulate such problems while ensuring continuity at the interface thanks to the Lagrange multipliers.

Figure 6: SV-plane wave hitting a plane interface between two semi-infinite elastic media.

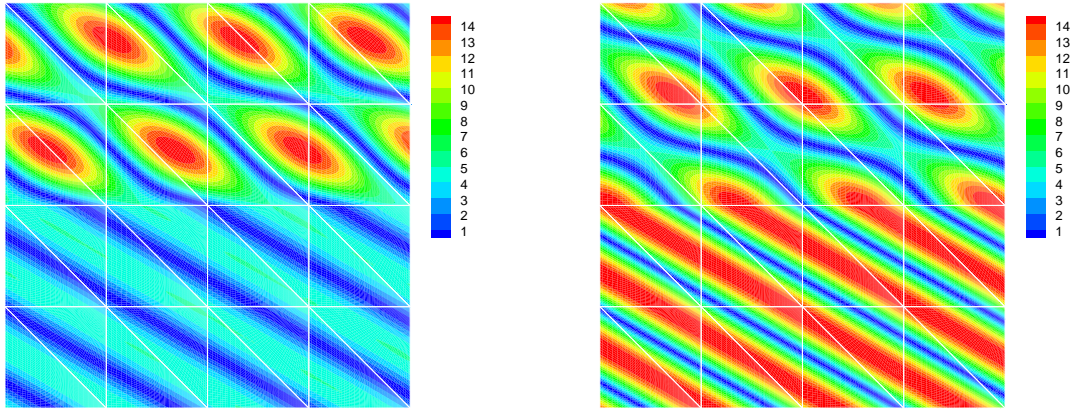

Figure 7: Real part of the displacement due to an SV-plane wave hitting a plane interface between two semi-infinite elastic media, $\omega = 10$, $m_P = 10$, $m_S = 14$, $\beta = 60^\circ$, (left) hard layer overlying soft layer $\varepsilon_2 = 0.8\%$, (right) soft layer overlying hard layer $\varepsilon_2 = 0.7\%$.

4 CONCLUSIONS

In this work, the PUFEM is extended to deal with wave problems in elastic layered media by incorporating Lagrange multipliers to ensure compatibility conditions at the interfaces between the layers. The model is validated by considering a simple example of an SV plane wave transmitted at the plane interface between two semi-infinite elastic media. The model is also shown to deal with Rayleigh wave propagation without explicitly including its wave number in the displacement approximation. It also simulates elastic wave problems in presence of evanescent modes.

The results presented above are preliminary. They provide an indication of the ability of the PUFEM model to deal with various elastic wave problems in homogeneous and inhomogeneous media. Robustness and Accuracy of this model are currently being assessed through the consideration of different parameters such as the mesh size, the number of plane wave basis in the approximation of the displacement field and in the Lagrange multiplier, the problem frequency and the significant variations in material properties between layers.

Keywords: Computational seismology, Non-conforming approximations, Mortar Spectral Element Method, Discontinuous Galerkin Spectral Element Method.

Abstract. *Non-conforming techniques as the Mortar spectral Element Method (MSEM) or the Discontinuous Galerkin Spectral Element Method (DGSEM) are variational approaches to discretize partial differential equations, that rely on a spectral finite element approximation of a non-overlapping subdomain partition of the computational domain. In this contribution we compare and analyse MSEM and DGSEM, giving more details on the algorithmic aspects of the two non-conforming approaches, and we address their applicability and flexibility to handle seismic wave propagation problems. The numerical strategies are implemented in the spectral elements based code GeoELSE [14].*

1 INTRODUCTION

During the last three decades seismology is undergoing a major transformation at both the research and the application level. In modern seismology the classical scientific approach based on laboratory experiments has been replaced by computer simulations. Indeed, the rapid development of efficient numerical methods, gives the chance to simulate, with high resolution the complete seismic waveform field in highly heterogeneous earth media with complex geometries and up to relatively large frequencies (about 3 Hz).

The recent developments on computational seismology have been based on high-order numerical modelling of wave propagation (see, for example, [5, 12, 13, 15, 16, 17]). The reasons for using spectral element based approximations are the following. Firstly the flexibility in handling complex geometries, retaining the spatial exponential convergence for locally smooth solutions. Secondly, spectral element methods are based on the weak formulation of the elastodynamic equations involving only first-order spatial derivatives. Finally spectral element methods retain a high level parallel structure, and are therefore well suited for parallel computers.

In this paper we consider two different non-conforming high-order techniques, namely the Mortar Spectral Element Method (MSEM) and the Discontinuous Galerkin Spectral Element Method (DGSEM) to simulate seismic wave propagation in heterogeneous media. In contrast to standard conforming discretizations, as Spectral Element Method (SEM), these techniques have the further advantages that they can accommodate discontinuities, not only in the parameters, but also in the wave-field, they are energy conservative and well suited for parallel implementation. In our contribution we compare their performances when effectively applied to real problems. The paper is organized as follows. In Section 2 we recall the model problem under investigation. In Section 3 the non-conforming formulations are summarized. In Sections 4 we introduce the corresponding algebraic formulations and next, in Section 5 we describe how two efficiently implement them in a numerical code. In order to show an effective application of the methods previously described, in Section 6 a complex soil-structure interaction is studied using the MSEM and the DGSEM discretizations. Finally, in Section 7, we draw some conclusions.

2 FORMULATION OF PROBLEM

Fixing the temporal interval $(0, T]$, with $T > 0$, the equilibrium equations for an elastic medium, occupying a finite region $\Omega \subset \mathbb{R}^d$, $d = 2, 3$, subjected to an external force \mathbf{f} read:

$$\rho \partial_{tt} \mathbf{u} - \nabla \cdot \underline{\sigma}(\mathbf{u}) = \mathbf{f} + \mathbf{f}^{visc}(\dot{\mathbf{u}}, \mathbf{u}), \quad (1)$$

where \mathbf{u} is the displacement of the body, $\underline{\sigma}$ the stress tensor, t the time and ρ the density of the material. Since we are dealing with viscoelastic materials, we introduce in model (1) a structural damping in the form of volumetric forces $\mathbf{f}^{visc}(\dot{\mathbf{u}}, \mathbf{u}) = -2\rho\zeta\dot{\mathbf{u}} - \rho\zeta^2\mathbf{u}$, where ζ is a spatially variable (i.e., piecewise constant) suitable decay factor with dimension of inverse of the time [8]. It is worth remarking that the introduction of \mathbf{f}^{visc} in (1) results in a frequency proportional quality factor, i.e. a non dispersive wave propagation (for further details see [18]). We denote by $\Gamma = \Gamma_D \cup \Gamma_N \cup \Gamma_{NR}$ the boundary of the physical domain Ω and without loss of generality on the boundary Γ we make the following assumptions (cf [22]):

- on Γ_D the body is rigidly fixed in the space,
- on Γ_N we prescribe surface tractions ($\underline{\sigma}(\mathbf{u}) \cdot \mathbf{n} = \mathbf{t}$),
- on Γ_{NR} non-reflecting boundary conditions are imposed: cf. [27], for example.

Hereafter, an underlying bar denotes matrix or tensor quantities, while vectors are typed in bold. Moreover, we adopt the standard notation $(\cdot, \cdot)_\Omega$ to denote the L^2 -inner product for scalar, vectorial and tensorial functions defined in Ω . To ease of presentation we describe the numerical methods in the case of null viscoelastic forces, i.e. $\mathbf{f}^{visc}(\dot{\mathbf{u}}, \mathbf{u}) = 0$ (see Section 4.1 below for the general case).

Defining $V = \{\mathbf{v} \in [H^1(\Omega)]^d : \mathbf{v} = \mathbf{0} \text{ on } \Gamma_D\}$, the variational formulation of (1) reads:
 $\forall t \in (0, T]$ find $\mathbf{u} = \mathbf{u}(t) \in V$ such that

$$d_{tt}(\rho \mathbf{u}, \mathbf{v})_\Omega + \mathcal{A}(\mathbf{u}, \mathbf{v})_\Omega = \mathcal{L}(\mathbf{v}), \quad \forall \mathbf{v} \in V, \quad (2)$$

where the bilinear form $\mathcal{A}(\cdot, \cdot) : V \times V \rightarrow \mathbb{R}^d$ is defined as $\mathcal{A}(\mathbf{u}, \mathbf{v})_\Omega = (\underline{\sigma}(\mathbf{u}), \underline{\varepsilon}(\mathbf{v}))_\Omega$, and the linear functional $\mathcal{L} : V \rightarrow \mathbb{R}^d$ as $\mathcal{L}(\mathbf{v}) = (\mathbf{t}, \mathbf{v})_{\Gamma_N} + (\mathbf{t}^*, \mathbf{v})_{\Gamma_{NR}} + (\mathbf{f}, \mathbf{v})_\Omega$. We suppose that the strain tensor $\underline{\varepsilon}$ and the stress tensor $\underline{\sigma}$ are related through the Hooke's law

$$\underline{\varepsilon}(\mathbf{u}) = \frac{1}{2}(\nabla \mathbf{u} + \nabla \mathbf{u}^\top), \quad \underline{\sigma}(\mathbf{u}) = \lambda \nabla \cdot \mathbf{u} \mathbf{I} + 2\mu \underline{\varepsilon}(\mathbf{u}),$$

where \mathbf{I} is the d -dimensional identity tensor and λ and μ are the Lamé elastic coefficients. We remark that for heterogeneous media ρ, λ and μ are bounded functions of the spatial variable, not necessarily continuous i.e., ρ, λ and $\mu \in L^\infty(\Omega)$. Finally, to complete problem (2), we prescribe initial conditions \mathbf{u}_0 and \mathbf{u}_1 for the displacement and the velocity, respectively.

It can be proved that the bilinear form $\mathcal{A}(\cdot, \cdot)$ is symmetric, V -elliptic and continuous. These conditions imply that problem (2) admits a unique solution, (cf. [4, 23]).

Let V_δ be a suitable finite dimensional approximation of the space V , the semi-discrete approximation of (2) reads : $\forall t \in (0, T]$ find $\mathbf{u}_\delta = \mathbf{u}_\delta(t) \in V_\delta$ such that

$$d_{tt}(\rho \mathbf{u}_\delta, \mathbf{v})_\Omega + \mathcal{A}(\mathbf{u}_\delta, \mathbf{v}) = \mathcal{L}(\mathbf{v}), \quad \forall \mathbf{v} \in V_\delta. \quad (3)$$

In general, in non-conforming approximations, the space V_δ is not a subspace of V . In the following section we describe how to build V_δ for both for the Mortar Spectral Element Method (MSEM) and the Discontinuous Galerkin Spectral Element Method (DGSEM).

3 NON CONFORMING FORMULATIONS

To approximate the problem (3) we start by a discretization of the spatial differential operators in Ω , that rely on a time-independent three-level spatial decomposition of the domain Ω .

At the first level, we subdivide Ω into K non overlapping regions Ω_k , $k = 1, \dots, K$, such that $\bar{\Omega} = \bigcup_{k=1}^K \bar{\Omega}_k$ with $\Omega_k \cap \Omega_\ell = \emptyset$ if $k \neq \ell$ and we define the skeleton of this (macro) decomposition as $\mathcal{S} = \bigcup_{k=1}^K \partial\Omega_k \setminus \partial\Omega$. Note that this decomposition can be geometrically non-conforming, i.e., for two neighbouring subdomains Ω_k, Ω_ℓ , the interface $\gamma = \partial\Omega_k \cap \partial\Omega_\ell$ may not be a complete side (for $d = 2$) or face (for $d = 3$) of Ω_k or Ω_ℓ .

To get the second level, in each Ω_k we introduce a (meso) partitioning \mathcal{T}_{h_k} , made by elements Ω_k^j that are image through an invertible mapping F_k^j of the reference element $\hat{\Omega} = (-1, 1)^d$. The quadrilaterals Ω_k^j , if $d = 2$, or hexahedra, if $d = 3$, have typical linear size h_k and $\bar{\Omega}_k = \bigcup_{j=1}^{J_k} \bar{\Omega}_k^j$.

The third (micro) level is represented by the so-called Gauss-Lobatto-Legendre (GLL) points in each mesh element Ω_k^j . Let $\mathbf{Q}_{N_k}(\hat{\Omega})$ be the space of functions defined on $\hat{\Omega}$ that are algebraic polynomials of degree less than or equal to $N_k \geq 2$ in each spatial variable x_1, \dots, x_d . Thus, we set

$$\mathbf{Q}_{N_k}(\Omega_k^j) = \left\{ v = \hat{v} \circ F_k^{j-1} : \hat{v} \in \mathbf{Q}_{N_k}(\hat{\Omega}) \right\},$$

and we define the finite dimensional space $X_\delta(\Omega_k)$ as

$$X_\delta(\Omega_k) = \left\{ v_\delta \in \mathcal{C}^0(\overline{\Omega}_k) : v_{\delta|\Omega_k^j} \in \mathbf{Q}_{N_k}(\Omega_k^j) \forall \Omega_k^j \in \mathcal{T}_{h_k} \right\},$$

and finally $V_\delta = \{ \mathbf{v}_\delta \in [L^2(\Omega)]^d : \mathbf{v}_{\delta|\Omega_k} \in [X_\delta(\Omega_k)]^d \forall k = 1, \dots, K : \mathbf{v}_{\delta|\Gamma_D} = \mathbf{0} \}$. Here $\delta = \{\mathbf{h}, \mathbf{N}\}$ with $\mathbf{h} = (h_1, \dots, h_K)$ and $\mathbf{N} = (N_1, \dots, N_K)$ are K -uplets of discretization parameters. Problem (3) is then equivalent to: $\forall t \in (0, T]$ find $(\mathbf{u}_{\delta,1}(t), \dots, \mathbf{u}_{\delta,K}(t)) \in V_\delta$ such that

$$\sum_{k=1}^K d_{tt}(\rho \mathbf{u}_{\delta,k}, \mathbf{v}_k)_{\Omega_k} + \mathcal{A}(\mathbf{u}_{\delta,k}, \mathbf{v}_k)_{\Omega_k} + \mathcal{B}(\mathbf{u}_{\delta,k}, \mathbf{v}_k)_{\partial\Omega_k \setminus \partial\Omega} = \sum_{k=1}^K \mathcal{L}(\mathbf{v}_k)_{\Omega_k}, \quad (4)$$

for all $(\mathbf{v}_1, \dots, \mathbf{v}_K) \in V_\delta$, where

$$\mathcal{A}(\mathbf{u}, \mathbf{v})_{\Omega_k} = (\underline{\sigma}(\mathbf{u}), \underline{\varepsilon}(\mathbf{v}))_{\Omega_k}, \quad \text{and} \quad \mathcal{B}(\mathbf{u}, \mathbf{v})_{\partial\Omega_k \setminus \partial\Omega} = (\underline{\sigma}(\mathbf{u}) \cdot \mathbf{n}, \mathbf{v})_{\partial\Omega_k \setminus \partial\Omega}. \quad (5)$$

Depending on the chosen non-conforming approach, the functional space V_δ is completed by additional conditions on $\mathbf{u}_{\delta,k}$, $k = 1, \dots, K$, on the skeleton of the macro decomposition which ensure that $\mathbf{u}_{\delta,k}$ is the restriction to Ω_k of $\mathbf{u}_\delta \in H^1(\Omega)^d$. The bilinear form $\mathcal{B}(\cdot, \cdot)$ may either be zero or gather all the contributions $(\sigma(\mathbf{u}_{\delta,k}) \cdot \mathbf{n}_k, \mathbf{v}_k)_{\partial\Omega_k \setminus \partial\Omega}$, $k = 1, \dots, K$, depending on the chosen approach. Equation (4) represents the starting point to introduce the MSEM and the DGSEM.

In the next sections we describe the two approaches. To ease the presentation, we suppose that $\Gamma_D = \partial\Omega$ and we assume that each partition \mathcal{T}_{h_k} of Ω_k consists in only one element, i.e., Ω is subdivided into K non-overlapping spectral elements $\Omega_1, \dots, \Omega_K$ so that $\overline{\mathcal{S}} = \bigcap_{k=1}^K \partial\overline{\Omega}_k \setminus \Gamma_D$. The more general case follows from similar arguments.

3.1 Mortar Spectral Formulation

In this section we introduce the MSEM for the solution of (4), see [11, 21] for a more detailed description. We denote by Γ_k^ℓ , $\ell = 1, \dots, 2d$, the edges (faces) of each subdomain Ω_k , $k = 1, \dots, K$, so that $\partial\Omega_k = \bigcup_{\ell=1}^{2d} \Gamma_k^\ell$. We then identify the skeleton \mathcal{S} as the union of elementary non-empty components called *mortars* (or *masters*), more precisely

$$\mathcal{S} = \bigcup_{k=1}^K (\partial\Omega_k \setminus \partial\Omega) = \bigcup_{m=1}^M \overline{\gamma}_m, \quad \text{with } \gamma_m \cap \gamma_n = \emptyset, \quad \text{if } m \neq n, \quad (6)$$

where each mortar is a whole edge (or face) $\Gamma_{k(m)}^{\ell(m)}$ of a specific element $\Omega_{k(m)}$ and m is an arbitrary numbering $m = 1, \dots, M$, with M a positive integer. Those edges or faces Γ_k^ℓ that do not coincide with a mortar are called *non-mortars* (or *slaves*) and provide a dual description of the skeleton, as

$$\mathcal{S} = \bigcup_{m \text{ mortar}} \gamma_m^+ = \bigcup_{n \text{ non mortar}} \gamma_n^-.$$

The intersection of the closures of the mortars defines a set of vertices or *cross-points*

$$\mathcal{V} = \{ \mathbf{x}_q = (\overline{\gamma}_r^+ \cap \overline{\gamma}_s^+), \mathbf{x}_q \notin \overline{\gamma}_m^+, m = 1, \dots, M \},$$

where q is an arbitrary numbering $q = 1, \dots, V$. We define as well the set $\widetilde{\mathcal{V}}$ of *virtual* vertices (that are not cross-points) as $\widetilde{\mathcal{V}} = \{ \widetilde{\mathbf{x}}_q = (\overline{\gamma}_r^+ \cap \gamma_s^+) \}$, where q is an arbitrary numbering

Figure 1: Nonconforming domain decomposition (left) and skeleton structure (right) showing a cross-point (\bullet), a virtual vertex (\square), the mortars (dark continuous lines) and the non-mortars (dark dashed lines).

$q = 1, \dots, \tilde{\mathcal{V}}$ (see Fig. 1). Let $\Lambda_\delta(\Gamma_k^\ell) = \mathbf{Q}_{N_k}(\Gamma_k^\ell)$ be the space of the traces of functions of $X_\delta(\Omega_k)$ over Γ_k^ℓ and $\hat{\Lambda}_\delta(\Gamma_k^\ell) = \mathbf{Q}_{N_k-2}(\Gamma_k^\ell)$. We can now define the nonconforming spectral element discretization space \tilde{V}_δ as the space of functions $\mathbf{v}_\delta \in V_\delta$ that satisfy the following additional *mortar matching condition*:

(MC) let Φ be the *mortar function* associated with \mathbf{v}_δ , i.e., a function that is continuous on \mathcal{S} , zero on $\partial\Omega$ and such that on each mortar $\gamma_m = \Gamma_{k(m)}^{\ell(m)}$ coincides with the restriction of $\mathbf{v}_{\delta,k} = \mathbf{v}_{\delta|\Omega_k}$ to γ_m ; then, for all indices (k, ℓ) such that Γ_k^ℓ is contained in \mathcal{S} but $(k, \ell) \neq (k(m), \ell(m))$ for all $m = 1, \dots, M$ (that is for all indices (k, ℓ) such that Γ_k^ℓ is a *non-mortar*) we require that:

$$\int_{\Gamma_k^\ell} (\mathbf{v}_{\delta,k} - \Phi) \cdot \hat{\Phi} \, d\gamma = 0 \quad \forall \hat{\Phi} \in [\hat{\Lambda}_\delta(\Gamma_k^\ell)]^d, \quad (7)$$

and that

$$\mathbf{v}_{\delta|\Omega_k}(\mathbf{x}_q) = \Phi(\mathbf{x}_q), \quad \forall \mathbf{x}_q \in \mathcal{V} \cup \tilde{\mathcal{V}}. \quad (8)$$

The integral matching condition (7) represents a minimization of the jump in functions at internal boundaries with respect to the L^2 norm. The vertex condition (8) ensures exact continuity at cross-points.

The Mortar Spectral Formulation is obtained by solving in each region Ω_k the elastodynamic variational problem (4) with homogeneous Neumann boundary conditions on \mathcal{S} ($\underline{\sigma}(\mathbf{u}) \cdot \mathbf{n} = \mathbf{0}$ so that $\sum_k \mathcal{B}(\mathbf{u}, \mathbf{v})_{\partial\Omega_k \setminus \partial\Omega}$ is identically zero), and enforcing weak continuity of the displacement on \mathcal{S} with *mortar condition* (7). Thus, the semi-discrete Mortar Spectral Formulation reads:

$\forall t \in (0, T]$ find $(\mathbf{u}_{\delta,1}(t), \dots, \mathbf{u}_{\delta,K}(t)) \in V_\delta^{mortar}$ such that

$$\sum_k d_{tt}(\rho \mathbf{u}_{\delta,k}, \mathbf{v}_k)_{\Omega_k} + \mathcal{A}(\mathbf{u}_{\delta,k}, \mathbf{v}_k)_{\Omega_k} = \sum_k \mathcal{L}(\mathbf{v}_k), \quad \forall (\mathbf{v}_1, \dots, \mathbf{v}_K) \in V_\delta^{mortar}, \quad (9)$$

where $V_\delta^{mortar} = \{(\mathbf{v}_1, \dots, \mathbf{v}_K) \in V_\delta : \text{the mortar condition (MC) is satisfied}\}.$

Figure 2: Nonconforming domain decomposition (left) and skeleton structure (right) showing the elementary components (dark continuous lines).

3.2 Discontinuous Galerkin Spectral Formulation

In order to introduce the Discontinuous Galerkin Spectral Formulations, we subdivide the skeleton \mathcal{S} in the set of elementary components (edges if $d = 2$, faces if $d = 3$) as follows:

$$\overline{\mathcal{S}} = \bigcup_{j=1}^M \overline{\gamma}_j, \quad \text{with } \gamma_i \cap \gamma_j = \emptyset, \quad \text{if } i \neq j, \quad (10)$$

where each edge (face) is given by $\overline{\gamma}_j = (\partial\overline{\Omega}_{k(j)} \cap \partial\overline{\Omega}_{\ell(j)}) \setminus \partial\Omega$, for some different positive integers k and ℓ . Notice that this decomposition is unique (see Fig. 2). Next, we collect all the edges (faces) in the set \mathcal{F}_I . For regular enough functions, we use the standard notation [2] to define the jumps ($[\![\cdot]\!]$) and the average ($\{\cdot\}$) operators on each edge (face) $\gamma \in \mathcal{F}_I$.

We obtain the following semi-discrete DG Spectral Formulation:

$\forall t \in (0, T]$ find $\mathbf{u}_\delta = (\mathbf{u}_{\delta,1}(t), \dots, \mathbf{u}_{\delta,K}(t)) \in V_\delta^{DG} \equiv V_\delta$ such that

$$\sum_{k=1}^K (d_{tt}(\rho \mathbf{u}_\delta, \mathbf{v})_{\Omega_k} + \mathcal{A}(\mathbf{u}_\delta, \mathbf{v})_{\Omega_k}) + \sum_{j=1}^M \mathcal{B}(\mathbf{u}_\delta, \mathbf{v})_{\gamma_j} = \mathcal{L}(\mathbf{v}) \quad \forall \mathbf{v} = (\mathbf{v}_1, \dots, \mathbf{v}_K) \in V_\delta^{DG}, \quad (11)$$

with

$$\mathcal{B}(\mathbf{u}_\delta, \mathbf{v})_{\gamma_j} = -(\{\underline{\sigma}(\mathbf{u}_\delta)\}, [\![\mathbf{v}]\!])_{\gamma_j} + \theta([\![\mathbf{u}_\delta]\!], \{\underline{\sigma}(\mathbf{v})\})_{\gamma_j} + \eta_{\gamma_j}([\![\mathbf{u}_\delta]\!], [\![\mathbf{v}]\!])_{\gamma_j}. \quad (12)$$

Here $\eta_{\gamma_j} = \frac{\alpha N_j^2}{h_j} \{\lambda + 2\mu\}_A$, where $\{\cdot\}_A$ represents the harmonic average, $N_j = \max(N_{k(j)}, N_{\ell(j)})$, $h_j = \min(h_{k(j)}, h_{\ell(j)})$ and α is a positive constant at our disposal. Corresponding to different values of θ we obtain different DG schemes, namely: $\theta = -1$ (resp. $\theta = 1$) leads to the symmetric (resp. non-symmetric) interior penalty method, while $\theta = 0$ corresponds to the so-called incomplete interior penalty method (see [2, 24, 25, 26] for more details).

4 ALGEBRAIC FORMULATION AND TIME INTEGRATION SCHEME

We discuss here the algebraic formulation of the two non-conforming approaches presented in the previous section. In particular we described how to build the linear systems coming from the mortar or DG discretization and discuss the time integration scheme.

4.1 Algebraic formulation of the problem

We denote by $D = \sum_{k=1}^K (N_k + 1)^2$ the dimension of each component of V_δ and we introduce a basis $\{\Psi_i^1, \Psi_i^2\}_{i=1}^D$ for the finite dimensional space V_δ , where $\Psi_i^1 = (\Psi_i^1, 0)^\top$ and $\Psi_i^2 = (0, \Psi_i^2)^\top$. We choose the set of shape functions in such a way that they are orthonormal with respect to the L^2 inner product on the reference element.

We denote by $\{\mathbf{p}_j\}_{j=1}^D$ the GLL nodes of the mesh and we suppose that $\Psi_i^1(\mathbf{p}_j) = \Psi_i^2(\mathbf{p}_j) = \delta_{ij}$, for $i, j = 1, \dots, D$, where δ_{ij} represents the Kronecker symbol. Dropping the subscript δ , we write the trial functions $\mathbf{u} \in V_\delta$ as a linear combination of the basis functions

$$\mathbf{u}(\mathbf{x}, t) = \sum_{j=1}^D \begin{bmatrix} \Psi_j^1(\mathbf{x}) \\ 0 \end{bmatrix} U_j^1(t) + \sum_{j=1}^D \begin{bmatrix} 0 \\ \Psi_j^2(\mathbf{x}) \end{bmatrix} U_j^2(t).$$

Next, we define $a_k = 1 + \sum_{j=1}^{k-1} (N_j + 1)^2$ and $b_k = \sum_{j=1}^k (N_j + 1)^2$ and we order the basis functions such that

$$\mathbf{u}|_{\Omega_k} = (u^1, u^2)_{|\Omega_k}^\top = \left(\sum_{j=a_k}^{b_k} \Psi_j^1 U_{j,k}^1, \sum_{j=a_k}^{b_k} \Psi_j^2 U_{j,k}^2 \right)^\top, \quad \text{for } k = 1, \dots, K.$$

With such a notation (11) can be rewritten as the following set of ODE

$$\begin{bmatrix} \underline{\mathbf{M}}^1 & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{M}}^2 \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{U}}^1 \\ \ddot{\mathbf{U}}^2 \end{bmatrix} + \begin{bmatrix} \underline{\mathbf{A}}^1 + \underline{\mathbf{B}}^1 & \underline{\mathbf{A}}^2 + \underline{\mathbf{B}}^2 \\ \underline{\mathbf{A}}^3 + \underline{\mathbf{B}}^3 & \underline{\mathbf{A}}^4 + \underline{\mathbf{B}}^4 \end{bmatrix} \begin{bmatrix} \mathbf{U}^1 \\ \mathbf{U}^2 \end{bmatrix} = \begin{bmatrix} \mathbf{F}^{ext,1} \\ \mathbf{F}^{ext,2} \end{bmatrix}, \quad (13)$$

where $\ddot{\mathbf{U}}$ represents the vector of the nodal acceleration and \mathbf{F}^{ext} the vector of externally applied loads. As a consequence of our assumptions on the basis functions, the mass matrices $\underline{\mathbf{M}}^1$ and $\underline{\mathbf{M}}^2$ have a block diagonal structure, i.e., $\underline{\mathbf{M}}^\ell = \text{diag}(\underline{\mathbf{M}}_1^\ell, \underline{\mathbf{M}}_2^\ell, \dots, \underline{\mathbf{M}}_K^\ell)$, for $\ell = 1, 2$, where each block $\underline{\mathbf{M}}_k^\ell$ is associated to the spectral element Ω_k and $\underline{\mathbf{M}}_k^\ell(i, j) = (\rho \Psi_j^\ell, \Psi_i^\ell)_{\Omega_k}$, for $i, j = a_k, \dots, b_k$. The matrix $\underline{\mathbf{A}}$ associated to the bilinear form $\mathcal{A}(\cdot, \cdot)$ defined in (5) takes the form

$$\underline{\mathbf{A}} = \begin{bmatrix} \underline{\mathbf{A}}^1 & \underline{\mathbf{A}}^2 \\ \underline{\mathbf{A}}^3 & \underline{\mathbf{A}}^4 \end{bmatrix},$$

where the block diagonal matrices $\underline{\mathbf{A}}^\ell$, $\ell = 1, \dots, 4$ are equal to $\underline{\mathbf{A}}^\ell = \text{diag}(\underline{\mathbf{A}}_1^\ell, \underline{\mathbf{A}}_2^\ell, \dots, \underline{\mathbf{A}}_K^\ell)$. The elements of the matrices $\underline{\mathbf{A}}_k^\ell$, $\ell = 1, \dots, 4$ and $k = 1, \dots, K$, are defined by

$$A_k^1(i, j) = \mathcal{A}(\underline{\sigma}(\Psi_j^1), \underline{\varepsilon}(\Psi_i^1))_{\Omega_k}, \quad A_k^2(i, j) = \mathcal{A}(\underline{\sigma}(\Psi_j^2), \underline{\varepsilon}(\Psi_i^1))_{\Omega_k}, \quad \text{for } i, j = a_k, \dots, b_k,$$

$$A_k^3(i, j) = \mathcal{A}(\underline{\sigma}(\Psi_j^1), \underline{\varepsilon}(\Psi_i^2))_{\Omega_k}, \quad A_k^4(i, j) = \mathcal{A}(\underline{\sigma}(\Psi_j^2), \underline{\varepsilon}(\Psi_i^2))_{\Omega_k}, \quad \text{for } i, j = a_k, \dots, b_k.$$

We remark that the matrices $\underline{\mathbf{M}}$ and $\underline{\mathbf{A}}$ are very similar to those coming from the discretization of the elastodynamic equation (2) with the conforming Spectral Element Method (see [6, 7]).

If we are using the mortar formulation, the matrix $\underline{\mathbf{B}}$, associated to the bilinear form $\mathcal{B}(\cdot, \cdot)$ defined in (5), is the null matrix, whereas in the DG approach, is the one that takes into account of the discontinuity of the numerical solution across the skeleton \mathcal{S} . More precisely,

$$\underline{\mathbf{B}} = \begin{bmatrix} \underline{\mathbf{B}}^1 & \underline{\mathbf{B}}^2 \\ \underline{\mathbf{B}}^3 & \underline{\mathbf{B}}^4 \end{bmatrix}, \quad (14)$$

where

$$\underline{\mathbf{B}}^\ell = \begin{bmatrix} \underline{\mathbf{B}}_{1,1}^\ell & \cdots & \underline{\mathbf{B}}_{1,K}^\ell \\ \vdots & \ddots & \vdots \\ \underline{\mathbf{B}}_{K,1}^\ell & \cdots & \underline{\mathbf{B}}_{K,K}^\ell \end{bmatrix}, \quad \text{for } \ell = 1, \dots, 4.$$

In particular the elements of each block $\underline{\mathbf{B}}_{k,n}^1(i, j) = \sum_{\gamma \in \mathcal{F}_I} \mathcal{B}(\Psi_j^1, \Psi_i^1)_\gamma$, $i = a_k, \dots, b_k$ and $j = a_n, \dots, b_n$. The elements of the matrices $\underline{\mathbf{B}}_{k,n}^\ell$, for $\ell = 2, 3, 4$ are defined in a similar way.

The situation is a little bit more complicated in the Mortar approach, since the weak continuity condition across the skeleton \mathcal{S} does not appear explicitly in the variational equation but it is a constraint in the functional space V_δ^{mortar} .

To take into account the **(MC)** we have to modify the system (13) as follows. Without loss of generality let us suppose that γ_n^- is a non mortar edge contained in \mathcal{S} and that it is shared by two regions Ω_m and Ω_n . We call *master* the side of γ_n^- belonging to $\overline{\Omega}_m$ and *slave* the other side. Thus, the *mortar conditions* can be recast as:

(i) $\Phi = \mathbf{u}_m$ on γ_n^- ,

(ii) $\int_{\gamma_n^-} (\mathbf{u}_n - \mathbf{u}_m) \cdot \hat{\Phi} ds = 0 \quad \forall \hat{\Phi} \in [\hat{\Lambda}_\delta(\gamma_n^-)]^d$.

At the algebraic level, the condition in (ii) is represented by the following linear system of equations

$$\begin{bmatrix} \underline{R}^1 & \underline{0} \\ \underline{0} & \underline{R}^2 \end{bmatrix} \begin{bmatrix} \mathbf{U}_n^1 \\ \mathbf{U}_n^2 \end{bmatrix} = \begin{bmatrix} \underline{P}^1 & \underline{0} \\ \underline{0} & \underline{P}^2 \end{bmatrix} \begin{bmatrix} \mathbf{U}_m^1 \\ \mathbf{U}_m^2 \end{bmatrix}, \quad (15)$$

where

$$\underline{R}^\ell(i, j) = \int_{\gamma_n^-} \Psi_j^\ell \hat{\Phi}_i^\ell ds \quad \text{and} \quad \underline{P}^\ell(i, j) = \int_{\gamma_n^-} \Phi_j^\ell \hat{\Phi}_i^\ell ds, \quad \ell = 1, 2. \quad (16)$$

By using that the shape functions are orthonormal on the reference element and suitable quadrature rules to integrate (16), (cf. [3, 11]), it is possible to easily invert the matrix \underline{R} and to reduce (15) to

$$\begin{bmatrix} \mathbf{U}_n^1 \\ \mathbf{U}_n^2 \end{bmatrix} = \begin{bmatrix} \underline{Q}_n & \underline{0} \\ \underline{0} & \underline{Q}_n \end{bmatrix} \begin{bmatrix} \mathbf{U}_m^1 \\ \mathbf{U}_m^2 \end{bmatrix},$$

where $\underline{Q}_n = (\underline{R}^1)^{-1} \underline{P}^1 = (\underline{R}^2)^{-1} \underline{P}^2$. To obtain a global projection operator $\tilde{\mathbf{Q}}$ we proceed as follows. For each component of \mathbf{u} we denote by $\mathbf{U}_{\text{slave}}$ the vector of unknowns associated to the dofs that lay on the slave side of \mathcal{S} and by $\mathbf{U}_{\text{master}}$ the vector of unknowns associated to all the remaining dofs. Then, for each γ_n^- contained into the skeleton \mathcal{S} we build the local projection operator \underline{Q}_n and we store it into the matrix $\tilde{\mathbf{Q}}$. In this way $\tilde{\mathbf{Q}}$ has a block structure of the form

$$\tilde{\mathbf{Q}} = \begin{bmatrix} \hat{\underline{Q}} & \underline{0} \\ \underline{0} & \hat{\underline{Q}} \end{bmatrix}, \quad (17)$$

where $\hat{\underline{Q}}$ is block diagonal matrix with a block equal to the identity and the other equal to the rectangular matrix \underline{Q}_n containing all the local matrices \underline{Q}_n . Thus, we have that the global linear system can be expressed as

$$\tilde{\mathbf{Q}}^\top \tilde{\mathbf{M}} \tilde{\mathbf{Q}} \ddot{\mathbf{U}}_{\text{master}} + \tilde{\mathbf{Q}}^\top \tilde{\mathbf{A}} \tilde{\mathbf{Q}} \mathbf{U}_{\text{master}} = \tilde{\mathbf{Q}}^\top \mathbf{F}^{\text{ext}}, \quad (18)$$

where the rows and the columns of the matrices $\tilde{\mathbf{M}}$ and $\tilde{\mathbf{A}}$ have been modified according to these latter assumptions on the unknown renumbering. We remark that it is possible to obtain

the linear system (18) using as a basis for V_δ^{mortar} , the functions $\{\tilde{\Psi}_i^1, \tilde{\Psi}_i^2\}_{i=1}^D$, where $\tilde{\Psi}_i^1 = (\tilde{\Psi}_i^1, 0)^\top$ and $\tilde{\Psi}_i^2 = (0, \tilde{\Psi}_i^2)^\top$ are defined by

$$\tilde{\Psi}_i^\ell = \begin{cases} \Psi_i^\ell & \forall i \text{ s.t } \mathbf{p}_i \text{ is a master node,} \\ \sum_j \hat{Q}_{ij} \Psi_j^\ell & \forall i \text{ s.t } \mathbf{p}_i \text{ is a slave node, } (\mathbf{p}_j \text{ master node on } \mathcal{S}). \end{cases}$$

All the terms appearing in the algebraic formulations presented so fare are computed using the Gauss-Lobatto quadrature rule in which the quadrature points coincide with GLL points. We notice that since the term $\Psi_j \Psi_i \in \mathbf{Q}_{2N_k}$, for some k , the spectral mass matrix is slightly under integrated. However, since the Gauss-Lobatto rule with N_k points is exact for polynomials up to degree $2N_k - 1$, the final accuracy of spectral methods is not damaged [6].

Finally, we point out that if $\mathbf{f}^{visc} \neq 0$ we must compute the following additional external forces:

$$\begin{bmatrix} \mathbf{F}^{visc,1} \\ \mathbf{F}^{visc,2} \end{bmatrix} = - \begin{bmatrix} \underline{\mathbf{C}}^1 & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{C}}^2 \end{bmatrix} \begin{bmatrix} \dot{\mathbf{U}}^1 \\ \dot{\mathbf{U}}^2 \end{bmatrix} - \begin{bmatrix} \underline{\mathbf{D}}^1 & \underline{\mathbf{0}} \\ \underline{\mathbf{0}} & \underline{\mathbf{D}}^2 \end{bmatrix} \begin{bmatrix} \mathbf{U}^1 \\ \mathbf{U}^2 \end{bmatrix},$$

where the matrices $\underline{\mathbf{C}}^\ell$ and $\underline{\mathbf{D}}^\ell$, for $\ell = 1, 2$ have a block diagonal structure. Each block $\underline{\mathbf{C}}_k^\ell$ and $\underline{\mathbf{D}}_k^\ell$ is associated to the spectral element Ω_k and

$$\mathbf{C}_k^\ell(i, j) = (\rho \zeta \Psi_j^\ell, \Psi_i^\ell)_{\Omega_k}, \quad \mathbf{D}_k^\ell(i, j) = (\rho \zeta^2 \Psi_j^\ell, \Psi_i^\ell)_{\Omega_k}, \quad \text{for } i, j = a_k, \dots, b_k,$$

respectively. Then the discretized system becomes:

$$\underline{\mathbf{M}}\ddot{\mathbf{U}} + \underline{\mathbf{C}}\dot{\mathbf{U}} + (\underline{\mathbf{A}} + \underline{\mathbf{B}} + \underline{\mathbf{D}})\mathbf{U} = \mathbf{F}^{ext}, \quad (19)$$

where the accelerations $\ddot{\mathbf{U}}$ and the velocities $\dot{\mathbf{U}}$ are approximated as described in the next section.

4.2 Time integration

Let now subdivide into N subinterval of amplitude $\Delta t = \frac{T}{N}$ the interval $(0, T]$: the time integration scheme for (13) is achieved with the second order central difference scheme, setting $t_n = n\Delta t$:

$$\ddot{\mathbf{U}}(t_n) = \frac{\mathbf{U}(t_{n+1}) - 2\mathbf{U}(t_n) + \mathbf{U}(t_{n-1}))}{\Delta t^2}, \quad \dot{\mathbf{U}}(t_n) = \frac{\mathbf{U}(t_{n+1}) - \mathbf{U}(t_{n-1}))}{2\Delta t}. \quad (20)$$

Thus, the equation (13) or (18) at each time step t_n becomes:

$$\underline{\mathbf{K}}\mathbf{U}(t_{n+1}) = \mathbf{b}(\mathbf{U}(t_n), \mathbf{U}(t_{n-1}), \mathbf{F}^{ext}(t_n), \underline{\mathbf{A}}, \underline{\mathbf{B}}), \quad (21)$$

with initial condition $\mathbf{U}(t_0) = \mathbf{u}_0$ and $\dot{\mathbf{U}}(t_0) = \mathbf{u}_1$. If we adopt a fully explicit time integration scheme the matrix $\underline{\mathbf{K}}$ is the mass matrix, i.e. $\underline{\mathbf{K}} = \underline{\mathbf{M}}$, if a DGSEM is employed and $\underline{\mathbf{K}} = \tilde{\mathbf{Q}}^\top \tilde{\mathbf{M}} \tilde{\mathbf{Q}}$ for the MSEM. In particular, for the latter approach, taking advantage of the structure of $\tilde{\mathbf{Q}}$ it is possible to decompose the linear system (21) as follows

$$\begin{bmatrix} \underline{\mathbf{M}}_{master} & 0 \\ 0 & \underline{\mathbf{Q}}^\top \underline{\mathbf{M}}_{slave} \underline{\mathbf{Q}} \end{bmatrix} \begin{bmatrix} \mathbf{U}_{master}^{\mathcal{I}} \\ \mathbf{U}_{master}^{\mathcal{S}} \end{bmatrix} = \begin{bmatrix} \mathbf{b}_{master}^{\mathcal{I}} \\ \underline{\mathbf{Q}}^\top \mathbf{b}_{slave}^{\mathcal{S}} \end{bmatrix}. \quad (22)$$

Here the superscripts \mathcal{I} and \mathcal{S} denote if the unknowns belong to the interior or to the skeleton of the domain. Then at each time step we solve separately the two blocks of the linear systems (22).

In particular for the non diagonal block we perform the LU-factorization with pivoting (cf [22]). To ensure stability, the explicit time integration scheme must satisfy the usual Courant-Friedrichs-Levy (CFL) condition (see [22]) that imposes a restriction on the amplitude of Δt . This limitation is proportional to the minimal distance Δx between two consecutive spectral nodes \mathbf{p}_i and \mathbf{p}_j , with $i \neq j$, of the numerical grid, see [8]. Since GLL points are clustered near the edges of spectral elements Ω_k , where the grid size is proportional to N_k^{-2} , the stability requirement on Δt may become too restrictive for very large approximation orders N_k . In such cases an implicit time scheme is recommended.

5 HOW IMPLEMENTING THE METHODS

In this section we describe the implementation of the MSEM and the DGSEM in the spectral element code GeoELSE [14] and we compare the two different algorithms from the efficiency view point. In this context the word "efficiency" has the meaning of low memory storage and executing program velocity. In this sense, the assembling of the matrices in (13)-(18) is performed once, outside the time loop.

After setting the initial condition \mathbf{u}_0 and \mathbf{u}_1 , we build the skeleton \mathcal{S} as explained in (6)-(10) for the MSEM or the DGSEM respectively. In the mortar solution scheme, see Algorithm 1, a further step is required in order to identify the *master* and the *slave* decomposition of \mathcal{S} .

For both algorithms we notice that in general, all the matrix-vector multiplications involving $\underline{\mathbf{M}}$, $\underline{\mathbf{A}}$, $\underline{\mathbf{B}}$ and $\underline{\mathbf{Q}}$ have to be intended subdomains per subdomains.

Algorithm 1: Mortar Solution Scheme

1. Set initial conditions \mathbf{u}_0 and \mathbf{u}_1 .
 2. Build the skeleton \mathcal{S} for the domain Ω .
 3. Decompose \mathcal{S} into the union of *master* and *slave* edges.
 4. Construct the projection operator $\underline{\mathbf{Q}}$ for the interface unknowns \mathbf{U}_{slave} .
 5. Perform the LU-factorization of $\underline{\mathbf{Q}}^\top \underline{\mathbf{M}}_{slave} \underline{\mathbf{Q}}$.
 6. For each discrete time t_n :
 - compute the internal forces $\mathbf{F}^{int}(t_n) = \underline{\mathbf{A}}\mathbf{U}(t_n)$;
 - assemble external forces $\mathbf{F}^{ext}(t_n)$;
 - solve for the *master* unknowns \mathbf{U}_{master} the systems (22);
 - perform the projection on the *slave* unknowns;
 - if the final time T is not reached set $t_n \leftarrow t_{n+1}$ and go to 6.
-

Algorithm 2 describes the DG solution scheme. Here we denote by $\mathbf{J}(t_n) = \underline{\mathbf{B}}\mathbf{U}(t_n)$ the vector containing the interface terms. Since the matrix $\underline{\mathbf{B}}$ defined in (14) has a highly sparsity structure, it is stored taking advantage of it.

Algorithm 2: DG Solution Scheme

1. Set initial conditions \mathbf{u}_0 and \mathbf{u}_1 .
2. Build the skeleton \mathcal{S} for the domain Ω .

3. Decompose \mathcal{S} into elementary components.
4. Construct the matrix $\underline{\mathbf{B}}$ for the interface unknowns.
5. For each discrete time t_n :
 - compute the internal forces $\mathbf{F}^{int}(t_n) = \underline{\mathbf{A}}\mathbf{U}(t_n)$;
 - assemble external forces $\mathbf{F}^{ext}(t_n)$;
 - compute the jumps at the interfaces $\mathbf{J}(t_n) = \underline{\mathbf{B}}\mathbf{U}(t_n)$;
 - solve the system $\underline{\mathbf{M}}\ddot{\mathbf{U}} = \mathbf{F}^{ext}(t_n) - \mathbf{F}^{int}(t_n) - \mathbf{J}(t_n)$;
 - if the final time T is not reached set $t_n \leftarrow t_{n+1}$ and go to 4.

According to [1, 9, 10], it seems that for elastic wave propagation problems the more effective method, in term of accuracy, grid dispersion and stability is the symmetric interior penalty Galerkin method (SIPG). However, if the symmetric approach is used we recall that the constant α in (12) must be sufficiently large to guarantee consistency of the method without affecting the conditioning of the stiffness matrix in (13).

6 A SOIL-STRUCTURE INTERACTION PROBLEM

In this section we aim at studying a soil-structure interaction problem, namely the seismic response of a railway viaduct (Acquasanta viaduct, Genova, Italy). We consider the viscoelastic model (1) in the computational domain $(x, z) \in \Omega = (0, 10^4 m) \times (0, f(x))$, where f describes the top profile of the bridge and of the surrounding valley, see Fig. 3. The size of the domain is chosen in order to avoid any possible interference with reflections of the waves of interest with the spurious ones eventually arising from the absorbing boundaries. The dynamic and mechanical properties of the structure and of the surrounding soil are summarized in Table 6. Depending on the material involved, we subdivided the computational grid into different regions, as shown in Fig. 3 (top panel). Note that the mesh was designed to propagate up to about 3 Hz.

We simulate a point source load of the form $\mathbf{f}(\mathbf{x}, t) = \mathbf{g}(\mathbf{x})h(t)$, where \mathbf{f} is the external force introduced in (1). The function \mathbf{g} describes the space distribution of the source and often is the body force $\mathbf{g}(\mathbf{x}) = \delta(\mathbf{x} - \mathbf{x}_S)\hat{\mathbf{w}}$, where δ represents the Dirac distribution, \mathbf{x}_S is the source location and $\hat{\mathbf{w}}$ is the direction of the body force. The source time history is given by a Ricker-type time function with maximum frequency $\nu_{max} = 3\text{Hz}$, defined as

$$h(t) = h_0[1 - 2\beta(t - t_0)^2] \exp[-\beta(t - t_0)^2], \quad (23)$$

where h_0 is a scale factor, $t_0 = 2$ seconds is the time shift and $\beta = \pi^2 \nu_{max}^2 = 9.8696 \text{ s}^{-1}$ is a parameter that determines the width of the wavelet (23).

In Fig. 3 we show the two different computational grids used for the numerical simulations. The conforming grid, Fig. 3 left, is used with SEM discretization to produce a reference solution for the problem. It provides, in fact, a sufficiently accurate discretization, as we verified that further mesh refinements generates quasi-identical seismograms. The non-conforming grid, shown in Fig. 3 right, is used for both DGSEM and MSEM simulations.

In our analysis we choose the polynomial approximation degree as described in Table 6. It is worth highlighting that the non-conforming approximations lead to a dramatic reduction of the size of the numerical model and, hence, of the computational costs (102.640 unknowns for

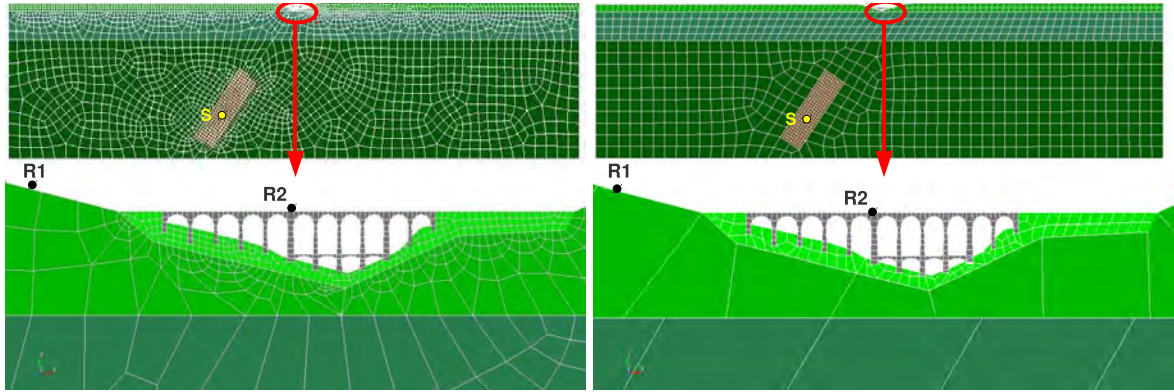

Figure 3: Conforming (left) and non conforming (right) grids. The full domain is displayed on the top and a zoom of the railway bridge is displayed on the bottom. The receivers R1 and R2, on the ground and on the bridge, respectively, are also highlighted.

Layer	$\rho [Kg/m^3]$	$c_P [m/s]$	$c_S [m/s]$	$\zeta [1/s]$	$N [SEM]$	$N [MSEM/DGSEM]$
1 (bridge)	1750	1218	716,7	0.6283	4	2
2 (stiff soil)	2400	1100	635	0.31416	4	2
3 (soft bedrock)	2400	1100	635	0.02513	4	4
4 (medium bedrock)	2600	1700	982	0.02284	4	4
5 (stiff bedrock)	2800	2300	1330	0.02094	4	4
6 (stiff bedrock)	2800	2300	1330	0.02094	4	4

Table 1: Dynamic and mechanical parameters and polynomial approximation degree N for each subregion of the domain decomposition (the factor ζ takes into account the visco-elastic linear soil behavior).

SEM vs. 41.322 for MSEM or DGSEM).

Such an advantage is expected to play a major role for 3D engineering applications. In Fig. 4 (resp Fig. 5 we analyse the synthetic seismograms recorded by the receiver R1 (resp. R2) on the top of the ground (resp. bridge) using the misfits criteria introduced in [19]. The results shown an excellent fit of the data for R1 and a good fit for R2. Probably, for the latter receiver, the results are affected by the grid dispersion phenomenon arising when low order polynomial approximation degrees are used [1, 9, 10].

7 CONCLUSIONS

In this paper we compared two different non-conforming high order numerical techniques, namely the Mortar Spectral Element Method and the Discontinuous Galerkin Spectral Element Method, for the approximation of the elastic wave equation in heterogeneous media. The key feature of these methods is to replace the exact continuity condition at the skeleton of the decomposition with a weak one, written in terms of the jumps of the displacements and the tractions across the interfaces. Relaxing the continuity condition is then possible, preserving the accuracy of high order methods, to deal with a geometrically non-conforming domain partitions where local meshes are independently generated from the neighbouring ones and associated with different spectral approximation degrees. Note that the subdomain partition is constructed according to the (available) material properties. Starting from a common weak formulation we describe both approaches in parallel in order to highlight their analogies and their differences. We gave a special attention to the implementation aspects of the two techniques in order to make the reader able to deal with an efficient numerical coding. Finally, we show that the MSEM and the DGSEM can be effectively used for complex seismic wave propagation problems, namely the soil-structure interaction between a valley and a railway bridge. The results, compared with those obtained with the SEM, show that both the non-conforming strategies are good in term of accuracy and computational effort. We refer to [1] for the full comparison of the methods in term of convergence, accuracy, grid dispersion and stability.

Keywords: Random heterogeneities, Stochastic wave, half space, dispersion curve, frequency spectrum, SH surface wave.

Abstract. *Horizontally polarized shear waves (SH waves) do not exist in a homogeneous half space according to the traditional elastic wave theory. However, in this study, we proved both theoretically and numerically that there will be surface waves in a half space which has small, random density, but the mean value of the density is homogeneous. Historically, this type of half space is often treated as a homogeneous one with deterministic methods. In this investigation, a closed-form dispersion equation was derived stochastically, and the frequency spectrum, dispersion equation, phase/group velocity were plotted numerically to study how the random inhomogeneities will affect the dispersion properties of the half space with random density. This research may find its application in seismology, non-destructive test/evaluation, etc.*

1 Introduction

In this study, the dispersion and attenuation properties of waves propagating in a half space (see figure 1) with random heterogeneities are investigated.

Figure 1: coordinate system of the half space

Shear horizontal surface waves (SHSW) are the most destructive waves in an earth quake and they can propagate through a very long distance without much loss of its energy. But, scientists have proved long ago that there is no SHSW in a homogeneous isotropic linearly elastic half-space [1]. However, in 1911, love predicted mathematically that SHSW could exist if the half-space is covered by a layer of a different material.

Since then, SHSW in a half space was mostly explained theoretically by Love's theory or its variant theories. But we know that the earth's surface is very complex. It is a mixture of many kinds of rocks, sands, soil, water, etc., and more complicatedly, these materials do not often distribute in deterministic ways, but distribute randomly. So do SHSW exist in such a complex, random half space?

Similar problems have been explored by some scientists. B. Collet et al. [3] studied SHSW in a Functionally Graded Material of which some material constants share the same depth-dependent function, and derived some of the depth-dependent functions which could be solved exactly. Using their solutions, they studied the influence of different inhomogeneity functions on the properties of SHSW. J. Achenbach et al. [2] studied SHSW in a purely elastic half-space whose shear modulus and mass density depend arbitrarily on the depth and gave a general solution that is quite exact for high frequencies. T.C.T. Ting [4] recently investigated SHSW in a half space of which C_{44} and ρ have the same function form, and C_{55} , C_{45} are correlated. Ting also got an asymptotic solution of general graded materials for large wave number k . Anti-plane shear waves for anisotropic graded materials have been considered for periodic half-spaces by A. Shuvalov et al. [5] and for a single plate by A. Shuvalov et al. [6]. Shear horizontal waves in functionally graded piezoelectric materials are also greatly studied by Tianjian Lu et al. [7, 8, 9].

But these researches haven't given an explicit solution of dispersion and attenuation of SHSW in a half space with random density in the depth direction by strict stochastic methods. In this study, we get the explicit dispersion equation by the first order smoothing approximation (FOSA) method. And we then analyze the dispersion and attenuation properties using the dispersion equation.

In this study we proved mathematically and numerically that SHSW could exist in a stochastically homogeneous half space. Some interesting properties of dispersion and attenuation found in this study could promote our understanding of waves propagating in a half space with random heterogeneities, e.g. earth's upper crust, alloys or composites. It will also help us to do the inverse problems, for example, to use seismic waves to detect the earth's crust structure,

and to use ultrasonic waves to evaluate a structure with randomly distributed micro-cracks or heterogeneities.

2 Modeling and mathematical analysis

The fundamental dynamic equation system for statistically homogenous, isotropic, linearly elastic solid is

$$\tau_{ij,j} + \rho f_i = \rho \ddot{u}_i \quad (1)$$

$$\tau_{ij} = \lambda \epsilon_{kk} \delta_{ij} + 2\mu \epsilon_{ij} \quad (2)$$

$$\epsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}) \quad (3)$$

To account for the random heterogeneities, we change the constants ρ, μ, λ in the equation system to functions of space, time and random variables.

Consider SH waves propagating in x direction in a half space (see Fig. 1).

It is known that for anti-plane waves that $u_x = u_y = 0$ and $\partial/\partial z = 0$. And if we assume that there is no body force, the equation system reduces to

$$\tau_{zj,j} = \rho \ddot{u}_z \quad (4)$$

$$\tau_{zj} = \mu u_{z,j} \quad (5)$$

in which, $j = x, y$. So the dynamic equation for SH waves in a random half space is

$$(\mu u_{z,j})_{,j} = \rho \ddot{u}_z \quad (6)$$

And the boundary condition is

$$\tau_{zy}|_{y=0} = 0 \quad i.e. \quad (7)$$

$$\mu u_{z,y}|_{y=0} = 0 \quad (8)$$

Assume here that there is randomness only in the y direction. Consider an harmonic wave motion of the form

$$u_z = f(y) \exp[i(k_1 x - \omega t)] \quad (9)$$

in which, $f(y)$ is a random function. To study the surface shear wave, we assume the averaged $f(y)$ to be

$$\langle f(y) \rangle = A e^{-by} \quad (10)$$

, in which $b > 0$. Thus the mean wave motion $\langle u_z \rangle$ could be written as

$$\langle u_z \rangle = A e^{-by} e^{i(k_1 x - \omega t)} \quad (11)$$

If there is no random heterogeneities in the solid, a solution of Eq. (6) would be of the form [1]

$$u_z = A e^{-by} e^{i(kx - \omega t)} \quad (12)$$

Substituting Eq. (12) into Eq. (6), we find

$$\frac{\omega^2}{C_s^2} - k_1^2 + b^2 = 0 \quad (13)$$

For a free surface, the boundary condition at $y = 0$ is

$$\frac{du_z}{dy} = 0 \quad (14)$$

The boundary condition Eq. (14) can be satisfied only if either $A = 0$ or $b = 0$. Therefore, there is no surface SH wave in an homogenous, isotropic, linearly elastic half space.

Firstly, we consider that random heterogeneities are only on the surface (as a practical example, the roughness of the earth surface could be viewed as a half space but with random density on the surface), then the boundary conditions at $y = 0$ can be written as

$$\begin{aligned} \mu \frac{\partial u_z}{\partial y} &= 0 \Rightarrow \\ (\mu_0 + \epsilon \mu_1) \frac{\partial (< u_z > + \epsilon u_{z1})}{\partial y} &= 0 \end{aligned} \quad (15)$$

By averaging both sides of Eq. (15), when $y = 0$, we get

$$\mu_0 \frac{d < u_z >}{dy} + \epsilon^2 < \mu_1 \frac{\partial u_{z1}}{\partial y} > = 0 \quad (16)$$

The randomness of the surface takes effect through the term $\epsilon^2 < \mu_1 \frac{\partial u_{z1}}{\partial y} >$. We assume here that

$$\epsilon^2 < \mu_1 \frac{\partial u_{z1}}{\partial y} > |_{y=0} = \mu_0 A \beta e^{i(k_1 x - \omega t)} \quad (17)$$

Substituting Eqs. (17) and (11) into Eq. (16), we get

$$b = \beta \quad (18)$$

Considering Eq. (13), the dispersion equation for SH waves in a half space with random heterogeneities only on the surface is

$$\frac{\omega^2}{C_s^2} - k_1^2 + \beta^2 = 0 \quad (19)$$

Next, we will investigate the problem of the half space with random heterogeneities in the whole depth direction. Substituting Eq. (9) in Eq. (6) gives

$$(\rho \omega^2 - \mu k_1^2) f + (\mu f_{,y})_{,y} = 0 \quad (20)$$

Assuming that ρ, μ differ slightly from the mean value of them, ρ, μ can be written as

$$\begin{aligned} \rho(y) &= \rho_0 + \epsilon \rho_1(y) \\ \mu(y) &= \mu_0 + \epsilon \mu_1(y) \end{aligned} \quad (21)$$

where, ϵ is a small parameter, and

$$< \rho_1 > = < \mu_1 > = 0 \quad (22)$$

Substituting Eq. (21) in Eq. (20), we have

$$(\rho_0 \omega^2 - \mu_0 k_1^2) f + \mu_0 f_{,yy} + \epsilon ((\rho_1 \omega^2 - \mu_1 k_1^2) f + (\mu_1 f_{,y})_{,y}) = 0 \quad (23)$$

According to FOSA theory (see Appendix A for a brief deduction of FOSA), the deterministic operator of Eq. (20) is

$$L_0(y) = \mu_0 \left(k_0^2 + \frac{\partial^2}{\partial y^2} \right) \quad (24)$$

in which,

$$k_0^2 = \frac{\omega^2}{C_s^2} - k_1^2 \quad (25)$$

and, C_s is the shear velocity of the homogeneous material without random heterogeneities,

$$C_s = \sqrt{\frac{\mu_0}{\rho_0}} \quad (26)$$

And the first order random operator of Eq. (20) is

$$L_1(y) = P(y) + \mu_1(y)_{,y} \frac{\partial}{\partial y} + \mu_1(y) \frac{\partial^2}{\partial y^2} \quad (27)$$

in which,

$$P(y) = \rho_1(y)\omega^2 - \mu_1(y)k_1^2 \quad (28)$$

Considering Eq. (22), we can see that $\langle L_1 \rangle = 0$. For steady waves, G_0 can be taken as

$$G_0(y_1, y_2) = -\frac{1}{2k_0\mu_0} \sin(k_0|y_1 - y_2|) \quad (29)$$

According to the stochastic theory, the FOSA equation is

$$L_0 \langle f(y_1) \rangle - \epsilon^2 \left\langle L_1(y_1) \int G_0(y_1, y_2) L_1(y_2) \langle f(y_2) \rangle dy_2 \right\rangle = 0 \quad (30)$$

To solve Eq. (30), let's calculate $L_1(y_1)G_0(y_1, y_2)$ first,

$$\begin{aligned} L_1(y_1)G_0(y_1, y_2) &= - \left(P(y_1) + \mu_1(y_1)_{,y_1} \frac{\partial}{\partial y_1} + \mu_1(y_1) \frac{\partial^2}{\partial y_1^2} \right) * \\ &\quad \frac{1}{2k_0\mu_0} \sin(k_0|y_1 - y_2|) \end{aligned} \quad (31)$$

When $y_2 < y_1$

$$\begin{aligned} L_1(y_1)G_0(y_1, y_2) &= Q_1 \sin(k_0(y_1 - y_2)) + Q_2 \cos(k_0(y_1 - y_2)) \\ &= M(y_1, y_2) \end{aligned} \quad (32)$$

in which,

$$Q_1 = \left(\frac{\mu_1(y_1)k_0}{2\mu_0} - \frac{P(y_1)}{2k_0\mu_0} \right) \quad (33)$$

$$Q_2 = -\frac{\mu_1(y_1)_{,y_1}}{2\mu_0} \quad (34)$$

and, when $y_2 > y_1$

$$L_1(y_1)G_0(y_1, y_2) = -M(y_1, y_2) \quad (35)$$

Then, using Eq. (10), $L_1(y_2) < f(y_2) >$ can be expressed as

$$\begin{aligned} L_1(y_2) < f(y_2) > &= \left(P(y_2) + \mu_1(y_2)_{,y_2} \frac{\partial}{\partial y_2} + \mu_1(y_2) \frac{\partial^2}{\partial y_2^2} \right) A e^{-by_2} \\ &= A \left(P(y_2) - \mu_1(y_2)_{,y_2} b + \mu_1(y_2) b^2 \right) e^{-by_2} \\ &= N(y_2) \end{aligned} \quad (36)$$

If we assume that $\mu_1 = 0$, we could study the influence of the randomness of the density on the dispersion properties of the plate.

The random function $\rho_1(y_1; \gamma)$ is taken as Uhlenbeck-Ornstein process [10]. Although its correlation function is not mean-square differentiable, this process has been used in a number of investigations because it fits experimental data the best [11]. This process is a centered and stationary random function [10] and its correlation function is

$$\begin{aligned} R_{\rho_1(y_1; \gamma) \rho_1(y_2; \gamma)} &= \int \rho_1(y_1; \gamma) \rho_1(y_2; \gamma) d\gamma \\ &= \zeta^2 e^{-\frac{|y_1 - y_2|}{R_c}} = R(y_1 - y_2) \end{aligned} \quad (37)$$

In which, $\zeta = \sqrt{\langle \rho_1^2 \rangle}$ and it is the standard deviation of the random density function; γ is a random variable. And R_c is the integral radius (the correlation length) of the correlation function, which physically means the scale of heterogeneity [12], and it should be positive.

From Eq. (10), we have

$$L_0 < f(y_1) > = \mu_0 \left(k_0^2 + \frac{\partial^2}{\partial y^2} \right) A e^{-by_1} = \mu_0 (k_0^2 + b^2) A e^{-by_1} \quad (38)$$

Substituting Eqs. (31), (36) and (38) into Eq. (30), we get the dispersion equation,

$$k_0^2 + b^2 - \frac{\omega^4 \zeta^2 \epsilon^2 b}{2k_0 \mu_0^2} \left(\frac{1}{(b + \frac{1}{R_c})^2 + b^2} + \frac{1}{(b - \frac{1}{R_c})^2 + b^2} \right) = 0 \quad (39)$$

It could be seen from the dispersion equation Eq. (39) that if there is no random fluctuation, i.e. $\epsilon = 0$ or $\zeta = 0$ then $k_0^2 + b^2 = 0$ —the equation becomes the dispersion equation without random heterogeneities;

Considering the surface condition Eq. (18), the dispersion equation could be written as,

$$k_0^2 + \beta^2 - \frac{\omega^4 \zeta^2 \epsilon^2 \beta}{2k_0 \mu_0^2} \left(\frac{1}{(\beta + \frac{1}{R_c})^2 + \beta^2} + \frac{1}{(\beta - \frac{1}{R_c})^2 + \beta^2} \right) = 0 \quad (40)$$

To conveniently evaluate numerically the effect of random heterogeneities, the dispersion equation Eq. (40) is transformed into a dimensionless equation in the following.

Introduce new dimensionless variables as,

$$\begin{aligned} \bar{\omega} &= \frac{2h\omega}{\pi C_s} & \bar{k} &= \frac{2hk_1}{\pi} \\ \bar{R}_c &= \frac{\pi R_c}{2h} & \bar{\zeta} &= \frac{\epsilon \zeta}{\rho_0} \\ \bar{\mu}_0 &= \frac{\mu_0}{\rho_0 C_s^2} = 1 & \bar{\beta} &= \frac{2h\beta}{\pi} \end{aligned} \quad (41)$$

From Eqs. (25) and (41), we get

$$k_0^2 = \frac{\omega^2}{C_s^2} - k_1^2 = \left(\frac{\pi}{2h}\right)^2 (\bar{\omega}^2 - \bar{k}^2) \quad (42)$$

so the dimensionless k_0 is defined as,

$$\bar{k}_0^2 = \bar{\omega}^2 - \bar{k}^2 \quad (43)$$

Using Eqs. (41), we could get the dimensionless dispersion equation from Eq. (19),

$$\bar{\omega}^2 - \bar{k}_1^2 + \bar{\beta}^2 = 0 \quad (44)$$

Using Eqs. (41) and (43), the dimensionless dispersion equation of Eq. (40) is,

$$\bar{k}_0^2 + \bar{\beta}^2 - \Lambda = 0 \quad (45)$$

Λ denote the random term,

$$\Lambda = \frac{\bar{\omega}^4 \bar{\zeta}^2 \bar{\beta}}{2\bar{k}_0} \left(\frac{1}{(\bar{\beta} + \frac{1}{R_c})^2 + \bar{\beta}^2} + \frac{1}{(\bar{\beta} - \frac{1}{R_c})^2 + \bar{\beta}^2} \right) \quad (46)$$

3 Numerical results and analysis

The SH surface waves propagating in a half space with random densities is further studied numerically. The dimensionless dispersion equation Eq. (45) is used to compute the curves. The numerical results are explained and discussed in the following.

3.1 Random heterogeneities only on the surface

The geomorphy of the earth's surface is always very complex. The reason for this complexity can come from both natural and man-made actions. In this study, we model the complex geomorphy by giving a surface parameter β . So in this section, we will study the dispersion properties for half spaces with random heterogeneities only on the surface. The dispersion curves are plotted according to Eq. (19).

From figure 2, it can be seen that the phase velocity will grow to 1 slowly, but for $\bar{k} < 2$, the phase velocity will be 0, i.e. the waves become standing waves in this circumstance.

From figure 3, it can be seen that, given a wave number, the phase velocity will decrease to 0 as the surface parameter $\bar{\beta}$ grows, i.e. the waves propagate more and more slowly when the surface becomes more and more rough, and all the waves will be blocked when $\bar{\beta}$ is large enough.

3.2 Frequency spectrum analysis

In the following, we will study the dispersion properties for half spaces with random heterogeneities not only on the surface but also in the whole half space. The related parameters are set to $\epsilon = 0.1, \bar{\zeta} = 2, \bar{R}_c = 0.4, \bar{\beta} = 2$ respectively.

From figures 4, 5 and 6, we can see that

1. As the wave number grows, the velocity will grow to a value—approximately 0.93 in this case. The reason that it can not reach to 1 could be that the waves are reflected and scattered by the random heterogeneities.

Figure 2: Normalized phase velocity—normalized wave number. $\bar{\beta} = 2$

Figure 3: Normalized phase velocity—normalized surface parameter. $\bar{k} = 10$

2. The wave number does not start from 0, but 2. We can call this value the cut-off wave number. 2 is also the value of $\bar{\beta}$. From Eq. (45), we can see that the cut-off wave number equals the surface parameter.

Also, from figure 5, it can be seen that the phase velocity will decrease to 0 when the wave number decreases. This phenomenon agrees with the common knowledge that when the wave number decreases (the wave length increases), the effect of the random heterogeneities will be averaged out gradually, that is, the stochastically homogeneous half space will be more and more like a homogeneous half space, and we know that SHSW could not exist in a homogeneous half space, therefore, the phase velocity will decrease gradually to 0.

The imaginary wave number represents the attenuation rate. Therefore, we know from figure 7 that the bigger the circular frequency is, the faster the wave attenuates. This phenomenon should be caused by reflection and scattering. And from figure 6 we see that the wave length will decrease as the circular frequency grows. It is known that the smaller the wave length is, the easier the waves can be reflected or scattered by the random heterogeneities. Thus the wave attenuates more fast as the frequency grows.

Figure 4: Normalized circular frequency—normalized wave number

Figure 5: Normalized phase velocity—normalized wave number

4 Conclusion

In this study, we proved that SHSW could exist in a stochastically homogeneous half space. The dispersion properties of SHSW in an half space with random density in the depth direction or only near the surface have been investigated both theoretically and numerically. The first order smoothing approximation method is used to solve the random differential equation. The dimensionless dispersion equation is obtained. And the dispersion properties is further studied numerically. The phase velocity is found increasing to an asymptotic value when the wave number is bigger than a critical value—the cut-off wave number, below which the phase velocity is 0. The interesting properties of dispersion and attenuation found here will help us understanding properties of waves in a half space with random heterogeneities, e.g. the earth's crust. It will also help us to do the inverse problems, for example, to use seismic waves to detect the earth's upper crust structure, and to extract information more exactly from the acoustic testing results.

Abstract. *We will present recent developments concerning the extensions of the ADER-DG method to solve three dimensional dynamic rupture problems on unstructured tetrahedral meshes. A remarkable feature of this method is the combination of the DG scheme and a time integration method using Arbitrarily high-order DERivatives (ADER) to provide high accuracy in space and time with the discretization on unstructured meshes. In the resulting discrete velocity-stress formulation of the elastic wave equations variables are naturally discontinuous at the interfaces between elements. The so-called Riemann problem can then be solved to obtain well-defined values of the variables at the discontinuity itself. This is in particular valid for the fault at which a given friction law has to be evaluated. Hence, the fault's geometry is honored by the computational mesh. This way, complex fault planes can be modeled adequately with small elements while fast mesh coarsening is possible with increasing distance from the fault. A further advantage of the scheme is that it avoids spurious high-frequency contributions in the slip rate spectra and therefore does not require artificial Kelvin-Voigt damping or filtering of synthetic seismograms.*

1 INTRODUCTION

Strong ground motion models for seismic hazard assessment are based on the understanding of earthquake sources and seismic wave propagation. The state of the art is the combination of earthquake dynamics together with wave propagation in a single simulation. Synergy effects are for instance basin effects on wave propagation from finite-extent earthquake sources, high-frequency source directivity in random media and in highly heterogeneous fault zones, and rupture propagation of and seismic radiation from dynamic source models on non-planar faults utilizing slip-weakening and rate-and-state friction models.

A variety of numerical methods have been used in the past to implement the dynamics of earthquake rupture, such as finite differences (FD) [1, 2, 3], boundary integral (BI) [4, 5], finite volume (FV) [6], or spectral element (SE) [7], to name only a few commonly used methodologies. All these techniques have certain advantages and drawbacks. The most accurate and efficient method is the BI method, but it is in general not suited for handling heterogeneous media and nonlinear materials. FD schemes provide flexibility in terms of the choice in the friction law or in different material properties. However, it is difficult to apply them to non-planar faults, and computational resource issues could occur when strong material contrasts are included in the model, like sedimentary basins with extremely low wave velocities. FV methods are geometrically flexible but are only implemented as low-order accurate operators that are very dispersive. This fact affects the wave form in the nearfield and in turn the rupture front evolution. The SE method is both accurate and flexible and well suited for seismic wave propagation, but is restricted to hexahedral element types. The generation of hexahedral meshes for complicated geometries in three dimensions, such as faults with branching, and adapting smoothly the element sizes to different material properties, are still very challenging tasks and a major bottleneck.

J. de la Puente [8] presented recently an alternative for the dynamic rupture problem, based upon a discontinuous Galerkin (DG) method combined with an arbitrary high-order derivatives (ADER) time integration [9]. The DG method combines features from high-order FV and finite element methods, where a polynomial basis is used inside each element to approximate the physical variables of the elastic wave equations. This formulation enables the use of fully unstructured meshes, i.e. triangles (2D) or tetrahedrons (3D), to better fit the constraints of a given model and in particular the fault shape. Another feature of DG methods, inherited from FV methods, is the concept of numerical fluxes at element interfaces. Between any two elements the variables of the elastic wave equations are discontinuous. This is valid, as the exact solution of the elastic wave equations at a discontinuity exists, and is obtained by the solution of the well-known Riemann problem [10, 11]. At a fault the solution of the Riemann problem has to be modified to take the frictional boundary conditions into consideration. The numerical dispersion properties of a DG method and the high accuracy of the flux concept for high-order formulations are the reasons why the solution of the ADER-DG method is relatively smooth and free of spurious high-frequency oscillations compared to other methods. Therefore, it does not require artificial Kelvin-Voigt damping or filtering of the seismograms. This is an important feature, since the damping reduces the time step of a simulation and, thus, increases the computational runtime significantly.

The extension of the scheme to three dimensional problems on tetrahedral meshes was presented by *C. Pelties* [12]. In this paper, we present recent developments.

2 DYNAMICS OF FAULT RUPTURE

The kinematics of a sliding process can be described by the slip rate $\Delta v = v^+ - v^-$, where $v^{+,-}$ are the velocities parallel to the fault, and the slip Δd , so that $\Delta v = \Delta \dot{d}$. We denote τ and σ the absolute shear and normal stresses on the fault, respectively.

Slip starts when the shear stress on the fault overcomes the fault strength. In the Coulomb friction model adopted here the strength is proportional to the normal stress. During active slip, the slip rate and the shear traction have opposite directions. These three phenomena are accounted for in the following expressions:

$$\begin{aligned} |\tau| &\leq \mu_f \sigma, \\ (|\tau| - \mu_f \sigma) \Delta v &= 0, \\ \Delta v |\tau| + |\Delta v| \tau &= 0, \end{aligned} \quad (1)$$

where μ_f is the friction coefficient. We adopt the linear slip weakening friction law [13]:

$$\mu_f = \begin{cases} \mu_s - \frac{\mu_s - \mu_d}{D_c} \Delta d & \text{if } \Delta d < D_c, \\ \mu_d & \text{if } \Delta d \geq D_c. \end{cases} \quad (2)$$

With increasing slip Δd the friction coefficient μ_f drops from the static value μ_s to the dynamic μ_d over the critical slip distance D_c , as shown in Fig. 1. Although we chose a simple friction law for demonstration reasons, the ADER-DG method is able to support any friction law.

Figure 1: The left sketch gives an idea about how a fault increment is respected by the mesh. The different sides are indicated by plus and minus. On the right we plot μ_f vs. Δd for the linear slip weakening friction law.

3 FAULT DYNAMICS WITHIN THE DISCONTINUOUS GALERKIN FRAMEWORK

In contrast to other dynamic rupture implementations, like traction-at-split-node which is popular for FD methods, *J. de la Puente* [8] followed a new approach employing the concept of fluxes. In this section, we will explain the basic ideas behind this and show the extension to three-dimensional problems.

3.1 Elastic wave equations in velocity-stress formulation

Omitting external sources (e.g. moments or body forces), the three-dimensional elasticity for an isotropic medium are written in velocity-stress form as the linear hyperbolic system

$$\begin{aligned}
\frac{\partial}{\partial t} \sigma_{xx} - (\lambda + 2\mu) \frac{\partial}{\partial x} u - \lambda \frac{\partial}{\partial y} v - \lambda \frac{\partial}{\partial z} w &= 0, \\
\frac{\partial}{\partial t} \sigma_{yy} - \lambda \frac{\partial}{\partial x} u - (\lambda + 2\mu) \frac{\partial}{\partial y} v - \lambda \frac{\partial}{\partial z} w &= 0, \\
\frac{\partial}{\partial t} \sigma_{zz} - \lambda \frac{\partial}{\partial x} u - \lambda \frac{\partial}{\partial y} v - (\lambda + 2\mu) \frac{\partial}{\partial z} w &= 0, \\
\frac{\partial}{\partial t} \sigma_{xy} - \mu \left(\frac{\partial}{\partial x} v + \frac{\partial}{\partial y} u \right) &= 0, \\
\frac{\partial}{\partial t} \sigma_{yz} - \mu \left(\frac{\partial}{\partial z} v + \frac{\partial}{\partial y} w \right) &= 0, \\
\frac{\partial}{\partial t} \sigma_{xz} - \mu \left(\frac{\partial}{\partial z} u + \frac{\partial}{\partial x} w \right) &= 0, \\
\rho \frac{\partial}{\partial t} u - \frac{\partial}{\partial x} \sigma_{xx} - \frac{\partial}{\partial y} \sigma_{xy} - \frac{\partial}{\partial z} \sigma_{xz} &= 0, \\
\rho \frac{\partial}{\partial t} v - \frac{\partial}{\partial x} \sigma_{xy} - \frac{\partial}{\partial y} \sigma_{yy} - \frac{\partial}{\partial z} \sigma_{yz} &= 0, \\
\rho \frac{\partial}{\partial t} w - \frac{\partial}{\partial x} \sigma_{xz} - \frac{\partial}{\partial y} \sigma_{yz} - \frac{\partial}{\partial z} \sigma_{zz} &= 0,
\end{aligned} \tag{3}$$

where λ is the first Lamé constant and μ is the shear modulus. ρ indicates the density. The normal stress components are given by σ_{xx} , σ_{yy} , and σ_{zz} , and the shear stresses are σ_{xy} , σ_{yz} , and σ_{xz} . The components of the particle velocities in the x -, y -, and z -directions are denoted by u , v and w , respectively. These nine equations are sufficient to describe the complete wave field developing with time as described in detail in *Dumbser et al.* [14].

The physical variables $Q = (\sigma_{xx}, \sigma_{yy}, \sigma_{zz}, \sigma_{xy}, \sigma_{yz}, \sigma_{xz}, u, v, w)^T$ are approximated in the DG approach within a tetrahedral element $T^{(m)}$ by high-order polynomials

$$Q_p^m(x, y, z, t) = \hat{Q}_{pl}^m(t) \Phi_l(x, y, z), \tag{4}$$

where Φ_l are orthogonal basis functions. Therefore, the physical variables are expressed within the DG scheme by a linear combination of these basis functions and time-dependent degrees of freedom $\hat{Q}_{pl}^m(t)$. The index p is associated with the unknowns in the vector Q and l indicates the l -th basis function.

3.2 Riemann problem

As mentioned above, between any two elements the variables of the elastic wave equations are in general discontinuous. This kind of problem, a discontinuous initial condition together with a partial differential equation, is called the Riemann problem. The solution of the Riemann problem at an element interface is the Godunov state and can be written in terms of explicit

values as [8, 10, 11]

$$\begin{aligned}
 \sigma_{xx}^G &= (\sigma_{xx}^+ + \sigma_{xx}^-)/2 + \frac{c_p \rho}{2}(u^- - u^+), \\
 \sigma_{yy}^G &= \sigma_{yy}^+ + (\sigma_{xx}^G - \sigma_{xx}^+)(1 - \frac{2c_s^2}{c_p^2}), \\
 \sigma_{zz}^G &= \sigma_{zz}^+ + (\sigma_{xx}^G - \sigma_{xx}^+)(1 - \frac{2c_s^2}{c_p^2}), \\
 \sigma_{xy}^G &= (\sigma_{xy}^+ + \sigma_{xy}^-)/2 + \frac{\mu}{2c_s}(v^- - v^+), \\
 \sigma_{yz}^G &= \sigma_{yz}^+, \\
 \sigma_{xz}^G &= (\sigma_{xz}^+ + \sigma_{xz}^-)/2 + \frac{\mu}{2c_s}(w^- - w^+), \\
 u^G &= u^+ + \frac{1}{c_p \rho}(\sigma_{xx}^G - \sigma_{xx}^+), \\
 v^G &= (v^+ + v^-)/2 + \frac{c_s}{2\mu}(\sigma_{xy}^- - \sigma_{xy}^+), \\
 w^G &= (w^+ + w^-)/2 + \frac{c_s}{2\mu}(\sigma_{xz}^- - \sigma_{xz}^+).
 \end{aligned} \tag{5}$$

We assume that the fault is located exactly in the XZ-plane and ruptures purely in the Y-direction. Hence, we have to impose the shear stress σ_{xy} according to the friction law Eq. 2 and obtain the new traction value $\tilde{\sigma}_{xy}$, which in the case of rupture is different from σ_{xy}^G . In turn, this provides boundary conditions for the fault parallel-velocities. Multiplying the fourth equation of Eq. 5 by c_s/μ and subtracting the eighth equation leads to

$$\tilde{v}^+ = v^+ + \frac{c_s}{\mu}(\tilde{\sigma}_{xy} - \sigma_{xy}^+) \quad \text{and} \quad \tilde{v}^- = v^- - \frac{c_s}{\mu}(\tilde{\sigma}_{xy} - \sigma_{xy}^-), \tag{6}$$

when we substitute σ_{xy}^G with its imposed value $\tilde{\sigma}_{xy}$. \tilde{v}^- is obtained by summing the equations instead of subtracting them.

These expressions are crucial for the understanding of fault dynamics using fluxes, as they state that an imposed traction instantly and locally generates an imposed velocity parallel to the fault. By subtracting them, the slip rate is obtained:

$$\Delta \tilde{v} = \frac{2c_s}{\mu}(\tilde{\sigma}_{xy} - \sigma_{xy}^G). \tag{7}$$

This way, the analytical form of the fault tractions is captured.

4 VERIFICATION

For most of the dynamic rupture problems there does not exist an analytical reference solution for comparison. Therefore, the Southern California Earthquake Center (SCEC) created the Dynamic Earthquake Rupture Code Verification Exercise, where different codes and methodologies are compared [15]. Here, we verify our method with the Test Problem Version 3 (TPV3).

4.1 The SCEC test case

The TPV3 uses the slip-weakening friction law in Eq. 2 and rupture on a stress-homogeneous vertical strike-slip fault set in a homogeneous full-space. The initial shear and normal stresses

are assigned to be homogeneous for the 30 km long by 15 km deep fault as shown in Fig. 2, with the exception of the nucleation zone that has higher initial shear stresses. The parameters can be found in Table 1. Rupture is not allowed beyond the fault boundaries. This fault is embedded in a large computational domain of 72 km width in each spatial dimension to avoid spurious reflections from non-perfectly absorbing boundaries.

Figure 2: Sketch of the SCEC test case with the nucleation zone (grey shaded). The fault is surrounded by a box with an edge length of 72 km. The black triangles indicate the in-plane receiver (PI) and the anti-plane receiver (PA).

Parameter	Nucleation Zone	Outside Nucleation Zone
Initial shear traction (MPa)	81.6	70.0
Initial normal stress (MPa)	120.0	120.0
Static friction coefficient	0.677	0.677
Dynamic friction coefficient	0.525	0.525
Critical slip distance (m)	0.4	0.4

Table 1: Parameters describing the fault for the SCEC test case.

4.2 Results

In Fig. 3 we compare our solution (red line) with the solution of *Day et al.* [2] (black line) which was well validated during the SCEC exercises. *Day et al.* used a FD staggered-grid split node method of accuracy order 2 with a 50 m grid interval (DFM0.05). The solution produced with our DG scheme is of accuracy order 3 (ADER-DGO3) and uses a triangular mesh with an edge length of 300 m to discretize the fault, but we allow for tetrahedrons with 600 m edge length around the fault in a small box of 10 km thickness. This box is embedded in the domain of 72 km side length where we let the element edge length of the tetrahedrons quickly increase from 600 m to 3000 m to reduce the computational effort. No artificial reflexions possibly caused by the mesh coarsening are observed.

The ADER-DG solution is in excellent agreement with the solution produced by DFM0.05. This includes the arrival time of the stopping face and the stress relaxation. Furthermore, in

Fig. 4 we see that the spectral behavior of the ADER-DG slip rate solution shows the theoretically expected frequency decay [16]. No spurious high-frequency oscillations are produced. Therefore, no artificial Kelvin-Voigt damping has to be applied which would further reduce the time step size and increase the computational effort.

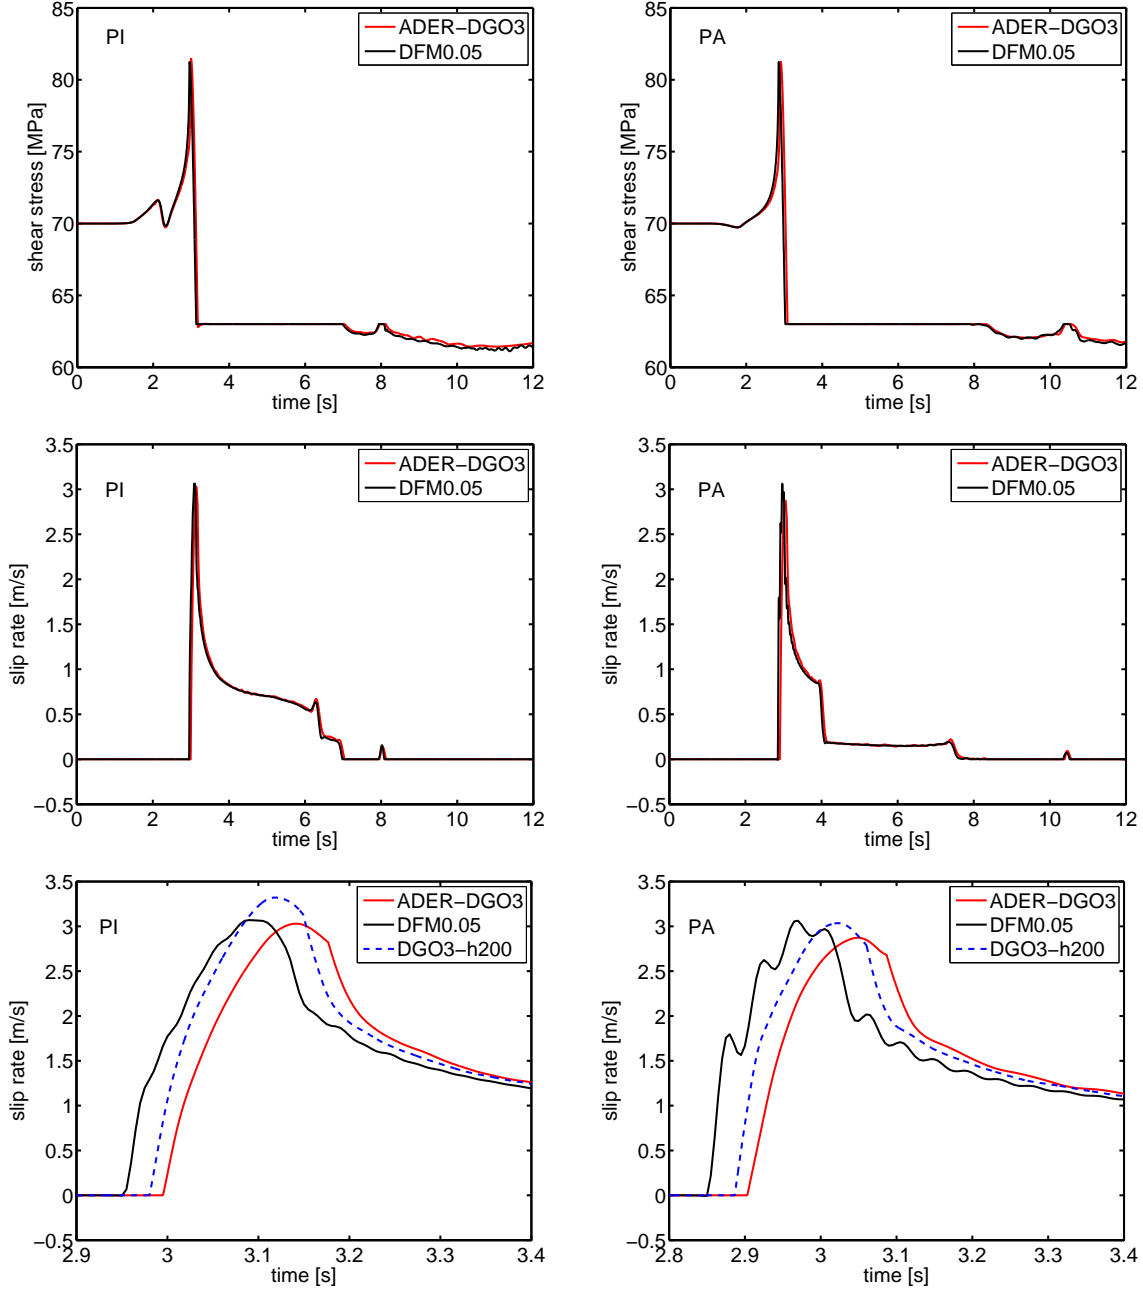

Figure 3: DFM0.05 (black line) indicates the FD staggered-grid split node method with 50 m grid interval of *Day et al.* [2]. This solution is in well agreement with the solution produced by our ADER-DGO3 scheme (red line) and a mesh spacing of 300 m at the fault. Shown is the shear stress and the slip rate. PI and PA denote the in-plane and the anti-plane receiver as shown in Fig. 2. In the bottom row we additionally plot the solution obtained with a 200 m fault discretization DGO3-h200 (blue dashed line) also with order 3 to demonstrate the trend of a convergence towards the DFM0.05 solution with increasing mesh refinement.

Figure 4: Spectrum of the slip rate obtained from receiver PA. The ADER-DGO3 solution does not show spurious high-frequency oscillations and, furthermore, it follows the frequency decay as theoretically expected.

5 CONCLUSIONS

We showed the successful adaption of 3D fault dynamics in the ADER-DG scheme under linear slip weakening friction. Accuracy was verified by employing the SCEC benchmark TPV3 for spontaneous rupture. Due to the properties of the Riemann problem in terms of the smoothness of the solution, the slip rate spectra remains free of spurious high-frequency oscillations. Furthermore, our implementation of the fault dynamics employing fluxes should allow for fault branching and surface rupture with little additional effort.

We conclude that the combination of meshing flexibility and high-order accuracy of the ADER-DG method will make it a very useful tool to study earthquake dynamics on complex fault systems. Future steps in the development could be the incorporation of bimaterial fault interfaces and more complex friction laws like rate- and state-dependent friction.

6 ACKNOWLEDGMENT

The authors thank the DFG (Deutsche Forschungsgemeinschaft), as the work was supported through the *Emmy Noether-Programm* (KA 2281/2-1). The data used for comparison in section 4.2 was provided by Luis A. Dalguer. Furthermore, we thank Luis A. Dalguer, Jean-Paul Ampuero, Cristóbal E. Castro and Josep de la Puente for very helpful and fruitful discussions. We also thank M. Mai for providing computational resources as many parallel tests and the SCEC benchmark have been computed on the BlueGene/P *Shaheen* of the King Abdullah University of Science and Technology, Saudi Arabia.

Abstract. *Stabilized hybrid and mixed finite element methods are proposed for solving Helmholtz problems in heterogeneous media. The methods are based on a hybridized dual mixed formulation in velocity (flux) and pressure fields stabilized by adding least squares residual of the governed equations. The local problems, in the velocity and pressure fields, are solved at element level to eliminate these variables in favor of the Lagrange multipliers, identified as the trace of the pressure on the element edges of the finite element mesh. A global system is assembled involving only the degrees of freedom associated with the Lagrange multipliers as usually in Hybrid methods. Polynomial bases are adopted to approximate the global problem in the Lagrange multipliers. Polynomial or special bases, such as plane-wave bases, can be also used to approximate the local problems at the element level. Numerical results are reported to illustrate the potential of the proposed formulation to efficiently solve Helmholtz problems in homogeneous or heterogeneous media at medium and high frequency regimes.*

1 INTRODUCTION

The linear model for propagation of acoustic waves in an ideal compressible fluid is governed by the wave equation

$$-\Delta\varphi + \frac{1}{c^2} \frac{\partial^2 \varphi}{\partial t^2} = 0, \quad (1)$$

where $\varphi(\mathbf{x}, t)$ represents small oscillations of the pressure and c is the velocity of the sound in the acoustic medium. Considering harmonic solutions in time with circular frequency ω , the pressure field is written as $\varphi(\mathbf{x}, t) = p(\mathbf{x})e^{-i\omega t}$, and the pressure amplitude p satisfies the Helmholtz equation

$$-\Delta p - k^2 p = 0, \quad (2)$$

where the parameter $k = \omega/c$, known as *wave number*, characterizes the oscillatory behavior of the solution φ .

Helmholtz problem has deserved especial attention in many physical applications associated with refraction and scattering of electromagnetic, elastic or sound waves, for example. From the numerical point of view k is a key parameter. It is well known that standard Galerkin finite element approximations deteriorate as k increases. For large values of k the solution p is highly oscillatory and, due to numerical dispersion and phase error, constructing finite element approximations for Helmholtz equation is a great challenge as reported in vast literature. See, for example, [4] and references therein. Several finite element methods have been developed to minimize the phase error. Stabilized finite element methods such as Galerkin Least-Squares (GLS) have been proposed with relative success [5]. An uniform nine node stencils with minimal pollution error, referred as QSFEM, is constructed in [6]. Variationally consistent finite element methods with stability properties equivalent to the QSFEM on uniform meshes have been proposed in [7] using a generalized GLS formulation, and in [8] using discontinuous Galerkin finite element methods. A Quasi Optimal Petrov-Galerkin (QOPG) finite element formulation for Helmholtz problem in two dimensions is introduced in [9] using polynomial weighting functions with the same support of the corresponding global test functions. The QOPG finite element formulation is naturally applied to non uniform and unstructured meshes. Generalized finite element methods using plane wave bases have been successfully developed in [3, 10, 11] to solve the Helmholtz equation with great accuracy when applied to problem with regular solutions.

Here, we consider stabilized hybrid and mixed finite element methods for solving Helmholtz problems in heterogeneous media with discontinuous wave number k . The proposed formulations is based on a hybridized dual mixed formulation in velocity (flux) and pressure fields stabilized by adding least squares residual of the governed equations. To simplify our presentation we consider as our model problem the Helmholtz equation

$$-\Delta p - k^2 p = f \text{ in } \Omega, \quad (3)$$

in a bounded domain $\Omega \subset \mathbb{R}^2$ with a Lipschitz continuous and piecewise smooth boundary Γ subjected to Dirichlet boundary condition

$$p = g \text{ on } \Gamma = \partial\Omega. \quad (4)$$

The reminder of the paper is organized as follows. In Section 2 our model problem is presented in a mixed form and a stabilized dual mixed formulation in continuous spaces is presented. In Section 3 we review the classical dual hybrid mixed formulation. The stabilized dual hybrid mixed formulation is proposed in Section 4. The finite element approximation of the proposed dual hybrid mixed formulation is presented in Section 5. Numerical results are shown in Section 6 and some concluding remarks are presented in Section 7.

2 MIXED FORMULATION

Introducing the vector field

$$\mathbf{u} = -\nabla p$$

we can rewrite the Helmholtz equation (3) in the mixed form

$$\mathbf{u} + \nabla p = 0 \quad \text{in } \Omega$$

$$\operatorname{div} \mathbf{u} - k^2 p = f \quad \text{in } \Omega,$$

which will be used as the starting point to construct stabilized mixed and hybrid finite element approximations.

2.1 Dual mixed formulation

Defining the space $V = L^2(\Omega)$ of scalar functions with the corresponding inner product

$$(p, q) = \int_{\Omega} p q d\Omega \quad \forall p, q \in V \quad (5)$$

and associated norm

$$\|p\|^2 = (p, p) \quad \forall p \in V, \quad (6)$$

and the space $W = H(\operatorname{div})$ of vector functions:

$$H(\operatorname{div}) = \{\mathbf{v} \in [L^2(\Omega)]^2, \operatorname{div} \mathbf{v} \in L^2(\Omega)\} \quad (7)$$

with inner product

$$(\mathbf{u}, \mathbf{v})_{H(\operatorname{div})} = (\mathbf{u}, \mathbf{v}) + (\operatorname{div} \mathbf{u}, \operatorname{div} \mathbf{v}) \quad \forall \mathbf{u}, \mathbf{v} \in W \quad (8)$$

and associated norm

$$\|\mathbf{u}\|_{H(\operatorname{div})}^2 = (\mathbf{u}, \mathbf{u}) + (\operatorname{div} \mathbf{u}, \operatorname{div} \mathbf{u}) \quad \forall \mathbf{u} \in W \quad (9)$$

we present the dual mixed formulation of our model problem as

Find $[\mathbf{u}, p] \in W \times V$ such that

$$(\mathbf{u}, \mathbf{v}) - (p, \operatorname{div} \mathbf{v}) - (\operatorname{div} \mathbf{u}, q) - k^2(p, q) - (f, q) + \int_{\partial\Omega} g \mathbf{v} \cdot \mathbf{n} ds = 0 \quad \forall [\mathbf{v}, q] \in W \times V \quad (10)$$

Dual mixed problems have been usually approximated using Raviart-Thomas (RT) or Brezzi-Douglas-Marini (BDM) spaces to get accurate approximations for the gradient of the pressure field. Stability of these mixed finite element methods depends on the well known inf-sup condition which preclude many desirable combinations of velocity and pressure interpolations. Stabilized mixed formulations have been successfully introduced to overcome these limitations. See references [12, 13, 14, 16] on stabilized mixed formulations for Darcy flow.

2.2 Stabilized dual mixed formulation

In [14] an unconditionally stable mixed formulation is proposed for Darcy flow with optimal rates of convergence in $H^1(\Omega)$ and $L^2(\Omega)$ norms for same order C^0 velocity and pressure approximations. Applied to the Helmholtz problem this formulation leads to the following weak form:

Find $[\mathbf{u}, p] \in W \cap [H^1(\Omega)]^2 \times V \cap H^1(\Omega)$ such that, for all $[\mathbf{v}, q] \in W \times V$,

$$(\mathbf{u}, \mathbf{v}) - (p, \operatorname{div} \mathbf{v}) - (\operatorname{div} \mathbf{u}, q) - k^2(p, q) - (f, q) + \int_{\partial\Omega} g \mathbf{v} \cdot \mathbf{n} ds + \quad (11)$$

$$\frac{\delta_1}{k^2}(\operatorname{div} \mathbf{u} - k^2 p - f, \operatorname{div} \mathbf{v} - k^2 q) + \delta_2(\mathbf{u} + \nabla p, \mathbf{v} + \nabla q) + \frac{\delta_3}{k^2}(\operatorname{rot} \mathbf{u}, \operatorname{rot} \mathbf{v}) = 0. \quad (12)$$

Of course, we should not expect unconditional stability and optimal rates of convergence for same order C^0 finite element approximations of the above dual mixed formulation of the Helmholtz problem, especially for heterogeneous media. Its stability will certainly be dependent on the choice of the stabilization parameters δ_i , $i = 1, 2, 3$. An other limitation of this formulation is the required C^0 approximations for both velocity and pressure which is not applicable to heterogeneous media with discontinuous material properties. In the next section we introduce hybrid formulations more appropriate to construct finite element approximations of our model problem on heterogeneous media.

3 HYBRIDIZATION

Let

$$\mathcal{T}_h = \{\mathcal{K}\} := \text{union of all elements } \mathcal{K}$$

be a regular finite element mesh on the two dimension domain Ω . To introduce the hybrid formulation we first consider equation $\mathbf{u} + \nabla p = 0$, in the local weak form

$$(\mathbf{u} + \nabla p, \mathbf{v})_{\mathcal{K}} = \int_{\mathcal{K}} \mathbf{u} \cdot \mathbf{v} d\Omega - \int_{\mathcal{K}} p \operatorname{div} \mathbf{v} d\Omega + \int_{\partial\mathcal{K}} p \mathbf{v} \cdot \mathbf{n} ds = 0,$$

defined on each element \mathcal{K} using integration by parts. Considering the spaces

$$Q_{\mathcal{K}} = \{q \in L^2(\mathcal{K}) \mid \forall \mathcal{K} \in \mathcal{T}_h\},$$

$$U_{\mathcal{K}} = \{\mathbf{v} \in L^2(\mathcal{K}) \times L^2(\mathcal{K}), \operatorname{div} \mathbf{v} \in L^2(\mathcal{K}) \mid \forall \mathcal{K} \in \mathcal{T}_h\},$$

of local functions defined on each element \mathcal{K} and defining the forms

$$a_{\mathcal{K}}([\mathbf{u}, p], [\mathbf{v}, q]) = (\mathbf{u}, \mathbf{v})_{\mathcal{K}} - (p, \operatorname{div} \mathbf{v})_{\mathcal{K}} - (\operatorname{div} \mathbf{u}, q)_{\mathcal{K}} + k^2(p, q)_{\mathcal{K}},$$

$$f_{\mathcal{K}}([\mathbf{v}_h, q_h]) = -(f, q)_{\mathcal{K}} - c_{\mathcal{K}}(\bar{p}, \mathbf{v}),$$

$$c_{\mathcal{K}}(\bar{p}, \mathbf{v}) = \int_{\partial\mathcal{K}} \bar{p} \mathbf{v} \cdot \mathbf{n} ds,$$

for given $p = \bar{p}$ on $\partial\mathcal{K}$ we can solve the local problems:

For each $\mathcal{K} \in \mathcal{T}_h$, find $[\mathbf{u}, p] \in U_{\mathcal{K}} \times Q_{\mathcal{K}}$, such that

$$a_{\mathcal{K}}([\mathbf{u}, p], [\mathbf{v}, q]) = f_{\mathcal{K}}([\mathbf{v}, q]) \quad \forall [\mathbf{v}, q] \in U_{\mathcal{K}} \times Q_{\mathcal{K}}.$$

Local Raviart-Thomas or BDM finite element approximations can be used to solve these local problems on each element \mathcal{K} . Following the classical hybrid formulation, an approximation for the pressure trace $p = \bar{p}$ on $\partial\mathcal{K}$ can be obtained by solving a global problem associated with the dual hybrid mixed formulation, as presented in the next section.

3.1 Dual Hybrid mixed formulation

To present the hybrid formulation some additional notations and definitions are need. Let

$$\mathcal{E}_h = \{e : e \text{ is an edge of } \mathcal{K} \text{ for all } \mathcal{K} \in \mathcal{T}_h\} \quad (13)$$

denote the set of all edges of all elements \mathcal{K} of the mesh \mathcal{T}_h ,

$$\mathcal{E}_h^0 = \{e \in \mathcal{E}_h : e \text{ is an interior edge}\} \quad (14)$$

the set of interior edges, and

$$\mathcal{E}_h^\partial = \mathcal{E}_h \cap \partial\Omega, \quad (15)$$

the set of edges of \mathcal{E}_h on the boundary of Ω .

Following the commonly adopted notation on DG (Discontinuous Galerkin) formulations, we consider the unit normal vectors \mathbf{n}^1 and \mathbf{n}^2 on e pointing exterior to \mathcal{K}^1 and \mathcal{K}^2 , respectively. For a scalar function φ , piecewise smooth on \mathcal{T}_h , with $\varphi = \varphi|_{\mathcal{K}}$ we define on each interior edge e

$$\{\varphi\} = \frac{1}{2}(\varphi^1 + \varphi^2), \quad \llbracket \varphi \rrbracket = \varphi^1 \mathbf{n}^1 + \varphi^2 \mathbf{n}^2 \quad \text{on } e \in \mathcal{E}^0 \quad (16)$$

and for a vector function \mathbf{v}

$$\{\mathbf{v}\} = \frac{1}{2}(\mathbf{v}^1 + \mathbf{v}^2), \quad \llbracket \mathbf{v} \rrbracket = \mathbf{v}^1 \cdot \mathbf{n}^1 + \mathbf{v}^2 \cdot \mathbf{n}^2 \quad \text{on } e \in \mathcal{E}^0. \quad (17)$$

Defining the function spaces $M = \{\mu \in L^2(e) \forall e \in \mathcal{E}_h^0\}$, $U = \prod_{\mathcal{K}} U_{\mathcal{K}}$, $Q = \prod_{\mathcal{K}} Q_{\mathcal{K}}$ and the bilinear and linear forms:

$$a([\mathbf{u}, p], [\mathbf{v}, q]) = \sum_{\mathcal{K}} a_{\mathcal{K}}([\mathbf{u}, p], [\mathbf{v}, q]) \quad \forall [\mathbf{u}, p], [\mathbf{v}, q] \in U \times Q$$

$$c(\mu, \mathbf{v}) = \sum_{\mathcal{K}} c_{\mathcal{K}}(\mu, \mathbf{v}) = \int_{\mathcal{E}^0} \mu \llbracket \mathbf{v} \rrbracket ds \quad \forall \mu \in M, \forall \mathbf{v} \in U$$

$$f([\mathbf{v}, q]) = \sum_{\mathcal{K}} (f, q) - \int_{\mathcal{E}_h^\partial} g \mathbf{v} \cdot \mathbf{n} ds \quad \forall \mathbf{v} \in U, \forall q \in Q$$

the dual hybrid formulation consists in:

Find $[\mathbf{u}, p] \in U \times Q$ and the Lagrange multiplier $\lambda \in M$, such that

$$a([\mathbf{u}, p], [\mathbf{v}, q]) + c(\lambda, \mathbf{v}) = f([\mathbf{v}, q]), \quad \forall [\mathbf{v}, q] \in U \times Q,$$

$$c(\mu, \mathbf{u}) = 0 \quad \forall \mu \in M,$$

with $\lambda = \bar{p}$, the trace of the pressure p on \mathcal{E}_h^0 and $\lambda = g$ on \mathcal{E}_h^∂ .

3.2 Recovering the dual mixed formulation

Considering that $c(\mu, \mathbf{u}) = 0 \quad \forall \mu \in M$ implies that $\llbracket \mathbf{u} \rrbracket = 0$ (continuity of the normal component of the velocity field \mathbf{u}), we note that the pair $[\mathbf{u}, p]$, solution of the above defined dual hybrid mixed method, satisfies the dual mixed formulation

Find $[\mathbf{u}, p] \in U \cap H(\text{div}) \times Q$, such that

$$a([\mathbf{u}, p], [\mathbf{v}, q]) = f([\mathbf{v}, q]) \quad \forall [\mathbf{v}, q] \in U \cap H(\text{div}) \times Q$$

or, more explicitly

Find $\mathbf{u} \in W = U \cap H(\text{div})$ and $p \in V = Q$ such that

$$\begin{aligned} (\mathbf{u}, \mathbf{v}) - (p, \text{div} \mathbf{v}) &= \int_{\partial\Omega} g \mathbf{v} \cdot \mathbf{n} ds \quad \forall \mathbf{v}_h \in W \\ -(\text{div} \mathbf{u}, q) &= -(f, q) \quad \forall q \in V \end{aligned}$$

which is the classical definition of the dual mixed formulation (Ravirat-Thomas) presented in Section 2.1.

4 STABILIZATION

Adding to the dual mixed formulation least squares stabilization terms defined in each element \mathcal{K} and on the element boundaries we obtained the following residual form

$$\begin{aligned} a([\mathbf{u}, p], [\mathbf{v}, q]) + c(\lambda, \mathbf{v}) + c(\mu, \mathbf{u}) - f([\mathbf{v}, q]) + \sum_{\mathcal{K}} \int_{\partial\mathcal{K}} \beta(\lambda - p)(\mu - q) ds + \\ \sum_{\mathcal{K}} \left(\frac{\delta_1}{k^2} (\text{div} \mathbf{u} - k^2 p - f, \text{div} \mathbf{v} - k^2 q)_{\mathcal{K}} + \delta_2 (\mathbf{u} + \nabla p, \mathbf{v} + \nabla q)_{\mathcal{K}} + \frac{\delta_3}{k^2} (\text{rot} \mathbf{u}, \text{rot} \mathbf{v})_{\mathcal{K}} \right) = 0 \end{aligned} \quad (18)$$

in which the added residual forms in the interior of the element, weighted by the stabilization parameters δ_i , $i = 1, 2, 3$, are the same considered in the stabilized dual mixed formulation presented Section 2.2 aiming at stabilizing the pair $[\mathbf{u}, p]$, while the residual form on the element boundaries multiplied by β is introduced to stabilize the multiplier λ .

4.1 Stabilized dual hybrid mixed formulation

Collecting appropriately the residual terms in (18) corresponding to the pair $[\mathbf{u}, p]$ and the multiplier λ , the stabilized dual hybrid mixed method can be presented as:

SDHM: Find $[\mathbf{u}, p] \in U \times Q$ and the Lagrange multiplier $\lambda \in M$ such that

$$a_{\delta}([\mathbf{u}, p], [\mathbf{v}, q]) + c(\lambda, \mathbf{v}) + \sum_{\mathcal{K}} \int_{\partial\mathcal{K}} \beta(p - \lambda) q ds = f_{\delta}([\mathbf{v}, q]) \quad \forall [\mathbf{v}, q] \in U \times Q \quad (19)$$

$$c(\mu, \mathbf{u}) + \sum_{\mathcal{K}} \int_{\partial\mathcal{K}} \beta(\lambda - p) \mu ds = 0 \quad \forall \mu \in M \quad (20)$$

where

$$a_{\delta}([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]) = \sum_{\mathcal{K}} a_{\mathcal{K}}^{\delta}([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]); \quad f_{\delta}([\mathbf{v}, q]) = \sum_{\mathcal{K}} f_{\mathcal{K}}^{\delta}([\mathbf{v}, q]) \quad (21)$$

with

$$\begin{aligned} a_{\mathcal{K}}^{\delta}([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]) &= a_{\mathcal{K}}([\mathbf{u}, p], [\mathbf{v}, q]) + \\ \frac{\delta_1}{k^2} (\text{div} \mathbf{u} - k^2 p, \text{div} \mathbf{v} - k^2 q)_{\mathcal{K}} &- \frac{\delta_2}{k^2} (\mathbf{u} + \nabla p, \mathbf{v} + \nabla q)_{\mathcal{K}} + \frac{\delta_1}{k^2} (\text{rot} \mathbf{u}, \text{rot} \mathbf{v})_{\mathcal{K}} \end{aligned} \quad (22)$$

$$f_{\mathcal{K}}^{\delta}([\mathbf{v}, q]) = f_{\mathcal{K}}([\mathbf{v}, q]) + \frac{\delta_1}{k^2} (f, \text{div} \mathbf{v} - k^2 q)_{\mathcal{K}}$$

Considering the definitions (16) and (17) we restate problem **SDHM** as:

SDHM: Find $[\mathbf{u}, p] \in U \times Q$ and the Lagrange multiplier $\lambda \in M$ such that $\forall [\mathbf{v}, q] \in U \times Q$

$$a_\delta([\mathbf{u}, p], [\mathbf{v}, q]) + \int_{\mathcal{E}_h^0} \lambda \llbracket \mathbf{v} \rrbracket ds + \int_{\mathcal{E}_h^0} 2\beta(\{p\} - \lambda)\{q\} ds + \int_{\mathcal{E}_h^0} \frac{\beta}{2} \llbracket p \rrbracket \cdot \llbracket q \rrbracket ds = f_\delta([\mathbf{v}, q]) \quad (23)$$

$$\int_{\mathcal{E}_h^0} 2\beta((\lambda - \{p\}) + \llbracket \mathbf{u} \rrbracket) \mu ds = 0 \quad \forall \mu \in M. \quad (24)$$

In Section 5 finite element approximations will be constructed for this stabilized dual hybrid formulation considering finite dimension polynomial spaces for all fields.

4.2 Hybridizable mixed DG method

Solving equation (24) for the multiplier λ we get

$$\lambda = \{p\} - \frac{1}{2\beta} \llbracket \mathbf{u} \rrbracket. \quad (25)$$

Replacing (25) in (23) yields the following stabilized mixed discontinuous Galerkin method

SMDG: Find $[\mathbf{u}, p]$ such that

$$\begin{aligned} a_\delta([\mathbf{u}, p], [\mathbf{v}, q]) + \int_{\mathcal{E}_h^0} (\{p\} \llbracket \mathbf{v} \rrbracket + \llbracket \mathbf{u} \rrbracket \{q\}) ds + \\ + \int_{\mathcal{E}_h^0} \frac{\beta}{2} \llbracket p \rrbracket \cdot \llbracket q \rrbracket ds - \int_{\mathcal{E}_h^0} \frac{1}{2\beta} \llbracket \mathbf{u} \rrbracket \llbracket \mathbf{v} \rrbracket ds = f_\delta([\mathbf{v}, q]) \quad \forall [\mathbf{v}, q] \in U \times Q \end{aligned} \quad (26)$$

Setting $\delta_i = 0$, for $i = 1, 2, 3$, the above **SMDG** formulation recovers the LDG-H (Local Discontinuous Galerkin - Hybridizable) method analyzed in [15] in the context of elliptic problems.

5 FINITE ELEMENT APPROXIMATIONS

Let us consider the finite dimension spaces

$$Q_h^l = \{q \in Q : \quad q|_{\mathcal{K}} \in \mathfrak{R}^l \quad \forall \mathcal{K} \in \mathcal{T}_h\},$$

$$U_h^m = \{\mathbf{v} \in U : \quad \mathbf{v}|_{\mathcal{K}} \in \mathfrak{R}^m \times \mathfrak{R}^m \quad \forall \mathcal{K} \in \mathcal{T}_h\},$$

$$M_h^n = \{\mu \in M : \quad \mu|_e \in \mathfrak{P}^n \quad \forall e \in \mathcal{E}^0\},$$

where \mathfrak{R}^l is the set of polynomial of degree less then or equal to l when \mathcal{K} is a triangle or less then or equal to l in each coordinate when \mathcal{K} is a quadrilateral, and \mathfrak{P}^n is the set of polynomials of degree less then or equal to n on each edge e .

We can now present a finite element approximation for the stabilized dual hybrid mixed formulation introduced in Section 4.1 as:

SDHM_h: Find $[\mathbf{u}_h, p_h] \in U_h^m \times Q_h^l$ and the Lagrange multiplier $\lambda_h \in M_h^n$ such that

$$\begin{aligned} a_\delta([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]) + \int_{\mathcal{E}_h^0} \frac{\beta}{2} \llbracket p_h \rrbracket \cdot \llbracket q_h \rrbracket ds \\ + \int_{\mathcal{E}_h^0} \lambda_h \llbracket \mathbf{v}_h \rrbracket ds + \int_{\mathcal{E}_h^0} 2\beta(\{p_h\} - \lambda_h)\{q_h\} ds = f_\delta([\mathbf{v}_h, q_h]) \quad \forall [\mathbf{v}_h, q_h] \in U_h^m \times Q_h^l \end{aligned} \quad (27)$$

$$\int_{\mathcal{E}_h^0} 2\beta ((\lambda_h - \{p_h\}) + \llbracket \mathbf{u}_h \rrbracket) \mu_h ds = 0 \quad \forall \mu_h \in M_h. \quad (28)$$

For $n \geq l$ and $n \geq m$ we can solve explicitly equation (28), for the multiplier λ_h , obtaining

$$\lambda_h = \{p_h\} - \frac{1}{2\beta} \llbracket \mathbf{u}_h \rrbracket, \quad (29)$$

which when replaced in (23) yields the following hybridizable discontinuous Galerkin method **SMDG_h** : Find $[\mathbf{u}_h, p_h] \in U_h^m \times Q_h^l$ such that

$$\begin{aligned} a_\delta([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]) + \int_{\mathcal{E}_h^0} (\{p_h\} \llbracket \mathbf{v}_h \rrbracket + \llbracket \mathbf{u}_h \rrbracket \{q_h\}) ds + \\ + \int_{\mathcal{E}_h^0} \frac{\beta}{2} \llbracket p_h \rrbracket \cdot \llbracket q_h \rrbracket ds - \int_{\mathcal{E}_h^0} \frac{1}{2\beta} \llbracket \mathbf{u}_h \rrbracket \llbracket \mathbf{v}_h \rrbracket ds = f_\delta([\mathbf{v}_h, q_h]) \quad \forall [\mathbf{v}_h, q_h] \in U_h \times Q_h. \end{aligned} \quad (30)$$

Computationally, the best option to solve the systems of linear equations (28) and (29) is to solve first (28) at element level to obtain $[\mathbf{u}_h, p_h]$ in terms of λ_h , replace $[\mathbf{u}_h, p_h]$ in (29) and assemble a global system in λ_h only. After solving the global system in λ_h , the pair $[\mathbf{u}_h, p_h]$ is computed by solving the following set of local problems defined at element level.

LP_h : For given λ_h , find $[\mathbf{u}_h, p_h] \in U_{\mathcal{K}}^m \times Q_{\mathcal{K}}^l$, at each element \mathcal{K} , such that

$$\begin{aligned} a_{\mathcal{K}}^\delta([\mathbf{u}_h, p_h], [\mathbf{v}_h, q_h]) + \int_{\partial\mathcal{K}} \beta p_h q_h ds = \\ f_{\mathcal{K}}^\delta([\mathbf{v}_h, q_h]) + \int_{\partial\mathcal{K}} \beta \lambda_h q_h ds - \int_{\partial\mathcal{K}} \lambda_h \mathbf{v}_h \cdot \mathbf{n} ds \quad \forall [\mathbf{v}_h, q_h] \in U_{\mathcal{K}}^m \times Q_{\mathcal{K}}^l, \end{aligned} \quad (31)$$

where $U_{\mathcal{K}}^m = \mathfrak{R}^m \times \mathfrak{R}^m$ and $Q_{\mathcal{K}}^l = \mathfrak{R}^l$.

This strategy, typical of hybridized mixed finite element methods, will be adopted here in the numerical experiments presented next.

6 NUMERICAL RESULTS

The parameters δ_i and β play an important role in the stability and accuracy of the proposed dual hybrid mixed formulation. However, here we will not invest in finding their optimal values. In all numerical results presented next we adopted the following choice:

$$\delta_1 = \delta_3 = -1; \quad \delta_2 = 1; \quad \beta = \frac{1}{h_e};$$

with h_e denoting the length of the edge e of the element \mathcal{K} . We have also adopted equal order approximations for all fields, that is, $l = m = n$.

6.1 Homogeneous media

Initially we consider Helmholtz equation, with $k^2 = \text{constant}$ and $f(x, y) = 0$, subject to Dirichlet boundary conditions such that the exact solution is a plane wave (real part only) propagating in θ -direction:

$$w(x, y) = \cos[k(x \cos \theta + y \sin \theta)].$$

The objective is check the convergence of the proposed formulation. In this study we consider $\theta = \pi/6$, $k = 30$ and $\Omega = [0, 1] \times [0, 1]$. First we check the h-convergence of the stabilized formulation for $l = m = n = 2$ and a sequence of 10×10 , 20×20 , 40×40 and 80×80 uniform meshes. Figure 1 shows convergence results in $L^2(\Omega)$ norm (left) and $H^1(\Omega)$ seminorm (right) for the pressure approximation p_h of the stabilized dual hybrid formulation (p_{DH}) compared to the its interpolant (p_I) and the local projection (p_{LP}), obtained by solving the local problems \mathbf{LP}_h replacing λ_h (approximation of the lagrange multiplier) by λ (exact value). In Figure 1 we observe pollution effects on both DH and LP solutions for coarse meshes, but these pollution effects disappear with refinement. Figure 2 show results of convergence study using a fixed 10×10 uniform mesh and varying the degree of the polynomial approximations by setting $l = m = n = 2, 3, 4, 5, 6, 7$ sequentially. We can see that highly accurate solutions are obtained by increasing the order of the polynomial approximations (l-refinement). In this study, neq is the the number of equation in the global system associated with the approximation of multiplier λ_h .

Figure 1: Convergence of the finite element approximations for the homogeneous problem with h-refinement. Error in the L^2 -norm (left) and H^1 -seminorm (right). Stabilized dual hybrid mixed (DH) solution compared to the local projection (LP) and the interpolant (I).

6.2 Heterogeneous media. Interface problem

We now solve Helmholtz equation in unite domain $\Omega = (-0.5, 0.5) \times (-0.5, 0.5)$ with a discontinuity in the *wavenumber*. We consider $k = k_1$ for $x < 0$, $k = k_2$ for $x > 0$ and impose Dirichlet boundary conditions, weakly as presented in the stabilized dual mixed formulation,

Figure 2: Convergence of the finite element approximations, with the polynomial degree l , for the homogeneous Helmholtz problem. Error in the L^2 -norm (left) and H^1 -seminorm (right). Stabilized dual hybrid mixed (DH) solution compared to the local projection (LP) and the interpolant (I).

such that the exact solution is given by

for $x < 0$:

$$u(x, y) = \exp[-ik_1(x \cos \theta_1 + y \sin \theta_1)] + R \exp[-ik_1(-x \cos \theta_1 + y \sin \theta_1)], \quad (32)$$

for $x > 0$:

$$u(x, y) = T \exp[-ik_2(x \cos \theta_2 + y \sin \theta_2)], \quad (33)$$

with :

$$R = (k_1 \cos \theta_1 - k_2 \cos \theta_2) / (k_1 \cos \theta_1 + k_2 \cos \theta_2) \quad (34)$$

$$T = 2k_1 \cos \theta_1 / (k_1 \cos \theta_1 + k_2 \cos \theta_2), \quad (35)$$

$$k_2 \sin \theta_2 = k_1 \sin \theta_1. \quad (36)$$

In this study we set $k_1 = 30$, $k_2 = 20$ and $\theta_1 = \pi/6$. Again, the same sequence of uniform meshes used in the previous example is adopted in the h-convergence study for $l = m = n = 2$. From Figure 3 we can see pollution effects even higher than those observe in previous example, corresponding to the homogeneous Helmholtz problem, probably due to the an inappropriate choice of the stabilization parameters. Much more accurate solutions are obtained by increasing the degree of the polynomial approximations as shown in Figure 4 where l-convergence results are presented for this heterogeneous problem using a fixed 10×10 uniform mesh and varying the degree of the polynomial approximations by setting $l = m = n = 2, 3, 4, 5, 6, 7$ sequentially, as in the previous study of the homogeneous Helmholtz problem. Finally, we present in Figure 5 a comparison of h-refinement and l-refinement convergence results. From 5 we clearly observe that higher order are much more accurate than lower lower order polynomial approximations for the the same number of degree of freedom (neq).

Figure 3: Convergence of the finite element approximations for the heterogeneous problem with h-refinement. Error in the L^2 -norm (left) and H^1 -seminorm (right). Stabilized dual hybrid mixed (DH) solution compared to the local projection (LP) and the interpolant (I).

Figure 4: Convergence of the finite element approximations, with the polynomial degree l , for the heterogeneous Helmholtz problem. Error in the L^2 -norm (left) and H^1 -seminorm (right). Stabilized dual hybrid mixed (DH) solution compared to the local projection (LP) and the interpolant (I).

7 CONCLUSIONS

Stabilized dual hybrid and mixed finite element methods are proposed for solving Helmholtz problems in homogeneous or heterogeneous media using Galerkin and least square residual of the governing equation. Local problems, in the velocity and pressure fields, are solved at element level and these variables are eliminated in favor of the Lagrange multipliers, identified

Figure 5: Convergence of the finite element approximations, with the polynomial degree l compared to h-refinement, for the heterogeneous Helmholtz problem. Error in the L^2 -norm (left) and H^1 -seminorm (right). Stabilized dual hybrid mixed (DH) solution and local projection (LP) corresponding to uniform meshes.

as the trace of the pressure on the element edges of the finite element mesh. A global system is assembled involving only the degrees of freedom associated with the Lagrange multipliers. Polynomial bases are adopted to approximate all fields. Numerical results are presented using equal order approximations for all fields to illustrate the potential of the proposed formulation to efficiently solve Helmholtz problems in homogeneous or heterogeneous media at medium and high frequency regimes. Higher order polynomial approximations are shown to be much more accurate than lower order polynomial approximations for the the same number of global degree of freedom.

Keywords: Full-waveform-based inversion, Perfectly-matched-layers, Site characterization, Forward transient elastic wave simulation, Mixed FEM.

Abstract. *We discuss recent progress in the full-waveform-based imaging of probed solids/soils, with geotechnical site characterization applications in mind. The primary goal is the reconstruction of the material profile of near-surface, arbitrarily heterogeneous formations using elastic waves as the probing agents.*

The problem requires efficient solutions of the forward wave simulation problem, robust strategies for tackling the inverse imaging problem, and designing of experimental protocols to best harness the limited field data that feed the imaging problem. To address the forward problem, the semi-infinite extent of the probed domains is truncated via the introduction of perfectly-matched-layers (PMLs) at the truncation interfaces. We discuss a new variational hybrid formulation for transient elastic wave simulations in PML-truncated domains that is computationally optimal when compared to competing schemes. We then discuss a full-waveform-based inversion framework driven by PDE-constrained optimization ideas: to address the imaging problem we seek to resolve simultaneously PML-endowed state and adjoint time-dependent BVPs, together with time-independent BV control problems that drive the material updates during inversion iterations. To address solution multiplicity and improve on the robustness of the inversion algorithms we deploy regularization schemes (Tikhonov and Total Variation), continuation schemes (frequency-, grid-, and regularization factor-continuations), and a new search-direction biasing scheme that seems to accelerate algorithmic convergence.

We report satisfactory results with numerical experiments targeting inversion of both smooth and sharp profiles in two dimensions, and also provide examples attesting to the quality and efficiency of the forward wave modeling.

1 INTRODUCTION

Recent advances in both algorithms and computer hardware architecture have renewed hope that problems associated with the non-invasive condition assessment of physical and biological systems are becoming more tractable with present means. The last thirty years have seen various developments aiming at the solution of such mathematically, algorithmically, and computationally challenging inverse problem that arises in various application domains ranging from seismic to medical imaging. The inverse medium problem in the context of geotechnical site characterization, reduces to the reconstruction of the soil's material profile, i.e., of the spatial distribution of the elastic material properties (Lamé parameters $\{\lambda, \mu\}$ or, to an extent, equivalently, of the P- and S-wave velocities, $\{c_p, c_s\}$).

Since the focus is on characterizing near-surface deposits, the truncation of the semi-infinite extent of the physical domain becomes necessary. We, thus, introduce perfectly-matched-layers (PMLs) [1, 2, 3, 4, 5, 6] to convert the semi-infinite physical domain to a finite computational model that mimics the physical behavior of the non-truncated domain. The PML is a truly absorbing condition, capable of handling heterogeneity, unlike any other competing methodology. The PML attenuates propagating waves without reflection from the interface for all non-zero angles-of-incidences and frequencies (Fig. 2(a)). Here, we address the numerical simulation of elastic wave motion in two-dimensional, PML-truncated, arbitrarily heterogeneous elastic media (*forward problem*). Specifically, we discuss a new hybrid, fully symmetric, variational formulation (mixed unsplit-field PML, coupled with a non-mixed approach for the interior domain) for direct transient analysis. The hybrid formulation leads to optimal computational cost and easy modification of existing interior-domain displacement-based codes to accommodate PMLs as a means of domain truncation.

To address the inverse medium problem, we favor a full waveform inversion approach that uses stress waves for interrogation, and is driven by the measurements collected directly in the time-domain at receivers on the soil's surface, as schematically shown in Figs. 1(a) and 1(b). We

Figure 1: Problem definition: (a) interrogation of a heterogeneous semi-infinite domain by an active source; (b) a 2D cross-section of the domain showing one source and multiple receivers; and (c) computational model truncated from the semi-infinite medium via the introduction of PMLs

cast the profile reconstruction problem as a PDE-constrained least-squares misfit optimization problem [7, 8], and then recast it with the aid of a Lagrangian, whereby the misfit functional is augmented with the side-imposition of the PML-endowed PDEs, initial, and boundary conditions via Lagrange multipliers. To enforce the stationarity of the Lagrangian, we derive next the first-order optimality conditions. Upon discretization, the coupled system results in a classic KKT (Karush-Kuhn-Tucker) system. To solve, we pursue a *reduced-space approach* in which

the coupled system of PDEs are solved in the reduced space of the control variables –the Lamé parameters. To alleviate the difficulties associated with solution multiplicity, we explore both Tikhonov (TN) and Total Variation (TV) regularization schemes. To aid the inversion process in reconstructing high-quality material profiles, we deploy regularization factor continuation and source-frequency continuation schemes. We present examples involving layered systems and smoothly-varying profiles, as well as layered systems containing inclusions to demonstrate the performance of the proposed inversion approach and associated algorithms.

2 2D ELASTIC WAVE HYBRID MODELING

First, the equilibrium equation and the kinematic condition combined with the constitutive law, are Fourier-transformed into the frequency-domain, to obtain

$$\operatorname{div} \hat{\mathcal{S}}^T + \hat{\mathbf{f}} = -\omega^2 \rho \hat{\mathbf{u}}, \quad \mathcal{D} : \hat{\mathcal{S}} = \frac{1}{2} \left[\nabla \hat{\mathbf{u}} + (\nabla \hat{\mathbf{u}})^T \right], \quad (1)$$

where \mathcal{S} , \mathcal{E} , and \mathcal{D} are the stress, strain, and compliance tensors, respectively; ρ is the density of the elastic medium, \mathbf{u} is the displacement vector, \mathbf{f} is the load vector, and $(:)$ denotes tensor inner product. Next, we introduce the coordinate-stretched form for each coordinate:

$$\begin{aligned} \tilde{s} &= \int_0^s \varepsilon_s(s') ds', & \varepsilon_s(s, \omega) &= \alpha_s(s) + \frac{\beta_s(s)}{i\omega}, \\ \frac{d}{d\tilde{s}} &= \frac{1}{\varepsilon_s(s, \omega)} \frac{d}{ds}, & s &= x, y, \end{aligned} \quad (2)$$

where ω denotes circular frequency, ε_s is a complex stretching function in the direction of coordinate s , and α_s and β_s denote scaling and attenuation functions, respectively. As the names imply, α_s “stretches” or scales s , whereas β_s is responsible for the amplitude decay of the propagating wave once it enters the PML.

The stretching is applied by replacing x and y in (1) with the stretched coordinates \tilde{x} and \tilde{y} . Making use of (2), (1) can be written in terms of the non-stretched coordinates, and then, inverted back into the time domain to obtain a mixed unsplit-field PML formulation:

$$\operatorname{div} \left(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p \right) + a \mathbf{f} = \rho (a \ddot{\mathbf{u}} + b \dot{\mathbf{u}} + c \mathbf{u}), \quad (3a)$$

$$\mathcal{D} : \left(a \ddot{\mathbf{S}} + b \dot{\mathbf{S}} + c \mathbf{S} \right) = \frac{1}{2} \left[(\nabla \dot{\mathbf{u}}) \tilde{\Lambda}_e + \tilde{\Lambda}_e (\nabla \dot{\mathbf{u}})^T + (\nabla \mathbf{u}) \tilde{\Lambda}_p + \tilde{\Lambda}_p (\nabla \mathbf{u})^T \right], \quad (3b)$$

in which $a = \alpha_x \alpha_y$, $b = \alpha_x \beta_y + \alpha_y \beta_x$, $c = \beta_x \beta_y$, and $\tilde{\Lambda}_e$ and $\tilde{\Lambda}_p$ define the diagonal stretch tensors where the subscripts “ e ” and “ p ” refer to attenuation functions associated with evanescent and propagating waves, respectively. In the regular domain, $\tilde{\Lambda}_e$ reduces to the identity tensor, whereas $\tilde{\Lambda}_p$ vanishes identically. In (3), we introduce an auxiliary variable $\mathbf{S}(\mathbf{x}, t)$, which physically represent stress memories or histories, defined as

$$\mathbf{S}(\mathbf{x}, t) = \int_0^t \mathcal{S}(\mathbf{x}, \tau) d\tau \quad \text{and consequently, } \dot{\mathbf{S}}(\mathbf{x}, t) = \mathcal{S}(\mathbf{x}, t). \quad (4)$$

Owing to the complexity of (3), one could not conceivably reduce (3) to a single unknown field, as it is routinely done in displacement-based interior elastodynamics problems, without increasing the temporal complexity. Here, we propose a hybrid approach, whereby we retain a displacement-based interior problem and couple it with the mixed unsplit PML. Thus, the

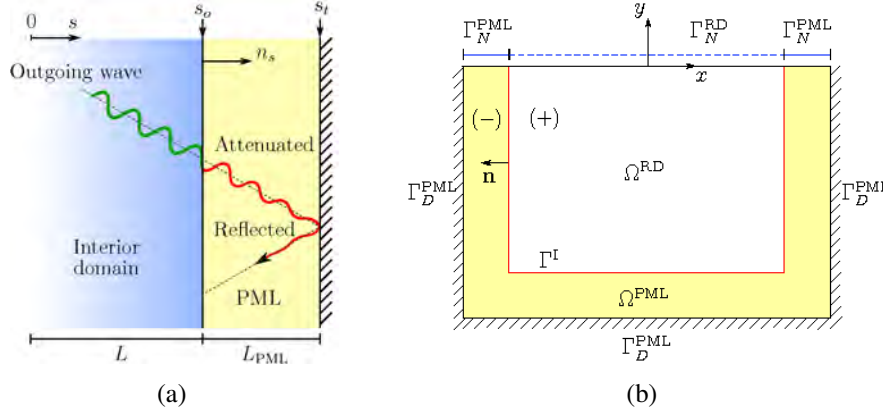

Figure 2: PML-truncated semi-infinite domains in 1D and 2D

wave motion in a PML-truncated domain (Figure 2(b)) over a time interval of interest, $(0, T]$ is governed by the hybrid system of equations:

$$\operatorname{div} \{ \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\operatorname{div} \mathbf{u}) \mathcal{I} \} + \mathbf{f} = \rho \ddot{\mathbf{u}} \quad \text{in } \Omega^{\text{RD}}, \quad (5a)$$

$$\operatorname{div} \left(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p \right) = \rho (a \ddot{\mathbf{u}} + b \dot{\mathbf{u}} + c \mathbf{u}) \quad \text{in } \Omega^{\text{PML}}, \quad (5b)$$

$$\mathcal{D} : \left(a \ddot{\mathbf{S}} + b \dot{\mathbf{S}} + c \mathbf{S} \right) = \frac{1}{2} \left[(\nabla \dot{\mathbf{u}}) \tilde{\Lambda}_e + \tilde{\Lambda}_e (\nabla \dot{\mathbf{u}})^T + (\nabla \mathbf{u}) \tilde{\Lambda}_p + \tilde{\Lambda}_p (\nabla \mathbf{u})^T \right] \quad \text{in } \Omega^{\text{PML}}, \quad (5c)$$

subject to silent initial, and the following boundary and interface conditions:

$$\{ \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\operatorname{div} \mathbf{u}) \mathcal{I} \} \mathbf{n} = \mathbf{g}_n \quad \text{on } \Gamma_N^{\text{RD}}, \quad (6a)$$

$$(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p) \mathbf{n} = \mathbf{0} \quad \text{on } \Gamma_N^{\text{PML}}, \quad (6b)$$

$$\mathbf{u} = \mathbf{0} \quad \text{on } \Gamma_D^{\text{PML}}, \quad (6c)$$

$$\mathbf{u}^+ = \mathbf{u}^- \quad \text{on } \Gamma^{\text{I}}, \quad (6d)$$

$$\{ \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\operatorname{div} \mathbf{u}) \mathcal{I} \} \mathbf{n} = -(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p) \mathbf{n} \quad \text{on } \Gamma^{\text{I}}, \quad (6e)$$

where \mathbf{g}_n denotes prescribed tractions. Note that the hybrid approach couples two initially-uncoupled sets of governing equations via the continuity of displacements and tractions at the interface.

We seek next the weak form, in the Galerkin sense, corresponding to the strong form (Eq. 5). We take inner products of (5) with test functions $\mathbf{w}_1(\mathbf{x})$, $\mathbf{w}_2(\mathbf{x})$, and $\mathbf{T}(\mathbf{x})$, and then integrate over Ω^{RD} , Ω^{PML} , and Ω^{PML} , respectively, where the integration by parts is applied to the equilibrium equations (5a) and (5b). By adding the equilibrium equations, the weak form of (5) can be cast as:

$$\begin{aligned} \int_{\Omega^{\text{RD}}} \nabla \mathbf{w}_1 : \{ \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\operatorname{div} \mathbf{u}) \mathcal{I} \} \, d\Omega &+ \int_{\Omega^{\text{PML}}} \nabla \mathbf{w}_2 : \left(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p \right) \, d\Omega \\ &+ \int_{\Omega^{\text{RD}}} \mathbf{w}_1 \cdot \rho \ddot{\mathbf{u}} \, d\Omega + \int_{\Omega^{\text{PML}}} \mathbf{w}_2 \cdot \rho (a \ddot{\mathbf{u}} + b \dot{\mathbf{u}} + c \mathbf{u}) \, d\Omega \\ &= \int_{\Gamma_N^{\text{RD}}} \mathbf{w}_1 \cdot \mathbf{g}_n \, d\Gamma + \int_{\Omega^{\text{RD}}} \mathbf{w}_1 \cdot \mathbf{f} \, d\Omega, \end{aligned} \quad (7a)$$

$$\begin{aligned} \int_{\Omega^{\text{PML}}} \mathbf{T} : \left[\mathcal{D} : \left(a\ddot{\mathbf{S}} + b\dot{\mathbf{S}} + c\mathbf{S} \right) \right] d\Omega \\ = \frac{1}{2} \int_{\Omega^{\text{PML}}} \mathbf{T} : \left[(\nabla \dot{\mathbf{u}}) \tilde{\Lambda}_e + \tilde{\Lambda}_e (\nabla \dot{\mathbf{u}})^T + (\nabla \mathbf{u}) \tilde{\Lambda}_p + \tilde{\Lambda}_p (\nabla \mathbf{u})^T \right] d\Omega. \end{aligned} \quad (7b)$$

For the mixed finite element implementation of the weak form, both $\mathbf{u}(\mathbf{x}, t)$ and $\mathbf{S}(\mathbf{x}, t)$ are treated as independent variables that need to be approximated separately now only within the PML domain. Let the basis functions be denoted by Φ and Ψ . The trial functions (\mathbf{u}, \mathbf{S}) and the test functions (\mathbf{w}, \mathbf{T}) are spatially discretized as

$$\begin{aligned} u_x(\mathbf{x}, t) &\cong \Phi^T(\mathbf{x}) \mathbf{u}_x(t), & u_y(\mathbf{x}, t) &\cong \Phi^T(\mathbf{x}) \mathbf{u}_y(t) \\ S_{xx}(\mathbf{x}, t) &\cong \Psi^T(\mathbf{x}) \mathbf{S}_{xx}(t), & S_{yy}(\mathbf{x}, t) &\cong \Psi^T(\mathbf{x}) \mathbf{S}_{yy}(t), & S_{xy}(\mathbf{x}, t) &\cong \Psi^T(\mathbf{x}) \mathbf{S}_{xy}(t), \\ w_x(\mathbf{x}) &\cong \mathbf{w}_x^T \Phi(\mathbf{x}), & w_y(\mathbf{x}) &\cong \mathbf{w}_y^T \Phi(\mathbf{x}), \\ T_{xx}(\mathbf{x}) &\cong \mathbf{T}_{xx}^T \Psi(\mathbf{x}), & T_{yy}(\mathbf{x}) &\cong \mathbf{T}_{yy}^T \Psi(\mathbf{x}), & T_{xy}(\mathbf{x}) &\cong \mathbf{T}_{xy}^T \Psi(\mathbf{x}). \end{aligned}$$

We, subsequently, obtain the *semi-discrete form* that is second-order in time and is resolved by the classical Newmark- β scheme. We note the resulting matrices are *symmetric*, and that their size is substantially smaller (up to 60% reduction in total number of unknowns in two dimensions) than that required by fully-mixed formulations (split- or unsplit-field), since the interior elastodynamics problem remains purely displacement-based.

To test the accuracy and efficiency of the hybrid formulation, we present two numerical experiments: a homogeneous semi-infinite domain (Fig. 3(a)), and a horizontally-layered medium (Fig. 3(d)). We use a Ricker pulse time signal with a central frequency $f_r = 15$ Hz as: (a) an explosive source placed at the center of the homogeneous domain, and (b) a surface stress load over a region $(-1\text{m} \leq x \leq 1\text{m})$ of the heterogeneous domain. The efficacy and quality of the PML is nicely corroborated by Fig. 3, which shows no discernible reflections from the PML interfaces, nor any residual reflections from the fixed external boundaries, even in the presence of heterogeneity. The various error metrics shown in Fig. 4 that include the domain energy decay, global and point-wise time-dependent norms, and a long-time stability run, all attest to the forward problem's performance.

3 THE INVERSE MEDIUM PROBLEM

We formulate the inverse problem initially as a PDE-constrained least-squares misfit minimization problem (à la [7, 8]), where the misfit is defined as the difference between the measured response (\mathbf{u}_m) at the receivers and a computed response (\mathbf{u}) that is obtained using trial distributions of the material parameters. The misfit least-squares minimization can be cast as

$$\mathcal{F} := \frac{1}{2} \sum_{j=1}^{N_r} \int_0^T \int_{\Gamma_m} (\mathbf{u} - \mathbf{u}_m)^2 \delta(\mathbf{x} - \mathbf{x}_j) d\Gamma dt + \mathcal{R}(\lambda, \mu), \quad (9)$$

and is subject to the physics of the problem, as expressed by the forward problem statement shown in the preceding section. In the above, \mathcal{F} denotes the objective functional, Γ_m denotes the part of the surface Γ_N^{RD} occupied by measuring stations, N_r denotes the total number of receivers on the surface, and \mathcal{R} has been introduced to alleviate the solution multiplicity. We explore both TN and TV regularization schemes.

We cast the PDE-constrained inverse medium problem (9) with the aid of a Lagrangian \mathcal{L} , whereby the misfit functional \mathcal{F} is augmented with the side-imposition of the governing PDEs

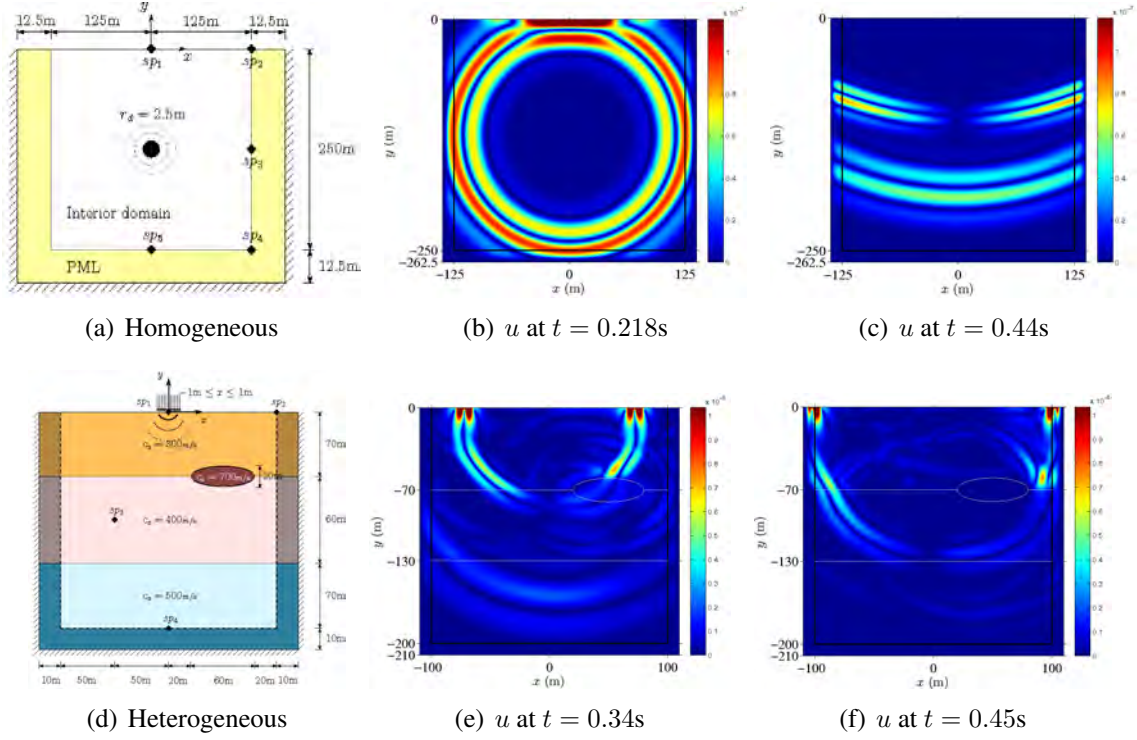

Figure 3: PML-truncated medium in two dimensions

and boundary conditions via Lagrange multipliers, per:

$$\begin{aligned}
 & \mathcal{L}(\mathbf{u}, \mathbf{S}, \boldsymbol{\theta}_{u1}, \boldsymbol{\theta}_{u2}, \boldsymbol{\theta}_s, \boldsymbol{\theta}_{b1}, \boldsymbol{\theta}_{b2}, \lambda, \mu) \\
 &= \frac{1}{2} \sum_{j=1}^{N_r} \int_0^T \int_{\Gamma_m} (\mathbf{u} - \mathbf{u}_m) \cdot (\mathbf{u} - \mathbf{u}_m) \delta(\mathbf{x} - \mathbf{x}_j) d\Gamma dt + \mathcal{R}(\lambda, \mu) \\
 &+ \int_{\Omega^{\text{RD}}} \int_0^T \boldsymbol{\theta}_{u1} \cdot [\text{div} \{ \mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\text{div } \mathbf{u}) \mathcal{I} \} + \mathbf{f} - \rho \ddot{\mathbf{u}}] dt d\Omega \\
 &+ \int_{\Omega^{\text{PML}}} \int_0^T \boldsymbol{\theta}_{u2} \cdot [\text{div} (\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p) - \rho (a \ddot{\mathbf{u}} + b \dot{\mathbf{u}} + c \mathbf{u})] dt d\Omega \\
 &+ \int_{\Omega^{\text{PML}}} \int_0^T \boldsymbol{\theta}_s : \left\{ \mathcal{D} : (a \ddot{\mathbf{S}} + b \dot{\mathbf{S}} + c \mathbf{S}) - \frac{1}{2} [(\nabla \dot{\mathbf{u}}) \tilde{\Lambda}_e + \tilde{\Lambda}_e (\nabla \dot{\mathbf{u}})^T + (\nabla \mathbf{u}) \tilde{\Lambda}_p + \tilde{\Lambda}_p (\nabla \mathbf{u})^T] \right\} dt d\Omega \\
 &+ \int_{\Gamma_N^{\text{RD}}} \int_0^T \boldsymbol{\theta}_{b1} \cdot \{ (\mu [\nabla \mathbf{u} + (\nabla \mathbf{u})^T] + \lambda (\text{div } \mathbf{u}) \mathcal{I}) \mathbf{n} - \mathbf{g}_n \} dt d\Gamma \\
 &+ \int_{\Gamma_N^{\text{PML}}} \int_0^T \boldsymbol{\theta}_{b2} \cdot [(\dot{\mathbf{S}}^T \tilde{\Lambda}_e + \mathbf{S}^T \tilde{\Lambda}_p) \mathbf{n}] dt d\Gamma. \tag{10}
 \end{aligned}$$

In the above and in the parlance customarily used for such problems, $\{\mathbf{u}, \mathbf{S}\}$ are the *state variables* (s), $\{\boldsymbol{\theta}_{u1}, \boldsymbol{\theta}_{u2}, \boldsymbol{\theta}_s, \boldsymbol{\theta}_{b1}, \boldsymbol{\theta}_{b2}\}$ are the Lagrange multipliers or *adjoint variables* (m), and $\{\lambda, \mu\}$ are the *control variables* (c). We seek to satisfy stationarity of \mathcal{L} by requiring that the first variations of \mathcal{L} vanish.

3.1 The 1st optimality condition (State problem)

The variation of \mathcal{L} with respect to the Lagrange multipliers must vanish; accordingly $\delta_m \mathcal{L} = 0$. There results the *state (or forward) problem*, identical to the IBVP given by (5-6).

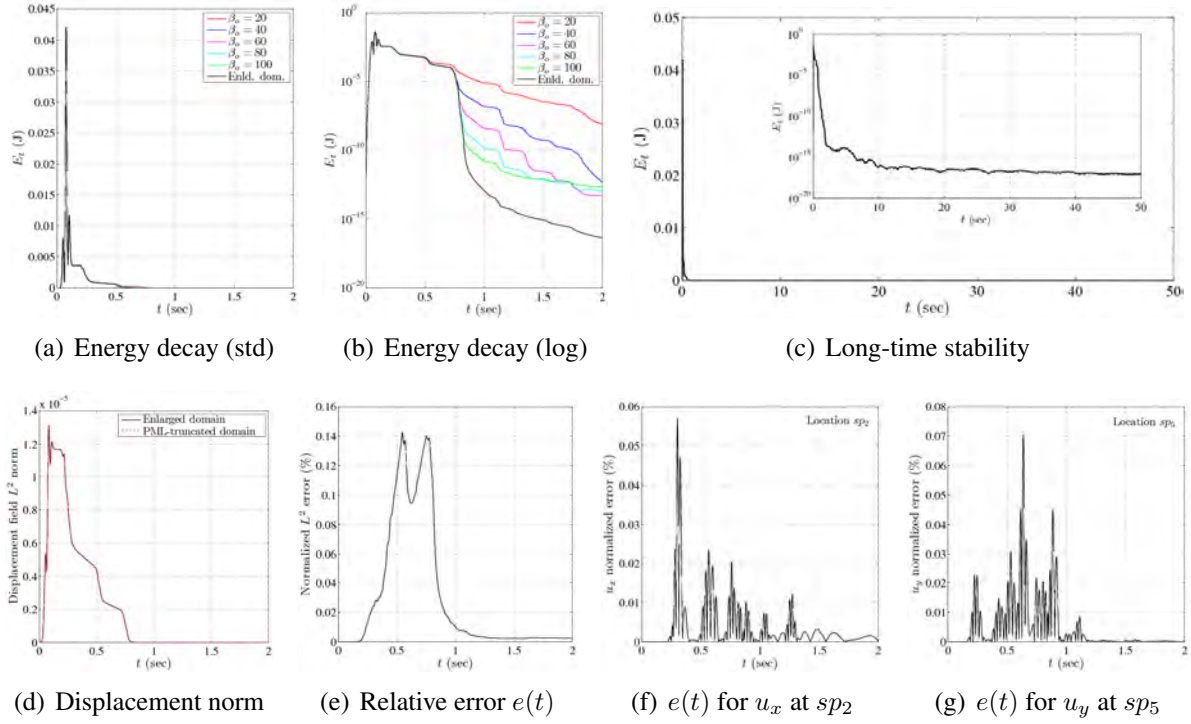

Figure 4: Error metrics for homogeneous domain

3.2 The 2nd optimality condition (Adjoint problem)

Similarly, we enforce the vanishing of the variation of \mathcal{L} with respect to the state variables, that is $\delta_s \mathcal{L} = 0$. There results the following *adjoint problem*:

$$\begin{aligned}
 \operatorname{div} [\mu(\nabla \boldsymbol{\theta}_{u1} + \nabla \boldsymbol{\theta}_{u1}^T) + \lambda \operatorname{div} \boldsymbol{\theta}_{u1} \mathcal{I}] &= \rho \ddot{\boldsymbol{\theta}}_{u1} & \text{in } \Omega^{\text{RD}}, \\
 \operatorname{div} (-\dot{\boldsymbol{\theta}}_s \tilde{\Lambda}_e + \boldsymbol{\theta}_s \tilde{\Lambda}_p) &= \rho (a \ddot{\boldsymbol{\theta}}_{u2} - b \dot{\boldsymbol{\theta}}_{u2} + c \boldsymbol{\theta}_{u2}) & \text{in } \Omega^{\text{PML}}, \\
 \mathcal{D} : (a \ddot{\boldsymbol{\theta}}_s - b \dot{\boldsymbol{\theta}}_s + c \boldsymbol{\theta}_s) &= \tilde{\Lambda}_p (\nabla \boldsymbol{\theta}_{u2})^T - \tilde{\Lambda}_e (\nabla \dot{\boldsymbol{\theta}}_{u2})^T & \text{in } \Omega^{\text{PML}},
 \end{aligned}$$

subject to

$$\begin{aligned}
 \{\mu(\nabla \boldsymbol{\theta}_{u1} + \nabla \boldsymbol{\theta}_{u1}^T) + \lambda \operatorname{div} \boldsymbol{\theta}_{u1} \mathcal{I}\} \mathbf{n} &= \sum_{j=1}^{N_r} (\mathbf{u} - \mathbf{u}_m) & \text{on } \Gamma_m, \\
 (-\dot{\boldsymbol{\theta}}_s \tilde{\Lambda}_e + \boldsymbol{\theta}_s \tilde{\Lambda}_p) \mathbf{n} &= 0 & \text{on } \Gamma_N^{\text{PML}}, \\
 \boldsymbol{\theta}_{u2} &= 0 & \text{on } \Gamma_D^{\text{PML}}, \\
 \boldsymbol{\theta}_{u1} &= \boldsymbol{\theta}_{u2} & \text{on } \Gamma^{\text{I}}, \\
 \{2\mu \nabla \boldsymbol{\theta}_{u1}^{\text{sym}} + \lambda \operatorname{div} \boldsymbol{\theta}_{u1} \mathcal{I}\} \mathbf{n} &= (\dot{\boldsymbol{\theta}}_s \tilde{\Lambda}_e - \boldsymbol{\theta}_s \tilde{\Lambda}_p) \mathbf{n} & \text{on } \Gamma^{\text{I}}, \\
 \boldsymbol{\theta}_{u1}(\mathbf{x}, T) &= 0, \quad \dot{\boldsymbol{\theta}}_{u1}(\mathbf{x}, T) = 0 & \text{in } \Omega^{\text{RD}}, \\
 \boldsymbol{\theta}_{u2}(\mathbf{x}, T) &= 0, \quad \dot{\boldsymbol{\theta}}_{u2}(\mathbf{x}, T) = 0 & \text{in } \Omega^{\text{PML}}, \\
 \boldsymbol{\theta}_s(\mathbf{x}, T) &= 0, \quad \dot{\boldsymbol{\theta}}_s(\mathbf{x}, T) = 0 & \text{in } \Omega^{\text{PML}}.
 \end{aligned}$$

The adjoint problem is a *final-value* problem (requires reverse marching along the time line) and is driven by the misfit between the computed and observed responses at measuring stations. We

note that the operators implicated in the adjoint PDEs are identical to the state operators, modulo the sign reversal for those terms implicating first-order time derivatives. By construction, the adjoint equations are also hybrid and PML-endowed, with $(\boldsymbol{\theta}_{u1}, \boldsymbol{\theta}_{u2})$ and $\boldsymbol{\theta}_s$ playing a role analogous to \mathbf{u} and \mathbf{S} of the state problem, respectively.

3.3 The 3rd optimality condition (Control problem)

Lastly, we impose $\delta_\lambda \mathcal{L} = 0$ and $\delta_\mu \mathcal{L} = 0$. The variations result in the following two boundary-value control problems:

λ -control problem:

$$-R_\lambda \Delta \lambda - \int_0^T (\operatorname{div} \boldsymbol{\theta}_{u1})(\operatorname{div} \mathbf{u}) \, dt = 0 \quad \text{in } \Omega^{\text{RD}}, \quad (13a)$$

$$\int_{\Gamma_N^{\text{RD}}} \nabla \lambda \cdot \mathbf{n} \, d\Gamma = 0 \quad \text{on } \Gamma_N^{\text{RD}}. \quad (13b)$$

μ -control problem:

$$-R_\mu \Delta \mu - \int_0^T \nabla \boldsymbol{\theta}_{u1} : 2\nabla \mathbf{u}^{\text{sym}} \, dt = 0 \quad \text{in } \Omega^{\text{RD}}, \quad (14a)$$

$$\int_{\Gamma_N^{\text{RD}}} \nabla \mu \cdot \mathbf{n} \, d\Gamma = 0 \quad \text{on } \Gamma_N^{\text{RD}}. \quad (14b)$$

In writing (13) and (14), we adopted the TN scheme for regularizing the solutions. If the TV regularization were to be used instead, the first terms in (13a) and (14a) are modified, and the control problems now read

$$-R_\lambda \nabla \cdot \left[(\nabla \lambda \cdot \nabla \lambda + \epsilon)^{-\frac{1}{2}} \nabla \lambda \right] - \int_0^T (\operatorname{div} \boldsymbol{\theta}_{u1})(\operatorname{div} \mathbf{u}) \, dt = 0 \quad \text{in } \Omega^{\text{RD}}, \quad (15)$$

$$-R_\mu \nabla \cdot \left[(\nabla \mu \cdot \nabla \mu + \epsilon)^{-\frac{1}{2}} \nabla \mu \right] - \int_0^T \nabla \boldsymbol{\theta}_{u1} : (\nabla \mathbf{u} + \nabla \mathbf{u}^T) \, dt = 0 \quad \text{in } \Omega^{\text{RD}}. \quad (16)$$

We remark that the TV scheme leads to a nonlinear operator in the control equations, as opposed to the Laplacian operator that results when TN regularization is used.

4 THE INVERSION PROCESS

To satisfy the stationarity of \mathcal{L} , all three problems must be solved. However, the simultaneous solution of the resulting KKT system using a *full-space method* is computationally expensive. Alternatively, a *reduced-space method*, in which the coupled system of PDEs are solved in the reduced space of the control variables, is preferable [7, 8]. The procedure is iterative: we start with an assumed initial spatial distribution of the control parameters (λ and μ) and solve the state problem. Then, we solve the adjoint problem. By doing so, we satisfy the first and second optimality conditions, and we iteratively update the control parameters using a conjugate gradient method with inexact line search so that the misfit reduces to a preset tolerance, thereby allowing the third optimality condition to be satisfied. We bring in two remedies that aid the inversion process in reconstructing high-quality material profiles: (a) a regularization factor continuation scheme to penalize high-frequency material oscillations during the early inversion stages, (b) a source-frequency continuation scheme in which a low-frequency excitation typically allows

for a rough resolution of the material profile, whereas an excitation with higher-frequency components fine-tunes the profile, and (c) a search-direction biasing scheme, whereby we seek to bias the λ -search directions by the μ -search directions, effectively forcing both parameters to increase simultaneously, during the early inversion iterations. The scheme is motivated by the physics of the problem, and is described by:

$$\mathbf{d}_k^\lambda \leftarrow \|\mathbf{d}_k^\lambda\| \left[W \frac{\mathbf{d}_k^\mu}{\|\mathbf{d}_k^\mu\|} + (1 - W) \frac{\mathbf{d}_k^\lambda}{\|\mathbf{d}_k^\lambda\|} \right] \quad (17)$$

where a weighted average of *unit* λ - and μ -search directions are used for the evolution of λ .

5 NUMERICAL EXPERIMENTS

To test the proposed inversion scheme, we discuss next numerical experiments, involving arbitrarily heterogeneous hosts and synthetic data. The first example is a fictitious medium that has material properties varying smoothly with depth. We reduce the half-plane, through truncation, to a $45\text{m} \times 45\text{m}$ computational domain, surrounded on its sides and bottom by a 5m-thick PML, as shown in Fig. 5(a). The material interfaces were extended horizontally into

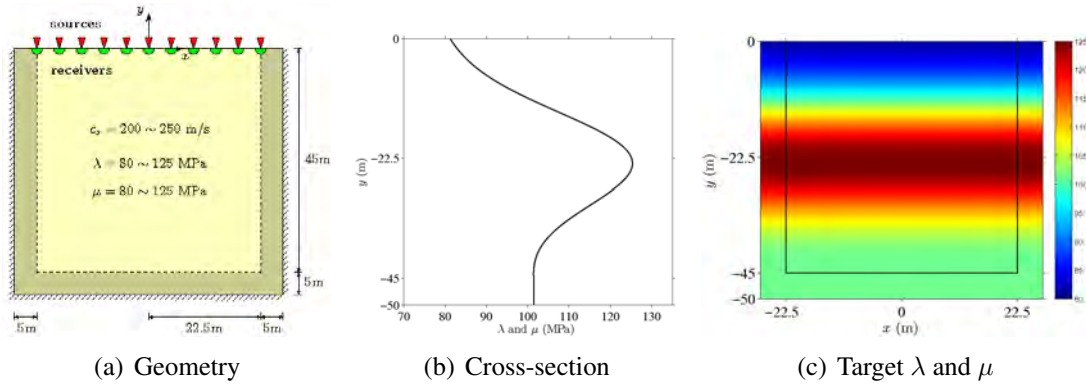

Figure 5: A PML-truncated semi-infinite domain in two dimensions

the PML, thereby, avoiding sudden material changes at the interface between the PML and the regular domain. We started the inversion process with a homogeneous profile that has both λ and μ set to 80 MPa. By applying a Gaussian pulse load with a maximum frequency of $f_r = 40$ Hz, we reconstructed the Lamé parameters shown in Fig. 6. Both Lamé parameters are satisfactorily inverted.

Example 2 involves a horizontally-layered medium with $\lambda(y) = \mu(y) = 80, 101.25$, and 125 MPa from top to bottom, as shown in Fig. 7(a). We use a source-frequency continuation scheme according to which a few time signals with different frequency content are used to probe the domain. We start the inversion process with a low-frequency source and feed the converged reconstructed λ and μ profiles as initial guesses to the problem excited with a higher-frequency source. Here, we considered four different Gaussian pulses with maximum frequencies of 10, 20, 30, and 40 Hz. Figure 8 shows the velocity profiles computed from the reconstructed Lamé parameter profiles. Both velocity profiles seem to be recovered quite satisfactorily.

The last example focuses on a layered medium with $\lambda(y) = \mu(y) = 320, 500, 720$ MPa from top to bottom and an embedded elliptic inclusion of 720 MPa in an effort to implicate arbitrary heterogeneity (Fig. 9). As in Example 2, we use a source-frequency continuation scheme with four distinct Gaussian pulses ($f_{\max} = 10, 40, 80$, and 120 Hz), to probe the

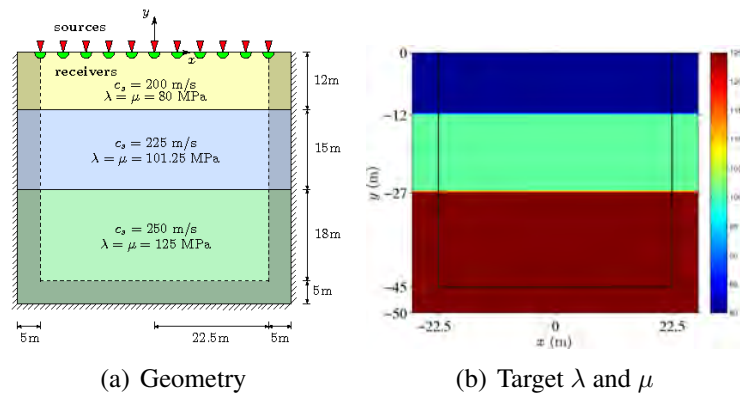

Figure 7: A PML-truncated horizontally-layered semi-infinite domain in two dimensions

Figure 8: Velocities computed from the reconstructed Lamé parameters

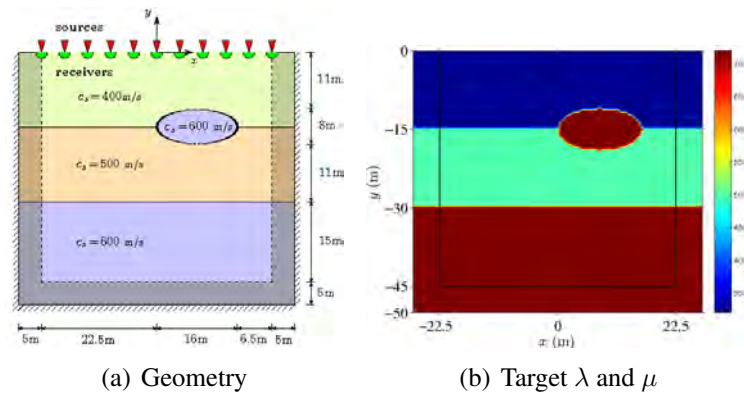

Figure 9: A PML-truncated layered semi-infinite domain with an elliptic inclusion

domain. Here we opted for using the TV regularization only. We initiated the inversion process with a homogeneous medium that has $\lambda = \mu = 310$ MPa. Figure 10 provides the velocity profiles computed from the reconstructed λ and μ . Once again, both velocity profiles seem to have been recovered with moderate success.

Figure 10: Velocities computed from the reconstructed Lamé parameters

6 CONCLUSIONS

We discussed a full-waveform-based inversion methodology in PML-truncated elastic media, suitable for geotechnical site characterization purposes, implemented directly in the time-domain, using stress waves for probing, and driven by the measured response at receivers situated on the ground surface.

We adopted a PDE-constrained optimization approach, and discussed the implementation of the resulting first-order optimality conditions. These gave rise to: a) a state problem that was treated by the a new symmetric hybrid method developed for the forward wave simulation; b) an adjoint problem that was treated also with the hybrid method similarly to the state problem; and c) control problems that were used to update the material parameters. The continuation schemes we deployed assisted the optimizer in narrowing the initial feasibility space by presenting subsequent iterations with improved initial guesses. Though the presentation here is limited to geotechnical applications, the overall structure of the inversion scheme is modular and very flexible, and could be adopted as a solution approach for a broader class of inverse problems. Its performance can be improved by introducing a nonlinear iterative solver that would achieve convergence rates better than the conjugate gradient method used herein, possibly similar to what was proposed in [7].

We discussed our experience in reconstructing heterogeneous profiles involving smoothly-varying profiles, as well as layered systems, and layered media with embedded inclusions, in order to demonstrate the performance of the proposed inversion approach. Here, we described only the two-dimensional case, but the axisymmetric and three-dimensional cases follow directly.

Keywords: E-Simulator, Steel Frame, Finite Element Method, Solid Element, Parallel Computing.

Abstract. *The project of E-Simulator is under way at Hyogo Earthquake Engineering Research Center (E-Defense), which belongs to National Research Institute for Earth Science and Disaster Prevention (NIED), Japan. E-Defense facilitates the world's largest shaking table. The E-Simulator uses the parallel EF-analysis software package called ADVENTURE-Cluster (ADVC) as a platform, and we carried out elastoplastic seismic response analysis of high-rise building frame with over 70-million DOFs. In this study, we report the results of high-precision FE-analysis for simulation of dynamic collapse behavior of the 4-story steel building frame. The whole frame is discretized into hexahedral elements with linear interpolation functions. In order to improve the accuracy of collapse simulation, a new piecewise linear combined isotropic and kinematic hardening rule is implemented for steel material, and its parameters are identified from the uniaxial material test result. The stud bolts are precisely modeled using multipoint constraints and nonlinear springs. The wire-meshes in the concrete slab are modeled using hexahedral elements. The damping due to plastic energy dissipation of exterior walls is modeled by shear springs between the floors. The accuracy of the model is verified in comparison to the physical test of steel-concrete composite beam subjected to static deformation. It will be shown that elastoplastic dynamic responses of the 4-story frame can be estimated with good accuracy using a high-precision FE-analysis without resort to macro-models such as plastic hinge and composite beam effect.*

1 INTRODUCTION

A project of Earthquake Simulator (E-Simulator) is being carried out at Hyogo Earthquake Engineering Research Center (E-Defense), which belongs to National Research Institute for Earth Science and Disaster Prevention (NIED), Japan. E-Defense facilitates the world's largest shaking table, and develops the E-Simulator, a virtual shaking table, which uses numerical computation to evaluate seismic response of structures. Advantage is taken of exclusive data that are measured in shake-table experiments. The E-Simulator will be applicable to a wide range of structures, such as steel buildings, reinforced concrete structures or ground structures.

A core element of the E-Simulator is a parallel finite element (FE) analysis software package, which is called ADVENTURECluster (ADVC). ADVC is capable to be operated in a large-scale parallel computation environment; indeed, it was operated on Blue Genes in 2006 and nominated as a finalist of 2006 Gordon Bell Prizes [1], [2]. Recently, the elastoplastic seismic response analysis is carried out by using ADVC, for a detailed frame model of a high-rise building, which consists of over 70-million DOFs [3]. The detailed model is made by using solid elements, so that only constitutive relations of materials (not of structure members) are used.

It is natural to be asked whether such a massively parallel computation is needed for the estimate of seismic structure responses; a standard practice is the use of FE-analysis of fiber models. In general, FE-analysis of a fiber model is able to satisfactorily reproduce experimental data if constitutive relations of structure members are tuned up. The E-Simulator needs constitutive relations of materials instead. Even though required computation is much larger, it can reduce efforts which are made to carry out experiments needed for structure member constitutive relations.

In this study, we report E-Simulator's recent results made for dynamic collapse behavior of a four-story steel building frame. A new constitutive model is developed for steel. A detailed and precise computer model is made for key members of the buildings, by using hexahedral elements with linear interpolation function. Large-scale parallel FE-analysis using the Coarse Grid based Conjugate Gradient (CGCG) method [1], which is fast and robust parallel solver, is applied to these models.

2 PROBLEM SETTING

The target of the E-Simulator virtual shake-table test is a frame structure for a four-story building as shown in Fig. 1 [4]; E-Defense experiments have been made using a full-scale model of this building. The height and the floor area are 14.4 m and 60 m², respectively.

Figure 1: 4-story steel frame model [4].

FE-models for this frame are presented in Fig. 2; meshes are generated using the data and documents that have been distributed for the blind analysis contest [5], [6], and all the members as well as the floor slabs are modeled in terms of 8-node hexahedral solid elements with tri-linear shape functions. The DOFs of each node are three translational displacement components.

Figure 2: FE-models of the three cases (drawn without mesh).

2.1 Steel Constitutive Relation

In order to improve the collapse simulation, a more accurate constitutive relation is used for steel. A piecewise linear hardening law with semi-implicit rules that is extended from the conventional combined isotropic and kinematic hardening law is implemented. The piecewise nature of the law has no theoretical background; it is more accurate representation of experimental observation of the hardening characteristics, that is, this law can simulate the yield plateau and the Bauschinger effect. Different rules are used for the first and subsequent loading states.

The parameters used in the piecewise linear law are determined from the cyclic uniaxial material test result. In the present law, it is set that there are six segments in which the hardening law is assumed to be linear, and eleven parameters including ratios between isotropic hardening and kinematic hardening are used to characterize each segment. The curve fitting is applied to determine these parameters, by minimizing the difference between the observed stress-strain relation and the computed one using an optimization algorithm. Figure 3 shows a typical example of the curve fitting for a cyclic uniaxial coupon test [7]. Note that a piecewise linear hardening law with seven segments is used in this example.

Figure 3: Parameter identification using the cyclic uniaxial coupon test [7].

2.2 Detailed and Precise Modeling

As mentioned, the E-Simulator project is aimed at developing an FE-analysis software package that uses solid elements so that the constitutive relation input is only for materials even though it results in large-scale computation. Detailed and fine meshing is needed for some structure members that have complicated configuration or complicated connection. Such detailed meshing is applied to concrete slabs and column bases as described in the followings.

While the configuration of concrete slabs of the present four-story building is relatively simple, it includes the following members that need special consideration: 1) wire meshes that are embedded in the slab to increase the stiffness; and 2) a set of stud bolts that connect the slab to beams of the floor. The wire-meshes are modeled using hexahedral elements, to evaluate accurately the reinforcement effects of the meshes; see Fig. 4. The wire-meshes are simplified, that is, the circular cross-section is changed to rectangular one and crossing reinforcements are modeled as a unified body. Figure 5 illustrates how the stud bolts are modeled. Rigid beam elements are placed at the location of the stud bolts. They are penetrated up to the second layer of the flange mesh. Note that the rigid beam should be connected to at least two nodes of the flange mesh because each node does not have rotational degree of freedom. Rigid rods are imposed to keep the distance between the beam and the slab constant. The upper end of the rigid beam is not connected to the slab, and that of the rigid rod is connected to a node of the slab mesh. The upper end of the rigid beam is connected to the upper end of the rigid rod by using the truss element. The stiffness of the truss element can be evaluated from the lateral stiffness of the stud considering the effect of the contacted concrete [8], although the lateral stiffness has not been considered for the current model yet.

Figure 4: Composite beam.

Figure 5: Modeling of stud bolt.

Figure 6: Column base.

Modeling of column base is illustrated in Fig. 6. The upper steel base plate and the lower mortar plate are modeled precisely. On the surface between the steel base plate and the mortar, frictionless contact condition is imposed though multipoint constraints (MPCs) are imposed for the relative displacements in horizontal X and Y directions. On the surface between the mortar and the base, the stick condition is imposed. The base plate and the base are connected by the anchor bolts that are modeled by the truss element. The base is reinforced by the seamless pipes that are also modeled by truss elements.

The extra damping of the exterior wall is due to the energy dissipation of the walls' plastic deformation. Therefore the walls are modeled by elastoplastic shear springs; see Fig. 2 (b) and (c).

Table 1: Model types.

Case	Column base	Stiffness of exterior wall	Slab	Hardening law for steel
Case A	Fixed.	Ignored.	No stud bolts, no wire-meshes	Isotropic hardening
Case B	Rotational spring based on the recommendation by Architectural Institute of Japan [9].	Shear spring (truss element) connecting the flanges of the beams in the upper and lower floors. Parameters are identified from the experimental results [10].	No stud bolts, no wire-meshes	Isotropic hardening
Case C	Solid model. Beam element for the anchor bolt with pretension. Contact with small friction between the lower face of base plate and the upper face of base.		With stud bolts and wire-meshes	Piecewise linear combined isotropic and kinematic hardening law with semi-implicit rules

3 RESULTS

In order to study the accuracy of the modeling of the column base, the slab, and the exterior wall, the three models, which are explained in Table 1, are made. Figure 2 depicts FE-models of these three cases.

3.1 Evaluation of Natural Period

If DOFs of the analysis model is large, there is always a possibility that mistakes are made in the pre-process of the model. Natural periods and modes are first examined in the E-Simulator project, in order to find out apparent errors in the pre-process.

Assuming linear elasticity, first 6 eigen-values are computed for the stiffness matrix, from which the natural periods and the associate modes are computed. The results are summarized in Table 2 and Fig. 7. The natural periods observed in the E-Defense experiment are also included in the table. As is seen, the E-Simulator model reproduces natural periods fairly well.

Table 2: Four lowest natural periods for Cases A, B, C and experiment.

Case	Natural period			
	1st	2nd	3rd	4th
Case A	0.8389	0.8144	0.5700	0.2702
Case B	0.8303	0.8203	0.5555	0.2700
Case C	0.7836	0.7653	0.5298	0.2549
Experiment [10]	0.80	0.76	---	---

(a) 1st mode

(b) 2nd mode

Figure 7: Two lowest eigenmodes of Case C.

3.2 Time-history Analysis for Nonlinear Collapse Behavior

Here only the results of the time-history analyses for the two models, Cases A and B are shown. The results of Case C will be shown in the presentation. Input strong ground motions are the JR-Takatori wave of the 1995 Hyogo-ken Nanbu Earthquake; the motions are scale by 0.6. The acceleration record measured on the shaking table of the E-Defense experiment is used rather than the numerically scaled ground motion record of the earthquake; see Fig. 8, where the EW, NS, or UD direction correspond to X-, Y-, or Z-directions, respectively. The duration of the motion is 20 s. The Rayleigh damping is used, where the damping factors are 0.02 for the 1st and 4th modes, which are the two lowest modes in the X-direction. The Hilber-Hughes-Taylor method is employed for the time integration; the parameters are $\alpha = -0.05$, $\beta = (1 - \alpha)^2/4 = 0.275625$. A super-computer SGI Altix 4700 Intel Itanium 1.66 GHz, 1 node \times 256 core, in NIED is used for computation. The computation time is 2,414 s for static analysis for self-weight, and average of 1,106 s for one step ($\Delta t = 0.01$ s) of the time-history analysis.

The time histories of inter-story drift angles and shear forces of the first story are plotted in Figs. 9 and 10, respectively. Better agreement with the experiment results is observed for Case B, than Case A. The maximum and minimum values of the inter-story drift angle are $\{0.01089, -0.01357\}$ rad in the X-direction, and $\{0.02300, -0.007942\}$ rad in Y-direction, whereas the experimental results are $\{0.0121, -0.0122\}$ rad in X-direction, and $\{0.0190, -$

0.00933} rad in the Y-direction. Moderately accurate values are obtained by the E-Simulator. Note that residual deformation is observed only in the Y-direction. The story shear forces are calculated by the summation of the products of concentrated mass of each layer and the acceleration at the center of gravity of each layer. The maximum and minimum values of the shear forces are {1142, -1153} kN in the X-direction, and {1385, -1229} kN in the Y-direction. The measured values in the experiment are {1169, -1173} kN in the X-direction, and {1423, -1058} kN in the Y-direction. The shear forces are estimated with good accuracy.

4 CONCLUSIONS

- A virtual shake-table test has been carried out using the prototype of the E-Simulator for investigation of elastoplastic dynamic behavior of the 4-story frame model as the specimen of full-scale shake-table test conducted in September 2007 at E-Defense. It has been shown that the large-strain elastoplastic dynamic behaviors can be estimated with good accuracy based on the solid elements and the constitutive relations of the steel material without resort to macro models and empirical parameters such as plastic hinge and stiffness amplification factor of the composite beam.
- The stiffness and strength of the exterior walls are modeled by elastoplastic shear springs. Hence, the use of ambiguous equivalent damping factor due to the friction and plastic deformation of the nonstructural components will be avoided by elaborating the model. This spring model will be further replaced by a solid model that is under development.
- The rotational spring at the column base is replaced by a precise model with hexahedral elements, multipoint constraints and truss elements. Contact between the base plate and the mortar is also considered. This model may reproduce the local behaviors such as collapse behavior at the column base.
- The effect of the wire-mesh on the stiffness of the concrete slab is considered by using a precise model of hexahedral elements. Also, the stud bolts that connect the concrete slab and the beam are modeled by the rigid beams and the truss elements. Contact between the concrete slab and the column is also considered. These modeling approaches may reproduce the behaviors of the composite beam.

5 ACKNOWLEDGEMENTS

This study is a part of E-Defense Seismic Experimental Study and Simulation System Construction Project conducted by E-Simulator Production Committee (Leader: Prof. Muneo Hori, The University of Tokyo). The authors acknowledge the valuable contribution from the committee members, and the financial support by NIED. The contribution by Dr. Yuyama of Allied Engineering Corporation for computation and mesh generation is also acknowledged.

The authors also acknowledge the valuable information from the NEES/E-Defense collaborative research program on steel structures (Leader: Prof. Kazuhiko Kasai, Tokyo Institute of Technology), which was pursued by the Analysis Method and Verification Working Group (Leader: Prof. Motohide Tada, Osaka University) and Building Collapse Simulation

Working Group (Leader: Prof. Keiichiro Suita, Kyoto University). The authors would like to show sincere appreciation to Prof. Satoshi Yamada of Tokyo Institute of Technology, Japan, who has provided us with the experimental results of steel materials.

Keywords: PDS-FEM, crack, concrete, seismic structure analysis

Abstract. *Particle-Discretization-Scheme (PDS) is a new discretization scheme which uses a pair of basis functions that discretize a function and its derivatives using characteristic functions, and PDS-FEM is an FEM which is implemented with PDS. It is straight forward to numerically solve a crack problem by means of PDS-FEM. This paper presents an application example of PDS-FEM to seismic structure response analysis of an RC bridge pier. A sophisticated non-linear elasto-plastic constitutive relation is used for concrete, and a detailed model is made. It is shown that the processes in which the pier is damaged and partially failed due to seismic loading are computed. Large plastic deformation as well as initiation and growth of local cracks in concrete are computed.*

Figure 1: Schematic view of C1-1 Reinforced Concrete Bridge Pier.

1 INTRODUCTION

Earth Defense (E-Defense)[1] is the world largest shaking table that is capable to shake a full scale four story building. A project of Earthquake Simulator (E-Simulator) is aimed at building a virtual shaking table which numerically computes seismic response of a structure which even E-Defense cannot shake[2]. A solid element finite element method is used in E-Defense, so that only material constitutive relations are implemented in it even though large scale numerical computation is inevitable. ADVC is used as a base finite element analysis method in E-Simulator.

Reinforced concrete pier is a core target of E-Defense as well as E-Simulator. As an example, C1-1 Reinforced Concrete Bridge Pier, which was shaken by E-Defense, is presented in Fig. 1; the height of the pier reaches 7.5 m. There are two major characteristics in concrete materials. The first is brittle failure that is induced by single or multiple cracking. Closure of cracking or contact of crack surfaces is important as well as initiation and propagation of cracks. The second is constitutive relations (CCR), which expresses transition from elastic state to elasto-plastic state that accompanies material damage.

The implementation of cracking treatment and a sophisticated CCR into E-Simulator is thus needed. Cracking treatment of E-Simulator is made by applying a new discretization scheme, called Particle Discretization Scheme (PDS). PDS is implemented in E-Simulator. The most complicated but most reliable CCR is being implemented.

This paper briefly reports the current state of implementing PDS and CCR into E-Simulator. Concise but rigorous formulation for PDS and CCR is presented in Section 2. An example problem of seismic structure analysis of a concrete pier is solved in Section 3. This problem uses an E-Defense experiment of a real scale reinforced concrete pier.

2 FORMULATION

2.1 PDS

The main idea of PDS is the use of a characteristic function as a basis function of discretization[3, 4]. Let us denote by D and $\{\Phi^\alpha\}$ the analysis domain and a set of sub-domains of D , respectively (D is decomposed into $\{\Phi^\alpha\}$). A basis function is ϕ^α , a characteristic function of Φ^α . A discretized function is thus expressed in terms of sub-domain-wise constant functions. This function has discontinuities across $\partial\Phi^\alpha$'s. Derivative of a function is computed by using a different domain decomposition of D . Denoting this decomposition by $\{\Psi^\beta\}$, the derivative is expressed in terms of ψ^β , which is a characteristic function of Ψ^β .

The implementation of PDS to FEM is straightforward. For simplicity, we consider the case that D is a linearly elastic body, and define the following functional for displacement, strain and stress (\mathbf{u} , $\boldsymbol{\epsilon}$ and $\boldsymbol{\sigma}$) is used:

$$J(\mathbf{u}, \boldsymbol{\epsilon}, \boldsymbol{\sigma}) = \int_D \frac{1}{2} \rho \dot{\mathbf{u}} \cdot \dot{\mathbf{u}} - \frac{1}{2} \boldsymbol{\epsilon} : \mathbf{c} : \boldsymbol{\epsilon} + \boldsymbol{\sigma} : (\boldsymbol{\epsilon} - \nabla \mathbf{u}) \, dv, \quad (1)$$

where \mathbf{c} and ρ are elasticity and density, $\nabla \mathbf{u}$ is the gradient of \mathbf{u} , and \cdot and $:$ stand for the first- and second-order contraction. The variation of this J leads to the wave equation,

$$\rho \ddot{\mathbf{u}} - \nabla \cdot (\mathbf{c} : (\nabla \mathbf{u})) = 0. \quad (2)$$

Discretizing \mathbf{u} in terms of $\{\phi^\alpha\}$ and discretizing $\boldsymbol{\epsilon}$ and $\boldsymbol{\sigma}$ in terms of $\{\psi^\beta\}$, we now compute variation for the discretization coefficients and obtain

$$[M][\ddot{u}] + [K][u] = [f] \quad (3)$$

where $[u]$ is a vector for the coefficient of ϕ^α for discretized \mathbf{u} and $[f]$ is a vector of the corresponding nodal force; $[M]$ is a diagonal mass matrix and its diagonal term is $\rho \Phi^\alpha$ with Φ^α standing for the volume of the sub-domain Φ^α ; and $[K]$ is

$$k_{ij}^{\alpha\alpha'} = \sum_{\beta} c_{ipjq} b_p^{\beta\alpha} b_q^{\beta\alpha'} \quad (4)$$

with $b_p^{\beta\alpha} = \int_D \psi^\beta (\nabla \phi^\alpha)_p \, dv$.

When a traction-free crack is initiated or propagated onto a facet of $\partial\Phi^\alpha$, the contribution of $\nabla \phi^\alpha$ in the integral of $b_p^{\beta\alpha}$ which is used in Eq. (4) is dropped. Additional boundary tractions need to be described on the facet, so that the traction free boundary conditions are met. As an approximation, the traction that has acted before cracking is cancelled. In this manner, the reduction of $[K]$ and the change in $[f]$ due to the crack initiation or propagation can be rigorously computed in PDS-FEM.

2.2 CCR

Maekawa and his group[5, 6, 7] have proposed the most sophisticated and reliable CCR, which has the following two key relations:

$$\boldsymbol{\sigma} = \mathbf{c} : \boldsymbol{\epsilon}^E, \quad d\boldsymbol{\epsilon}^P = \boldsymbol{\ell} : d\boldsymbol{\epsilon}^E, \quad (5)$$

where d stands for the increment, superscript E or P designates elastic or plastic parts, respectively; \mathbf{c} and $\boldsymbol{\ell}$ are functions of $\boldsymbol{\epsilon}^E$ which have been determined as experimental relations. An elasto-plasticity or instantaneous modulus tensor which gives strain increment-stress increment relation is thus given as

$$\mathbf{c}^{EP} = (\mathbf{c} + (\nabla \mathbf{c}) : \boldsymbol{\epsilon}^E) : (\mathbf{I} + \boldsymbol{\ell})^{-1}. \quad (6)$$

where $\nabla \mathbf{c}$ is a six-order tensor which gives the derivative of \mathbf{c} with respect to $\boldsymbol{\epsilon}^E$ and \mathbf{I} is the fourth-order symmetric unit tensor.

As is seen, \mathbf{c}^{EP} is not symmetric. Furthermore, it loses the positive-definiteness as $\boldsymbol{\epsilon}^E$ increases. The loss of the positive-definiteness will be a bottle neck for a solver which uses a conjugate gradient (CG) method or its extension. Beside the loss of symmetry and positive-definiteness, the numerical computation of \mathbf{c}^{EP} is not trivial since it involves the computation of derivatives and an inverse tensor.

Table 1: Material properties used in numerical simulation.

a) concrete		b) steel	
Young's modulus	25,200 MPa	Young's modulus	197,100 MPa
Poisson's ratio	0.2	Poisson's ratio	0.3
compression strength	29.4 MPa	density	7,930 kg/m ³
density	2,300 kg/m ³		
critical strain for tensile failure	0.001339		

The authors are proposing reformulation of Maekawa's CCR, assuming that an experimental relation between plastic and elastic invariants is a yield function, i.e., $J_2^P - H(J_2^E) = 0$, with H being an experimentally determined function and J_2 being the second invariant of the deviatoric part; this function yields a consistency condition that fully determines plastic strain increment. Indeed, when $d\epsilon^P = dg \mathbf{d}$ is assumed with \mathbf{d} being a second-order tensor which is experimentally determined, the increment of this yield function produces $dg \frac{\mathbf{e}^P \mathbf{d}}{2J_2^P} = H' \frac{\mathbf{e}^E d\epsilon^E}{2J_2^E}$. Thus, the reformulated elasto-plasticity tensor is

$$\mathbf{c}^{EP} = (\mathbf{c} + (\nabla \mathbf{c}) : \epsilon^E) : (\mathbf{I} - \mathbf{L}). \quad (7)$$

where $\mathbf{L} = \left(DP \delta + \frac{\mathbf{e}^E}{J_2^E} \right) \otimes \left(\left(\frac{\mathbf{e}^E \mathbf{e}^P}{H' J_2^P} + 2 \right)^{-1} \mathbf{e}^E \right)$.

Unlike the original equation, Eq. (6), \mathbf{c}^{EP} of Eq. (7) does not involve computation of the inversion. Explicit expression of $\nabla \mathbf{c}$ is obtained to further reduce numerical computation. Finally, the stress increment-strain increment is rewritten as

$$d\sigma = \mathbf{c} : \epsilon + d\sigma^*, \quad (8)$$

where

$$d\sigma^* = -\mathbf{c} : d\epsilon^P + (\nabla \mathbf{c} : \epsilon^E) : d\epsilon^E. \quad (9)$$

Since \mathbf{c} always satisfies the symmetry and the positive-definiteness, a solver based on the CG method is applicable.

3 NUMERICAL SIMULATION RESULTS

As an illustrative example of PDS-FEM implemented with Maekawa's CCR, we compute the seismic response of the C1-1 which is shown in the introduction; see Fig. 1. The material properties of concrete and steel are summarized in Table 1. Linear tetrahedron elements are used, and the element number, the node number and the degree-of-freedom are 29,740,000, 4,860,000 and 14,580,000, respectively. Concrete and rebars are separately discretized; see Fig. 2. The input strong ground motion is presented in Fig. 3.

A super-computer SGI Altix 4700 Intel Itanium 1.66 GHz, 1 node \times 256 core, is used for the computation. It takes 300 s for the computation of linear response at one increment of 0.01 s. The CPU time increases when plastic deformation becomes large as well as cracking takes place in the element. Cracking or the reduction of the element stiffness matrix is made according to the strength of material criterion; if the principal value of the element stress reaches the critical value of the strength, cracking takes place on a facet that is close to the principal value. It should be emphasized that the value of the reduced components of the element that suffers cracking is rigorously computed by using Eq. (4).

First, we examine the quality of the model. Eigen-values and eigen-vectors of the linear elastic deformation is computed, and the eigen-values are converted to the natural frequencies.

0.911914	20,273	20,181	72180	38100
total	62,509	63,621		

Figure 5: Schematic view of cracking at $t = 8.81$ s.

The first five natural frequencies are shown in Table 2. These values are slightly larger than the experimentally measured data of the natural frequencies of the C1-1. The mode that corresponds to the natural frequency is described in the table.

At this moment, the numerical computation is finished up to the input of first large shaking. The response of the top part of the pier is shown in Fig. 4. This response will be compared with the experimental data of E-Defense.

In PDS-FEM, cracking is made element-wise. The stiffness element and the nodal force increment are changed when one facet of an element is broken. Thus, it could take an unacceptable CPU time if non-linear computation is made every time one facet is broken, in order to carry out the most accurate computation. In this paper, we use the simultaneous cracking by specifying the maximum number of the facets of elements that are broken during one increment (0.01 s). The results of the number of broken element are summarized in Table 3, where the maximum number of the facets which are broken simultaneously is set as 30 or 60. As is seen, the number of the broken element does not differ significantly for the two cases. From now on, we set the maximum number as 60.

A schematic view of cracking is presented in Fig. 5; a) is the whole view of the pier and b) and c) are the closed-up view of the connecting part. The spatial distribution of the vertical normal

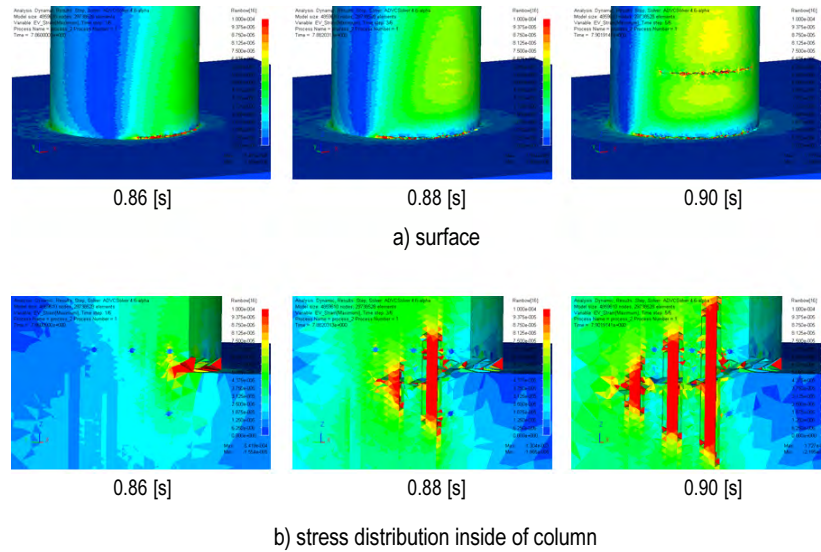

Figure 6: Distribution of broken elements.

stress component is shown. On the surface of the pier, cracking takes place at the connecting part (Fig. 5b)). The crack penetrates inside the pier (Fig. 5c)). The time series of cracking is presented in Fig. 6; a) is for the broken elements on the surface that have cracking and, and b) is for the broken elements inside the pier. The spatial distribution of the vertical normal stress component is plotted, to show that the stress is carried by steel rebars when cracking takes place in concrete.

We first have to admit that the results presented here are tentative and that a systematic evaluation will be made when the numerical computation is finished. At this moment, however, it is shown that PDS-FEM is capable to simulate *multiple* cracking. In concrete, the crack tip is not broken uniformly, and a few parts of the crack tip are broken. By choosing suitable facets, PDS-FEM computes this cracking. Branching of cracks frequently occurs in concrete, and this cracking is computed, as well. It is certainly true that a model with the same configuration but different meshing will produce different processes of cracking since PDS-FEM uses mesh boundary (or $\{\partial\Phi^\alpha\}$) as candidates of crack facets. A Monte-Carlo simulation of evaluating cracking processes or crack paths will be made by using a few models of the C1-1.

4 CONCLUDING REMARKS

This paper presents an application example of PDS-FEM to the seismic structure response analysis of the C1-1 that was shaken by E-Defense. A sophisticated CCR is implemented into ADVIC, and detailed model is constructed. While the numerical computation is not finished, multiple cracking that is often observed in concrete is reproduced.

A systematic comparison of the numerical results of PDS-FEM with the experimental data will be made, in order to clarify the limitations of PDS-FEM and to improve the treatment of cracking. A Monte-Carlo simulation of using different meshing will be made, as well, in order to evaluate the variability of failure processes.

Keywords: Fault-structure system, multiscale, nuclear power plant.

Abstract. *An approach to estimate the response of a model of nuclear power plant (NPP) that includes the rupture of a nearby fault using a multiscale approach is demonstrated. The conceptual model is the fault-structure system: a system that models the 3D fault rupture process, wave propagation through the irregular crust structure, effect of local geologic setting at the NPP location, and response of NPP structure. A multiscale method, called Macro-Micro Analysis is employed, which resulted to reduction in computation cost. A reproduction of a recent earthquake event in Kanto region is performed to check the earthquake wave propagation and compare the resulting synthetic seismogram to the recorded seismogram in an observation station. A scenario earthquake simulation is then conducted and the response of NPP under this scenario is obtained. Results have revealed irregular structure deformation caused by the varying phase and amplitude characteristics of the input wave caused by the scenario earthquake.*

1 INTRODUCTION

Estimating the seismic response of nuclear power plant (NPP) structures poses a big computational challenge because of the need to account for the geologic settings of the site. Past earthquakes generated from the nearby fault have shown that NPP is vulnerable to large deformations and large amplitude acceleration. To obtain a reliable structure response, the components of seismic analysis should be modeled with high resolution. It is known that the input ground motion is affected by the following factors: fault-rupture process, irregular crust structure, soft basin layer, and site-specific conditions such as topography and nature of soil at site vicinity. Thus, aiming to model all processes related to these factors is desirable, but as mentioned, to satisfy the high resolution modeling, a large computational environment is needed.

In computation, the above problem is called fault-structure system (FSS). FSS is a conceptual model that includes modeling all the significant processes in the problem of seismic wave propagation and seismic response of structure. The aim of this approach is to account for the three-dimensional (3D) variability of each process (as examples: radiation of seismic waves from the source, response of structure with geometrical irregularities). To reduce the heavy demand for computational resources, a multiscale-based method, called the Macro-Micro Analysis (MMA) has been proposed by Ichimura and Hori [1]. MMA decomposes the FSS problem into two scales and refines the solution as each scale is solved. It is noted that MMA's applicability has been earlier demonstrated on the analysis of large-scale underground structure [1]. This study extends the applicability of this multiscale approach to NPP seismic response estimation.

2 METHODOLOGY

2.1 Multiscale Approach and the Macro-Micro Analysis

It can be observed that two length scales are being considered when solving the FSS – the geologic-length scale (for seismic wave propagation) and engineering-length scale (for seismic structural response). In these two scales, the spatial dimensions would vary from about 10^5 meters for the domain size for seismic wave propagation to about 10^{-1} meters for the structure mesh to obtain high resolution output. Thus, if all components are simultaneously solved, the resulting computation cost can be very high which may not be practical to run in the present computational environment. MMA derives the mathematical basis for performing a multiscale approach applicable to these two scales that reduces the cost of solving the FSS.

The MMA applies the perturbation technique to the elastodynamic problem,

$$d_i(c_{ijkl}d_l(u_k)) - \rho \ddot{u}_j = 0 \quad (1)$$

where c_{ijkl}, ρ, u_k, d_i are the component of elasticity tensor, mass density, displacement component, partial differentiation, and temporal differentiation, respectively.

The singular perturbation expansion method [2] expands the solution u_k of the wave equation as,

$$u_k \approx u_k^{(0)} + \varepsilon u_k^{(1)} + \dots \quad (2)$$

where $u_k^{(0)}$ is solution at low resolution, $u_k^{(1)}$ is solution at high resolution, and $\varepsilon = X_i/x_i$ is a very small parameter ($\ll 1$) that relates the slow spatial variable, X to fast-changing variable, x .

Using Equation (2) on Equation (1) results to two equations that first, computes the solution in the domain of the slow spatial variable, and then refines this solution using the properties near the structure:

$$D_i(C_{ijkl}D_l u_k^{(0)}) - R \ddot{u}_j^{(0)} = 0 \quad (3)$$

$$d_i(c_{ijkl}(d_l u_k^{(1)} + d_l u_k^{(0)})) - \rho(\ddot{u}_j^{(1)} + \ddot{u}_j^{(0)}) = 0 \quad (4)$$

where D_i is differentiation with respect to X_i , R is the effective density, and C_{ijkl} is the equivalent elasticity tensor in the domain of the slow spatial variable. Equation (3) and Equation (4) are called the Macro and Micro analysis of the MMA, respectively. Figure 1 shows the sche-

matic of the MMA in relation to FSS. The details of derivation of these equations can be found in Ichimura and Hori [1, 3]

Figure 1: Decomposition of FSS (left) to Macro Analysis (bottom right) and Micro Analysis (top right).

2.2 Computing the Macro and Micro Analysis

In MMA, modeling the earthquake wave generation and propagation (Macro analysis) includes accounting for the fault-rupture settings and the properties of irregular crust structure and basin velocity structures. Given Equation (3), the spatial component is discretized using the Galerkin method, and the time integration method used is Newmark- β ($\beta=1/4$) method. A Rayleigh damping term is added to account for material (layer) damping:

$$\left(\mathbf{K} + \frac{2}{\Delta t} \mathbf{C} + \frac{4}{\Delta t^2} \mathbf{M} \right) \mathbf{u}^{n+1} = \left(\frac{2}{\Delta t} \mathbf{C} + \frac{4}{\Delta t^2} \mathbf{M} \right) \mathbf{u}^n + \left(\mathbf{C} + \frac{4}{\Delta t} \mathbf{M} \right) \mathbf{v}^n + \mathbf{M} \mathbf{a}^n + \mathbf{f}^n \quad (5)$$

where \mathbf{K} , \mathbf{C} , \mathbf{M} , \mathbf{u} , \mathbf{v} , \mathbf{a} , \mathbf{f} , n , Δt are stiffness matrix, Rayleigh damping matrix, mass matrix, displacement vector, velocity vector, acceleration vector, external force vector, temporal counter, and time step size, respectively.

In the Macro analysis simulation, the response at the nodes that are shared with the boundary of the Micro model is stored as input boundary condition for the Micro analysis. The Micro model includes the site-specific conditions such as soft soil layers that will add to the coarse solution of Macro analysis as refinement. The Micro analysis is carried out following Equation (4). Discretization in space using the Galerkin method and in time using Newmark- β ($\beta=1/4$) method, results to an equation similar to Equation (5) without the external force term.

In Macro and Micro modeling, hybrid-grid FEM (HyFEM) [3] is implemented to reduce memory usage and computation time. HyFEM uses the background cell, voxel [4], and octree technique [5] for finite element mesh arrangement and for the analysis, element-by-element method [6] and preconditioned conjugate gradient method (PCG) are implemented. For the details of the Macro and Micro analysis and implementation of the computation techniques, the reader is referred to the following related papers: [1, 3, 7, 8].

3 APPLICATION EXAMPLE

3.1 Reproduction of observed ground motion

The Macro analysis code is validated for application to earthquake simulation by conducting a reproduction of an observed earthquake event. An earthquake that occurred on May 9, 2010 in Tokyo is selected. For the simulation, a region that includes a small part of Kanto region is selected, as shown in Figure 2. The crust layer information derived by Tanaka et al. [9] for this selected region is given on Table 1. The earthquake information (fault parameter) were taken from F-NET [10], and the recorded seismograms on seismic station TKY 021 (about 14.4 km from the epicenter) were taken from K-NET [11]. This earthquake is modeled as a

double-couple point source with settings as given in Table 2. In this simulation, the target accuracy is 0.5 Hz. Time step size is 0.01 seconds and total time duration is 40.96 seconds. The criterion for spatial discretization is 10 elements for one wavelength (minimum element size is 100 m). The iterative solver is PCG method with convergence criteria of 1×10^{-6} .

Layer	P-wave velocity (m/s)	S-wave velocity (m/s)	Density (kg/m ³)	Quality factor
1	1850	500	1950	60
2	2560	1000	2150	150
3	3200	1700	2300	200
4	5800	3360	2700	500
5	6600	3700	2800	600
6	8040	4480	4400	800

Table 1. Layer material properties used in reproduction of observed earthquake [9].

Date	2010/05/09
Latitude	35.6757 N
Longitude	139.6613 E

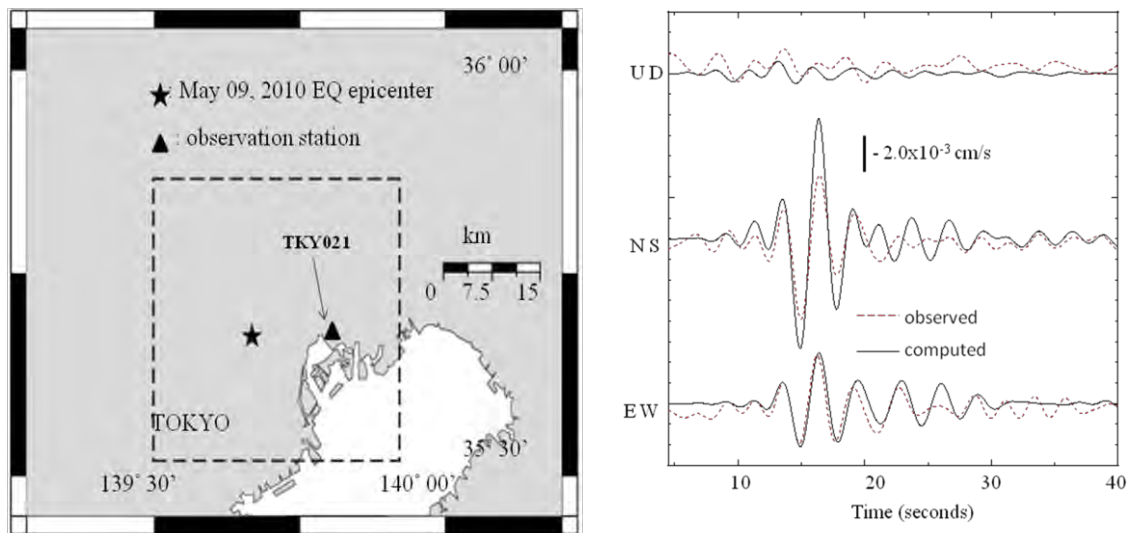

Figure 2: Reproduction of observed earthquake: Left: simulation region and location of epicenter and observation point; Right: comparison of observed and synthetic seismograms at observation station TKY021 (bandpass-filtered [0.0Hz-1.0Hz]).

Figure 2 (right) shows the comparison between the observed and computed (synthetic) seismograms. The comparison shows both agreements and disagreement in amplitude and

wave phases at different points, wherein the disagreements can be attributed to the uncertainty in the crust structure data (verified at less than 0.5Hz) and earthquake parameters (moment tensors were derived from inversion analyses using horizontal layered velocity structure [10]). Nevertheless, the results validate the application of Macro analysis code for earthquake wave propagation simulation and for estimating the input boundary condition to the Micro analysis.

3.2 Scenario earthquake and response estimation of NPP

In this section, a scenario earthquake simulation is conducted to perform the complete Macro-Micro Analysis for NPP. For this scenario earthquake, several of the fault parameters are based from the CDPC report for East-Central Tokyo Earthquake Scenario [12] (fault dip and rake, fault rupture speed and fault depth). The fictitious problem setting (as shown in Figure 3) is that the position of the NPP is 13.0 km from the epicenter of a reverse fault close to the surface. The scenario is generated from rupture of a fault plane (modeled as a sequential rupture of points in the fault plane) of about 1.8 km x 1.8 km in dimensions that dips at 45° from the horizontal plane (see Figure 3). The depth of the top portion of the fault is about 6 km and rupture propagation speed from the hypocenter (at the depth of 7.2 km) is 2.5 km/s. The details of the point source settings are shown on Table 3.

Hypocenter depth	7.20 km
Rupture speed	2.5 km/s
Source time function	$M_0(2t^2/T_0^2) \quad 0 \leq t \leq T_0/2$
	$M_0(1-2(t-T_0)^2/T_0^2) \quad T_0/2 \leq t \leq T_0$
	$M_0 \quad t \geq T_0$
Magnitude	$M_w = 5.3$
Strike, Dip, Rake	$30^\circ, 45^\circ, 90^\circ$
Rise time, T_0	0.216 sec

Table 3. Scenario earthquake point source setting

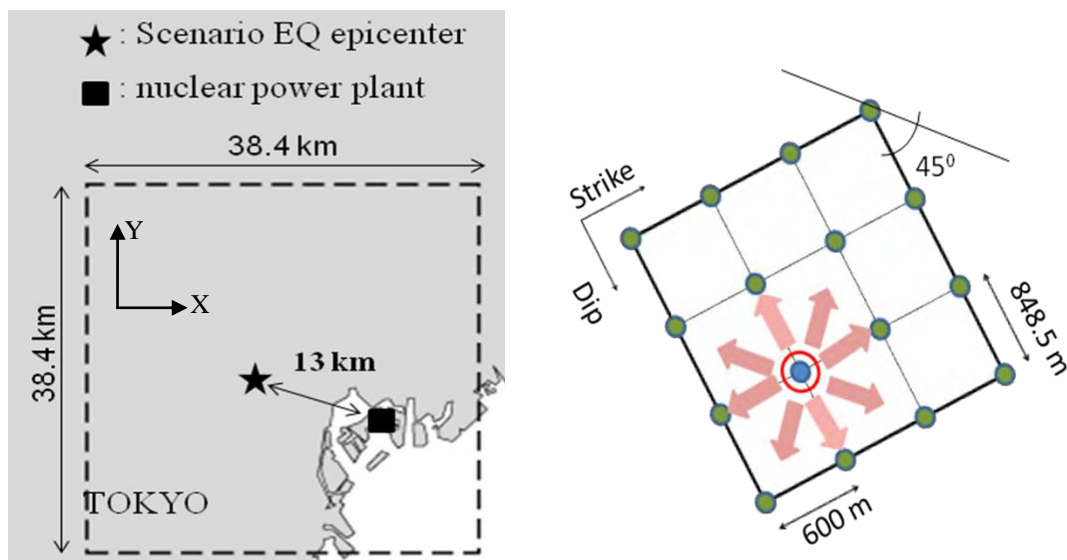

Figure 3: Fictitious problem settings for the scenario earthquake simulation. Left: The relative location of the fault-plane epicenter and the NPP; Right: The fault-plane showing the point sources (in green) that have varied rupture starting time. Hypocenter is encircled in red. Settings of each point source are given on Table 3.

The same model domain and crust layer properties as 3.1 are used. The target accuracy is set at 0.5 Hz. The time increment is 0.01 seconds and total time step is 2048. Criterion for spatial discretization is ten (10) elements for one wavelength (minimum element size is 100 m). The iterative solver is PCG method with convergence criteria of 1×10^{-6} . Figure 4 shows

the Micro model derived from the Macro model (with location of NPP embedded on engineered fill) and the configuration of the NPP meshed model. The material properties of the NPP and engineered-fill are given on Table 4.

Material	P-wave velocity (m/s)	S-wave velocity (m/s)	Density (kg/m ³)	Quality factor
Engineered fill	1500	400	1600	50
NPP	3373	2127	2500	200

Table 4. Material properties

The location of NPP partially-embedded in an engineered-fill is located at the center of the Micro model; Right: The meshed NPP model and dimensions. The embedded portion is 36.0m from the bottom.

Figure 5: Snapshots of simulation result at surface: displacement norm. The wavefield is made complicated by the effect of the earthquake source, irregular crust structure, and surface topography.

Figure 6: NPP structure deformation (x1500) at time, $T = 8.47$ seconds. Shown are deformations viewed at three orthogonal directions. Both lateral and vertical deformations are significant because of the effect of configuration of fault plane and direction of rupture.

Figure 5 shows snapshots of the waves at different time intervals as outputted by the Macro Analysis. The corresponding structure response at a given time, as outputted by the Micro Analysis is shown on Figure 6.

Implementing the FSS for estimating the seismic response of NPP from a rupture of a nearby fault is an advantage because the three-dimensional variation of the input wave can be modeled. As shown in Figure 6, the deformation of the NPP varies on all three orthogonal views, evident that the input wave varies in amplitude and phase characteristics in all its spatial components. For an actual NPP, which is geometrically-irregular, the response can be more complicated, and modeling by FSS can aid in identifying the critical locations of the NPP based on the scenario earthquake.

In solving the FSS in a multiscale manner, analysis in geologic- and engineering-length scales are solved efficiently, leading to reduction in computation cost. Thus this methodology would allow for simulations aiming for higher target frequency, which will improve the seismic response estimation of NPP. Given the results presented here, FSS analysis is now being studied for extension to fracture analysis of NPP structures. Moreover, to further reduce the computation time in modeling and analysis, shared and distributed memory parallelization is presently being implemented to the MMA codes.

4 CONCLUSION

An approach to estimate the response of NPP that includes the rupture of a nearby fault using a multiscale approach is presented. This approach, called the FSS, models the important processes related to earthquake wave propagation and seismic response of NPP structure. A multiscale method, called Macro-Micro Analysis is used which resulted to reduction in computation cost. A reproduction of a recent earthquake event in Kanto region is performed to check the earthquake wave propagation and compare the resulting synthetic seismogram to the recorded seismogram in an observation station. A scenario earthquake is then conducted and the response of NPP under this scenario is obtained. Results have shown irregular struc-

ture deformation caused by the varying input wave characteristics of the scenario earthquake. These results emphasize the importance of three-dimensional modeling of different components of earthquake wave propagation and structure response for reliable estimation of future strong ground motions.

Abstract. *There is increasing concern about the three-dimensional finite element analysis of large underground tunnels due to the threat of a nearby earthquake generating large strong motion on the tunnel with spatial variation. Using a new numerical analysis method based on massive numerical computation, we carried out a 3-D seismic response analysis of an underground ramp tunnel structure. Based on the finite element method, this method can analyze a large-scale computer model consisting of a nearby ground structure as well as the entire tunnel structure to be studied. As expected, the 3-D seismic response of the tunnel is complicated due to the complex configuration of the tunnel structure. While the intensity of response is smaller than the design criterion, the calculations show large deformation and stress for the part where the ramp tunnel passes through the interface between soft and hard ground layers, with stress and section force varied on the connection with the ramp tunnel. These results suggest that 3-D seismic response analyses should be performed for underground tunnels with complicated configuration which could be subjected to a nearby earthquake.*

1 INTRODUCTION

The working report of the International Tunneling Association (ITA) in 2001 [1] was a state-of-the-art review of earthquake-induced damages and researches on earthquake-resistant designs of tunnels, focusing on practice in the US. In order to perform rational earthquake-resistant design of large tunnels, the report suggested that appropriate aseismic investigations are needed which correctly evaluate the 3-D earthquake motions, response characteristics of the tunnel and dynamic interaction between the tunnel and ground. Since several subway stations were damaged during the Hyogoken-Nanbu Earthquake in 1995 [2], more attention has been paid to the aseismic capability of underground structures. Large-scale underground infrastructures are now being planned and constructed in many countries, and aseismic measures have been employed in many large-scale tunnels such as the Trans-Tokyo Bay Highway tunnel [3] and the Marmaray tunnel crossing the Bosphorus strait [4]. In order to perform rational earthquake-resistant design of large tunnels, we propose a 3-D numerical analysis.

We have developed a large-scale 3-D numerical analysis technique for practical design, and are researching application of the technique to the earthquake-resistant design of actual large tunnels having complicated structures [5, 6]. To make effective use of the expressway networks in metropolitan Tokyo efficiently, a circular route of highway network is being constructed to carry traffic away from the city center. The construction uses tunnels to help preserve the environment. In the case of a highway tunnel, a number of ramp tunnels are necessary for the main tunnel to access the ground surface. These ramp tunnels diverge from and merge into the main tunnel, and pass through several ground layers between the main tunnel and the ground surface. In addition, sections of the ramp tunnels vary in a complex manner and so their seismic response is very complicated. We have been investigating the seismic response of ramp tunnels and the dividing and merging parts between the ramp tunnels and main tunnel.

This paper outlines our large-scale 3-D dynamic FEM analysis technique, and the results of a full-scale 3-D seismic response analysis of a center-ramp-type road tunnel and the surrounding ground. The tunnel is being constructed as part of the Yamate tunnel of the Tokyo Metropolitan Expressway. In past studies [5, 6] the tunnel structure was simplified, but in the present study a very detailed model of the tunnel structure was used to quantitatively evaluate the seismic behavior for practical design. Based on the results, the deformation, displacement, stress and section force of the tunnel structure are evaluated, and the applicability of 3-D numerical analysis for the aseismic design of large tunnels is investigated.

2 3-D DYNAMIC FINITE ELEMENT ANALYSIS METHOD

The material is assumed to be linearly elastic. By reducing the continuous system to a discrete idealization and employing Newmark's β method in the time domain ($\delta=1/2$, $\beta=1/4$), the governing equation can be expressed as:

$$\left(K + \frac{2}{\Delta t} C + \frac{4}{\Delta t^2} M \right) u^{n+1} = \left(\frac{2}{\Delta t} C + \frac{4}{\Delta t^2} M \right) u^n + \left(C + \frac{4}{\Delta t} M \right) v^n + M a^n, \quad (1)$$

where K , M , C and Δt are global stiffness matrix, lumped mass matrix, Rayleigh damping matrix and time increment. u , v , and a are displacement vector, velocity vector, and

acceleration vector, respectively. Rayleigh damping is defined as $C = aK + bM$ using K and M , and parameters a and b are determined such that the damping can be appropriately set.

To solve the problem of many degrees of freedom, K_u is built by the element-by-element method [7], and the preconditioned conjugate gradient method [8], which is an iterative analysis method, is adopted. As stiffness matrix of element is evaluated step-by-step, K need not be kept in memory and therefore the problem of significantly many degrees of freedom is overcome. In addition, a combination of non-structure elements and structure elements is used to reduce the computation cost in evaluating stiffness matrix of element in the element-by-element method. Structure elements are used in the large region without approximation of geometrical shape, and non-structure elements are used in the narrow region with complicated shape close around the structure. As there is a single shape of structure element, the number of element stiffness matrixes needed to be kept in memory is the same as the number of materials, and thus the computational cost for the element stiffness matrix is significantly reduced. In this study, second-order tetrahedron elements are used for the non-structure elements, and hexahedron isoparametric elements (voxel elements) for the structure elements. As second-order tetrahedron elements are used for non-structure elements, the response variation in the complicated region close to the structure can be simulated with relatively few elements.

3 ANALYSIS METHOD

The numerical analysis was applied to the center-ramp type road tunnel of the Yamate Tunnel of the Tokyo Metropolitan Expressway, as shown in Fig. 1. The geological section of the ground around the tunnel is shown in Fig. 2. The two main tunnels (outside diameter 12.83 m), 7.25 m apart, employ steel segments. The RC divergence/confluence part and exit/entrance tunnel (called “ramp tunnel” hereafter) are constructed between the two main tunnels. As shown in the figure, the ramp tunnel extends to the surface with a complicated,

and varied cross-section of structure. The ground between the main tunnel and ramp tunnel varies from a hard layer with V_s of 400 m/s or more to a soft sedimentary layer with V_s of around 150 m/s. Past studies [5, 6] have clarified that the local structure such as the transverse section depends on the response of the tunnel as a whole. Therefore, the external appearance of the tunnel and main internal structure are very finely modeled, except for some detailed structures that would not affect the main response characteristics.

Figure 1: Overview of target ramp tunnel structure in the Tokyo Metropolitan Expressway Central Circular Route: the Yamate Tunnel.

Figure 2: Vertical section of geological profile.

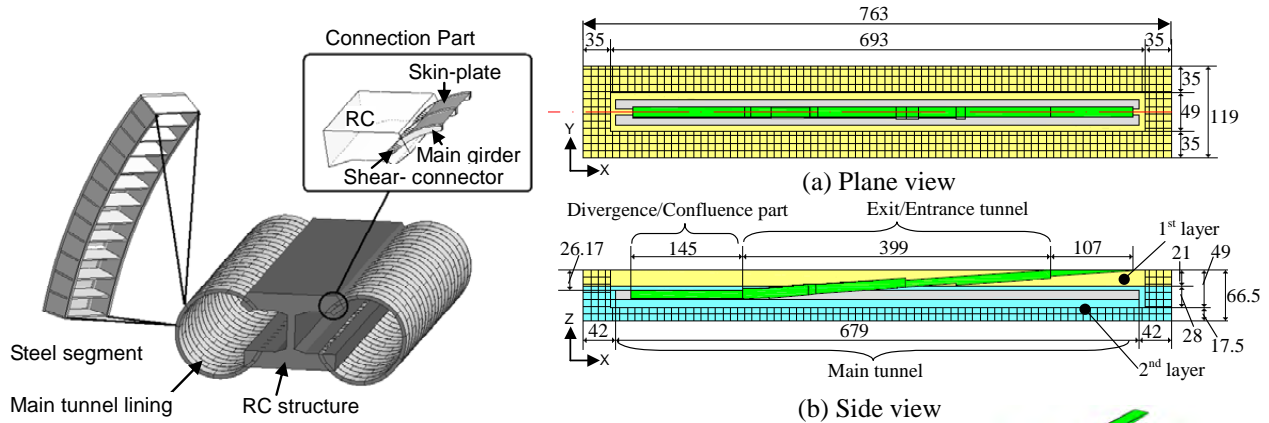

Figure 3: Connection part between main tunnel and RC structure.

The connection part between the ramp tunnel and main tunnels is important in terms of transferring seismic loading, and therefore the new type of connection structure where a part of the steel shell is embedded in the RC structure is also modeled in detail as shown in Fig. 3. The numerical analysis model is generated as shown in Fig. 4, based

(c) Bird's-eye view for the tunnel structure
Figure 4: Overview of numerical model.

on the results of studying the appropriate range for the numerical model used for dynamic analysis [5]. The design strength of concrete in the RC structure is 40 N/mm^2 (40 MN/m^2). As parameters used in the analysis, the elastic constants and Poisson's ratio corresponding to the design strength are employed. As shown in Fig. 3, the steel segment of the main tunnel consists of main girders and skin plates. For simplicity, the steel segment section is modeled as a solid with the lining being the same thickness as the height of the girders. The elastic constant is determined such that the in-plane bending stiffness of the solid section model is the same as that of the original steel segment. The mass of the solid section model is set such that the unit weight in the longitudinal direction of the tunnel remains the same as the original steel segment (see Table 1). As for Poisson's ratio, the value for steel (of which the segment is made) is used. As the shear-wave velocity impedance ratio is significantly different, the ground is set as a two-layer model with the upper boundary of the Tog layer as the geological interface between the two layers. A level 2 acceleration wave is used as input motion, as described later. An earthquake response analysis of the free field is performed first using SHAKE, and the converged stiffness and damping ratio are obtained. The parameters for 3-D analysis are determined based on the converged stiffness and damping ratio of the free field, so that the maximum response of the linear analysis matches that obtained through analysis by SHAKE. Therefore, the nonlinear behavior of the ground could be approximately simulated through linear analysis. The parameters for 3-D analysis are listed in Table 2.

Based on the fundamental frequency of ground (0.7 Hz) obtained by analysis using SHAKE, and the predominant frequency range of earthquake waves, the upper limit of the frequency range within which an accurate analysis is assured, is set as 2 Hz. Assuming that the analysis is accurate if the wavelength can cover 10 elements, the element size is set at

	Real structure	Model

3.5 m for second-order elements, and 1.75 m for first-order elements. In the meshing of the structure part, at least one element is placed in the cross-section direction to appropriately simulate the distribution of the stress and section force of the structure, and the mesh size is 1 m. It was confirmed that the accuracy of displacement is appropriate and the distributions of stress and section force are tolerable. Figure 5 shows the 3-D finite element model of the structure and ground. The total number of nodes and the total number of elements are 2,638,078 and 2,268,533, respectively. As for the input wave, the maximum design earthquake (T2E-B-3) with maximum acceleration of 702.7 Gal is employed, which is one of the largest earthquake ground motions assumed in current earthquake-resistant design in Japan (Fig. 6). The input wave is epicentral earthquake ground motion (directly underneath type), and the duration of main shaking is 10.23 seconds with a time interval of 0.01 second. The seismic response of free-field ground is performed first, and the input wave is applied at the depth of the bedrock in the actual earthquake-resistant design, which is 5 m below the bottom of the main tunnel. The seismic response at the depth corresponding to the bottom of the 3-D numerical model is computed, which is used as the input wave for the 3-D analysis. Two cases are analyzed: one with the input direction perpendicular to the tunnel longitudinal axis, and the other parallel with the tunnel longitudinal axis.

4 ANALYSIS RESULTS

Figure 7 shows the deformation and displacement of the tunnel when the response of the ground is large. The response of the entrance/exit part of the tunnel in the upper ground layer, where the response is remarkable, is large in the direction of the input wave. When the direction of the input wave is along the tunnel longitudinal axis, compressive stress and

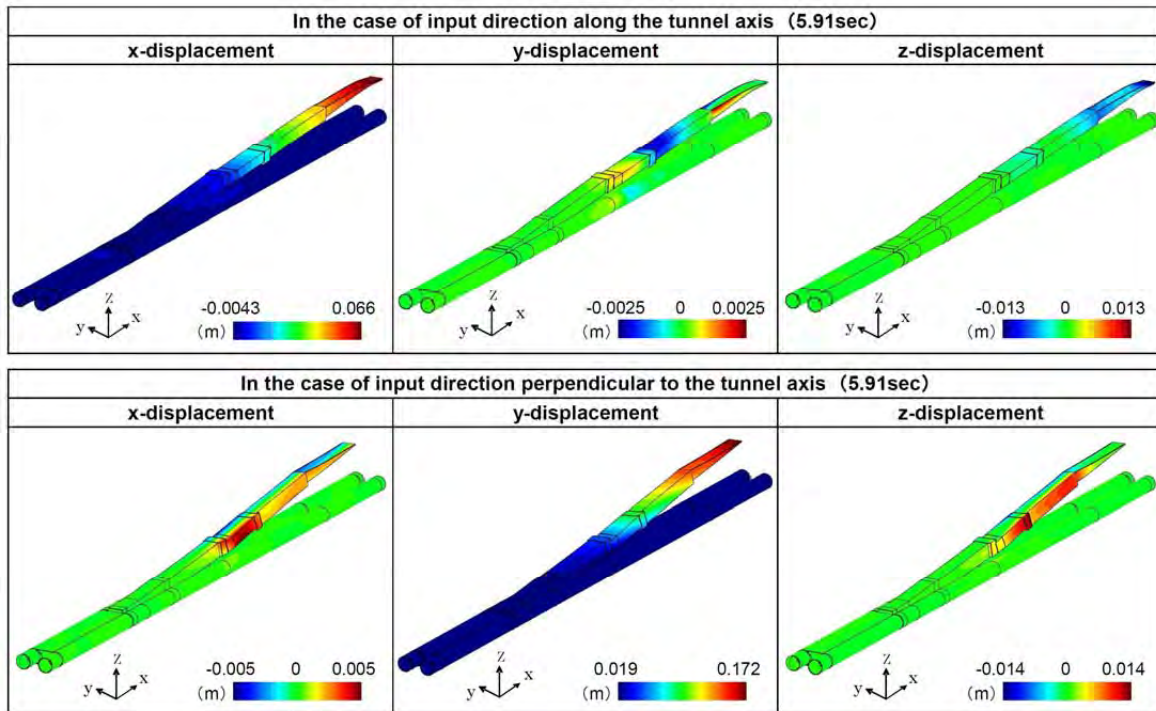

Figure 7: Deformation and displacement of the tunnel.

tensile stress are observed in the tunnel. When the input direction is perpendicular to the tunnel longitudinal axis, the tunnel deforms in the direction perpendicular to the tunnel longitudinal axis, and sectional shear deformation of the tunnel can be observed together with bending and rotating deformation. When the input direction coincides with the tunnel longitudinal axis, the displacement in the x-direction significantly varies at the location where the tunnel structure changes, and also in the area from the ground layer boundary to the middle depth of the upper layer. Due to the large stiffness of the tunnel in the longitudinal direction, the displacement of the tunnel is 0.09 m at the ground surface level, contradicting the larger displacement of the free field ground, which is 0.21m. On the other hand, when the input direction is perpendicular to the tunnel longitudinal axis, the displacement in the y-direction of the tunnel at the ground surface level is 0.17 m, indicating that the tunnel closely follows the ground deformation in the direction of the input wave. In comparison to 0.17 m which is the displacement of the tunnel in the y-direction, the perpendicular displacements in the x-direction and z-direction are 0.005 m and 0.014 m, respectively, and are symmetrically distributed about the central axis of the tunnel. When the input direction is perpendicular to the tunnel axis, a larger response concentrates in the part of the tunnel where the structure is varying, and in the part of the ground where the ground condition is changing.

Figure 8 shows the distribution of stress. The area subject to large stress is shown enlarged in Fig. 9. The main component of stress (with the maximum value shown in parentheses) is σ_{xx} (27 MN/m²) when the input direction is along the tunnel axis, and the normal stresses are σ_{xx} (25 MN/m²), σ_{yy} (34 MN/m²), σ_{zz} (41 MN/m²) and shear stress is σ_{yz} (29 MN/m²) when the input direction is perpendicular to the tunnel axis. In each case, the stress in the RC structure is large, and the maximum value is 63–102% of the design strength of concrete. Though the response tends to be large on assumption of the conventional design earthquake assuming plane wave, the increase in stress due to earthquake should be taken into account in the design.

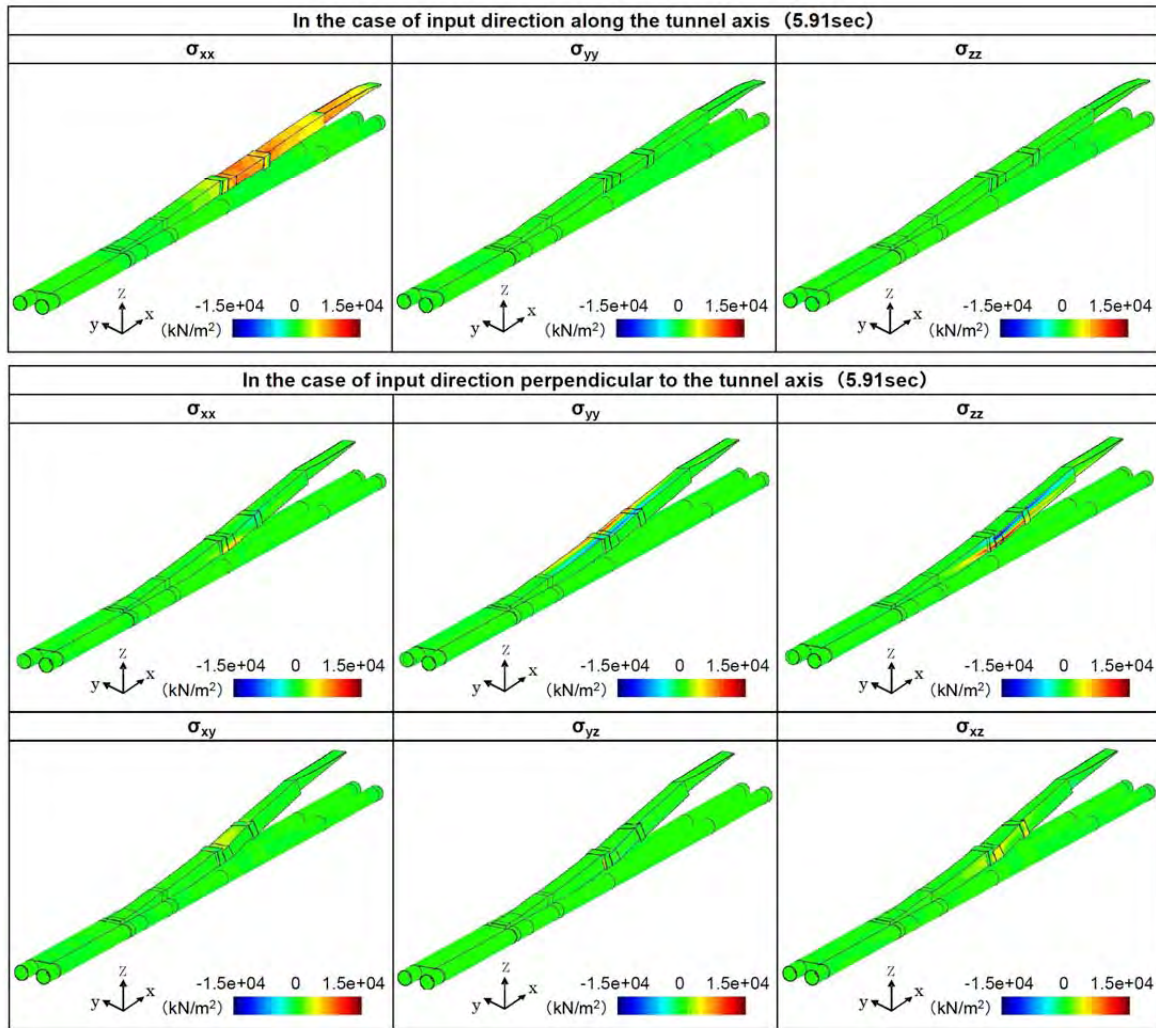

Figure 8: Stress of the tunnel.

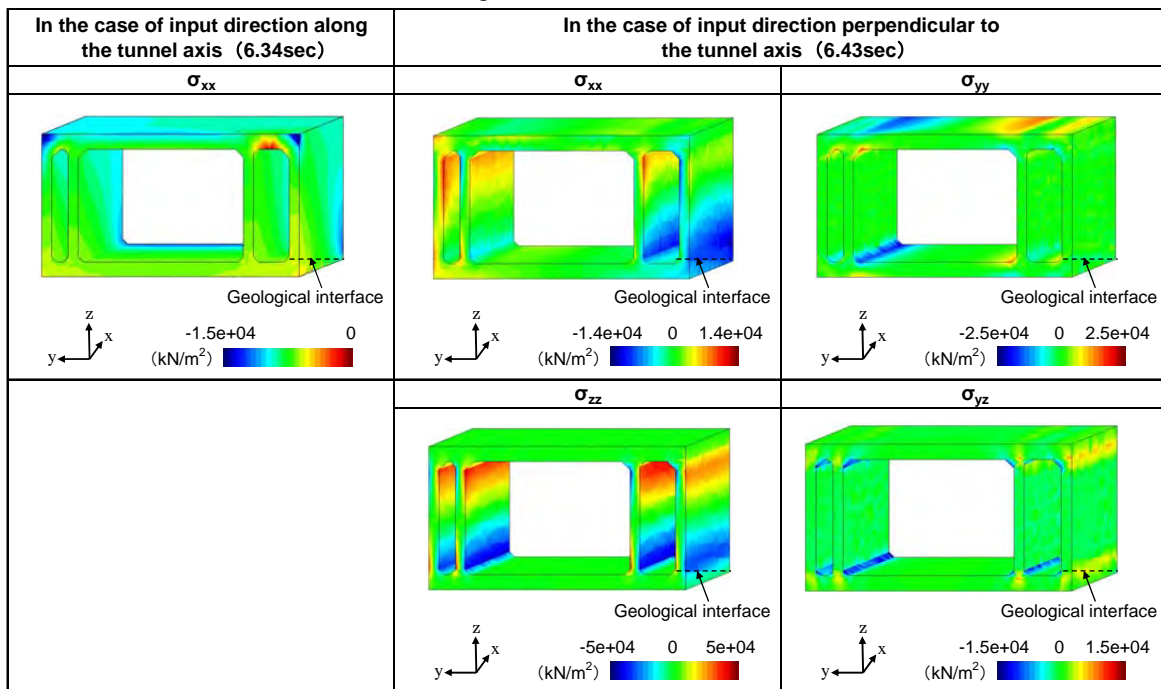

Figure 9: Stress of the tunnel around geological interface at the time when the maximum stress occurs

When the input direction is along the tunnel axis, as shown in Fig. 9, σ_{xx} is not evenly distributed in the transverse section, and becomes large at the corners in some sections. On the other hand, when the input direction is perpendicular to the tunnel axis, the sign of the stress on the left part of the tunnel section differs from that on the right part due to bending in the longitudinal direction of the tunnel, and large stress occurs in the lower part of the side wall of the tunnel above the ground layer boundary. In addition, bending moment is large at the end of the structure member due to the shear deformation of the transverse section of the tunnel, resulting in large fringe stress σ_{yy} , σ_{zz} in the slab and side wall. σ_{yz} is shear stress in the transverse section of the tunnel. In this analysis, although the distribution of stress is reasonably smooth, slight dispersion can be observed in the area with stress concentration due to the use of single elements in the direction of thickness of the tunnel. Therefore, the maximum value of stress may depend on the way of meshing; finer meshing could improve the accuracy of analyzing stress in the stress concentration area.

In the case of input direction perpendicular to the tunnel axis (5.91sec)

Figure 10: Mises stress around nose point

Figure 10 shows the distribution of Mises stress at the nose part which connects the divergence/confluence part and the exit/entrance tunnel. The distribution of section force in the connection part along the tunnel axis is shown in Fig. 11. It can be seen that the stress locally varies at the nose part where the tunnel section changes (Fig. 10). As for the distribution of section force in the connection part, the section force varies around the nose part and over the middle wall although the transverse section is constant (Fig. 11). By carrying out a 3-D analysis using a more detailed model for the local structure in the connection part, a structure with rational cross-section for the connection part to assure the capacity of the connection structure can be determined.

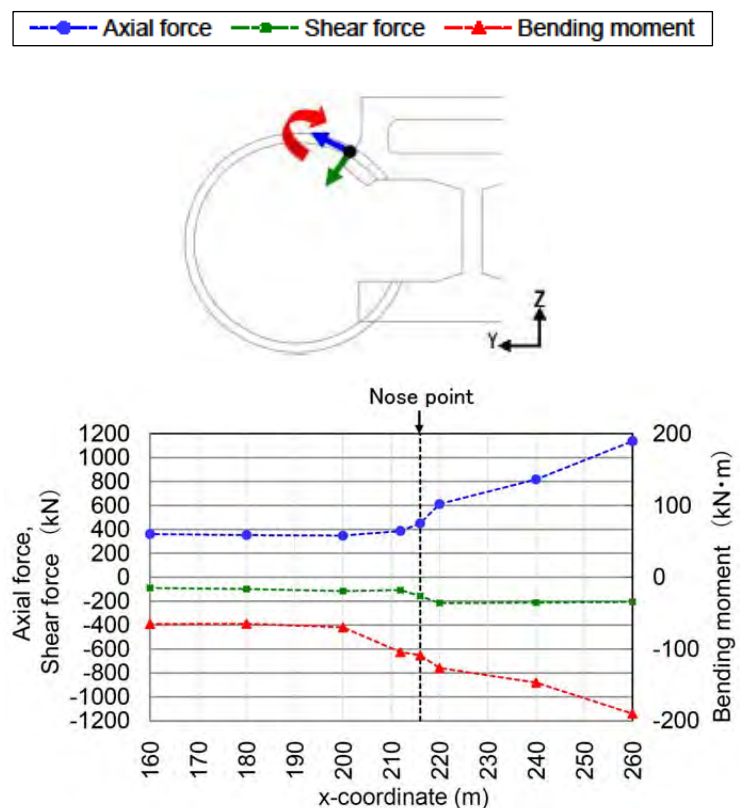

Figure 11: Section force at connection part around nose point

The above stress and section forces are induced due to 3-D interaction. Especially, the shear deformation of ground concentrates in the tunnel within the upper ground layer, and stress in the tunnel significantly increases in the part where the structure varies. It is difficult to rationally evaluate these kinds of behavior by the 2-D response-seismic-coefficient method, which is currently used in practical design, or by the response displacement method for investigating the behavior in the longitudinal direction, where the tunnel and ground are modeled using beam and spring elements. 3-D analysis could identify the location where the aseismic capacity needs to be clarified, and thus it is possible to evaluate their aseismic capability. In addition, the conventional aseismic design method using simplified models tends to overestimate the seismic response [1], and it is possible to perform a more rational design of tunnel structure and to reduce the construction cost by using 3-D analysis. In the actual design of the tunnel in this study, the structure joint is placed in the transverse section of the tunnel at the location of the ramp tunnel above the ground layer boundary to enhance the aseismic capacity of the ramp tunnel around the ground boundary, based on the results of 3-D analysis of the response.

5 CONCLUSIONS

We have developed a large-scale 3-D dynamic FEM analysis technique, and used it to analyze the earthquake response of a center-ramp type road tunnel (ramp tunnel of the Yamate Tunnel of the Tokyo Metropolitan Expressway) with a complicated structure. We clarified that the ramp tunnel with complicated structure displays complex 3-D behavior, and the 3-D analysis could quantitatively evaluate the seismic behavior. In addition, by carrying out seismic response analysis using a full-scale model of the tunnel and ground, it is possible to evaluate the displacement, stress, and section force of the tunnel more precisely, and to determine the location where displacement and stress significantly increase. In order to increase the evaluation accuracy, the forces in the tunnel computed by 3-D analysis could be used as external loading forces for a separately generated detailed model of the local part of the tunnel structure taking nonlinearity into consideration, and thus it is possible to optimally design the tunnel. Through 3-D numerical analysis, a more suitable aseismic design of large tunnel with complicated structure could be realized, and 3-D numerical analysis is an effective approach to rationalize the tunnel structure in the practical design.

Keywords: NISRAF, Earthquake Impact Assessment, Hybrid Simulation, Hazard Characterization, Model Calibration, Hybrid Fragility Analysis, Uncertainty Quantification.

Abstract. *NEES Integrated Seismic Risk Assessment Framework (NISRAF) integrates several components in order to obtain the most reliable earthquake impact assessment results: hybrid simulation with free-field and structural sensor measurements, hazard characterization, system identification-based model updating technology, hybrid fragility analysis, and impact assessment tool. Software has been built and verified, concurrently, via applications to an actual test bed in California. Regional impact assessment results of the Los Angeles area under the 1994 Northridge earthquake, using the generated hazard map and fragility curves, showed reasonable accurate, although conservative. Also, the implemented uncertainty quantification analysis aids decision-makers to judge the estimated losses easily and quickly, which will contribute to the development of more suitable and more confident recovery plans and emergency responses.*

The novelty of the proposed system derives primarily from the integration of components of earthquake impact assessment—most of which have not been deployed in such an application before. To achieve seamless integration and to arrive at an operational system, several components were used innovatively, tailored to perform the role required by NISRAF. The integrated system brings the advanced tools of earthquake hazard and structural reliability analyses into the context of societal requirement for accurate evaluation of the impact of earthquakes on the built environment.

1 INTRODUCTION

The 2008 Sichuan, China, earthquake caused thousands of deaths and over \$150 billion economic losses [1]. In 2010 an earthquake in Port-au-Prince, Haiti, killed more than a quarter of million people, and resulted in losses over \$14 billion [2]. These catastrophes show the severe damage earthquakes can inflict. Since 1960s, practitioners and researchers—through field investigations after devastating earthquakes, along with theoretical and experimental studies—have significantly improved our understanding of earthquakes and strategies to mitigate the impact. Examples of disciplinary developments are strong-motion measurements, system identification, model updating, structural performance evaluation through experimental and analytical simulations, fragility derivation, and the development of consequence estimation software.

The above component-specific studies allow researchers to focus on a particular problem at a fundamental level. Even though these specific studies have progressed considerably and produced mature research results, uncertainties remain in their outcomes not only because of their inherent characteristics, but also because of the interactions between them. For example, the derivation of fragility curves requires that a large amount of simulations be performed. It is essential to have an accurate structural model which closely represents the response of the real structure. In most fragility simulations, however, either a very simplified structural model is used or a complicated numerical model is used without being calibrated to measured response. Such methods, therefore, introduce significant and by-and-large unquantifiable uncertainties in the derived fragility curves. Moreover, the fragility curves heavily depend on input ground motions, particularly when the fragility curves are defined in terms of peak ground acceleration (PGA) [3]. The ground motion is in turn influenced by source, path, and site characterization, each of which is a formidable challenge in its own right. The realism of both model and input is therefore essential to the accuracy and applicability of the ensuing fragility relationships.

Earthquake impact assessment is the basis for emergency planning, mitigation, response, and recovery. The realism of the outcome, such as the effect on civil infrastructure systems, economy, and societal activities, is the essential ingredients to developing plans that adequately protect vulnerable communities. As mentioned above, significant progress has been made in earthquake impact assessment, including consequence estimation methodology as well as developing software that provides decision-makers with a tool to assess the impact [4]. Generally, the impact assessment software is composed of three main components: namely, (i) Hazard, (ii) Fragility, and (iii) Inventory. Among these, the inventory can be improved through the development and application of survey methods and technologies. This renders the accuracy of the assessment dependent on the reliability of the fragility curves and hazard characterization. Unquantifiable uncertainty and inaccuracies in the latter two components of hazard and fragility lead to earthquake impact assessments—that are unreliable and that do not form a viable basis for societal readiness.

2 METHODOLOGY

To reduce the above-mentioned uncertainties and unreliability in impact assessment, an integrated framework is proposed, developed, and demonstrated via application to an actual test bed. Figure 1 illustrates the proposed framework and how its components are combined to achieve the main goal of this research. As can be seen, the proposed framework, referred to as NEES Integrated Seismic Risk Assessment Framework (NISRAF), integrates hybrid simulation with free-field and structure sensor measurements, hazard characterization analysis, system identification-based model updating technology, hybrid fragility analysis, and earthquake

impact assessment tools. The procedure is specifically proposed and programmed for ease of use.

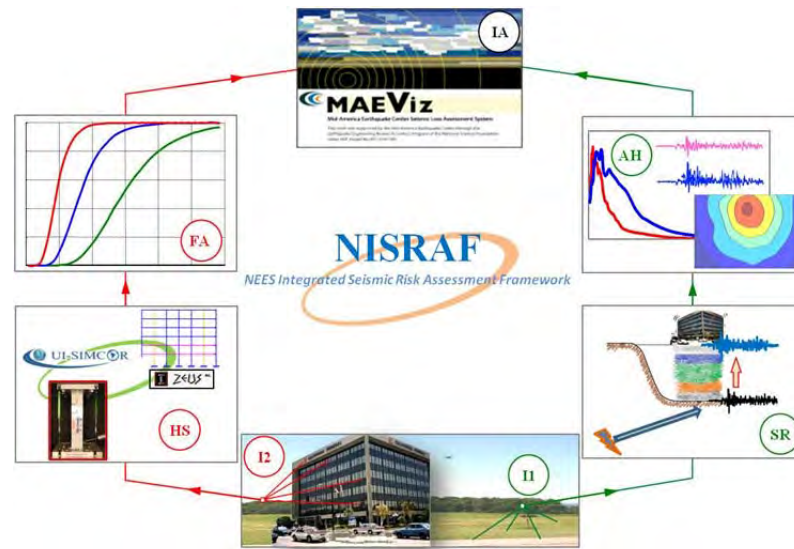

Figure 1: Schematic of the proposed integrated framework

In the schematic representation of the integrated framework given in Figure 1, free-field measurements (**I1**) along with nonlinear site response analysis (**SR**) are used to generate the advanced hazard map and ground motion records (**AH**). The measured and synthetic records are then used as seismic inputs in hybrid simulation and fragility analysis. Meanwhile, the structural model is calibrated with the measured structural response (**I2**). Next, hybrid simulations (**HS**) are performed with the most critical component of the structural system tested in the laboratory and the remainder of the structure simulated analytically. These simulations are conducted to derive the mean seismic intensity value (PGA, for example) of the corresponding performance limit state. The fragility curves (**FA**) of the structure are then generated using the hybrid simulation data and the dispersions from the literature. Finally, the derived fragility curves and the calibrated hazard map are fed into the impact assessment tools, such as MAE-viz [5] (**IA**) to evaluate the seismic losses.

The integrated system provides an opportunity to bring together all the sub-disciplines, capitalizing on the respective advances of each sub-discipline. This method of integration is not only intended to provide a tool, but it is also intended to stimulate the sub-communities of researchers to investigate the problems at the interfaces between them. Through this systematic and transparent framework, uncertainties from each sub-discipline can be managed more effectively and the use of the instrumentation will increase. For example, the reliability of probabilistic seismic hazard can be significantly improved through the use of free-field strong-motion measurements. Analytical and hybrid (analytical-experimental) simulations can be more realistic due to calibration with system identification results from sensor measurements. The uncertainties resulting from deriving fragility relationships can be greatly reduced through the use of more reliable representation of hazard and more accurate structural models. Confidently, with seismic hazard from field measurements and fragility curves from more accurate models, NISRAF can significantly improve upon earthquake impact assessment results with higher reliability. In the subsequent sections, the methodologies and techniques utilized in each component will be discussed and then followed by the development and implementation of this integrated framework.

3 ADVANCED COMPONENTS UTILIZED IN NISRAF

To achieve a seamless integration and to arrive at an operational and verified system, several components were used innovatively, tailored to perform the role required by NISRAF. The integrated system brings the advanced tools of earthquake hazard and structural reliability analyses into the context of societal requirement for accurate evaluation of the impact of earthquakes on the built environment.

3.1 Advanced hazard analysis

Owing to uncertainties from seismo-tectonic, earthquake energy attenuation and site conditions, it is difficult to estimate accurately the ground motion parameters. Many methods for seismic hazard analysis have been developed over the past decades, such as the Deterministic Seismic Hazard Analysis (DSHA) and Probabilistic Seismic Hazard Analysis (PSHA). Due to the probabilistic nature and the simple assumption for the local site effect, i.e. site coefficients F_a , F_v [6], uncertainties remain in the procedure and outcome. To reduce these uncertainties, an hazard characterization analysis component, including site response analysis is proposed.

As shown in Figure 3, this approach is composed of (i) seismic hazard analysis, (ii) synthetic ground motion generation, (iii) site response analysis, and (iv) hazard map generation. First of all, the natural records are directly investigated to evaluate the hazard characterization. Synthetic records of different hazard levels are then generated to evaluate the hazard as well as to provide various ground motions for further use in hybrid simulation and fragility curves derivation. Step-by-step procedure to generate synthetic ground motion with the advanced method is given below:

Step 1: At the beginning of the analysis, the user is prompted to define the seismic parameters (magnitude, distance, fault mechanism and site condition).

Step 2: User specified response spectra or spectra based on strong motion attenuation relationships (the Next Generation Attenuation (NGA) models [7], for example) and the predicted duration [8] are produced.

Step 3: Finally, synthetic ground motions for different hazard levels are generated through SIMQKE [9] based on the information defined previously.

Subsequently, both the natural and synthetic records are ready to be modified to reflect the local site effect. DEEPSOIL [10]—a 1-D site response analysis program—is implemented in NISRAF to conduct the site response analysis.

In addition to the hazard analysis, synthetic ground motion generation and site response analysis, the advanced hazard characterization method also provides a function to generate hazard map, which is the exposure of the impact assessment. To generate the hazard map, users are prompted to define the scenario events, the site conditions and the region of interest. The hazard map is then generated and shown on NISRAF.

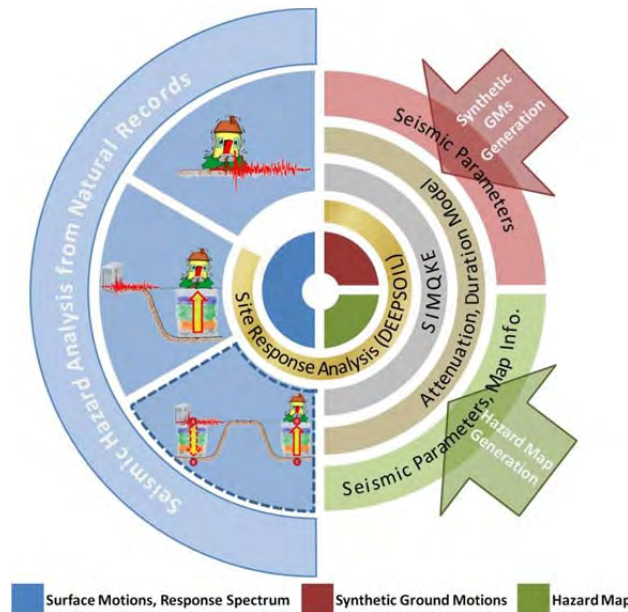

Figure 2: Methodology and procedures of the advanced hazard characterization analysis method

3.2 Efficient model calibration

Finite element model simulation provides a powerful way to understand the response of structures. Unfortunately, even well-constructed models may produce significant differences in some dynamic response predictions, in particular when the structure behaves nonlinearly. The difference is from the uncertainties of the material, boundary conditions and the contribution of the non-structural elements in the real structures. In order to overcome this drawback, a model calibration component based on the experimental or real response—which is composed of system identification and model updating techniques—is proposed. The following sections give an overview of these techniques.

System Identification

Among the many state-space based system identification methods, the Eigensystem Realization Algorithm (ERA) [11] is implemented in NISRAF due to its wide application and good performance in multi-input multi-output (MIMO) problems. The basic idea of ERA is to find a minimum realization of the system (a state-space representation with minimum dimensions) using the Singular Value Decomposition (SVD) on the Hankel matrix built by the Markov parameters (impulse response functions), so that the modal properties can be extracted from the realized minimum state-space representation.

A two-step strategy is applied to filter out computational and noise modes. Since more singular values are retained, more potentially genuine modes can be identified. In NISRAF, the dimension of the realized system N is increased until an adequate number of modes are included. For each particular order of a system, three commonly used mode accuracy indicators, namely Modal Amplitude Coherence (MAC) [11], Extended Modal Amplitude Coherence (EMAC), and Modal Phase Colinearity (MPC) [12] are used to filter out the computational or noise modes. The retained modes are then deemed trustable and a stabilization diagram is plotted for further confirmation. All modes—which are based on the idea that a genuine mode should always be identified with a different order of realized system, as long as the system order is adequate for that mode—are gathered in this diagram. Among the same order of

modes identified and plotted in the stabilization diagram, the one with highest EMAC value is then selected as the confirmed mode.

Model Updating

Model updating aims to minimize the discrepancies between the numerical and real model by adjusting the stiffness and mass matrices. The objective function is formed as a linear combination of the natural frequency residuals and mode shape residuals, with different weighting factors for each residual.

$$F(x) = w_f \sum_{k=1}^{N_f} \left(\frac{f_{ak} - f_{ek}}{f_{ek}} \right)^2 + w_m \sum_{k=1}^{N_m} \frac{\cos^{-1}(\sqrt{MAC_k})}{(\pi/2)} \quad (1)$$

f_{ak} and f_{ek} denote the analytical and experimental natural frequencies; w_f and w_m are weighting factors applied to the frequency residuals and mode shape residuals, respectively. MAC (Modal Assurance Criteria) is a measurement of mode shape discrepancy and is defined as [13].

$$MAC_i = \frac{(\phi_{ai}^T \phi_{ei})^2}{(\phi_{ai}^T \phi_{ai})(\phi_{ei}^T \phi_{ei})} \quad (2)$$

ϕ_{ai} and ϕ_{ei} are analytical and experimental mode shapes. $MAC = 1$ means ϕ_{ai} and ϕ_{ei} are perfectly matched; $MAC = 0$ means they are orthogonal. It is known that MAC is rather insensitive to the change of mode shape. It is also noted that the MAC is actually the square of the inner product between the two mode shape vectors. Therefore, the objective function for the mode shape residual is formed as the normalized angle between the two mode shape vectors, which are much more sensitive to the changes in the mode shape.

3.3 Advanced hybrid fragility analysis

Fragility, or vulnerability, presents the probability of reaching or exceeding a specific performance level under a specific seismic hazard. Fragility curves relate the effects of seismic hazard to the damage of the structures. Through the application of fragility curves, loss from earthquake hazard is estimated.

Generally, fragility curves are sub-divided into four categories based on data sources, namely empirical, judgmental, analytical, and hybrid fragility curves [14]. Empirical fragility curves are developed through field investigations after earthquakes—are the most realistic. However, this observation data is scarce and clustered in the low damaged range. Judgmental fragility curves are based on expert opinion, and are therefore subjective. Unlike the empirical and judgmental fragility curves, analytical fragility curves are more general, curves are allowed to be generated for different limit states and different structural types, although at a higher computation cost. Due to this limitation, most analytical fragility curves are generated either by simple models or by complicated models without calibration to the real structural response, which can result in uncertainties in these curves.

To reduce the uncertainties, a hybrid fragility analysis method is proposed. In this approach, hybrid simulation with critical element tested in the laboratory and the rest simulated in the calibrated finite element model is performed to evaluate the structural response. By scaling ground motions, several hybrid tests are conducted to reach the target structural response. The PGA of the scaled ground motion is then assumed as the mean PGA for the current limit state. Here, the target structural response is defined for different limit states, such as

interstory drift angle of 0.7% for immediate occupancy limit state for steel moment frame building. With the mean PGA values and the dispersions from similar structures found in the literature, the fragility curves are generated based on the lognormal distribution assumption. Figure 3 illustrates the methodology and procedures of the proposed advanced hybrid fragility analysis method.

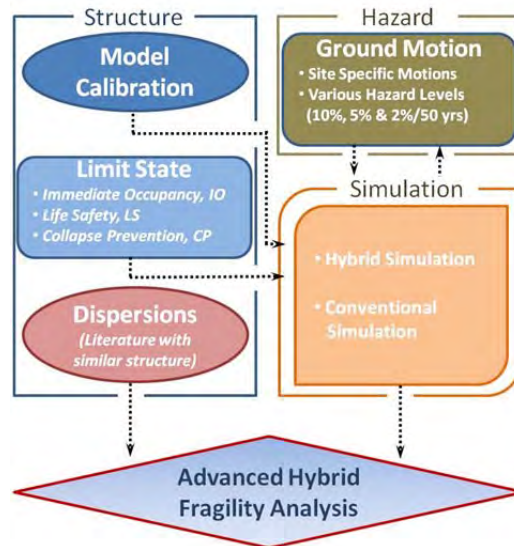

Figure 3: Methodology and procedures for the advanced hybrid fragility analysis

4 NEES INTEGRATED SEISMIC RISK ASSESSMENT FRAMEWORK

NISRAF, a software package with a graphical user interface (GUI) under the MATLAB environment has been developed for the purpose of making impact assessment more efficient and more reliable. Several components—instrumentation, advanced hazard characterization, system identification, model updating, hybrid simulation, advanced hybrid fragility analysis and impact assessment tools—have been implemented and tailored with novel methods to build the seamless, transparent and extensible framework. Figure 4 shows several components with GUI implemented in NISRAF.

Figure 4: Components with GUI in NISRAF

Several advanced features contained in this integrated framework are given below:

1. *Open source software with friendly GUI:* In NISRAF, each component (module) is developed separately before being incorporated into the framework. Consequently, it is easy to understand and maintain. This software, as well as the source code, will be open to the public. The open source feature will allow NISRAF to be utilized efficiently, as well as improve its integrity and robustness.
2. *Extensible and accessible:* As mentioned previously, each component is developed and verified separately. Hence, it is extensible and accessible to any of the latest research findings and program techniques.
3. *Efficient and reliable impact assessment:* This is the first time that all the components for impact assessment are integrated and work seamlessly in just one software platform. Concurrently, the integrated feature brings the most advanced tools of earthquake hazard and structural reliability analyses into the context for accurate evaluation of impact assessment. Surely, with these seamlessly integrated advanced techniques, which provide a more accurate hazard and structural model and hence generate superb fragility curves, the assessment of earthquake impact will be more efficient and more reliable

As mentioned previously, this is the first time to integrate all components of earthquake impact assessment in one analysis platform. Through NISRAF, uncertainties from hazard and fragility can be reduced or managed efficiently; therefore the results from impact assessment can be more realistic and reliable. Meanwhile, NISRAF provides a chance for seismologists, geotechnical and structural earthquake engineers, structural control and impact assessment experts to ameliorate algorithms in order to bring out more confident assessment results. Through its extensible and accessible feature, the new or improved algorithm can be easily incorporated into NISRAF.

5 CASE STUDY

NISRAF has been successfully developed and demonstrated via a heavy-instrumented building in Burbank, California [15]. Earthquake impact assessment on a single building provides the possible damage and loss under scenario or historical earthquake events for this specific building. It indeed provides valuable information to reduce and mitigate losses in particular for the essential buildings, such as hospitals and schools. However, regional impact assessment—seismic losses for a region, especially urban area—is more valuable for decision-makers to develop emergency response and recovery planning. In this section, earthquake impact assessment in the Los Angeles area was carried out; comparison and uncertainty were also presented and discussed, respectively.

5.1 Introduction

Los Angeles, California—a high seismic urban region—was selected to demonstrate the regional impact assessment. Near one million inventory data exported from HAZUS-MH was used as the inventory input. The hazard map of PGA for the 1994 Northridge earthquake in the Los Angeles area and fragility relationships for all building types and code levels were fed into MAEviz to perform earthquake impact assessment. Reference was made to Lin [15] for more detailed information about the generation of the hazard map. Below, fragility relationships utilized in this application will be illustrated, followed by the discussion on the impact assessment result and uncertainty analysis in NISRAF.

5.2 Parameterized fragility method

A database contained fragility relationships for all building types is an essential ingredient of regional impact assessment. The proposed advanced hybrid fragility analysis provides an alternative method to derive more reliable fragility relationships. Definitely, this hybrid approach can be applied to any other building types to generate the related fragility curves. However, considerable time and effort are required. For the mid-rise steel moment resisting frame building in Los Angeles area, its fragility relationships have been generated in order to demonstrate fully the hybrid fragility analysis implemented in NISRAF [15]. Extension of the database for fragility relationships to other building types is underway. Currently, an alternative method to derive fragility relationships for other building types is the Parameterized Fragility Method, PFM [16]. In the following paragraphs, PFM will be reviewed first, followed by the derivation of fragility relationships for other building types using PFM.

Parameterized Fragility Method, an analytical fragility analysis approach, derives fragility curves through dynamic time history analysis on a single-degree-of-freedom (SDOF) model. It is, therefore, parameters corresponded with structure types and ground motions representative of site hazard characterization are essential for this methodology's use in regional impact assessment.

In HAZUS-MH, 36 building types (from W1: wood, light frame to MH: mobile homes) are defined [17]. Meanwhile, structural parameters (i.e. period, yield and ultimate strength) for 36 building types under 4 code levels (i.e. pre-code, low-code, moderate-code, and high-code) are tabulated. However, the majority of these parameters are based on engineers' opinions and experts' judgment. To be more realistic and reasonable, the latest research findings on structural capacity were incorporated. For example, parameters for wood frame and unreinforced masonry buildings were replaced according to the more comprehensive investigations [18, 19]. In addition, sets of ground motions specific for Los Angeles area were used as earthquake demand when performing dynamic time history analysis in PFM.

Consequently, fragility relationships for 36 building types under 4 code levels particularly for the Los Angeles area were generated based on structural parameters and specific ground motions.

5.3 Assessment results and comparison

The MAEviz interface depicted in Figure 5 presents the distribution of the direct economic building loss for the Los Angeles area in the 1994 Northridge earthquake, using the hazard map and fragility curves generated by NISRAF. The mean total loss was 20.7 billion dollars. Table 1 provides a comparison of the direct economic building loss of the study area between NISRAF and observed data. In this table, Lower_B. and Upper_B. stand for Lower Bound and Upper Bound, respectively. In general, results of Lower_B. and Mean NISRAF loss provide bounding values of the observed loss. Therefore, NISRAF predicted reasonable accurate and modestly conservative assessment results for the Los Angeles area in the 1994 Northridge earthquake.

Table 1: Direct economic building loss (Los Angeles county under the 1994 Northridge earthquake)

	Observed*	NISRAF		
		Lower_B.	Mean	Upper_B.
Dollar in Millions	18,500	17,938	20,706	23,474
Difference (%)	0.00	-3.13	10.65	26.89

*[20]

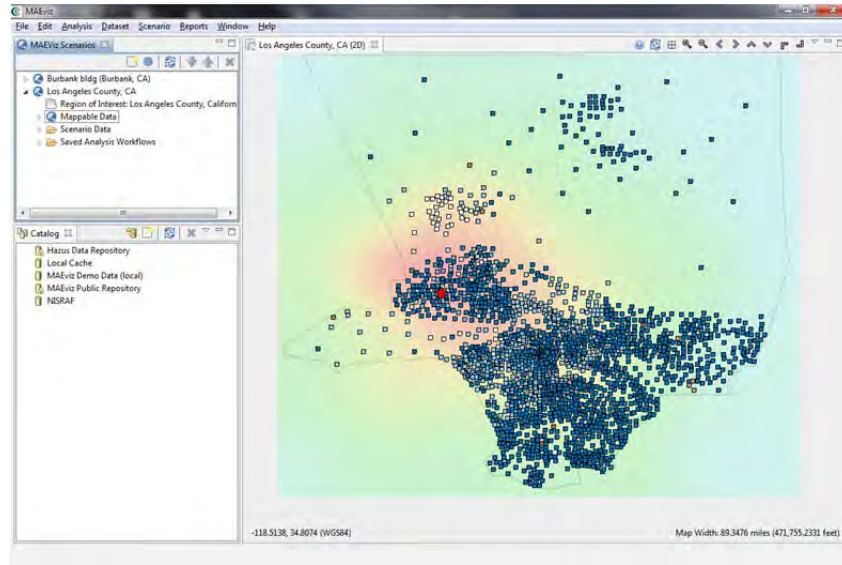

Figure 5: Earthquake impact assessment in Los Angeles area

5.4 Uncertainty analysis

Earthquake impact assessment is essential for disaster planning as well as developing risk reduction policies and emergency responses. As mentioned previously, an impact assessment package is composed of seismic hazard, fragility function, and inventory data. Mathematically, the loss estimation can be described by the following equation [21]:

$$P[Loss] = \sum_s \sum_{LS} \sum_d P[Loss|D = d] \cdot P[D = d|LS] \cdot P[LS|IM = s] \cdot P[IM = s] \quad (3)$$

where $P[\blacksquare]$ is the probability of loss (direct or indirect loss from the earthquake events), IM is the intensity measure of the seismic hazard (PGA or S_a), and s is the realization of the intensity measure. $P[LS|IM = s]$ is the conditional probability of reaching or exceeding structural limit states, and $P[D = d|LS]$ is the conditional probability of reaching damage. Here the term $P[LS|IM = s]$ refers to fragility or vulnerability discussed in previous section.

Due to the random nature and limited knowledge in earthquake engineering, numerous assumptions are made and many approximated methods are applied when performing impact assessment. Therefore, various types (aleatory and epistemic) of uncertainties exist in earthquake impact assessment, for example, the prediction of seismic intensity, the generation of fragility functions, the assumption of distribution of damage ratio, the inventory uncertainties and others. With additional investigation and knowledge, it is definitely possible to reduce the epistemic uncertainties, such as by providing more realistic seismic hazard characterization, more reliable fragility relationships generated through NISRAF, and more accurate inventory data. Nevertheless, uncertainties are unavoidable, particularly in the case of aleatory uncertainties (randomness).

One advanced feature of MAEviz that distinguishes it from HAZUS-MH is its uncertainty quantification analysis, which not only provides users with the mean value of the predicted losses, but also the uncertainty information (the standard deviation values). With this contribution of uncertainty analysis in MAEviz, NISRAF—to be consistent with its user-friendly feature—presents the uncertainties through an intuitive and friendly interface [15], as shown in Figure 6. Through this intuitive interface, a pie-chart of different losses (i.e. structural, non-

structural, and contents) is presented. Also, losses with upper-bound and lower-bound vary with the different confidence level which was selected by the users.

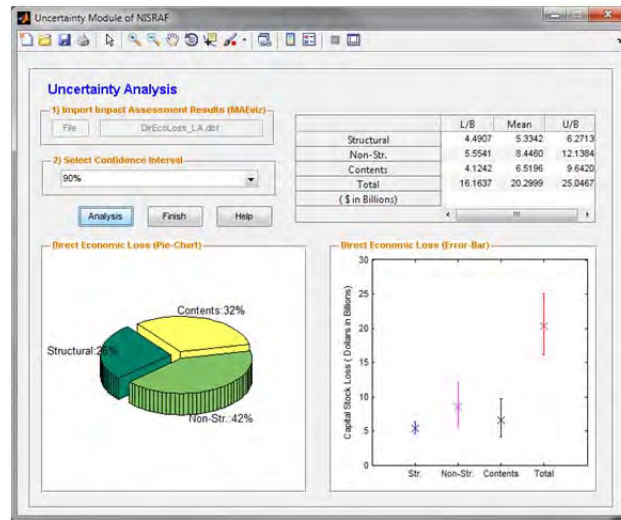

Figure 6: Uncertainty qualification analysis in NISRAF

The actual test bed in California, the regional impact assessment in the Los Angeles area, was carried out to demonstrate the integrated framework as well as its components. This example demonstrated not only the seamlessly-integrated, extensible, and transparent framework, but also that all the elements required for impact assessment can be performed under just one software platform. Consequently, the reasonable accurate, although conservative impact assessment results confirmed one of the advanced features of NISRAF, which is more efficient and more reliable impact assessment. Meanwhile, the implemented approximate uncertainty quantification analysis can assist decision-makers to judge the losses easily and quickly, which will contribute to the development of more suitable and more confident recovery plans and emergency responses.

6 CONCLUSIONS

NISRAF is intended to serve as a user-friendly software platform through which impact assessment can be efficiently and reliably performed by combining hazard (exposure) and fragility (sensitivity), to provide assessment of impact on the built environment at the regional scale. Concurrently, it is intended to extend the state-of-the-art hybrid simulation approach to fragility analysis, and propose refined methods for hazard characterization and model calibration. The successful completion of the development of the framework and verification of its components demonstrates that these objectives have been achieved. In addition, the application of NISRAF will be a stimulus for cooperation between not only for geotechnical and structural earthquake engineers, and impact assessment experts, but also for seismologists and structural control researchers improving their algorithms in order to pursue the ultimate goal of accurate and reliable earthquake impact assessment.

Keywords: strong motion, earthquake record selection, Eurocode 8, FEMA P-750, structural analysis, response spectra, spectral matching.

Abstract. *Despite the major advancements in earthquake engineering research and the novelty of most modern seismic codes, the selection of the earthquake ground motions used for the design or assessment of structures in the framework of structural analysis still induces significant dispersion in the calculated dynamic response of structures. For this reason, the current study presents a new, freely available, computational system developed for improving the reliability of the code-based earthquake record selection and scaling procedure, as a means to reduce the resulting structural response scatter. Through a set of preliminary criteria, related to the magnitude, epicentral distance, soil conditions, intensity measure (i.e., PGA), components of excitation (2D or 3D) and structural system (building or bridge), the proposed algorithm searches through internet the entire PEER-NGA Strong motion Database for appropriate seismic records and then ranks them in terms of their spectral matching to a target response spectrum within a prescribed frequency range. A key feature of the software is that it implements the new Application Programming Interface (API) of the computer program SAP2000 and proceeds in applying the selected records to the finite element model that the designer is assumed to have prepared at the background. In this way, both the variation of the response quantities in the time domain and the relative structural response dispersion under various records are automatically retrieved. The presentation concludes with a demonstration regarding the assessment of a real, irregular in plan, multi-storey, RC building, where the importance of adopting a structure-specific earthquake record selection process is highlighted.*

1 INTRODUCTION

During the last decades, elastic and inelastic dynamic analyses have been made feasible for the design and assessment of complex structures with thousands of degrees of freedom, thanks to the rapid evolution in computational processing power and the enhancements in engineering software. As a result, the vast majority of modern seismic codes prescribes the application of the response history analysis as an equally eligible method to assess the response of a structural system. However, current research work [1]-[3] has demonstrated that among all possible sources of uncertainty stemming from the structural and soil material properties, the design and analysis assumptions and the earthquake-induced ground motions, the latter seems to affect most seriously the structural response variability, as determined by the dynamic analyses. Therefore, the selection of a “reliable” set of earthquake ground motions for conducting response history analysis becomes an important prerequisite as it affects the reliability of the procedure as a whole.

This truly complex task, which is still undertaken by the engineers without detailed seismic code guidelines, cannot be accomplished without understanding the fundamental concepts behind selection and scaling of earthquake records and their implication in the predicted structural response. For this reason, numerous alternative methods have been proposed for enhancing the reliability of the earthquake records selection and scaling process, most of them being summarized recently by Katsanos et al. [4].

Quite typically, implicit parameters such as the earthquake magnitude M and the source-to-site distance R are widely used as preliminary criteria combined with desirable filters that are related to the soil conditions of the site of interest, code or seismic hazard prescribed levels of different intensity measures, as well as of the seismotectonic environment features (i.e. the source mechanism, the path of seismic waves, strong-motion duration). Nevertheless, the concurrent application of all the above parameters significantly restricts the number of the records eligible for selection and thus relaxation of these criteria may be inevitable to ensure a reasonable number of records for dynamic analyses. Furthermore, research work has shown that application of site-specific M - R criteria did not reduce the structural response discrepancy in various structural systems, while highlighted the relative independence of nonlinear response on the distance (e.g. [2, 5 and 6]) with the exception of cases where the cumulative damage measures are of interest [7] or for structures where the contribution of higher modes is significant [2].

As the most common earthquake record selection procedures involve spectral matching of the average response spectrum of the records to be used, with a target, code-prescribed or seismic hazard-defined elastic response spectrum [8, 9], or even a conditional mean spectrum [10], recent work evolved to develop methods for quantifying (e.g. [11, 12]) and/or optimizing [13,14] this spectrum compatibility.

Especially in case of the performance-based design approach, the selection of acceleration time series is considered with the goal of accurate prediction of the structural response at a specified ground motion intensity measure, IM. The Peak Ground Acceleration of records and some other characteristic parameters (i.e. the spectral acceleration, SA) have been used as suitable IMs (e.g. [2]). Nevertheless, advanced intensity measures, including information about the spectral shape and structural characteristics, are expected to be preferable for records selection and scaling procedures resulting in a more accurate and reliable estimate of the seismic demand [6,15,16].

Despite the aforementioned state-of-the-art evolution in this quite recent research field, a rather rough framework is prescribed by most of the modern seismic codes concerning the motions to be used for time history analysis while most of the aforementioned record selec-

tion methods proposed in the literature have not yet been incorporated in the codes. Furthermore, specific guidelines of the codes have been proven either inadequate or misleading [17]. In fact, most of the current earthquake resistant codes share a lot of similar provisions, thus revealing that most probably, specific selection provisions have been widespread among seismic codes used in other parts of the world without systematic review, needless to say, quantification of their implications in structural design and assessment [8].

Along these lines, this paper presents a new, freely available, computational scheme for selecting and scaling earthquake records which aims at maximizing both the applicability and efficiency of the code-based earthquake record selection procedure, while minimizing the potential scatter that is commonly induced in structural response. More specifically, the proposed Matlab-based software **ISSARS** (**I**ntegrated **S**ystem for **S**tructural **A**nalysis and **R**ecord **S**election) utilizes the extensive PEER-NGA ground-motion database to form suites of records complying with specific criteria while exhibiting spectral matching with a user defined target spectrum. These suites of records, which have been ranked based on their compatibility with the design spectrum, can be further used as the required seismic loading for the dynamic analyses of a structural model studied. This is made feasible by using the Applications Programming Interface (API) of the finite element program SAP2000 [18] to run numerical analyses at the background and quantify the produced discrepancy of structural response as a part of the earthquake record selection process.

To this end, the scope of the paper is to present the integrated, computational system developed that permits:

- (a) the rapid code-based selection of earthquake records required for the design and assessment of buildings and bridges, that are characterized by best matching with a target response spectrum at specific structural periods and;
- (b) the automatic prediction of the impact that the selected suites can have on the dispersion of the structural response of the specific structure under study. This can be used as an additional criterion before finally approving an eligible earthquake record suite.

An illustrative example regarding the application of the current integrated system for the case of a real, irregular in plan, multi-storey, RC building, in Thessaloniki, Greece is also presented in order to highlight the above advantages. The description of the computational framework and the application case study are presented in the following.

2 CODE-BASED FRAMEWORK FOR EARTHQUAKE RECORD SELECTION

As already mentioned, the computational framework developed aims to maximize the applicability and efficiency of the code-based earthquake record selection procedures with emphasis on those prescribed in Eurocode 8, Part 1 for buildings, Eurocode 8, Part 2 for bridges [19] and NEHRP Recommended Seismic Provisions for New Buildings and Other Structures [20], abbreviated in the following as FEMA P-750. According to EC8 Part1, the seismic motion to be used for response history analysis may be either artificial, simulated or recorded, depending on the application nature and the information available at the location of the structure. It is notable that the use of artificial records is described in more detail in EC8 Part1 compared to the use of real and simulated records. FEMA P-750 and EC8 Part2 limit the use of simulated seismic motions only in cases of inadequate number of real accelerograms, the latter being selected in terms of magnitude, fault distance and source mechanisms that control the hazard at the site of interest. The source mechanism and path characteristics are also adopted as preliminary criteria, while EC8 Part1 imposes compatibility with the soil category at the location of the building studied.

Concerning the spectral matching procedure, FEMA P-750 guidelines are almost identical to those in EC8 Part2 for bridges; in particular, the SRSS spectrum is determined by taking the square root of the sum of squares of the 5%-damped elastic spectra of each selected component of the horizontal motions and then, the average values of the SRSS spectra of the individual earthquakes define the final average spectrum. Spectral matching is imposed within the period range $0.2T_1 - 1.5T_1$ where T_1 is the fundamental period of the structure. On the other hand, EC8 Part1 requires that the mean 5%-damped elastic spectrum, calculated from all the response spectra of the individual records, has to be compatible with the target spectrum. However, the period range of the foreseen spectral matching is wider (i.e., $0.2T_1 - 2T_1$). The comparative presentation of the above criteria is made in Table 1.

Seismic code	Selection criteria	Ensemble Spectrum	Spectral matching period range	Lower bound
EC8 Part1	source mechanism, soil type	mean of individual spectra	$0.2T_1 - 2T_1$	$0.9 \cdot SA_{\text{design}}$
EC8 Part2	source mechanism, M, R	mean of SRSS spectra	$0.2T_1 - 1.5T_1$	$1.3 \cdot SA_{\text{design}}$
FEMA P-750	source mechanism, M, R	mean of SRSS spectra	$0.2T_1 - 1.5T_1$	$1.17 \cdot SA_{\text{design}}$

Table 1: Earthquake record selection and spectral matching criteria prescribed in the seismic codes studied herein.

FEMA P-750 also specifies that each one of the recorded ground motions can be scaled by different factors as a means to facilitate spectral matching, while Eurocode 8 prescribes the use of a unique scaling factor, uniformly applied to all the selected records. In addition, both Eurocode 8 and FEMA P-750 share identical provisions concerning the post-processing of the structural analysis results. More specifically, they require that the maximum of the structural response quantities arising from the individual response history analyses has to be used as the design value, when the number of records n is between $3 \leq n \leq 6$, while the average of the response quantities from all analyses has to be computed in case that more than 7 records are used.

3 OVERVIEW OF THE PEER-NGA STRONG MOTION DATABASE

The computational framework developed for earthquake record selection and structural analysis utilizes online the PEER-NGA Next Generation Attenuation strong-motion database [21,22] (PEER-NGA, Copyright © 2005, The Regents of the University of California, available in http://peer.berkeley.edu/peer_ground_motion_database). Currently, the data-set consists of 3551 publicly available, three-components seismic records (i.e., about 10650 individual earthquake acceleration time series) that have been recorded during 173 shallow crustal earthquakes from active tectonic regions world-wide. As can be seen in Figure 1, most of these earthquakes have occurred in California. The corresponding seismic events range in magnitude from 4.2 to 7.9 and cover epicentral distances in the range 0.2km-600km (detailed distribution is illustrated in Figures 2 and 3).

Besides the magnitude and the distance, the earthquake database contains basic information about the seismic source including date and time of the event, hypocenter location, faulting mechanism, seismotectonic environment and others. Detailed data about 1600 strong-motion stations are also provided (i.e. site characterizations, surface geology, shallow subsur-

face conditions, the location of the instrument inside the structure's installation place). Furthermore, each acceleration time-history has been corrected for the response of the strong-motion instrument itself and filtered out the noise included. As a result, all the above features of the NGA-Strong Motion Database enable to conduct a reliable and efficient searching for "suitable" earthquake accelerograms among the thousands of available records.

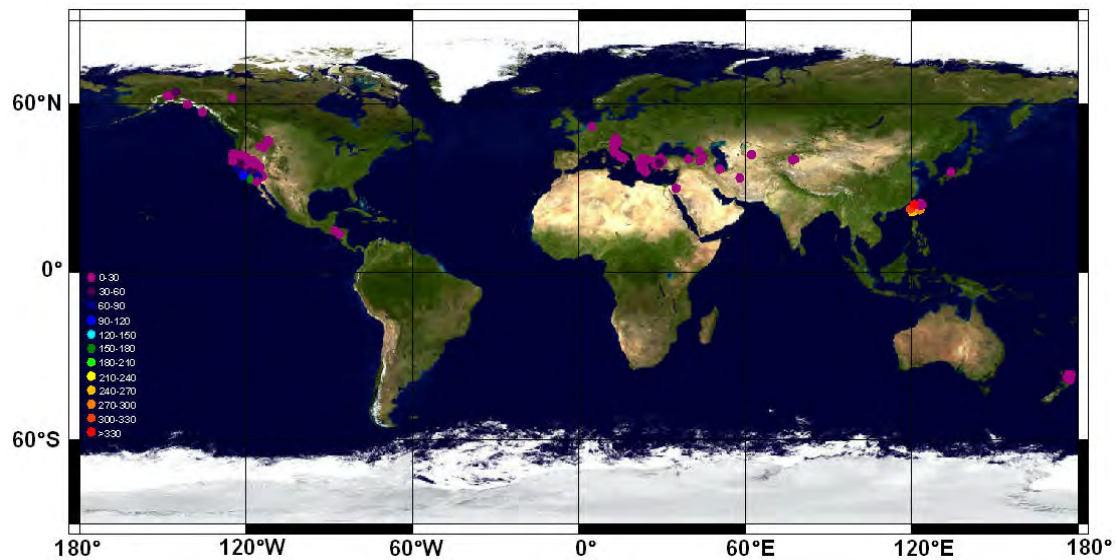

Figure 1: World map illustrating the distribution of the seismic events associated to the 173 earthquakes stored in the PEER-NGA database (distribution computed based on the information available online in http://peer.berkeley.edu/peer_ground_motion_database).

Figure 2: Magnitude and Distance distribution of strong motion records available in the PEER-NGA database (distribution computed by the ISSARS software based on the information available online in http://peer.berkeley.edu/peer_ground_motion_database).

Figure 3: Magnitude and Peak Ground Acceleration distribution of strong motion records available in the PEER NGA database (distribution computed by the ISSARS software based on the information available online in http://peer.berkeley.edu/peer_ground_motion_database).

4 OVERVIEW OF THE COMPUTATIONAL FRAMEWORK DEVELOPED

The computer program ISSARS has been developed in Matlab programming environment, utilizing a series of scripts assembled and coordinated within a graphical environment. It consists of two major modules, (a) the Ground-Motion Selection Module, which is oriented to search for suitable seismic waves that comply with specific criteria and target spectrum, and (b) the Structural Analysis Module which enables automated finite element analysis of the structure under study and quantification of the record set-dependent structural response scatter. Additionally to the above, an auxiliary visualization module permits the quick visualization of the generated response spectra, their means as well as the target spectrum. These modules are described in more detail below.

4.1 Ground-Motion Selection Module

The earthquake magnitude, M , and the epicentral distance, R , of the seismic events, the peak ground acceleration, PGA, of the strong-motion records as well as the site classification, S , of the recording instruments constitute the preliminary criteria for records searching through the web-based NGA-Strong Motion Database. Most of these seismological parameters, which are familiar to the structural engineers, are usually determined either through a site-specific deterministic seismic hazard analysis, SHA, or resulted from the disaggregation of a probabilistic SHA. Apart from the above criteria, both the earthquake name and the region of the seismic event can be used as a means to further refine the searching criteria.

After the establishment of the preliminary seismological criteria, the algorithm core script requires the determination of the seismic code-based parameters, which are necessary for the calculation of the target response spectrum and the consecutive implementation of the spectral matching procedure. Since both Eurocode 8 (including Part1 and Part2) and FEMA P-750 provisions can be considered, the present software may be used for the design or assessment of structures both in Europe and the U.S.

In the first case of applying the Eurocode 8 procedure for selecting earthquake records, the calculation of the elastic, damped, code spectrum involves the definition of: (a) the spectrum

type, (b) the importance factor of the structure studied, (c) the site classification, (d) the viscous damping and (e) the reference peak ground acceleration. On the other hand, the determination of the FEMA P-750-based target spectrum requires, apart from site classification, some characteristic seismic ground motion values, such as, the mapped uniform-hazard ground motion parameters (S_{SUH} , S_{IUH}), the mapped risk coefficients (C_{RS} , C_{RI}), the mapped deterministic ground motion parameters (S_{SD} , S_{ID}) as well as the mapped long-period transition period (T_L). Regardless of the seismic code adopted, the fundamental dynamic characteristics of the structure under study have also to be defined.

Based on the aforementioned preliminary criteria and spectrum-related parameters, ISSARS connects to the online PEER-NGA-Strong Motion Database [21] and defines the eligible seismic events (Figure 4). The user chooses any number s (or the entire group) of the compatible motions and the records are grouped into appropriate suites (“bins”) of m records. The number of the suites formed, $N_{tot.suites}$, is given by the following factorial formula:

$$N_{tot.suites} = \binom{s}{m} = \frac{s!}{m!(s-m)!} \quad (1)$$

The number m of records forming each suite of ground motions is taken by default equal to 7 according to Eurocode 8 and FEMA P-750 provisions about the minimum value of strong-motions that allows for the definition of the design response value as the average of the response quantities from all the analyses. This number can be easily modified through the code scripts. However, it has to be noted that for cases that $m > 7$, it is quite possible that the fit of the average spectrum of the suite to the target one will be eventually inferior, unless the list of the selected seismic events is relatively large. Kottke and Rathje [23] showed that if m exceeds 10, a larger list of records than 70 may be necessary to achieve adequate spectral convergence. Such a number of records is often difficult to be achieved given the multiple selection criteria applied while at the same time leads to an increased number of response history analyses.

Figure 4: Preliminary seismological criteria, Code-based parameters and list of eligible seismic events.

Having formed all the eligible suites of m records, the average spectra for each suite are calculated and the appropriate scaling factors sf_{avg} (unique for each suite), required to comply with the spectral matching criteria (Table 1), are computed as follows:

$$sf_{avg} = \left\{ \min \left(\frac{Sa_{avg}(T_i)}{Sa_{target}(T_i)} \right) \right\}^{-1}, \quad i = 1 \text{ to } N \quad (2)$$

where $Sa_{avg}(T_i)$ is the ordinate of the average response spectrum of the records suite corresponding to the period T_i , Sa_{target} is the spectral acceleration of the code spectrum derived at the same period and N is the number of values within the code-imposed range of periods (Table 1). The suites, which consist of scaled of motions, are then ranked according to their "goodness-of-fit" to the target spectrum. The level of spectral matching between the scaled average spectra of the record combinations and the target spectrum is quantified by the expression of the normalized root-mean-square-error, $NRMSE$, also used by Iervolino *et al.* [24].

$$NRMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N \left(\frac{S_{avg}(T_i) - S_{target}(T_i)}{S_{target}(T_i)} \right)^2} \quad (3)$$

The final list of the eligible suites of m records, appropriately ranked according to the spectral matching criterion of Eq. (3), is shown in Figure 5. Additionally, the algorithm provides an extensive output data file that includes all related input data (i.e. the preliminary seismological criteria, the seismic code parameters and the dynamic characteristics of the structural system under study) and the associated meta-data concerning the eligible seismic events and their acceleration time series as well as the final hierarchy of the suites formed (Figure 6).

Figure 6: ISSARS's output file.

The computational time, required for calculating 480700 suites of scaled records (formed for the case of 25 selected seismic events), is about 60 seconds on a 8GB RAM 1.60 GHz quad core processor. This computational efficiency permits the concurrent use of the software for multiple ranges of preliminary criteria.

4.2 Visualization Module

The results of the previous module can be visualized by calling the plot module. For each one of the formed suites of records, ISSARS provides a figure illustrating (a) the target spectrum, (b) the code-imposed lower bound of the design spectrum (necessary for the spectral matching procedure, Table 1), (c) the individual 5% damped response spectra of all records within a given suite (d) the average spectrum of the suite, and (e) the scaled average spectrum. This schematic illustration of the calculated spectra (Figure 7) enables a preliminary but useful visual assessment regarding the "goodness-of-fit" of a particular suite of records to the target spectrum, which may reveal period ranges of inappropriately unsuccessful fit that may be otherwise suppressed by the averaging *NRMSE* values of Eq. (3).

Figure 7: Sample plot of individual, average and target spectra computed for each suite.

4.3 Structural Analysis Module

Although it is not explicitly stated in modern seismic codes, one of the main objectives of selecting and scaling accelerograms is to form suites of records that will eventually induce adequately stable estimates of the predicted elastic or inelastic structural response; otherwise, the associated dispersion in response quantities may undermine the reliability of the predicted design values [25, 26]. At the same time, the consideration of the structural response variability in the decision-making procedure for selecting earthquake records is only implicitly considered by seismic codes through the rough estimate of the fundamental period and the associated period range for spectral matching.

In the computational framework developed, the discrepancy induced in the response quantities by the selection of a given suite of records, is quantified and utilized as a selection criterion itself. This is made feasible by using the recently introduced Application Programming Interface (API) of the finite element software SAP2000 [18]. This API permits the execution of specific build-in functions to run and control SAP2000 in the background, during the ex-

ecution of the Matlab script, provided that the designer/engineer has developed and made available the finite element model of the structure in advance.

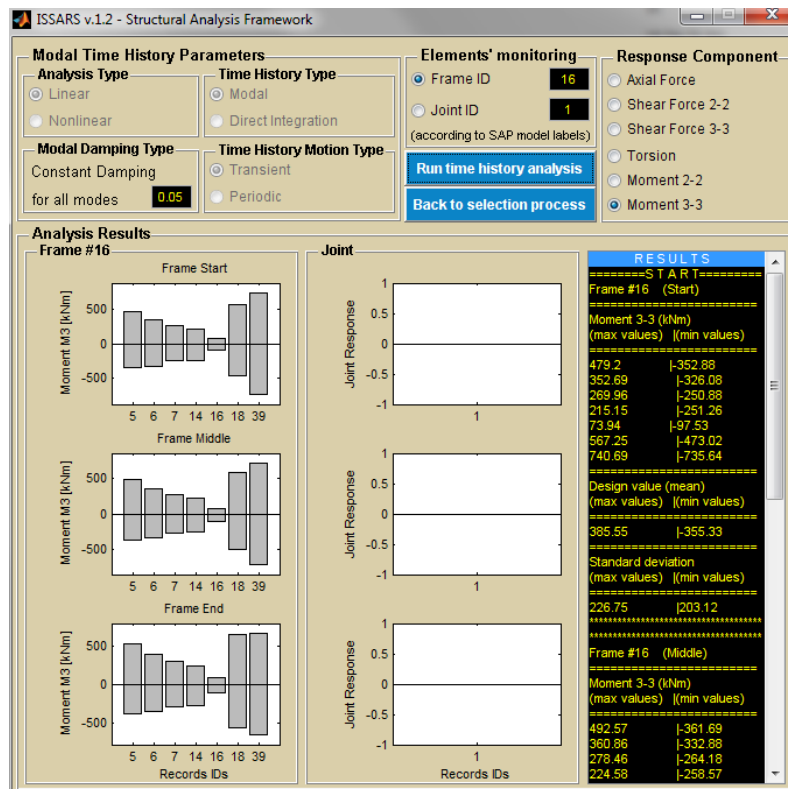

Figure 8: Structural Analysis Module.

Through this interactive link, response history analyses are performed using the record suites, which are defined according to the preliminary criteria set and the “goodness-of-fit” ranking system, while the Matlab-based script retrieves post-processing structural analysis data, such as the action effects (i.e. forces and displacements) maxima, monitored at the frames and joint locations (Figure 8). Another advantage of the interactive record selection procedure is that, it can be followed, regardless of the complexity of the finite element model, that is, the type of the structure, the number of degrees of freedom, its geometry, the potential for material or geometrical nonlinearities, the consideration of soil flexibility, the direction of excitation or any unconventional structural characteristic. The complexity of the structure is resolved by the designer and once the finite element model is made available to the Matlab script, the structure-specific earthquake record selection runs effortlessly.

5 APPLICATION OF THE PROPOSED COMPUTATIONAL FRAMEWORK FOR THE ASSESSMENT OF AN EXISTING RC STRUCTURE

In an attempt to illustrate the applicability of the proposed computational framework, a demonstration is presented herein for the case of an existing, multi-storey R/C building, located in Thessaloniki, Greece. The overview of the case study as well as the results derived are presented in the following.

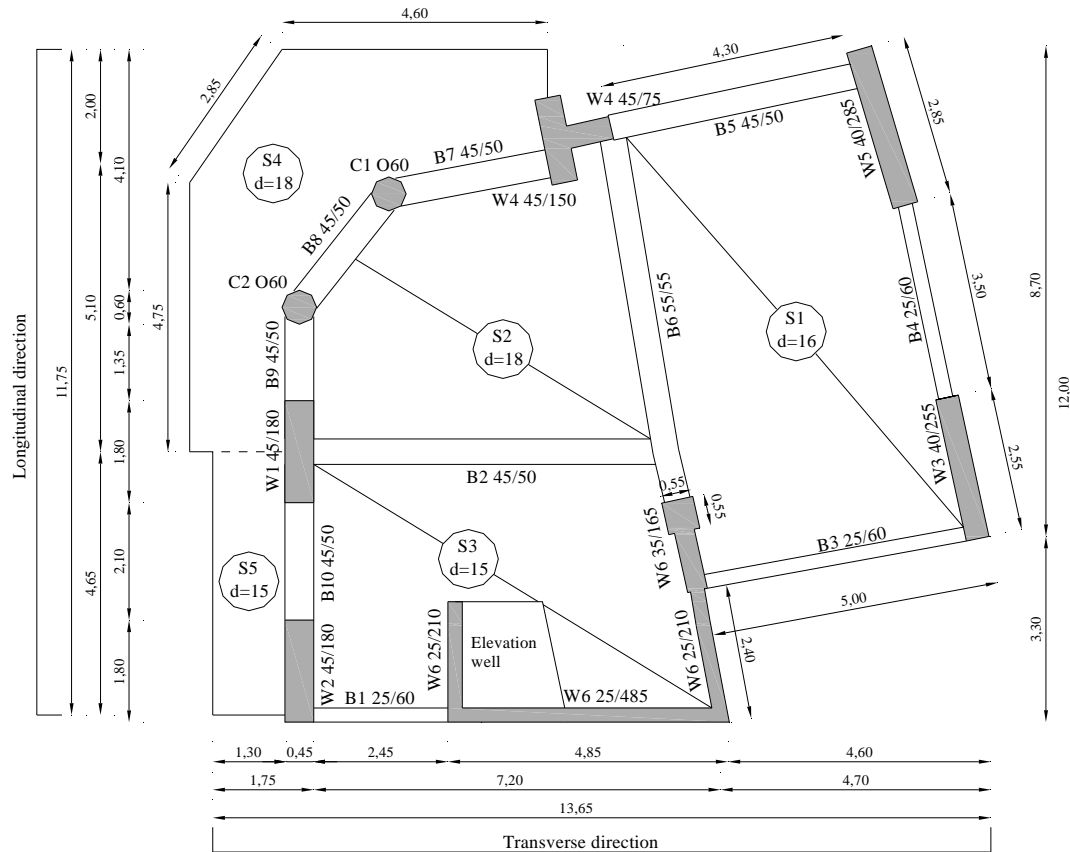

Figure 9: Plan view of the typical floor of the case study building.

Figure 10: A 3-Dimensional finite element model of the building under study.

5.1 Case study building: Structural configuration and numerical modeling aspects

The building studied is an irregular in plan, seven-storey R/C dual system, with a pilotis and a basement, which is located in the city of Thessaloniki, in Greece, whose plan view is presented in Figure 9. The total area of the typical storey is 135.0 m^2 and the storey height is 3.0 m. The lateral strength of the building is provided by four shear walls of relatively equally dimensions and a reinforced concrete core eccentrically. The concrete class used was C20/25

(i.e., compressive strength $f'_c=20 \text{ N/mm}^2$), and St.III steel bars (i.e. yield strength $f'_y=500 \text{ N/mm}^2$) were applied for the longitudinal and transverse reinforcement. The building under study was constructed in 2008 according to the latest version of the Greek Seismic Code EAK2000 [27] which is currently in parallel enforcement with the Eurocodes. The design ground acceleration, a_g , has been set equal to 0.16g as corresponding to the lowest seismic hazard category in Greece. The soil conditions have been classified as category C according to both EAK2000 and EC8 site categorization. Figure 10 illustrates the fixed-base model [28], developed with the use of SAP2000 finite element software [18] using both frame elements for the beams and the columns and shell elements for the shear walls and slabs.

5.2 Coupled earthquake record selection and structural analysis

After the development of the finite element model of the building studied, a seismic scenario was determined for the seismic hazard of the particular site using the following seismological criteria: (a) earthquake magnitude, $6.5 \leq M \leq 7.5$, (b) source-to-site distance, $20 \leq R \leq 50$ (km), (c) peak ground acceleration, $\text{PGA} \geq 0.16\text{g}$ and (d) soft soil conditions, corresponding to Eurocode 8 soil category C. Regarding the target spectrum, the EC8 5% damped, elastic spectrum was defined for soil category C while the reference peak ground acceleration value was taken equal to 0.16g for the reason described previously. The fundamental period of the structure was found equal to 0.621s and was used to establish the EC8 prescribed spectral matching period range (i.e. $0.2T_1=0.12\text{s} < T < 2T_1=1.24\text{s}$). Based on the above, ISSARS was performed to search online within the PEER-NGA Strong Motion Database and 36 different seismic events have been returned as eligible. Analytical description of the resulting sample is summarized in Table 2. It is notable that each one of these eligible earthquakes consists of two horizontal seismic records, which are required for the bi-directional seismic loading of the particular multi-storey R/C building.

Due to the enormous computational cost that would be required in case of calculating all the possible records suites from the 36 eligible seismic events (i.e., 8,347,680 suites of seven pairs of horizontal components of strong motions would be required), 28 different earthquakes were selected, leading to the generation of 1,184,040 suites of records (Figure 11). The required computational time for this calculation did not exceeded 120-150 s using a 8GB RAM 1.60 GHz quad core processor.

In the following, ranking of the suites of records took place in terms of their spectral compatibility to the Eurocode 8 target spectrum and according to the hierarchical concept adopted. The first suite of records, characterized by the highest matching score, was selected as the first candidate for the dynamic analysis of the structure under study. More specifically, the seven pairs of strong motions, which are included in the first suite, were automatically transferred and applied as the seismic excitation of the case study finite element model, thus, seven bi-directional, elastic response history analyses were performed in the background using the Structural Analysis Module and the built-in API functions of the SAP2000 program. The results of these consecutive analyses were returned, processed and finally presented by ISSARS (Figure 12) in the form of maximum absolute values of all response quantities at the monitored frames and joints, as well as their average values and standard deviations. The designer may also choose alternative top ranked suites of earthquake records, compare the resulting discrepancy of the computed response quantities and decide on the most representative combination (suite) of records to be eventually used for design or assessment purposes.

6 CONCLUSIONS

An integrated computational system that couples the code-based earthquake records selection procedure and the structural response is developed and presented herein as a means to increase both the applicability and the effectiveness of the current state-of-the-practice in conducting response history analyses. The proposed Matlab-based algorithm utilizes the on-line PEER-NGA strong motion database in order to search for compliant strong motions, which are required for the seismic loading of dynamic analyses. After an initial records filtering procedure in terms of magnitude, epicentral distance, soil conditions, intensity measure, components of excitation (2D or 3D) and structural system (building or bridge), the eligible acceleration time series are grouped into numerous suites and finally ranked on the basis of their spectral similarity with the design spectrum. Through the recently released Application Programming Interface (API) of the computer program SAP2000, the selected records are applied to excite the finite element model that the designer is assumed to have prepared at the background. The variation of the response quantities in the time domain are automatically computed and the relative structural response dispersion under various records sets is assessed. The presentation concludes with a demonstration assessment of an existing, irregular in plan, multi-storey, RC building, where the importance of adopting a structure-specific earthquake record selection process is highlighted. It is deemed that the structure-specific earthquake record selection procedure presented herein is a promising alternative to the existing procedures and a significant improvement compared to the conventional application of the current seismic code provisions.

Abstract. *Seismic assessment of bridge structures often requires inelastic (static or dynamic) analysis methods to be used, in order to draw a realistic evaluation of the structural behaviour beyond the elastic range. While the widely-used non-linear static (pushover) analysis provides a low-computational-cost approach to this direction, it is inherently limited by the assumption that the structure's response is solely controlled by its fundamental mode. This limitation is raised by an extension of the “standard” pushover analysis (SPA) to take into consideration the effect of higher modes, a method known as Modal Pushover Analysis (MPA). This method however, can often prove to be time-consuming and strenuous both for pre- and post processing. The latter, provided the motivation for investigating the feasibility to take advantage of the recently released SAP2000 application programming interface (API) in order to develop a new computational tool that implements the MPA specifications for evaluating the seismic behavior of bridges in an organized and automatic fashion. The paper concludes with the application and demonstration of the software developed, for the case of an existing reinforced concrete bridge located along the Egnatia Highway in Greece.*

1 INTRODUCTION

Nonlinear static procedures have become a commonly used tool for assessing the seismic performance of buildings and bridges. Nevertheless, its main advantage of lower computational cost, compared to non-linear time-history analysis (NL-THA), is counter-balanced by its inherent restriction to those structures, wherein the fundamental mode dominates the response. To this end, Modal Pushover Analysis, as introduced by Chopra and Goel [1], [2] for buildings and extended by Paraskeva et al. [3], [4] for bridges, is deemed a useful alternative, as it can provide a reliable estimate of the non-linear structural response, based on the repeated application of a given nonlinear static analysis procedure for each of the significant vibration modes of the structure, followed by an adequate combination of the results. However, this procedure is time-consuming and the significant effort required for pre- and post-processing of the required and obtained data, respectively, quite often cancels the advantage of simplicity compared to the non-linear time-history analysis.

This limitation is raised herein by making use of the new SAP2000 [5] Application Programming Interface (API), for developing an interactive front-end for the modal pushover analysis of bridges. This API was recently introduced by CSI, the developer of the finite element code SAP2000, and grants access to the SAP2000 advanced numerical modules, thus permitting pre- and post-analysis computations to be efficiently programmed. An introduction to using this new computational tool is made herein and the capabilities that are opened for developing third-party earthquake engineering applications to be coupled with SAP2000 are also discussed. Subsequently, the architecture of the front-end is presented in detail, presenting the implementation approach that was followed and the way that the procedure's specifications were encapsulated into the software.

Finally, the front-end developed is also applied for the assessment of seismic response of an existing bridge structure in Greece, which is presented in this paper for testimonial purposes. It is shown that with the use of the new SAP2000 API and the aforementioned interactive front-end, the time and effort required for studying the inelastic response of bridges through a modal pushover analysis scheme is greatly reduced.

2 STANDARD AND MODAL NONLINEAR ANALYSIS

2.1 Nonlinear Static (Pushover) Analysis

When it comes to estimating the nonlinear behavior of structures that are subjected to seismic forces, pushover analysis is the most widely-used method, capable of providing a reliable estimate of the structural capacity. During this procedure, monotonically increased lateral loads are statically applied to the structure, in an invariant pattern that aims to resemble the distribution of the fundamental mode forces that the structure is subjected to when excited seismically along a given direction. Under the increasing load application, a series of plastic hinges develop at critical sections of the structure, leading force redistribution and gradually to a failure mechanism. As a result, it is possible to obtain the non-linear relationship between the lateral force applied and the deformation of the structure which is monitored at a specific location, usually expressed in the form of the pushover curve, that is, a "base reaction versus control node displacement".

By converting the base shears and roof displacements obtained to equivalent spectral accelerations and displacements ($S_a(T)$ and $S_d(T)$) and superimposing an earthquake demand curve (typically the prescribed seismic hazard spectrum for the site), the non-linear (pushover) analysis can then provide an estimation of the inelastic response of the structure at a given level of

target earthquake intensity. It is therefore a useful structural assessment tool as it offers a number of advantages, primarily being the fact that:

- it is a conceptually simple methods which is straightforward to apply low computational cost, in comparison to the nonlinear response history analysis (NL-RHA).
- the results obtained by SPA can be easily post-processed and interpreted, especially compared to NL-RHA. It is recalled that the latter method leads to time variant action effects (i.e., forces and displacements) and computing the statistics of response can be a demanding task. Moreover, the inelastic response results obtained by NL-RHA are very sensitive to both the characteristics (i.e, frequency content, amplitude, duration etc) of the suite of earthquake ground motions used and the assumptions made in modelling the cyclic response of RC members; thus the discrepancies associated with structural response are often large.

On the other hand, the applicability of nonlinear static analysis is limited by its:

- incapability of considering the contribution of higher than the fundamental modes and insensitivity to the dynamic characteristics of the structure.
- problematic application to three-dimensional, non-symmetrical or irregular systems.

As a result, in most realistic cases, “standard” nonlinear static (pushover) analysis (SPA) can only provide a rough estimate of the inelastic response, and more accurate procedures have to be followed.

2.2 Modal Pushover Analysis for the seismic assessment of bridges

Given the above limitations, as already mentioned, Chopra & Goel [1], [2] developed an improved Modal Pushover Analysis (MPA) procedure where the total seismic demand of inelastic systems is computed based on the combination of individual “modal” demands. With a series of adaptations and further assumptions, the method was extended for the assessment of the inelastic response of bridges ([3], [4]). The main steps of this method are summarized in the following [3]:

- *Step 1:* Calculation of the “elastic” natural periods T_n and the modes φ_n of the bridge. Due to the physical characteristics of bridges, the number of modes that need to be taken into account during the procedure may reach even a few hundred modes, until the total mass contribution sums up to a level of at least 90%, which is considered to be adequate.
- *Step 2:* Separate SPA are performed for each significant mode of the bridge, from which the base shear force – control node displacement relationship ($V_{bn} - u_{rn}$) is extracted, in order to form the pushover curve that corresponds to each mode.
- *Step 3:* The pushover curve is transformed appropriately into an idealized bilinear equivalent, so that the yield point and the ductility factor can be obtained.
- *Step 4:* The earthquake displacement demand is defined. The idealized pushover curve of the multi-degree-of-freedom (MDOF) system is converted into a capacity diagram of the equivalent single-degree-of-freedom (SDOF) system, using the following relationships:

$$S_a = \frac{V_{bn}}{M_n^*} \quad (1)$$

$$S_d = \frac{u_{rn}}{\Gamma_n \cdot \varphi_{rn}} \quad (2)$$

wherein S_a and S_d are the spectral acceleration and displacements, correspondingly, φ_{rn} is the value of φ_n at the monitoring point, $M_n^* = L_n \cdot \Gamma_n$ is the effective modal mass, $L_n = \varphi_n^T \cdot m$, $\Gamma_n = L_n / M_n$ and $M_n = \varphi_n^T \cdot m \cdot \varphi_n$ is the generalized mass, for the n^{th} natural mode. In this way, by applying the capacity spectrum method ([6], [7]) it is possible to estimate the displacement demand corresponding to the applied earthquake intensity.

- *Step 5:* The displacement demand of the n^{th} mode inelastic SDOF system that was calculated in the previous step is converted back to the peak displacement of the monitoring point u_{rn} of the MDOF representing the actual bridge.
- *Step 6:* The values of the desired responses r_n are extracted from the analysis step at which the displacement at the monitoring point is equal to u_{rn} defined in Step 5.
- *Step 7:* Steps 3 to 6 are repeated for all the modes considered “important”.
- *Step 8:* An appropriate modal combination rule, such as SRSS or CQC, is applied to the peak modal responses r_{no} (i.e., for displacements and plastic hinge rotations) that correspond to each “important” mode, in order for the total value of the desired response to be estimated.

The procedure described briefly in the aforementioned steps is subjected to a number of important key-factors that should be taken into account while performing the analysis, such as the appropriate selection of the monitoring point (i.e., deck mass center, top of the nearest pier, location of maximum displacement etc) for each pushover analysis or the rule that is used during the idealization of the pushover curves. Further investigation of the details that describe MPA is beyond the scope of the present work. However, wherever applicable, additional reference to the specifications, which were followed along the development of the MPA software, will be made.

3 INTRODUCTION TO THE SAP2000 APPLICATION PROGRAMMING INTERFACE

Facing the challenge of developing new, more accurate and, inevitably, more sophisticated procedures for the needs of structural engineering does not come at no cost; the need for computational power and the subsequent requirement to embrace bleeding-edge technology tools and resources are demanding. Reversing the argument, it is this very availability of increasingly productive computational systems that motivates the researchers to investigate more advanced and optimized tools for the assessment of structures, leading in this way to a recursive pattern of development and adoption of new information technologies achievements. Furthermore, the need of simplifying the application of available procedures and making effective use of the computational methods already established is not to be neglected, as this can greatly improve the productivity and quality of performing every-day tasks. In this direction, the recently introduced computational tool SAP2000 API, which accompanies the structural analysis software SAP2000 as of version 11, has come to significantly expand the usage of its parent-application into wider research fields beyond the structural analysis framework currently established.

3.1 Description of the SAP2000 API

The SAP2000 Application Programming Interface (API) is a programming tool which aims to offer efficient access to the analysis and design technology of the SAP2000 structural analysis software, by allowing, during run-time, a direct bind to be established, between a third-party application and the analysis software itself [Fig. 1]. Additionally, through the use of this API, one has the option of developing plug-ins, which extend the program's usability and are totally embedded within the SAP2000 environment. In terms of computer programming, the API consists of a software library that offers access to a collection of objects and functions capable of “remotely” controlling the way that the SAP2000 behaves, thus, overriding the standard point-and-click procedure. A highlight of the main features that the API provides are summarized below:

- Direct, fast and robust coupling with the SAP2000 design and analysis methods.
- Two-way data flow as it can be used to facilitate both pre- and post-processing procedures.
- No need of using intermediate files, which reduces significantly the time needed for data exchange when working on large models.
- Compatibility with most major programming languages.
- Concurrent data transfer and control of a structural model by different third-party applications.
- Development of third-party applications that will remain compatible with future releases of SAP2000.
- Ability to develop a custom interface for SAP2000, calibrated to the user's needs, or to embed one in an application that allows for user programming.

3.2 Using the SAP2000 API

In order to make use of the above SAP2000 API features for developing new computing tools, usually a solid programming background is required, as the process may prove demanding, in terms of programming skills. However, this is not always the case, when it comes to simple computing tasks. In either case, the SAP2000 API offers a broad range of programming languages that it can be used which cover the vast majority of the modern software development options including Visual Basic.NET, Visual Basic for Applications (VBA), Visual C#, Visual C++, Visual Fortran and Matlab.

To get started with, accessing the API requires nothing more than a functional SAP2000 installation, as all the components that it consists of are automatically installed during the main program's setup. Using it, however, depends at large on the programming language that the developer is familiar with and the programming environment that is selected for this purpose. Different integrated development environments (IDEs) offer several options in order for the programming project to link successfully with the API and, additionally, in each case the syntax to be used and the potential planning of the application to be developed differ according to the language's standards. One should bear in mind, however, that in order to make effective use of the API it may be appropriate that the programming style, to which one is accustomed to, has to be adapted to the way the API is structured, due to its non-deviant attitude, regarding the SAP2000 approach to designing an assessing a structure; in any case though, the steps necessary to accomplish a task via the API resemble vastly the corresponding point-and-click procedure required by the standard usage of the parent-application.

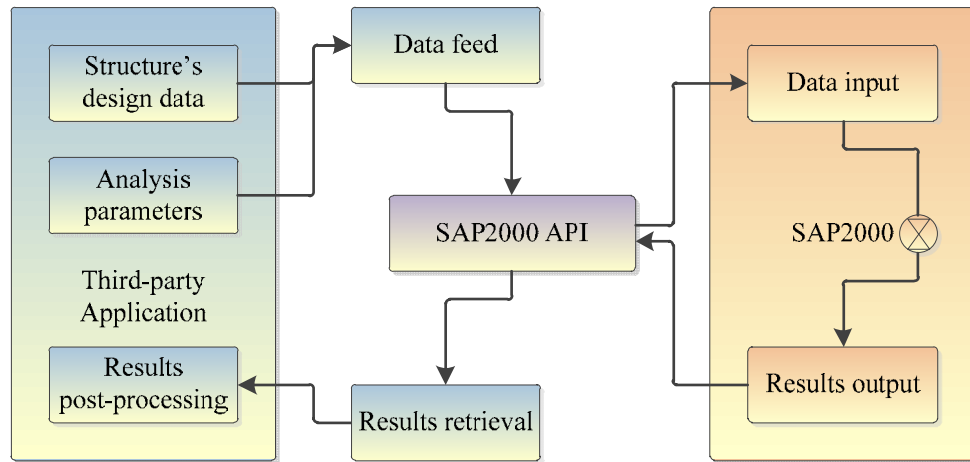

Figure 1: Application binding and typical data flow using the SAP2000 API.

As a general assistant in utilizing the SAP2000 API, a detailed documentation file is also provided along with the installation (SAP2000_API_Documentation.chm) including all the required information that will assist in getting accustomed to the API programming. This guide is to be used side-by-side when developing SAP2000 collaborated software, as it contains a full list of every single function provided, accompanied by its exact syntax, a detailed description of the arguments that it handles and a commented example of usage.

4 MODAL PUSHOVER ANALYSIS IMPLEMENTATION

Implementing an innovative scientific method requires thorough planning and well-balanced decisions to be made, regarding the usability, flexibility and layout of the final product. Developing software capable of applying the MPA procedure to bridges involves taking into account a considerable amount of analysis parameters, storing and manipulating a large number of variables and ensuring that access is granted to important information at every stage of the analysis. Herein, an effort for simplicity and integrity to be respected has been made, while fulfilling the need for optimizing and supervising the applied procedure.

4.1 Software architecture

The scheme chosen, so as to implement the MPA method, consists of an application arranged in modules, separated according to the tasks that are intended to perform. The analysis flow is controlled through an interactive graphical user interface (GUI), which consists of a main window that contains all the components necessary to define and review the analysis procedure. Linked to the interface is an external graphics component, which is used in order to visualize the bridge's deck deformation during the various analysis cases, while the pre- and post-processing is made entirely inside a separate dynamic link library (DLL) that binds the interface with the SAP2000 software. This is accomplished through the use of the SAP2000 API, which aims to regulate the flow of data within the bipartite scheme [Fig. 2].

The user is expected to interact entirely with the interface provided, while SAP2000 runs silently in the background of the operating system's desktop, throughout the analysis runtime. What is more, the required actions related to the manipulation of the SAP2000 model file are transferred, via the API, to the MPA software's interface. However, if needed, the user is allowed to bring the SAP2000 interface to the foreground, in order to make explicit definition of any advanced parameters that the MPA software does not provide, gaining, thus, complete control over the procedure.

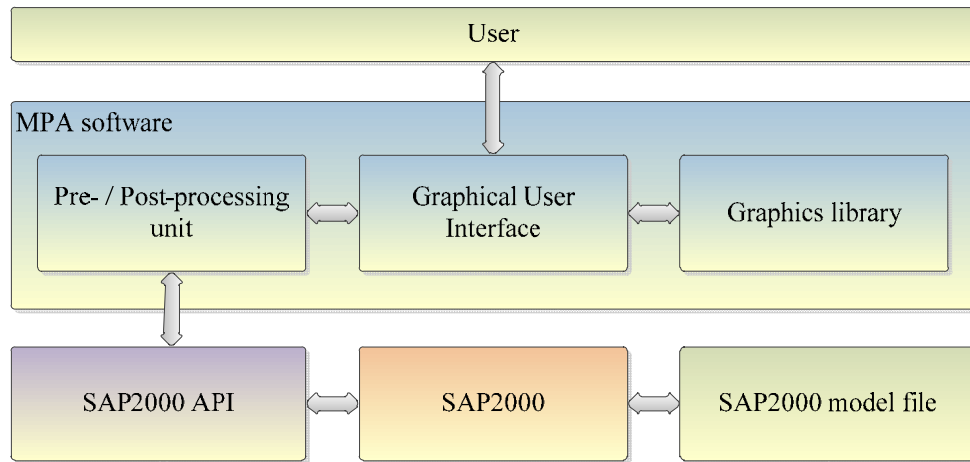

Figure 2: Modal Pushover Analysis software structure.

4.2 Description of the implementation

Researching and developing an innovative computational method is one thing, implementing one, however, into productive software requires combining a variety of different development tools in a way that sticks to the procedure. Furthermore, using the SAP2000 API, while expands greatly the computational power that lays before the engineer, raises the limitation of having to follow the SAP2000-way of arranging the analysis flow. In respect to the MPA procedure and taking the above into consideration, the approach that was selected in order to implement the analysis method concluded to an application providing the following features:

- Direct collaboration between the application and the SAP2000 suite, by making use of the dynamic data exchange capabilities that the API offers.
- SAP2000 model's loading and specification of the appropriate analysis parameters.
- Automated selection of the modes which are deemed as "important", allowing the user to interfere manually as needed.
- Automated creation of the necessary analysis cases, modal and non-linear, as well as using pre-run, user-specified cases.
- Visualization of intermediate steps' results, where applicable, in order to provide adequate information for the user's supervision of the procedure.
- Embedded calculation of the Design Spectrum required for the analysis, according to the EC8-Part 1 specifications [8], or making use of a spectrum data-file.
- Automated application of an appropriate combination rule, in order to calculate the analysis' final results – SRSS and CQC included.
- Visualization of the final deck deformed shape.
- Results' extraction to file, using plain text or comma-separated values format.

Finally, the implementation of the aforementioned was arranged as described by the following flowchart [Fig. 3]:

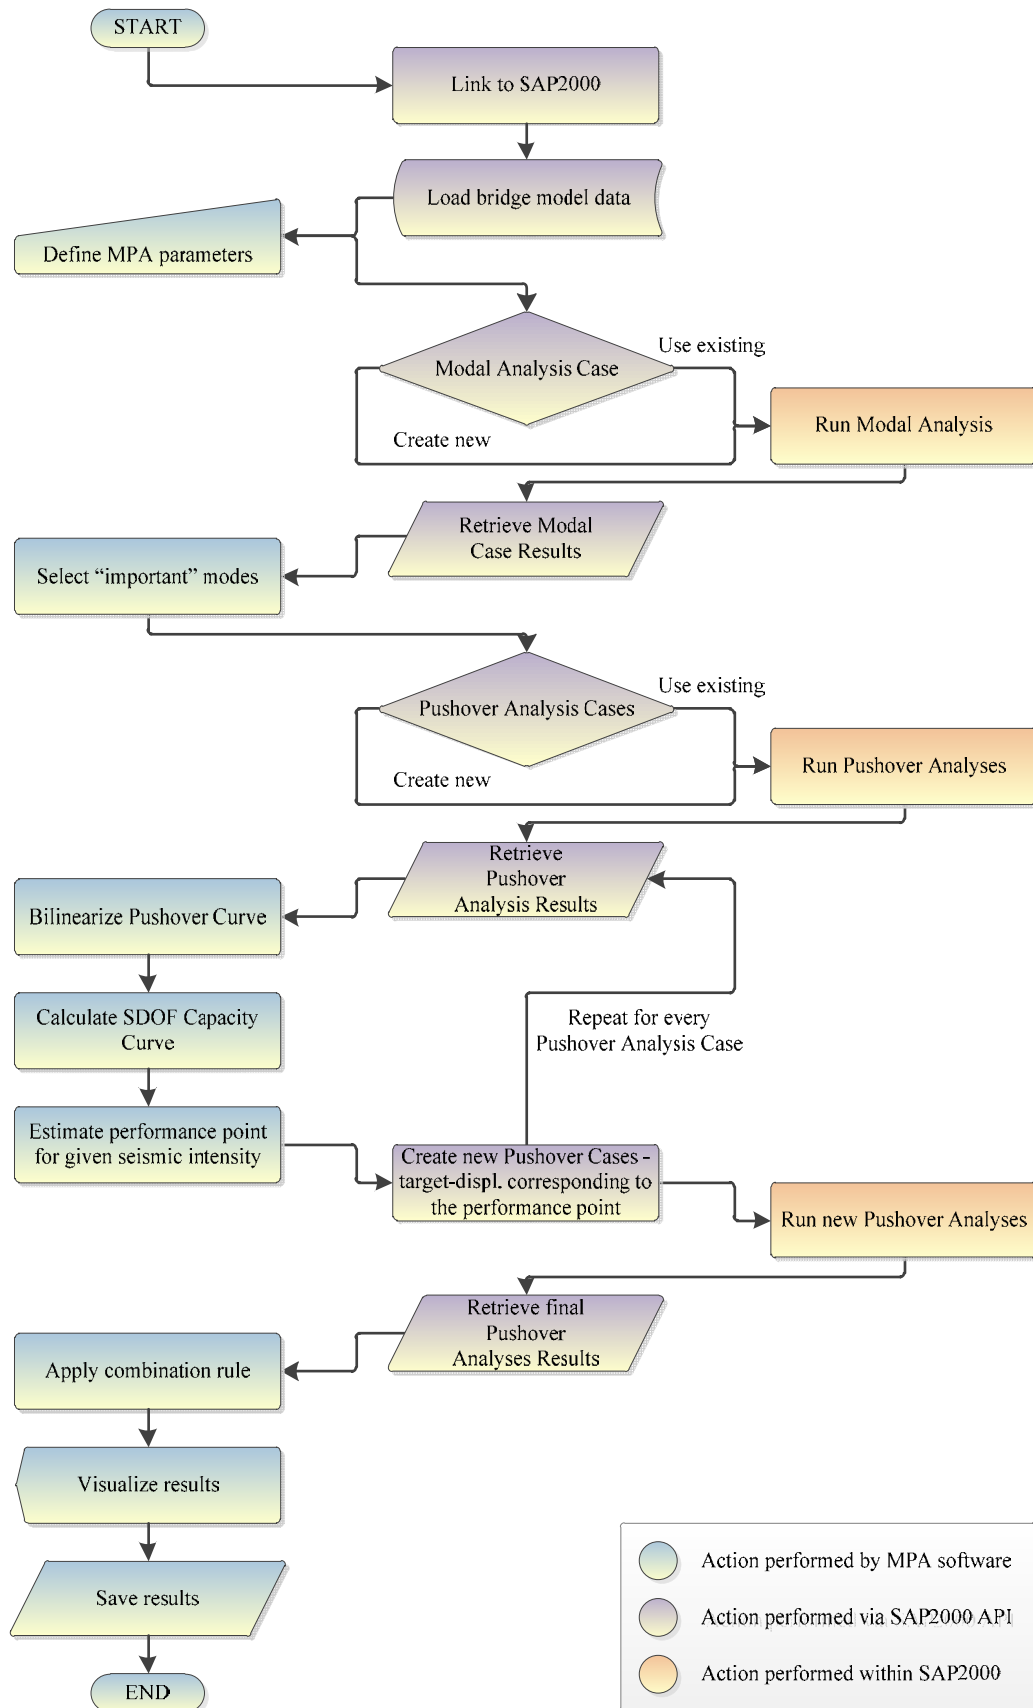

Figure 3: Modal Pushover Analysis software flowchart.

5 APPLICATION FOR THE CASE OF AN EXISTING BRIDGE

In order to investigate the accuracy and efficiency of the software developed around the MPA procedure, it was deemed appropriate to estimate the seismic assessment of an actual bridge structure, whose physical characteristics result to a reasonable contribution of higher modes. What follows is the description of the analysis procedure through the MPA software.

5.1 Description of studied bridge

The bridge selected for this task is a typical straight, three-span, symmetrical bridge, constructed of reinforcement concrete, that belongs to the highway network of EGNATIA ODOS A.E. (bridge T7). Its length sums up to 99.00m, divided into spans of 27.00 – 45.00 – 27.00 m, while the deck consists of a 10.00 m wide pre-stressed concrete box girder section. The deck has a slope of 7%, along the longitudinal direction, and it is supported by two solid piers of circular section, P1 and P2, of length 7.94 m and 9.34 m, accordingly, which are linked in a monolithic way, while each of the bridge's edges, A1 and A2, lay on two laminated elastomeric bearings [Fig. 4].

5.2 Preparation of the bridge model

Prior to performing any task within the application, it is necessary to have the structural model of the bridge properly prepared, in accordance to certain standards that will allow for its usage. This can be summarized into the following steps:

- Definition of the geometrical characteristics of the structure, within the SAP2000 application, including the applied sections, the required non-linear hinges etc.
- Creation of a new object group, named “DECK”, to which all the nodes, that the bridge's deck consists of, will be assigned.
- Definition of the gravity loads of the structure, in the form two Load Patterns named “G” and “Q”, referring to the constant and moving loads applied, accordingly.
- Subsequently, a new non-linear load case named “GRAV” is required in order for the gravity loads to be applied, which, however, can be created either manually or automatically via the MPA software's interface, at a later stage of the procedure.
- Saving the model into a new file, with the extension “.sdb” and terminating the execution of SAP2000.

Figure 4: Three-span bridge model for the case of the T7 bridge along the Egnatia Highway in Greece.

After performing the steps described above, and in order to bring the model into a form able to be utilized, the file can be loaded into the MPA software. This is accomplished by running the application and using the menu “File → Open”, which will prompt for locating the file previously created. Following this, SAP2000 will be executed at the background of the operating system’s desktop and, via the API, the bridge model will be eventually loaded. When every parameter needed has been retrieved, the un-deformed shape of the bridge’s deck will be displayed at the center of the main window.

5.3 Definition of analysis parameters

Coming after the proper setup of the bridge model is the definition of the MPA parameters that is accomplished through the “Options” window, which emerges by selecting the sub-menu “Analysis → Options”. The parameters to be applied are grouped into tabs, in accordance with the intermediate stages of the MPA procedure. An effort has been made, in order to keep the analysis parameters required to a minimum, self-explanatory but adequate level.

For the bridge that was selected for testimonial reasons, the selected options defined in the “General” options tab will lead to a MPA along the “Y” directional “Degree Of Freedom” (DOF) of the bridge, as defined by SAP2000, using the “Advanced Solver” offered by the same analysis software and applying a “SRSS” combination rule at the end of the procedure, in order for the final displacement of the deck nodes to be estimated [Fig. 5a].

Subsequently, the parameters required for performing the modal analysis are defined as creating a new Modal Load Case, which will calculate the structure's natural modes up until the 99% of the participating mass ratio of the structure is reached, according to the pre-selected direction (Y). Among the modes that will be retrieved, those that sum up to a level of 97% will be selected as “important”, excluding those that participate less than 1%, in order to avoid computational instability during the remaining procedure [Fig. 5b].

Regarding the intermediate pushover analysis cases, for this particular bridge $P - \Delta$ effects are excluded, while the monitoring point is defined, for each case, as the node that presents maximum modal displacement according to the corresponding mode. Additionally, the previously-defined Load Case “GRAV”, referring to the gravity loads, is selected as the starting point of each Pushover Analysis case [4][Fig. 6a].

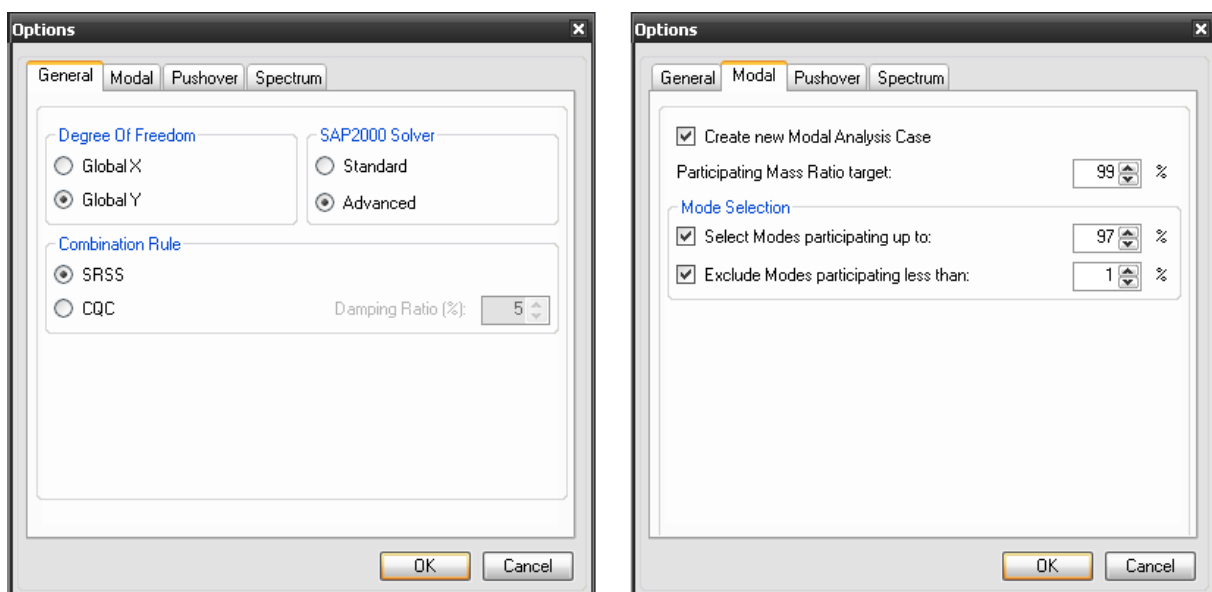

Figure 5: Definition of General and Modal Analysis parameters.

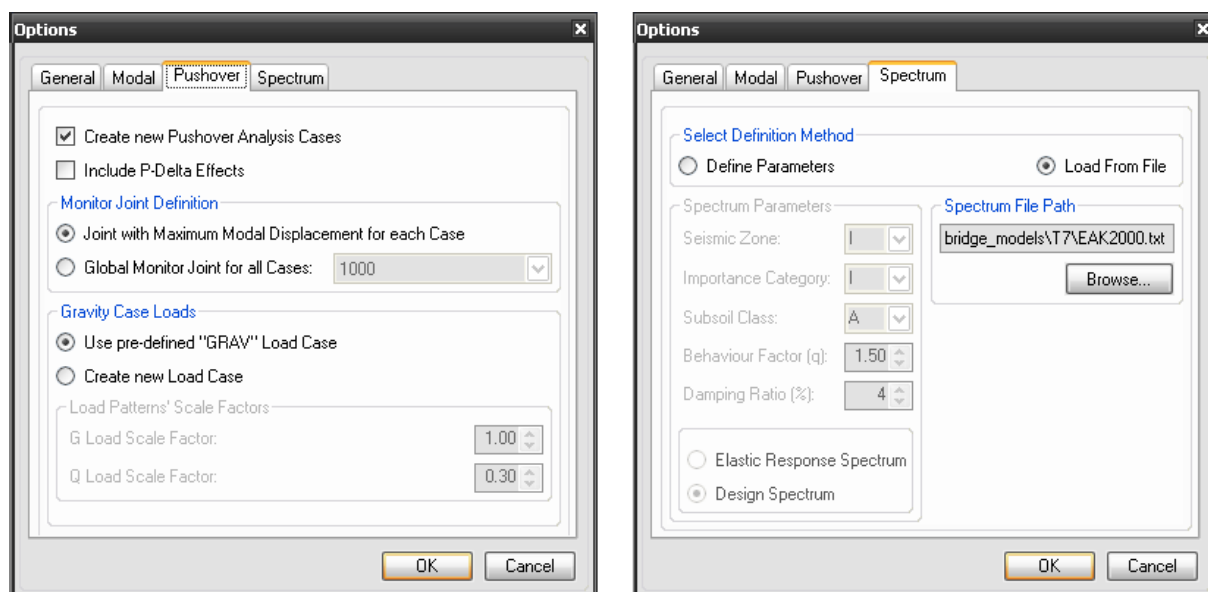

Figure 6: Definition of Pushover Analysis cases and Design Spectrum parameters.

Finally, using the “Spectrum” tab, an appropriate Design Spectrum data file is located on the system, which will be used in order to define the displacement demand for a given earthquake intensity. Alternatively, a spectrum following the EC8 specifications could be defined through the appropriate field that is provided [Fig. 6b].

5.4 Performing the analysis

After the parameters’ definition is complete, selecting the menu “Analysis → Run → Modal Analysis” triggers the MPA procedure to begin, by firstly performing the Modal Analysis. With the completion of the analysis, the modal data of the bridge are retrieved and a list of the computed modes is displayed, allowing for the viewing of the mode-shapes through the main window’s graphics component. What comes next is the selection of the modes considered “important”, according to the user’s preference; this can be done in addition to the program’s prior automatic selection, which resulted, in this case, in pre-selecting the first three modes of the bridge, summing up to a percentage of 97.4% total mass contribution of the structure [Fig. 7].

When the desired modes have been selected, through the “Analysis → Run → Pushover Cases” sub-menu, the procedure continues to performing the separate Pushover Analysis Cases, one corresponding to each selected mode. This stage is the most time-consuming of the MPA procedure and it vastly depends on the bridge’s characteristics as well as on the “SAP2000 Solver” engine that was previously selected [Fig. 8].

By completing this step, the MPA software automatically proceeds to retrieving the pushover curves, for each case, their bi-linearization, according to the FEMA 356 [6] specifications, and the estimation of the peak displacement of the monitoring point. Subsequently, the desired node displacements are extracted and the analysis concludes by applying the combination rule that was selected, in this case a SRSS combination [Fig. 9].

The results of the MPA procedure, as well as the results of the intermediate non-linear static cases can be reviewed by the time the analysis is complete. By selecting the menu “View”, the user is capable of exploring the individual steps performed, which will provide useful data, adequate to indicate whether the analysis followed the desired or estimated route. Moreover, a graphical display of the deck’s final deformed shape, as assessed by the MPA software, is

available for visual evaluation of the analysis results. Finally, by selecting the sub-menu “File → Export Results”, the estimated displacement of the deck’s nodes can be saved in a file, using either a simple text format (.txt) or a “comma-separated values” format (.csv), which is suitable for inserting the extracted data in a spreadsheet application, should any further processing is considered necessary.

6 CONCLUSIONS

The aim herein was to introduce a new, effective approach to developing software for the seismic assessment of bridges, by implementing modal pushover analysis. The aforementioned was achieved by making use of some of the latest technology available in software development for engineers, such as the SAP2000 Application Programming Interface. In order to fulfil the targeted scope, a new application has been developed, capable of controlling the SAP2000 workflow through its API, while performs pre- and post-processing of the relative data. What is to be noted is that, as the use of generic programming tools has solely been made, the following conclusions are to be taken into account in virtually every case of modern procedures' implementation, through SAP2000 API, and are summarized as such:

- MPA proved a balanced example of a procedure strenuous enough, yet able to be divided to logical, repetitive subtasks, in order for being worthy of implementing via SAP2000 API. What is more, the benefits that occur by automating the procedure include the potential of improving faster and more efficiently its further, in-depth investigation.
- Developing software that is built around the SAP2000 platform, through its API, is considered feasible and, with most modern programming languages being supported, getting started with developing new earthquake engineering software should be a fast and effective task, at least for an engineer with reasonable programming skills.
- As the SAP2000 API is a generic programming tool able to control the internal structure of the analysis software that is bound to, programming style may need to be adapted to the API's guidelines, in order to allow for a productive development route. Moreover, prior experience to using the SAP2000 application is considered necessary, as the API's approach "mimics" the standard point-and-click procedure.
- Thorough consideration of every aspect, regarding the method's specifications, prior to commencing any engineering programming attempt, is crucial and can make the difference between easy-flowing and stalling development; setting clear and realistic goals during planning the software is essential, in order to achieve a well-balanced relationship

between time investment and productivity. Furthermore, forming collaborative development teams of experts, covering every scientific aspect encountered, is an effective the path to be taken, if possible, in order to maintain a flexible, and productive scheme.

- Finally, the importance of human supervision over the application of any scientific procedure, performed by computational tools, is not to be neglected, especially in cases that quantifying a problem's solution approach cannot be deemed adequate; the user's capability of parameterizing appropriately the MPA procedure, selecting applicable analysis variables, interfering with the software's pre-selected options and, above all, interpreting the analysis results to a meaningful perception are the most important factors of the analysis.

7 ACKNOWLEDGEMENTS

The authors would like to acknowledge the contribution of Andreas Kappos, Professor at the Civil Engineering Department of Aristotle University Thessaloniki and Mrs. Themelina Paraskeva, Ph.D. candidate at the same department for their precious feedback regarding the applicability and efficiency of the software developed.

Keywords: pile foundation, kinematic interaction, rocking, soil-structure interaction

Abstract. *The scope of this study is to investigate the response of RC bridges, founded on single cast-in-drilled-hole (CIDH) piles, under simultaneous earthquake-induced translational and rocking excitation. This rotational excitation results from pile bending under vertically propagating S-waves which, in turn, is dependent on pile's relative flexibility with respect to the surrounding soil, a phenomenon known as "kinematic interaction". Typically, the rotational component of seismic excitation of the superstructure is not taken into consideration; neither is it prescribed in any of the modern seismic codes, despite the fact that analytical solutions have been proposed in the literature. Moreover, the potential impact of such a pile-induced rocking of CIDH supported bridges has also not been quantified yet. Along these lines, an effort is made in this paper to present an analytical and computational framework for parametrically studying both: (a) the nature of the rotational excitation component and: (b) the additional displacement demand imposed to the superstructure. For this reason, a Matlab-based program is developed and the lateral response of multiple 4-DOF oscillators representing typical bridge structures is analytically studied, for various scenarios of excitation frequencies, superstructure height and soil stiffness. The resulting displacement demand is then compared to the displacements that would develop by ignoring the rotational component of ground excitation). From the set of parametric analyses conducted, it is concluded that ignoring kinematically induced rocking, transverse deck displacements may be significantly increased, especially in frequencies associated with the dynamic characteristics of the soil and the superstructure.*

1 INTRODUCTION

Bridge construction industry comprises nowadays the second most demanding construction sector in terms of overall investment; therefore, the safety of bridges constitutes a field of extensive research worldwide. Following a series of catastrophic earthquakes around the world (San Fernando 1971, Loma Prieta 1989, Costa Rica 1990, Northridge 1994, Kobe 1995, Ko-

caelli 1999, Chile 2010, Japan 2011) that caused serious damage and collapse in numerous bridges, the safety issue becomes more emerging. The reason is that bridges are part of commercial and transportation networks whose vulnerability determines the level of social impact that can be caused by a seismic event. As a result, nearly all modern seismic codes prescribe means to ensure a target level of performance related to bridge integrity and serviceability for various levels of earthquake loading, so that the probability of massive human loss is reduced and the disruption of the social and financial activity is as limited as possible.

Bridges, despite their relatively simple structural system compared to buildings, may exhibit quite complex seismic response due to their larger dimensions, their various non-linear mechanisms (stoppers, shear keys, gaps, bearing-type connections), the more significant contribution of higher modes, their higher sensitivity to the spatially variable properties of the surrounding soil and ground motion, the high soil compliance, as well as to the overall topography of the area crossed. As a result, it is not uncommon that the overall superstructure-foundation-subsoil system is studied as a whole and the dynamic interaction among its sub-components is taken into consideration. Research on the dynamic interaction of such systems has long been studied; significant progress was achieved thanks to field observations, structural health monitoring data and strong ground motion records obtained during major seismic events [1-3]. Moreover, analytical solutions and advanced numerical simulation models have been developed [4-6] with particular emphasis on the response of pile foundations [7-14], lateral spread of soil [15], lateral excitation in layered deposits [16-19] and soil liquefaction [20-23]. Experimental results, involving complex bridge structures and pile foundations, are also currently available [24-26] while significant research effort was shed light in the nature of kinematic soil-pile interaction [27-31].

Despite the extensive research, an issue that has not yet been thoroughly studied is the additional rocking that is imposed to the bridge superstructure due to earthquake-induced pile bending. In particular, it is well known that the presence of a pile foundation modifies the amplitude and frequency content of the incoming seismic waves, thus resulting into a “Foundation Input Motion” that is different from the free field one, while analytical expressions have been proposed for computing the aforementioned additional pile head rotation [32]; still, however, there is no comprehensive approach available for practical purposes that can simultaneously account for the translational and rotational component of seismic acceleration neither has this effect ever been quantified for the case of realistic structures. This approach would be of particular use, especially for bridges supported on cast-in-drilled-hole (single) pile foundations, a common design alternative, primarily in the U.S.

Along these lines, the scope of this paper is to:

- (a) present a comprehensive methodology and computational framework for considering the translational and rotational excitation of the soil-pile-superstructure system, and
- (b) highlight those cases where ignoring the rotational component of seismic excitation, the displacement demand imposed to the superstructure may be significantly underestimated.

The fundamental concepts of the approach as well as the parametric analysis scheme and the subsequent results, are presented in the following.

2 PROBLEM VARIABLE DEFINITION

The study of pile-induced pier rocking requires definition of different variables that can be grouped into four major categories, specifically relating to the soil, the foundation, the superstructure (in terms of both material and geometry) and seismic excitation (primarily defined in terms of frequency). It is noted that some of these variables are dimensional, while others are dimensionless, as summarized in Table 1 below. The fundamental dimensions of the variables involved are mass (M), time (T) and length (L).

Variable category	Variable	Dimensions	Fundamental dimensions	Kind of variable
Super-structure	Modulus of elasticity, E	kN/m^2	M, T, L	Dimensional
	Mass of superstructure, m	t (of mass)	M	Dimensional
	Pier height, h	M	L	Dimensional
	Pier density, ρ	kg/m^3	M, L	Dimensional
	Pier material damping, ζ	%	-	Dimensionless
Foundation (RC CIDH pile)	Modulus of elasticity, E_p	kN/m^2	M, T, L	Dimensional
	Pile diameter, d_p	M	L	Dimensional
	Poisson's ratio, ν_p	-	-	Dimensionless
	Density, ρ_p	kg/m^3	M, L	Dimensional
	Material damping, ζ_p	%	-	Dimensionless
Soil	Modulus of elasticity, E_s	kN/m^2	M, T, L	Dimensional
	Stratum thickness, H_s	M	L	Dimensional
	Poisson's ratio, ν_s	-	-	Dimensionless
	Density, ρ_s	kg/m^3	M, L	Dimensional
	Material damping, ζ_s	%	-	Dimensionless
Excitation	Cyclic frequency, ω	T	T	Dimensional

Table 1: Problem Variables

Due to the fact the seismic excitation is assumed sinusoidal, its cyclic frequency, ω , is used to characterize the excitation; the amplitude of the pulse is irrelevant since the analysis is linear elastic. Based on the above, a total number of 11 dimensional and 5 dimensionless variables is derived, in particular: E , m , h , ρ , E_p , d_p , ρ_p , E_s , H_s , ρ_s , ω and ζ , ν_p , ζ_p , ν_s , ζ_s respectively. Eventually, it is only 9 out of 11 different dimensional variables that remain as part of the problem, due to the fact that the (concrete) material between the superstructure and the pile is identical, hence, it can be assumed that $E=E_p$.

In the framework of the parametric analysis conducted herein, the modulus of Elasticity of concrete was taken equal to $E_p=29\text{GPa}$, thus corresponding to a concrete strength of $f_c=20\text{MPa}$, while the stiffness of the soil, as expressed by the shear wave velocity V_s , was assumed to parametrically vary between 100 and 250 m/sec. It is recalled out that circular frequency of the soil ω_{soil} is expressed as:

$$\omega_{soil} = 2\pi V_s / 4H \quad (1)$$

where H the (uniform) soil stratum thickness, as defined in Table 1.

3 ANALYSIS OUTLINE

Rocking of a bridge supported on CIDH piles occurs along both longitudinal and transverse direction, however the latter is more critical the lower level of redundancy. It is therefore the transverse response of the bridge that is studied herein, assuming a 4-degree-of-freedom oscillator, with translational and rotational DOFs at the locations of its two concentrated masses, one at the top of the pier and one at its bottom as it is seen in Figure 1 (m , J_m , m_p and J_{mp} being the mass and moments of inertia of the pier top and base respectively, h denotes the oscillator height, e the eccentricity that eliminates the conjugation stiffness term K_{xy} , E the pier modulus of elasticity, ζ the damping ratio, b the pier diameter, and D the pile diameter. The spring properties required for providing the translational (K_{xx}) and rotational (K_{rr})

stiffness of the soil-pile system are derived using appropriate equations from the literature [32].

Figure 1: Overview of the system studied and the related variables and degrees of freedom.

The so-called kinematic response factors, I_u for the translational and I_θ for the rocking seismic component which express the frequency-dependent translational and rotational amplification of motion compared to that of the free-field are also derived based on expressions proposed in the literature [32]. As the pile of diameter d is assumed to be excited by vertically propagating, harmonic S-waves with amplitude U_r and frequency ω , the rotation that is eventually imposed to the superstructure can be simply derived as [18]:

$$\theta(t) = 2I_\theta(\omega)U_{ff}(z=0)/d_p \quad (2)$$

for each time step, t of the incoming harmonic motion. The overall process to derive the rotational excitation time history can be summarized in the following successive steps described below.

1st step: Assessment of the relevant problem variables (related to the soil, foundation, superstructure and seismic excitation) as it described in Table 1.

2nd step: Calculation of the pile moment of inertia and mass:

$$\begin{aligned} I_p &= \pi d_p^4 / 64 \\ m_p &= 25 \left(\frac{\pi d_p^2}{4} \right) L / g \end{aligned} \quad (3)$$

where L : length of the pile (assumed equal to the thickness of the stratum, H_s)
 g : acceleration of gravity

3rd step: Assessment of soil modulus of elasticity E_s and shear wave velocity V_s

4th step: Calculation of the free field motion at the surface ($z=0$) for each frequency ω in the time domain [33]:

$$U_{ff} = U_r e^{i\omega t} = \left(\frac{U_g}{\cos \frac{\omega}{V_s^*} L} \right) \cos \left(\frac{\omega}{V_s^*} z \right) e^{i\omega t} \quad (4)$$

where U_{ff} : free-field motion amplitude
 U_g : amplitude of the bedrock motion (i.e., base of the soil stratum)
 z : depth from the ground surface

5th step: Calculation of the foundation impedance functions assuming a Beam on Dynamic Winkler Foundation [34]:

$$S_x = k_x(\omega) + i\omega c_x(\omega)$$

where $k_x = \delta E_s$, $\delta = 1.67 \left(\frac{E_p}{E_s} \right)^{-0.053}$

$$c_x(\omega) = 2a_0^{-1/4} \rho_s V_s d_p \left[1 + \left(\frac{V_{La}}{V_s} \right)^{5/4} \right] + 2\zeta_s \frac{k_x}{\omega} \quad (5)$$

$$a_0 = \frac{\omega d_p}{V_s} \text{ and } V_{La} = \frac{3.4V_s}{\pi(1-\nu)}$$

6th step: Calculation of the translational, kinematic interaction factor for a free head single pile [35]:

$$I_u(\omega) = \frac{k_x + i\omega c_x}{E_p I_p (q^4 + 4\lambda^4) - m_p \omega^2} \cdot \left[1 + \frac{1}{2} \left(\frac{\omega}{V_s \lambda} \right)^2 \right] \quad (6)$$

where: $q = \frac{\omega}{V_s}$ and $\lambda = \left(\frac{k_x + i\omega c_x}{4E_p I_p} \right)^{1/4}$ (7)

7th step: Calculation of the rocking, kinematic interaction factor for a free head single pile [35]:

$$I_\theta(\omega) = \frac{k_x + i\omega c_x}{E_p I_p (q^4 + 4\lambda^4) - m_p \omega^2} \cdot \left(\frac{\omega}{V_s} \right)^2 \cdot \frac{d_p}{\lambda} \quad (8)$$

8th step: Calculation of the imposed rotation [18]:

$$\theta(t) = \frac{I_\theta(\omega) U_{ff}(t, z=0)}{d_p/2} \quad (9)$$

9th step: Calculation of the translational (K_{xx}) and rotational (K_{rr}) stiffness properties of the soil-pile system springs according to Maravas et al. [32]. It is noted that the discrete sign e which refers to the dynamic impedance terms after appropriate spring-pile head eccentricity and stiffness decoupling:

$$\begin{aligned}
K_{xx} &= 4E_p I_p \lambda^3 \\
K_{xr} &= 2E_p I_p \lambda^2 \\
K_{rr} &= 2E_p I_p \lambda \\
K_{xe} &= K_{xx} \\
K_{re} &= 0 \\
K_{rre} &= K_{rr} - 2K_{xr} \cdot e + K_{xx} \cdot e^2 \\
e &= \frac{K_{xr}}{K_{xx}} = \frac{1}{2\lambda}
\end{aligned} \tag{10}$$

where K_{xx} : translational stiffness of the soil-pile system along the x direction
 K_{xr} : coupled rotational-translational stiffness of the soil-pile system
 K_{rr} : rotational-translational stiffness of the soil-pile system
 K_{rre} : uncoupled rotational stiffness of the soil-pile system
 e : spring-pile head eccentricity

Having defined the translational and rotational foundation input motion and the dynamic properties of the flexible supported bridge structure along the transverse direction, the dynamic response of the 4DOF system can be analytically defined. The equation of motion has the general form:

$$M \cdot \ddot{u} + C \cdot \dot{u} + K \cdot u = p(t) \tag{11}$$

while the initial conditions can be set cast as, $u(0) = 0$ and $\dot{u}(0) = 0$. In this case, the matrix of the displacements relative to the moving base takes the following form, $u = [u \ \theta \ u_p \ \theta_p]^T$ where (u, θ) represent the displacement and rotation of the deck mass and (u_p, θ_p) of the foundation mass respectively. The solution of the equation of motion (11) is given from the well-known Duhamel's integral:

$$q_n(t) = \frac{1}{M_n \omega_{dn}} \int_0^t \tilde{p}_n(\tau) \cdot e^{-\zeta \omega_n(t-\tau)} \sin \omega_{dn}(t-\tau) d\tau, \quad n = 1, 2, 3, 4 \tag{12}$$

Thus, the ultimate, geometric coordinates of the vector $u(t)$ can be written as:

$$u(t) = \sum_{n=1}^N \varphi_n \cdot q_n(t) \tag{13}$$

Assuming that due to the elastic response of the system considered, the damping matrix, C , equals to $C=2m\zeta\omega$, the mass matrix is quadratic and given as:

$$M = \begin{bmatrix} m & 0 & 0 & 0 \\ 0 & Jm & 0 & 0 \\ 0 & 0 & m_p & 0 \\ 0 & 0 & 0 & Jm_p \end{bmatrix} \tag{14}$$

The computation of the stiffness matrix requires the calculation of its individual values, i.e. the generalized stiffness factors of the system, $K_s = [k_{ij}]$, where $i, j=1, 2, 3, 4$. The ultimate

stiffness matrix diversifies for each excitation frequency, as the foundation impedance is frequency dependent. In general however, stiffness matrix maybe written in the following form:

$$K = \begin{bmatrix} \frac{12EI}{h^3} & \frac{6EI}{h^2} & \frac{-12EI}{h^3} & \frac{6EI}{h^2} \\ \frac{6EI}{h^2} & \frac{4EI}{h} & \frac{-6EI}{h^2} & \frac{2EI}{h} \\ \frac{-12EI}{h^3} & \frac{-6EI}{h^2} & \frac{12EI}{h^3} + K_{xx}(\omega) & \frac{-6EI}{h^2} \\ \frac{6EI}{h^2} & \frac{2EI}{h} & \frac{-6EI}{h^2} & \frac{4EI}{h} + K_{rre}(\omega) \end{bmatrix} \quad (15)$$

It is noted that the external load vector $p(t)$ considers both the translational and rotational component of seismic excitation, which for the purpose of linear elastic analysis, can be decoupled and then the individual structural response due to base translation and rotation be superimposed. For instance, the translational seismic component is:

$$-m \cdot \delta \cdot \ddot{u}_0(t) \quad (16)$$

where m is the oscillator (deck) mass, δ the vector of rigid body displacements and $u_0(t)$ the base excitation time history, which is in turn equal to the second derivative of the free-field ground displacement expressed by equation (4). The vector of rigid body displacements, in this case, receives the following form for a unit displacement of the oscillator base.

$$\delta = [1 \ 0 \ 1 \ 0]^T. \quad (17)$$

Similarly to the above, the rocking excitation component is induced separately in the right-hand side of the equation of motion, while the rocking acceleration results from the double derivative of the rotation, with respect to time, as it has been calculated from equation (9) above. For a unit rotation of the pier base, vector δ takes the following form:

$$\delta = [h \ 1 \ 0 \ 1]^T. \quad (18)$$

and the two equations of motion for the two distinct translational and rotational base excitation mechanism can be written as:

$$\begin{aligned} M \cdot \ddot{u}(t) + 2m\zeta\omega \cdot \dot{u}(t) + K \cdot u(t) &= -M \cdot \delta \cdot \ddot{u}_{ff}(t, z = 0) \cdot I_u \\ M \cdot \ddot{u}(t) + 2m\zeta\omega \cdot \dot{u}(t) + K \cdot u(t) &= -M \cdot \delta \cdot \ddot{\theta}(t) = -M \cdot \delta \cdot I_\varphi(\omega) \cdot \frac{\ddot{u}_{ff}(t, z = 0)}{d_p/2} \end{aligned} \quad (19)$$

4 COMPUTATIONAL FRAMEWORK

The above analysis steps are implemented computationally through a specifically developed graphical MatLab environment, a sample of which is illustrated in Figure 2. The user defines the properties of the pile (i.e., modulus of elasticity, diameter, length, density and damping ratio), soil data (expressed in terms of the ratio E_p/E_s , Poisson's ratio, damping, density and shear waves velocity) and the desired excitation frequency range. In turn the program returns the variation of the translational and rotational kinematic interaction factors (I_u and I_ϕ) with the dimensionless frequency $\omega d/V_s$. The translational and rotational excitation time histories are also computed to be used as the foundation input motion to the (spring-supported) superstructure.

Following the computation of the kinematic interaction factors, the seismic response of the 4DOF system representing the pier-foundation-soil is derived for each excitation frequency (Figure 3). The fundamental period of both the fixed and flexibly supported structure is also computed and the maximum response quantities are derived and stored. The resulting displacement maxima are compared to the deck displacements that would have been derived if the conventional approach (i.e., translation-only foundation input motion) was followed. Results are plotted in appropriate diagrams of dimensionless quantities as will be described below.

5 ANALYSIS RESULTS

Having established the analytical and computational framework, a detailed parametric analysis scheme was formed and the effect of rotational excitation was investigated. In particular, the parametric study was performed by modifying four analysis parameters, related to the:

- *Soil stiffness*: of the upper soil layer (taken uniform along the pile height) expressed in terms of shear wave velocity V_s which was taken equal to 100m/sec or 250m/sec, thus corresponding to very soft and medium soft soil conditions respectively. It is noted that the above variation of soil stiffness corresponds to a modulus of Elasticity of the soil E_s , between 2.9MPa (very soft clay) to 29MPa (moderately soft clay), in other words, to a dimensionless variable E_p/E_s lying within the range of 100-1000. (2 cases)
- *Pier Height*: taken equal to 5m, 7.5m, 12.5m and 20m leading, after appropriate mass modification, to fundamental periods in the transverse direction between the range 0.4-2.5sec. (4 cases)
- *Frequency of excitation*: harmonic pulses were used ranging between (0.1-2.0sec), that is, having frequencies 0.5,1,2,3,4,5,6,7,8,9 and 10Hz. (11 cases)
- *Excitation component*: the flexibly supported pier was excited in the transverse direction by (a) the translational, (b) the rotational and (c) the combined translational and rotational components of the foundation input motion. (3 cases)

The analysis of the above $2 \times 4 \times 11 \times 3 = 264$ parametric analysis were plotted in a normalized ratio, versus the dimensionless frequency term ($\omega d/V_s$). The ratio adopted for illustrating the relative effect of the different (i.e., translational and rotational components of the kinematically modified seismic wave field) was:

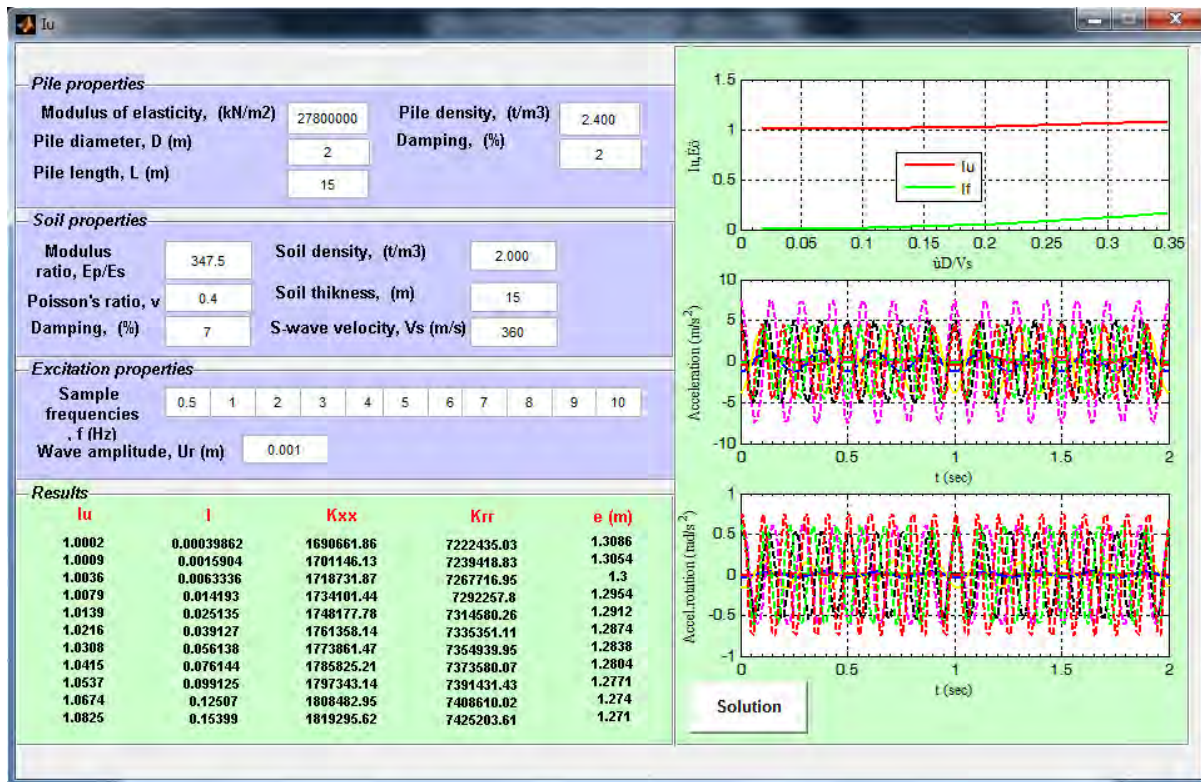

Figure 2 : MatLab application for computing the translational and rotational interaction factors (I_u , I_ϕ) and the subsequent uncoupled dynamic impedance matrix terms (K_{xx} , K_{rre}).

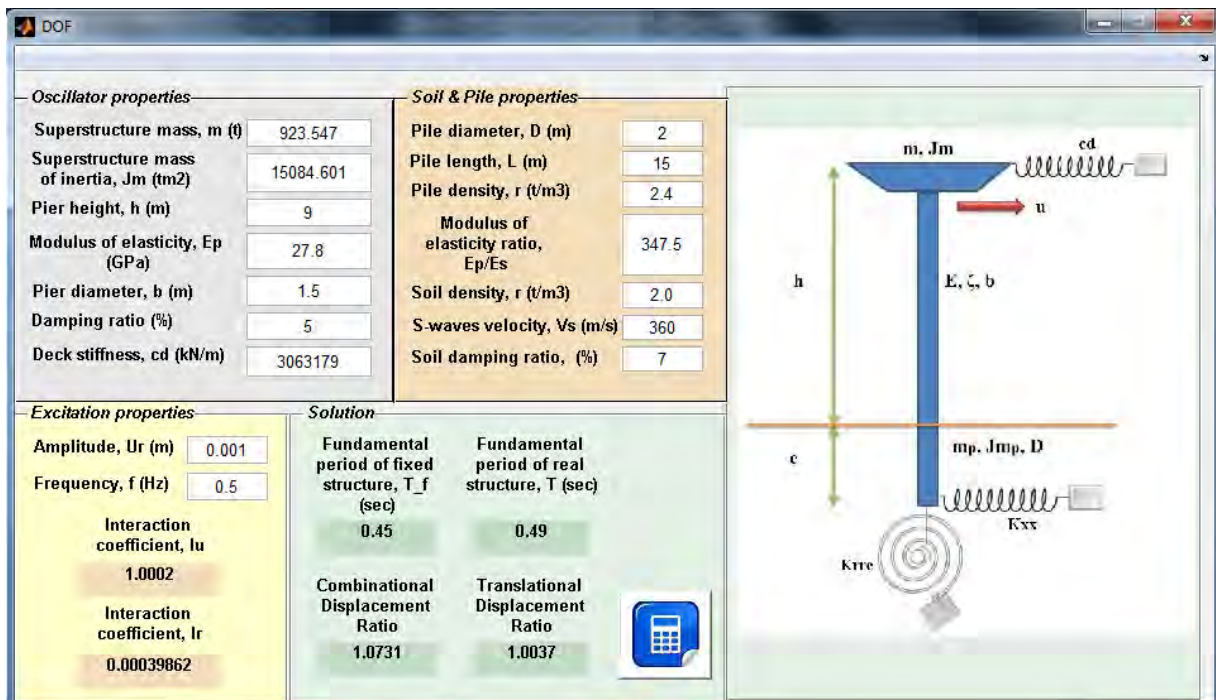

Figure 3 : MatLab-based solution of the soil-pile-superstructure system under combined translational and rotational excitation.

$$I_u = \frac{u_{max, FIM,u}(t)}{u_{max,ff}(t)} \quad (20)$$

expressing the maximum displacement in time of the deck (pier top) when the kinematic interaction between the soil and the pile is taken into consideration and the deck is excited exclusively by the translational component of the foundation input motion (F.I.M.), over the maximum displacement in time of the deck due to free field base excitation (a ratio essentially identical to the standard kinematic interaction factor I_u of equation (6)), and

$$I_{u+\theta} = \frac{u_{max, FIM,u+\theta}(t)}{u_{max,ff}(t)} \quad (21)$$

expressing the maximum displacement in time of the deck (pier top) when the kinematic interaction between the soil and the pile is taken into consideration and the deck is excited by both the translational and the rotational component of the foundation input motion (F.I.M.), over the maximum displacement in time of the deck due to free field base excitation.

The absolute values of pier top displacements are also plotted so that the relative contribution of each excitation component can be assessed. The results are discussed in the following.

5.1 Very Soft Soil, $V_s=100\text{m/s}$

The first set of figures (Figures 4,6,8,10) illustrates the kinematic interaction factors for translational or combined translational base excitation of the bridge pier under study, together with the corresponding absolute displacements of the deck (Figures 5,7,9,11) for decreasing pier heights (i.e., 20m, 12.5m, 7.5m, 5.0m) and a constant, uniform soil profile of $V_s=100\text{m/sec}$. A first observation is that the kinematic interaction factors are significantly higher in the case of combined translational and rotational foundation input motion compared to the conventional approach of translational base excitation only, for the whole dimensionless frequency range $0 < \omega D/V_s < 1.4$. These factors, $I_{u+\theta}$, can exceed the value of 10, at specific frequencies, for the case of a very flexible pier ($h = 20\text{m}$) and decay to 6.5 for the case of stiffer bridge structures ($h = 5\text{m}$) in contrast to the translational kinematic interaction factor which does not exceed 2 in the entire frequency range. This situation is also confirmed by the absolute displacement depicted in Figures 5, 7, 9 and 11 where it is clear that the deck displacements are dominated by the base rotational excitation.

It has to be noted that such a significant effect of rotational excitation cannot be generalized, as the case studied clearly represents the extreme condition where the structure is excited at a single and critical frequency (in contrast to the broad frequency content of an actual earthquake loading), in the transverse direction which is more prone to base rotations due to limited redundancy, while the pier height is significant ($h = 20\text{m}$) and at the same time, the soil is very soft ($V_s = 100 \text{ m/sec}$). One could even argue that in such cases of soft soil profiles, a single CIDH pile wouldn't be a desirable foundation type anyway. As a general trend though, the aforementioned diagrams are

indicative of the fact that the earthquake –induced head rotation of a (single) CIDH pile imposes, apart from the inertial component, an additional rigid body motion to the pier-deck superstructure which has a direct effect on the pier deck displacements as it is proportional to the pier height (i.e., the displacement vector $\delta_{\text{rocking}} = [h \ 1 \ 0 \ 1]^T$). As a result, the importance of rotational foundation input motion in piles casted in soft soils is non-negligible under certain circumstances and has to be further studied.

Figure 4: Displacements ratio as function to dimensionless frequency for $V_s=100\text{m/s}$, $h=20\text{m}$.

Figure 11: Absolute displacements as a function of dimensionless frequency for $V_s=100\text{m/s}$, $h=5\text{m}$.

5.2 Medium Soft Soil, $V_s=250\text{m/s}$

Similarly to the case of soft soil, the same set of parametric analyses were conducted for the case of medium soil, characterized by a shear wave velocity of 250m/sec . The corresponding variation of the kinematic interaction factors with and without the effect of rotational excitation as well as the variation of the absolute bridge deck displacements with the dimensionless frequency is illustrated in Figures 12,14,16,18 and 13,15,17,19 respectively. Again, the impact of rotational excitation on the overall pier top displacements is clearly visible: the combined kinematic interaction factor $I_{u+\theta}$ ranges from 3.8 to 8, always being higher than the conventional I_u which does not exceed 1.1 along the entire frequency range and for all pier heights. On the other hand, as anticipated, this effect of the rotational component of foundation input motion, although significant, is lower than the one observed for the case of soft soil, and as such it is expected to be smaller for stiffer soils as well. The overall (i.e., rigid body and inertial) mechanism described previously, in which the rotational excitation affects the transverse bridge deck displacements, is again confirmed.

6 CONCLUSIONS

A comprehensive analytical study was presented for the rocking effects of seismic motion in reinforced concrete bridges supported on cast-in-drilled-hole piles in homogeneous soil deposits. The study focuses on a 4-degree-of-freedom spring-supported pier subjected to simultaneous translational and rotational foundation input motion. The analytical approach is implemented into a comprehensive computational framework, programmed in Matlab environment, with the use of which a set of linear, elastic analyses was performed for different soil types, dynamic characteristics of the bridge and frequencies of harmonic excitations.

Through the above set of parametric analyses it is concluded that the combined consideration of the translational and rotational seismic components produced by the kinematic response of the pile foundation to vertically propagating S-waves, may reveal specific combinations of excitation frequency content and dynamic characteristics where the additional transverse deck displacements induced by the base rotation can indeed dominate the system response. It was also confirmed that the effect of the rotational component is higher for cases of soft soil profiles and flexible, tall piers.

Further research is certainly needed for quantifying the importance of the rotational excitation, in case of more complex seismic motions, structural systems and foundation types.

Abstract. *This paper addresses the prediction of the seismic collapse capacity of flexible non-deteriorating multi-story frame structures with regular layout, which are vulnerable to the destabilizing effect of gravity loads. The proposed time-saving and yet sufficient accurate methodologies are based on an equivalent single-degree-of-freedom system capable to cover the significant dynamic properties of the structure, and collapse capacity spectra. For a series of generic frame structures the global collapse capacity is assessed both with the proposed methodologies and the computationally expensive Incremental Dynamic Analysis procedure. From the outcomes of both methods it can be concluded that in the initial design process the proposed methodologies are an appropriate tool to assess sufficiently accurate the collapse capacity of P-delta sensitive regular moment resisting frame structures subjected to severe earthquake excitation.*

1 INTRODUCTION

Prediction of sidesway collapse of a structural building induced by severe earthquake excitation is the most prominent challenge in earthquake engineering [1]. Sidesway collapse may be the consequence of successive reduction of the lateral load bearing capacity due to strength and stiffness degradation. In very flexible buildings the destabilizing effect of gravity loads may lead to a negative post-yield stiffness, and thus, the structural collapse capacity is exhausted at a rapid rate when driven into its inelastic range of deformation even for stable hysteretic component behavior [2]. In many buildings the components are successively deteriorated until gravity takes over, and consequently the structure collapses. [1]

The focus of this paper is on the prediction of earthquake induced sidesway collapse of non-deteriorating flexible frame structures, which are vulnerable to the destabilizing effect of gravity loads, or, expressed in other words, vulnerable to the global P-delta effect. For a realistic *elastic* building the P-delta effect is usually negligible. However, it may become of significance for inelastic structural behavior when P-delta induces a negative post-yield slope of the lateral load-displacement relationship.

In earthquake engineering the global P-delta effect has been studied analytically, numerically, and experimentally in a series of papers. Representatively, the publications of Jennings and Husid [3], Bernal [4, 5], MacRae [6], Gupta and Krawinkler [7], Vian and Bruneau [8], and Lignos et al. [9] are cited. Asimakopoulos et al. [10], Villaverde [11], Ibarra and Krawinkler [12], Krawinkler et al. [1], and Haselton et al. [13] provide profound insights into the literature on studies dealing with dynamic collapse of earthquake excited structures. In comprehensive parameter studies, Adam and Jäger [14, 15, 16] treat rigorously the effects of P-delta on the collapse capacity of non-deteriorating SDOF systems, and the results are graphically displayed by means of collapse capacity spectra. In further studies, Adam and Jäger [2, 17] propose the collapse capacity spectrum methodology, based on an equivalent single-degree-of-freedom system and collapse capacity spectra, in an effort to determine the global collapse capacity of regular multi-story frame structures vulnerable to P-delta both time-efficient and yet accurate.

In the presented contribution the application of the original collapse capacity spectrum methodology as introduced in [2, 17] is described in detail. Additionally, a simplified collapse capacity spectrum methodology is recommended. The underlying concepts of equivalent single-degree-of-freedom (ESDOF) systems and collapse capacity spectra are reviewed. Both collapse capacity spectrum methods are evaluated for a series of generic frame structures, and the outcomes are set in contrast to “exact” collapse capacities of corresponding IDA studies.

2 GLOBAL COLLAPSE CAPACITY

2.1 Initial assessment of the structural vulnerability to global P-delta effects [2]

At first it must be assessed whether the considered structure is vulnerable to P-delta effects. Strong evidence delivers the result of a global pushover analysis [7]. During this nonlinear static analysis gravity loads are applied, and subsequently the structure is subjected to lateral forces. The magnitude of these forces with a predefined invariant load pattern is amplified incrementally in a displacement-controlled procedure. As a result the global pushover curve of the structure is obtained, where the base shear is plotted against a characteristic deformation parameter. In general the lateral displacement of the roof is selected as characteristic parameter. It is assumed that the shape of the global pushover curve reflects the global or the local mechanism involved when the structure approaches dynamic instability.

In Figure 1 the effect of gravity loads on the global pushover curve of a multi-story frame structure is illustrated. Figure 1(a) shows the global pushover curve, where gravity loads are either disregarded or of marginal importance. The pushover curve of Figure 1(b) corresponds to a very flexible multi-story frame structure with a strong impact of the P-delta effect leading to a reduction of the global lateral stiffness. In very flexible structures gravity loads even may generate a negative post-yield tangent stiffness as shown in Figure 1(b) [18]. If severe seismic excitation drives such a structure in its inelastic branch of deformation a state of dynamic instability may be approached, and the global collapse capacity is attained at a rapid rate. From these considerations follows that a gravity load induced negative post-yield tangent stiffness in the global pushover curve requires an advanced investigation of P-delta effects [7].

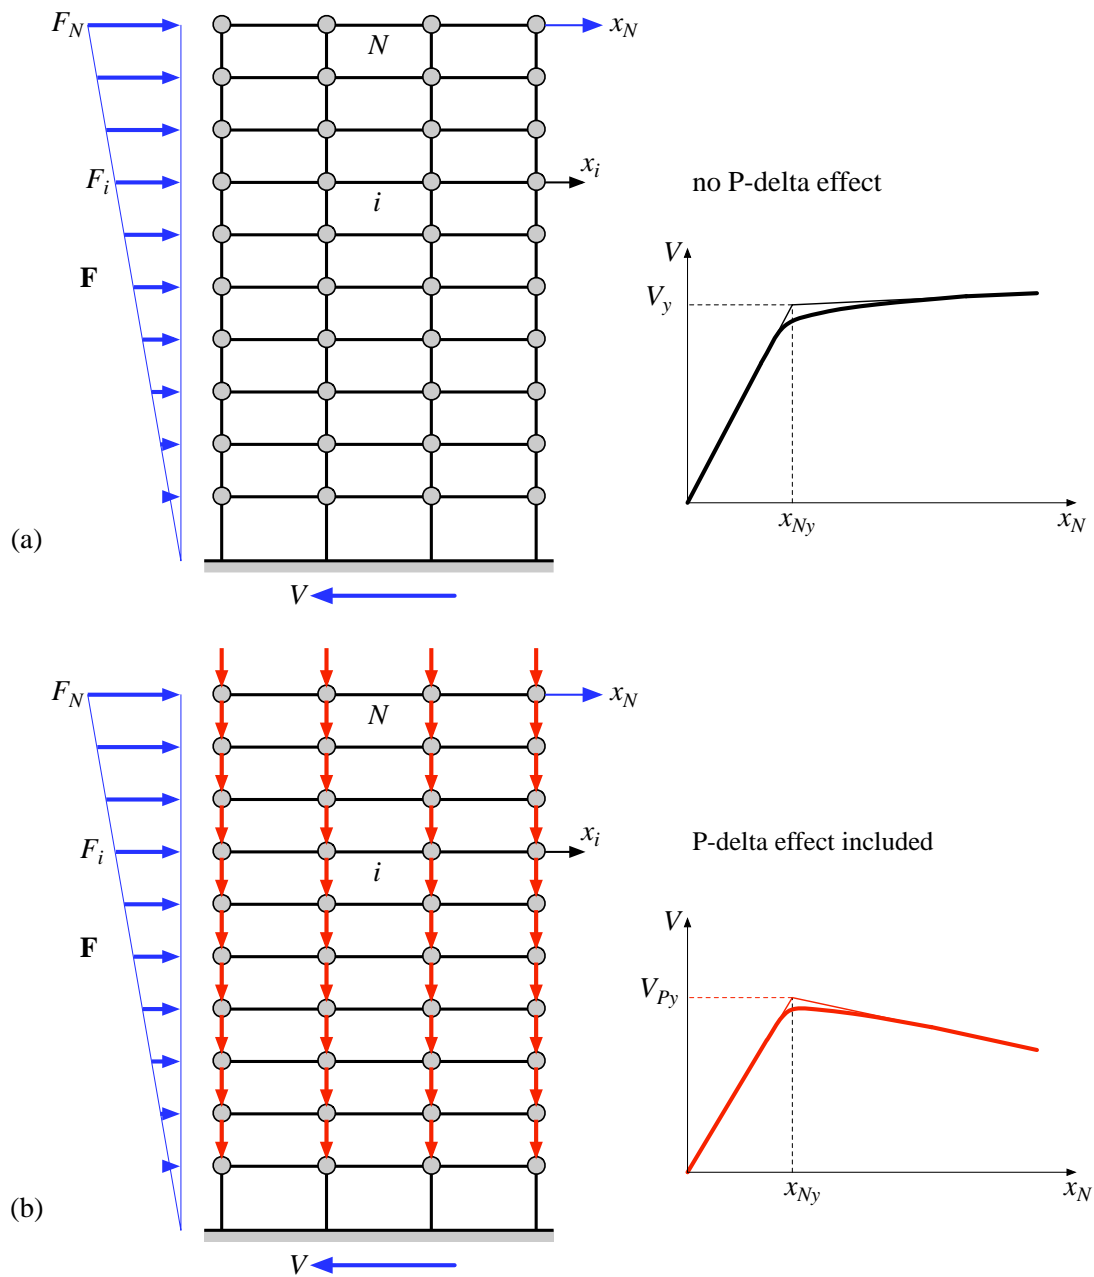

Figure 1: Multi-story frame structure and corresponding global pushover curves. (a) Pushover analysis disregarding P-delta. (b) Pushover analysis considering P-delta [2].

2.2 Assessment of the global collapse capacity

In the most general approach the Incremental Dynamic Analysis (IDA) procedure [19] is applied to determine the smallest earthquake intensity, which leads to structural collapse [2]. Thereby, for one acceleration time history of an earthquake record dynamic time history analyses are performed repeatedly, where in each subsequent run the intensity of the ground motion is incremented. As an outcome a characteristic seismic intensity measure is plotted against the corresponding maximum characteristic structural response quantity for each analysis. The procedure is stopped when the response grows to infinity, i.e. structural failure occurs. The corresponding intensity measure of the ground motion is referred to as collapse capacity of the building for this specific ground motion record. There is no unique definition of intensity of an earthquake record, however, the normalized 5% damped spectral acceleration at the structure's fundamental period $S_a(T_1)$ normalized by the product of the gravity of acceleration g and the base shear coefficient γ , $S_a(T_1) / (g \gamma)$, is widely accepted to characterize the intensity appropriately. γ is defined as ratio between yield base shear V_y (from the pushover curve without P-delta) and total weight W ($\gamma = V_y / W$).

Since the result of an IDA study strongly depends on the selected record, IDAs are performed for an entire set of n ground motion records, and the outcomes are evaluated statistically. In particular, the median of the sorted individual collapse capacities CC_{MDOF}^i , $i = 1, \dots, n$, is considered as the representative collapse capacity for the examined structure and the regarded set of ground motion records,

$$CC_{MDOF} = \text{med} \left\langle CC_{MDOF}^i, i = 1, \dots, n \right\rangle, \quad CC_{MDOF}^i = \frac{S_{a,i}}{g\gamma} \Big|_{\text{collapse}} \quad (1)$$

Further significant statistical values of the collapse capacity are 16% and 84% percentiles of the individual outcomes, CC_{MDOF}^{16} and CC_{MDOF}^{84} , respectively.

The IDA procedure requires the numerical solution of the equations of motions in each time step of each time history analysis, and as a consequence, is both time-consuming and computationally expensive. Thus, in [2, 17] for regular multi-story frame structures the so-called collapse capacity spectrum methodology has been proposed to obtain a quick but yet accurate approximation of the collapse capacity without performing time history analyses. The proposed methodology is based on the observation that the global P-delta effect is mainly governed by the fundamental mode. This holds also true if higher modes play a significant role in the dynamic structural response. Consequently, the collapse capacity is assessed utilizing an equivalent single-degree-of-freedom (ESDOF) system, and a collapse capacity spectrum [14, 15, 16]. This methodology is particular useful in engineering practice, because the structure can be evaluated with respect to its seismic collapse capacity in the initial design process.

3 FUNDAMENTALS OF THE COLLAPSE CAPACITY SPECTRUM METHODOLOGIES

3.1 Equivalent single-degree-of-freedom system

The ESDOF system is based on a time-independent shape vector ϕ , which describes the displacement vector \mathbf{x} of the N -story MDOF frame structure regardless of its magnitude,

$$\mathbf{x} = \phi x_N, \quad \phi_N = 1 \quad (2)$$

and on global pushover curves of the MDOF structure disregarding and considering gravity loads. In the corresponding pushover analyses the lateral load pattern must be selected to be affine to the displacement vector \mathbf{x} ,

$$\mathbf{F} = \boldsymbol{\phi} F_N \quad (3)$$

and thus to the shape vector $\boldsymbol{\phi}$. x_N denotes the roof displacement, and F_N is the peak magnitude of the pushover load at the top of the frame structure, see Figure 1. The components ϕ_i of the shape vector $\boldsymbol{\phi}$ and the story masses m_i , $i = 1, \dots, N$, of the MDOF structure enter mass and participation factor of the ESDOF system. Transformation of bilinear idealizations of the global pushover curves, Figure 2(a), into the domain of the ESDOF system renders its backbone curves, Figure 2(b). However, consideration of the P-delta effect in the ESDOF system is not straight forward, because in contrast to a real SDOF system an ESDOF does not exhibit a unique stability coefficient. This behavior can be led back to the underlying global pushover curves with and without gravity loads. In a bilinear approximation of the pushover curves the stability coefficient θ_i in the post-yield range of deformation is larger than the elastic stability coefficient θ_e : $\theta_i > (\theta_e)$ [18], compare with Figure 2(a). Thus, in [12, 2] it is proposed to assign an auxiliary backbone curve to the ESDOF system, which yields the backbone curve with applied gravity load by means of a single auxiliary stability coefficient θ_a [15]. Backbone curves of the ESDOF system are depicted in Figure 2(b): The blue bilinear curve represents the auxiliary backbone curve, and the corresponding red graph is the backbone curve with applied gravity load. For details of the ESDOF system it is referred to Fajfar [20], Adam et al. [21], and Ibarra and Krawinkler [12].

Figure 2: (a) Pushover curves with and without considering P-delta of a multi-story frame structure.
(b) Backbone curves of the corresponding equivalent single-degree-of-freedom system.

The essential parameters of the ESDOF system required for the application of the collapse capacity spectrum methodology are the period T_a of the auxiliary ESDOF system, the auxiliary stability coefficient θ_a , and coefficient λ_{MDOF} . λ_{MDOF} transforms the collapse capacity from the SDOF domain into the domain of the MDOF system [2]. In [21, 12] these parameters are derived as:

$$T_a = 2\pi \sqrt{\frac{1-\alpha_S}{v}} \sqrt{\frac{x_{Ny}}{V_y}} \sqrt{\sum_{i=1}^N \phi_i m_i} \quad , \quad \theta_a = \frac{\theta_i - \theta_e \alpha_S}{v} \quad , \quad v = 1 - \theta_e + \theta_i - \alpha_S \quad (4), (5), (6)$$

$$\lambda_{MDOF} = \frac{\left(\sum_{i=1}^N \phi_i m_i \right)^2}{\sum_{i=1}^N m_i \sum_{i=1}^N \phi_i^2 m_i} \quad (7)$$

Thereby, x_{Ny} denotes the roof displacement at onset of yield of the global pushover curve (without P-delta), see Figure 1.

If all story masses are equal, $m_i = m_s$, $i = 1, \dots, N$, then the expressions T_a and λ_{MDOF} reduce to

$$T_a = 2\pi \sqrt{\frac{1-\alpha_S}{v}} \sqrt{\frac{x_{Ny}}{V_y}} \sqrt{m_s \sum_{i=1}^N \phi_i} \quad , \quad \lambda_{MDOF} = \frac{\left(\sum_{i=1}^N \phi_i \right)^2}{N \sum_{i=1}^N \phi_i^2} \quad (8), (9)$$

For a linear shape vector with components $\phi_i = i / N$, $i = 1, \dots, N$, and constant story height h , period T_a and coefficient λ_{MDOF} read as:

$$T_a = 2\pi \sqrt{\frac{1-\alpha_S}{v}} \sqrt{\frac{x_{Ny} m_s}{2V_y}} \sqrt{N+1} \quad , \quad \lambda_{MDOF} = \frac{3}{2} \frac{N+1}{2N+1} \quad (10), (11)$$

If the number of stories N is larger than 9, λ_{MDOF} can be approximated according to

$$\lambda_{MDOF} \approx \frac{3}{4} \quad \forall N > 9 \quad (12)$$

3.2 Collapse capacity spectrum

In [14, 15] it is shown that the record dependent collapse capacity of a real non-deteriorating SDOF system with bilinear backbone curve, which is vulnerable to the P-delta effect, is governed by the following quantities:

- Initial period of vibration T
- Viscous damping coefficient ζ
- Negative post-yield stiffness ratio $\theta - \alpha$
- Hysteretic loop

If the collapse capacity of a system with assigned hysteretic loop and fixed parameters ζ and $\theta - \alpha$ is plotted against the period of vibration, the resulting graph is referred to as collapse capacity spectrum for an individual ground motion record. Statistical evaluation of individual collapse capacity spectra, which belong to a specific set of earthquake records, leads to median, 16% and 84% percentile collapse capacity spectra. In [15] a rigorous study of the impact of the parameters specified above on collapse capacity spectra is presented.

In an effort to provide engineers a tool, which allows a quick estimation of the collapse capacity, in the same publication [15] design collapse spectra with a “smooth” shape have been derived via non-linear regression analyses. For a certain set of parameters an analytic relation

for base case median design collapse capacity spectra are defined. The impact of parameters, which differ from the base case, is considered by influence coefficients. For details see again [15]. Exemplarily, Figure 3 shows median design collapse capacity spectra (marked by circles) for a series of post-yield stiffness ratios $\theta - \alpha$, and the corresponding design collapse capacity spectra depicted by full lines. These collapse capacity spectra are based on the ATC63 far-field set of 44 ordinary ground motions [22], and have been derived for SDOF systems with bilinear hysteretic loops, and a viscous damping coefficient of $\zeta = 0.02$.

Application of design collapse capacity spectra is simple. An estimate of the elastic period of vibration T , damping coefficient ζ , stability coefficient θ , and hardening ratio α of the actual SDOF structure is to be determined. Subsequently, from the chart the corresponding collapse capacity CC can be read. Furthermore, in [15] analytic approximations of fragility curves based on a log-normal distribution of the collapse capacities are presented.

Figure 3: Median collapse capacity spectra (blue circles) and corresponding design collapse capacity spectra. Underlying parameters specified in the figure.

4 COLLAPSE CAPACITY SPECTRUM METHODOLOGIES

4.1 Original collapse capacity spectrum method

The procedure to derive an estimate of the collapse capacity of an MDOF frame structure based on the corresponding ESDOF system and collapse capacity spectra can be summarized as follows [2, 17]:

- Derive global pushover curves of the MDOF structure without and with gravity loads with an appropriate horizontal load pattern, e.g. according to the fundamental mode shape. If the post-yield stiffness of the gravity loaded structure is negative, determine the global collapse capacity as subsequently described.
- If feasible, perform a bilinear approximation of the pushover curves and identify the global hardening ratio α_S , and the elastic and inelastic stability coefficient θ_e and θ_i , respectively.
- Derive the auxiliary stability coefficient θ_a according Eq. (5), and derive the negative post-yield stiffness ratio $\theta_a - \alpha_S$.

- Select the shape vector ϕ affine to the horizontal load pattern of the pushover analyses, and derive the period T_a of the auxiliary ESDOF system according to Eqs (4), (8), or (10).
- Consult the appropriate design collapse capacity spectrum with respect to the underlying ground motion set, viscous damping ζ , hysteretic loop, and the negative post-yield stiffness $\theta_a - \alpha_S$, and read at the period T_a the median collapse capacity CC .
- Derive the coefficient λ_{MDOF} according Eq. (7), (9), or (11) and transform CC into the domain of the ESDOF system [2]:

$$CC_{ESDOF} = \frac{CC}{\lambda_{MDOF}} \quad (13)$$

This outcome is an estimate of the actual median collapse capacity $CC_{MDOF} \approx CC_{ESDOF}$.

- If required, determine the 16% and 84% collapse capacities CC_{ESDOF}^{p16} and CC_{ESDOF}^{p84} , respectively, in analogy to the relations for a real SDOF system as derived by Adam and Jäger [15]:

$$CC_{ESDOF}^{p16} = CC_{ESDOF} / s_l^*, \quad s_l^*(T_a) = \frac{10}{7} T_a^{1/20} \quad (14, 15)$$

$$CC_{ESDOF}^{p84} = CC_{ESDOF} s_u^*, \quad s_u^*(T_a) = \frac{3}{2} T_a^{1/20} \quad (16, 17)$$

- Assuming that the uncertainties in the collapse capacities follow a log-normal distribution derive the fragility curve from [15]

$$\ln N(m, \sigma^2) \quad (18)$$

with

$$m = \ln(CC_{ESDOF}), \quad \sigma = \ln \sqrt{s_l^* s_u^*} \quad (19, 20)$$

4.2 Simplified collapse capacity spectrum method

In the following, a further simplification of the collapse capacity spectrum method for an even faster assessment of the global collapse capacity is suggested.

Inspection of Eqs (4), (8), and (10) reveals that only for large stability coefficients, i.e. $\theta_a - \alpha_S \gg 0$, the P-delta effect has a severe impact on the auxiliary period T_a . However, for flexible systems the gradient of collapse capacity spectra is small, if $\theta_a - \alpha_S \gg 0$, as it can be seen from Figure 3. Consequently, the collapse capacity CC is not much affected, if an approximation of the period enters the collapse capacity spectrum. Thus, it is proposed that a rough estimate of the fundamental structural period without taking account the gravity loads can be utilized instead of the auxiliary period T_a . This period replaces T_a in all relations of the original collapse capacity spectrum methodology.

A second simplification concerns the negative post-yield stiffness ratio. It can be shown that the auxiliary stability coefficient is always in-between the elastic and the inelastic stability coefficient. Hence, $\theta_i - \alpha_S$ is always larger than $\theta_a - \alpha_S$. Assuming that $\theta_i - \alpha_S$ is the characteristic post-yield stiffness ratio, the corresponding collapse capacity estimation is more

conservative compared to the value based on $\theta_a - \alpha_S$. For a fast and rough assessment of the collapse capacity the negative stiffness ratio derived according to $\theta_i - \alpha_S$ may be utilized.

Finally, for an initial collapse assessment a transformation coefficient of $\lambda_{MDOF} = 3/4$ may be employed, compare with Eq. (12).

5 EVALUATION OF THE COLLAPSE CAPACITY SPECTRUM METHODOLOGIES

For several generic multi-story frame structures as depicted in Figure 4(a) the original collapse capacity spectrum methodology and its simplified counterpart is evaluated setting its results in contrast with the “exact” collapse capacity based on IDAs. All stories of the single-bay structures of N stories are of uniform height h , and they are composed of rigid beams, elastic flexible columns, and rotational springs at the ends of the beams. Nonlinear behavior at the component level is modeled by non-degrading bilinear hysteretic behavior of the rotational springs (compare with Figure 4(b)) to represent the global cyclic response under seismic excitation. The strength of the springs is tuned such that yielding is initiated simultaneously at all spring locations in a static pushover analysis (without gravity loads) under an inverted triangular design load pattern. To each joint of the frames an identical point mass $m_i / 2 = m_s / 2$, $i = 1, \dots, N$, is assigned. The bending stiffness of the columns and the stiffness of the springs are tuned to render a straight line fundamental mode shape. Identical gravity loads are assigned to each story to simulate P-delta effects. This implies that axial column forces due to gravity increase linearly from the top to the bottom of each frame. The frame structures have a fundamental period of vibration of $T_1 = 0.2 N$, which makes them rather flexible.

Figure 4: (a) Planar generic multi-story frame structure. (b) Bilinear hysteretic loop of the rotational springs.

In a first example problem an 18-story frame structure is considered. The fundamental period is $T_1 = 3.6$ s. The hardening coefficient of all rotational springs is chosen to be $\alpha = 0.01$, the ratio of dead load plus life load to dead load is $\vartheta = 1.0$. Structural damping is considered by means of mass and stiffness proportional Rayleigh damping of 2% of the first mode and 2% of that mode, where the sum of modal masses exceeds 95% of the total mass.

In Figure 5 the outcomes of an IDA procedure utilizing the 44 records of the ATC63-FF set are shown. Each IDA curve displayed with light gray lines belongs to a specific record. Thereby, the non-dimensional excitation intensity $S_a / (g\gamma)$ is plotted against the normalized roof displacement x_N / S_d . S_a and S_d are the spectral acceleration and spectral displacement, respectively, at the period $T = T_1$ of the 5% damped response spectrum of the considered record. The lowest intensity, where a specific IDA curve exhibits a horizontal tangent, is the collapse capacity of the MDOF structure for the corresponding earthquake record. This figure reveals the large record dependent dispersion of the individual collapse capacities. A blue fat line represents the median IDA curve. From the results the “exact” median collapse capacity of $CC_{MDOF} = 3.33$ can be identified. Additionally, fat black lines correspond to the 16% percentile and 84% percentile IDA curves. The 16% percentile and 84% percentile collapse capacities are $CC_{MDOF}^{16} = 2.33$ and $CC_{MDOF}^{84} = 5.45$, respectively.

The assessment of the collapse capacity according to the collapse capacity spectrum methodology requires the identification of the elastic and the inelastic stability coefficient, and the global hardening ratio from global pushover curves without and with P-delta effect. The pushover curves of the structure are depicted in Figure 6. The parameters are determined as: $\theta_e = 0.073$, $\theta_i = 0.222$, $\alpha_s = 0.013$. Subsequent evaluation of Eqs (5) and (10) yields the auxiliary stability coefficient and the auxiliary period, respectively: $\theta_a = 0.195$, $T_a = 3.35$ s. The transformation coefficient λ_{MDOF} , Eq. (11), is derived as 0.770. The required post-yield stiffness ratios are: $\theta_a - \alpha_s = 0.182$, $\theta_i - \alpha_s = 0.209$.

Figure 7 shows the utilized 2% damped median design collapse capacity spectra for bilinear hysteretic behavior and the ATC63-FF record set [15]. Herein, it is illustrated, how the median collapse capacities for the proposed methodologies are determined.

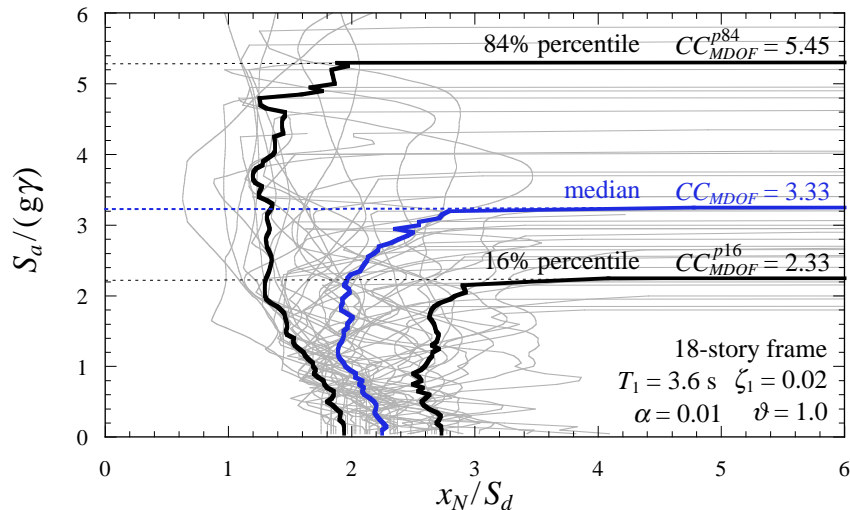

Figure 5: IDA curves for 44 ground motions of the ATC63-FF set. Median, 16% percentile, and 84% percentile IDA curves. Generic 18-story frame structure with a fundamental period of vibration of 3.6 s.

Figure 6: Backbone curves of the equivalent single-degree-of-freedom system for a generic 18-story frame structure.

Figure 7: Median design collapse capacity spectra applied for prediction of the median collapse capacity of a generic 18-story frame structure. Different collapse capacity spectrum methodologies.

In Table 1 the outcomes of different collapse capacity assessment methodologies are specified. The collapse capacity of the second column corresponds to the “exact” outcome of an IDA study based on the 44 earthquake records of the ATC63-FF set, whereas the results of columns three, four and five are based on ESDOF systems and collapse capacity spectra. Furthermore, in this table the underlying parameters of the different collapse capacity spectrum approximations are listed.

Inspection reveals that the median collapse capacity of the third column, $CC_{ESDOF} = 3.10$, determined by the original collapse capacity methodology, is about 93% of the “exact” counterpart, and thus a conservative estimate. The simplified collapse capacity spectrum methodology yields a median collapse capacity $CC_{ESDOF} = 2.91$, compare with column five. An “intermediate” simplified capacity spectrum methodology, where the negative post-yield stiffness of the auxiliary ESDOF $\theta_a - \alpha_s$, and the fundamental period T_1 of the frame structure enters the collapse capacity spectrum leads to $CC_{ESDOF} = 3.16$, which is the approxima-

tion closest to the “exact” outcome. The difference between the “exact” and approximated percentile collapse capacities is of the same order as for the median values, compare with Table 1.

Figure 8 shows the counted collapse fragility curve from the IDA study, and several approximated “smooth” fragility curves of the considered 18-story frame structure. The blue line is a “best fit” of the counted fragilities employing the maximum likelihood method. The black and red lines are based on log-normal approximations taking into account different values of the percentiles. The fragility curves according to the collapse capacity spectrum methodologies (displayed in red color) are derived employing Eqs (14) to (20). The curve displayed in black color has been derived using counted median, 16% and 84% percentiles from the IDA study.

Subsequently, the median collapse capacity of 12 generic multi-story frame structures vulnerable to P-delta is evaluated. The number of stories N ranges from 15 to 24. Spring hardening ratios α of 1%, 2%, and 3% are employed, and viscous damping ζ_1 of the fundamental mode of 2% and 5% is taken into account. The considered dead load plus life load to dead load ratios ϑ are 1.0, 1.2, and 1.4. In Table 2 the properties of the individual frames are specified.

Methodology	IDA study	Original collapse capacity spectrum methodology	Simplified collapse capacity spectrum methodology	Simplified collapse capacity spectrum methodology
Period		$T_a = 3.35$ s	$T_1 = 3.60$ s	$T_1 = 3.60$ s
Post-yield stiffness ratio		$\theta_a - \alpha_S = 0.182$	$\theta_a - \alpha_S = 0.182$	$\theta_i - \alpha_S = 0.209$
Transformation coefficient		$\lambda_{MDOF} = 0.770$	$\lambda_{MDOF} = 0.770$	$\lambda_{MDOF} = 3/4$
CC from spectrum		2.39	2.44	2.18
Median collapse capacity	$CC_{MDOF} = 3.33$	$CC_{ESDOF} = 3.10$	$CC_{ESDOF} = 3.16$	$CC_{ESDOF} = 2.91$
16% percentile collapse capacity	$CC_{MDOF}^{16} = 2.33$	$CC_{ESDOF}^{16} = 2.04$	$CC_{ESDOF}^{16} = 2.07$	$CC_{ESDOF}^{16} = 1.91$
84% percentile collapse capacity	$CC_{MDOF}^{84} = 5.45$	$CC_{ESDOF}^{84} = 4.94$	$CC_{ESDOF}^{84} = 5.05$	$CC_{ESDOF}^{84} = 4.65$
CC_{ESDOF} / CC_{MDOF}	1	0.93	0.95	0.87
$CC_{ESDOF}^{p16} / CC_{MDOF}^{p16}$	1	0.88	0.89	0.82
$CC_{ESDOF}^{p84} / CC_{MDOF}^{p84}$	1	0.91	0.93	0.85

Table 1: Median, 16% percentile, and 84% percentile collapse capacity of a generic 18-story frame structure. “Exact” outcome of an IDA study, and results from collapse capacity spectrum methodologies based on equivalent single-degree-of-freedom systems.

Figure 8: Counted fragility curve and “smooth” approximations based on log-normal distribution of an generic 18-story frame structure.

Frame ID	Number of stories N	Fundamental period T_1 [s]	Spring hardening ratio α	Damping ratio ζ_1	Gravity load ratio ϑ
1	18	3.6	0.03	0.05	1.0
2	18	3.6	0.03	0.05	1.2
3	18	3.6	0.03	0.05	1.4
4	15	3.0	0.03	0.05	1.0
5	21	4.2	0.03	0.05	1.0
6	24	4.8	0.03	0.05	1.0
7	18	3.6	0.02	0.05	1.0
8	18	3.6	0.01	0.05	1.0
9	18	3.6	0.03	0.02	1.0
10	18	3.6	0.03	0.02	1.2
11	18	3.6	0.01	0.02	1.0
12	18	3.6	0.02	0.02	1.2

Table 2: ID and properties of the considered generic multi-story frame structures.

Figure 9 shows for each frame the median collapse capacity from an IDA study of the actual multi-story structure (black bar), and from application of the collapse capacity spectrum methodologies (colored bars). The outcomes of the original collapse capacity spectrum methodology, based on the auxiliary structural period T_a and the auxiliary stability coefficient θ_a , are depicted in red. The blue bar corresponds to results from the simplified collapse capacity spectrum methodology utilizing the fundamental structural period T_1 and the inelastic stability coefficient θ_i . The collapse capacities depicted in green are derived from an “intermedi-

ate” simplified collapse capacity spectrum methodology, where T_1 and θ_a enter the analysis. It is readily observed that the 15-story frame (frame ID 4) exhibits the largest global collapse capacity. The median collapse capacity of structures with ID 3, 6, and 12 is of the same magnitude. Comparison reveals that for all considered structures the “exact” IDA results are of the same magnitude as their counterparts of the collapse capacity spectrum methodologies.

Figure 9: Global collapse capacities for a series of generic multi-story frame structures according to Table 2. “Exact” outcome from IDA studies, and results from collapse capacity spectrum methodologies based on equivalent single-degree-of-freedom systems.

Figure 10: Global collapse capacity ratios for a series of generic multi-story frame structures according to Table 2. Results from collapse capacity spectrum methodologies based on equivalent single-degree-of-freedom systems related to the “exact” outcome from IDA studies.

The difference in percent of the individual results for each frame is illustrated in Figure 10, where the ratios of collapse capacities from ESDOF considerations to the “exact” outcomes are shown. A ratio of one implies that both considered methods predict the same collapse capacity. If the ratio is smaller than one, the collapse capacity is underestimated by the collapse capacity spectrum methodology, i.e. the outcome is conservative compared to the “exact” value. It can be seen that for frames 1, 2, 4, 7, and 9 the collapse capacity spectrum method-

ologies lead to slightly non-conservative predictions up to 12%. For frames 5 and 6 predictions are very conservative.

Setting in contrast the results of the individual collapse capacity spectrum methodologies for each frame separately reveals that the simplified method renders the smallest collapse capacity, and thus, for some structures over-conservative predictions.

However, taking into account the underlying simplifications it can be concluded that all applied collapse capacity spectrum methodologies are capable to yield a collapse capacity estimate, which is sufficiently accurate for the initial design process of buildings.

6 CONCLUSIONS

The seismic collapse capacity of a series of non-deteriorating multi-story frame structures vulnerable to the destabilizing effect of gravity loads was assessed employing the collapse capacity spectrum methodology, a simplified subspecies of this methodology, and the IDA procedure. Evaluation of the results reveals that both the original and simplified capacity spectrum methodology render sufficient accurate estimates of the global collapse capacity, and thus can be utilized efficiently in the initial design process of buildings.

Abstract. *The paper deals with the applicability of a simplified nonlinear method (N2 method) to base-isolated plan-asymmetric building structures. In the first part of the paper the modifications that have been implemented into the originally proposed N2 method – such as the new three-linear idealization and inclusion of isolator damping by reduction factor R_ξ – are shortly described. In the paper the proposed procedure is used for the seismic analysis of a base-isolated 4-storey RC asymmetric building isolated with lead rubber bearings (LRBs). For the base isolation system we have considered three different types of isolators with different stiffness. The results of nonlinear dynamic time-history analyses are compared with the results of the N2 method in terms of obtained top, base and relative displacements. Comparisons of the results of the simplified method with the ‘exact’ results of the nonlinear dynamic analyses have shown a very good agreement. It has been shown that the presented simplified approach might be a valuable tool for design, analysis and verification of the behavior of symmetric as well as moderately asymmetric base-isolated structures.*

1 INTRODUCTION

Over the last decade simplified non-linear methods based on pushover analysis, the equivalent single degree of freedom (SDOF) system, and the response spectrum approach have been implemented in guidelines, standards and codes for the seismic resistant design of new buildings and the evaluation of existing buildings. One of these simplified non-linear methods is the N2 method, which has been successfully applied to the analysis of symmetric [1] and asymmetric buildings (extended N2 method – [2]) with different building system types. The method combines the pushover analysis of a multi degree of freedom (MDOF) model with the response spectrum analysis of an equivalent SDOF model. In the paper the method is applied for symmetric and moderately asymmetric base-isolated structures with the mass centre of the superstructure coinciding to the stiffness centre of the isolation system. The modifications of original method include: 1) a new three-linear idealization of the pushover curve based on the first yield of the superstructure, and 2) the introduction of the reduction factor R_ξ to account for damping of isolators [3,4].

2 PROPOSED CAPACITY CURVE FOR BASE-ISOLATED STRUCTURES

For the idealization of the capacity curve of a base-isolated structure the authors have considered that the first yielding point of the superstructure is far more important than the "average yielding" point of the structure used for bilinear idealization in the original N2 method for fixed base structures. In this way the N2 method should be able to detect the first yielding of the superstructure, as well as to estimate the behavior of the superstructure further into the nonlinear range directly in relation to the first yielding of the superstructure.

Figure 1: Idealized capacity curve of base-isolated structures and estimation of target top displacement.

The first yielding of the superstructure is determined by a pushover analysis for the selected lateral load distribution. The initial stiffness is obtained by equalizing the areas below and above the actual pushover curve of the base-isolated structure. The secondary slope is obtained in such a way that it best fits the real pushover curve. Alternatively it can be determined from the failure mechanism obtained by pushover analysis. After the mechanism has occurred, a zero slope is suggested. A consequence of such idealization is a much more pro-

nounced hardening secondary slope which does not correspond to the assumptions used in the original N2 method (see Figure 1). A similar model with a higher secondary slope was suggested also by [5] for structures with incorporated hysteretic dampers. It should be noted that the range of interest for base-isolated structures is practically limited to the secondary hardening part of the idealized curve, since it is not expected that base-isolated structures would experience damage close to the failure mechanism.

3 DESCRIPTION OF THE PROCEDURE

Due to the non-zero hardening slope α , the actual reduction factor R_α is smaller than the assumed factor R from original N2 method. The relations between R and R_α depend on the hardening slope α and can be obtained by using equation (1). Assuming that the equal displacement rule applies the equations can be obtained by using relatively simple geometric relations.

$$R_\alpha = \frac{R}{\alpha R - \alpha + 1} \quad (1)$$

The use of the N2 method remains practically the same as was suggested in the original N2 method [1]. The inelastic spectra can be obtained as:

$$S_a = \frac{S_{ae}}{R_{tot}} \quad (2)$$

where R_{tot} can be obtained as a product of the reduction factor R_ξ and the reduction factor R_α :

$$R_{tot} = R_\xi \cdot R_\alpha \quad (3)$$

R_α represents the reduction due to the nonlinear behavior and damping of the superstructure, whereas R_ξ represents the strength reduction due to the higher damping of the isolators:

$$R_\xi = \frac{1}{\eta^2}, \text{ where } \eta = \sqrt{10/(5 + \xi)} \geq 0.55 \quad (4)$$

where η is the correction factor which takes into account damping effects (see [6], equation (3.6)) and ξ is the damping of the isolation system. A graphical representation of the procedure is presented in Figure 1. The reduction factor that relates the proposed procedure with the quantities from the general N2 method can be expressed as a product of R_ξ and R . It should be noted that the damping of the isolation system ξ used in equation (4) depends on the achieved base displacement D_d . In our study we have obtained it by means of Jacobsen's equation [7]:

$$\xi_{LRB}(D_d) = \frac{4 Q (D_d - D_y)}{2 \pi K_{eff} D_d^2} \quad (5)$$

where D_y and K_{eff} are the yield displacement and effective stiffness of the selected LRB isolator and Q is its characteristic strength. Since the actual base displacement D_d it is not known in advance, some iteration steps are required in order to obtain the correct results. In each step the top displacement of the MDOF system is obtained as $D_{top} = \Gamma \cdot S_d$, whereas the corresponding base displacement can be obtained by pushover analysis. The new damping value is then calculated by substituting D_d in equation (5) by the obtained D_{base} , until a satisfactory agreement is reached.

The extension of the N2 method to fixed base plan-asymmetric building structures has been described in detail in [2]. It has been proposed to combine the results obtained by usual 3D pushover analysis with the results of a linear dynamic (spectral) analysis in order to determine the torsional correction factor (c_T) to correct the results obtained by pushover analysis. This factor is defined as the ratio between the normalized top displacements obtained by elastic modal analysis and by pushover analysis (equation (6)). The normalized top displacement is the top displacement at an arbitrary location divided by the top displacement at the centre of mass (CM). If the normalized top displacement obtained by elastic modal analysis is smaller than 1.0, it is suggested to assume it to be equal to 1.0. This recommendation, which in case of base-isolated structures seems to be too conservative, was not applied in the presented case study. Correction factors are defined for each horizontal direction separately and they depend on the considered location in the plan. Then all the relevant quantities obtained by pushover analyses for considered location (e.g. distance from the CM) should be multiplied with appropriate torsional correction factor for this location in order to obtain the target values of relevant quantities.

$$c_T = \frac{\bar{u}_e^{top}}{\bar{u}_{push}^{top}} \quad \bar{u}^{top} = \frac{u^{top}}{u_{CM}^{top}}; \text{ if } \bar{u}_e^{top} < 1.0, \text{ take } 1.0 \quad (6)$$

In the presented case study we have used the same presumptions as for symmetric base-isolated structures and we have treated the frame in the vertical plane passing through the CM in the same manner as the frame in a symmetric structure. All quantities were therefore observed in this plane, where also the horizontal loads for pushover analysis have been also applied [8, 9].

4 CASE STUDY: A BASE-ISOLATED RC FRAME STRUCTURE

4.1 Building description

A four-storey base-isolated RC frame building, which is presented in Figure 2, was used as a test example. The symmetric variant of the same structure was already used for example in [4], where all data about the geometry, masses, and periods can be found, as well as some design details for the fixed-based variant of the building ($a_g = 0.35g$). More detailed data about asymmetric variants can be found in [10]. For the purpose of this study, only one-directional asymmetry was introduced by moving the mass centre CM by 10% (A10), 20% (A20) or 30% (A30) of the larger floor plan dimension (L_x). The torsional to lateral frequency ratio (Ω_s) of the original (symmetric) superstructure amounts to 1.0.

4.2 Base isolation system

A widely used base isolation system, consisting of an orthogonal mesh of RC foundation beams and 24 identical round lead rubber bearings, was used. In order to verify the applicability of the proposed simplified N2 method, the stiffness of the isolator compound was intentionally varied so as to correspond to three different protection levels: a) "Hard" isolators (H), which cannot adequately protect the superstructure; b) Elastic limit or "normal" (N) isolators, which have been designed to bring the symmetric superstructure subjected to the design ground acceleration ($a_g = 0.35g$, soil class B and $q = 1$) exactly to the limit of its elastic range; c) "Soft" isolators (S), which could be actually used in practice. The used isolators are described in detail in [4]. The positions of individual isolators have been adjusted for the given eccentricity level of the superstructure (Figure 2) in order to ensure that the centre of the iso-

lation system CI corresponds to the centre of mass of the superstructure CM. In this case, torsion is a consequence of the eccentricity between the CS and CM of the superstructure.

Figure 2: Geometry, basic characteristics and positions of LRBs for the analyzed structural variants.

4.3 Mathematical modeling and seismic ground motions

The nonlinear analyses were performed using the program SAP2000 (v12.0.1) [11]. The nonlinear behavior of the superstructure was modeled using bi-linear moment hinges without a load drop, located at both ends of each beam and column. An ensemble of seven accelerograms was used to represent the seismic action (2 from Friuli 1976, 3 from Montenegro 1979, 1 from Banja Luka 1981 and 1 from Vrancea 1986). The accelerograms were further modified to match the target EC8 [6] elastic spectrum for soil type B, scaled to a peak ground acceleration of $a_g = 0.35g$ (considered as the design basis earthquake – DBE) and $0.525g$ (considered as the maximum credible earthquake – MCE). More detailed data about the used ground motion records can be found in [3, 4, 10]. Only uni-directional input has been considered where the N-S components of the accelerograms were applied in the Y direction of the building. For the pushover analyses three different lateral load distributions were investigated: (a) "triangular"; (b) "1st mode"; and (c) "PSC" – the proposal of the Protective Systems Committee of SEAONC [12].

4.4 Comparison of selected top, base and relative displacements

The results are presented in terms of the maximum top, base and relative displacements of the base-isolated structure where the relative displacements of the superstructure were calculated as the maximum total difference between the top and base displacements (in NLDA they do not necessarily occur at the same time). Figures 3-6 present comparisons of the displacements and ductility factors obtained by the extended N2 method and NLDA for selected analyzed models. The displacements are presented as absolute values at the CM (u_{CM}), and as normalized values (u/u_{CM}) for the flexible and stiff sides, in order to present the effects of the torsional twist. In the presented results, the correction factor c_T was taken exactly as calculated from equation (6), taking into account the obtained top displacements.

Observing the displacements at the CM (Figures 3 and 4), it is evident that the softer isolators – as expected – result in larger top and base displacements and smaller relative displacements than the harder ones. It can be seen that the agreement between the results of NLDA and the ext. N2 method is fairly good, and within the standard deviation boundaries until the eccentricities of the superstructure do not exceed a certain level for selected type of isolator

(approximately 20% for normal and 15% for hard type of isolator). For larger eccentricities, where much more damage occurs in the superstructure, all the displacements obtained by the ext. N2 method tend to be underestimated. The best results were obtained in the case of the 1st and PSC distributions, which give similar results, whereas the results of triangular distribution tend to be underestimated, especially for the top and base displacements. Similar conclusions were obtained in the case of the symmetric base-isolated structures [3, 4].

Figure 3: Top displacements (at the CM).

Figure 4: Base and relative displacements (at the CM) for $a_g = 0.525g$.

Observing the normalized displacements (Figure 5) it can be seen that, on the flexible side, the agreement with the results obtained by NLDA is very good; although it appears that the ext. N2 method slightly underestimates the demands for eccentricities equal to 20% or larger. The severest effects of torsion were observed in the case of the harder types of isolators. The amplification factors are in very good correlation with those obtained by NLDA. There is no significant difference between the lateral load distributions; however the best correlations with NLDA were obtained for the 1st mode and PSC distribution.

Figure 5: The torsional amplification factors for the base and relative displacements for $a_g = 0.525g$.

In Figure 6 the rotational ductility factors obtained by the ext. N2 method (for the PSC lateral load distribution) are presented and compared with the average ductility factors obtained by NLDA for $a_g = 0.525g$. The damage patterns are shown for all analyzed types of isolators but only for the A10 model and they are presented for the stiff as well as the flexible frames. It can be seen that there is more damage in the case of harder isolators, whereas in the case of soft isolators the structure practically remains elastic (ductility < 1.0). In all the analyzed cases, it turns out that the ext. N2 method is able to follow the spread of damage in the superstructure with sufficient accuracy. The agreement with the results obtained by NLDA is satisfactory, and the results obtained by the ext. N2 method remain conservative for presented eccentricity (A10). In the case of larger eccentricities, however, it was shown that the ductility factors (damage patterns) obtained by the ext. N2 method may slightly underestimate the response of the superstructure. In all cases the obtained correction factors (c_T) have values which are close to 1.0, which means that in all these cases the usual 3D pushover analysis would give similarly good results.

In the presented case study we have analyzed the base isolation system with the CI corresponding to the CM and we have treated the frame in the vertical plane passing through the CM as the plane under observation where also the horizontal loads for pushover analysis have been applied. In general, the distribution of the isolators could be also asymmetric where the CI does not correspond to the CM. In our previous studies we have found out that the distribution $CI=CS$ or even $CI=-CM$ are even more effective for the protection of the superstructure because they minimize the rotations of the superstructure [10]. In those cases where the CI does not correspond to the CM, we have proposed that the loads for pushover analysis should be applied at the plane through the mid-point between the CI and the CM (Figure 7) where also all quantities should be observed [9]. The point of application of the lateral loads might be eventually also determined with higher accuracy considering additional influencing parameters, but here we should be also aware of the limitations of simplified methods to follow all the changes of parameters in complex dynamic nonlinear 3D structural response.

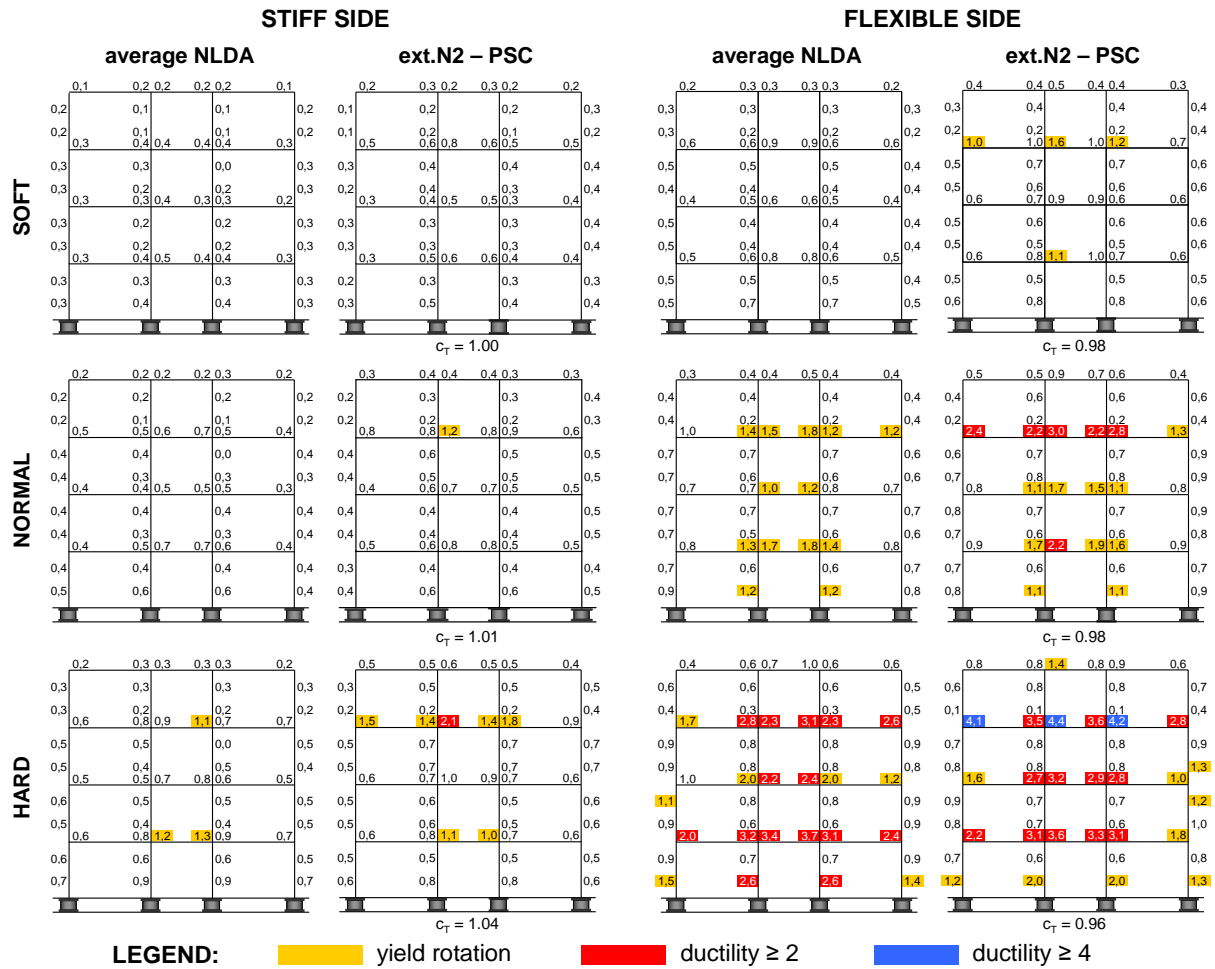

Figure 6: Maximum ductility factors for the stiff and flexible side, for the model A10 and $a_g = 0.525g$.

Figure 7: Points (vertical plane) of lateral load application in case of different positions of the center of the isolation system (CI).

5 CONCLUSIONS

It was found that the proposed N2 method procedure provides results which are in very good agreement with the results obtained by NLDA, if the eccentricity of the superstructure is moderate (e.g. in extreme cases limited to approximately $e_m = 20\%$). In case of larger eccentricities all the displacements obtained by the ext. N2 method tend to be underestimated, especially in the cases with harder isolators, where the superstructure is exposed to deeper nonlinear behavior and consequently, the centre of stiffness of the superstructure (CS) is shifted towards the stiff side. The influence of different lateral load distributions and the effect of the ground motion intensities on the torsional amplifications were shown not to be very important. However, the distribution with additional force at the base (PSC) tends to work

better, while the triangular load distribution seems less appropriate. For the analyzed CI=CM distribution of the isolators, the usual 3D pushover analysis yields good results, and the usage of the correction factor c_T is not absolutely necessary. The originally proposed ext. N2 method requires that the corrected displacement on the stiff side should not be taken smaller as in CM. For base-isolated structures this requirement leads toward a considerable overestimation of displacements on the stiff side, which is, however, on the conservative side.

Keywords: Torsionally flexible, asymmetric buildings, SSAP, Modified-SSAP

Abstract. *Storey Shear-Based Adaptive Pushover (SSAP) procedure has originally been developed for estimating seismic demands of planar frames. An extension and modification of the SSAP, has recently been proposed to estimate seismic demands of asymmetric buildings, represented by a 3D structural model. In order to investigate the capability of the proposed Modified-SSAP in severe mass asymmetric buildings, in the current paper, the method is evaluated for a 12-story asymmetric reinforced concrete moment resisting building with a torsionally dominant fundamental natural mode, representing torsionally flexible buildings. Results of the storey drift predictions of the Modified-SSAP are compared with Nonlinear Response History Analysis (NRHA) as well as estimations of the well-known Modal Pushover Analysis (MPA) procedure, subjected to a set of seven near-field ground motions. Alternative correction factors for the target displacement to improve the results are also examined. An acceptable compatibility of storey drift estimations of pushover procedures is observed, while Modified-SSAP is more compatible with the results of rigorous NRHA when proper correction factors for the target displacement are applied.*

1 INTRODUCTION

Conventional pushover analysis procedures are based on the assumption that the structure predominantly vibrates in a single mode. This assumption is not straightforward particularly for tall and irregular buildings. In recent years many attempts has been made worldwide to take the higher modes effects and the changes of modal characteristics into consideration while structure responds in inelastic range. Many of the proposed methods enjoy from strong theoretical background and acceptable degree of accuracy. However, they have merely been introduced to estimate seismic demands of planar frames. In this respect, development of the nonlinear static methods, originally for planar frames, so that are able to analysis of irregular building represented by 3D structural model has been considered. Backed by an extensive range of studies N2 method [1] has been extended for asymmetric buildings based on the assumption that torional effects in the elastic and inelastic domains are very close and mostly overestimated by an elastic analysis [2]. The well-known modal pushover analysis [3] has also been developed for asymmetric building [4] by extending the formulations in accordance with dynamics of structures theories. An alternative of conventional capacity spectrum method in an adaptive framework [5] has also been proposed another indication of development of conventional methods.

Storey Shear-Based Adaptive Pushover (SSAP) originally has been proposed for planar frames taking into account reversal signs of applied load pattern as well as changes in modal attribute within inelastic range [6]. In this paper an extension of the SSAP introduced first in [7] has been summarized. The extension has been done through extending the formulations based on structural dynamics theory. Modifications for load pattern and target displacement have also been proposed [7] which are currently in their premature stages of development. In the current study, a torsionally flexible 12 storey building subjected to uni-directional excitation is validated by extended SSAP. Proposed Modifications of load pattern and target displacement are further evaluated for the example building when standard design spectrum is utilized in the algorithm of the method. Therefore the accuracy of the method is investigated by using standard design spectrum instead of individual spectrum.

2 SUMMARY OF THE EXTENDED SSAP METHOD

The overall trend of the procedure is similar to its original for planar frames developed by Shakeri et al. [6], except the fact that formulations have been converted to three dimensional based on the concepts of structural dynamic. Extended story shear-based adaptive pushover analysis to asymmetric plan buildings under uni-directional excitation can be summarized in the following steps:

- Step 1: Create a 3D structural model incorporating nonlinear material characteristics.
- Step 2: Perform a nonlinear static analysis to consider gravity loads on the structure.
- Step 3: Compute instantaneous natural frequencies, ω_n and mode shapes, ϕ_n by performing an eigenvalue analysis using the current stiffness characteristics of the structure.
- Step 4: For a selected number of modes considered, compute modal story forces and torques associated with the global x, y , and z directions using the following equation:

$$f_{nx} = \Gamma_n \phi_{nx} m A_n \quad f_{ny} = \Gamma_n \phi_{ny} m A_n \quad f_{n\theta} = \Gamma_n \phi_{n\theta} I_o A_n \quad (1)$$

Where \mathbf{f}_{nx} and \mathbf{f}_{ny} are the vectors of modal story forces, $\mathbf{f}_{n\theta}$ is the vector of torsional moments at each floor diaphragm. $\boldsymbol{\phi}_{nx}$, $\boldsymbol{\phi}_{ny}$, and $\boldsymbol{\phi}_{n\theta}$ are three sub vectors of the n -th instantaneous translational and torsional natural mode shapes associated with x , y , and z directions, respectively. A_n is the ordinate $A(T_n, \xi_n)$ of the earthquake pseudo-acceleration response spectrum for the n -th mode single degree of freedom system. \mathbf{m} is the diagonal sub matrix of the global mass matrix, \mathbf{M} , with $m_{ii} = m_i$, the lumped mass at the i -th floor diaphragm:

$$\mathbf{M} = \begin{Bmatrix} \mathbf{m} \\ \mathbf{m} \\ \mathbf{I}_o \end{Bmatrix} \quad (2)$$

\mathbf{I}_o is a diagonal matrix with $I_{ii} = I_{oi}$, the polar moment of inertia of the i -th floor diaphragm about a vertical axis through the center of mass. Γ_n is the modal participation factor obtained as the following:

$$\Gamma_n = \frac{L_n}{M_n} \quad M_n = \boldsymbol{\phi}_n^T \mathbf{M} \boldsymbol{\phi}_n \quad L_n = \begin{cases} \boldsymbol{\phi}_{xn}^T \mathbf{m} \mathbf{1} & \text{for } \ddot{u}_{gx}(t) \\ \boldsymbol{\phi}_{yn}^T \mathbf{m} \mathbf{1} & \text{for } \ddot{u}_{gy}(t) \end{cases} \quad (3)$$

Step 5: Calculate modal story shears of x and y directions and summation of torsional moments of the considered story and all upper storeys:

$$SS_{inx} = \sum_{k=i}^N f_{knx} \quad SS_{iny} = \sum_{k=i}^N f_{kny} \quad SM_{i\theta} = \sum_{k=i}^N f_{kn\theta} \quad (4)$$

Step 6: Combine the story shear forces and torsions obtained by Eq. (4) using modal combination rules such as SRSS and CQC to define forces and torsional moment of each floor diaphragm. In this study the SSRS rule has been used because of its simplicity as the following:

$$SS_{ix} = \sqrt{\sum_{n=1}^m SS_{inx}^2} \quad SS_{iy} = \sqrt{\sum_{n=1}^m SS_{iny}^2} \quad SM_{i\theta} = \sqrt{\sum_{n=1}^m SM_{in\theta}^2} \quad (5)$$

Step 7: Define the amount and sign of the incremental load pattern, including forces in translational directions and torsional moments about a vertical axis through the center of mass, by subtracting the consecutive story shears and moments:

$$\begin{aligned} F_{ix} &= SS_{ix} - SS_{(i+1)x} & F_{iy} &= SS_{iy} - SS_{(i+1)y} & F_{i\theta} &= SM_{i\theta} - SM_{(i+1)\theta} & i &= 1, 2, \dots, (i-1) \\ F_{Nx} &= SS_{Nx} & F_{Ny} &= SS_{Ny} & F_{N\theta} &= SM_{N\theta} & i &= N \end{aligned} \quad (6)$$

Step 8: Use any appropriate quantity to normalize the lateral load patterns. As an alternative larger value of the base shear associated with x and y directions can be taken for normalizing the lateral loads pattern using the following equations:

$$V = \max(\sum F_{ix}, \sum F_{iy}) \quad (7)$$

$$\bar{F}_{ix} = \frac{F_{ix}}{V} \quad \bar{F}_{iy} = \frac{F_{iy}}{V} \quad \bar{F}_{i\theta} = \frac{F_{i\theta}}{V} \quad (8)$$

Step 9: Consider an incremental base shear and multiply it to the normalized lateral loads pattern to obtain forces and torques which are applied in each step to each floor diaphragm:

$$\Delta F_{ix} = \Delta V_b \times \bar{F}_{ix} \quad \Delta F_{iy} = \Delta V_b \times \bar{F}_{iy} \quad \Delta F_{i\theta} = \Delta V_b \times \bar{F}_{i\theta} \quad (9)$$

Where ΔV_b is the incremental base shear and ΔF_{ix} , ΔF_{iy} , $\Delta F_{i\theta}$ are the i -th components of the incremental applied loads at each step.

Step 10: Apply the scaled incremental load profile (Eq. 9) to the structural model considering $P - \Delta$ effects; compute displacements, inter-story drifts, element forces, etc.

Step 11: compute the assumed fundamental mode shape vector for step k employing the following equation:

$$\phi^k = \mathbf{M}^{-1} \mathbf{F}^k \quad (10)$$

Where k denotes the step number, ϕ^k is the assumed mode shape at step k , \mathbf{M}^{-1} is the inverse of the global mass matrix, and \mathbf{F}^k is vector of total forces applied up to the step k , consisting of three sub vectors, as it is shown by Eq. 11.

$$\mathbf{F}^k = \begin{Bmatrix} \mathbf{F}_x^k \\ \mathbf{F}_y^k \\ \mathbf{F}_\theta^k \end{Bmatrix} \quad (11)$$

Step 12: Based on the assumed fundamental mode shape (Eq. 10), convert base shear of the Multi Degree Of Freedom (MDOF) system to the equivalent force of the Single Degree Of Freedom (SDOF) system using the following equation:

$$F^* = S_a = \frac{V_b}{M^*} \quad (12)$$

Where F^* is the equivalent force of the SDOF system, V_b is the base shear of the applied forces in the direction of excitation, and M^* is the effective modal mass considering the mode shape acquired by Eq. (10).

Step 13: Calculate the equivalent displacement of the SDOF system by means of an energy concept using Eqs. (13) to (15).

$$\sum_{i=1}^N \left(\left(F_i^{(k-1)} + \frac{1}{2} dF_i^{(k)} \right) \times \Delta d_i^k \right) = \left(\sum_{i=1}^N \left(F_i^{(k-1)} + \frac{1}{2} dF_i^{(k)} \right) \right) \times \Delta D^k \quad (13)$$

$$\Delta D^{(k)} = \sum_{i=1}^N \left(\left(F_i^{(k-1)} + \frac{1}{2} dF_i^{(k)} \right) \times \Delta d_i^k \right) / \left(\sum_{i=1}^N \left(F_i^{(k-1)} + \frac{1}{2} dF_i^{(k)} \right) \right) \quad (14)$$

$$D^{(k)} = D^{(k-1)} + \Delta D^k \quad (15)$$

where $F_i^{(k-1)}$: the existing story force in the direction of excitation at the end of step $k - 1$, $dF_i^{(k)}$: incremental applied force in the story i at step k , Δd_i^k : incremental displacement of the story i in the direction of the excitation due to increased applied load at step k , ΔD^k : incremental displacement of the equivalent SDOF system at step k , $D^{(k)}$ displacement of the equivalent SDOF system at step k .

Step 14: Go back to step 3 and repeat the process until an extreme value of base shear is achieved or the structure fails.

Step 15: Develop the Force-Displacement curve, ($F^* - D$ curve) of equivalent inelastic SDOF system with unit mass based on the computed values in steps 12 and 13 in the previous cycles and idealize it as a bilinear curve.

Step 16: compute the peak inelastic displacement of the equivalent SDOF system by performing a nonlinear time history analysis to obtain the target displacement. Alternatively, target displacement can be computed by plotting the capacity curve (i.e. $F^* - D$ curve) against the inelastic acceleration-displacement response spectra.

Step 17: Determine the corresponding step to the target displacement in the pushover procedure and obtain the interested pseudo seismic demands.

3 DESCRIPTION OF PARAMETRIC STUDIES

3.1 Structural system

A twelve-storey moment resisting concrete frame has been selected with a structural plan as shown in Fig. 1. A distance equal to 10% of the plan dimension has been considered between the centre of mass (CM) and centre of stiffness (CS). Since the first natural vibration mode of the structure is dominantly torsional the building is considered as a torsionally flexible structure. Fig. 2 demonstrates the natural vibration modes of the structure. The building has been loaded as majority of common residential buildings are loaded in Iran. However, polar moment of inertia has been multiplied to represent a torsionally flexible structure. Nonlinear behaviour of the structure occurs at discrete hinges at both ends of beam and column elements which were defined in accordance with provisions of FEMA356 [8]. First 10 natural vibration modes of the structure have been considered to implement the SSAP method.

Figure 1. Plan view of the selected structure

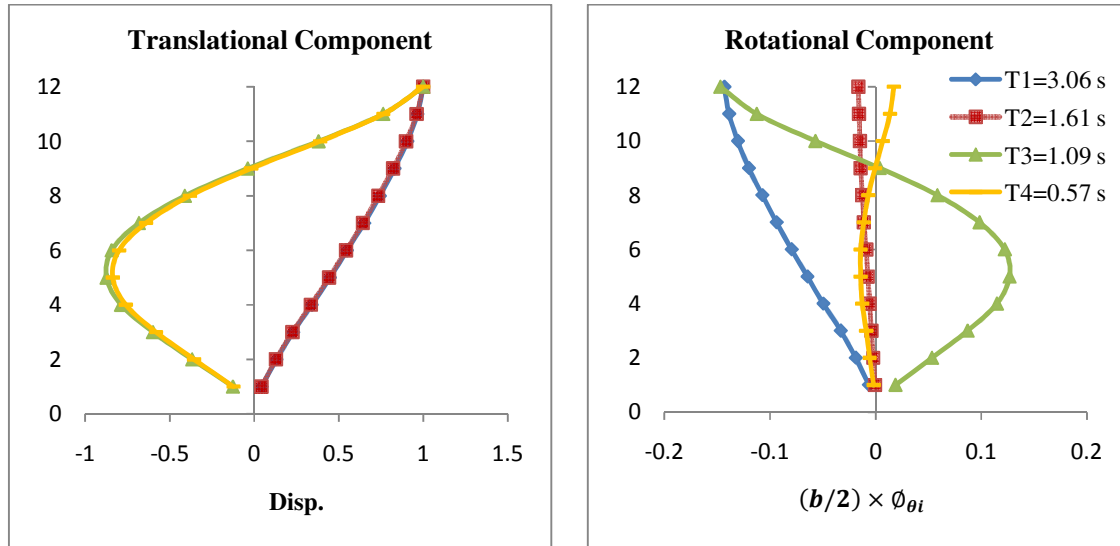

Figure 2. Natural periods and modes of vibration of the selected torsionally flexible structure

3.2. Ground motions

The building is subjected to a set of seven near-field seismic actions in the X-direction where torsion occurs throughout the analysis. Table 1 depicts the ensemble of selected motions. In addition, Fig.3 depicts pseudo-acceleration response spectrum of the records along with the design response spectrum of FEMA356 [8] for site class D in a high seismic region having short period response spectral acceleration (S_s) equal to 2.05g and spectral acceleration response at a period of 1 (S_1) equal to 0.82g. In order to ensure that the building responds within the inelastic range, records have been scaled such that the acceleration response spectrum of individual records are identical to pseudo acceleration response spectrum of FEMA356 at the structural fundamental period.

4 RESULTS OF NUMERICAL STUDIES

4.1. SSAP method via FEMA356 standard spectrum

Previous studies conducted to validate the SSAP procedure and its extended form (e.g. [6] and [7]) have been done by utilizing response spectrum of individual records, i.e. response spectrum of each record is used for A_n in eq. 2.1. One the main purposes of the current paper is to make the SSAP more practical. In this regard, the response spectrum of FEMA356 [8] has been used for the SSAP method instead of utilising individual spectrum for each record. Therefore, seven NLRHA have been performed and storey drifts were compared to the results of SSAP. To compute the target displacement, NLRHA of equivalent single degree of freedom system has been done. Since SSAP is performed once for seven earthquakes, mean of maximum displacement response of the equivalent single degree of freedom system from NLRHA of seven ground motions is taken as the target displacement. Fig.4. demonstrates the storey drift predictions of the extension of SSAP method versus mean of NLRHA obtained from seven ground motions selected for the study. As it is indicated in the figure, SSAP estimates are fairly acceptable at lower storeys while results are markedly under estimated at the upper storeys up to a level of roughly 60 percent at both flexible and stiff edges of the plan.

4.2. Modified-SSAP method via FEMA356 standard spectrum

Modifications already been defined in [7] to improve results of the extended form of SSAP are evaluated in this section while design spectrum is used in the method. To find the best matched storey drift profiles between pushover analysis and NLRHA, correction factor of the load pattern is applied and target displacement amplification is then evaluated such that best results for the pushover are obtained. To modify the load pattern, applied force to the top level is amplified based on the instantaneous period of first natural vibration mode, i.e. eq. (9) is replaced by the following equation:

$$\begin{cases} \Delta F_{ix} = \Delta V_b \bar{F}_{ix}, \Delta F_{iy} = \Delta V_b \bar{F}_{iy}, \Delta F_{i\theta} = \Delta V_b \bar{F}_{i\theta} & i = 1, \dots, N-1 \\ \Delta F_{ix} = \Delta V_b \bar{F}_{ix}(1 + 0.9T_1), \Delta F_{iy} = \Delta V_b \bar{F}_{iy}(1 + 0.9T_1), \Delta F_{i\theta} = \Delta V_b \bar{F}_{i\theta}(1 + 0.9T_1) & i = N \end{cases} \quad (16)$$

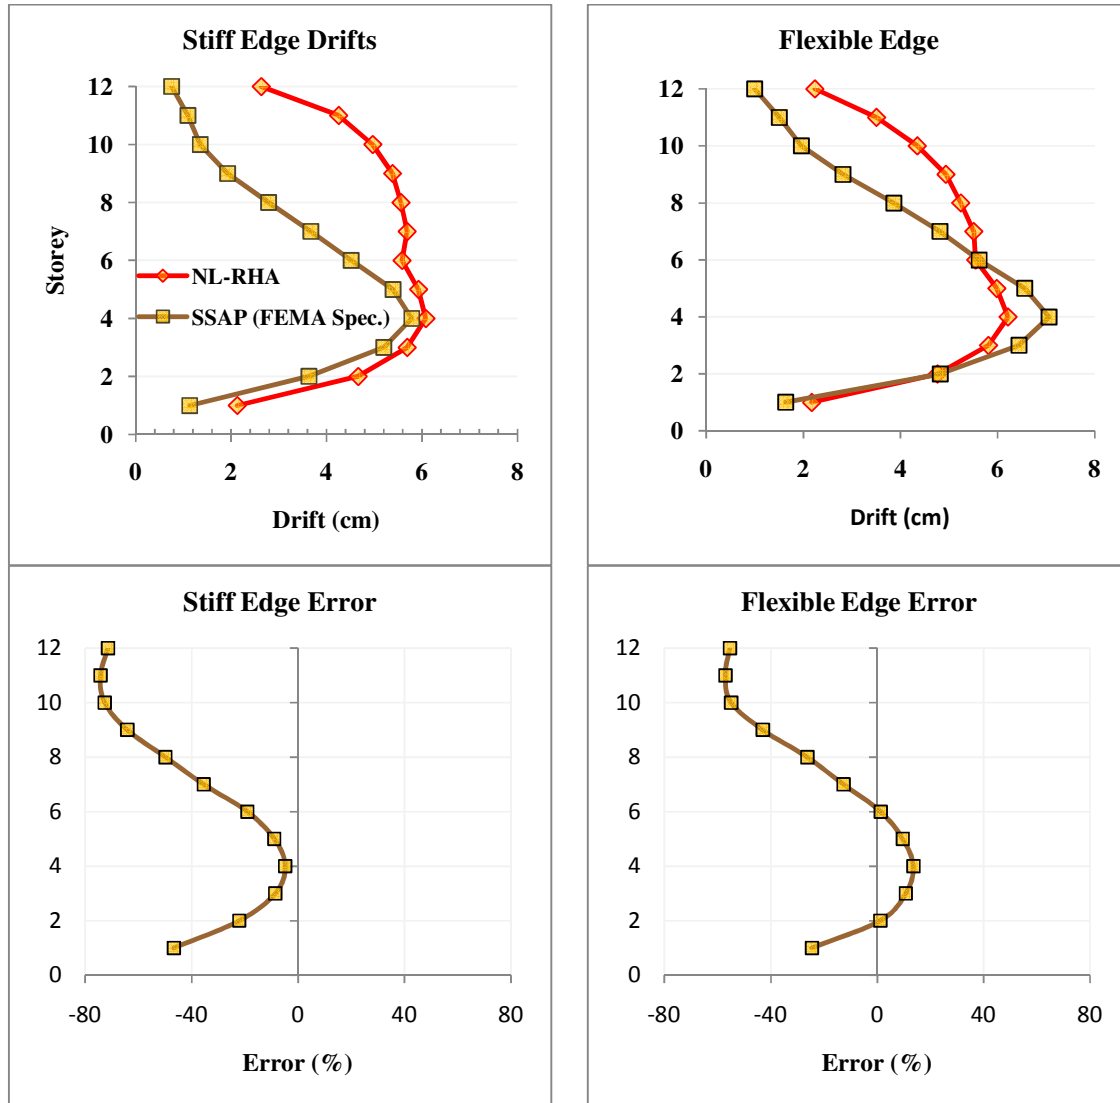

Figure 4. Height-wise storey drift predictions and errors of extended SSAP in comparison with mean of NLRHA from seven ground motions

where T_1 is instantaneous period of the first mode at each step obtained by stiffness characteristics of the structure at the end of the previous step.

As in the case of extended SSAP method described earlier, pushover analysis is performed once and the storey drift predictions of Modified-SSAP is compared with the mean of the results of NLRHA from seven ground motions. Figure 5 illustrates height-wise distribution of storey drifts in both flexible and stiff edges of the plan for SSAP when the modification factor of load pattern has been implemented in the algorithm. In order to be able to investigate the influence of the response spectrum shape in accuracy of the applied load pattern, depicted also in Figure 5 is a comparison of Modified-SSAP using FEMA356 spectrum as well as mean spectrum of the seven selected records. In both cases, target displacement correction factors have been multiplied which can lead to the best possible compatibility of the result compared to NLRHA. In this respect, correction factor 1.45 has been multiplied to target displacement

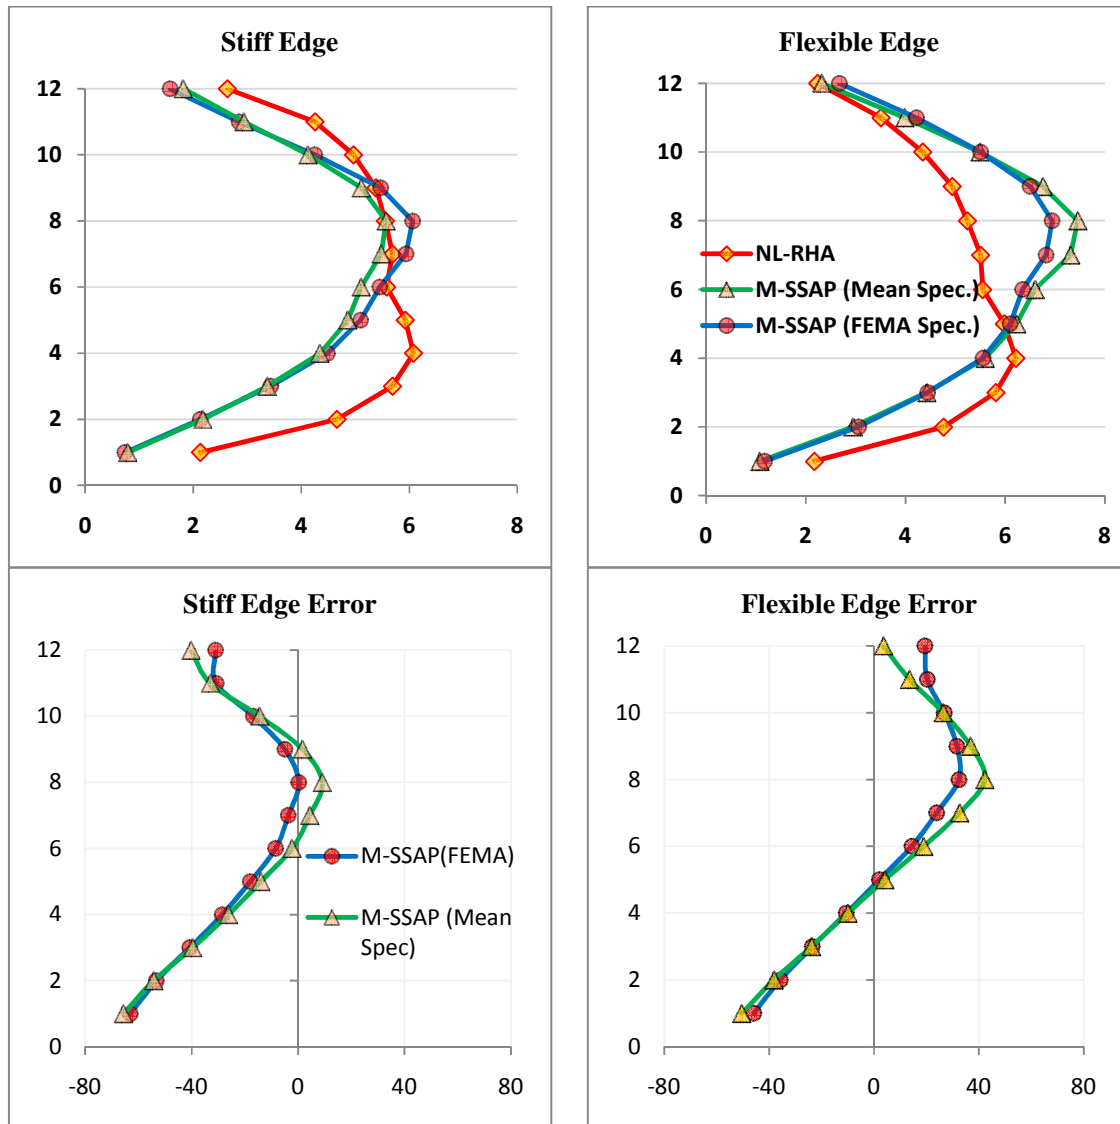

Figure 5. Height-wise storey drift predictions and errors of Modified-SSAP using mean as well as FEMA spectra in comparison with mean of NLRHA from seven ground motions

when the mean spectrum is used, and correction factor 1.5 has been used for the FEMA356 spectrum. Errors of the pushover analyses with respect to NLRHA have also been depicted in the figure. Clearly, it is expected to see much better results in the case where mean spectrum is utilised in the method. However a small difference is observed using two different spectra. This implies that design spectra can be used in the SSAP method while errors do not dramatically increase. The observation is important as far as the applicability of SSAP practically is concerned.

Comparison of figure 4 and 5 indicates that implication of modification of load pattern has been effective to improve the storey drift profile of the example building. Nevertheless, errors in the lower levels have been increased particularly in stiff edge. As it can be seen in the figure the little quantities of storey drifts in lower storey makes the errors larger while the differences are not very big. Therefore, definition of the error percentage as the ratio of drifts difference between pushover analysis and NLRHA should be taken into consideration.

5 CONCLUSIONS

A twelve storey building with torsionally dominant fundamental natural mode was evaluated in the paper by extended SSAP and NLRHA. FEMA356 design spectrum was used in SSAP to investigate the applicability of design spectra in the procedure algorithm instead of utilizing individual records spectra. Relatively acceptable degree of compatibility of results was observed in lower levels while results deteriorated in upper storeys. Multiplying the load pattern at the top storey by a factor related to the instantaneous period of the structure appeared to be effective to improve the compatibility of SSAP and NLRHA for the example building. However, modification factor leads to the underestimation of drift responses in lower storeys. Also, flexible edge estimates were better compatible to those of stiff edge. The impact of the selection of response spectrum on the accuracy of procedure seemed to be negligible.

Following the results of the example building studied in the paper, modifications of the original algorithm of the SSAP for planar frames looks to be a promising approach to improve the results of SSAP method. Needless to say that a very wide range of study is required to find most suitable correction factors for load pattern as well as target displacement.

Abstract. *Shear deformations may considerably affect the capacity and the failure mode of reinforced concrete members. Simplified beam-column models typically are not able to capture this effect and usually are suitable only for members that exhibit a flexure-dominated response. Modeling approaches of increasing complexity for the simulation of reinforced concrete shear walls are compared in this work. More specifically, we compare the common fiber beam element, a simplified fiber beam element based on the Timoshenko theory that considers separately shear and bending deformations and a third Timoshenko beam element where a multidimensional concrete law is used. The various approaches are discussed and compared against experimental results. It is worth noting that experiments implemented for the comparison exhibit different failure modes, flexural as well as shear failure. The numerical study provides an insight to the efficiency of the above methods in terms of computing demand, accuracy and ease of implementation.*

1 INTRODUCTION

Recent earthquakes have demonstrated that often reinforced concrete (RC) members fail under shear. Moreover, shear walls increase the stiffness and the deformation capacity of RC structures when subjected to inelastic cyclic deformations such as those imposed by strong seismic ground motions. Therefore, proper modeling of members of the effect of shear is essential for the seismic capacity assessment of RC structures.

Four alternative modeling approaches for the simulation of reinforced concrete frame members are here compared. The first approach is the common fiber-based beam element where shear effects are neglected. The second approach is also a fiber beam-column formulation, based on the Timoshenko theory. This element uses the fiber approach to capture bending and a separate shear force-shear strain relationship (V - γ) to capture the shear in the section level. Since separate laws are used for the fibers and the shear effect, this approach is called the “decoupled approach” [1, 2]. A more elaborate approach, also based on a Timoshenko fiber beam-column formulation, is adopted. In the latter case, a three-dimensional constitutive law for the concrete fibers is used, thus offering a full coupling between bending and shear strains [2, 3]. Our study includes also the Multiple-Vertical-Line-Element Model (MVLEM) approach as discussed by Massone and Wallace [4]. MVLEM is a macro-model element, able to incorporate important response parameters such as confinement, nonlinear shear behavior and migration of the neutral axis.

After a brief presentation of the models adopted, a comparative assessment on RC members subjected to different loading is presented. To evaluate the effectiveness and the reliability of the modeling approaches, our results are compared with available experimental data.

2 FINITE ELEMENT FORMULATIONS

The beam-column formulations implemented follow the force-based formulation, also known as flexibility formulation [5] for fiber-based, beam-column elements. Compared to displacement-based elements, this approach improves considerably the accuracy and the efficiency of the analysis [2, 3]. According to the force-based approach, the element flexibility matrix is calculated after integrating the section stiffnesses \mathbf{k}_{sec} , as:

$$\mathbf{F}_N = \left[\int_{-1}^1 \mathbf{b}^T(\xi) [\mathbf{k}_{\text{sec}}]^{-1} \mathbf{b}(\xi) d\xi \right] \quad (1)$$

where \mathbf{F}_N is the element flexibility matrix and $\mathbf{b}(\xi)$ is the force shape function matrix which calculates the section forces from the element forces. The element natural stiffness matrix is therefore calculated as:

$$\mathbf{K}_N = [\mathbf{F}_N]^{-1} \quad (2)$$

The element Cartesian stiffness is obtained from the expression:

$$\mathbf{K} = \mathbf{a}_N^T \mathbf{K}_N \mathbf{a}_N \quad (3)$$

where \mathbf{a}_N contains algebraic calculations and relates the displacements in the local cartesian and the natural system. The section stiffness matrix \mathbf{k}_{sec} of Equation (1) is obtained as the partial derivative of the section forces \mathbf{D}_{sec} over the section deformations \mathbf{d}_{sec} , and is calculated as [2,3]:

$$\mathbf{k}_{\text{sec}} = \int_A \mathbf{a}_s^T \mathbf{C} \mathbf{a}_s dA \quad (4)$$

where \mathbf{C} is the material constitutive matrix and \mathbf{a}_s is the section strain distribution matrix.

$$\boldsymbol{\varepsilon}(\boldsymbol{\xi}, y, z) = \mathbf{a}_s(y, z) \mathbf{d}_{sec}(\boldsymbol{\xi}) \quad (5)$$

More details about the fiber element formulation and the notation used above can be found in [2, 3].

2.1 Fiber element based on Euler-Bernoulli beam theory

The simplest force-based fiber element formulation (Bernoulli EB) is based on the Euler-Bernoulli assumption and therefore shear deformations are neglected. In this case, the section stiffness will be:

$$\mathbf{k}_{sec} = \int_A \mathbf{a}_{s,EB}^T \mathbf{C} \mathbf{a}_{s,EB} dA = \sum_{i=1}^{n_{fib}} \begin{bmatrix} E_i A_i & -y_i E_i A_i & z_i E_i A_i \\ -y_i E_i A_i & y_i^2 E_i A_i & -y_i z_i E_i A_i \\ z_i E_i A_i & -y_i z_i E_i A_i & z_i^2 E_i A_i \end{bmatrix} \quad (6)$$

where \mathbf{C} is a scalar and equal to the tangent Young modulus E_i of the i^{th} fiber, A_i is the area of the fiber, and y_i, z_i denote the coordinates of the fibers with respect to the centroid of the cross-section.

In Eq. (6) $\mathbf{a}_{s,EB}$ is the section strain distribution matrix of Eq. (5) which here takes the form:

$$\mathbf{a}_{s,EB}(y, z) = [1 \quad -y \quad z]. \quad (7)$$

2.2 Decoupled fiber element

This model consists of a shear spring connected in series with a beam-column element. This idea was initially presented by Marini and Spacone [1]. In order to take into consideration shear strains, a phenomenological V - γ shear law is implemented at the section level, and therefore the shear strains are uncoupled from axial and bending strains. This is a simplifying assumption that maintains all the advantages of fiber elements in terms of robustness and simplicity of the material laws adopted. The section stiffness will be:

$$\mathbf{k}_{sec} = \begin{bmatrix} \mathbf{k}_{sec}^{EB} & 0 & 0 \\ \mathbf{0} & dV_y / d\gamma_{xy} & 0 \\ \mathbf{0} & 0 & dV_z / d\gamma_{xz} \end{bmatrix}. \quad (8)$$

where \mathbf{k}_{sec}^{EB} is the stiffness matrix of Eq. (6) and $dV/d\gamma$ is the slope of the V - γ relationship.

A bilinear or a trilinear V - γ relationship can be used as discussed in a following section. In the linear elastic range $dV/d\gamma$ is equal to the product of the shear modulus times the area of the section (GA). It is noted that since this approach (Decoupled TB) is based on the Timoshenko assumption, the elastic stiffness of the element is different than that of the Euler-Bernoulli case.

2.3 Shear-Deformable fiber element

Compared to the previous two elements this is a more elaborate formulation that considers the axial-moment-shear interaction. In this case the material matrix \mathbf{C} has dimensions 3×3 and is given by the expression:

$$\mathbf{C} = \frac{\partial \boldsymbol{\sigma}}{\partial \boldsymbol{\varepsilon}} = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & q_y C_{22} & C_{23} \\ C_{31} & C_{32} & q_z C_{33} \end{bmatrix}. \quad (9)$$

In Eq. (9) in order to take into consideration that the shear stresses are not constant throughout the section, as Timoshenko beam theory assumes, the scaled shear stress distribution factors q_y , q_z are introduced. Moreover, the section strain distribution matrix of Eq. (5) takes the form:

$$\mathbf{a}_s(y, z) = \begin{bmatrix} 1 & -y & z & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} \mathbf{a}_{s,EB} & 0 & 0 \\ \mathbf{0} & 1 & 0 \\ \mathbf{0} & 0 & 1 \end{bmatrix}. \quad (10)$$

Eq. (10) leads to the section stiffness matrix:

$$\mathbf{k}_{sec} = \int_A \mathbf{a}_s^T \mathbf{C} \mathbf{a}_s dA = \sum_{i=1}^{n_{fib}} \begin{bmatrix} C_{11}^i \mathbf{a}_{s,EB}^T \mathbf{a}_{s,EB} & C_{21}^i \mathbf{a}_{s,EB} & C_{31}^i \mathbf{a}_{s,EB} \\ C_{21}^i \mathbf{a}_{s,EB}^T & q_y C_{22}^i & C_{23}^i \\ C_{31}^i \mathbf{a}_{s,EB}^T & C_{32}^i & q_z C_{33}^i \end{bmatrix}. \quad (11)$$

where y and z are the coordinates of an arbitrary point in the section.

Complicated materials are often described in the 3D continuum, thus hampering their application to structural elements such as beams, plates or shells. In order to incorporate a 3D material law we impose a condition of transverse equilibrium at every monitoring section [6].

$$\sigma_{y,c} A_{y,c} + \sigma_{y,s} A_{y,s} = 0 \Leftrightarrow \sigma_{y,c} + \rho_v \sigma_{y,s} = 0. \quad (12)$$

where $\sigma_{y,c}$ and $\sigma_{y,s}$ are the stresses developed in the concrete and the stirrups respectively, $A_{y,c}$ and $A_{y,s}$ are the area of concrete and the stirrups, respectively, in the monitoring vertical section and ρ_v is the shear reinforcement ratio.

2.4 The Multiple-Vertical-Line-Element Model approach

The generic Multi-Vertical-Line-Element model (Figure 1) consists of a series of truss elements (or macro-fibers) connected to infinitely rigid beams at their top and bottom. The number of truss elements can be increased to obtain a more refined description of the wall cross section. The shear response of the wall element is simulated with a horizontal spring, as originally suggested by Vulcano *et al.* [7].

The relative rotation between the top and bottom end of the wall element occurs around a point placed on the central axis of the element at height $h_c = c \times h$, where h is the height of the shear wall. A suitable value of parameter c is based on the expected curvature distribution along the element height. Although an accurate assessment of c is not necessary, if we use a moderate number of MVLEM elements within the yielding region are used, a value of $c=0.4$ is recommended based on experimental results [8, 9].

Figure 1: Schematic representation of the MVLEM.

The shear wall is modeled as a stack of m elements, placed one upon the other [4, 8]. A single two-dimensional MVLEM has 6 degrees of freedom, located at the center of the rigid beams of its top and its bottom cross-sections (Figure 1). In order to calculate the strains of the truss elements, it is assumed that the top and bottom sections remain plane. The stiffness matrix of an MVLEM element, will be:

$$\mathbf{K}_e = \mathbf{e}^T \mathbf{K} \mathbf{e} . \quad (13)$$

where \mathbf{e} is a transformation matrix used to extract the extension and the relative rotations at the two ends from the element Cartesian degrees of freedom (Figure 1). The transformation matrix \mathbf{e} is given by the formula:

$$\mathbf{e} = \begin{bmatrix} 0 & -1 & 0 & 0 & 1 & 1 \\ -1/h & 0 & 1 & 1/h & 0 & 0 \\ -1/h & 0 & 0 & 1/h & 0 & 1 \end{bmatrix} \quad (14)$$

and the element stiffness matrix \mathbf{K}_e of Eq. 14 will be:

$$\mathbf{K} = \begin{bmatrix} \sum_{i=1}^n k_i & -\sum_{i=1}^n k_i x_i & \sum_{i=1}^n k_i x_i \\ -\sum_{i=1}^n k_i x_i & k_H c^2 h^2 + \sum_{i=1}^n k_i x_i^2 & k_H c(1-c)h^2 - \sum_{i=1}^n k_i x_i^2 \\ \sum_{i=1}^n k_i x_i & k_H c(1-c)h^2 - \sum_{i=1}^n k_i x_i^2 & k_H (1-c)^2 h^2 + \sum_{i=1}^n k_i x_i^2 \end{bmatrix} \quad (15)$$

where k_H is the stiffness of the horizontal spring, k_i is the stiffness of the i^{th} truss element and x_i is the distance of the i^{th} truss element to the central axis of the MVLEM element.

3 MATERIAL MODELS

The uniaxial stress-strain relationship used for the concrete fibers follows the modified Kent and Park model [10]. In the coupled shear-deformable fiber element where a 3D material

law is necessary, the same relationship for each of the principal axes is adopted, while in order to take fracture into consideration, a three-dimensional rotating crack model is employed [2, 3]. Although this is not strictly a multidimensional concrete law, this approach is able to yield robust results of increased accuracy. The hysteretic response of reinforcing steel follows according to the stress–strain relationship proposed by Menegotto and Pinto [11], as extended by Filippou *et al.* [12] to include isotropic strain hardening.

When a shear V - γ law is used for the decoupled–shear deformable beam element, a bilinear curve is defined. Two different approaches for calculating the V - γ law were examined. The first approach is based on the shear law proposed by Gerin and Adebar [13] and the second approach is discussed in Mergos and Kappos [14]. The two different V - γ curves are shown in Figure 2.

Figure 2: Shear force versus shear strain (V - γ) relationship used for the shear component is obtained as discussed in [13] and [14].

According to the first approach [13], the envelope is primarily defined by the shear stress and strain at yield, which are used to estimate the ultimate shear strain. The first branch connects the origin with the peak point (V_{Rd} , γ_y). The section shear capacity V_{Rd} was calculated according to Eurocode 2 (2004) [15], while the shear strain at yield is given by the following equation:

$$\gamma_y = \frac{f_y}{E_s} + \frac{v_y - n}{\rho_v E_s} + \frac{4v_y}{E_c} \quad (16)$$

where f_y is the reinforcement yield stress, E_s is the reinforcement modulus of elasticity, v_y is the applied shear stress (at yield), n is the vertical axial compression, ρ_v is the vertical reinforcement ratio and E_c is the tangent stiffness of the concrete. The ultimate shear strain γ_u is obtained using the shear strain at yield from the following relationship for the shear strain ductility μ_γ :

$$\mu_\gamma = \frac{\gamma_u}{\gamma_y} = 4 - 12 \frac{v_y}{f_c} \quad (17)$$

Here perfect plasticity is assumed, so the section shear capacity at ultimate strain coincides with that of the shear strain at yield ($V_{Rd} = V_u$).

According to the second approach discussed in [14], the bilinear curve is defined by a cracking point and the failure point. The shear force at cracking is given by the relationship of Sezen and Moehle [16]:

$$V_{cr} = \frac{f_{ctm}}{L_s / h} \sqrt{1 + \frac{N}{f_{ctm} \cdot A_g}} \cdot 0.80 A_g \quad (18)$$

where f_{ctm} is the mean concrete tensile strength, N is the compressive axial load, L_s/h is the shear span ratio, and A_g is the gross area of the concrete section. Assuming a parabolic shear strength distribution along the cross section, the initial shear stiffness GA_{eff} is calculated as $GA_{eff} = G \cdot (0.80 A_g)$ where G is the elastic shear modulus. The second and third branches share the same slope, connecting the cracking point to the failure point, and separated at the flexural yielding point (V_y, γ_y). The mean shear strain γ_u is estimated using the truss analogy [17, 18]:

$$\gamma_u = \frac{V_{cr}}{GA_{eff}} + \frac{V_{Rd,s}}{(d-d')} \cdot \left(\frac{s}{E_s \cdot A_{sw} \cdot (\cot \theta)^2} + \frac{1}{E_c \cdot b \cdot (\sin \theta)^3 \cdot \cos \theta \cdot \cot \theta} \right) \quad (19)$$

where A_{sw} is the area of the transverse reinforcement oriented parallel to the shear force, $d-d'$ is the distance between the centers of the longitudinal reinforcement, s the spacing of transverse reinforcement, b is the width of the cross-section, E_c is the elastic modulus of concrete, E_s the elastic modulus of steel, θ is the angle defined by column axis and the direction of the diagonal compression struts and $V_{Rd,s}$ is the shear strength contributed by the transverse reinforcement [15].

4 NUMERICAL EXAMPLES

A numerical investigation has been carried out using two RC shear walls and an RC column specimen. The two shear walls (denoted as SW30 and SW33) were tested under monotonic and cyclic loading by Lefas and Kotsovos [19], while the RC column was subjected to cyclic loading by Xiao *et al.* [20].

The dimensions and the arrangement of the reinforcement of the wall specimens are shown in Figure 3. They are 0.65m wide, 1.3m high and their thickness is 0.065m. Both walls were monolithically connected to a beam in their base. The vertical and the horizontal reinforcement comprises of high-tensile deformed steel bars of 8mm and 6.25mm diameter, respectively. Additional reinforcement in the form of stirrups confine the wall edges using mild steel bars of 4mm diameter. The properties of the reinforcing bars are shown in Table 1. The cube strength f_{cu} at the day of testing was 30.1 MPa for the SW30 and 49.2 MPa for the SW33 shear wall.

Diameter(mm)	f_{sy} (MPa)	f_{su} (MPa)
8	470	565
6.25	520	610
4	420	490

Table 1: Properties of the reinforcing bars.

Figure 3: Geometry and reinforcement of the shear wall specimens.

The SW30 wall was modeled using the Bernoulli EB, Decoupled TB and Shear-deformable TB simulation with a single force-based element. For all elements five Gauss-Lobatto integration points were used. For the MVLEM approach, one macroelement has been adopted. The analysis results of all models are compared to experimental results and are summarized in Figure 4. Considerable differences between numerical and experimental results for both stiffness and ultimate strength are observed for the Bernoulli EB model. The Decoupled TB model curve gives improved results but still is not able to closely predict the experimental results. The curve obtained by the shear-deformable fiber element exhibits good accuracy compared to the experimental curve. Implementing the MVLEM approach, the discrepancy for the ultimate strength is reduced, but the stiffness is overestimated for displacements between 5 and 10 mm.

Figure 4: Experimental and numerical results for specimen SW30.

The sensitivity of the numerical results to the shear law assigned to the shear spring for the Decoupled TB element is shown in Figure 5. The results correspond to the two different envelope curves of Figure 2 and are compared with experimental results and those of the common fiber element (Bernoulli EB). It can be observed that numerical models overestimate the initial stiffness and the ultimate strength of the wall compared to the experimental results. However, they give a more representative response compared to Bernoulli EB model, since shear deformations have been taken into consideration, even though the model neglects the interaction between moment and shear.

Figure 5: Influence of the shear – law used for the decoupled shear–deformable element on SW30 shear wall.

Figure 6: Influence of the number of MVLEM elements used for the uncoupled shear–deformable element on SW30 shear wall.

A parametric study on the sensitivity on the number of MVLEM elements is shown in Figure 6. The initial stiffness is correctly calculated regardless of the number of MVLEM elements. Contrary to the initial stiffness, the ultimate strength is affected by the number of elements. When one MVLEM element is implemented, the ultimate strength is overestimated, while increasing the number of elements leads to underestimating it. The more elements are implemented for the analysis, the underestimation is increased and converges to the curve of

the 100 elements. It is worth noting that analyses with 20, 27, 42 MVLEM elements was conducted and the results were similar to those of the 100 elements.

The second shear wall specimen (SW33) is similar to the first but is subjected to cyclic instead of monotonic loading. The history of the displacement which was forced at the top of the wall is shown in Figure 7.

Figure 7: The displacement history adopted of the cyclic tests.

Figure 8: Experimental and numerical results for specimen SW33 of the Bernoulli EB model.

According to Figure 8, the Bernoulli EB model overestimates both stiffness and ultimate strength. When the Decoupled TB (Figure 9) is implemented, a clear improvement on the stiffness prediction can be observed. However, again the ultimate strength is overestimated. Good agreement with experimental results in the prediction of the wall flexural behavior has been obtained with the MVLEM (Figure 10). The difference on the ultimate strength has been reduced, while the stiffness is predicted sufficiently in comparison with the Bernoulli EB and the Decoupled TB models.

Figure 9: Experimental and numerical results for specimen SW33 implementing Decoupled TB.

Figure 10: Experimental and numerical results for specimen SW33 implementing MVLEM model.

The next specimen examined is an RC column. The column is 0.61m wide, 1.83m high and 0.406m thick. The vertical and horizontal reinforcement consists of steel bars of $22\Phi 19.05\text{mm}$ and $1\Phi 6.35\text{mm}/107\text{mm}$ diameter, respectively. The yield strength f_{sy} of the vertical and horizontal reinforcement is 470MPa and 324MPa respectively. The cube strength f_{cu} at the day of testing was 32.75 MPa. The reason for examining this specimen was that sudden loss of strength was observed during the experiment, due to the opening of large shear cracks which lead to shear failure mode.

Implementing the Bernoulli EB model, an overestimation on stiffness, strength and dissipated energy is observed (Figure 11). As far as the Decoupled TB model is concerned, sensitivity to the adopted shear law curve was detected as in the previous specimens. Consequently, numerical results obtained for different shear law curves will also be presented. The first shear law curve was obtained according to reference 12, while the second is adopted as proposed for a similar cross-section in reference [1] (Figure 12).

Figure 11: Experimental and numerical results for specimen SW33 implementing Bernoulli EB.

Figure 12: Shear force versus shear strain (V - γ) relationship used for the shear component (I: Gerin and Adebar [13], II: Marini and Spacone [1]).

Despite the fact that strength is underestimated, a clear improvement is noticed in the prediction of stiffness and energy dissipated when Decoupled TB model (I and II) is adopted compared to Bernoulli EB model (Figures 13 and 14). According to Figures 13 and 14 the load-displacement curves follow the trends imposed by the shear V - γ curves, since the failure mode of this specimen is shear.

Figure 13: Experimental and numerical results for RC column specimen implementing the Decoupled TB shear law I [12].

Figure 14: Experimental and numerical results for RC column implementing the Decoupled TB shear law II [1].

When the MVLEM (I and II) model is adopted (Figures 15 and 16), considerable underestimation of the strength was again observed, while the calculation of the stiffness and energy dissipation is improved compared to Bernoulli EB model, regardless of the shear model. The results shown has been obtained with the V - γ curve of reference [12, 1].

5 CONCLUSIONS

Several modeling approaches for the modeling of RC shear walls have been compared. In order to validate the numerical results monotonic and cyclic experimental data were adopted. The analyzed walls exhibited flexural as well as shear failure modes. It is shown that the beam element based on the Euler-Bernoulli theory, although suitable for its simplicity, is not capable to properly simulate various phenomena related to shear effects and therefore produced erroneous predictions. No particular advantage was observed implementing beam element based on Timoshenko beam theory, with no coupling between shear and flexural deformations, despite the fact that a slight improvement in stiffness prediction is apparent compared to the Euler-Bernoulli EB model. The MVLEM model predicts relatively accurately the wall response as identified from the previous seen work. However, no damaging effects were captured. Sufficient results were obtained but still there are differences from the experimental results. The shear-deformable fiber element proved to be more suitable to predict the inelastic static behavior of slender walls. It successfully balances the simplicity of a beam model and

the refinements offered by a 3D law, while it enables modeling some important features which are ignored by other models.
