evidenced by the corresponding stiffness curves also depicted in Figure 7. Softening nonlinearity is typical of bolted connections [17, 18]. Similar nonlinear effect occurs for the front connections, but they participate much less in the considered response. Finally, the deviation between the right and left connections seems to show asymmetry of the connections.

Although purely qualitative, the RFS results therefore indicate that the tank connections present a softening stiffness in the vertical direction. As previously mentioned, a model with piecewise characteristic might be consistent with the experimental observations. However, the NNM algorithm, in its present form, cannot handle nonsmooth nonlinearities. Alternatively, linear and negative cubic stiffness terms are one possible manner of describing the observed nonlinear behavior. Indeed, the reconstructed stiffness curve obtained by fitting to the data the mathematical model

$$f_{r,c} = kx_{rel} + k_{nl}^- x_{rel}^3 \quad (k_{nl}^- < 0) \quad (22)$$

is in relatively good agreement.

In view of the qualitative value of this approach, we note that the objective followed here is to derive a simplified realistic model in order to illustrate the numerical computation procedure of NNMs. Accordingly, in the present study, the nonlinear behavior is modeled by adding negative cubic stiffness nonlinearities into the linear part of the connections. An indicative value of -10^{13}N/m^3 is adopted for each connection. Finally, the nonlinear system is then constructed from the reduced-order model by means of cubic springs positioned vertically between both corresponding nodes retained on either side of connections.

4.2 Nonlinear Normal Modes

From the nonlinear reduced-order model, the numerical computation of NNMs is realized in the MATLAB environment using the previously developed algorithm. The goal followed here is to show that the proposed method can deal with complex structures such as this real-aircraft model. In this context, this section focuses on some specific modes.

4.2.1 Fundamental NNMs

The modes of the aircraft can be classified into two categories, depending on whether they correspond to wing motions or not. The modes localized mainly on other structural parts (such as the vertical stabilizer, the horizontal tail or the fuselage) are almost unaffected by the nonlinear connections located at the wing tips. Only the modes involving wing deformations are perceptibly affected by nonlinearity. According to the relative motion of the fuel tanks, these modes are more or less altered for increasing energy levels.

An unaffected mode is first examined in Figure 8. It corresponds to the nonlinear extension of the first tail bending LNM (mode 13 in Table 2). In this figure, the computed backbone and related NNM motions are depicted in the FEP. The modal shapes are given in terms of the initial displacements (with zero initial velocities assumed) that realize the NNM motion. It clearly confirms that the modal shape and the oscillation frequency remain practically unchanged with the energy in the system.

Modes involving wing deformations are now investigated. The first wing bending mode (i.e., the nonlinear extension of mode 10 in Table 2) is illustrated in Figure 9. The FEP reveals that this mode is weakly affected by the nonlinearities. The frequency of the NNM motions on the backbone slightly decreases with increasing energy levels, which results from the softening characteristic of the nonlinearity. Regarding the modal shapes, they are almost similar over the

energy range and resemble the corresponding LNM. MAC value between the NNM shapes at low and high energy levels (see (a) and (b) in Figure 9) is 0.99.

Figure 10 represents the FEP of the first (symmetric) wing torsional mode (i.e., mode 19 in Table 2). For this mode, the relative motion of the fuel tanks is more important, which enhances the nonlinear effect of the connections. As a result, the oscillation frequency have a more marked energy dependence along the backbone branch. On the other hand, the modal shapes are still weakly altered. MAC value between the NNM shapes on the backbone at low and high energy levels (see (a) and (b) in Figure 10) is equal to 0.98. In addition, the FEP highlights the presence of three tongues, revealing the existence of internal resonances between this symmetric torsional mode and other modes. These observed modal interactions are discussed in the next section.

Finally, the second (anti-symmetric) wing torsional mode (i.e., mode 20 in Table 2) is plotted in the FEP of Figure 11. While the oscillation frequency is noticeably altered by nonlinearity, modal shapes are again slightly changed. Over the energy range of interest, the decrease in frequency is around 5% along the backbone branch. MAC value between the modal shapes at low and high energy levels (see (a) and (b) in Figure 11) is 0.97. It shows that the nonlinearities spatially localized between the wing tips and the tanks weakly influence the NNM spatial shapes. Besides the NNM backbone, one tongue is present at higher energy. For information, the computation of the backbone branch up to the tongue needs 20 min with 100 time steps over the half period (using Intel i7 920 2.67GHz processor). Due to the presence of turning points, the computation of the tongue is more expensive and demands about one hour.

Similar dynamics were observed for the higher modes and are not further described herein.

4.2.2 Internally Resonant NNMs

Besides the backbone branches, the previous FEPs show the presence of tongues of internally resonant NNMs. Following a resonance scenario similar to that described in [3], these additional branches emanate from the backbone of a specific NNM and coalesce into the backbone branch of another NNM, thereby realizing an internal resonance between the two modes.

This is briefly illustrated in Figure 12 regarding the 3:1 tongue emanating from the backbone of the first wing torsional mode (see Figure 10). Modal shapes are given at three different locations on the tongue (see (a), (b) and (c) in Figure 12). When the energy gradually increases along the tongue, a smooth transition from the first wing torsional mode to a higher tail torsional mode clearly occurs. Interestingly, Figure 12(b) shows an inherently nonlinear mode with no counterpart in the underlying linear system. It corresponds to a 3:1 internal resonance as evidenced by the evolution of the time series and the frequency content, also represented in Figure 12, of the periodic motions along the tongue. A third harmonic progressively appears, and the structure vibrates according to a subharmonic motion characterized by two dominant frequency components. The relative importance of the third harmonic grows along the tongue, until the mode transition is realized.

Similarly, two other tongues corresponding to a 5:1 and a 9:1 internal resonance between this first wing torsional mode and higher modes are observed in the FEP of Figure 10. Moreover, the FEP of Figure 11 reveals the presence of a 9:1 internal resonance between the second wing torsional mode and another higher mode of the aircraft. We note that the practical realization of these internal resonances is questionable in view of the low frequency changes.

5 Conclusion

In this paper, a numerical method for the computation of NNMs of mechanical structures was introduced. The approach targets the computation of the undamped modes of structures discretized by finite elements and relies on the continuation of periodic solutions.

This computational approach turns out to be capable of dealing with complex real-world structures, such as the full-scale aircraft studied herein. Through a reduced-order model accurate in the [0-100Hz] range, the NNMs were indeed computed accurately even in strongly nonlinear regimes and with a reasonable computational burden. Internal resonances were also computed by the algorithm and were briefly discussed.

Keywords: SWAP, PROBA2, optical membranes, vibro-acoustics.

Abstract. *During its intensive testing campaign, SWAP (Sun Watcher using Active Pixel System detector and image Processing), an optical instrument developed by Centre Spatiale de Liège (CSL) and mounted onto the Belgian satellite PROBA2, was subjected to a multitude of load cases to verify the integrity of the instrument during and after the launch and during the operational phase.*

The front and rear filters of SWAP, 200 nm thin films, survived intensive vibration tests on the qualification model and acceptance tests on the flight model, both at an instrument level. During the acoustic test on the spacecraft, the front filter exploded while the rear one was undamaged. A new, strengthened filter, coated with a very fine metal mesh was mounted in the instrument. However, this new filter has less good optical properties due to optical diffraction. Therefore a profound analysis of the filter failure is necessary to provide the best possible optical accuracy for future missions with similar equipment.

Three load cases are further studied in this paper: the acceleration of the rocket, the instrument depressurisation and the vibro-acoustic behaviour under the large sound and vibration levels. The acceleration and depressurisation are studied together in a two-level computational fluid dynamics (CFD) analysis to assess the effect of the venting of the instrument on the differential pressure over the filter. The main focus of this paper is on a numerical vibro-acoustic analysis, following the procedures used by CSL and ESTEC (European Space Research and Technology Centre). This analysis needs special attention because of the presence of a stochastic excitation (diffuse field) and the very nonlinear behaviour of the filter itself due to its small thickness. Also, an additional postprocessing step based on filter displacements, rather than differential pressure, as done in the ESTEC procedure, is discussed.

1 INTRODUCTION

On November 2nd 2009 PROBA2¹, the second completely Belgian mini-satellite, produced by the company Verhaert (now QinetiQ), was launched from the ESA-base in Plesetsk, Russia. The goals of the mission were dual: providing a proving ground for new technologies to test their flightworthiness and studying the interaction between the Earth and the Sun and the impact on the so called space weather. One of the scientific instruments on board was the SWAP²-instrument, an optical instrument designed by Centre Spatiale de Liège (CSL) to study the solar corona. For this purpose, it is equipped with two optical filters that retain only the frequencies of the solar spectrum relevant to the spaceweather (eUV-frequencies).

The instrument (roughly 50 cm x 15 cm x 10 cm in size) is constructed as is illustrated in Figure 1(a). The instrument cavity is closed, a.o. for cleanliness of the instrument, by a heavy door maintained by a launch lock mechanism with a dedicated labyrinth for depressurisation. Behind that door, which is designed to protect the instrument from acoustic overload, lies a first (small) cavity. Between this small cavity and the large instrument cavity lies the front optical filter, an aluminum membrane with a thickness of 200 nm, which can withstand an ultimate differential pressure of 200 Pa.

(a) SWAP architecture [1].

(b) Strengthened filter [2].

Figure 1: General SWAP architecture and strengthened filter.

The front and rear filters of SWAP survived intensive vibration tests on the qualification model and acceptance tests on the flight model, both at an instrument level. During the acoustic tests of the spacecraft, as in-flight images indicate, the front filter exploded, while the rear one was undamaged. Because of the tight schedule for further testing and launch, the problem had to be dealt with very quickly. Therefore, a new, strengthened filter, coated with a very fine (20 lpi) nickel mesh was mounted (figure 1(b)). This however degrades the optical properties of the filter due to optical diffraction and is therefore not the optimal solution. To learn lessons for future missions, a profound analysis is necessary to assess the true cause of failure for the original filter. A preliminary vibro-acoustic analysis, as performed at ESTEC³, raised quite some questions. Therefore, CSL proposed to K.U.Leuven to further explore the problem in the context of the master's thesis study [3] of the first author of this paper.

This paper discusses three load cases that can cause filter failure. Apart from the apparent (acoustic) cause of failure in the tests, which was first studied at ESTEC and then at K.U.Leuven

³European Space Research and Technology Centre

adopting the ESTEC procedures, the more or less steady-state acceleration of the rocket and the instrument depressurisation, which were tackled by GDTech [4] in a preliminary design study commissioned by CSL, is also discussed.

This acceleration and depressurisation will be studied together in a two-level computational fluid dynamics (CFD) analysis to assess the effect of the venting of the instrument on the differential pressure over the filter.

The main focus of this paper, however, lies on a numerical vibro-acoustic analysis. The analysis needs special attention because of the presence of a stochastic excitation (diffuse sound field), the very nonlinear nature of the filter itself due to its small thickness and the imprecise impact behaviour of the door, which can start flapping and whose acoustic effect is unclear. The procedure followed the same lines as the analysis procedures used by CSL and ESTEC. An additional postprocessing step based on the filter displacements, rather than pressure differences in arbitrary points was added. This approach leads to better, but nevertheless inconclusive results.

The application of these procedures for this type of vibro-acoustic analysis shows that it may in some cases be very hard, or even impossible, to make accurate predictions of the system behaviour when strong nonlinearities are present. Despite the fact that some predictions on the system behaviour can be made in an approximative manner, these predictions have to be used with great care.

2 FLUID DYNAMICS: DEPRESSURISATION AND ACCELERATION

A first important loading on the filter arises from the air escaping the instrument. This so called venting is caused by two effects: the cavity depressurisation and the inertia of the air while the rocket accelerates. These effects are elaborated in the following subsections.

To allow this air to escape smoothly, ventilation labyrinths are put at five distinct locations (see Figure 2(a)). Of these vents, the two utter left on the figure (near the door and just behind the filter) are the most interesting from a filter loading point of view. Since no light is allowed to enter or leave through these ventilation holes (otherwise the instrument would not be able to exclusively study the eUV-spectrum), these vents are engineered as labyrinths (Figure 2(b)). This way, unwanted light is attenuated by means of multiple reflections.

The analyses presented in this section were performed by GDTech [4] in a preliminary study commissioned by CSL. In the analysis, the air was considered to be an ideal gas at 20°C. A preliminary study showed laminar flow in all of the vents.

Figure 2: Instrument venting system.

2.1 Depressurisation

Due to the rocket gaining height, the pressure of the instrument environment decreases in time (Figure 3(a)). This causes a pressure difference between the inside and the outside. This creates a flow which is governed by Cauchy's momentum equation.

$$\rho \frac{D\vec{v}}{Dt} = \nabla \cdot (-p\mathbb{I} + \mathbb{T}) \quad (1)$$

with ρ being the fluid density, v the fluid velocity, t the time, p the pressure, \mathbb{I} the identity tensor, \mathbb{T} the fluid stress tensor.

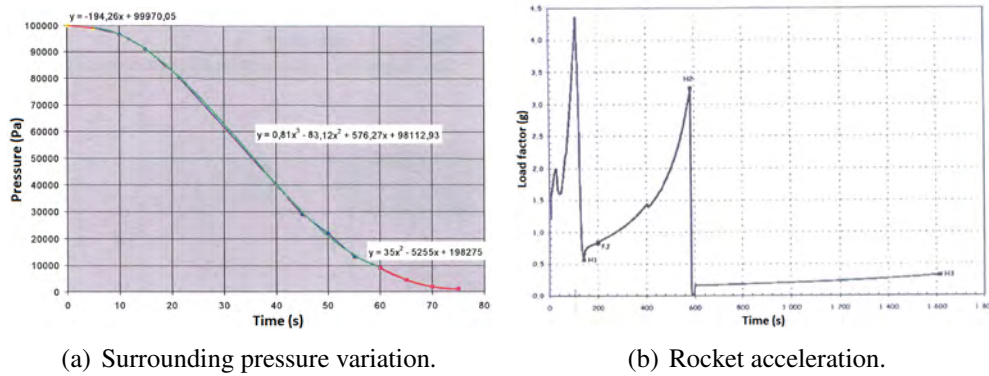

Figure 3: Variation of the imposed loading conditions in time [4].

2.2 Acceleration

The acceleration of the rocket produces a loading on the filter because of the inertia of the air surrounding it. This section will not discuss acceleration effects on the filter itself, which will be quite small because of the very low mass.

The acceleration profile can be found in Figure 3(b). The most penalising situation⁴, being a loading perpendicular to the filter, is considered here, for the first eighty seconds.

This inertial loading is introduced into the governing momentum equation (Equation 1) by means of a source term $\rho\vec{a}$, with \vec{a} the rocket acceleration, resulting in:

$$\rho \frac{D\vec{v}}{Dt} = \nabla \cdot (-p\mathbb{I} + \mathbb{T}) + \rho\vec{a} \quad (2)$$

2.3 Analysis

The analysis of the flow effects was performed on two levels: a lower, very detailed level, and a higher, more general one, using approximated results from the lower level.

On the low level we consider the flow inside the venting labyrinths in a detailed 2D CFD analysis (Figures 4(a) and 4(b)).

$$dP_i = aV_{ref} + b\frac{1}{2}\rho_i V_{ref}^2 \quad (3)$$

where a is related to a friction pressure loss (via e.g. the Hagen-Poiseuille equation) and b to a singular pressure drop. This approach was inspired by [5].

⁴This is not the true situation.

By carrying out CFD calculations for several fluid densities ρ_i , the unknown coefficients a and b can be easily determined.

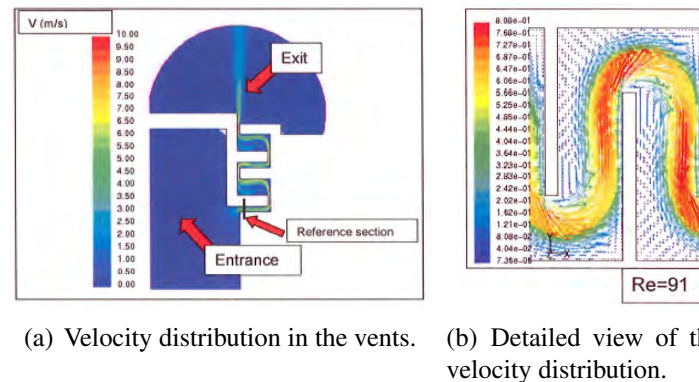

Figure 4: Detailed 2D velocity distribution in the venting labyrinths [4].

These pressure laws for the different labyrinths are then plugged in a higher-level calculation. This makes it possible to evaluate the pressure difference over the filter caused by the dynamics of the fluid. These results, for the first 80 seconds, are represented in Figure 5.

From this graph it becomes clear that neither the acceleration, nor the depressurisation could be the cause for the failure of the filter. The maximal value for the differential pressure never even comes close to the allowed value of 200 Pa. Other possibilities for the filter failure thus have to be considered.

Figure 5: Pressure difference over the filter caused by depressurisation and acceleration effects [4].

3 (VIBRO-)ACOUSTIC ANALYSIS

This section describes the numerical vibro-acoustic analysis that was performed upon the instrument. The focus lies on the acoustic part of the vibro-acoustics, studying the instrument response under the acoustic load caused by the rocket engine. The structural loading was tested extensively by CSL in all types of shaker tests [6]. However, no measurement data of the filter is available for these tests. Visual inspections showed that vibrations alone could not have damaged the filter.

Before discussing this numerical analysis itself, the paper treats the implementation that was used, which differs from standard deterministic vibro-acoustic analyses and the numerical model. Then the (preliminary) results of the analysis itself will be covered. The analysis is concluded with the postprocessing of the acquired results.

3.1 Model

From an initial model, used by CSL for a static structural analysis, the vibro-acoustic system is built by coupling two derived models: a structural model (Figure 6(a)) and an acoustic model (Figure 6(b)).

The structure is modelled using the Finite Element Method (FEM [7]). This procedure discretises the problem domain into nodes and elements. The exact solution within these elements is approximated using simple polynomial shape functions. The application of a weighted residual formulation of the governing differential equation and boundary conditions leads to a system of equations which can be solved for the unknowns, in this case the nodal structural displacements. In a postprocessing step, strains and stresses can then be calculated.

The acoustics are modelled using the Indirect Boundary Element Method (iBEM [8],[9]). This method uses a boundary integral formulation of the governing differential equations. The boundary is discretised into nodes and elements similarly to the FEM. The resulting system of equations is then solved for the unknowns, here acoustic potentials related to pressure and velocity differences across the considered surface. In a next step, the results can be postprocessed to obtain acoustic pressures and velocities anywhere in the field.

Finally, both models are coupled to each other to account for the interaction between structural vibrations and acoustics: structural vibrations impose acoustic normal velocity fields, thus generating pressure waves, while acoustic pressures produce a dynamic loading on the structure. This leads to a vibro-acoustic model in which the structural model (50,000 degrees of freedom) is fully coupled to the acoustic model (20,000 degrees of freedom).

The frequency band for which the models are valid, is determined by the size of the elements. One of the core concepts of the element based methods (FEM and BEM), namely the representation of the dynamic behaviour by polynomial shape functions, limits the frequency range in which these methods are valid. The application of polynomial shape functions introduces two types of numerical errors: interpolation errors, since the dynamic behaviour cannot be exactly covered using polynomials, and pollution errors, caused by a difference between the physical wavelength and the calculated wavelength for the discretised problem. Using the rules of thumb presented in [10],[11], the limiting frequency can be found to be in the structural mesh at 800 Hz. The main acoustic and structural resonances, as well as the highest excitation levels (reaching up to 500 Hz) are located below this frequency. Therefore the mesh is valid in the studied frequency band from 26 to 700 Hz.

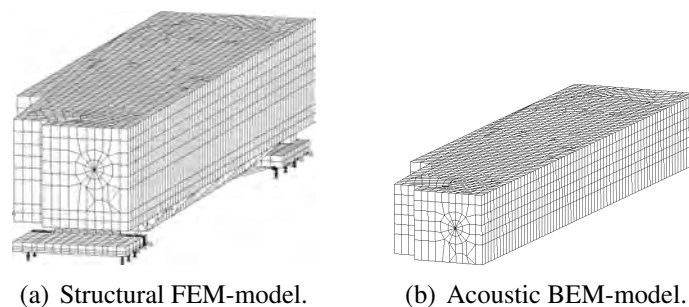

Figure 6: Models for the vibro-acoustic analysis.

Figure 7: Deflection curve of the filter's central point as a function of differential pressure [2].

3.1.1 Sensitivity parameters

A straightforward analysis is impeded by two pronounced nonlinearities in the problem. Firstly there is the complex behaviour of the door. Secondly the nonlinear filter behaviour is discussed.

The complexity of both effects requires the behaviour to be divided into 'extreme' cases. The door will be modelled in a sealed (no more door behaviour as such) and a completely open way (door removed) and the filter in a very flexible and a very rigid way.

Modelling the door A numerical structural analysis shows that the door might not always perfectly close the cavity. This would introduce acoustic leakage and partially expose the filter to the large sound pressure levels. Also, when the door starts 'flapping', repeated impact of the door introduces an additional nonlinearity. Creating an accurate structural model that captures these effects is very difficult. One could create a model based on plate elements that have the kinematic freedom to rotate around a hinge line. The door lock would then be provided by a nodal relationship.

This way of modelling, however, poses serious problems for the acoustics. It is very difficult to impose the correct acoustic boundary conditions since they depend on the degree of structural deformation, which in turn depends on the acoustic behaviour and thus on the acoustic boundary conditions themselves. To account for a possible vibration of the door, two cases are considered. The true situation lies somewhere in between.

1. Door closed: A model with the door completely sealed, thus protecting the filter from any direct exposure to the diffuse sound field.
2. Door open: A model in which the door is completely removed, thus exposing the filter directly to the diffuse sound field.

It is impossible to account for the repeated impact of the door in a steady-state vibro-acoustic analysis. Filter failure caused by this phenomenon will therefore not be detected in the following analysis. This poses an important limitation on the validity of the results and the possible conclusions that can be drawn from it.

Modelling the filter From static deflection tests performed by CSL upon several filter types with and without different protective measures (see.g. Figure 7), it becomes clear that all filters exhibit a very nonlinear behaviour, caused by high membrane forces.

With the software that is commercially available, which is aimed at linear vibro-acoustics, it is impossible to create an accurate model that accounts for these membrane forces and that can be plugged into a fully coupled vibro-acoustic analysis. One can however attempt to incorporate these membrane forces into the flexural behaviour by means of a linearisation of the deflection curve, using the well-known analytical expressions for the deflection of a simply supported, circular plate under a uniform differential pressure (Equation 4).

$$w(0) = \Delta p \frac{r_0^4(5 + \nu)}{64D(1 + \nu)} \quad (4)$$

$$D = \frac{Et^3}{12(1 - \nu^2)}$$

In this equation $w(0)$ stands for the deflection of the central point, Δp for the differential pressure, r_0 for the radius of the filter, D for the flexural rigidity, ν for Poisson's ratio, E for the Young's modulus, t for the thickness of the filter.

It is clear from Equation 4 that the flexural rigidity D mainly depends on two parameters: the Young's modulus E and the thickness t . Adjusting the thickness t , however, would not only change the stiffness of the filter, but would also alter the mass. Therefore only the Young's modulus will be varied since this only affects the filter stiffness and not the filter mass.

As a reference, the deflection under a differential pressure of 200 Pa is used. This point is chosen because here the results for a cyclic increase of the differential pressure with intermediate zero difference (○ on Figure 7) and the results for a continuous increase of the differential pressure (Δ on Figure 7) start to diverge. This divergence indicates irreversible behaviour and thus filter damage. A calculation based on Equation 4 leads to an equivalent value of the Young's modulus $E_{eq} = 2.30 \cdot 10^9$ GPa. The high value shows the large impact of the membrane forces on the flexural behaviour. The reader should however bear in mind that this is a linearisation around a working point and is thus only exact in that single working point. Also, this altered Young's modulus will lead to a less accurate acoustic behaviour of the filter because by using E_{eq} , the filter is modelled too stiff for small deflections.

For the reasons listed above, two values for the Young's modulus will be studied, one acoustically more correct and the other one more correct from a structural side. The actual situation will again lie somewhere in between.

1. The acoustically more correct $E_{mat} = 70$ GPa, which is standard value for aluminum.
2. The structurally more correct $E_{eq} = 2.30 \cdot 10^9$ GPa (= 2.30 ExaPascal).

3.1.2 Boundary conditions and excitation

Apart from the coupling conditions between the structural and the acoustic model two additional boundary conditions are imposed.

Structural Both 'feet' of the structural model are clamped at six points (see the arrows on Figure 6(a)). This clamping represents the bolting of the instrument onto the base plate on PROBA2.

Acoustic For the case of the filter with E_{eq} , the large cavity is locally opened near the filter to retain the acoustic open-closed behaviour. By doing so, a clear image of the deformations and stresses can be created, unlike when using the acoustically more correct E_{mat} , where there are problems due to a very high modal density in the filter (see page 14). The acoustic impact of the ventilation labyrinths, intended to protect the filter from depressurisation effects (see page 3), is neglected in this analysis. Even though low-frequent noise will easily diffract through the labyrinth, and some noise will thus penetrate into the instrument, there will be a lot of reflection in the ducts. Further analyses could incorporate a better estimate for the acoustic admittance of these labyrinths.

The model is acoustically loaded by a diffuse sound field that has the same third octave spectral content and amplitude as the noise generated by the rocket engines.

3.2 Analysis

The following section treats the conducted vibro-acoustic analysis itself and the specific details of the followed implementation.

3.2.1 Implementation

The stochastic nature of the excitation, a diffuse sound field, requires an approach that differs from (standard) deterministic vibro-acoustic analyses. There are different approaches to deal with the stochasticity, like Statistical Energy Analysis (SEA [12]). We are however interested in filter deformations and thus (quasi) deterministic results that indicate whether or not the filter will fail. We therefore need to incorporate the stochastic diffuse field excitation into a deterministic framework. Figure 8 shows the practical implementation of the analysis, which is the way it is implemented in LMS Sysnoise® [13].

From the structural model a modal basis is calculated which contains the mode shapes and modal stresses at the structural resonance frequencies. This modal basis is then imposed on the elements that couple to the acoustic model.

The diffuse field input $X(\omega)$ is decomposed into uncorrelated deterministic excitations $\widetilde{X}_i(\omega)$, in this case plane waves, and their participation factors $q_i(\omega)$ using a Principal Component Analysis [14].

$$X(\omega) = \sum_{i=1}^n \widetilde{X}_i(\omega) q_i(\omega) \quad (5)$$

Next, a vibro-acoustic analysis is performed upon the fully coupled structural and acoustic model. A first postprocessing step provides the acoustic power spectral density of the pressure, and the structural power spectral density of the displacements. In the performed analysis a structural modal basis from 0 to 1400 Hz is used, following the rule of thumb to take into account modes with eigenfrequencies up to twice the studied frequency. The diffuse field input is decomposed into 24 uncorrelated plane wave sources.

3.2.2 Analysis

In the vibro-acoustic analysis, as was mentioned earlier (section 3.1.1), four cases are studied: door closed and door open, both for E_{mat} and E_{eq} , based on the procedures followed by CSL and ESTEC.

Figure 8: Flow chart of the analysis implementation (based on [15]).

The response is studied in terms of power spectral density of the pressure, in three arbitrary points as defined in Table 1, and the power spectral density of the out-of-plane filter displacements.

Position	Code
1 m outside	□
1 mm in front of filter	×
1 mm behind filter	+

Table 1: Points for Pressure Power Spectral Density.

Door closed A first set of subcases is based on the assumption that the door perfectly seals the instrument cavity and protects the filter from the harmful sound pressure levels outside. Firstly the purely acoustic behaviour is studied for the cavity as such. Subsequently the vibro-acoustic response is calculated for both E_{mat} and E_{eq} .

Acoustic behaviour Figure 9(a) shows the frequency response function of pressure in the instrument. The pressure distributions corresponding to the resonances are shown in Figure 9(b). The first (332 Hz) and third resonance (674 Hz) can be related to the analytical case of an acoustically rigid closed box with similar dimensions.

Vibro-acoustic behaviour (E_{mat}) The case with E_{mat} is, as indicated earlier, acoustically closer to reality because of the (usually small) deflections caused by an acoustic field.

Figure 10(a) shows that the presence of the sealed door gives adequate protection to the filter; the sound levels inside the instrument are much lower than outside. At the higher frequencies, acoustically driven resonances appear, but these don't appear to cause problems.

Vibro-acoustic behaviour (E_{eq}) The case with the equivalent Young's modulus gives a more accurate structural model for high deflections because it attempts to incorporate the effect of the membrane forces into the bending behaviour.

The (too) rigid filter will however seal the large cavity so that it becomes a closed-closed cavity on its own. This results in the frequency shift of the resonances that is observed when

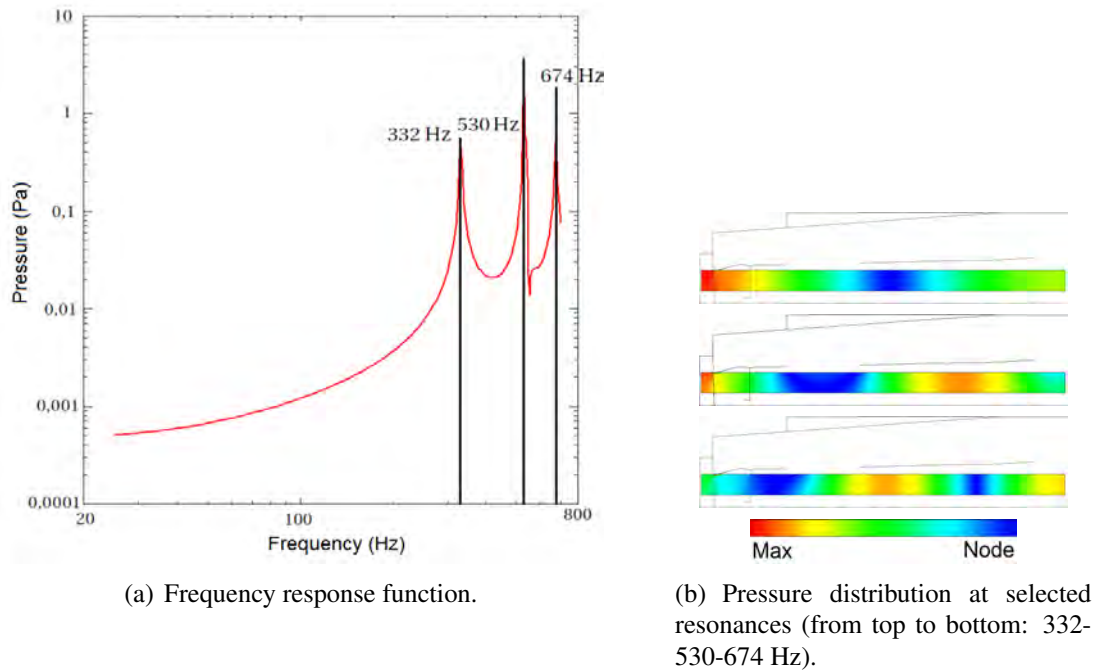

Figure 9: Acoustic behaviour of the cavity with a closed door.

comparing Figure 10(b) to Figure 10(a). The differential pressure appears to stay well below the 200 Pa mentioned on page 8. Following sections (page 12) will however show the relativity of using pressure power spectral data.

Door open When the door is open, the front of the filter is directly exposed to the diffuse sound field, leading to a large sound level in the small cavity. This produces a large loading on the filter. Similar to the cases with the door closed, firstly the purely acoustic behaviour will be studied and secondly the vibro-acoustic behaviour for both E_{mat} and E_{eq} .

Acoustic behaviour Figure 11(a) shows the acoustic frequency response function of the instrument. The pressure distributions corresponding to the peaks are shown in figure 11(b). The three resonances (135-398-667 Hz) can all be related to the acoustic modes of an acoustic open-closed box with similar dimensions.

Vibro-acoustic behaviour (E_{mat}) Figure 12(a) shows that for low frequencies the power spectral density of the pressure in front of the filter, as well as behind the filter, follows the sound pressure level outside of the instrument. This is caused by the very low flexural rigidity of the filter which allows the high sound pressure levels in the small cavity in front of the filter to penetrate into the large cavity behind the filter.

Especially at the first two acoustic resonances (135-398 Hz), a considerable differential pressure over the filter may arise.

The location of the resonances corresponds again very well to the purely acoustic case. The resonances are again acoustically driven.

Vibro-acoustic behaviour (E_{eq}) Figure 12(b) shows results that are counterintuitive since we would expect the very rigid filter to practically seal off the instrument cavity.

The differences can be explained by the extra boundary condition that locally opens up the

Figure 10: Power spectral density of the pressure (door closed).

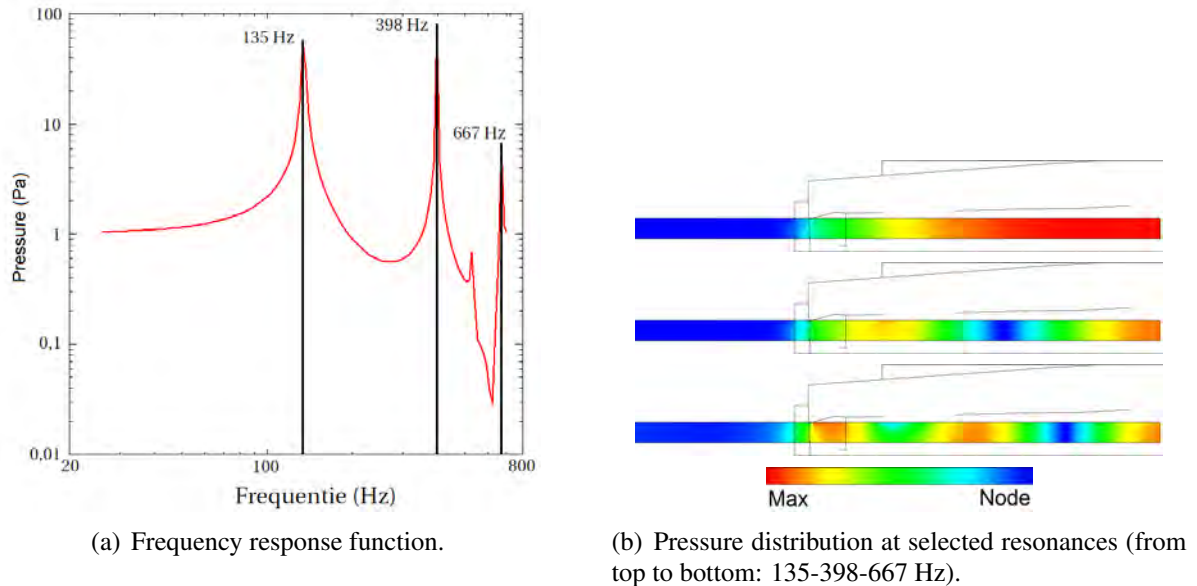

Figure 11: Acoustic behaviour of the cavity with the door open.

large cavity, as was discussed on page 8. Without this boundary condition, the results for the point in the rear (+) would be practically indistinguishable from the results on Figure 12(a) since the larger cavity is closed by the very stiff filter, rather than by the door.

3.3 Postprocessing

The power spectral data obtained in the vibro-acoustic analysis can now be used to further assess filter failure and filter failure mechanisms. The practical use of both pressure and displacement data is studied in more detail. Firstly the method using the pressure difference in two arbitrarily chosen points as an estimate of the differential pressure over the filter, as done in the ESTEC procedure, is discussed. Then a more profound approach based on the filter deformation is elaborated.

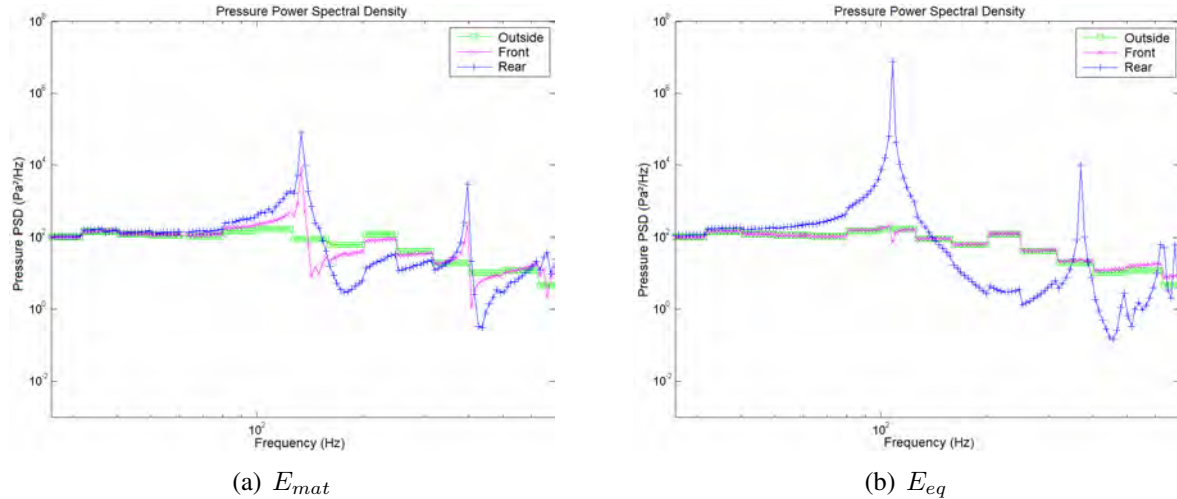

Figure 12: Power spectral density of the pressure (door open).

3.3.1 Differential pressure

A first way to assess the loading on the filter is to estimate the differential pressure across the filter. At first sight this differential pressure can be derived, based on the pressure difference between two points, one in front of the filter and one in the rear, as was done earlier (page 9). Moreover, there is experimental data available about the maximal differential pressure the filter can withstand without irreversible deformation or failure (Figure 7), so this variable seems very appealing.

The method has however a major disadvantage that jeopardises its applicability. The results are very sensitive to the estimation for the filter rigidity and the location of the evaluation points. When this rigidity is very low, the main effect that causes a difference between two evaluation points near the filter, is the distance between these points and the mode shapes that govern the response at the given frequencies, rather than the differential pressure over the filter itself. When the rigidity is very high, the filter is acoustically too stiff, and the pressure difference is largely overestimated.

These problems make the interpretation of the results based on the power spectral density of the pressure extremely difficult and even dangerous since it can easily lead to wrong conclusions when the observation points, or the (approximated) filter rigidity are chosen badly. Furthermore this method is not able to show failure mechanisms, it can only (at most) determine whether failure occurs.

3.3.2 Deformations and stresses

A more fundamental way to assess the state of the filter is to look at the deformation of the filter itself by evaluating the displacement of the filter nodes.

Since we model the filter as a plate because no membrane model was available in the software for the vibro-acoustic analysis, and thus not take the membrane behaviour into account, the modal bases for the filter (displacements and stresses) are only partially correct. As a result, it will be impossible to get accurate information on the actual displacements and stresses.

An attempt to ease the problems in a postprocessing step can however be made. By applying (more) appropriate displacement-strain relationships, the distribution of the stresses in the filter

elements can be calculated. This will make it possible to identify possible causes for the filter failure, but it will remain impossible to assess whether or not failure itself will occur.

Constitutive relationships For a membrane, which exhibits large deflections compared to its thickness, the linearisations made in the plate theory are no longer valid. Higher-order (quadratic) terms also have to be taken into account. Considering these higher-order terms, the displacement-strain relations can, with $\bullet_{i,j} = \frac{\partial \bullet_i}{\partial j}$, be written as [16]

$$\epsilon_{\alpha\beta} = \frac{1}{2}(u_{\alpha,\beta} + u_{\beta,\alpha} + w_{,\alpha}w_{,\beta}) \quad (6)$$

From these equations, the in-plane membrane displacements u and v can be deleted since all calculations were made with a plate assumption, which has no in-plane deformation, only out-of-plane deformation w . The calculated values do not account in any way for in-plane rigidity. This means no failure mechanisms corresponding to membrane behaviour can be identified. Equation 6 can be rewritten for the different strain components as

$$\epsilon_{xx} = \frac{1}{2}w_{,x}^2 \quad \epsilon_{yy} = \frac{1}{2}w_{,y}^2 \quad \gamma_{xy} = w_{,x}w_{,y} \quad (7)$$

Using a proper constitutive relationship, stresses can be calculated from the strains. We assume, because of the small thickness of the membrane, a plane stress situation.

Secondly, an isotropic, linear elastic material is chosen. This is another simplification since failure of the filter is linked with irreversible deformations and thus with plastic behaviour of the material.

These assumptions result in following relationship.

$$\sigma_{ij} = \frac{Et}{(1 - \nu^2)} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix} \begin{bmatrix} \epsilon_{xx} \\ \epsilon_{yy} \\ \gamma_{xy} \end{bmatrix} \quad (8)$$

For the numerical implementation of this deformation-based postprocessing step, a FEM-procedure was used.

Results E_{mat} In absence of membrane forces, the filter will have a low flexural rigidity and thus a low flexural eigenfrequency. The filter will exhibit unrealistically large deflections and, in the considered frequency range, a high modal density (Figures 13(a) and 13(b) for the door opened and Figure 14 for the door closed). Because of this high modal density, it is impossible to assess filter stresses. The mesh would need to be drastically refined to be able to calculate the deformations accurately. This is, however, impossible since the calculation time would very strongly increase. But even if this would be feasible, the added value of this refinement is doubtful since the membrane behaviour would still not be incorporated.

When we compare Figure 14 to Figure 13(a), the effect of the closed door on the filter is very clear. The deflection of the filter, and thus its loading, is reduced significantly because of the shielding effect of the door.

Figure 13: Out-of-plane displacements of the filter (door open - E_{mat}).

Figure 14: Power spectral density of the out-of-plane displacements of the filter (door closed - E_{mat}).

Results E_{eq} When the equivalent Young's modulus is used to incorporate the membrane behaviour, the deflections will be a lot smaller and the high modal density disappears (Figure 15(a) and 15(b)). Therefore the mesh is fine enough to create an accurate image of the deflection and the stresses.

Door open Because of the extra boundary condition that locally opens the cavity (see page 8), the case with E_{eq} and the door opened, exhibits acoustic open-closed behaviour. In that way, it is possible to look at the deformations in the filter for the acoustically open instrument (Figure 15(b)). This image shows an asymmetric deflection of the filter, caused by the excentric position of the filter with respect to the door opening (thick line in Figure 15(b)). This creates large gradients in the deformations, leading to very local stress peaks (see Figure 16 for von Mises-stresses).

Filter failure may thus be caused by an asymmetry of the door with respect to the filter.

Door closed The deformation pattern for the case with a closed door (Figure 17(a)) is very different. Because the sound pressure level in the cavity is a lot smaller since the cavity is acoustically closed, the differential pressure over the filter is lower. Also, the filter is modelled very stiff, thus giving low deformations. The global instrument deformations under the diffuse field however, remain relatively unchanged. Therefore Figure 17(b) shows a structural mode of the instrument as a whole, rather than the deflection of the filter. These deformations are thus

of no relevance to the filter loading by cavity acoustics.

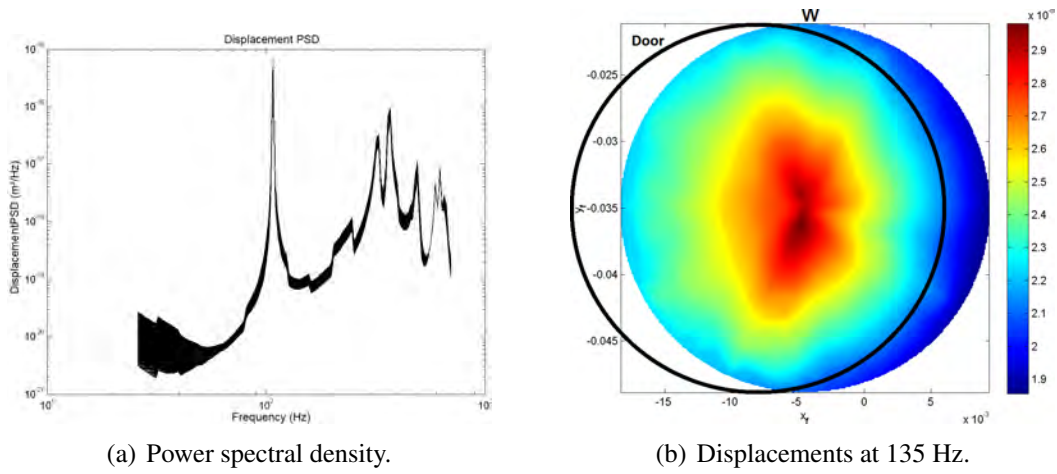

Figure 15: Out-of-plane displacements of the filter (door open - E_{eq}).

Figure 16: von Mises stresses in the filter at 135 Hz (door open - E_{eq}).

Figure 17: Out-of-plane displacements of the filter (door closed - E_{eq}).

3.4 Summary

To conclude the discussion of the vibro-acoustic analysis, this section provides a small summary. The reader should however bear in mind the simplifications (Table 2) that were introduced to make a linear vibro-acoustic analysis possible.

Assumption	Cases	Simplification
Door behaviour	Closed and Open	No impact loading Both cases are extremes
Filter model	E_{mat} and E_{eq}	Overestimation stiffness for acoustics E_{eq} is a linearisation
Ventilation labyrinths	–	Vents have no acoustic impact

Table 2: Simplifications and assumptions made.

Door closed When the door is completely sealed, we have a closed acoustic cavity which is almost completely isolated from the diffuse field loading. The pressures in front and behind the filter (Figure 10) practically coincide and stay at a level well below the level of the diffuse sound field outside. The deformations in the filter are also very low, as Figures 14 and 17 indicate. Although the analysis cannot prove undeniably that the door provides enough protection, because it is difficult to estimate the filter rigidity, it does however show that an acoustically sealing door is a very effective protective measure.

Door open When the door is removed, the situation changes. The cavity becomes acoustically halfopen and the diffuse field loading can penetrate into the instrument. A substantial pressure difference arises over the filter (Figure 12). It is however difficult to draw conclusions based on this pressure data because of the strong dependency of the results on the studied points. When looking at the more fundamental deformations (Figures 13 and 15), we see that the filter exhibits a substantial deformation. The precise magnitude of this deformation is very hard to predict due to the assumptions (Table 2) made about the filter rigidity, but the (partially) opened door might cause irreversible filter deformation, e.g. by the asymmetric deformation mechanism which was indicated in Figure 15(b).

4 CONCLUSIONS

Several analyses were performed at very different stages of development; in the design stage (CFD analysis), after the testing campaign and even (partially) after the launch of the instrument itself (vibro-acoustic analysis), to check what was the problem that caused a front filter failure, which occurred during pre-launch testing.

A CFD analysis was performed by GDTech to assess the effect of the depressurisation and acceleration and the impact of the venting system on the differential pressure over the filter. This analysis was performed on two different levels. Firstly a detailed CFD calculation of the flow through the labyrinths was made and translated to a relation between the entrance velocity and the pressure drop over the labyrinth. These pressure laws were then used in a larger scale analysis to assess the depressurisation of the instrument as a whole. The resulting differential

pressure over the filter is very small and never comes near the allowed value. Filter failure caused by depressurisation is therefore not very likely.

The eventually most probable cause for filter failure was linked with the (vibro-)acoustic behaviour of the instrument cavity, which was studied at ESTEC and later on at K.U.Leuven, following the ESTEC procedures. Though a door was foreseen, a first numerical analysis indicated that this door could start flapping, thus partially opening the acoustic cavity and exposing the filter front to large sound pressure levels. In this way a larger than allowed differential pressure may arise over the front filter. The analysis was, nevertheless, very difficult to do with the currently available commercial software since the optical membrane has a pronounced nonlinear behaviour which cannot be retained entirely in a fully coupled linear vibro-acoustic analysis. Therefore, there is no firm proof that the filter fails indeed due to a mere acoustic overload. Anyhow, the analysis has raised out a plausible cause of this failure (if to be acoustically driven), namely an eccentricity between the door and the filter.

ACKNOWLEDGEMENT

The authors would like to thank the Institute for the Promotion of Innovation through Science and Technology in Flanders (IWT-Vlaanderen) for their support of the doctoral research of Stijn Jonckheere and Bart Bergen.

Abstract. *Micro-vibration is a low level disturbance, which cannot be controlled or reduced by the Attitude and Orbit Control System of a spacecraft. It can emanate from various sources on a typical spacecraft, notably subsystems with moving parts such as reaction wheels or cooler mechanisms. Micro-vibration can also result from thermo-elastic effects due to stick-slip from differential expansion of parts. It causes problems for sensitive payloads especially high resolution cameras where the demand for higher resolution (which drives stability requirements), has made analysis and control of microvibrations relevant for a larger number of satellites. The availability of mathematical models to represent the disturbance sources in a format that can themselves be coupled to the mathematical model of the structure to perform end-to-end analysis to obtain predictions of the stability level at the receiver is crucial.*

In the simplest form the sources can be represented with forces and moments of appropriate characteristics, adding also some inertia at the source location. But even for this simplistic implementation it is necessary to have available the details of the forces and moment produced by a source, and these can be either calculated from schematic models of the functioning of the device, or experimentally determined, or a mixture of the two. Typical test techniques applied to micro-vibration measurement /characterization will be described, highlighting advantages and drawbacks of the various methods. A simple experimental apparatus for the measurement of the micro-vibrations emitted by a reaction wheel is presented. A mathematical model of the reaction wheel disturbances is also presented together with its coupling to a typical spacecraft structural model.

1 INTRODUCTION

Since the early 1990's, the resolution and pointing stability required for Earth and deep space astronomical observation spacecraft instruments have continuously increased. Current high resolution military reconnaissance satellites have achieved centimeter-level ground resolution. For example, the KH-13 surveillance satellite recently launched has reached a ground resolution of 0.05 m. Space telescopes for astronomical observations usually have a resolution one to two orders of magnitude higher than Earth observation satellites [1], and looking at the future, the James Webb Space Telescope (JWST) planned to launch in 2014 or 2015 should reach a pointing stability 0.004 arcsec [2].

On board satellites there is often equipment (e.g. Reaction & Momentum Wheel Assemblies, Cryocoolers, pointing mechanisms, switches etc) in this context called sources, which during their functioning produce dynamic disturbances, micro-vibrations that are transmitted through the platform affecting the performance of sensitive payloads receivers also mounted on the platform. The micro-vibration produced by the sources can also be amplified by structural resonances thus making micro-vibration prediction complicated.

In this context, the term micro-vibration refers to low-level mechanical disturbances in the range of micro-g's (μg), typically occurring at frequencies from a few Hz up to 1000 Hz [3]. In some extreme cases of high precision spacecraft [4-6] even disturbances at frequencies down to 10-2 Hz are relevant. Micro-vibration can be considered as excitations resulting from impulsive phenomena (device release); translating parts (cryocoolers); or rotating parts (RWAs/MWAs), for example, which are sinusoidal (or multi-tone) or broad band frequency in nature.

Generally speaking, micro-vibration sources exist on most spacecraft; however, due to their small amplitudes and often high frequencies they do not have serious impacts (e.g. typical satellites for telecommunication) and thus are ignored. Spacecraft with optical instruments and cameras are generally those most affected by micro-vibration issues. Micro-vibration generally cannot be controlled or reduced by the Attitude and Orbit Control System (AOCS) because they usually involve the flexible modes of the spacecraft structure (rather than its rigid body motion, which is controlled by the AOCS) and because the frequency range of the spacecraft AOCS usually has an upper limit of controllable frequency of a few Hz, whereas micro-vibration generally occurs at higher frequencies.

Micro-vibration can be managed passively and/or actively at the source, along the transmission path and at the receiver location. For example, in order to reduce disturbances, RWAs can be placed on a vibration isolation mount [7] or bracket [8] which is connected to the primary structure, micro-vibration isolators can be incorporated in to primary structure components [9], and/or active optics such as an image stabilization system used within optical payloads [10]. Passive or active isolation may also be used between the receiver and the spacecraft structure.

2 MICRO-VIBRATION NOISE SOURCES

Micro-vibration disturbances mainly arise from fast moving (rotating and translating) mechanisms installed onboard such as RWAs, cryocoolers and pointing systems, etc. [11]. They may also arise from non-moving systems such as electronics and sensors [12], the release of strain energy at structural interfaces (joints, latches, hinges) during "thermal snap" events [13, 14] and the bending of solar arrays, antennas, etc. due to sudden temperature change [15].

The mechanical disturbances produce by the noise sources are usually characterized by forces and torques that appear at the interface between the equipment and spacecraft. These forces/torques propagate through the primary structure to the sensitive instruments. Since the spacecraft is an isolated system, the mechanical energy produced by these excitations must be dissipated into this system.

Generally micro-vibration sources can be divided into two broad groups:

- Single disturbance event
- Continuous disturbances.

The single disturbance event, also known as transient loads, are clanks and intermittent disturbances, which may occur randomly (sudden stress release due to slippage between parts with differential temperatures and/or thermal expansion of their materials; micro-cracking in laminates and sandwiches; and buckling of foils due to thermal expansion/contraction) or at specified commands (for example firing a thruster). These disturbances are low level shock type forces with small dynamic amplitudes.

The continuous disturbances, also known as vibratory loads, are accelerations which are sinusoidal (or multi-tone) or broad band frequency in nature. The continuous disturbance can be further broken down based on the speed, magnitude and noise source type. For example, based on the first criteria high speed moving mechanisms include RWAs/MWAs, gyros, etc.; medium ones include liquid flowing and sloshing, cryocoolers, etc and low speed ones include antennas, solar arrays, etc. Based on the second criteria, mechanical mechanism induced disturbances include those mentioned above except those induced from liquid flowing and sloshing, which are regarded as non-mechanical mechanisms. Either way, these sources produce permanent disturbances in spacecraft, and are usually considered as "internal noise" [1, 12]. Other possible disturbances include inductive electromagnetic forces between wires and heaters; electrical noise, etc.

2.1 Physical causes of micro-vibrations

Within the noise sources micro-vibration arises from common mechanical components or phenomenon. These are summarized below

- Rotor imbalance: Rotating devices such as RWA, MWA, gyroscope, etc. can produce large disturbances in spacecraft, especially when spin speed is very high. At nominal high speed, rotor imbalance is considered as the major disturbance source in these devices. It cannot be totally avoided because of manufacturing tolerances. Usually rotor imbalance is con-

sidered as the sum of static and dynamic imbalance, both of which produce disturbance forces and torques. These forces and torques are proportional to spin speed squared with a fundamental frequency equal to spin speed.

- **Mechanical bearing irregularity:** Disturbances caused by mechanical bearing irregularity are mainly due to ball irregularities; internal race irregularities; external race irregularities and cage disturbances. These are also due to manufacturing tolerances. For high speed continuous rotation devices such as brushless DC motor and stepper motor, interactions between them, e.g. abnormal contacts between balls and raceway, balls and cage, cage and raceways, create non-linear disturbance force and torque, they appear as sub- and super-harmonics in the device disturbance signature.

- **Bearing friction:** Bearing friction occurs in all rotating devices through their entire operational range, but it is particularly important at low speed. If a device needs to reverse directions (crossing zero speed), e.g. an RWA, there are two disturbance possibilities either the device will stop rotating briefly (there will be a dead band) or there will be a discontinuity in acceleration (due to the change in the relative signs of the friction and motor torque).

- **lubrication degradation:** In rotating devices, such as RWA and SADM, lubrication degradation over life can lead to increased noise or as is with some systems using a sacrificial lubrication system can change the noise performance during life as the cages wears or can lead to periodic high torque (noise).

- **Motor cogging, Motor ripple:** For a permanent magnet brushless DC motor, motor disturbances include cogging and torque ripple. These disturbances generally only become significant when wheel speed is low or the motor reverses spin direction. Motor cogging torque originates from the magnetic interaction between stator slots and rotor permanent magnets, and it is an undesirable effect that prevents the smooth rotation of the flywheel and results in noise. Motor ripple torque is defined as the change in motor torque with respect to the angular position, or simply by the profile of the Back-Electro Motive Force (B-EMF) and current waveform, which is not exactly sinusoidal.

- **Stepper motors, gear meshing and contact:** For APMs, usually two or three phase stepper motor actuators are used to drive antenna in two axes (azimuth and elevation), respectively. Each actuator step imparts a small disturbance torque into the spacecraft. Also gear meshing and contacts are also sources of vibration.

- **Axial motion of inertias,** such as the compressor and other moving parts in a cryocooler can become sources of vibration [16]. The linearly reciprocating motion of the elements gives rise to a momentum imbalance. Particularly for cryocoolers the piston is typically driven with a sinusoidal signal, it oscillates against a non-linear gas spring formed by the compression space, resulting in a non-sinusoidal piston motion. A disturbance of this type manifests itself in the vibration signature as the presence of harmonics of the moving inertia's drive frequency [17].

As rotor imbalance is one of the main causes of microvibrations this article focuses on the modeling of this phenomena and its integration with a structural model of the satellite.

3 MATHEMATICAL MODEL

The wheel imbalance typically consists of the flywheel static imbalance (offset of the center of mass (CoM) of the flywheel with respect to its spin axis) and dynamic imbalance (misalignment of the flywheel's principal axis and the rotation axis). The wheel-induced vibrations are mostly sinusoidal (often multi-tone) in nature, and below the first resonant frequency, the imbalance causes a disturbance force and moment respectively at the flywheel's spin rate (the fundamental harmonic) with amplitude proportional to the rotational speed squared.

Common flywheel configurations of a WA are either symmetrical (flywheel at mid-span of the shaft) or cantilevered (flywheel at one end of the shaft), see Fig. 1. Flywheel imbalance analytical models of such configurations have been studied in the literature.

Fig. 1 Two typical RWA configurations a) symmetrical b) cantilever

In this article, the WA studied has a cantilevered flywheel supported by a soft suspension system, which provides both rotational and translational support (see Fig. 2). The soft suspension system is designed as a passive system that filters the vibrations produced by the motor (e.g. its bearings), thus minimizing the mechanical disturbances emitted by the WA when spinning. Also the WA is designed to have a speed range beyond 10000 rpm, making it suitable for use as either a RWA or MWA.

Based on the energy method (i.e. the Lagrange's approach), the flywheel imbalance analytical model of the wheel is coupled with an arbitrary supporting structure (in this case, an aluminum "cube" acting as a seismic mass), see Fig. 2. The analytical model representing the flywheel imbalance can then be integrated with disturbance empirical models (i.e. the semi-empirical models) and linked to a complete satellite numerical model to predict its performance at the receivers' location (e.g. the effect on the line of sight of an optical instrument).

The whole system (WA and seismic mass, which also includes the wheel base) is suspended using elastic cords on each side of the seismic mass, thus simulating a "free-free" condition. The elastic cords were chosen such that the system resonant frequency is less than 1 Hz (verified with a "tap" test), and not in the frequency range interested in this article.

The seismic mass has coordinate $x_c y_c z_c$ with origin C at its CoM; θ_c , φ_c and ψ_c are the corresponding rotations around each axis. Note that, in the shaft pointing direction, the kinetic energy of the wheel is much larger than that of the seismic mass, thus the perturbation of the seismic mass about this axis, ψ_c is ignored. M_c is the mass of the seismic mass; $I_{c_{xx}}$ and $I_{c_{yy}}$ are moment of inertias of the seismic mass about x_c and y_c axis respectively. The vertical distance from the soft suspension system-wheel base interface to the CoM of the seismic mass is l .

Fig. 2 Simplified model of reaction Wheel coupled with seismic mass

The seismic mass can be considered as a rigid body connected with a flywheel (another rigid body) by the soft suspension system. With small displacement assumption, the kinetic energy of the seismic mass T_c is obtained as:

$$T_c \approx \frac{1}{2} \left[M_c (\dot{x}_c^2 + \dot{y}_c^2 + \dot{z}_c^2) + I_{c-xx} \dot{\theta}_c^2 + I_{c-yy} \dot{\phi}_c^2 \right] \quad (1)$$

The potential energy U_s of the system can be obtained (using the small displacement assumption) through the relative motion at the soft suspension system/flywheel base interface:

$$U_s = \frac{1}{2} \left[k_z (z_w - z_c)^2 + k_r (\theta_w - \theta_c)^2 + k_t [(y_w - y_c) + (d\theta_w + l\theta_c)]^2 + k_r (\phi_w - \phi_c)^2 + k_t [(x_w - x_c) - (d\phi_w + l\phi_c)]^2 \right] \quad (2)$$

The fully linearized EoMs of the system with respect to each of the ten DoFs (the axial rotation of flywheel and seismic mass are not included) are obtained. They are written in matrix form as:

$$\mathbf{M}_s \ddot{\mathbf{q}}_s + \mathbf{G}_s \dot{\mathbf{q}}_s + \mathbf{K}_s \mathbf{q}_s = \mathbf{F}_s \quad (3)$$

The mathematical model was validated against test results, and various tests were carried out to validate the effect of the stiffness of the mechanism supporting the rotor.

In particular Figure 3 shows a comparison of waterfall plot for the in-plane force emitted by the wheel for tow cases a soft suspension system, and a rigid one. It is possible to notice that the rigid assembly emits considerable more vibration in the frequency range between 200Hz and 400Hz.

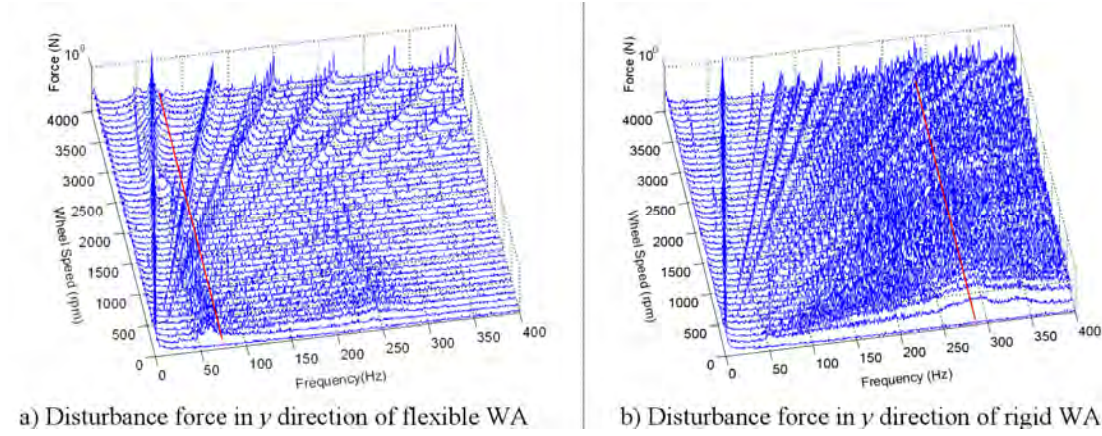

Fig.3 Waterfall plots for flexible and rigid WA

4 SOURCE-STRCUTRE INTEGRATION

Measured interface disturbance force and torque generated by mechanisms need to be integrated with the spacecraft model in order to assess performance at receivers. Methods of disturbance source implementation vary depending on the source and spacecraft model type, i.e. sources could be analytical, empirical or semi-analytical, the spacecraft model could be FE model or Matlab/Simulink model. The most common method is to implement semi-analytical source models and integrate them in typical spacecraft FE model (whose behavior is described using its transfer functions). Typically, this can be described mathematically as:

$$\mathbf{Z} = \mathbf{G}\mathbf{W} \quad (4)$$

where \mathbf{Z} is the performance metrics at some point, such as displacement or acceleration at the receivers. \mathbf{G} is the transfer function matrix between the receivers and sources, usually obtained from the spacecraft FE model. \mathbf{W} is the disturbance sources. Eq. (4) is most often written into spectral density form:

$$\Phi_{ZZ} = \mathbf{G}\Phi_{FF}\mathbf{G}^H \quad (5)$$

where Φ_{FF} is the measured disturbance in spectral density matrix form - usually a 6×6 matrix in the form:

$$\Phi_{FF} = \begin{bmatrix} \Phi_{F_x} & \Phi_{F_x F_y} & \Phi_{F_x F_z} & \Phi_{F_x M_x} & \Phi_{F_x M_y} & \Phi_{F_x M_z} \\ \Phi_{F_y F_x} & \Phi_{F_y} & \Phi_{F_y F_z} & \Phi_{F_y M_x} & \Phi_{F_y M_y} & \Phi_{F_y M_z} \\ \Phi_{F_z F_x} & \Phi_{F_z F_y} & \Phi_{F_z} & \Phi_{F_z M_x} & \Phi_{F_z M_y} & \Phi_{F_z M_z} \\ \Phi_{M_x F_x} & \Phi_{M_x F_y} & \Phi_{M_x F_z} & \Phi_{M_x} & \Phi_{M_x M_y} & \Phi_{M_x M_z} \\ \Phi_{M_y F_x} & \Phi_{M_y F_y} & \Phi_{M_y F_z} & \Phi_{M_y M_x} & \Phi_{M_y} & \Phi_{M_y M_z} \\ \Phi_{M_z F_x} & \Phi_{M_z F_y} & \Phi_{M_z F_z} & \Phi_{M_z M_x} & \Phi_{M_z M_y} & \Phi_{M_z} \end{bmatrix} \quad (6)$$

where diagonal Φ_{ii} are the PSD, Φ_{ij} are the CSD. The spectral matrix Φ_{FF} is the input in the spacecraft FE model.

Methods to obtain the Φ_{FF} are usually empirical test results or a semi-analytical model.

For the first method, for every speed, disturbance force and moment $\mathbf{F}(\omega)$ in frequency domain at the mechanism interface is obtained through load cell or Kistler table, i.e. a 6×1 vector.

$$\mathbf{F}(\omega) = \begin{Bmatrix} F_x \\ F_y \\ F_z \\ M_x \\ M_y \\ M_z \end{Bmatrix} \quad (7)$$

This vector is then converted into spectral density matrix (Eq. (6)) utilizing signal processing technique, which can then be used in Eq. (5).

The second methods involves semi-analytical model of disturbance. In general, wheel imbalance induced disturbance has the analytical form of:

$$F(t) = \sum_{i=1}^n C_i f_{rwa}^2 \sin(2\pi h_i f_{rwa} t + \phi_i) + W(t) \quad (8)$$

where $F(t)$ is the disturbance force or torque in time domain; n is the number of harmonics; C_i is the amplitude of the i^{th} harmonic; f_{rwa} is the flywheel speed rate in Hz; h_i is the i^{th} harmonic number and ϕ_i is a random phase; $W(t)$ is the random noise disturbance.

Note Eq. (8) is an alternative form of the excitation, i.e. right hand side, of the Eq. (3). From Eq. (8), parameters for each harmonic and the number of harmonics need to be mapped from experimental data (i.e. empirical results) for each speed (the choice of these values depends on the accuracy of the model want to obtained). And high frequency random (white) noise has to be generated and incorporated with the model. Once the disturbance force and moment in time domain obtained, they can processed into frequency domain to obtain $\mathbf{F}(\omega)$, the following analysis becomes the same as the first method.

5 CONCLUSIONS

In this article, the importance of microvibrations modeling has been briefly discussed to highlight its importance in the design of high stability satellite platforms. The various physical mechanisms that produce microvibrations on board a typical satellite have been reviewed and

a mathematical model of a typical source, i.e. a reaction wheel, has been described. Finally the article describes a possible method to introduce the loads produced by the source(s) in a model describing the structure transfer functions, which could be obtained using any modeling technique such as the Finite Element Method.

Keywords: Dimensional Stability, Random Vibration, Cyclic Plasticity.

Abstract. *Highly stable structures that are destined for space use are vulnerable to dimensional stability loss due to random vibration loads experienced during launch and ground testing. Small movements at structural interfaces and non-recoverable strains induced in metering elements can have negative implications for optical performance on-orbit.*

Often the dimensional stability aspects of optical bench structures are verified by environmental tests on Engineering or Protoflight Model instruments. It is proposed that a better understanding of vibration-induced structural dimensional stability loss could enable the assessment of stability loss through analysis at an early stage.

To this end, several tests have been developed at RAL to assess dimensional stability loss in materials and joints in a controlled manner under random vibration. One test has been used to assess Al alloy and CFRP material samples in a 4-point bending configuration, and another has been used to assess micron-level slipping at a bolted interface.

The aim of these tests was to provide useful material data, and also to assess the feasibility of predicting stability loss caused by random vibration events. It was found that the classical frequency domain random vibration Finite Element Analysis commonly performed to assess safety margins against structural failure on space structures is probably insufficient to predict instability. This is because the results are highly dependent on non-symmetry in the stress response (ie, due to gravity, pre-stress, or non-linear response). However a good correlation with test results was achieved with a time domain FEA model which incorporates nonlinear kinematic hardening rules in the materials.

This paper will outline the Al alloy sample test and results, as well as propose a way to estimate random vibration-induced dimensional stability loss using static microyield test results.

1 INTRODUCTION

Optical instruments used in space typically require that vital components are maintained in alignment within certain tolerances throughout their operational lifetime in order to guarantee adequate system performance. This is particularly true for low-cost Earth observation missions which seek to package large optics in small lightweight instruments with minimal or no need for on-orbit readjustment mechanisms.

For a camera structure which is aligned in a ground based cleanroom, a number of potential sources of instability exist during the ground test, launch and operational phases. Thermal expansion is possibly the most significant, driving the use of low expansivity materials such as CFRP. Moisture desorption is another issue, as are gravity release, creep, erosion by atomic oxygen, and dynamic loads during launch. This paper deals with the last of these effects.

Payload structures are subject to a period of dynamic loading during launch. These loads originate from aeroacoustic noise and stage separation events. During the design and development of such structures, there is often some uncertainty over the exact vibration levels that will be witnessed during launch. This leads to potentially high qualification test specifications. These test specifications can be used to dimension a structure in the early part of the design process, and validate it against gross structural failure using Finite Element Analysis (FEA). Dimensional stability failures due to random vibration can be harder to assess however, and this aspect of the design is usually verified by test at a later stage.

This paper seeks to introduce methods of reducing the risk to structural dimensional stability earlier in the development process, using FEA methods. It draws on the test results of some dimensional stability tests recently performed at RAL, and demonstrates that these can be replicated with a simple FEA model using cyclic plasticity material properties.

2 TEST DESCRIPTION

The aim of the test was to investigate the dimensional stability response of various material samples to random vibration. The material described here is aluminium alloy 2024 T3.

The test setup made use of a simply supported material test sample in strip form. There were a pair of masses attached inboard of the support positions (see Figure 1). The sample was then subject to random vibration in the direction that induces bending in the strip. The masses were selected such that the first modeshape of the sample approximates a standard four-point bending test, at a frequency of 41 Hz. Three identical samples were tested simultaneously, using an LDS V8-440 SPA56K shaker.

The simple support was achieved by clamping the samples between a pair of stainless steel rods at each support point (see Figure 2). The clamping force was achieved using extension springs. The spring force was determined to be enough to just prevent unloading under the highest loads possible from the shaker.

Figure 1 : Test setup.

Figure 2 : Support clamp.

The random vibration loads were provided by the shaker. They started with very low level shakes, increasing in severity from 0.8 to 36 gRMS in increments of 3 or 6dB. The test spectra were based on the baseline shown in Table 1. This is similar to a typical verification test spectrum [1], though with the plateau starting at a fairly low frequency to ensure that it fully covers the first mode. Test durations were 60 s each.

Frequency	Level
20-30 Hz	+3dB/oct
30-200 Hz	0.1 g ² /Hz
200-2000Hz	-5dB/oct

Table 1 : Baseline test spectrum (6.44 gRMS).

Between each shake, metrology data were recorded to assess residual plastic strains in the samples as a result of the prior shake. This was accomplished with two separate methods – strain gauges and optical autocollimation. A pair of strain gauges was mounted on each test sample, one on the upper surface and one on the lower surface in the beam centre. Strain gauge resolution was quoted by the manufacturer to be ± 0.25 μ strain. The optical method made use of a pair of mirrors at either end of the samples. The angle between these mirrors was measured very accurately with an autocollimator to derive an average bending strain along the samples. The resolution of this method was ± 0.17 μ strain. Experimental errors due to the test setup were about ± 10 μ strain.

A fourth sample was subjected to static testing on a Testometric tensile test rig. The setup for this test was a four-point configuration, equivalent to the dynamic tests. The purpose of this test was to compare static and dynamic test data, and assess whether static test results in the microyield region could be used to predict dynamic results.

3 TEST RESULTS

The test results are summarized in Figure 3. There are several clear conclusions. Firstly, the low-level shakes (up to 13 gRMS) produce little discernable effect outside the error range. Secondly, at high levels, a definite trend in residual strains is observed – all samples start to show an increase in positive (tensile) residual strain for both top and bottom strain gauges. Effectively the samples are growing in length.

Figure 3 : Test results summary.

This result was somewhat unexpected – it was thought that the residual strains would be dominated by bending strains, which would be manifested in top and bottom strain gauges giving roughly equal and opposite responses. To better visualize the residual strain response, it was divided into a residual axial strain (from the average of the top and bottom strain gauges) and a residual bending strain (from the difference between them). These are shown in Figure 4 and Figure 5, in a traditional stress versus strain format. The RMS stress was obtained from the strain spectral density response of the strain gauges during the test.

Figure 4 : Residual axial strain.

Figure 5 : Residual bending strain.

The axial strain results follow the same trend as the static test results, albeit at a lower stress level. The bending strain results generally increase in magnitude with increasing dynamic stress, but do not generally increase in the same direction.

As the test items are simply supported, the dynamic stresses are almost purely due to bending, with tensile stresses on one surface being equal and opposite to compressive stresses on the other. At the mounting positions, there is a small axial force due to friction between the test sample and the clamp rods. This force is very small by comparison though – for the penultimate dynamic test (25.6 gRMS), the RMS bending stress was 56 MPa, while the friction-induced axial component was only 0.5 MPa.

4 ANALYSIS

It was decided to investigate these results further using Finite Element Analysis, with cyclic plasticity material behaviour. It was assumed that the residual strain response was due to the first vibration mode, and that the contribution of higher modes to residual strain was negligible. ANSYS Version 12.1 was used, and the model was two-dimensional with large deformations and nonlinear material properties. The 25.6 gRMS test run was chosen for analysis, as this was the first run where a significant plastic strain response was seen. The results of Sample “B” were used.

There were two parts to the analysis. The first part was to correlate the model with the test results in order to validate the model and boundary condition assumptions. The second part was a time-domain analysis, with a large number of quasi-static load reversals applied to the model to simulate the time history of the stresses within the sample. The responses of the correlated model at the centre of the sample (where the accelerometer was located) and the FEA model are shown in Figure 6. The responses are well correlated for the first two modes, but

not after this (the difference in high frequency behaviour is probably due to the FEA model being only two-dimensional).

Figure 6 : Comparison between FEA model and test PSD responses.

The PSD response was then truncated between the first and second modes (at a factor of $\sqrt{2}$ from the first natural frequency). The RMS value of this truncated response was obtained, and assumed to be the quasi-static acceleration load applied to simulate the first modeshape for the static analysis (39.1 g). The FEA model with quasi-static loads applied is shown in Figure 7 and Figure 8. It contained 232 elements and 1658 degrees of freedom. It was constructed in two dimensions to minimize the solution time for a large number of sequential nonlinear solutions.

Figure 7 : FEA model showing quasi-static acceleration upwards

Figure 8 : FEA model showing quasi-static acceleration downwards

The X-direction stress response is shown in Figure 9, and enlarged in Figure 10. The stresses on the upper and lower surfaces (56.7 and 55.7 MPa) compare well with the RMS stress recorded by the strain gauges, of 58.9 and 57.9 MPa.

Figure 9 : Stress response to quasi-static acceleration

Figure 10 : Stress response enlarged at sample centre

To simulate the time history of the loads, an approach similar to Miner's rule [2] was taken. Load cycles of 1- σ , 2- σ and 3- σ (ie, 39.1, 78.2 and 117.3 g) were applied. The number of cycles of each were determined from the probability of exceedance multiplied by the total number of first mode cycles witnessed during the test (the natural frequency multiplied by the test duration). The number of fully reversed cycles was 779, 112 and 7 for the 1- σ , 2- σ and 3- σ cases respectively.

To model material cyclic plasticity, it was decided to use the nonlinear kinematic hardening model of material behaviour [3]. This model was chosen for several reasons – it was a supported material model in the FEA code used; it can effectively model plastic strain evolu-

tion effects such as ratchetting and shakedown; some material data can be found in the literature for materials similar to the one tested here.

The model requires three basic parameters to be defined: k , C_i and γ_i . Here, k is the elastic limit or yield stress, C_i is the initial hardening modulus, and γ_i is a parameter that controls the rate at which the hardening modulus decreases with increasing strain. All three parameters are best determined from cyclic stress tests where a stable hysteresis cycle is obtained for several levels of plastic strain of interest. Additional values of C_i and γ_i (representing additional kinematic models) can be superimposed to better represent additional strain ranges. In this case, two superimposed kinematic models were used - C_1 and γ_1 were obtained from the static test data using a “goal-seek” spreadsheet function (representing a very low range of plastic strain, $10^{-6} - 10^{-5}$) and C_2 and γ_2 were obtained from [4] for alloy 2024 T4 (for a much higher strain range, above about 10^{-3}). It should be noted that the static test data used to determine C_1 and γ_1 was monotonic – ideally this would have been cyclic. The superimposed model is shown in Figure 11, along with test data and the model from [4]. As the first kinematic model is based on test data only up to about 40 μ strain (plastic), and the second is intended for a much higher strain range, there is effectively a gap in the validity of this model after about 40 μ strain. Fortunately, most of the dynamic stress effects observed in this test are covered in the lower strain range. The material constants used are summarized in Table 2.

Figure 11 : Determination of material constants

Constant	Value	Units
k	4.37e7	Pa
C_1	6.57e12	Pa
γ_1	2.29e4	-
C_2	1.18e10	Pa
γ_2	1.03e2	-

Table 2 : Material constants

For ease of load application, the cycles were applied in groups of the same level – ie, the 3- σ cycles were applied first, followed by the 2- σ and 1- σ cycles. The results are shown in Figure 12 for a node in the same location as the strain gauge on the upper surface.

Figure 12 : Plastic strain results

There are several points to note about this curve. Firstly, the plastic strain amplitudes are high (as expected) for the 3- σ case, in the region of ± 57 μ strain. This reduces to about ± 8 μ strain for the 1- σ case. Secondly, shakedown is apparent. This is mostly complete following the 2- σ case, and results in a mean plastic strain of around 16 μ strain. As this mean plastic strain is positive, the trend is for a growth in length of the sample, as witnessed during testing. The mean value from testing, effectively the average of residual strain on the upper and lower surfaces, is 14 μ strain (from Figure 4). Thus there is also a good agreement with the level of residual axial strain.

The difference between upper and lower surface residual strain was 23 μ strain under testing. From results in Figure 12, it is clear that the equivalent FEA results are somewhat dependent on the level of the final stress cycle, in this case 1- σ . Here, the difference is 16 μ strain, suggesting that a level slightly higher than 1- σ would have been appropriate for this last cycle.

5 MORE COMPLEX STRUCTURES

It is proposed that the method applied here could be used for more complex structures, such as a mirror mounted on flexures that requires very high levels of dimensional stability following random vibration exposure. For such structures, a fully kinematic mounting design may mean that structural pre-stresses are low. However the results of this test have shown that even a low level of stress asymmetry in cases where peak stresses exceed the material's elastic limit can lead to significant residual strain. Also, gravity and static launch accelerations may be important.

For a complex structure, the first modeshape must firstly be determined with some accuracy. Next, acceleration loads must be determined that generate a deformed shape that approximates this modeshape. This will necessarily be an approximation – even for the simple geometry described in this paper, the first modeshape is not identical to the deformed shape under static acceleration. Next, the magnitude of the acceleration loads should be adjusted so that the deflections are equivalent to $1\text{-}\sigma$ deflections from a random vibration run. These accelerations can finally be applied in reversed cycles at several levels (ie $1\text{-}\sigma$, $2\text{-}\sigma$ etc) with the commensurate number of cycles. For areas where microyield is expected, the material properties must include nonlinear kinematic hardening. This will probably mean a bespoke material test, as there appears to be a paucity of data in the literature for these levels of plastic strain. A single kinematic model would probably suffice unless a very large range of stresses above the elastic limit is expected. A final issue to tackle will be determining the number of cycles to apply for each load level. Nonlinear kinematic hardening makes use of the von Mises ductile failure criterion. It is a well known problem in random vibration analysis that von Mises equivalent stresses do not observe a Gaussian probability density function, even if the component x, y and z stresses do. However there are methods to determine or estimate the correct von Mises probability density function [5], [6] that could be applicable.

6 CONCLUSION

Aluminium strip samples in a four-point bending configuration were subject to random vibration in order to assess their dimensional stability. At moderate levels of dynamic stress, the samples exhibited significant residual strain along the length of the strip. A finite element model using nonlinear kinematic hardening material properties was produced to investigate this behaviour. This model was solved in the time domain with a number of reversed load cycles superimposed on a small frictional force. The results of this analysis exhibited a shake-down effect which agreed well with the test observations. This method of analysis has been proposed for more complex structures with high dimensional stability requirements.

Keywords: Shape sensing, Frame structures, Inverse Finite Element Method, Strain gauge.

Abstract. *A robust and efficient computational method for reconstructing the three-dimensional displacement field of truss, beam, and frame structures, using measured surface-strain data, is presented. Known as “shape sensing”, this inverse problem has important implications for real-time actuation and control of smart structures, and for monitoring of structural integrity. The present formulation, based on the inverse Finite Element Method (iFEM), uses a least-squares variational principle involving strain measures of Timoshenko theory for stretching, torsion, bending, and transverse shear. Two inverse-frame finite elements are derived using the interdependent interpolations whose interior degrees-of-freedom are condensed out exactly at the element level. In addition, relationships between the order of kinematic-element interpolations and the number of required strain gauges are established. As an example problem, a thin-walled, circular cross-section cantilevered beam subjected to harmonic excitations in the presence of structural damping is modeled using iFEM; where, to simulate strain-gauge values and to provide reference displacements, a high-fidelity MSC/NASTRAN shell finite element model is used. Examples of low and high-frequency dynamic motion are analyzed and the solution accuracy examined with respect to the increased fidelity of the iFEM’s discretization and the number of strain gauges.*

1 INTRODUCTION

Real-time reconstruction of structural deformations, using measured strain data, is a key technology for actuation and control of smart structures, as well as for Structural Health Monitoring (SHM) [1]. Known as “shape sensing”, this inverse problem is commonly formulated with the assumption that multiple strain sensors at various structural locations provide real-time strain measurements. Most inverse algorithms use some type of Tikhonov’s regularization, which is manifested by constraint (regularity) terms that ensure a certain degree of solution smoothness (refer to [2-5] and references therein.)

Most of the shape sensing efforts focused exclusively on beam-bending problems. Davis et al. [6] used optimized trial functions and weights to reconstruct a simple static-beam response from discrete strain measurements. To model more complex deformations, their approach requires a large number of trial functions and strain sensors. Kang et al. [7] used vibration mode shapes to reconstruct the beam response due to dynamic excitation. In their approach, modal coordinates are computed using strain-displacement relationship and measured surface strain measurements; the method requires the same number of mode shapes and strain sensors. Kim et al. [8] and Ko et al. [9] used classical beam equations to integrate the discretely measured strains to determine the deflection of a beam. By regression of experimental strain data and by accounting for the applied loading, Kim et al. [8] obtained a continuous curvature function, leading to the evaluation of the beam deflection. Ko et al. [9] developed a load-independent method by approximating the beam curvature using piece-wise polynomials; the authors demonstrated the validity of this one-dimensional scheme by evaluating the deflection and cross-section twist of an aircraft wing.

To enable shape-sensing analyses of plates undergoing bending deformations, Bogert et al. [10] examined a modal transformation method that allows the development of suitable strain-displacement transformations. The approach makes use of a large number of natural vibration modes. When applied to high-fidelity finite element models, however, the method requires a computationally intensive eigenvalue analysis and a detailed description of the elastic and inertial material properties. Jones et al. [11] employed a least-squares formulation for shape sensing of a cantilever plate, where the axial strain was fitted with a cubic polynomial. The strain field was then integrated with the use of approximate boundary conditions at the clamped end to obtain plate deflections according to classical bending assumptions. Shkarayev et al. [12,13] used a two-step solution procedure: the first step involves the structural analysis of a plate/shell finite element model, and the second, a least-squares algorithm. The methodology reconstructs the applied loading first, which then leads to the displacements. In a series of four papers, Mainçon and co-authors [14-17] developed a finite element formulation that seeks the solution for the displacements and loads simultaneously, requiring a priori knowledge of a subset of applied loading and the material properties. The solution procedure minimizes a cost function consisting of unknown loads and differences between the measured and estimated quantities (displacements or strains); the cost function is regularized by way of equilibrium constraints. The number of unknowns is three times the number of the degrees-of-freedom in the finite element discretization. Importantly, the accuracy of the solution strongly depends on the choice of suitable weights; these are computed from a complex procedure involving the probability distributions of the unknown loads and measured data. In [16,17], sensitivity analyses were carried out for truss structures, investigating variations in the input data as well as the modeling errors. Nishio et al. [18] employed a weighted-least-squares formulation to reconstruct, on the basis of measured strain data, the deflection of a composite cantilever plate. The weighting coefficients in the least-square terms were adjusted in order to account for the inherent errors in the measured strain data. The

weights were computed for the given data-acquisition apparatus, load case, and test article, with the consequent difficulties in generalizing the procedure.

Many of the aforementioned inverse methods either lack generality with respect to structural topology and boundary conditions, or require sufficiently accurate loading and/or elastic-inertial material information – the kind of data that are either unavailable or difficult to obtain outside the laboratory environment; for these reasons, such approaches are generally unsuited for use in on-board SHM algorithms. An algorithm that is well-suited for SHM should be: (1) able to model general structural topologies and boundary conditions (e.g., built-up aircraft structures), (2) robust, stable, and accurate under a wide range of loadings, material systems, inertial/damping characteristics, and inherent errors in the strain measurements, and (3) sufficiently fast for real-time applications.

An algorithm that appears to fulfill the aforementioned requirements, labeled the inverse Finite Element Method (iFEM), was recently developed by Tessler and Spangler [1,19]. The methodology employs a weighted-least-square variational principle which is discretized by C^0 -continuous finite elements that accommodate arbitrarily positioned and oriented strain-sensor data. The iFEM framework, providing accurate and stable solutions of the displacement and strain fields for the discretized structural domain, is amenable to any type of structural modeling including frame (truss and beam), plate, shell, and solid idealizations. Because only strain-displacement relations are used in the formulation, both static and dynamic regimes can be modeled without any a priori knowledge of the material, inertial, loading, or damping structural properties. To model arbitrary plate and shell structures, Tessler [20] developed, using the first-order shear-deformation theory, a three-node *inverse shell element* formulation. The numerically generated [20] and experimentally measured-strain data [21,22] were used to assess the formulation's robustness and accuracy.

This paper consolidates the authors' recent efforts in [23-25], presenting the development and assessment of simple and efficient inverse-frame finite elements. The methodology permits effective and computationally efficient shape-sensing analyses to be performed on truss, beam, and frame structures instrumented with strain gauges. The kinematic assumptions are those of Timoshenko shear-deformation theory [26]; they incorporate stretching, torsion, bending, and transverse shear deformation modes in three dimensions. The formulation uses a least-squares variational principle that is specialized from [19] for three-dimensional frame analysis. The variational framework, in conjunction with suitable finite element discretizations involving inverse finite elements, yields a system of linear algebraic equations; the equations are efficiently solved for the unknown displacement degrees-of-freedom (dof's), thus providing the deformed structural-shape predictions.

In the remainder of the paper, the kinematic assumptions for a three-dimensional frame are discussed, followed by the description of the least-squares variational principle suitable for three-dimensional deformations of frame structures. This is followed by a discussion of two C^0 -continuous, inverse-frame elements that use the well-established interdependent interpolations that resolve the shear locking effect. Finally, to examine the predictive capabilities of the inverse elements for a given set of distributed strain gauges, shape-sensing studies are carried for a cantilevered beam undergoing harmonic excitations in the presence of structural damping.

2 GOVERNING EQUATIONS

Consider a straight frame member of constant cross-section positioned in the three-dimensional Cartesian coordinates (x,y,z) as depicted in Figure 1; the coordinate origin, O , is located at the cross-section's center of mass, which is also coincident with the shear center. The longitudinal, elastic x -axis is normal to the cross-sectional plane (y, z) , where y and z are the

cross-section's principal inertial axes. The frame member has length L and its cross section has area A , area moments of inertia with respect to the y - and z -axis I_y and I_z , respectively, and polar moment of inertia $I_p = I_y + I_z$ (Figure 1). The frame member is made of an isotropic material, represented by the elastic constants: E (Young's modulus), G (shear modulus), and ν (Poisson ratio).

Neglecting the effect of axial warping due to torsion, and assuming the kinematics of Timoshenko theory [26] in three dimensions, i.e., each cross-section remains flat and rigid with respect to thickness-stretch deformations along the y and z axes, gives rise to the three Cartesian components of the displacement vector of the form

$$\begin{aligned} u_x(x, y, z) &= u(x) + z\theta_y(x) - y\theta_z(x) \\ u_y(x, y, z) &= v(x) - z\theta_x(x) \\ u_z(x, y, z) &= w(x) + y\theta_x(x) \end{aligned} \quad (1)$$

where u_x , u_y , and u_z are the displacements along the x , y , and z axes, respectively, with u , v , and w denoting the displacements at $y = z = 0$; θ_x , θ_y , and θ_z are the rotations about the three coordinate axes. The positive orientations for the six *kinematic variables*, $\mathbf{u} \equiv [u, v, w, \theta_x, \theta_y, \theta_z]^T$, are depicted in Figure 1.

Figure 1: Beam geometry and kinematic variables.

Adhering to the small-strain hypothesis, the non-vanishing strain components have the form

$$\begin{aligned} \varepsilon_x(x, y, z) &= e_1(x) + z e_2(x) + y e_3(x) \\ \gamma_{xz}(x, y) &= e_4(x) + y e_6(x) \\ \gamma_{xy}(x, z) &= e_5(x) - z e_6(x) \end{aligned} \quad (2)$$

where $\mathbf{e}(\mathbf{u}) \equiv [e_1, e_2, e_3, e_4, e_5, e_6]^T$ denote the strain measures of the theory, related to the kinematic variables by first-order partial differentiation

$$\begin{aligned}
 e_1(x) &\equiv u_{,x}(x) & e_4(x) &\equiv w_{,x}(x) + \theta_y(x) \\
 e_2(x) &\equiv \theta_{y,x}(x) & e_5(x) &\equiv v_{,x}(x) - \theta_z(x) \\
 e_3(x) &\equiv -\theta_{z,x}(x) & e_6(x) &\equiv \theta_{x,x}(x)
 \end{aligned} \tag{3}$$

The forces $\{N, Q_y, \text{ and } Q_z\}$ and moments $\{M_x, M_y, \text{ and } M_z\}$ are related to the strain measures, e_i , by way of the constitutive equations (refer to Figure 2)

$$\begin{aligned}
 N &= A_x e_1 & M_x &= J_x e_6 \\
 Q_y &= G_y e_5 & M_y &= D_y e_2 \\
 Q_z &= G_z e_4 & M_z &= D_z e_3
 \end{aligned} \tag{4}$$

where $A_x \equiv EA$ is the axial stiffness, $G_y \equiv k_y^2 GA$ and $G_z \equiv k_z^2 GA$ are the shear stiffnesses (with k_y^2 and k_z^2 shear correction factors), $J_x \equiv GI_p$ is the torsional stiffness, and $D_y \equiv EI_y$ and $D_z \equiv EI_z$ are the bending stiffnesses.

Figure 2: Beam resultant forces and moments.

If $q_x(x)$, $q_y(x)$, and $q_z(x)$ are the distributed loads applied along the x , y and z directions, respectively, the frame-member equilibrium equations become

$$\begin{aligned}
 \frac{dN}{dx} &= -q_x & \frac{dM_x}{dx} &= 0 \\
 \frac{dQ_y}{dx} &= -q_y & \frac{dM_y}{dx} &= Q_z \\
 \frac{dQ_z}{dx} &= -q_z & \frac{dM_z}{dx} &= Q_y
 \end{aligned} \tag{5}$$

To reconstruct the deformed shape of a frame structure for which certain in-situ strain measurements are known, a functional $\Phi(\mathbf{u})$ that matches, in a least-square sense, the complete set of

the analytic strain measures, $\mathbf{e}(\mathbf{u})$, to those corresponding to the strain measurements, \mathbf{e}^ε , is minimized with respect to the kinematic variables, \mathbf{u} ; where the superscript ε denotes those quantities that are computed from the in situ strain measurements. Thus, the $\Phi(\mathbf{u})$ functional can be written in compact notation as

$$\Phi(\mathbf{u}) = \|\mathbf{e}(\mathbf{u}) - \mathbf{e}^\varepsilon\|^2 \quad (6)$$

$\Phi(\mathbf{u})$ is then discretized by the piecewise-continuous displacements, \mathbf{u}^h , i.e.,

$$\mathbf{u}(x) \simeq \mathbf{u}^h = \mathbf{N}(x)\mathbf{u}^e \quad (7)$$

where $\mathbf{N}(x)$ denotes C^0 -continuous shape functions and \mathbf{u}^e the nodal dof's. Consequently, the total least-squares functional is a sum of the individual element contributions, $\Phi^e(\mathbf{u}^h)$, i.e., $\Phi = \sum_{e=1}^N \Phi^e$, with N denoting the total number of elements. Accounting for the axial stretching, bending, twisting, and transverse shearing, the element functional is given by

$$\Phi^e(\mathbf{u}^h) \equiv \sum_{k=1}^6 \lambda_k^0 \Phi_k^e \quad (8)$$

where

$$\boldsymbol{\lambda} \equiv [\lambda_1^0 \quad \lambda_2^0 A^e \quad \lambda_3^0 A^e \quad \lambda_4^0 \quad \lambda_5^0 \quad \lambda_6^0 A^e] \quad (9)$$

with λ_k^0 ($k=1, \dots, 6$) denoting the dimensionless weight coefficients, and A^e the cross-sectional area of the element. The six components of the element functional are given as the Euclidean norms

$$\Phi_k^e \equiv \frac{L^e}{n} \sum_{i=1}^n [e_k(x_i) - e_k^{\varepsilon i}]^2 \quad (k=1, \dots, 6) \quad (10)$$

where L^e denotes the element length, n is the number of strain sensors, x_i ($0 \leq x_i \leq L^e$) are the positions at which the strain sensors are located, and the superscript εi is used to denote the strain measures that are computed from the strain-sensor values (experimental values) at the location x_i .

Substituting Eq. (7) into Eq. (3) gives the strain measures in terms of the nodal dof's as

$$\mathbf{e}(\mathbf{u}) = \mathbf{B}(x)\mathbf{u}^e \quad (11)$$

where the matrix $\mathbf{B}(x)$ contains the derivatives of the shape functions $\mathbf{N}(x)$. Substituting Eq. (11) into Eq. (8) results in the following quadratic form

$$\Phi^e = \frac{1}{2}(\mathbf{u}^e)^T \mathbf{k}^e \mathbf{u}^e - (\mathbf{u}^e)^T \mathbf{f}^e + \mathbf{c}^e \quad (12)$$

where \mathbf{k}^e and \mathbf{f}^e are defined in terms of $\mathbf{B}(x)$ and \mathbf{c}^e is a constant. Note that \mathbf{k}^e depends only on the measurement locations, x_i , whereas \mathbf{f}^e depends on the experimentally measured strain values. Minimization of the functional Φ^e with respect to \mathbf{u}^e leads to the inverse element matrix equation

$$\mathbf{k}^e \mathbf{u}^e = \mathbf{f}^e \quad (13)$$

The assembly of the finite element contributions, while accounting for the appropriate coordinate transformations and by specifying problem-dependent displacement boundary conditions, results in a non singular system of algebraic equations of the form

$$\mathbf{K}\mathbf{U} = \mathbf{F} \quad (14)$$

The solution of these equations for the unknown dof's is efficient: the \mathbf{K} matrix is inverted only once, since it is independent of the values of the measured strains. The \mathbf{F} vector, however, is dependent on the measured strain values that change during deformation. Thus, at any strain-measurement update during deformation, the matrix-vector multiplication provides the solution for the unknown nodal displacement dof's, $\mathbf{U} = \mathbf{K}^{-1} \mathbf{F}$, where \mathbf{K}^{-1} remains unchanged for a given distribution of strain sensors¹.

The remaining part of the element formulation involves the selection of suitable shape functions, symbolically defined by Eq. (7), and the computation of the experimental strain measures, e_k^{ei} , appearing in Eq. (10). In Section 3, the shape functions for two alternative inverse-frame elements, each having two nodes and twelve dof's, are derived. In Section 4, a procedure for computing e_k^{ei} is described; it relates the number of strain gauges to the interpolation order of the shape functions.

¹ Depending on the selected shape functions (refer to Section 3), interior dof's may be present. These are condensed out at the element level by straightforward partitioning of the element equations, $\mathbf{k}^e \mathbf{u}^e = \mathbf{f}^e$, and then by solving exactly for the condensed dof's in terms of the end-node dof's. This process results in the reduced element equations (without the interior dof's), $\mathbf{k}_R^e \mathbf{u}_R^e = \mathbf{f}_R^e$, where \mathbf{k}_R^e is a function of the partitioned parts of the original \mathbf{k}^e matrix, and \mathbf{u}_R^e contains the end-node dof's. Since the unreduced \mathbf{k}^e matrix is independent of the strain values, so is the \mathbf{k}_R^e matrix. This implies that even for the elements with the condensed-out interior dof's, the corresponding system matrix, \mathbf{K} , is also strain-value independent.

3 ELEMENT SHAPE FUNCTIONS

In this section, inverse frame elements of 0th and 1st order are formulated. The elements use the interdependent interpolations that enable excellent predictions even for very slender frame members, without incurring any form of excessive stiffening due to shear locking [27]. The 0th-order shape functions are guided by Timoshenko equilibrium equations, Eq. (5), that correspond to the forces and moments applied exclusively at the end nodes, resulting in constant distributions of the transverse-shear strain measures. The 1st-order shape functions accommodate Eq. (5) for uniformly distributed transverse loads, giving rise to linear distributions of the transverse-shear strain measures.

A frame element is referred to a local axial coordinate $x \in [0, L^e]$, where L^e denotes the element length. Furthermore, a non-dimensional coordinate $\xi \equiv (2x/L^e - 1) \in [-1, 1]$ is used to define the element shape functions (Figure 3). The initial nodal configurations are defined by the two end nodes, 1 (at $\xi = -1$) and 2 (at $\xi = +1$) and one or three interior nodes. Thus, the initial configuration for the 0th-order element has the interior node, r (at the midspan, $\xi = 0$); whereas the interior nodes of the 1st-order element are q (at $\xi = -1/2$), r (at $\xi = 0$), and s (at $\xi = +1/2$).

Figure 3: Inverse finite element geometry and nodal topology.

The initial nodal configurations of the 0th- and 1st-order elements are readily reduced to two nodes and twelve dof by condensing out the interior dof's at the element level, Eq. (13), in a manner analogous to static condensation. The resulting elements have three-displacement and three-rotation dof's at each end node (Figure 4)

Figure 4: Two-node inverse finite element.

3.1 0th-order element

The formulation of the 0th-order element is guided by Eq. (5) for the loading case of end-node forces and moments. For this case, the axial force, twisting moment, and shear forces are constant along the element; whereas the bending moments are linear. Equations (5) in terms of

the strain measures (after Eq. (4) have been introduced) indicate that the strain measures e_i ($i=1, 4-6$) are constant, and e_i ($i=2,3$) are linear. From Eq. (3), it is deduced that u and θ_x are linear, θ_y and θ_z parabolic, v and w cubic.

Thus, u and θ_x are interpolated using the linear Lagrange polynomials $L_i^{(1)}(\xi)$ ($i=1,2$)

$$\begin{aligned} u(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) u_i \\ \theta_x(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) \theta_{xi} \end{aligned} \quad (15)$$

The polynomial degrees for the deflection, v and w , and bending rotation, θ_y and θ_z , variables are interrelated: if v and w are defined by cubic polynomials, then θ_y and θ_z need to be represented by quadratic polynomials to form consistent, free of locking, transverse shear-strain measures e_4, e_5 (This is a key requirement of the interdependent interpolation strategy, IIS.) Thus, the remaining kinematic variables, which enable both bending and shear deformation along the x and y orthogonal directions, are interpolated as

$$\begin{aligned} v(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) v_i - \sum_{j=1,r,2} N_j^{(3)}(\xi) \theta_{zj} \\ w(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) w_i + \sum_{j=1,r,2} N_j^{(3)}(\xi) \theta_{yj} \\ \theta_y(\xi) &= \sum_{j=1,r,2} L_j^{(2)}(\xi) \theta_{yj} \\ \theta_z(\xi) &= \sum_{j=1,r,2} L_j^{(2)}(\xi) \theta_{zj} \end{aligned} \quad (16)$$

where $L_j^{(2)}(\xi)$ are standard quadratic Lagrange polynomials, and $N_j^{(3)}(\xi)$ ($j=1,r,2$) are special-form cubic polynomials; these functions are obtained from standard cubic Lagrange polynomials by enforcing the transverse shear-strain measures to be constant along the element, i.e.,

$$\begin{aligned} e_4 &= (w_{,x} + \theta_y) = \text{const.} \\ e_5 &= (v_{,x} - \theta_z) = \text{const.} \end{aligned} \quad (17)$$

The expression for $L_i^{(1)}(\xi)$, $L_j^{(2)}(\xi)$, and $N_j^{(3)}(\xi)$ ($i=1,2$; $j=1,r,2$) are summarized in the Appendix. The element has fourteen dof's, six at each element end, plus the rotations θ_{yr} and θ_{zr} at the element's midspan

$$\mathbf{u}^e \equiv \{u_1, v_1, w_1, \theta_{x1}, \theta_{y1}, \theta_{z1}, \theta_{yr}, \theta_{zr}, u_2, v_2, w_2, \theta_{x2}, \theta_{y2}, \theta_{z2}\}^T \quad (18)$$

Thus, in order to achieve a two-node element with twelve dof's (Figure 4), the internal dof's, θ_{yr}, θ_{zr} , are condensed out statically.

3.2 1st-order element

Consider a frame element loaded by uniformly distributed transverse loads, $q_y(x)$ and $q_z(x)$. From Eqs. (5), after the substitution of Eqs. (4), it is readily deduced that (e_4, e_5) need to be linear and (e_2, e_3) parabolic. The u and θ_x variables remain linear and interpolated by Eq. (15). Moreover, (v, w) and (θ_y, θ_z) are respectively quartic and cubic, and are interpolated as

$$\begin{aligned} v(\xi) &= \sum_{k=1,q,r,s,2} L_k^{(4)}(\xi) v_k \\ w(\xi) &= \sum_{k=1,q,r,s,2} L_k^{(4)}(\xi) w_k \\ \theta_y(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) \theta_{yi} + \sum_{k=1,q,r,s,2} \bar{N}_k^{(3)}(\xi) w_k \\ \theta_z(\xi) &= \sum_{i=1,2} L_i^{(1)}(\xi) \theta_{zi} - \sum_{k=1,q,r,s,2} \bar{N}_k^{(3)}(\xi) v_k \end{aligned} \quad (19)$$

where $\bar{N}_k^{(3)}(\xi)$ ($k=1,q,r,s,2$) are cubic polynomials that satisfy the conditions (for the detailed expressions, refer to the Appendix)

$$\begin{aligned} e_4 &= (w_{,x} + \theta_y) = \text{linear} \\ e_5 &= (v_{,x} - \theta_z) = \text{linear} \end{aligned} \quad (20)$$

Interpolation described by Eqs. (15) and (19) leads to a formulation with eighteen dof's

$$\mathbf{u}^e \equiv \{u_1, v_1, w_1, \theta_{x1}, \theta_{y1}, \theta_{z1}, v_q, w_q, v_r, w_r, v_s, w_s, u_2, v_2, w_2, \theta_{x2}, \theta_{y2}, \theta_{z2}\}^T \quad (21)$$

The interior dof's are condensed out at the element level, leading again to a twelve dof's inverse element (Figure 4).

4 INPUT DATA FROM SURFACE STRAIN MEASUREMENTS

A key step in the iFEM formulation is to compute the strain measures due to experimentally measured surface strains. Herein, the relationships between the measured surface strains and the six strain measures, e_i , are established. Also discussed are strain-gauge positions along the frame axis and their angular orientations that enable the complete description of the experimental strain

measures. The present analysis is restricted to frame members with circular cross sections; the cylindrical coordinate system (θ, x, r) is shown in Figure 5.

Figure 5: Orthogonal and cylindrical coordinate systems.

4.1 Strain measures from linear strain gauge measurements

Taking the usual assumption of negligible σ_y and σ_z , σ_x and $\tau_{x\theta}$ are the only non-zero stress components acting on the external surface $r = R_{ext}$ (Figure 6(a)). The corresponding strain state is (Figure 6(b))

$$\varepsilon_x = \frac{\sigma_x}{E}, \quad \varepsilon_\theta = -\frac{\nu}{E} \sigma_x = -\nu \varepsilon_x, \quad \gamma_{x\theta} = \frac{\tau_{x\theta}}{G} \quad (22)$$

Figure 6: Stress and strain states on the frame external surface ($r=R_{ext}$) in the cylindrical coordinate system.

Consider a linear strain gauge placed on the external surface at $x = x_i$, at a particular θ and with an angle β with respect to the beam axis (Figure 7); (x_1, x_2, x_3) is a local Cartesian coordinate system having x_2 -axis along the strain gauge measurement axis, x_1 -axis on the frame surface and x_3 -axis normal to the frame surface and coincident with r -axis.

Figure 7: Location and coordinate system of a linear strain gauge placed on the frame external surface.

Using the appropriate strain-tensor transformations, from the (θ, x, r) to (x_1, x_2, x_3) coordinates [28], the relationship between the measured strain ε_2 and the strain tensor in Eq. (22) becomes

$$\varepsilon_2 = \varepsilon_x \cos^2 \beta + \varepsilon_\theta \sin^2 \beta + \gamma_{x\theta} \cos \beta \sin \beta \quad (23)$$

or, using the second of Eqs. (22),

$$\varepsilon_2 = \varepsilon_x (\cos^2 \beta - \nu \sin^2 \beta) + \gamma_{x\theta} \cos \beta \sin \beta \quad (24)$$

Expressing Eq. (2) for $r = R_{ext}$, yields [23-25]

$$\begin{aligned} \varepsilon_x &= e_1 + e_2 R_{ext} \sin \theta + e_3 R_{ext} \cos \theta \\ \gamma_{x\theta} &= e_4 \cos \theta - e_5 \sin \theta + e_6 R_{ext} \end{aligned} \quad (25)$$

Substituting Eq. (25) into Eq. (24) results in the relation between the measured strain ε_2 and the six strain measures at $x = x_i$

$$\begin{aligned} \varepsilon_2(x_i, \theta, \beta) &= e_1(x_i) (c_\beta^2 - \nu s_\beta^2) \\ &\quad + e_2(x_i) (c_\beta^2 - \nu s_\beta^2) s_\theta R_{ext} \\ &\quad - e_3(x_i) (c_\beta^2 - \nu s_\beta^2) c_\theta R_{ext} \\ &\quad + e_4(x_i) c_\beta s_\beta c_\theta \\ &\quad - e_5(x_i) c_\beta s_\beta s_\theta \\ &\quad + e_6(x_i) c_\beta s_\beta R_{ext} \end{aligned} \quad (26)$$

where the following notation has been used: $c_\theta \equiv \cos \theta$, $s_\theta \equiv \sin \theta$, $c_\beta \equiv \cos \beta$, $s_\beta \equiv \sin \beta$.

4.2 Strain gauge distributions

The 0th-order element, having constant e_1 , e_4 , e_5 , and e_6 and linear e_2 and e_3 , requires eight strain measurements. This number may be reduced to six by invoking the moment-shear equilibrium equations, Eq. (5). Substituting Eq. (4) into Eq. (5) results in

$$D_y e_{2,x} = G_z e_4, \quad D_z e_{3,x} = G_y e_5 \quad (27)$$

The 1st-order element has constant e_1 and e_6 , linear e_4 and e_5 , and parabolic e_2 and e_3 , thus requiring twelve strain measurements. For this element, each of the equations in Eqs. (27) is linear in x , thus four constraint equations are obtained; the number of the strain-gauge measurements is thus reduced from twelve to eight. This procedure should be viewed as a convenient means of reducing the required number of strain gauges by solving for e_4 and e_5 analytically rather than measuring these quantities experimentally. Since the magnitudes of e_4 and e_5 are generally much smaller compared to the bending strain measures, this treatment should be quite adequate for both static and dynamic applications. In Section 5, the validity of this constraint strategy for dynamically loaded beams is examined quantitatively.

Since the strain gauges can be placed anywhere along the beam surface, the distributions summarized in Table 1 are considered in this study (also refer to Figures 8 and 9); additional strain-gauge locations have been examined in [24]. To refer to a specific combination of the element type and strain-gauge configuration, a compact notation, #-#E, is used; where the first position, #, refers to the element order (0 or 1), the second position, #, indicates the number of strain gauges per element (6 or 8), and the letter “E” indicates that Eqs. (27) have been used in the formulation. The strain gauges are placed at different positions $x = (L^e/3, L^e/2, 2L^e/3)$ along the element. The strain-gauge angular orientations (θ, β) are also allowed to be different; for example, $(\theta, \beta) = (-2\pi/3, \pi/4)$ indicates that the strain gauge is placed at the circumferential angle $\theta = -2\pi/3$ and is oriented with an angle $\beta = \pi/4$ with respect to the frame x -axis (Figure 7).

Element-strain gauge notation	Orientation (θ, β) of strain gauges at $x=L^e/3$	Orientation (θ, β) of strain gauges at $x=L^e/2$	Orientation (θ, β) of strain gauges at $x=2L^e/3$
0-6E	-	$(-2\pi/3, 0), (-2\pi/3, \pi/4), (0, 0), (0, \pi/4), (2\pi/3, 0), (2\pi/3, \pi/4)$	-
1-8E	$(-2\pi/3, \pi/4)$	$(-2\pi/3, 0), (-2\pi/3, \pi/4), (0, 0), (0, \pi/4), (2\pi/3, 0), (2\pi/3, \pi/4)$	$(2\pi/3, \pi/4)$

Table 1: Strain-gauge distributions $x, (\theta, \beta)$ corresponding to the 0th- and 1st-order elements.

5 NUMERICAL RESULTS

A simple cantilevered beam subjected to dynamic loading is analyzed to assess the accuracy of the inverse finite element method. The beam is made of an aluminum alloy ($E=73,000$ MPa, $\nu=0.3$, and $\rho=2557$ Kg/m³) and has a thin-walled circular cross-section with the average radius $R=39$ mm, wall thickness $s=2$ mm, and length $L=800$ mm. The beam is fully clamped on one end and subjected at the other end to a harmonic vertical force $F_z(t)$ (where t denotes time) acting in the z -direction at frequency f_0 , i.e.,

$$F_z(t) = F_{z0} \sin(2\pi f_0 t) \quad (28)$$

where F_{z0} is the force amplitude ($F_{z0}=10^3$ N.) To simulate the experimental-strain measurements and to assess the accuracy of the inverse method, high-fidelity forward FE analyses are performed using QUAD4 shell elements in MSC/NASTRAN. The model consists of 114 elements along the cross-sectional circumference and 360 elements along the beam axis, for a total of 41,040 elements and 41,156 nodes. The tip force is applied at the cross-sectional center at a node which is connected to all other nodes within the cross-section by means of multi-point constraints (or MPC's) [29].

The dynamic response of the beam is calculated via a modal transient analysis keeping the modes up to 5,000 Hz, with the inclusion of viscous damping of magnitude 5% with respect to the critical value at each frequency. In the frequency range from 0 to 5,000 Hz, 51 modes are present: these include the first lowest flexural beam modes, 1F-5F, appearing twice due to the

cross-section symmetry, and the first membrane mode (1M). Table 2 summarizes the order of the global modes, their type, and corresponding frequency value f ; the first three flexural mode shapes are shown in Figures 10-12. The other modes in the same frequency range are associated with the shell modes describing the cross-sectional distortion.

Mode order	1 st and 2 nd modes	3 rd and 4 th modes	12 th mode	13 th and 14 th modes	30 th and 31 st modes	40 th and 41 st modes
Mode type	1F	2F	1M	3F	4F	5F
f frequency [Hz]	126.8	729.5	1,670	1,835	3,187	4,671

Table 2: Global modes of the cantilevered beam in the frequency range of 0-5,000 Hz. (F-type modes are flexural; M-type modes are membrane.)

Figure 10: 1st flexural mode (1F, $f = 126.8$ Hz).

Figure 11: 2nd flexural mode (2F, $f = 729.5$ Hz).

Figure 12: 3rd flexural mode (3F, $f = 1,835$ Hz).

To investigate the accuracy of the iFEM modeling for dynamic applications in both low- and high-frequency regimes, three different values of the applied-force frequency f_0 have been con-

sidered, namely: $f_0=60$ Hz (about half of the fundamental frequency), $f_0=450$ Hz (halfway between 1F and 2F modes), and $f_0=1,400$ Hz (halfway between 2F and 3F). Figures 13-15 compare the tip-deflection time histories, $w_{\max}(t)$, calculated by means of a high-fidelity FEM shell model using MSC/NASTRAN and the corresponding iFEM frame-element models. The tip deflection of the NASTRAN model corresponds to the cross-sectional center, and is computed at a node which is connected to all other nodes within the cross-section by means of MPC's. The present iFEM models used the strain-gauge distributions in Table 1 and the uniform weight coefficients $\lambda_k^0 = 1$ ($k=1, \dots, 6$) in Eq. (9); the strain values were taken from the nodes (at the specific locations in Table 1) of the NASTRAN model. It is noted that slightly more accurate strain values reside at the element Gauss points. However, considering the high fidelity of the reference FEM model, the “measured” strains taken at the nodes are quite satisfactory.

For the low-frequency loading of $f_0=60$ Hz, a single 0th-order inverse element gives accurate results, with a maximum error in the tip deflection of 2.3% (Figure 13). At this excitation frequency, when $t \geq 0.1$, viscous damping has reduced the structural vibrations to a steady state response, proceeding at a constant amplitude and the same frequency as the forcing function. When the excitation frequency of the forcing function is increased, the response has a longer transient region, which is manifested by interactions between the natural modes of vibration and those due to the applied dynamic loading. To model the transient response at higher frequencies, finer discretizations are required. Thus, for $f_0 = 450$ Hz, a two-element, 1st-order model yields a 1.1% error in the maximum deflection (Figure 14). At the $f_0=1,400$ Hz frequency, a three-element iFEM discretization using the 1st-order element results in the maximum deflection error of 1.3% (Figure 15). These results clearly demonstrate that the methodology is highly efficient, requiring only few inverse elements and strain-gauge measurements, and is applicable not only for the steady state portion of the response but also for the transient regime at high frequencies.

Figure 13: Tip deflection w_{\max} of the beam loaded by a transverse concentrated force F_z at $f_0=60$ Hz.

Figure 14: Tip deflection w_{\max} of the beam loaded by a transverse concentrated force F_z at $f_0=450$ Hz.

Figure 15: Tip deflection w_{\max} of the beam loaded by a transverse concentrated force F_z at $f_0=1,400$ Hz.

6 CONCLUSIONS

In search of a suitable computational method for use in Structural Health Monitoring (SHM) systems, an inverse Finite Element Method (iFEM) has been formulated to perform the displacement-field reconstruction analysis (shape-sensing) of three-dimensional frame structures undergoing dynamic motion. The methodology uses a least-squares variational principle, which is discretized by C^0 -continuous displacement-based *inverse* frame elements. Linear strain-displacement relations and their components, known as strain measures, are based on the Timoshenko (first-order) shear deformation theory that includes the deformations due to stretching, torsion, bending, and transverse shear. The variational statement enforces experimentally measured strains to be least-square compatible with those interpolated within the inverse frame elements. The implementation of this least-square compatibility is accomplished using the individual strain measures.

Two inverse frame elements, each having two nodes and twelve dof's, have been developed. The 0th-order element has a shear-strain measure which is constant along the element length; whereas the 1st-order element has a linear shear-strain measure. The element shape functions are based on interdependent interpolations that ensure free-of-shear-locking bending of slender frame members. The element interpolation order is linked to the definition of the number and orientation of the uniaxial strain gauges that are necessary for the analysis. Two simple and effective strain-gauge distributions have been selected and used in the numerical examples.

The present shape-sensing capability has been demonstrated on a thin-walled, circular cross-section cantilevered beam subjected to harmonic excitations in the presence of structural damping. To provide the *simulated* strain-gauge measurements, as well as the reference displacements, a high-fidelity shell finite element model was developed using the MSC/NASTRAN commercial code. Low- and high-frequency dynamic beam motions were analyzed and time history of the tip deflection examined, comparing several iFEM discretizations and strain-gauge schemes. The iFEM shape-sensing analysis, which is based only on the strain-displacement relations and the measured strain data (without any reliance on the material, inertial, or damping properties of the structure), has been shown to be highly effective and efficient in predicting the dynamic structural response of a damped beam. Accurate predictions of both the steady-state and transient response required only few elements and strain-gauge measurements, where the higher-frequency excitations necessitated somewhat higher fidelity of the iFEM models.

Although beyond the scope of the present effort, additional studies need to be performed, including: (a) shape-sensing analysis of spatial frame structures using the strains measured in a laboratory, and (b) studies of the strain-gauge distributions that provide optimal (or nearly optimal) solutions.

APPENDIX

The 1st, 2nd, and 4th-degree Lagrange shape functions are given as

- 1st degree

$$\left[L_1^{(1)}, L_2^{(1)} \right] \equiv \frac{1}{2} \left[(1-\xi), (1+\xi) \right] \quad (\text{A1})$$

- 2nd degree

$$\left[L_1^{(2)}, L_r^{(2)}, L_2^{(2)} \right] \equiv \frac{1}{2} \left[\xi(\xi-1), 2(1-\xi^2), \xi(\xi+1) \right] \quad (\text{A2})$$

- 4th degree

$$\begin{aligned} \left[L_1^{(4)}, L_2^{(4)} \right] &\equiv \frac{1}{6} \xi (4\xi^2 - 1) \left[(\xi-1), (\xi+1) \right] \\ \left[L_q^{(4)}, L_r^{(4)}, L_s^{(4)} \right] &\equiv \frac{1}{3} (1-\xi^2) \left[4\xi(2\xi-1), 3(1-4\xi^2), 4\xi(2\xi+1) \right] \end{aligned} \quad (\text{A3})$$

where $\xi \equiv 2x / L^e - 1 \in [-1, 1]$ is a non-dimensional axial coordinate; $x \in [0, L^e]$ and L^e denotes the element length. The subscripts 1 and 2 represent the end nodes, whereas q , r , and s denote the uniformly spaced interior nodes.

The 3rd-degree shape functions, $N_j^{(3)}(\xi)$, of the 0th-order element have the form

$$\left[N_1^{(3)}, N_r^{(3)}, N_2^{(3)} \right] \equiv \frac{L^e}{24} (1-\xi^2) \left[(2\xi-3), -4\xi, (2\xi+3) \right] \quad (\text{A4})$$

whereas the $\overline{N}_k^{(3)}(\xi)$ shape functions of the 1st-order element are

$$\left[\overline{N}_1^{(3)}, \overline{N}_q^{(3)}, \overline{N}_r^{(3)}, \overline{N}_s^{(3)}, \overline{N}_2^{(3)} \right] \equiv \frac{4}{3L^e} (1-\xi^2) \left[(4\xi-3), -2(8\xi-3), 24\xi, -2(8\xi+3), (4\xi+3) \right] \quad (\text{A5})$$

EFFICIENT MODEL UPDATING OF THE GOCE SATELLITE BASED ON EXPERIMENTAL MODAL DATA

Abstract. *The accurate prediction of the structural response of spacecraft systems during launch and ascent phase is a crucial aspect in design and verification stages which requires accurate numerical models. The enhancement of numerical models based on experimental data is denoted model updating and focuses on the improvement of the correlation between finite element (FE) model and test structure. In aerospace industry the judgment of the agreement between model and real structure involves the comparison of the modal properties of the structure. Model updating techniques have to handle several difficulties, like incomplete experimental data, measurement errors, non-unique solutions and modeling uncertainties. To cope with the computational challenges associated with the large-scale FE-models involving up to over one million degrees of freedom (DOFs), enhanced strategies are required. A large-scale numerical example, namely a satellite model, will be used for demonstrating the applicability of the employed updating procedure to complex aerospace structures.*

1 INTRODUCTION

The dynamic loads acting on a spacecraft during the launch and ascent phase are modeled by the spacecraft-launcher coupled dynamic analysis. The accuracy of the structural response in this low-frequency mechanical environment depends on the quality of the underlying mechanical model of the spacecraft. Therefore, it is mandatory to ensure that the FE-model represents the real structure accurately enough. This level of accuracy to be reached for aerospace structures is defined in [1] and is based on the agreement of experimentally and computationally determined modal properties, respectively. Possible sources for discrepancies between test data and respective computed values are e.g. uncertainties in the modeling process arising from inadequate theory for some system behaviors, simplifying assumptions made in order to reduce the complexity of the model and uncertainties about model parameter values. Hence, the need for improving the mechanical model based on experimental data arises which is referred to as model updating and the consecutive corroboration of the model by means of modal properties is denoted by validation [2, 3, 4].

The use of deterministic updating procedures does not allow for a quantification of the involved uncertainties in the design and verification processes which will subsequently affect the accuracy of the predictive structural response. Probabilistic methods for model updating provide a means for tackling these problems and for avoiding a wrong conclusion about the fit of the experimental data and analytical results [5]. A significant obstacle in the consideration of uncertainties when performing model updating of complex structures is posed by the associated computational efforts. Therefore, the most frequently used approaches for model updating performed by industry are deterministic approaches (see e.g. [6, 7, 8, 9]). While stochastic methods have been developing successfully in this research field, applications in industry are relatively limited (see e.g. [10]). Hence, in this work it is aimed at a computationally efficient application of a stochastic model updating procedure to complex aerospace models.

The thereby adopted updating process is the Bayesian approach which is based on updating the initial engineering knowledge about the ranges of the adjustable parameters using experimental data [11, 12, 13]. In this way, a revised information about the parameters is obtained, which is expressed by posterior probability density functions. Probability is therefore not interpreted in the usual frequentist sense, where it refers to the relative frequency of occurrence in case of many events, but it is based on the idea of reasonable expectation, i.e. probability is interpreted as a measure of plausibility of the hypothesis. This interpretation makes it possible to extend the application of probability theory to fields where the frequentist interpretation may not be directly intuitive, as it is the case for one-of-a-kind structures, where no ensemble exists, and also in the case of limited data, where classical statistics is of limited applicability. Therefore, Bayesian statistics makes it possible to deal with the usual situation in aerospace industry, where a large amount of experimental data is infeasible due to the enormous costs associated with test campaigns, and it provides a means for making decisions based on limited, incomplete information.

The computational tools for the Bayesian updating procedure are sampling-based algorithms, where a multi-level Markov chain Monte Carlo algorithm is adopted in this approach [14]. As a remedy for the large computational efforts associated with the Bayesian updating procedure, the application of a surrogate model (a so-called “meta-model”) is proposed. This meta-model

is formulated with respect to the repeated analysis tasks, which are the eigensolutions in case of model updating based on modal data. Hence, a simple relation between the input data and output quantity of interest has to be established in order to replace the computationally intensive evaluation of a full finite element analysis by a function evaluation at low computational costs. Several techniques, e.g. linear or polynomial regression, kriging and the radial basis functions have been developed in this context (see e.g. [15]), where in this work neural networks [16] will be adopted in order to approximate the modal properties of the structure.

This manuscript will demonstrate the feasibility of the application of Bayesian model updating procedures on spacecraft structures using eigenfrequencies and mode shape vectors. Sec. 2 is devoted to the presentation of the basic steps of Bayesian model updating, and in Sec. 3 the algorithm for the generation of samples in the solution space is summarized. Computational aspects will be addressed in the following (Sec. 4), where the basic concepts of neural networks are discussed. In order to apply these outlined concepts to an FE-model of a spacecraft structure, the use of a surrogate model within the updating process is adopted for the FE-model of the GOCE satellite (Sec. 5).

2 BAYESIAN MODEL UPDATING

2.1 Introduction

The fundamental rule that governs the Bayesian updating procedure is Bayes' Theorem, which is formulated in general terms as [17]

$$P(H|\mathcal{D}, I) = \frac{P(\mathcal{D}|H, I)P(H|I)}{P(\mathcal{D}|I)}, \quad (1)$$

where H is any hypothesis to be tested, \mathcal{D} denotes the data and I is the available background information. Bayes' Theorem provides a means to update the prior probability density function (PDF) of H , $P(H|I)$, by using the data in the likelihood function $P(\mathcal{D}|H, I)$ in order to obtain the posterior distribution of H , $P(H|\mathcal{D}, I)$. The denominator $P(\mathcal{D}|I)$ is a normalizing constant and does not affect the shape of the posterior PDF. All probabilities in Eq. (1) are conditional on I , which means that the outcome of the updating procedure depends on the available information.

2.2 Bayesian updating using modal data

If applying Bayes' Theorem for structural model updating [11, 12], the hypothesis H is interpreted as the vector of unknown (i.e. adjustable) parameters, which will be referred to as θ in the following, and \mathcal{D} denotes the experimental data, which consist of the measured modal properties of the investigated structure. The available information I is interpreted as the experience and knowledge of the engineer which is reflected by the established model itself and is therefore denoted as \mathcal{M} . This leads to the following form of Eq. (1):

$$p(\theta|\mathcal{D}, \mathcal{M}) = \frac{p(\mathcal{D}|\theta, \mathcal{M})p(\theta|\mathcal{M})}{p(\mathcal{D}|\mathcal{M})}. \quad (2)$$

The prior distribution $p(\theta|\mathcal{M})$ expresses the initial knowledge about the adjustable parameters. The choice of the distribution can be based on the principle of maximum entropy [18]. In this

case, the PDF used for describing the initial uncertainty maximizes the uncertainty subject to the prescribed constraints, which can be given by e.g. imposing moment constraints. The likelihood function $p(\mathcal{D}|\theta, \mathcal{M})$ gives a measure of the agreement between the system data and the corresponding structural model output. This measure of the data fit of each model defined by the parameters vector θ , is given by the probability model established for the system output. The derivation of the likelihood function for modal data will be summarized in Sec. 2.3. The posterior distribution $p(\theta|\mathcal{D}, \mathcal{M})$ expresses the revised knowledge about the parameters θ conditional on the initial knowledge and the experimental data.

2.3 Formulation of the likelihood function for modal data

In general terms, the connection between the model output $q(\theta)$ and the corresponding system output y is given by the prediction error e in the form of

$$y = q(\theta) + e. \quad (3)$$

The choice for the probability model of the prediction error e , which is the difference between the model output for a certain value of θ and the corresponding system output, is based on the maximum entropy principle [18] which yields a multi-dimensional Gaussian distribution with zero mean and covariance matrix Σ . The Gaussian PDF arises because it gives the largest amount of uncertainty among all probability distributions for a real variable whose first two moments are specified. Hence, the predictive PDF for the system output conditional on the parameter vector θ is given by

$$p(y|\theta, \mathcal{M}) = \frac{1}{(2\pi)^{N/2}|\Sigma|^{1/2}} \exp \left[-\frac{1}{2}(y - q(\theta))^T \Sigma^{-1}(y - q(\theta)) \right], \quad (4)$$

where N_0 N denotes the length of the vector y , i.e. the number of observed points. If a set of measured output $\mathcal{D} = \{y_j : j = 1, \dots, N_s\}$ is available, then the likelihood function can be constructed as $p(\mathcal{D}|\theta, \mathcal{M}) = \prod_{j=1}^{N_s} p(y_j|\theta, \mathcal{M})$ if the prediction errors are modeled as statistically independent.

The formulation of the likelihood function using modal data is derived in [19] and is summarized in the following. The experimental data \mathcal{D} from the structure is assumed to consist of N_s sets of modal data, $\mathcal{D} = \{\hat{\omega}_{1,j} \dots \hat{\omega}_{N_m,j}, \hat{\Psi}_{1,j} \dots \hat{\Psi}_{N_m,j}\}_{j=1}^{N_s}$ comprised of N_m modal frequencies $\hat{\omega}_r$ and N_m incomplete mode shape vectors $\hat{\Psi}_r \in \mathbb{R}^{N_0}$, where N_0 is the number of observed DOFs. The model output $q(\theta)$ is the set of corresponding modal properties of the structural model, i.e. eigenfrequencies $\omega_r(\theta)$ and partial eigenvectors $\psi_r(\theta)$, $r = 1, \dots, N_m$, defined by the parameter vector $\theta \in \Theta \in \mathbb{R}^{N_p}$.

The probability model conditional on the parameter vector θ is chosen to have statistical independence between the mode shape vectors and modal frequencies, between the different modes, and between one data set to another. Therefore, the likelihood function can be written as the product of the probability density functions for the modal frequencies and mode shape components:

$$p(\mathcal{D}|\theta, \mathcal{M}) = \prod_{j=1}^{N_s} \prod_{r=1}^{N_m} p(\hat{\omega}_{r,j}^2|\theta, \mathcal{M}) p(\hat{\psi}_{r,j}|\theta, \mathcal{M}), \quad (5)$$

where $p(\hat{\omega}_{r,j}^2|\theta, \mathcal{M})$ and $p(\hat{\psi}_{r,j}|\theta, \mathcal{M})$, $r = 1, \dots, N_m$ and $j = 1, \dots, N_s$, are, respectively, the PDFs for the squared modal frequency and the mode shape vector of the r th mode in the j th

data set.

In the first step, the likelihood function for the mode shape vectors is formulated by rewriting Eq. (3) as

$$\hat{\psi}_{r,j} = a_r \psi_r(\theta) + e_{\psi_r}, \quad (6)$$

where a_r is an optimal scaling factor to relate the scaling of the model mode shape vector $\psi_r(\theta)$ to that of the experimental mode shape vector $\hat{\psi}_{r,j}$, which is assumed to be normalized so that its Euclidean norm $\|\hat{\psi}_{r,j}\| = 1$. Since the latter is usually constituted by an incomplete set of observed DOFs N_0 , the corresponding model mode shape vector is given by $\psi_r = \Gamma \phi_r$, where the matrix Γ picks the observed degrees of freedom from the complete model eigenvector ϕ_r . Using a Gaussian distribution for the probabilistic characterization of the prediction error for the mode shape vector, the likelihood function for the mode shape vector, after some algebraic manipulation, may be written as:

$$p(\hat{\psi}_{r,j}|\theta, \mathcal{M}) = c_1 \exp \left(\frac{\psi_r^T (I - \hat{\psi}_{r,j} \hat{\psi}_{r,j}^T) \psi_r}{2\delta_r^2 \|\psi_r\|^2} \right) \quad (7)$$

$$= c_1 \exp \left(\frac{1}{2\delta_r^2} \left[1 - \frac{|\psi_r^T \hat{\psi}_{r,j}|^2}{(\psi_r^T \psi_r)^2} \right] \right) \quad (8)$$

where I is the identity matrix of dimension N_m and $\delta_r^2 I$ denotes the mode shape prediction error covariance matrix for the r th mode. The equality in Eq. (8) shows that the probability density function for $\hat{\psi}_{r,j}$ involves the MAC (Modal Assurance Criterion) between $\hat{\psi}_{r,j}$ and $\psi_r(\theta)$, the experimental and model partial mode shapes of the r th mode, respectively.

Secondly, Eq. (3) is formulated for the squared modal frequencies, which yields

$$\hat{\omega}_{r,j}^2 = \omega_r^2(\theta) + e_{\omega_r^2}. \quad (9)$$

Using again a Gaussian probability model for the prediction error of the modal frequencies, the likelihood function for the modal frequencies is given by

$$p(\hat{\omega}_{r,j}^2|\theta, \mathcal{M}) = c_2 \exp \left[-\frac{1}{2} \left(\frac{1 - \hat{\omega}_{r,j}^2/\omega_r^2}{\varepsilon_r} \right)^2 \right], \quad (10)$$

where ε_r^2 denotes the variance of the prediction error of the squared r -th eigenfrequency, i.e. of $e_{\omega_r^2}$. Using the probability distributions for the mode shape vectors and modal frequencies given in Eqs. (8) and (10), the likelihood function in Eq. (5) can be written as

$$p(\mathcal{D}|\theta, \mathcal{M}) = c_3 \exp \left(-\frac{1}{2} \sum_{r=1}^{N_m} J_r(\theta) \right), \quad (11)$$

where the modal measure of fit $J_r(\theta)$ is defined by

$$J_r(\theta) = \sum_{j=1}^{N_s} \left[\left(\frac{1 - \hat{\omega}_{r,j}^2/\omega_r^2}{\varepsilon_r} \right)^2 + \left(1 - \frac{|\psi_r^T \hat{\psi}_{r,j}|^2}{(\psi_r^T \psi_r)^2} \right) / \delta_r^2 \right] \quad (12)$$

3 TRANSITIONAL MARKOV CHAIN MONTE CARLO ALGORITHM

The evaluation of Eq. (2) requires the computation of high-dimensional integrals for the determination of the normalizing constant of the posterior PDF, which cannot be tackled analytically or numerically. Recently, efficient stochastic simulation algorithms have been proposed which generate samples of the posterior distribution and which hence identify the parameter regions with the highest posterior probability mass. In this work, the so-called Transitional Markov Chain Monte Carlo (TMCMC) algorithm [14] is applied whose basic steps are discussed in the following.

The main idea of this algorithm is to iteratively proceed from the prior to the posterior distribution. It starts with the generation of samples from the prior PDF in order to populate the space in which also the most probable regions of the posterior distribution lie. Then, some intermediate PDFs are defined, where the shape does not change remarkably from the intermediate PDF $p[j]$ to the next $p[j + 1]$. The small change of the shape makes it possible to efficiently sample according to $p[j + 1]$ if samples according to $p[j]$ have been generated. The intermediate distributions are defined by

$$p[j + 1] \propto p(\mathcal{D}|\theta, \mathcal{M})^{\beta_j} p(\theta|\mathcal{M}), \quad (13)$$

with $j = 0, \dots, m$ as the step index and $0 = \beta_0 < \beta_1 < \dots < \beta_m = 1$. Hence, the exponent β_j can be interpreted as the percentage of the total information provided by the experimental data which is incorporated in the j th iteration of the updating procedure: $\beta_0 = 0$ corresponds to the prior distribution and for $\beta_m = 1$ the samples are generated from the posterior distribution.

Samples of the subsequent intermediate distribution $p[j + 1]$ are obtained by generating Markov chains where the lead samples are selected from the distribution $p[j]$ by computing their probability weights with respect to $p[j + 1]$, which are given by

$$w(\theta_j^{(l)}) = \frac{p(\mathcal{D}|\theta, \mathcal{M})^{\beta_{j+1}} p(\theta|\mathcal{M})}{p(\mathcal{D}|\theta, \mathcal{M})^{\beta_j} p(\theta|\mathcal{M})} = p(\mathcal{D}|\theta, \mathcal{M})^{\beta_{j+1} - \beta_j}, \quad (14)$$

where the upper index $l = 1, \dots, N_j$ denotes the sample number in the j th iteration step. Each sample of the current step is generated using the Metropolis-Hastings algorithm [20, 21]: the starting point of a Markov chain is a sample from the previous step that is selected according to the probability equal to its normalized weight

$$\bar{w}(\theta_j^{(l)}) = \frac{w(\theta_j^{(l)})}{\sum_{l=1}^{N_j} w(\theta_j^{(l)})} \quad (15)$$

and the proposal density for the Metropolis-Hastings algorithm is a Gaussian distribution centered at the preceding sample of the chain and with a covariance matrix Σ_0 which is equal to the scaled version of the estimated covariance matrix of the current intermediate PDF:

$$\Sigma_0 = c^2 \sum_{l=1}^{N_j} \bar{w}(\theta_j^{(l)}) (\theta_j^{(l)} - \bar{\theta}_j)^T (\theta_j^{(l)} - \bar{\theta}_j), \quad (16)$$

where

$$\bar{\theta}_j = \sum_{l=1}^{N_j} \bar{w}(\theta_j^{(l)}) \theta_j^{(l)}. \quad (17)$$

The parameter c is a scaling parameter that is used to control the rejection rate of the Metropolis-Hastings algorithm at each step. These steps are repeated until $\beta_j = 1$ is reached, i.e. until the samples are generated from the posterior distribution.

4 COMPUTATIONAL ASPECTS

4.1 General remarks

Due to the repeated execution of the normal mode analysis of the FE-model, the computational effort of the Bayesian updating method might become infeasible for large FE-models. Hence, in order to reduce the wall clock time, i.e. the time between submitting the updating analysis and its completion, a strategy based on the reduction of the computational efforts associated with the normal mode analysis of the full FE-model is applied in this manuscript. This strategy is based on the use of neural networks for the modal parameters, which will be addressed in the following.

4.2 Neural networks

An Artificial Neural Network (ANN) is a machine-learning algorithm that tries to simulate the structure and functional aspects of biological networks of neurons in order to approximate a relation $f : \theta \rightarrow q$ by a simple mathematical model at low computational efforts. It consists of an interconnected group of computational units, called neurons or nodes, and processes information using consecutively connected layers of neurons. In the following, the most widely used neural network, namely the so-called feed-forward neural network, is discussed (see e.g. [22, 23]). It is composed of a multi-layered structure, with a first layer of nodes, called input layer, one or more intermediate layers, called hidden, and a final output layer. For simplicity, but without loss of generality, the scheme is discussed when using one single hidden layer.

Each layer is characterized by a different number of neurons, indicated by N_{inp} , N_{hid} and N_{out} for the input, hidden and output layers, respectively. Each node of the hidden layer receives as input a linear combination $\sum_{i=1}^{N_{inp}} w_{i,j} \theta_i$ of the input values θ_i of all the nodes of the input layer, scaled by a so-called connection weight $w_{i,j}$, where j denotes the number of the hidden node. Then, the node proceeds this function value through a non-linear function K , which is called activation function and which is of the form $g_j = K(\sum_{i=1}^{N_{inp}} w_{i,j} \theta_i)$. This collection of function values $(g_1, \dots, g_{N_{hid}})$ is then sent to all the nodes of the subsequent, i.e. output, layer, where the approximated model output $\hat{q}_k(\theta) = K(\sum_{j=1}^{N_{hid}} w_{j,k} y_j)$, $k = 1, \dots, N_{out}$ is evaluated. A schematic representation of this algorithm is shown in Fig. 1.

Hence, the connection weights act as parameters of the meta-model which have to be adapted through a calibration procedure of supervised learning, called also training, by means of e.g. the error back-propagation algorithm. In this calibration phase, the network, which is initialized with random weights, is fed with a set of input/output values which is called calibration set and which is obtained from the target physical model. The network processes the inputs and produces then an estimation of the outputs; such outputs are compared with the real outputs through a predefined error measurement (typically, a sum of the squared errors of each output). The training consists thus of an optimization problem which aims to minimize the error of the network in the output prediction. Such optimization is carried out by computing the gradient of the error with respect to the connection weights, and it is interrupted when a target error is reached or when a certain number of input/output pairs have been processed.

An important indicator of the goodness of the network after training is the coefficient of

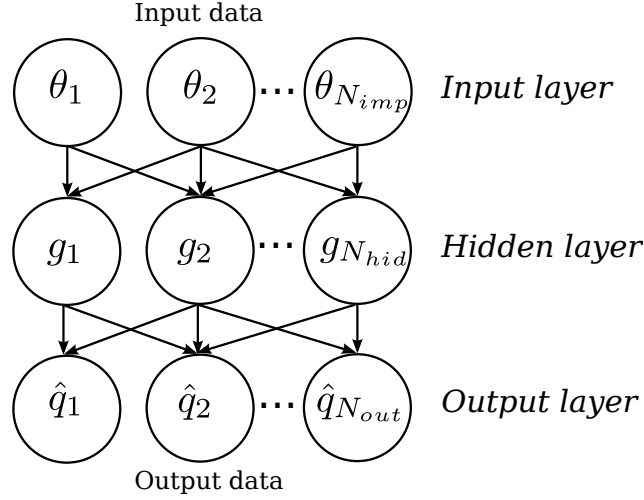

Figure 1: Schematic representation of the concept of neural networks

determination R^2 , defined as

$$R^2 = 1 - \frac{\sum_{i=1}^{N_{data}} (q_i - \hat{q}_i)^2}{\sum_{i=1}^{N_{data}} (q_i - \bar{q}_i)^2} \quad (18)$$

where q_i are the real outputs of the physical model, $\bar{q}_i = \frac{1}{N_{data}} \sum_{i=1}^{N_{data}} q_i$ and \hat{q}_i are the output values predicted by the meta-model. The accuracy of the output prediction of the neural network can be judged by the closeness of the value R^2 to the target value of 1.0, which expresses an exact match of the network prediction and the output of the full model. This quantity is computed both using the calibration set and a new set of input/output values, called validation or verification set. In the latter case, a qualitative indication of the generalization capabilities of the network is obtained.

The freely available Fast Artificial Neural Network (FANN) library [24], which is an implementation of the here discussed Neural Network and learning algorithm, has been used for the approximation of the modal properties in the following numerical example.

5 NUMERICAL EXAMPLE: GOCE SATELLITE

5.1 Problem statement

The use of a meta-model within the Bayesian updating procedure is illustrated using the Gravity Field and Steady-State Ocean Circulation Explorer (GOCE) satellite. The mission of the GOCE satellite is to determine the geoid and to measure the gravitational field of Earth with a very high degree of accuracy in a low Earth orbit. The particularities of the GOCE are its arrow-shape with winglets and its ion propulsion engine, used to compensate the air-drag induced orbit-decay. The total length of the satellite is 5.3 m, and the mass amounts to approximately 1,000 kg including the fuel of the propulsion system.

Figure 2: FE model of the GOCE satellite (courtesy of Thales Alenia Space Italy)

Fig. 2 shows the FE model of the satellite, provided by Thales Alenia Space (Italy) for use within the commercial FE code MSC.Nastran [25]. Approximately 360,000 DOFs and 74,000 elements compose the FE model, with half of the elements used in the main satellite platform and half in the gravitational gradiometer.

In the main GOCE platform, quadrilateral (QUAD4) and triangular (TRIA3) shell elements are used to model the body panels, the wings and the winglets, the internal floors and the solar panels. Beam elements (BAR, ROD and BEAM) constitute the connections of the wings to the main structure and of the instrumentation to the floors. Solid elements (HEXA and PENTA) are used in the Launch Vehicle Adapter (LVA) ring, and scalar spring elements (CELAS2) represent the connection between the solar panels and the structure, as well as the fixing of the wing to the main octagonal body.

A total number of 18 groups combining 3047 structural parameters are defined according to the type and location of the respective materials or geometric specifications (see Tab. 1). This grouping is carried out with the purpose of remarkably reducing the number of parameters to be used within the Bayesian updating procedure since an independent processing of all involved parameters might become infeasible. Hence, the updating procedure is carried out with the goal of identifying as to which changes have to be performed to the single parameter groups in order to obtain a better agreement of the numerical model with the real satellite structure.

5.2 Experimental modal data

The experimental data used for model updating consists of $N_s = 1$ set of 7 modal frequencies and partial mode shapes vectors (83 components) which have been determined from the vibration responses during the GOCE structural model qualification test. The dynamic qualification test was performed on the multi-axis vibration test facility of ESA/ESTEC in Noordwijk (The Netherlands). The correlation of the experimental and computed eigenvectors of the initial model is shown by means of the MAC matrix in Fig. 3 and the initial comparison of the eigenfrequencies can be found in Tab. 2. The large discrepancies, especially for the first two modes,

Table 2: Comparison of the analytical eigenfrequencies f_a and the experimental data f_e

5.3 Accuracy analysis of the neural network

A set of $N_{data} = 2,000$ finite element simulations have been performed using Gaussian distributions with the mean values equal to the nominal values and coefficients of variation of 10%. Out of these samples, 1,900 have been dedicated to calibrate the neural networks, and 100 have been kept to verify the generalization capabilities of the networks after training. Each of the 14 neural networks, constituted by $N_{inp} = 18$ inputs and $N_{out} = 1$ output, predicts either one of the eigenfrequencies or one of the diagonal terms of the MAC matrix.

An automated training procedure has been implemented such that various network topologies are tested and the best networks, characterized by the highest R^2 value (see Eq. (18)) obtained with the verification data, are kept. As an indication of the accuracy of the network, Fig. 4 shows the regression plots for the neural network of the first eigenfrequency, using the calibration and verification data, respectively. Moreover, the values of R^2 of all the networks obtained with the verification data are listed in Tab. 3.

5.4 Bayesian model updating

The prior distributions assigned to the 18 groups of parameters to be updated are all Gaussian with the moments as specified for the calibration of the neural networks. For these ranges, the

Table 3: R^2 values of the 14 neural networks

neural networks of the considered modal properties show high accuracy as discussed in the previous section and are therefore applied for substituting the full FE-analysis when evaluating the likelihood function within the updating process.

The results of the updating procedure are shown exemplarily for three parameter groups, namely the thickness, the Young's moduli of the orthotropic materials and the group of stiffnesses of joints between the wings and the main structure (groups no. 10, 3 and 14 in Tab. 1). The prior and posterior histograms of these parameters, which are all transformed in standard normal space, are depicted in Figs. 5-7. This representation in standard normal space is advantageous due to the fact that these figures do not show one single parameter each but a parameter group, where the members of each group may have different initial values. Hence, in order to obtain the posterior values in physical space, a back-transformation has to be performed for each parameter of a group, which is achieved by

$$\theta_i = \theta_i^* \sigma_i + \theta_{i,\text{nom}}, \quad (19)$$

where θ_i denotes the i -th parameter in the physical space, θ_i^* the value in the standard normal space, σ_i the prior standard deviation and $\theta_{i,\text{nom}}$ the prior (nominal) mean of this parameter.

In Fig. 5, the prior and posterior histograms of the thickness of shell elements are depicted. This figure leads to the conclusion that the information contained in the experimental data suggests a decrease of these values. A reduction of approximately 10% of the mean value of the prior distribution leads to a better fit with the experimental modal properties. Also for the Young's modulus of the orthotropic material in the longitudinal direction (material card MAT8 in the MCS.Nastran input file), the updating process suggests a decrease of the mean values (see Fig. 6). As opposed to these two parameter groups, all other 16 out of 18 parameter groups used in the updating process show small changes if compared to the prior distribution. As an example, the stiffness values of the joints of the main structure to the wings (used for the specification of the CELAS2 elements in the MCS.Nastran input file) is shown in Fig. 7. Due to the information extracted from the experimental values, the prior uncertainty about these parameters could be reduced which is visible through the smaller variation of the posterior distribution.

The effect of the choice of the prior on the posterior distribution has not been investigated in this example, however a few remarks will be added in this context: in general, the influence

Figure 5: Histograms of the prior and posterior samples of the group of thicknesses (group no. 10 in Tab. 1)

of the prior distribution on the results decreases with increasing amount of experimental data. This is due to the fact that the likelihood function becomes the dominant term in comparison to the prior distribution in Eq. (2). In this case, also values in the tails of the prior distribution can be identified and only values with zero probability (e.g. values out of the interval of uniform distributions) cannot be reached since they are excluded from the possible solution space due to the prior knowledge. In case of limited data the selection of the prior distribution clearly has an influence on the results. The prior distribution can therefore be seen as a means to incorporate initial knowledge about parameter ranges into the identification process and it is subjective in the sense that people with different experience may use different priors leading to broader ranges of the solution in case smaller amount of prior information is available. The selection can therefore be seen as part of the modeling process since also the model itself is affected by a certain amount of subjectivity of the designer. However, the probability content of the prior PDF is updated by the data and if one felt uncomfortable with the choice of the prior distribution the effect of different prior PDFs on the posterior PDF can be studied.

5.5 Effect on the correlation of modal data

The effect of the updating procedure on the correlation of the experimental and computed modal properties is shown exemplarily for the two lowest and highest considered modes. Figs. 8-11 are devoted to the eigenfrequencies and Fig. 12 to the corresponding diagonal MAC-values. The figures show that a successful shift of the PDFs towards the experimental values could be achieved, as it can be seen for modes 1, 2 and 7, where it shall be annotated that the correlation of the eigenvector no. 7 with respect to the corresponding experimental data reveals to be high already for the initial model (initial $MAC_{7,7}=0.92$).

However, for the 6th eigenfrequency and eigenvector no improvement could be achieved. The reasons might lie in the fact that there is no parameter combination possible which affects an improvement of the fit with respect to all 14 target values defined by the first 7 modal frequencies and mode shape vectors. Only a revision of the model itself might lead to the situation where the

Figure 6: Histograms of the prior and posterior samples of the group of Young's moduli of the orthotropic materials (group no. 3 in Tab. 1)

Figure 7: Histograms of the prior and posterior samples of the group of stiffnesses of the joints between wings and main structure (group no. 14 in Tab. 1)

Figure 8: Prior (dashed-dotted line) and posterior (shaded bars) histograms of the 1st eigenfrequency with experimental value (solid line) and nominal value (dashed line)

prior distributions span the full solution space, meaning that posterior samples provoke a high correlation with all targets. As opposed to the first numerical example, where a perturbed model is used for the generation of the target modal data, the present example uses real experimental data and hence a fit with respect to all targets might not be possible without revising the FE-model itself.

5.6 Computational aspects

In the first example, the most time-consuming task of the updating algorithm, namely the parts involving eigensolutions, have been parallelized. In the present example, the eigensolution of the full FE-model is replaced by an approximate relation at low computational costs which is given by a neural network for each modal property. If considering that on the above described dual quad-core Xeon server *i)* the replacement of the nominal parameter values θ_{nom} by the current value θ in the FE-input file, the normal mode analysis of the full model performed with MSC.Nastran and the import of the modal quantities into Matlab [26] requires 220 sec (see Appendix A for details on the interaction of Matlab with MSC.Nastran), *ii)* the updating process of the present model involves approximately 32 iterations \times 2,000 eigensolutions and *iii)* the remaining part of the updating process lasts for about 96 min, then the total time amounts up to a theoretical value of

$$t_{\text{full}} = 64,000 \cdot 220 \text{ sec} + 96 \cdot 60 \text{ sec} \approx 160 \text{ days}.$$

In the present example, the computational time of 220 sec of a normal mode analysis of the full FE-model is replaced by the evaluation of the neural networks which takes 0.0014 sec. Hence, in this way the analysis time can be remarkably reduced to

$$t_{\text{NN}} = 64,000 \cdot 0.0014 \text{ sec} + 96 \cdot 60 \text{ sec} \approx 100 \text{ min}.$$

However, it shall be noted that in addition 2,000 calibration samples have been generated (see Sec. 5.3), which require evaluations of the full FE-model lasting for a total time of approx-

imately 5 days if performed sequentially (see Appendix A for the interaction with 3rd party software).

6 CONCLUSIONS

In this manuscript, the basic steps of model updating within the Bayesian framework using modal data have been summarized and strategies for reducing the analysis time are proposed. The numerical example shows the applicability of the Bayesian updating procedure on complex aerospace structures. It demonstrates that ill-conditioned inverse problems in the high-dimensional parameter space can be tackled and that the limited, incomplete data can be used for reducing the initial uncertainty about the adjustable parameters. As a remedy for the large computational efforts of model updating the establishment of a surrogate model has been proposed which approximates the modal properties at a low computational cost. In this way, model updating of a finite element model of a full satellite structure of a size of approximately 360,000 DOFs becomes feasible as shown in the numerical example.

ACKNOWLEDGEMENTS

This research was partially supported by the European Space Agency (ESA) under Contract No. 20829/07/NL/EM, which is gratefully acknowledged by the authors. The authors thank Thales Alenia Space Italy for the FE-model of the GOCE satellite and the experimental modal data. The first author is a recipient of a DOC-forte-fellowship of the Austrian Academy of Science at the Institute of Engineering Mechanics (University of Innsbruck).

A INTERACTION WITH 3RD PARTY SOFTWARE

FE models are defined uniquely by one or more ASCII input files. These files contain the definition of the nodes and elements constituting the model, as well as the structural parameters and boundary and loading conditions in form of fixed numerical values. However, in a stochastic analysis some of these values change, since they are samples from a given probability distribution function. Thus, it is envisioned to automatically manipulate the input files such that in each simulation the respective sample values are inserted into the FE-input file. For this purpose, XML-like tags, called identifiers, are inserted into the master input files in order to define the parameters which have to be changed in each simulation, as shown in Fig. 13. An identifier defines the name of the random variable used within the stochastic analysis, the format in which the number is written into the file as well as the original value of the parameter.

```

```

Figure 13: Excerpt of a master input file with identifiers

The code used to drive the simulation is COSSAN-X, a software for computational stochastic structural analysis [27]. This code parses the master input files in order to identify the positions and the insertion formats of all variables. In each analysis, these identifiers are replaced by sampled numerical values, obtaining a valid input file which is then used for the finite element analysis (see Fig. 14). It shall be noted that this software is not restricted to a particular FE-code, but it is applicable to any FE-solver which uses ASCII input files.

Abstract. *The DYNAMITED project realised by a European space industry and university team associated around EADS ASTRIUM and funded by the European Space Agency (ESA) aimed to assess and improve dynamic test data. In the field of post test activities, the detection, characterisation, identification and prediction of the non-linear behaviour of space structures during tests is of prime importance. The paper therefore starts with a short overview of such methods. Present evaluation methods for spacecraft vibration tests are based on the assumption of linear structural behaviour. The resonance shifts and frequency response (FRF) peak variations observed in the case of non-linear structural behaviour are generally not reflected in practice by non-linear evaluation procedures. In order to avoid overloading of the structure during the qualification test on a shaking table the dynamic response is generally controlled at specified levels and locations by input notching. This approach generates an effectively quasi linear structural behaviour at the different input levels which enables the utilization of classical linear modal extraction tools to be applied separately at each level. However, the measured dynamic responses (transmissibilities) reveal peak shifts and amplitude changes depending on the input level of the base excitation. In the paper an approach is presented where three different input levels are used with the response levels controlled to be constant within a narrow frequency band around the dominant resonances. The premises of a technique will be described and how its aim of predicting the responses to not measured input*

levels is achieved by applying interpolation and extrapolation techniques to the modal data extracted by conventional modal analysis from the transmissibilities measured at three different input levels. Results are presented from an application of the technique to the vibration test data measured during a typical qualification test campaign of a satellite structure.

1 INTRODUCTION

In space industry present experimental vibration test evaluation methods are generally based on the assumption of linear structural behaviour. Test procedures to check the linearity assumption are described in the European Space Agency (ESA) standard on modal survey assessment (ECSS-E-ST-32-11C see www.ecss.nl for details) and are applied for base driven tests on the shaking table (an application is shown in Figure 1) as well as in modal survey testing. The resonance shifts and FRF peak variations observed in the case of non-linear structural behaviour are generally not reflected in practice by non-linear analytical modelling. Instead, equivalent linear modelling adapted to a specified load level is used.

This approach can be tolerated since experience shows that in many practical cases the non-linear structural behaviour is not too strong so that the experimental modal data still lie within the natural scatter generated by other sources of test data variability like fabrication tolerances, multiple assembly or test reproducibility.

When evaluating test data obtained from spacecraft (S/C) qualification testing on a shaking table it is an important goal to characterise the non-linear behaviour of the structure with respect to its magnitude (weak or strong) to enable a decision if equivalent linear modelling is applicable or not. Examples of techniques for detection, characterisation and identification of structural non-linearities are described in this paper.

Since existing codes for experimental modal analysis (EMA) rely on the linearity assumption, the scatter of the modal identification results when applying such codes to non-linear vibration test data will be particularly high. It was therefore one of the goals of a research project realized by a consortium of European space industry and universities associated around EADS ASTRIUM and funded by the European Space Agency (ESA) to identify non-linear modal parameters in addition to the traditional modal parameters related to the underlying linear system. The method that was developed and presented in this paper is fully based on experimental data and does not need an analytical model of the structure. In addition, the method was required to be compatible with the test procedures typically applied in vibration testing of spacecraft structures. This means, it is based on transmissibilities of at least three different input levels. Other test data is not required for the method.

2 DETECTION OF NON-LINEAR RESPONSE PROPERTIES

A large number of methods are described in the literature directed towards detection and quantification of structural non-linearities (e.g. refs. [1] – [6]). Examples of the most promising and practically relevant methods will be presented here. A first classification of the available methods is based on the type of data to be used by these methods. Methods for characterizing non-linear structural behaviour may be based on:

- combined analytical/experimental data
- experimental frequency-domain response data
- experimental time-domain response data
- dedicated excitation signals

2.1 Methods based on Combined Analytical/Experimental Data

The methods described in this subchapter are based on the idea to compare measured characteristic non-linear response features with a catalogue of basic analytical formulations. The response features to be used can either be frequency domain response data measured at different excitation force levels, such as frequency response functions and transmissibilities, or modal features measured at different excitation force levels, such as eigenfrequencies and damping ratios.

(a) Distortions of frequency response functions calculated by harmonic balancing

A simple approach for the detection and characterization of non-linearities is the comparison of FRFs measured at different levels of constant harmonic excitation force with analytical solutions. The different FRF distortion characteristics shall be discussed in the following on a single degree of freedom oscillator with a non-linear equation of motion in the frequency domain:

$$\left(-\Omega^2 m + j\Omega c_{eq}(\hat{u}) + k_{eq}(\hat{u})\right)\hat{u} = \hat{f} \quad (1)$$

where m denotes the mass, c_{eq} and k_{eq} the equivalent damping and stiffness which depends on the vibration amplitude \hat{u} . Ω is the excitation frequency and \hat{f} the excitation force.

Analytical representations for c_{eq} and k_{eq} are typically calculated by the harmonic balance method and have been derived for many types of non-linearities (see e.g. refs. [1] and [7]) such as

- pre-loaded bilinear spring (e.g. gapping of bolted flanges),
- clearance type non-linearity and piecewise linear springs, (e.g. structures assembled with joints that have freeplay),
- cubic spring and other polynomial type stiffness non-linearities, (e.g. non-linear elastomer springs and geometric non-linearities due to large displacements),
- quadratic damper (e.g. polynomial type damping non-linearity such as vibration absorbers with elastomer material),

- elasto-slip friction non-linearity such as the 3-parameter Masing model (e.g. structures with loosely assembled bolted joints and rivet joints) or
- combined stiffness and damping non-linearities (e.g. combinations of the aforementioned types of non-linearities).

The equivalent non-linear stiffness of a pre-loaded bilinear spring is characterised by the stiffness parameters k_1 and k_2 and the transition parameter u_c shown in Figure 2(a). These parameters can be calculated by the harmonic balance method (e.g. [7]) resulting in

$$k_{eq}(\hat{u}) = \begin{cases} k_1, & \forall \hat{u} \leq u_c \\ k_1 + \frac{k_2 - k_1}{2\pi} \left(\pi - 2\alpha + \sin \left(2\alpha - \frac{4u_c}{\hat{u}} \cos \alpha \right) \right), & \forall \hat{u} > u_c \end{cases} \quad (2)$$

with $\sin \alpha = \frac{u_c}{\hat{u}}$.

Figure 2: Force-displacement diagram and equivalent stiffness of a pre-loaded bilinear spring

The evolution of the equivalent stiffness k_{eq} according to equation (2) is shown in Figure 2(b) for a particular single- DOF example. It can be observed that k_{eq} equals the underlying linear stiffness k_1 until the displacement amplitude \hat{u} exceeds the stiffness transition point u_c . After exceeding the stiffness transition point the equivalent non-linear stiffness changes dramatically from its underlying linear value and finally converges towards the average stiffness $\frac{1}{2}(k_1 + k_2)$ for very large displacement amplitudes. The complex response calculated by iteratively solving equation (1) with the amplitude dependent equivalent non-linear spring according to equation (2) exhibits characteristic distortions of the frequency response function (FRF), $h = \hat{u} / \hat{f}$. Analytical FRFs of the non-linear single-DOF oscillator with pre-loaded bilinear spring simulated by using different constant excitation force levels are shown in Figure 3. It can be seen that for low excitation force levels (and hence low vibration amplitudes) the non-linear FRF does not deviate much from the linear one. In fact, the system remains linear as long as the vibration amplitudes remain smaller than the stiffness transition point. The FRF distortions increase with increasing vibration amplitudes. The resonance frequency shift de-

creases at large vibration levels which can be explained by the convergence behaviour of the equivalent non-linear stiffness:

$$\omega_{eq}(\hat{u}) = \sqrt{\frac{k_{eq}(\hat{u})}{m}} \quad (3)$$

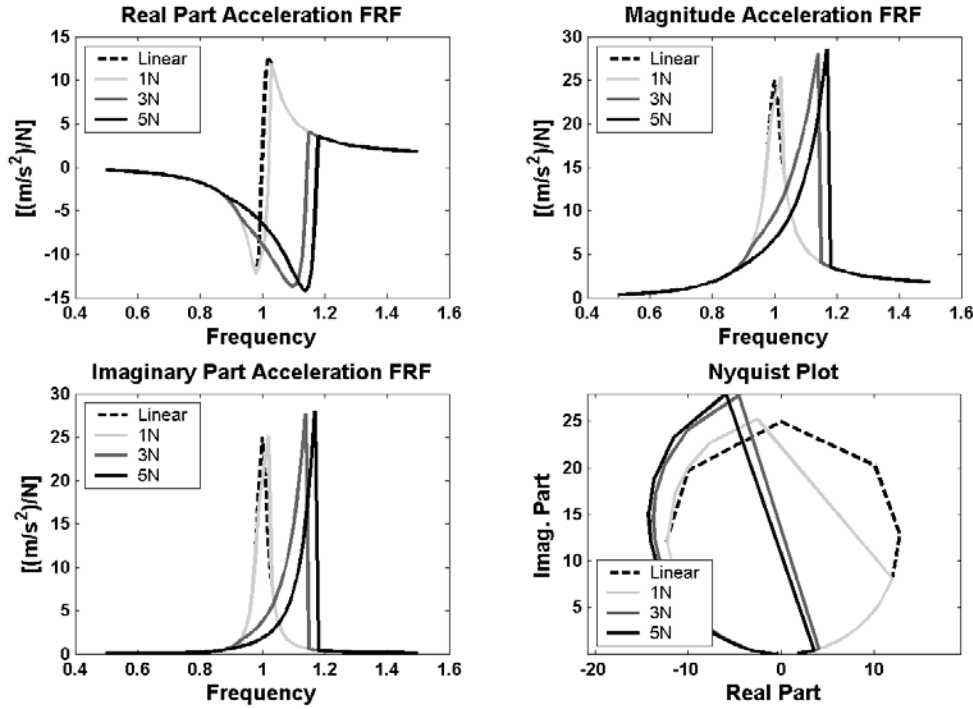

Figure 3: FRF distortion caused by pre-loaded bilinear spring (upper stable response branch only)

It should be noted that the equivalent non-linear stiffness of the bilinear spring without pre-load is independent from the response amplitude and equals the average stiffness $\frac{1}{2}(k_1 + k_2)$. Even though the force-displacement curve of the pure bilinear spring is definitely non-linear, it would not cause distortions to the fundamental harmonic FRF. Thus, the bilinear spring without pre-load cannot be analyzed with the (single-) harmonic balance method.

The comparison of analytical non-linear FRFs like those of Figure 3 with experimental FRFs represents a useful tool for characterizing the type of non-linearity, especially when analytical non-linear FRFs are available for a set of oscillators with practical types of non-linearities. For the computation of non-linear FRFs, the response amplitude dependent equivalent stiffness and damping formulations for many different types of non-linearities like those mentioned above can be found in textbooks, e.g. refs. [1] and [8] and other publications, e.g. [7], and [9] – [12].

(b) Industrial Example: Aero engine at large response amplitudes

Within the EU research project CERES (refs. [6], [13]), a subassembly of an aircraft engine has been tested at different constant harmonic excitation force levels using stepped sine excitation. The force levels were sufficiently high to drive the structure into the non-linear regime. Figure 4 shows the experimental set-up. The Finite Element model is shown in Figure 5 together with the global bending mode exhibiting the strongest non-linear behaviour. In this case, the bolted flange joint between the component IMC and the component CCOC was as-

sumed to be the source of non-linear behaviour. This bolted flange joint interface is highly loaded when the global bending mode contributes to high response levels. Other bolted flange joints were loaded much less and are therefore not assumed to cause significant non-linear behaviour.

Figure 4: Aero-engine subassembly supported by bungee cords with a shaker attached¹

Figure 5: FE model, Pick-up locations (a) and bending mode (b) of an aero-engine subassembly

From the measured non-linear driving point FRFs in Figure 6(a) it can be observed that the resonance shifts towards lower frequencies with increasing excitation force level. In addition, the peak response is increasing indicating a reduction of damping with respect to the load level. When comparing the measured non-linear FRFs with analytical FRFs of different types of non-linearity one could conclude that the most appropriate type would be the assumption of a pre-loaded (softening) bilinear spring and a quadratic damper, see restoring force diagrams

¹ Photo of test set up at MTU, Munich, and Imperial College, London, UK

in Figure 7. A number of such non-linear elements were introduced into the FE model between the components IMC and CCOC.

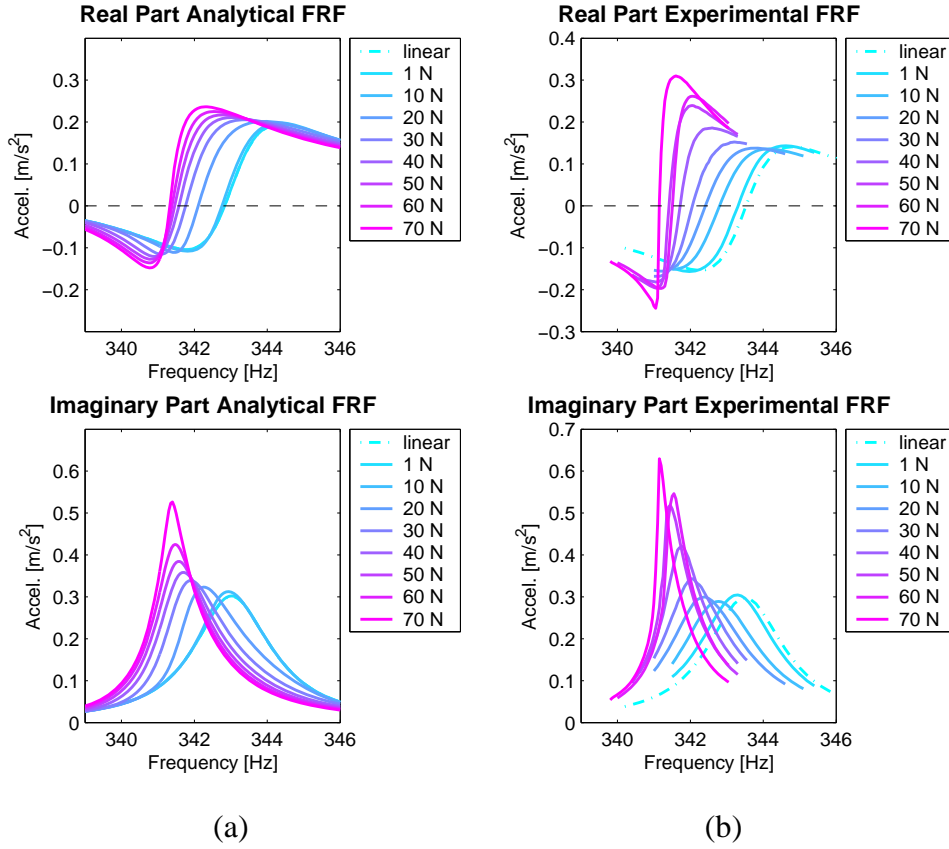

Figure 6: Comparison of analytical (a) and experimental (b) non-linear FRFs

Figure 7: Restoring force functions of non-linear elements used to model the joint non-linearity

From the comparison of the analytical results in Figure 6(b) obtained from computational updating of the non-linear flange joint parameters k_1 , k_2 , u_c and c_{nl} with the experimental results in Figure 6(a) one may conclude that the characteristics and the magnitude of the analytical response is well reflected. See ref. [6] for details of the procedure for numerical parameter updating.

2.2 Methods Based on Experimental Frequency-Domain Response Data

One way to characterise the non-linear behaviour of a structure is the application of different kinds of signal processing and visualisation tools to the measured frequency response functions. The comparison of the processed data to a certain reference indicates possible deviations from linear behaviour. Most of the techniques, however, only provide the possibility for detection but not for quantification of non-linear behaviour.

The following methods are widely used for non-linearity detection

- Overlay of FRF plots
- Frequency isochrones in Nyquist plots
- Hilbert transformation of measured FRFs
- Inverse FRF plots
- Carpet plots of modal damping
- Analysis of coherence functions

Many examples are reported in the literature for the application of these techniques, e.g. refs. [2], [4] and [14]. The most simple and most appropriate for practical industrial applications is the analysis of experimental FRF plots measured under different load levels. Such plots are shown in Figures 15 and 19 for the transmissibility test data² obtained from shaking table testing of the SWARM satellite. The non-linear behaviour is clearly detected from the peak shifts and the amplitude variations depending on the magnitude of load levels.

In a Nyquist plot the imaginary parts of the FRF are plotted versus the real parts at each measured frequency point. Linear responses appear as (almost) circular curves in the Nyquist plot, whereas non-linearities cause distortions from the circular shape.

When the frequency responses (forced response, not FRF) obtained at different levels of excitation are overlaid in a single Nyquist plot, then the deviation of the frequency isochrones (lines connecting points of equal frequency among a set of different response curves) from straight lines indicate the presence of non-linearity, ref.[11]. This can be observed in Figure 8 where the Nyquist plots with frequency isochrones of a linear and a non-linear system are shown. Examples for the other methods mentioned above are described in refs. [1], [2] and [14].

Figure 8: Nyquist plots with frequency isochrones of linear and non-linear system

² the transmissibility is calculated from the response divided by the table acceleration which is equivalent to the FRF where the response is divided by the excitation force

2.3 Methods Based on Experimental Time-Domain Response Data

Time domain methods for the detection and characterization of non-linearities have significant advantages over frequency-domain methods. The most obvious point is the typical low sampling rate when acquiring frequency domain data. Usually, Shannon's Theorem is applied, which states that at least two data samples per period of vibration must be acquired to avoid error in subsequent Fourier transformation. It is known, however, that non-linear effects can cause higher harmonic responses. These higher harmonic responses can easily be measured in the time domain by using a sampling rate which can be set 5 or even 10 times higher than for typical FRF measurements. Thus, more information is available from high frequency responses and this can be used to characterize or even identify the non-linearities.

An accepted time-domain approach for the characterization of non-linearities is the *restoring force surface method* according to [15], which has later been published as force-state mapping according to [16].

The restoring force methods are based on the non-linear equation of motion of a single degree of freedom system:

$$m\ddot{u}(t) + \underbrace{d(\dot{u})\dot{u}(t) + k(u)u(t)}_{f_R(u,\dot{u},t)} = f(t) \rightarrow m\ddot{u}(t) + f_R(u,\dot{u},t) = f(t) \quad (4)$$

$$\rightarrow f_R(u,\dot{u},t) = f(t) - m\ddot{u}(t) \quad (5)$$

Here, m is the mass of the system, $\ddot{u}(t)$ is the acceleration response, $f(t)$ is the time history of the excitation force. If these quantities are known by measurements, the restoring force $f_R(u,\dot{u},t)$ can be calculated as a function of time. It is obvious from the above equations, that in case of a linear system, the restoring force is a linear function of displacement $u(t)$ and also a linear function of velocity $\dot{u}(t)$:

$$f_R(u,\dot{u},t) = k u(t) + d \dot{u}(t) \quad (6)$$

If displacement and velocity response are also available, e.g. from measurements or from numerical integration of the measured acceleration response, the restoring force can be plotted as a 3D surface over displacement and velocity. In case of a linear system, the restoring force surface is a planar flat surface. The slope of the surface in the displacement direction (i.e. sections of constant velocity but variable displacement) equals the stiffness k . On the other hand, the damping d is the slope of the restoring force surface in the direction of velocity (i.e. sections of constant displacement but variable velocity).

If velocity and displacement response are not available from measurements, they can be derived numerically by integrating the measured acceleration response. Digital filtering and/or offset removal is necessary in this case because otherwise numerical integration can lead to unsatisfactory results.

The utilization of dedicated excitation signals can also be applied for experimental analysis of non-linear structures. For example, when using sinusoidal excitation, the acceleration response of a non-linear system will be periodic (fundamental harmonic plus a number of

higher harmonics). It would be possible to curve-fit the response and to integrate each harmonic individually. This can be done most effectively in the frequency domain.

The three-dimensional restoring force surface produced by the restoring force surface method can be used not only to characterize the type of stiffness and damping non-linearity. By curve-fitting of the 3D surface using a reasonable model for the type of non-linearity, it is possible to identify the coefficients of the non-linear model used. By proceeding this way, a mathematical description for the observed non-linearity can be obtained which is a valuable feedback information for finite element modelling. Based on the identified mathematical model of the non-linearity, it can be assessed up to which response levels an equivalent linear model is sufficient, or respectively, if the non-linearity must be included in the FE model to improve the prediction capabilities in the large response amplitude regime.

As can be seen from equation (6), the restoring force is indeed only a function of the status of the system defined by displacement and velocity. Individual response points of velocity and displacement at each time step will form a repeatable surface provided that the damping non-linearity is not too severe with strong hysteresis character. If this is not the case, the nature and shape of the surface will be independent of the time history of the applied force. This, however, requires that a sufficiently large number of independent states are included in the test data for the generation of the restoring force surface. For example, if a pure sinusoidal signal of constant amplitude is used for excitation, only one ellipse in the displacement/velocity plane is generated. This is obviously not enough to generate the complete restoring force surface. In [16] a pure sine excitation with continuously increasing amplitude is used to generate the restoring force surface. In [15], Chebyshev polynomials are used to extrapolate the restoring force surface to unmeasured state points.

If the non-linear restoring force is not only a function of the status of the system, i.e. if hysteresis effects are present in the dynamics of the system under consideration (e.g. systems with elasto-slip type friction non-linearities), the interpretation of the restoring force surface might not be obvious and the method may even fail to produce a repeatable 3D surface.

The simulated response signals of a non-linear single degree of freedom system with a cubic hardening spring were analyzed as an example. Due to the relatively low number of independent states (i.e. independent combinations of displacement and velocity response) in case of sinusoidal excitation, the restoring force surface is not well populated (see Figure 10) even though the harmonic amplitude has been increased linearly. In contrast to sinusoidal excitation, random excitation provides a huge number of independent displacement/velocity combinations. Consequently, a well populated restoring force surface can be generated (see Figure 9). It must be stated, however, that this is a rather academic statement, because in case of random excitation, the excitation energy is distributed over a broad frequency range so that very high force RMS values would be required to reach the same response levels compared to harmonic excitation. This can be difficult to achieve with standard laboratory equipment.

In the case of multi- DOF systems selected single modes have to be excited by appropriated exciter configurations since the restoring force method is a single- DOF technique. This allows for applying the restoring force method on a single non-linear modal equation of motion. It should be noted that broadband random excitation is not suited for force appropriation. Extensions of the restoring force method to multi DOF systems were developed by Dimitriadis [17], Wright [18] and Göge [19].

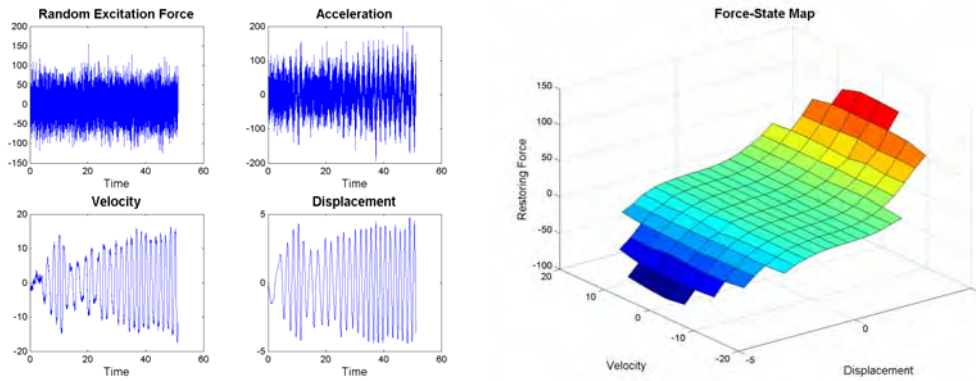

Figure 9: Restoring force surface generated from high level random excitation

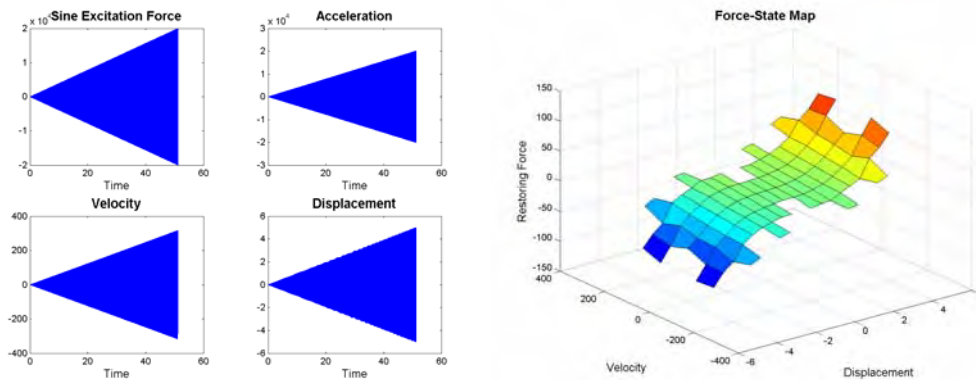

Figure 10: Restoring force surface generated from sinusoidal excitation with increasing force amplitude

2.4 Methods Based on Dedicated Excitation Signals

One of the best ways of dealing with non-linearities in practical structures is to control the vibration levels during the measurements. For example, Figure 11(a) shows the frequency response functions (i.e. upper branch of non-linear FRF) of an analytical single-DOF system with a cubic stiffness non-linearity calculated under harmonic excitation force with different constant excitation force amplitudes. It can be seen that the distortion of the FRFs is increasing with increasing force level. As a result, problems can be expected when applying classical (linear) experimental modal analysis to such deformed FRFs. The modal parameters extracted this way will suffer from inaccuracy, especially for the damping and the modal mass due to the distortion of the response curve. Non-linear distortion characteristics of FRFs may lead to additional (artificial) eigenvalues that are difficult to distinguish from true eigenvalues of the system analyzed, see ref. [22]. However, the analysis of FRF distortions can be used for the characterization of the non-linearity, e.g. by comparison with analytical non-linear FRFs of different types of non-linearities as discussed before. Keeping the excitation force level constant would mean to increase the level of the drive signal of the electro-dynamic shaker when approaching resonance. This involves an unavoidable risk of damaging the structure in the test, especially in case of lightly damped structures and powerful shakers.

Figure 11(b) shows the calculated FRFs of the same non-linear system now keeping the response amplitude constant. The legend in Figure 11(b) shows the levels of the constant displacement responses of the different simulations. In contrast to Figure 11(a) it can be seen that the excitation force was changed in order to maintain constant response level. By proceeding this way the non-linearity was also kept constant and thus each FRF in Figure 11(b) reflects a

linear characteristics (not distorted) with slightly different underlying linear stiffness (in contrast to Figure 11(a) where all FRFs exhibit non-linear distortions). This approach generates an effectively quasi linear structural behaviour around the main resonances at the different input levels which enables the utilization of classical linear modal extraction tools to be applied separately at each response level. However, the measured dynamic responses (transmissibilities) reveal peak shifts and amplitude changes depending on the input level of the base excitation which can be utilized to describe the non-linear behaviour.

Another advantage of constant response level testing is that the structure under test can be prevented from being damaged. This requires that the response levels to be investigated have to be defined carefully. It should be mentioned that constant response amplitude levels can only be realized in a narrow frequency band around the resonance of an isolated non-linear mode that is investigated in detail. If broad frequency ranges are considered, many modes may contribute to the response of a structure so that constant response amplitudes can only be realized at a single response DOF. In industrial qualification procedures for spacecraft testing it is common practice to apply input notching in order to avoid overloading of the structure during the qualification test on a shaking table which requires the control of the dynamic response at specified levels and locations. In this case the table acceleration levels are reduced in the range of the main resonances such that the response of the structure at selected locations does not exceed a specified limit. It could therefore be expected that the responses and load levels around the notching ranges would exhibit similar characteristics like that of Figure 11(b).

This behaviour has been investigated at a typical example taken from a STM satellite structure (Structural Test Model) test campaign. The measured sinusoidal shaking table accelerations (input) for three different load levels are shown in Figure 13. The absolute response amplitudes of the 17 largest DOFs around resonance shown in Figure 14 confirm that the goal of constant output control was fulfilled satisfactorily. The corresponding transmissibilities obtained from dividing the responses by the table accelerations are shown in Figure 15. The similarity of the curves in Figures 13 and 15 with the curves in Figures 11(b) for the analytical example is obvious. It can be observed that like in Figure 11(b) the transmissibilities in Figure 15 do not exhibit significant distortions so that the utilization of classical linear modal extraction tools may be applied separately for each input level.

3 INTERPOLATION METHOD

In the following a technique is described that is aimed at predicting the responses to *other than the measured* input levels which is achieved by applying interpolation and extrapolation techniques to the modal data extracted from the transmissibilities measured at three measured input levels, i.e. the experimental data base is formed by *three sets* of natural frequencies, mode shapes, modal damping values and modal masses related to each load level. The response prediction at unmeasured load levels is subsequently performed by standard modal synthesis using the inter- or extrapolated modal data.

At least three load levels have to be used for identifying equivalent linear modal data with classical EMA (Experimental Modal Analysis) techniques. This interpolation forms the basis of the ISSPA_NL code which is described in the following. The interpolation starts from classical linear modal analysis data extracted by any existing EMA code (the in-house code ISSPA has been used, ref. [20]) from experimental frequency response functions (FRF) measured at three load levels. Figure 12 shows the principle of the interpolation and extrapolation scheme.

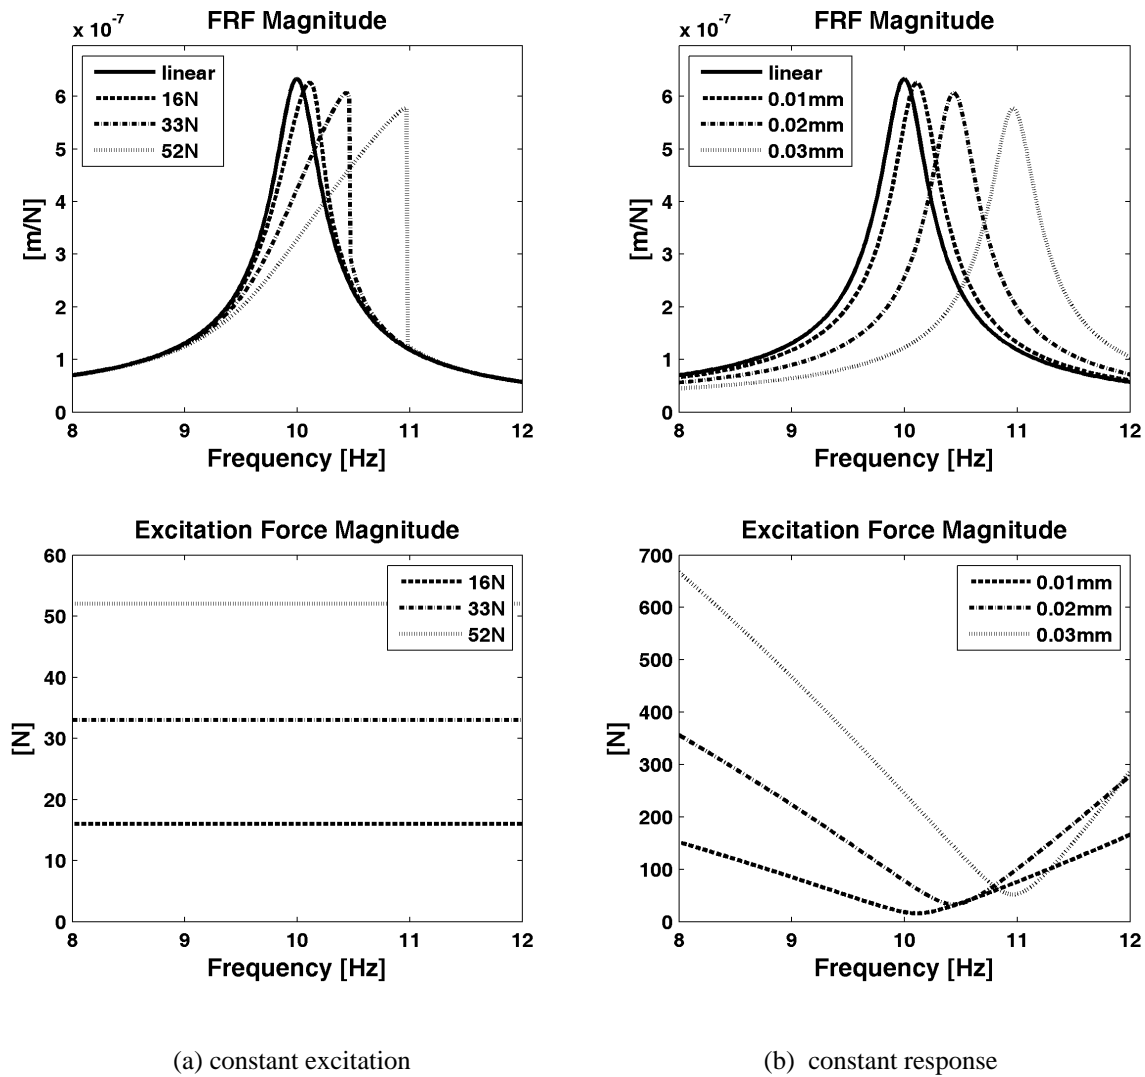

Figure 11: FRFs obtained with constant excitation force levels (a) and constant response levels (b)

The three data points for the variable Z on the vertical axis stand for any of the extracted natural frequencies, modal displacements, modal damping values or modal masses. The variable A stands for the load level used during the test (e.g. the g -level used on the shaking table). A distinction is made for input levels that lie within the input level range covered by test data (i.e. $A_{\text{int},i}$ with $i=1,2,\dots$) and input levels that lie outside the range covered by test data (i.e. $A_{\text{low},i}$ and $A_{\text{up},i}$). Polynomial interpolation is performed inside the input level range covered by test data, whereas linear extrapolation is applied for input levels that lie outside the range covered by test data. In principle, any suitable polynomial interpolation can be used. However, in the qualification test campaigns of spacecraft structures, three different input levels are typically used, that is a low level, an intermediate level, and the final qualification level. Due to this, the polynomial interpolation cannot go higher than quadratic (parabolic) interpolation in order to maintain compatibility with the spacecraft structures test procedures.

Figure 12: Interpolation and extrapolation scheme

It must be stated that the parabolic interpolation of modal parameters lacks physical significance. Nonetheless, it is a suitable interpolation between test data points observed at different input levels. Therefore, it is clear that the linear extrapolation to input levels outside the input level range covered by test data must be bounded by meaningful limits. In general, the validity bounds of the extrapolation are dependent on the character and strongness of the non-linearity. The validity range of the linear extrapolation are given by $A_{\text{low}} \leq A_{\text{low},i} \leq A_1$ and $A_3 \leq A_{\text{up},i} \leq A_{\text{up}}$ where the bounds A_{low} and A_{up} have to be specified by the user. Practical limits can be, for example, $A_{\text{low}} = 0.9A_1$ and $A_{\text{up}} = 1.1A_3$.

The parabolic interpolation scheme between levels A_1 and A_3 is described by

$$Z_{\text{int},i} = a_1 + a_2 A_{\text{int},i} + a_3 A_{\text{int},i}^2 = [A_{\text{int}}]_i^T \{a\} \quad (7)$$

Since this equation must also be valid at the measured load levels A_1 to A_3 one gets three equations for determining the interpolation constants $a_1 - a_3$:

$$\begin{Bmatrix} Z_1 \\ Z_2 \\ Z_3 \end{Bmatrix} = \begin{bmatrix} 1 & A_1 & A_1^2 \\ 1 & A_2 & A_2^2 \\ 1 & A_3 & A_3^2 \end{bmatrix} \begin{Bmatrix} a_1 \\ a_2 \\ a_3 \end{Bmatrix} = [A] \{a\} \quad (8)$$

The vector $\{Z\}$ holds the measured variables at the three load levels. This equation can easily be solved for the interpolation constants:

$$\{a\} = [A]^{-1} \{Z\} \quad (9)$$

Any interior variable $Z_{\text{int},i}$ at any interior load level $A_{\text{int},i}$ ($i=1,2,\dots,n$) is calculated from

$$\begin{Bmatrix} Z_{\text{int},1} \\ \vdots \\ Z_{\text{int},n} \end{Bmatrix} = \{Z\}_{\text{int}} = [A]_{\text{int}}^T [A]^{-1} \{Z\} \quad (10a)$$

where the matrix $[A]_{int}^T$ holds the n interior load levels in the form

$$[A]_{int}^T = \begin{bmatrix} 1 & A_{int,1} & A_{int,1}^2 \\ \vdots & \vdots & \vdots \\ 1 & A_{int,n} & A_{int,n}^2 \end{bmatrix} \quad (10b)$$

For the linear extrapolation scheme the tangents of the parabola at load levels A_1 and A_3 as shown in figure 12 are used which results in the interpolation formula for the lower and the upper range

$$Z_{low,i} = Z_1 + \tan(Z(A_1))(A_{low,i} - A_1) \quad (11a)$$

$$Z_{up,i} = Z_3 + \tan(Z(A_3))(A_{up,i} - A_3) \quad (11b)$$

with $\tan(Z(A_1)) = a_2 + 2a_3A_1$ and $\tan(Z(A_3)) = a_2 + 2a_3A_3$ where a_2 and a_3 denote the interpolation coefficients of eq.(9).

As stated above, this interpolation and extrapolation scheme can be applied to any modal parameter. In detail, the eigenfrequencies, the damping ratio, the generalized mass, and the elements of the mode shape vectors are interpolated. The new modal parameters interpolated or extrapolated to a new (unmeasured) input level can be used for response synthesis.

4 INDUSTRIAL APPLICATIONS

Test data for the first application were measured during a vibration test campaign of a typical STM satellite structure (Structural Test Model). The shaking table was driven in lateral direction at low, intermediate and qualification g – levels as shown in Figure 13. The data shown in Figure 15 represent the transmissibilities (transfer functions) calculated by division of the sensor responses (at altogether 164 DOFs) by the pilot response which was chosen as the maximum of the four pilot sensors located on the shaking table.

The test data evaluation procedure consisted of the following steps:

- (a) Analysis of the transmissibilities over the whole frequency range in order to identify the most significant response areas.
- (b) Selection of a frequency range which is considered to be representative for non-linear behaviour. The frequency range around the fundamental resonance in lateral x -direction is presented here which exhibited the most significant peak shifts and large deviations of amplitudes.
- (c) Identification of natural frequencies, mode shapes and modal damping values for each load level within the frequency range selected under (b) using ISSPA, ref. [20], classical modal extraction technique.
- (d) Extraction of input levels at resonance from pilot response spectra.
- (e) Application of ISSPA_NL for prediction of modal data and responses at not measured input levels.

(a) Table acceleration (input) notched around resonances

$f_{\text{qual}} = 13.10 \text{ Hz}$ (qualification level), $f_{\text{inter}} = 13.38 \text{ Hz}$ (intermediate level), $f_{\text{low}} = 13.56 \text{ Hz}$ (low level)
 $L_{\text{qual}} = 0.0715 \text{ g}$ $L_{\text{inter}} = 0.0350 \text{ g}$ $L_{\text{low}} = 0.0162 \text{ g}$

(b) Table acceleration (pilot sensor) zoomed around first resonances

Figure 13: Sinusoidal shaking table accelerations (input)

Figure 15: Amplitudes of the 17 largest transmissibilities
Low level (black), intermediate level (green), qualification level (red)

4.1 Identification of Modal Parameters

The characteristics of the transmissibilities in Figure 15 permitted the extraction the modal data separately for each load level using classical curve fitting procedure (ISSPA) which is based on the linearity assumption. The results of experimental modal analysis are summarized in Table 1:

Table 1: Results of linear modal analysis of three different input levels

Description	Input Level [g]	Eigen-freq. [Hz]	Damping Ratio [%]
Low	0.0162	13.56	0.8
Intermediate	0.0350	13.38	1.3
Qualification	0.0715	13.10	1.7

The following MAC-values compare the mode shapes extracted from the three load levels (100% would mean perfect agreement):

- MAC (low/ intermediate) 93.2 %,
- MAC (low/ qualification) 93.0 %,
- MAC (intermediate/qualification) 96.9 %.

These numbers and the plot in Figure 17 show

- a small variation of the resonance frequency,
- a significant increase of the damping values with the load level,
- a small influence of the load level on the mode shapes.

In Figure 16 the good correlation between test and modal synthesis is shown for one representative measurement DOF on top of the structure (the correlation for other DOFs was similar). This confirms the assumption that due to controlled output levels the response of the structure exhibited linear behaviour and that the identified modal parameters are meaningful. Figure 16(a) compares the indicator functions which indicate the quality of modal excitation. In the ideal case when just one single mode contributes to the response the indicator value equals zero. This figure shows that the mode around 13.4 Hz was very well excited. The shift of the resonance frequencies and the variation of the response peaks in Figure 16(b) show the

load level dependent nonlinear behaviour equivalent to the analytical system shown in Figure 11(b).

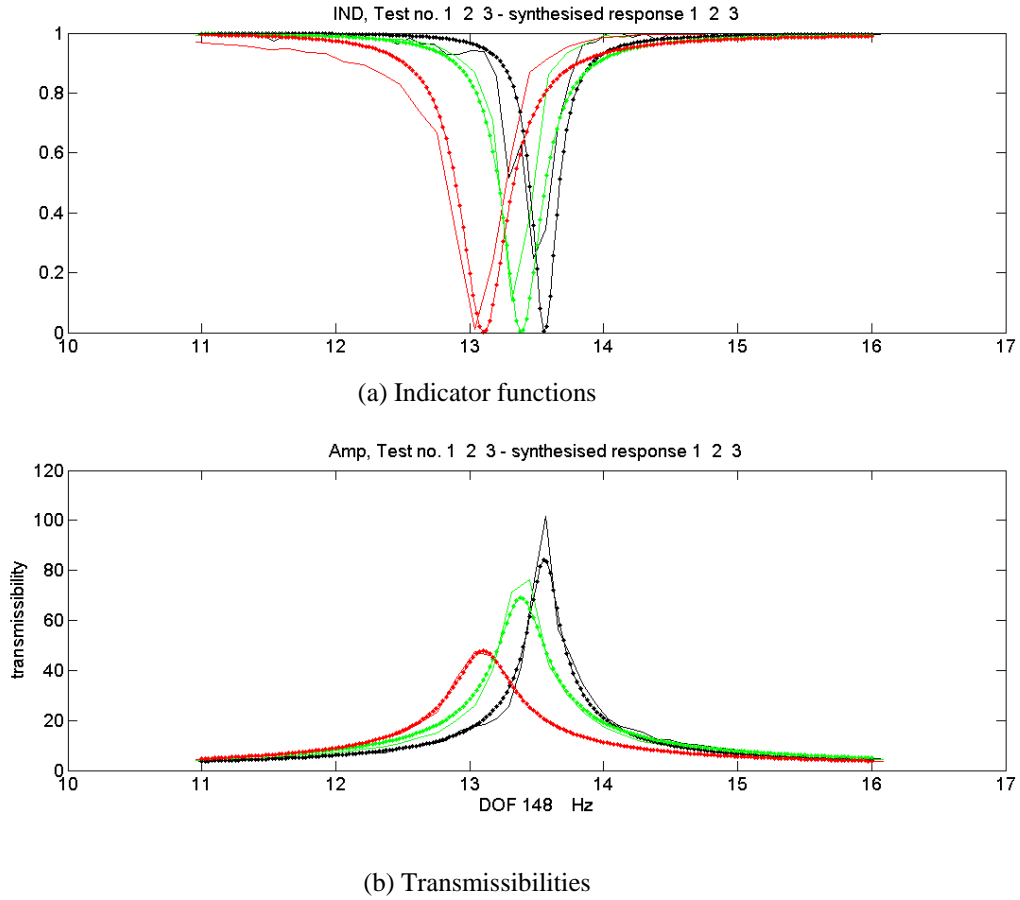

Figure 16: Measured (—) and synthesised (•••) indicator functions (a) and transmissibility amplitudes (b) low level (black), intermediate level (green), qualification level (red)

4.2 Application of the Interpolation Method

The application of the interpolation method seeks to predict the modal data and the responses at any other than the measured load levels. In the present application two additional load levels were chosen, one at $X1_{add} = (L_{low} + L_{inter})/2 = 0.0256$ g and the other at $X2_{add} = (L_{inter} + L_{qual})/2 = 0.0532$ g, $L_{low} = 0.0162$ g, $L_{inter} = 0.0350$ g and $L_{qual} = 0.0715$ g denote the load levels taken at $f_{low} = 13.56$ Hz, $f_{inter} = 13.38$ Hz and $f_{qual} = 13.10$ Hz (see Figure 13b).

The basic modal data extracted by the classical (linear) modal extraction technique ISSPA, ref. [20], using the transmissibilities of each load level are used as data points for the interpolation functions as described before.

The results of interpolating the modal data between the load levels $L_{low} = 0.0162$ g at 13.56 Hz and $L_{qual} = 0.0715$ g at 13.10 Hz are shown in Figure 17 (the modal displacements are not shown because of their low variability).

A considerable variation of the modal damping was observed whereas the maximum variation of the resonance frequency is restricted to not more than about 0.5 Hz. Using the modal data at the additional load levels $X1_{add} = 0.0256$ g and $X2_{add} = 0.0532$ g together with the mo-

dal data from the measured load levels yields the indicator functions and the transmissibilities shown in Figure 18.

It may be noted that the indicator functions and the transmissibilities at the additional load levels exhibit a physically meaningful interpolation between the measured levels and thus seems to confirm the achievement of the goals of the interpolation technique implemented in ISSPA_NL. It should also be noted that the calculation of the load level dependent modal data was based on experimental modal data only, i.e. there was no mathematical model involved.

Figure 17: Resonance frequency and modal damping vs. load level [g]

Figure 18: Indicator functions and transmissibilities using the modal data at two additional load levels (blue) together with the modal data from the measured load levels (qualification level red, intermediate level green, low level black)

From the viewpoint of verifying the predictions it was a disadvantage that the additional load level were not measured during the test campaign. Therefore, the technique was applied to the data available from the SWARM [21] qualification test campaign where **one additional** intermediate load level was measured. Figure 19 shows the measured transmissibilities at all

181 test DOFs which exhibit the peak shifts and the amplitude variations depending on the magnitude of load levels.

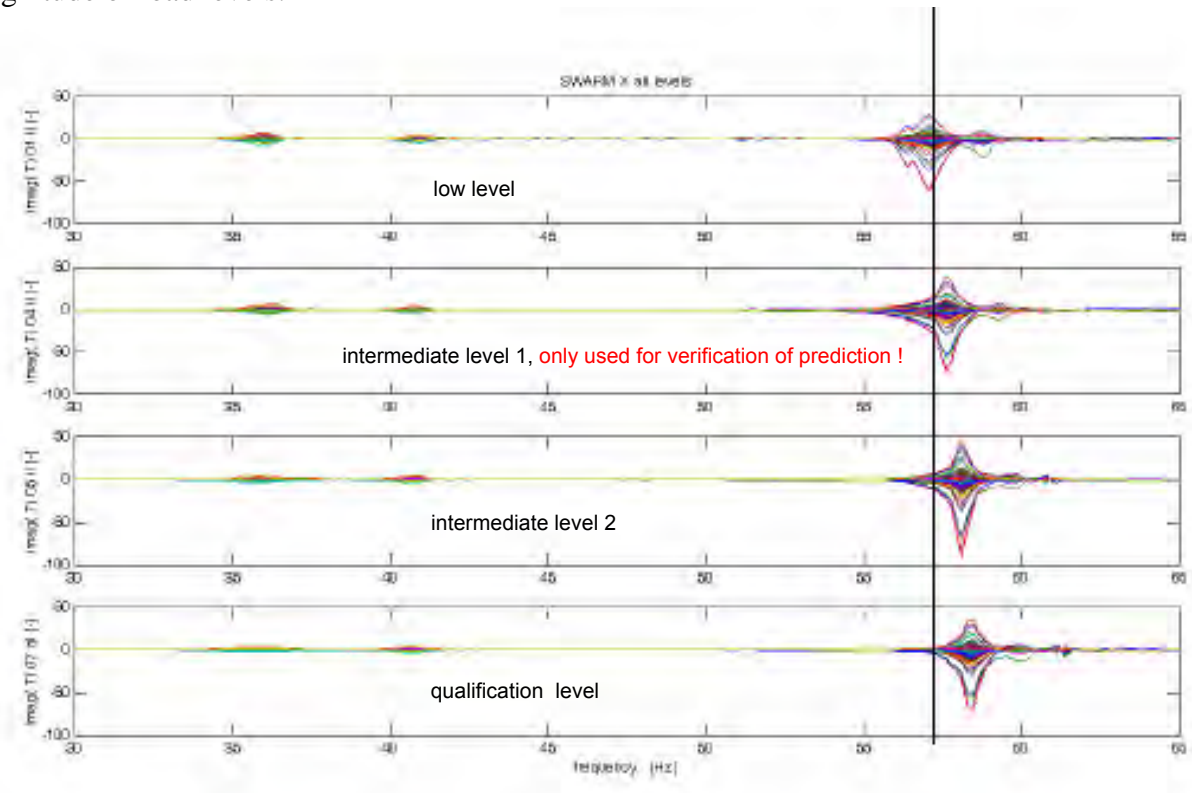

Figure 19: Measured transmissibilities at all 181 test DOFs

The success of constant output control can again be assessed from the 15 largest responses plotted in Figure 20. This plot shows that the requirement of constant responses within the notch range was not fulfilled as good as with the data of the previous application in Figure 14. Nonetheless, the described procedure was applied.

Figure 20: Absolute response amplitudes of the 15 largest DOFs around resonances at 58 Hz
low level (black), intermediate level (green), qualification level (red)

At first the modal data in the narrow frequency range around the resonance at about 58 Hz were extracted by linear experimental modal analysis techniques which subsequently were used for interpolation. The results from linear identification of modal parameters from three

sets of transmissibilities with x-excitation is summarized in Table 2 and displayed in Figure 21 together with the interpolated data at the additional level. The results of the SWARM linear modal identification shows:

- variation of the resonance frequency between 57 Hz and 58.4 Hz,
- significant change of the damping values with the load level,
- small influence of the load level on the mode shapes (not shown here).

Table 2: Results of SWARM linear modal analysis of three different input levels

Description	Input Level [g]	Eigen-freq. [Hz]	Damping Ratio [%]
Low	0.06	57.00	0.7
Intermediate	0.12	58.14	1.3
Qualification	0.21	58.38	0.5

Using the modal data at the additional load level together with the modal data from the three measured load levels which were used to derive the fix points for the modal data interpolation yields the synthesized transmissibilities shown in Figure 22.

From the results in Figure 22 a very good correlation of the synthesized and experimental response can be observed, not only at those three measured load levels which were used to derive the fix points for modal data interpolation but in particular at the **one additional load level**. The results thus seem to confirm the achievement of the research goal.

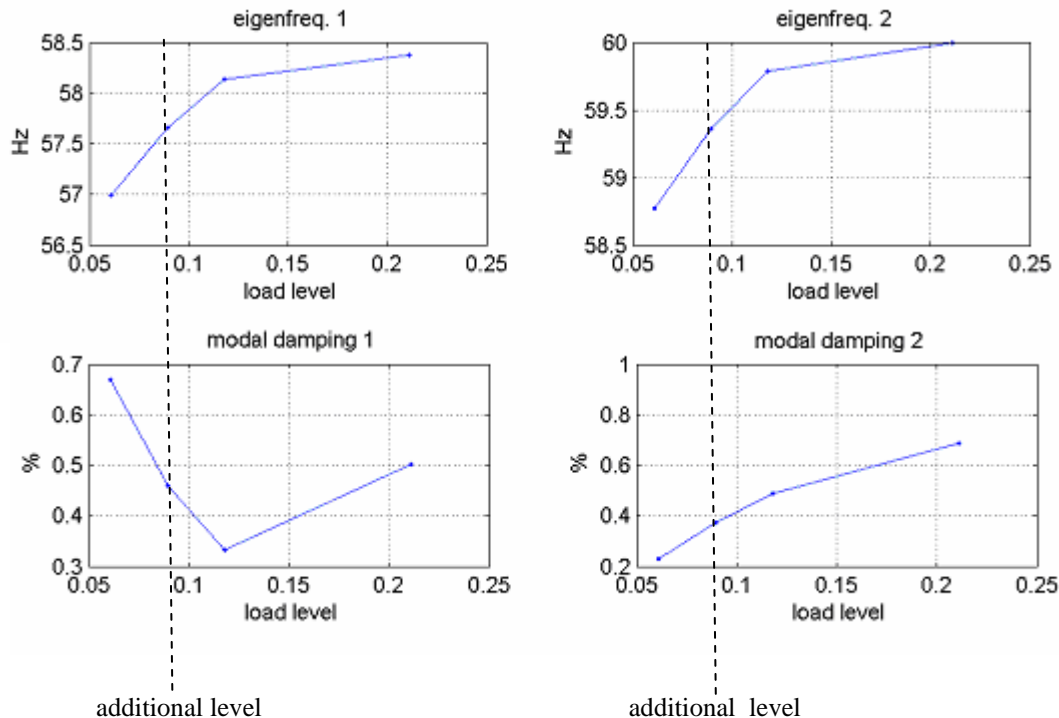

Figure 21: Modal data interpolated at one additional load level

Figure 22: Measured (—) and synthesised (...) transmissibilities for three load levels: low level (black), intermediate level (green), qualification level (red) and *one additional level* (synthesized $\circ-\circ-\circ$, measured —)

5 CONCLUSIONS

Many different tools and methods have been described in the literature for characterization of non-linearities from vibration test data, e.g. in ref. [23]. This paper does not claim to present a comprehensive list of such methods. Instead, selected methods have been presented which either utilize combined analytical/experimental data or experimental frequency domain response data obtained with controlled input levels or controlled output levels. According to the experience of the authors, application of methods for characterization of non-linear systems is largely dependent on the compatibility with standard test processes and the respective results that these processes can provide. It was therefore one of the objectives of the DYNAMITED project to summarize available tools and finally to set up a process for identification of non-linear systems.

Due to response control at selected sensor locations during a vibration test on a shaking table it can be observed that the transmissibilities do not exhibit significant non-linear distortions so that the utilization of classical linear modal extraction tools may be applied separately for each input level. However, the measured dynamic responses (transmissibilities) reveal peak shifts and amplitude changes depending on the notched input level of the base excitation which can be utilized to describe the non-linear behaviour.

The technique described in the paper utilizes this well established industrial test procedure to analyze the non-linearity based on controlled response at three different table acceleration levels all of them assumed to be constant within the notching frequency ranges. The technique (implemented in the ISSPA_NL code) aimed at predicting the responses to *other than the measured* input levels which is achieved by applying interpolation and extrapolation techniques to the modal data extracted by classical (linear) experimental modal analysis from the transmissibilities measured at three measured input levels.

The procedure was applied using the test data from a STM satellite structure (Structural Test Model) and also from the SWARM satellite test campaign. For each application one characteristic frequency range was selected exhibiting non-linear behaviour around a dominant resonance. Subsequently, natural frequencies, mode shapes and modal damping values were extracted for each load level within the selected frequency ranges which subsequently were used for inter- or extrapolation and used for predicting the responses at one or more unmeasured load levels.

It was found that for the first application the predicted indicator functions and the transmissibilities at the two additional (not measured) load levels exhibit a physically meaningful in-

terpolation between the measured levels. In particular this holds for the response prediction for the second application (SWARM satellite), where an additional second intermediate load level was measured but was only used for verification purposes. The good results from both applications thus seem to confirm the achievement of the research goals.

It could be of interest for future research to investigate how the load dependent modal data could be utilized for the parameter identification of a physical non-linear Finite Element model.

Keywords: Unreinforced masonry, Flexible diaphragms, Seismic Loads, Design guide.

Abstract. *It is well established and routinely observed that unreinforced masonry buildings perform poorly in large earthquakes. This knowledge directly points to the need for a detailed procedure for the seismic assessment and retrofit of unreinforced masonry buildings. Pivotal to the entire assessment and retrofit process is the accurate treatment of the dynamic characteristics of flexible timber floor diaphragms, and the development of a straightforward and accurate method for determining the in-plane seismic loads on walls when accounting for both excitation due to self weight, and seismic demand transmitted via wall-diaphragm connections.*

Pertinent details of the M7.1 2010 Darfield (Canterbury) earthquake are presented, followed by a review of results from a large scale experimental program that investigated the strength and stiffness characteristics of timber diaphragms. Next, details are provided of a procedure for determining diaphragm dynamic characteristics recognizing that diaphragm deformations are primarily associated with shear rather than flexure. Finally, details are summarised of a methodology now adopted in New Zealand for determining the in-plane seismic demand on unreinforced masonry walls.

1 INTRODUCTION

Unreinforced masonry (URM) buildings represent the predominant architectural heritage of many nations, and outside of Europe were typically constructed with solid clay brick perimeter walls and comparatively flexible timber floor diaphragms. Unfortunately the preservation of these buildings in seismically active regions is threatened due to their well established inadequacy to withstand earthquakes, as recently demonstrated again in the 2010 Darfield earthquake, which was the largest natural disaster to occur in New Zealand since the 1931 Hawke's Bay earthquake. Observed damage in the earthquake included toppled chimneys and parapets, failure of gables and poorly secured face-loaded walls, and in-plane damage to masonry frames.

Timber floor diaphragms are widely recognized to have significant impact on the overall seismic response of URM structures, and the accurate assessment of diaphragms is therefore crucial during the seismic assessment and retrofit of URM buildings. A series of full-scale diaphragm tests that were performed to generate data to aid in understanding the dynamic characteristic of flexible timber diaphragms is presented.

When compared to the URM buildings of most countries worldwide, the URM building stock in New Zealand is comparatively homogeneous in terms of age, material properties, and architectural form. This observation presents an opportunity to develop a detailed seismic assessment guideline for these buildings that has the dual goals of providing clarification on the appropriate method for deploying existing recommendations, plus incorporating new research results to arrive at the most accurate assessment of seismic capacity currently possible. Such an exercise allows the seismic strength of the URM building to then be expressed in terms of the 'percentage of New Building Strength' (%NBS) and to establish whether seismic improvement of the building is necessary.

2 OVERVIEW OF THE 2010 DARFIELD EARTHQUAKE

2.1 Introduction

At 4.35 am on the morning of Saturday the 4th of September 2010 a magnitude 7.1 earthquake occurred approximately 40 km west of the city of Christchurch NZ at a depth of about 10 km [1], having an epicentre located near the town of Darfield. The ground motion had a peak ground acceleration of about 0.25g and a spectral acceleration in the plateau region of about 0.75g, which corresponds well with the design spectra for a site class D soil site in Christchurch for spectral periods greater than 0.2 seconds. In general, the earthquake represented 67-100% of the design level event, depending upon the spectral period being considered (see Figure 1), with most of Canterbury reporting damage consistent with MM8 on the Modified Mercalli intensity scale. The single most striking statistic was that there were no fatalities directly associated with the earthquake (although there was one heart attack fatality and one person hospitalised due to a falling chimney [2]), and the overall impression is that damage in the central business district (CBD) was reasonably contained, restricted primarily to URM buildings and damage to windows in taller steel and concrete structures. The absence of fatalities and more extensive damage was attributed to the comparatively high level of seismic design capability in New Zealand, and the fact that the CBD, which is the region containing the highest density of URM buildings, was almost completely unoccupied at 4.35 am [3].

The soil conditions in Christchurch have three separate material types: river outwash gravels, sands, and marshy ground in former swamp areas, with the central city built mainly on

gravels, although there are pockets of sand and soft soil in former marsh deposits. The earthquake ground motion characteristics shown in Figure 1 reflect the underlying soil condition, with the long period nature of the motion resulting from the soft soils upon which Christchurch is founded. These soft soils effectively act as a filter and remove high frequency ground motion (leading to smaller PGA values than on rock sites) but amplify long period motion, resulting in significantly larger longer period motion at about 2.5 second. As most URM buildings have a fundamental period of 0.2-0.3 seconds, the underlying ground conditions appear to have assisted in reducing the seismic demand in this period range to approximately 70% of the design level loading stipulated in the current New Zealand Loadings Standard. As can be seen in Figure 1(b), strong ground shaking in the CBD had a duration of approximately 30 seconds with similar amplitudes in the two orthogonal recording directions. This lack of distinct directionality probably explains why parapet failures were observed in streets running in both the North-South and East-West directions.

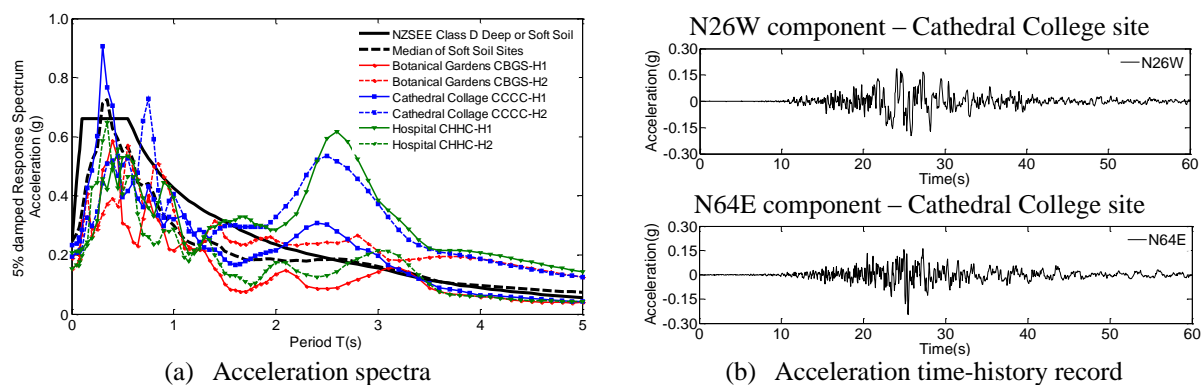

Figure 1: Details of earthquake ground motion [2]

2.2 Building Damage Statistics

In general, the observed damage to URM buildings in the 2010 Darfield Earthquake was consistent with the expected seismic performance of this building form [4]. As part of the emergency response to this earthquake, building were tagging with either a green, yellow or red placard depending, respectively, upon whether a building was safe for public use, had limited accessibility for tenants/occupants, or was not accessible. Many examples of earthquake damage were observed during this exercise, as well as many examples of seismic retrofits to URM buildings that had performed well [5].

2.3 Parapet failures

Numerous parapet failures were observed along both the building frontage and along their side walls, and for several URM buildings located on the corners of intersections, the parapets collapsed on both perpendicular walls (refer Figure 2). Restraint of URM parapets against lateral loads has routinely been implemented since the 1940s, so whilst it is difficult to see these restraints unless roof access is available, it is believed that the majority of parapets that exhibited no damage in the earthquake were provided with suitable lateral restraint. In several cases, it appears that parapets were braced back to the perpendicular parapet, which proved unsuccessful.

2.4 Anchorage failures

Falling parapets typically landed on awnings, resulting in an overloading of the braces that supported these awnings and leading to collapse. Most awning supports in Christchurch involved a tension rod tied back into the building through the front wall of the building. Many of these connections appear to consist of a long, roughly 25 mm diameter rod, with a rectangular steel plate (about 5 mm thick) at the wall end that is about 50 mm wide x 450 mm long and fastened to the rod and positioned either inside the brick wall or in the centre of a masonry pier or wall. In most cases the force on the rod exceeded the capacity of the masonry wall anchorage, causing a punching shear failure in the masonry wall identified by a crater in the masonry (refer Figure 3).

(a) Multiple front wall parapet failures

(b) Corner of Sandyford and Colombo Street

(c) Side wall parapet collapse onto roof.

(d) Corner Columbo and Tuam Street

Figure 2: Examples of typical parapet failures.

2.5 Wall failures

Out-of-plane wall failures were the first images to appear on television directly after the earthquake. Inspection of this damage typically indicated poor or no anchorage of the wall to its supporting timber diaphragm. Several examples of wall failure are shown below. Figure 4(a) shows a corner building that had walls fail in the out-of-plane direction along both directions. Figure 4(b) shows a 3-storey building where walls in the upper two stories suffered out-of-plane failures and Figure 4(c) shows similar damage for a 2-storey building. In all three of these instances, it appears that the walls were not carrying significant vertical gravity loads, other than their self weight, due to the fact that the remaining roof structures appear to

be primarily undamaged. In contrast, Figure 4(d) shows an out-of-plane failure of a side wall which was supporting the roof trusses prior to failure.

3 FLEXIBLE TIMBER DIAPHRAGMS

While URM buildings outside of Europe are typically comprised of rigid clay brick perimeter walls, the floors are usually constructed of comparatively light timber framing. These floors are generally made up of either straight-edge or tongue & groove floorboards nailed perpendicular to joists that span between the URM walls. When perimeter walls are close enough (approximately less than 6 m) joists often span continuously between these elements. For larger spans, joists are typically lapped or butted over intermediate steel or timber cross-beams supported on columns. Diaphragm blocking and chord elements are almost never present, and timber cross-bracing is typically fitted intermittently between joists to prevent out-of-plane buckling. Joist ends are typically either simply supported on a brick ledge resulting from the perimeter walls reducing in width at each storey height, or pocketed into the wall to a depth equal to one brick width. Examples of timber floor configurations are given in Figure 5.

(a) Anchorage failure (b) Close-up of failed anchorage detail

Figure 3: Anchorage failure of awning brace due to parapet collapse.

Timber floors in URM buildings act as diaphragms that have routinely demonstrated significant influence on the seismic performance of the complete URM structure due to their flexible nature and often inadequate connection to the perimeter URM walls [6] (Bruneau 1994). The in-plane strength and stiffness of these diaphragms is therefore crucial to the overall performance of the URM building and accurate assessment of their performance is essential for the design of appropriate retrofitting techniques when seismic strengthening is required. Due to a complete lack of experimental data and appropriate analysis [7-9], the validity of diaphragm assessment procedures offered in current state-of-the-art assessment documents [10-11] are questionable. Furthermore, communication from engineering practitioners suggests that such documents are difficult to understand and to follow with confidence. Given these shortcomings, significant motivation currently exists to investigate the performance of timber floor diaphragms and the accuracy of assessment procedures. Before non-destructive testing techniques are considered as a viable assessment tool, it is necessary to generate in-plane performance data for timber diaphragms with which to appropriately update and improve current seismic assessment desktop procedures.

Results of a series of full-scale diaphragm tests are summarized and are used to review the validity of the current desktop assessment procedures published in [10] and [11]. Performance

predictions using the assessment techniques are compared against experimental results and where possible, recommendations to improve their accuracy are suggested.

3.1 As-built diaphragm testing

A total of four diaphragm specimens labeled FS1a to FS4a, constructed with new pine timber, were tested. Each specimen measured 10.4 m x 5.535 m and was comprised of 135 mm x 18 mm straight edge floorboards nailed perpendicular to 45 mm x 290 mm joists spaced at 400 mm centers. Joists were orientated in the 5.535 m dimension. Cross-bracing was fitted between the joists at 1/3 joist length locations using 45 mm x 75 mm framing. Every floor-board-joist connection was fastened using two 75 mm x 3.15 mm bright power driven nails spaced at approximately 95 mm.

(d)

Figure 4: Examples of out-of-plane failures in solid masonry walls.

Diaphragms FS1a and FS2a were tested in the direction parallel to joists so that the diaphragm span to depth ratio was 1.88 to 1. In this direction the two side joists were bolted to steel frames that were fastened to the warehouse concrete slab which replicated in-situ boundary conditions where the edge joists would simply be bolted intermittently to the perimeter URM walls (see Figure 6(a)). Lateral loading was introduced into the diaphragm using a hinged steel frame „whiffle tree’ on castors that distributed the hydraulic actuator point load into four equal point loads. It can be observed in Figure 6(b) that the loading frame was comprised of a main truss and two secondary beams that were capable of rotating with the deforming diaphragm. Reversed cyclic loading was achieved by positioning loaders on both ends of the loaded joists, and post-tensioning these loaders together using M16 threaded rods that spanned the depth of the diaphragm (Figure 6(b)). The diaphragm was supported verti-

cally by Teflon pads that allowed the diaphragm to deform laterally without measurable friction. Diaphragm FS1a shown in Figure 6(a) was a homogenous diaphragm while diaphragm FS2a shown in Figure 6(c) included a corner penetration measuring 3.2 m x 1.08 m that represented a typical stairwell present in many timber diaphragms.

Diaphragms FS3a and FS4a were tested in the direction perpendicular to joists so that the diaphragm span to depth ratio was 1 to 1.88. Realistic conditions were created for this set-up by constructing URM walls on each side of the diaphragm for the joists to pocket into, similar to that illustrated in Figure 5(b). Sliding of the brick walls was prevented by post-tensioning the walls with M16 rods epoxied into the warehouse concrete slab (measurement of wall position during testing showed that no wall displacement was observed). Loading was introduced into the diaphragm using the same hinged steel frame as for the previous set-up but with only two points of loading. Diaphragms FS3a and FS4a were equivalent in construction except that diaphragm FS3a had continuous joists spanning between the brick walls while diaphragm FS4a had discontinuous joists with a two-bolt lapped central connection.

Figure 5: Typical timber diaphragm configuration

3.2 Test Results

Overall the diaphragms displayed flexible and highly nonlinear characteristics with low levels of hysteretic pinching, as illustrated in the force versus midspan displacement plots in Figure 7. The open hysteretic loops demonstrate that these diaphragms are capable of dissipating considerable amounts of energy when subject to lateral loading. No splitting of timber, nail tear-out or other failure mechanisms were observed during testing, even at displacements in excess of 150 mm, and all diaphragms appeared to remain completely serviceable at the conclusion of each test.

A comparison of the force-displacement responses of specimens FS2a and FS1a suggests that a small diaphragm opening such as a stairwell does not significantly affect the diaphragm's performance, with these responses being largely indistinguishable. It is appreciated that larger penetrations may worsen this effect however. Another interesting observation is that diaphragms FS3a and FS4a behaved analogously despite the presence of a central discontinuity in the joists in diaphragm FS4a. This could be explained by the deformation profile of the diaphragms displaying little amounts of relative displacement between the two point-load locations. With the majority of deformation occurring in the outer regions of the diaphragm, the curvature near the centralized joist connection was low and therefore considerably reduced its effect on diaphragm response.

Figure 6: Experimental program

It is difficult to directly compare force-displacement response between the two principal loading directions due to the influence of diaphragm geometry. Diaphragms FS3a and FS4a demonstrated greater stiffness and strength than FS1a and FS2a, but this is clearly due to a considerably lower span to depth ratio. As a general observation, the hysteretic loops are larger in the direction parallel to joists which could result from greater engagement of the yielding nail couples in this direction as opposed to loading in the direction perpendicular to joists, where the nail couples are less engaged and the out-of-plane bending of the joists has greater influence on response.

Figure 8 shows the bilinear curves produced for diaphragm tests FS1a to FS4a. The bilinear curves defined the yield force (F_y), yield displacement (Δ_y), maximum force at $\Delta = 150$ mm (F_{max}), and initial and secondary stiffness (K_1 and K_2) values presented in Table 2 that were used to calculate the desired diaphragm performance parameters. Diaphragm stiffness K_d was defined as initial stiffness K_1 while shear strength R_n was calculated by simply dividing yield force by two times the diaphragm depth. Ductility was determined using the conventional assumption of elastic-perfectly plastic response and calculating the ratio between maximum displacement and yield displacement. These values are presented in Table 1 for comparison.

3.3 Discussion

Overall, the guidelines offered in both assessment documents poorly predict diaphragm performance. The values listed in Table 1 illustrate that diaphragm shear strength, stiffness, shear stiffness and ductility are either under predicted or over predicted using the NZSEE [10] and ASCE 41-06 [11] assessment procedures. Shear strength is the most accurately predicted parameter with approximately 10% discrepancy from experimentally determined values, with the exception of the alternative default value offered by NZSEE that grossly over estimates strength. The reason for this large discrepancy remains unknown. Diaphragm stiffness and shear stiffness is considerably under predicted using the methodology in NZSEE, while is over predicted using ASCE 41-06 guidelines. NZSEE offers no explicit guidance for diaphragm ductility while ASCE 41-06 provisions where shown to under estimate diaphragm ductility by up to five times.

An important observation from the experimental performance parameters listed in Table 1 is the highly orthotropic behavior demonstrated by the timber diaphragms. The shear strength and shear stiffness values, which are independent of diaphragm geometry, are significantly different in each principal direction of the diaphragm, yet the current assessment documents offer no provisions to address this behavior. In order to improve the transparency and accuracy of the assessment procedures, diaphragm performance parameters should be explicitly provided for in each principal direction.

It is recognized that heritage diaphragm performance may differ from the experimental performance values presented in Table 1 due to out-dated construction materials and the effects of age and decay. A component of the current research program involves testing extracted floor sections and nail connections from ~100 year old timber floor diaphragms. It is hoped that the data generated from testing will provide the necessary information to appropriately modify the performance parameters to ensure they are representative for heritage con-

struction. For the interim, the considerable difference observed between predicted and measured diaphragm performance suggests that the current procedures offered in NZSEE and ASCE 41-06 require updating. In addition, it is believed that these documents should be harmonized so that international assessment procedures are consistent with one another.

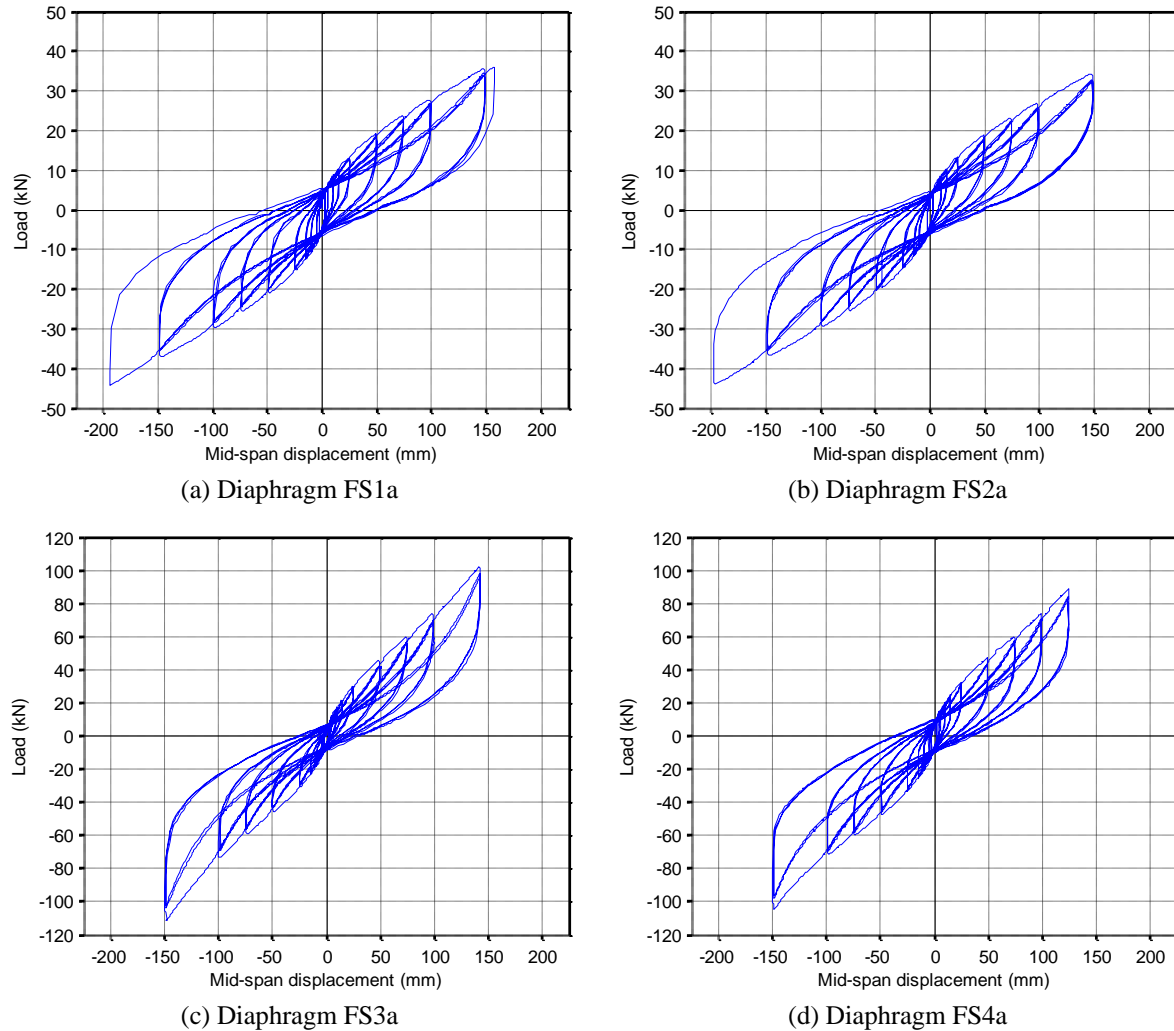

Figure 7: Full-scale diaphragm testing results

4 PERIOD OF FLEXIBLE DIAPHRAGM

Common assessment guides [10, 11] stipulate a diaphragm fundamental period that is calculated as:

$$T = \sqrt{3.07\Delta_d} \quad (1)$$

However neither document clarifies the source of this equation, and as period values derived using Equation 1 can appear somewhat questionable, it is useful to outline the derivation of this equation. If we consider a fixed-ended flexural beam with distributed mass, then the deformed shape and mid-span deflection are as shown in column 1 of Table 3. Note that the period calculation is independent of the magnitude of applied acceleration, but that for convenience it is useful to evaluate deflections when subjected to gravity acceleration, g , even

though horizontal deformations are being considered in the plane of the diaphragm, rather than vertical deflections due to sagging. As outlined in [12], a shape function can be used to describe the beam deformations, which can then be used to develop a generalised mass $m^* = \int_0^L \bar{m} \varphi(x)^2 dx$ and generalised stiffness $k^* = \int EI \varphi''(x)^2 dx$ (for flexural) or $k^* = \int_0^L \frac{GA}{\kappa} \varphi'(x)^2 dx$ (for shear). This information can then be introduced to the generalised period equation to obtain a specific expression for the period.

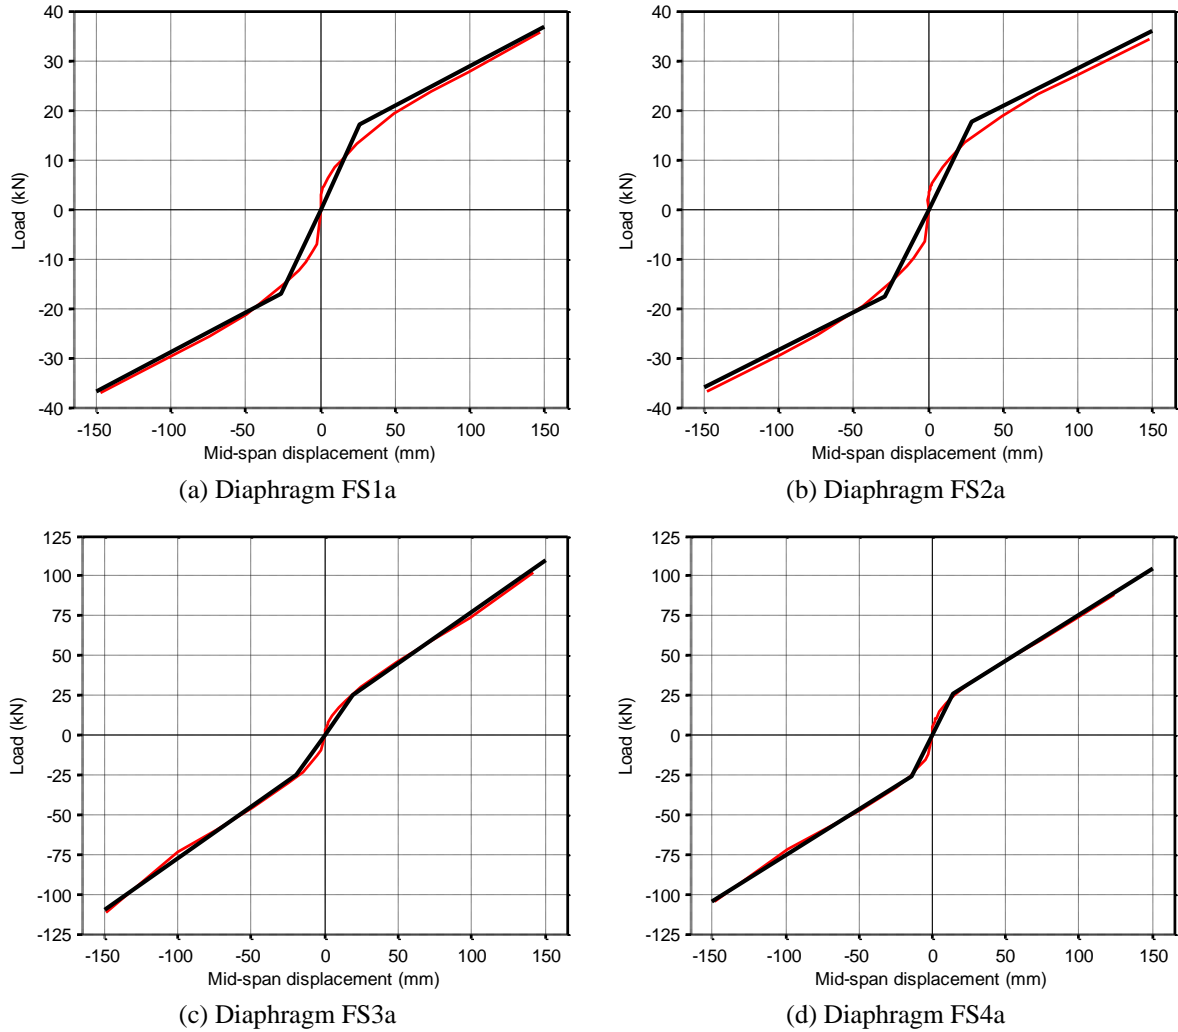

Figure 8: Bilinear curves for tested as-built diaphragms

Whilst the above discussion satisfactorily explains the origin of the equation in [10-11], there are several further issues to consider. Firstly, the assumption of the diaphragm having a fixed boundary condition when connected to the in-plane walls is inconsistent with the nature of most diaphragm connection details, and the corresponding period calculations for a pin-ended flexural beam would appear to be more realistic. This information is provided in column 2 of Table 1, illustrating that the boundary effects had an inconsequential influence on the equation coefficient, but a 230% change on the calculated period. More importantly, as flexible diaphragm deformations are governed by shear deformations rather than flexural deformations. Hence the corresponding process is presented in column 3 of Table 3, showing that again this modification has had only a small impact on the coefficient used in the period

	Fixed end flexural beam	Pin ended flexural beam	Shear beam
Deflected geometry, $\delta(x)$	$\delta(x) = \frac{\bar{m}gx^2}{24EI}(L-x)^2$	$\delta(x) = \frac{\bar{m}gx}{24EI}(x^3 - 2Lx^2 + L^3)$	$\delta(x) = \frac{\bar{m}g\kappa}{GA}\left(\frac{L}{2}x - \frac{x^2}{2}\right)$
Maximum deflection	$\Delta_{ff} = \frac{\bar{m}gL^4}{384EI}$	$\Delta_{pf} = \frac{5\bar{m}gL^4}{384EI} = 5\Delta_{ff}$	$\Delta_{sb} = \frac{\bar{m}g\kappa L^2}{8GA}$
Shape function	$\varphi(x) = \frac{16x^2}{L^4}(L-x)^2$	$\varphi(x) = \frac{16x}{5L^4}(x^3 - 2Lx^2 + L^3)$	$\varphi(x) = \frac{8}{L^2}\left(\frac{Lx}{2} - \frac{x^2}{2}\right)$
Generalised mass	$m^* = \frac{256}{630}m$	$m^* = \frac{23808}{47250}m$	$m^* = \frac{8}{15}m$
Generalised stiffness	$k^* = \frac{1024}{5}\frac{EI}{L^3}$	$k^* = \frac{36864}{750}\frac{EI}{L^3}$	$k^* = \frac{16}{3}\frac{GA}{L\kappa}$
General period expression	$T = 2\pi\sqrt{\frac{m^*}{k^*}}$	$T = 2\pi\sqrt{\frac{m^*}{k^*}}$	$T = 2\pi\sqrt{\frac{m^*}{k^*}}$
Specific period expression	$T = \sqrt{3.07\Delta_{ff}}$ $= 1.75\sqrt{\Delta_{ff}}$ $= 1.75\sqrt{\frac{\omega L^4}{384EI}}$ $= 0.0894\sqrt{\frac{\omega L^4}{EI}}$	$T = \sqrt{3.17\Delta_{pf}}$ $= \sqrt{15.85\Delta_{ff}}$ $= 1.78\sqrt{\frac{5\omega L^4}{384EI}}$ $= 0.2032\sqrt{\frac{\omega L^4}{EI}}$	$T = \sqrt{3.21\Delta_{sb}}$ $= 1.79\sqrt{\Delta_{sb}}$ $= 1.79\sqrt{\frac{\omega L^2}{4G_d b}}$ $= 0.8958\sqrt{\frac{\omega L^2}{G_d b}}$

Table 3: Period of flexible diaphragm accounting for boundary effects and deformation modes

calculation. The deflection used in column 3 is consistent with calculated diaphragm deflections according to [11]:

$$\Delta_d = \frac{\bar{m}gL^2}{4G_d b} = \frac{\omega L^2}{4G_d b} \quad (2)$$

In Equation 2 it is important to appreciate that G_d refers to a shear stiffness (having units of kN/m), whereas in the derivation in Table 1, G refers to the Shear Modulus (having units of MPa or kN/m²). By equating the resulting mid-span deflections and recognising that the shape factor $\kappa = 1.2$ for rectangular sections, we arrive at the relationship:

$$G_d = \frac{2Gt}{\kappa} = \frac{5Gt}{3} = 1.667Gt \quad (3)$$

where t is the diaphragm thickness.

5 IN-PLANE LOADS ON SHEAR WALLS

The in-plane loads on shear walls are calculated from two components, one based on the diaphragm response, and the other based on the wall in-plane response. The dynamic response of a multi-storey unreinforced masonry building with flexible diaphragms is concentrated in the diaphragms. The equivalent static method assumes that the in-plane wall is rigid in comparison to the flexible diaphragm for the purpose of calculating the inertial force induced in the diaphragm. Adequate connections between the diaphragm and the in-plane loaded walls are required in order to transfer the inertial force induced in the diaphragms and the out-of-plane loaded walls into the in-plane loaded walls. The wall in-plane response component is based on the shear wall behaving in its fundamental mode. For solid shear walls, calculation of the elastic stiffness and therefore period is relatively simple, but for the case of perforated walls this calculation is much more complicated and hence the recommendation that the in-plane loaded wall period is assumed to lie in the constant acceleration region of the response spectra.

5.1 Damping

Unreinforced masonry does not respond in a classical elastic-plastic manner, exhibiting more of a nonlinear elastic response with pinched hysteretic loops. From analysis of full scale pseudo-static tests on in-plane loaded flanged walls and spandrel/pier sub-structures, a range of 5-15% equivalent hysteretic damping was found. The past recommendation of 15% of critical was formed from a combination of approximately 5% inherent viscous damping associated with elastic structures, 5% hysteretic damping and 5% damping from dynamic impact [10]. The hysteretic damping includes Coulomb (or “dry”) damping associated with sliding shear, radiation damping, pinched hysteretic damping associated with flexural/diagonal shear softening and equivalent damping due to impact on rocking. The current recommendation of 5% is supported by the increase in displacement ductility recommended for use in finding demand on in-plane loaded URM shear walls which allows for a reduction in loads based on nonlinear behaviour. The recommendation of 5% of critical is based on the understanding that the increase in ductility to 2, and the reduction due to the structural performance factor, allows for the reduction in load due to nonlinear response and therefore the reduction would be two-fold if damping was also increased.

5.2 Ductility

Unreinforced masonry is generally considered a brittle material and therefore it has been justified in the past to use a displacement ductility factor of 1. The notion of URM as a brittle material is inaccurate and conservative. Ductility is present not from conventional yielding of steel reinforcing bars, but from inelastic response and energy dissipation due to shear sliding along mortar joints and rocking of masonry block elements. When URM walls respond in-plane, particularly with a rocking mechanism, there is significant inelastic displacement capacity and a strongly nonlinear behaviour. A typical shear response is shown in Figure 9(a), and shows no rapid and severe strength loss as associated with a typical brittle failure. The force-displacement plot associated with pier and pier/spandrel sub-structure testing indicates that a flexural failure mechanism, or a flexural/shear combined failure mechanism, is capable of ultimate displacements that greatly exceed the yield displacement, as shown in Figure 9(b). URM buildings have multiple sources of ductility that develop from energy dissipation drawn from shear mechanisms in the in-plane loaded walls, rocking of in-plane loaded URM elements, and energy dissipation from deformations of the timber diaphragms. The recommendation for using a displacement ductility of 2 recognises the nonlinear response of URM walls to

in-plane loading and the energy dissipation that occurs during loading cycles beyond the elastic state.

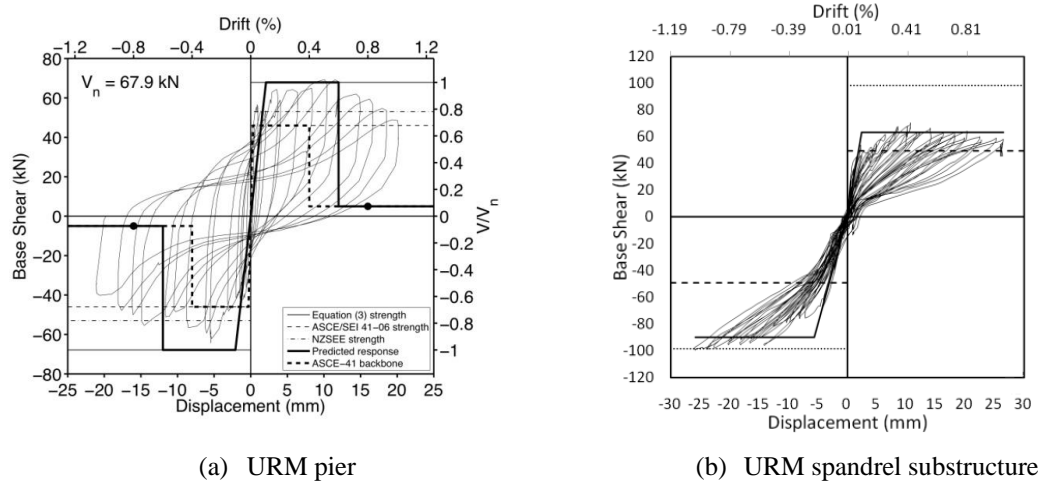

Figure 9: Plots of Force-displacement response of URM assemblages

5.3 Vertical Distribution of Inertial Shear Load

A rectangular distribution of the inertial shear load vertically up the height of the building reflects the assumption of effectively rigid wall response in comparison to the flexible diaphragm response. A rectangular distribution implies no modification of the ground accelerations up the height of the wall. Storey shear load is the addition of the diaphragm shear load and the component of in-plane inertial shear load distributed to that level using the Square Root of Sum of Squares rule. Summation of the inertial storey shear load and the individual diaphragm shear loads using a CQC or SRSS method allows for the individual elements to respond at different periods and therefore not necessarily in phase.

6 CONCLUSIONS AND RECOMMENDATIONS

- The significant number of URM buildings damaged in the 2010 Darfield earthquake was consistent with the level of damage that can be expected for an earthquake of this scale.
- The types of failure modes to URM buildings that were observed in the 2010 Darfield earthquake are consistent with those routinely observed in previous last earthquakes.
- Timber floor diaphragms have proven to significantly influence the overall seismic performance of URM buildings.
- Stiffness and strength data generated from a series of full-scale diaphragm tests will lead to improved accuracy of dynamic modeling of URM buildings.
- Diaphragm deformations are governed by shear deformations rather than flexure deformations.
- In-plane loads on URM walls are comprised of inertial loads and diaphragm transfer loads.

ACKNOWLEDGMENTS

The authors would like to gratefully acknowledge Stuart Oliver of Holmes Consulting Group for his continued guidance, and David Moore of Grayson Engineering and Warwick

Banks of Carter Holt Harvey Woodproducts for their generous support that ensured the successful completion of the flexible diaphragm experimental program reported herein.

Keywords: Seismic rehabilitation, ASCE 41-06 standard, Un-reinforced masonry building, Steel I-beam jack arch slab, Iran.

Abstract. *Un-reinforced masonry buildings are a major population of residential and school buildings in Iran which have been shown severe damages during past earthquakes e.g. Bam earthquake in 2003 with at least 26000 fatalities. The most important weaknesses of this sort of buildings are coming from the in-adequate lateral load resisting system and the weakness in the element connections. This kind of construction is not (or rarely) used anymore in urban regions. However, any effort for the seismic rehabilitation of the current buildings can save a reasonable amount of life in a future earthquake. That is, a detailed seismic rehabilitation for a typical un-reinforced masonry building in Iran has been described in this paper. The rehabilitation methodology is based on the ASCE 41-06 standard recommendations but adopted in details for the Iranian traditional masonry construction type. The rehabilitation cost is around thirty percent of the re-construction procedure which is quite promising.*

1 INTRODUCTION

Most of the un-reinforced masonry (URM) buildings in Iran have not been engineered whereas constructed based on experiences. Moreover, the construction of URM buildings varies from country to country in many aspects including material properties, layering methods, floor systems, connections and etc. Therefore, despite a considerable amount of research in the behaviour of masonry buildings subjected to the seismic actions carried out in many countries during last decades [1, 2 and 3], it seems difficult to extrapolate the previous research results in order to predict the seismic behaviour of URM buildings in Iran. It is worth to emphasis that most of the researches have been focused on the behaviour of a single URM wall and the corresponding results cannot be extrapolated to the behaviour of a URM structure.

Most URM buildings, which are more than fifty percent of the buildings population in Iran, are characterized by un-reinforced masonry walls and many openings on exterior walls and either a one-way concrete joist slab or a steel I-beam jack arch slab. The traditional URM buildings usually are limited to the two stories with or without a basement. The steel I-beam jack-arch flooring system was, as shown typically in Figure 1, developed in early Victorian Britain and was used to cover large floor areas at warehouses. By the middle of the twentieth century it became a popular flooring system in many Middle Eastern countries. The popularity of this flooring system stems from its relatively low cost and easy construction process. This old system of flooring has shown robustness under normal gravity loading but serious lacks of criteria for an earthquake resistant slab as shown in Figure 2. An example of bam earthquake, from several cases that this kind of flooring system has been collapsed during sever earthquakes, is shown in Figure 2. As a number of advantages, the traditional jack-arch slabs are still very popular in the Middle East, particularly in Iran where even many medium rise steel framed buildings are still floored by this method. Some of these advantages include; simple construction technique, speed in construction, low cost of construction, availability of materials and workmanship and the possibility of altering the slab after construction. The floor slabs, constructed using the steel I-beam jack arch system, are stable under normal static conditions as the brick arches transfer the gravity loads mainly in compression along the arch to the supporting beams. The load is then transferred along the unconnected parallel steel beams to the supporting walls or beams. The geometric form of the steel I-beam jack-arch system and the load path through the steel beams make the slab act as a one-way system. For the purpose of simplicity the total dead load is usually assumed to be used for the design of the steel beams whereas the brick arches are not taken into the design procedure. The large stresses which usually develop in the brick arches due to the gravity loads and the earthquake out-of-plane dynamic loads are ignored by this assumption. The disadvantages of the traditional steel I-beam jack arch floor system make it inconsistence for the seismic loads. The inconsistency of the floor prevents it to act as a semi-rigid diaphragm in which significant damages including the floor collapse were observed during past earthquakes (Figure 2). The most deficiencies of the traditional un-reinforced masonry buildings are discussed in Section 2 and the detailed seismic rehabilitation procedure is then illustrated in Section 3.

2 SEISMIC VULNERABILITY ASSESSMENT

The third chapter of the ‘Iranian code of practice for the seismic resistant design of buildings, 3rd Edition of Standard No. 2800-05’ contains some criteria for designing the URM buildings which are based on engineering judgments and past earthquake experiences [5]. The seismic vulnerability assessment of any URM building can be obtained based on the following criteria.

- Limitations for the number and height of stories and opening dimensions
- Plan’s shape and aspect ratio limitations
- Symmetry
- Minimum structural walls
- Complete 3D tie system
- Floor integrity
- Floor to wall connection adequacy

By satisfaction of the above criteria, it is expected that the building can resist against the design (475 years return period) earthquake. It is equivalent to satisfy at least the “Basic Safety Rehabilitation Objective” on the basis of [6]. On the other hand, the main typical deficiencies of URM buildings in Iran can be summarized as Table I. By considering the mentioned deficiencies, in the most cases, the traditional masonry buildings are vulnerable.

Table I. The common deficiency sources in URM buildings in Iran.

Deficiency Source	Description
Floors	Inadequate connection between floor and walls
	No connection between floor components
	Floor is without integrity and diaphragm action performance
Masonry Bearing Walls	Low values for mortar shear strength
	Insufficient shear area in each storey
	Weakness of slender bearing walls due to out of plane force
3D Tie System	Large distance (more than 500 cm in most cases) between vertical tie beams
	Lack of horizontal tie beams in some axes
	Insufficient connection between tie joints
Openings	The short distance between window and the edge of wall
	The long width of window
	The large area of window
Non-Structural Masonry Walls	Weakness of non-structural walls due to out of plane earthquake force
	Insufficient connection with bearing walls (in some cases)

3 SEISMIC REHABILITATION METHODOLOGY

The ASCE 41-06 guidelines [6] introduce eight general strategies for the seismic rehabilitation of buildings which are (1) local modification of components; (2) removal or lessening of existing irregularities; (3) global structural stiffening; (4) global structural strengthening; (5) mass reduction; (6) seismic isolation; (7) supplemental energy dissipation and (8) occupancy changing. A combination of the three mentioned strategies (No. 1, 3 and 4) has been used for the seismic rehabilitation of the Iranian traditional URM buildings. For this purpose the floor integrity has been improved, the wall to wall connection was enhanced and the floor to wall connection was improved. These modifications increase the stiffness and the integrity of the floor as well as changing the boundary condition of bearing walls, load distribution and failure modes. On the other hand, the strengthening of the weak bearing walls and the opening modification has been applied. In this step the strength of the local elements were increased. All the rehabilitation procedures are summarized in this section.

3.1 Openings modification

The openings height or width in the masonry walls has been changed in order to reduce the opening dimensions as well as increasing the coupling beams dimensions. The new part of the masonry wall, as seen in Figure 3, should be connected to the existing part of the masonry wall by enough number of U shape rebars to be able to transfer the shear forces.

Figure 3. Decreasing of the opening dimensions.

3.2 Floor integrity

The traditional jack arch floor slab, as described in Section 3, can not act as an integrate slab. Hence, $50 \times 5\text{mm}$ flat bar was welded to the bottom flange of all steel I beams of the floor as shown in Figure 4. The added bar was welded, at the end, to the steel angle which is in the wall and floor intersection. The last steel I beam joist, which usually has the brick floor in only one side, should be connected to the adjacent I beam steel joist by steel flat bars at each 2 m.

Figure 4. Adding $50 \times 5\text{mm}$ steel plates in order to integrate the traditional jack arch slab joists.

3.3 Floor to wall connection

The floor to wall connection, as described in Section 3, is usually without enough strength. That is, a steel angle $60 \times 60 \times 6\text{mm}$ was added to all intersections between floor and walls. The function of the new angle can be summarized as (1) to connect the floor to the wall; (2) acts as a horizontal tie beam; (3) prevents relative movement of the steel joists in earthquake movements and (4) increases the steel joist support length. The details of the added angel are shown in Figure 5 and Figure 6, respectively, in the case of the floor slab joists are perpendicular or parallel to the wall.

Figure 5. Adding an $60 \times 60 \times 6\text{mm}$ angle to connect the wall to the floor where the floor slab joists are perpendicular to the wall.

Figure 7. A typical view of the ties enhancement.

3.5 Enhancement of the shear capacity of bearing walls

The masonry wall is enhanced by jacketing with the wire mesh and cement plaster where the capacity of the bearing wall is less than the induced earthquake forces. The details of this method, which is one of the URM wall enhancing methods, can be seen in Figure 8. The enhancement layer should be connected properly to the surrounded ties to be able to transfer the load through stories and deliver it to the foundation. Approximately nine bricks are pulled out from the existing masonry wall, as shown in Figure 9, to make the shear keys between the new layer and the existing masonry wall. The added steel mesh connects to the existing masonry wall by enough number of steel nails. The steel mesh is welded to the corner steel angels, as seen in Figure 10, to make a robust connection between the bearing wall and the floor slab. However the bearing wall is not always without openings. Hence, as shown in Figure 11, the bars should be placed around the openings and the 45° added bars should be placed around the electrical equipment boxes.

Figure 11. (left) A typical view of the enhanced bearing wall around the openings, (right) A typical view of the enhanced bearing wall around the electrical equipments box.

4 CONCLUSION

A detailed seismic rehabilitation program for a traditional un-reinforced masonry building in Iran has been described in this paper. The walls, floors, openings, and connections were enhanced in order to comply with the code requirements.

The rehabilitation program has been applied to the building under consideration in 50 days. The expense of the project was around 30% of the reconstruction cost which is quite reasonable. The minor architectural modifications were happened mainly in the size of large openings and the overall view has not been changed. This issue is important if it belongs to the client's interest or the building has any historical value.

Abstract. *In this paper the second-order homogenization of periodic masonry based on a computational analysis of the unit cell representative of the masonry wall is derived. The multi-scale approach is based on an appropriate representation of the micro-displacement field as the superposition of a local macroscopic displacement field, represented in a polynomial form related to the macro-displacement field, and an unknown micro-fluctuation field accounting for the effects of the heterogeneities. By this approach a continuous micro-displacement field is obtained, i.e. in each unit cell and across the interfaces between adjacent unit cells. The computational procedure is applied in two steps: the first one corresponds to the standard homogenization, while the second step is a second-order homogenization based on the results of the first step. Two numerical examples are presented concerning running bond and English bond masonry. For both the masonry patterns the overall elastic moduli of the second-order model and the corresponding characteristic lengths are obtained; the effects on the characteristic lengths of the stiffness mismatch between the brick phase and the mortar phase are considered. Moreover, the wave propagation in the homogenized medium is considered and dispersive waves are obtained. It is shown that remarkable differences in the phase and group velocities between the first-order and the second-order homogenized models are obtained for wavelengths shorter than ten times the average brick unit size.*

1 INTRODUCTION

The non-local homogenization of periodic masonry is a subject of some interest because in many cases the brick size is not negligible if compared with the structural size, the characteristic length of applied forces or, finally, the wavelength of waves propagating in the wall.

Cosserat constitutive models of periodic masonry have been proposed by several Authors [1-4] as result of homogenization procedures based on an idealization of the masonry as an assemblage of rigid blocks interacting through linear elastic interfaces represented as a Lagrangian system. To overcome the limits deriving from the assumption of rigid blocks Casolo [5] proposed a Cosserat homogenization based on a heuristic evaluation of the mean local rotation of the brick units. The Cosserat homogenization technique proposed by Forest and Sab [6] for continuously deformable heterogeneous media has been extended to periodic masonry by Bacigalupo and Gambarotta [7,8] and by Addessi *et al.* [9], the last contribution to include elasto-damage constitutive equations at the microscale. In Bacigalupo and Gambarotta [8] an evaluation of the reliability of Cosserat homogenization has been carried out by analysing a boundary shear layer problem concerning a masonry wall. The extension of this analysis to second-order homogenization has shown this last one to be more suitable with respect to the micropolar models (Cosserat and Couple-stresses models).

Although second-order homogenization techniques have been proposed through an extension of the classical asymptotic homogenization theory [10-13], they have not been applied in the past to the homogenization of periodic masonry because, as observed by Peerlings and Fleck [14], they result to be computationally burdensome.

The second-order computational procedure here considered is obtained by the analysis of the unit cell representative of the heterogeneous periodic material and is based on an enhanced representation of the micro-displacement field as the superposition of a local macroscopic displacement field, expressed in a polynomial form related to the macro-displacement field, and an unknown micro-fluctuation field accounting for the effects of the heterogeneities [15]. This assumption guarantees the resulting micro-fluctuation field to be continuous on the masonry domain, i.e. in each unit cell and across the interfaces between adjacent unit cells.

Running bond masonry and English bond masonry are analyzed through the second-order homogenization procedure here considered and the elastic moduli and the characteristic lengths of the equivalent continuous are obtained. Moreover, the wave propagation along the symmetry lines of the equivalent orthotropic continuum is analysed. Dispersive waves are obtained and the resulting phase and group velocity are evaluated at different wavelengths.

2 MULTI-SCALE IN-PLANE MODELLING OF PERIODIC MASONRY

Let us consider a masonry wall with periodic arrangement of the bricks in its own plane as shown in Figure 1.a. If only in-plane loads are envisaged and body forces are neglected, the masonry wall may be represented as a plane domain under the simplifying assumption of plane stress condition. The obtained heterogeneous model is analysed as a Cauchy continuum undergoing small strains and the phases are assumed to behave elastically. The position vector \mathbf{x} of a material point is denoted by its components (x_1, x_2) with respect to the reference $(0, \mathbf{e}_1, \mathbf{e}_2)$. The periodic continuum is fully characterized by the unit cell $\mathcal{A} = [0, d_1] \times [0, d_2]$ shown in figure 1.b (width d_1 and height d_2), i.e. the smallest plane portion that contains all the essential information about the masonry pattern. This unit cell is spanned by the two independent orthogonal vectors $\mathbf{v}_1 = d_1 \mathbf{e}_1$, $\mathbf{v}_2 = d_2 \mathbf{e}_2$, so that the boundary C of the unit cell is made up of two pairs of opposite sides corresponding to each other by means of a translation

along \mathbf{v}_1 or \mathbf{v}_2 . According to this representation, a variable is periodic in the unit cell \mathcal{A} , or \mathcal{A} -periodic, if it takes identical values at two points on the boundary of the unit cell whose difference is a vector of periodicity. In this sense, the elasticity tensor $\mathbb{C}^m(\mathbf{x})$ is \mathcal{A} -periodic, i.e. $\mathbb{C}^m(\mathbf{x} + \mathbf{v}_i) = \mathbb{C}^m(\mathbf{x})$, $i=1,2$.

Fig. 1 (a) Periodic masonry; (b) Unit cell and periodicity vectors.

At the material point \mathbf{x} of the heterogeneous elastic medium the micro-displacement $\mathbf{u}(\mathbf{x}, t)$ is considered together with the corresponding micro-strain tensor $\boldsymbol{\varepsilon}(\mathbf{x}, t) = \text{sym} \nabla_{\mathbf{x}} \mathbf{u}(\mathbf{x}, t)$ and the micro-stress tensor $\boldsymbol{\sigma}(\mathbf{x}, t) = \mathbb{C}^m(\mathbf{x}) \boldsymbol{\varepsilon}(\mathbf{x}, t)$ which has to satisfy the local equation of motion $\text{div}_{\mathbf{x}} \boldsymbol{\sigma}(\mathbf{x}, t) = \rho \ddot{\mathbf{u}}(\mathbf{x}, t)$. The resulting set of partial differential equations

$$\text{div}_{\mathbf{x}} (\mathbb{C}^m(\mathbf{x}) \nabla_{\mathbf{x}} \mathbf{u}(\mathbf{x}, t)) = \rho \ddot{\mathbf{u}}(\mathbf{x}, t) \quad (1)$$

has to be solved in terms of the micro-displacement components on the whole masonry wall domain with a remarkable computational burden.

Being the solution of this fine-scale computational approach out of reach, it is convenient to replace the heterogeneous model of masonry wall by an equivalent homogeneous one so obtaining equations whose coefficients are not rapidly oscillating while their solutions are close to those of the original equations. In general, an equivalent standard (Cauchy) continuum is considered, but in cases for which the unit cell size is non vanishing if compared to the wall size or to the wavelength it is convenient to introduce an equivalent second-order continuum model [16]. This continuum model is defined at the macroscale where the slow varying macroscopic position vector \mathbf{y} is considered and the displacement field $\mathbf{U}(\mathbf{y}, t)$ is defined (with component U_i in the assumed reference). The displacement gradient is denoted by $\mathbf{H}(\mathbf{y}, t) = \nabla_{\mathbf{y}} \mathbf{U}(\mathbf{y}, t)$ and, according to Germain [17], the strain field in the second gradient continuum is represented by the symmetric first-order strain tensor and by the second-order strain tensor, respectively,

$$\mathbf{E}(\mathbf{y}, t) = \text{sym} \nabla_{\mathbf{y}} \mathbf{U}(\mathbf{y}, t), \quad \boldsymbol{\kappa}(\mathbf{y}, t) = \nabla_{\mathbf{y}} \otimes \nabla_{\mathbf{y}} \mathbf{U}(\mathbf{y}, t), \quad (2)$$

the latter being a third-order tensor having components $\kappa_{ijk} = \kappa_{ikj}$ symmetric with respect to j and k .

The stress field is described by the symmetric first-order stress tensor $\Sigma(\mathbf{y}, t)$ ($\Sigma_{ij} = \Sigma_{ji}$) and by second-order stress tensor $\mu(\mathbf{y}, t)$ (third-order tensor having components $\mu_{ijk} = \mu_{ikj}$ symmetric with respect to j and k). From these stress tensors the real stress at the macro-scale is defined as $\mathbf{T}(\mathbf{y}, t) = \Sigma(\mathbf{y}, t) - \text{Div}_{\mathbf{y}} \mu(\mathbf{y}, t)$ so that, in general, $\mathbf{T}(\mathbf{y}, t)$ is not symmetric. In case of vanishing body forces, the equation of motion is expressed according to Mindlin [16] in the form

$$\text{Div}_{\mathbf{y}} (\Sigma(\mathbf{y}, t) - \text{Div}_{\mathbf{y}} \mu(\mathbf{y}, t)) = \rho_M [\ddot{\mathbf{U}}(\mathbf{y}, t) - (\nabla_{\mathbf{y}} \otimes \nabla_{\mathbf{y}} \ddot{\mathbf{U}}(\mathbf{y}, t)) \mathbf{J}], \quad (3)$$

being the inertia properties defined by the mass density at the macro-scale ρ_M and the inertia tensor $\mathbf{J} = \int_{\mathcal{A}} \rho \mathbf{y} \otimes \mathbf{y} da / \int_{\mathcal{A}} \rho da$, where ρ is the mass density at the micro-scale. The first-order and second-order stress tensors are energetically conjugate to the corresponding strain tensors by the virtual power theorem; therefore, the constitutive equations in case of linear elasticity take the form

$$\Sigma = \mathbb{C} \mathbf{E} + \mathbb{Y} \kappa, \quad \mu = \mathbb{Y} \mathbf{E} + \mathbb{S} \kappa, \quad (4)$$

\mathbb{C} being the (standard) fourth-order elasticity tensor, \mathbb{S} the sixth order tensor related to second-order stress and strain tensors and \mathbb{Y} a fifth order tensor taking into account the coupling between the first and second-order stress and strain tensors. The equation of motion of the second order continuum is obtained for centro-symmetric unit cells, namely with vanishing tensor \mathbb{Y} , from the field equations (2), (3) and (4) and takes the form

$$\text{Div}_{\mathbf{y}} (\mathbb{C} \nabla_{\mathbf{y}} \mathbf{U}(\mathbf{y}, t) - \text{Div}_{\mathbf{y}} \mathbb{S} \nabla_{\mathbf{y}} \otimes \nabla_{\mathbf{y}} \mathbf{U}(\mathbf{y}, t)) = \rho_M [\ddot{\mathbf{U}}(\mathbf{y}, t) - (\nabla_{\mathbf{y}} \otimes \nabla_{\mathbf{y}} \ddot{\mathbf{U}}(\mathbf{y}, t)) \mathbf{J}], \quad (5)$$

or in components

$$C_{ijhk} U_{h,kj} - S_{ijkpq} U_{r,pqjk} = \rho_M (\ddot{U}_i - J_{kk} \ddot{U}_{i,kk}), \quad i = 1, 2, 3. \quad (6)$$

In order to replace the first-order heterogeneous model, where the micro-fields are defined, with the second-order homogeneous equivalent medium, the variables defined at the corresponding scales have to be properly coupled by means of transition strategies for the strains and strains gradients from the macroscale to the described microstructure. In the following, a kinematic multi-scale model proposed by the Authors [15] is considered.

3 SECOND ORDER HOMOGENIZATION OF PERIODIC MATERIALS

In order to couple the kinematics of the classical continuum at the micro-scale to the kinematics of the second-order continuum at the macro-scale, the micro-displacement field in the unit cell is represented in the form $\mathbf{u}(\mathbf{x}, t) = \mathbf{u}(\mathbf{y}, \mathbf{z}, t)$. Here, \mathbf{y} denotes the position vector of the unit cell in which \mathbf{x} is located and vector $\mathbf{z} = \mathbf{x} - \mathbf{y}$ its relative position. This representation highlights the dependence of the displacement field on both the unit cell position \mathbf{y} , called the macro-position, and the local position \mathbf{z} at a point of interest. The effective micro-displacement field $\mathbf{u}(\mathbf{y}, \mathbf{z}, t)$ is approximated by the vector field

$$\mathbf{u}(\mathbf{y}, \mathbf{z}, t) \approx \mathbf{u}^a(\mathbf{y}, \mathbf{z}, t) = \mathbf{U}(\mathbf{y}, t) + \mathbf{H}(\mathbf{y}, t) \mathbf{z} + \frac{1}{2} \kappa(\mathbf{y}, t) : (\mathbf{z} \otimes \mathbf{z}) + \tilde{\mathbf{u}}(\mathbf{y}, \mathbf{z}, t), \quad (7)$$

superposition of a polynomial function depending on both the macro-displacement and the macro-strain fields and a complementary displacement field $\tilde{\mathbf{u}}(\mathbf{y}, \mathbf{z}, t)$ that represents the microstructural displacement fluctuation field at the microscale due to the inhomogeneities. To obtain continuous micro-displacement fields across the unit cell interfaces, the complementary displacement field is assumed according to [15], in the form

$$\tilde{\mathbf{u}}(\mathbf{y}, \mathbf{z}, t) = \mathbf{r}^1(\mathbf{y}, \mathbf{z}, t) + \mathbf{r}^2(\mathbf{y}, \mathbf{z}, t), \quad (8)$$

each of them having the following representation in components

$$r_i^1(\mathbf{y}, \mathbf{z}, t) = \theta_{ikl}^1(\mathbf{z}) [H_{kl}(\mathbf{y}, t) + \kappa_{klp}(\mathbf{y}, t) z_p], \quad r_i^2(\mathbf{y}, \mathbf{z}, t) = \theta_{iklp}^2(\mathbf{z}) \kappa_{klp}(\mathbf{y}, t), \quad (9)$$

where the functions $\theta_{ikl}^1(\mathbf{z})$ and $\theta_{iklp}^2(\mathbf{z})$ have to satisfy the condition of \mathcal{A} -periodicity, namely $\theta_{ikl}^1(\mathbf{z}_0^i + \mathbf{v}_i) = \theta_{ikl}^1(\mathbf{z}_0^i)$ and $\theta_{iklp}^2(\mathbf{z}_0^i + \mathbf{v}_i) = \theta_{iklp}^2(\mathbf{z}_0^i)$, $\forall \mathbf{z}_0^i \in C_i$, $i=1,2$.

The representation of the micro-displacement fluctuation field (9) in the unit cell $\mathcal{A}(\mathbf{y})$ is the key point on which the following two-step computational homogenization is based. The first step is the standard first-order homogenization in which the unknown functions $\theta_{ikl}^1(\mathbf{z})$ have to be evaluated. Here the function $\theta_{ikl}^1(\mathbf{z})$ represents the fluctuation displacement along direction \mathbf{e}_i associated to the homogeneous component $H_{kl}=1$ of the macro-displacement gradient; it is obtained by the computational analysis of the unit cell $\mathcal{A}(\mathbf{y})$ with prescribed classic periodic boundary conditions on the micro-displacement field

$$\mathbf{u}^I(\mathbf{z}_b + \mathbf{v}_i) - \mathbf{u}^I(\mathbf{z}_b) = \mathbf{H} \mathbf{v}_i, \quad \forall \mathbf{z}_b \in C_i, \quad i=1,2, \quad (10)$$

where \mathbf{z}_b is the local position vector at a point on the boundary C_i , $i=1,2$ (see figure 2.b). Once the micro-displacement $\mathbf{u}^I(\mathbf{z})$ in the unit cell $\mathcal{A}(\mathbf{y})$ is obtained for $H_{kl}=1$ prescribed, the 2^3 unknown functions $\theta_{ikl}^1(\mathbf{z})$ are evaluated $\theta_{ijk}^1(\mathbf{z}) = u_{ijk}^I(\mathbf{z}) - \delta_{ij} z_k$. Following this procedure for all the components of tensor \mathbf{H} the overall (Cauchy) elasticity tensor \mathbb{C} is evaluated through an application of the Hill-Mandel condition.

Fig. 2 Displacement vectors of points at the boundary of the unit cell.

The second step is carried out by considering a homogeneous second-order strain field and vanishing macro-strain $\mathbf{E} = \mathbf{0}$. The 2^4 unknown functions $\theta_{ijkl}^2(\mathbf{z})$ are obtained by analysing the unit cell $\mathcal{A}(\mathbf{y})$ with prescribed boundary conditions on the micro-displacement field derived from the \mathcal{A} -periodicity condition (9.2). For an arbitrary prescribed homogeneous second-order strain tensor $\boldsymbol{\kappa}$, the micro-displacement $\mathbf{u}''(\mathbf{z})$ is written at corresponding points on the boundary \mathbf{z}_b and $\mathbf{z}_b + \mathbf{v}_i$ (see figure 2) according to representation (7), (8), (9) and including the condition of \mathcal{A} -periodicity on the functions $\theta_{ijkl}^2(\mathbf{z})$

$$\mathbf{u}''(\mathbf{z}_b + \mathbf{v}_i) - \mathbf{u}''(\mathbf{z}_b) = \mathbf{u}^*(\mathbf{z}_b + \mathbf{v}_i) - \mathbf{u}^*(\mathbf{z}_b) + \boldsymbol{\Theta}^1(\mathbf{z}_b) : \boldsymbol{\kappa} \mathbf{v}_i, \quad \mathbf{z}_b \in C_i, \quad i=1,2, \quad (11)$$

$\boldsymbol{\Theta}^1$ being the third order tensor having components $\theta_{ikl}^1(\mathbf{z})$.

The boundary conditions referred to the vertical side C_1 and horizontal side C_2 are written in components in the following form, respectively:

$$\begin{aligned} u_i''(z_1^+) - u_i''(z_1^-) &= u_i^*(z_1^+) - u_i^*(z_1^-) + \theta_{i11}^{1+} d_1 \kappa_{111} + \theta_{i12}^{1+} d_1 \kappa_{112} + \theta_{i21}^{1+} d_1 \kappa_{211} + \theta_{i22}^{1+} d_1 \kappa_{221}, \\ u_i''(z_2^+) - u_i''(z_2^-) &= u_i^*(z_2^+) - u_i^*(z_2^-) + \theta_{i11}^{1+} d_2 \kappa_{112} + \theta_{i12}^{1+} d_2 \kappa_{122} + \theta_{i21}^{1+} d_2 \kappa_{212} + \theta_{i22}^{1+} d_2 \kappa_{222}, \end{aligned} \quad (12)$$

where the notation $z_i^\pm = \pm d_i/2$, $i=1,2$ and $\theta_{hkl}^{1+} = \theta_{hkl}^1(z_i^+)$ is assumed.

The corresponding micro-displacement field $\mathbf{u}''(\mathbf{z})$ is obtained by a FE analysis of the unit cell under the assumption $\mathbf{E} = \mathbf{0}$ and $\boldsymbol{\kappa}$ homogeneous in the unit cell. Each displacement functions $\theta_{iklp}^2(\mathbf{z})$ is obtained from the displacement field $u_{iklp}''(\mathbf{z})$ resulting by the FE analysis of the unit cell with prescribed non-zero component $\kappa_{klp} = 1$, as follows

$$\theta_{iklp}^2(\mathbf{z}) = u_{iklp}''(\mathbf{z}) - \frac{1}{2} (\delta_{ik} z_l z_p + \theta_{ikl}^1(\mathbf{z}) z_p + \theta_{ikp}^1(\mathbf{z}) z_l), \quad (13)$$

being the fluctuation $\theta_{ijk}^1(\mathbf{z})$ known from the first-order homogenization.

The elastic moduli of the second-order continuum are evaluated in the unit cell with reference to the macro-strain vectors $\underline{E} = \{H_{11} \ H_{22} \ H_{12} + H_{21}\}^T$ and $\underline{\kappa} = \{\kappa_{111} \ \kappa_{222} \ \kappa_{122} \ \kappa_{211} \ \kappa_{121} \ \kappa_{212} \ \kappa_{112} \ \kappa_{221}\}^T$. The Hill-Mandel macro-homogeneity condition is applied $\mathcal{E}_M^{\mathcal{C}} = \mathcal{E}_m^{\mathcal{C}}$, where $\mathcal{E}_M^{\mathcal{C}}$ is the macro-strain energy at a point \mathbf{y} of the homogenized continuum written in the following quadratic form

$$\mathcal{E}_M^{\mathcal{C}}(\underline{E}, \underline{\kappa}) = \frac{1}{2} \left\{ \begin{bmatrix} \underline{E}^T & \underline{\kappa}^T \end{bmatrix} \right\} \begin{bmatrix} \underline{\underline{C}} & \underline{\underline{Y}} \\ \underline{\underline{Y}}^T & \underline{\underline{S}} \end{bmatrix} \begin{bmatrix} \underline{E} \\ \underline{\kappa} \end{bmatrix}. \quad (14)$$

In equation (14) $\underline{\underline{C}}$, $\underline{\underline{Y}}$ and $\underline{\underline{S}}$ are the sub-matrices of the second-order elastic stiffness matrix written according to the constitutive equations (4); $\mathcal{E}_m^{\mathcal{C}} = \frac{1}{2A} \int_A \underline{\underline{\varepsilon}}^T \underline{\underline{C}}^m \underline{\underline{\varepsilon}} da$ is the mean value of the micro-strain energy over the unit cell. According to the multi-scale kinematics here considered the micro-strain field $\underline{\underline{\varepsilon}} = \{\varepsilon_{11} \ \varepsilon_{22} \ 2\varepsilon_{12}\}^T$ in the heterogeneous cell may be written in the following linear form $\underline{\underline{\varepsilon}} = \underline{\underline{B}}^E(\mathbf{z}) \underline{E} + \underline{\underline{B}}^\kappa(\mathbf{z}) \underline{\kappa}$, $\underline{\underline{B}}^E(\mathbf{z})$ and $\underline{\underline{B}}^\kappa(\mathbf{z})$ being matrices de-

pending on the functions $\theta_{ikl}^1(\mathbf{z})$ and $\theta_{iklp}^2(\mathbf{z})$, i.e. on the microstructure of the unit cell. As a consequence the mean value of the micro-strain energy turns out to be a quadratic form in the variables \underline{E} , $\underline{\kappa}$ and may be compared with the macro-strain energy (14) in order to obtain the sub-matrices

$$\underline{\underline{C}} = \frac{1}{A} \int_A \underline{\underline{B}}^{ET} \underline{\underline{C}}^m \underline{\underline{B}}^E da, \quad \underline{\underline{Y}} = \frac{1}{A} \int_A \underline{\underline{B}}^{ET} \underline{\underline{C}}^m \underline{\underline{B}}^\kappa da, \quad \underline{\underline{S}} = \frac{1}{A} \int_A \underline{\underline{B}}^{\kappa T} \underline{\underline{C}}^m \underline{\underline{B}}^\kappa da. \quad (15)$$

The matrices $\underline{\underline{C}}$ and $\underline{\underline{S}}$ are symmetric and because of the symmetry of the second-gradient strain $\kappa_{ijk} = \kappa_{ikj}$ the additional symmetries are obtained: $S_{i5} = S_{i7}$, $S_{i6} = S_{i8}$, $Y_{i5} = Y_{i7}$ and $Y_{i6} = Y_{i8}$, $i = 1, \dots, 8$. In general, the stiffness matrix of the second-order elastic plane model is characterised by 45 elasticities (matrix $\underline{\underline{C}}$ - 6 elasticities, matrix $\underline{\underline{S}}$ - 21 elasticities, matrix $\underline{\underline{Y}}$ - 18 elasticities). In the case of centro-symmetric unit cell one obtains $\underline{\underline{Y}} = \underline{\underline{0}}$ and the first order-strain and the second-order strain are uncoupled.

Finally, the constitutive equations are written in the matrix form $\underline{\underline{\Sigma}} = \frac{\partial \mathcal{E}_M}{\partial \underline{\underline{E}}} = \underline{\underline{C}} \underline{\underline{E}} + \underline{\underline{Y}} \underline{\underline{\kappa}}$, $\underline{\underline{\mu}} = \frac{\partial \mathcal{E}_M}{\partial \underline{\underline{\kappa}}} = \underline{\underline{Y}}^T \underline{\underline{E}} + \underline{\underline{S}} \underline{\underline{\kappa}}$, being the stress vectors written in the form $\underline{\underline{\Sigma}} = \{\Sigma_{11} \quad \Sigma_{22} \quad \Sigma_{12}\}^T$ and $\underline{\underline{\mu}} = \{\mu_{111} \quad \mu_{222} \quad \mu_{122} \quad \mu_{211} \quad \mu_{121} \quad \mu_{212} \quad \mu_{112} \quad \mu_{221}\}^T$, respectively.

4 IN-PLANE DISPERSIVE WAVES IN PERIODIC MASONRY

The homogenization technique presented in the previous Section allows to analyse the in-plane wave propagation in a masonry wall. Let us consider the wave propagation along the orthotropy direction \mathbf{e}_β , with $\beta = 1, 2$, represented at the macro-scale by the component of the displacement vector $U_\alpha(y_\beta, t)$ with $U_\gamma \equiv 0$ where $\alpha, \beta, \gamma = 1, 2$ and $\alpha \neq \gamma$ (see figure 3). The equation of motion of a second-order continuum is specialized to the case of an orthotropic material that is equivalent to a heterogeneous periodic material characterized by centro-symmetric unit cells and from equation (6) is written in the form

$$C_{\beta\alpha\beta\alpha} U_{\alpha,\beta\beta} - S_{\alpha\beta\beta\alpha\beta\beta} U_{\alpha,\beta\beta\beta\beta} = \rho_M (\ddot{U}_\alpha - J_{\beta\beta} \ddot{U}_{\alpha,\beta\beta}). \quad (16)$$

By noting that $\hat{c}_\beta^\alpha = \sqrt{C_{\beta\alpha\beta\alpha}/\rho_M}$ denotes the velocity of the longitudinal ($\alpha = \beta$) and transverse ($\alpha \neq \beta$) waves along direction \mathbf{e}_β in a corresponding Cauchy continuum ($S_{\alpha\beta\beta\alpha\beta\beta} = J_{\beta\beta} = 0$ in equation (16)), $\lambda_\beta^\alpha = \sqrt{S_{\alpha\beta\beta\alpha\beta\beta}/C_{\beta\alpha\beta\alpha}}$ denotes the extensional ($\alpha = \beta$) and shearing ($\alpha \neq \beta$) characteristic length of the masonry bond as shown in [15], and $J_{\beta\beta} = \eta d^2$, being d the cell size and η a parameter that depends on the geometrical and mechanical properties of the cell, the displacement equation of motion may be written in the form

$$(\lambda_\beta^\alpha \hat{c}_\beta^\alpha)^2 U_{\alpha,\beta\beta\beta\beta} - \hat{c}_\beta^{\alpha^2} U_{\alpha,\beta\beta} = \ddot{U}_\alpha - \eta d^2 \ddot{U}_{\alpha,\beta\beta}. \quad (17)$$

To evaluate the dispersion functions, the solution of equation (17) is considered having the form $U_\alpha(y_\beta, t) = A \exp[i(ky_\beta - \omega t)]$, where $i^2 = -1$, k is the wave number and ω is the an-

gular frequency. The wavelength and the phase velocity of the in-plane waves along direction \mathbf{e}_β are $\lambda = 2\pi/k$ and $c_\beta^\alpha = \omega/k$, respectively. The dispersion function corresponding to the longitudinal ($\alpha = \beta$) transverse ($\alpha \neq \beta$) oscillatory motion of the derived equivalent continuum takes the following form

$$\omega = k\hat{c}_\beta^\alpha \sqrt{\frac{1 + \lambda_\beta^{\alpha 2} k^2}{1 + \eta d^2 k^2}} = k\hat{c}_\beta^\alpha \sqrt{\frac{1 + 4\pi^2 (\lambda_\beta^\alpha / \lambda)^2}{1 + 4\pi^2 \eta (d/\lambda)^2}}, \quad (18)$$

that depends on the wave number k . From equation (18) it results that for large wavelengths ($\lambda \rightarrow \infty$) the angular frequency tends to the value related to the standard continuum, i.e $\omega \rightarrow k\hat{c}_\beta^\alpha$.

Fig. 3 Shear wave propagation along the orthotropy direction \mathbf{e}_1 .

5 NUMERICAL EXAMPLES

The computational homogenization procedure described in the previous Sections has been applied to the in-plane analysis of both running bond and English bond masonry. In both cases the bricks and the mortar are assumed elastic and isotropic in order to assess the reliability of the procedure and to analyze the propagation of elastic waves. The two steps of the homogenization procedure are carried out by a FE analysis of the unit cell and the overall elastic moduli of the second-order equivalent continuum model are obtained for different stiffness ratios E_b/E_m , being E_b and E_m the Young's modulus of the brick and the mortar, respectively. Moreover, the unit cells analysed for the two considered masonry patterns are characterized by orthogonal axes of symmetry z_1 and z_2 , so that the constitutive equations of the equivalent second-order continuum are orthotropic. The propagation of shear waves along the two axes of orthotropy z_1 and z_2 of the considered masonry bonds is analysed assuming the ratio $E_b/E_m = 10$ between the brick and the mortar Young modulus, respectively.

5.1 Running bond masonry

The considered running bond masonry having the unit square cell shown in figure 1.b is analysed. The brick dimensions are 120mm x 60mm and the mortar thickness is 10mm; the unit cell size is $d = 130\text{mm}$. The constituents are assumed isotropic, perfectly bonded and in plane stress condition. The Young's modulus $E_m = 500\text{MPa}$ of the mortar is assumed and for

both the constituents equal Poisson ratios are assumed $\nu_m = \nu_b = 0.1$. The elastic moduli of the homogeneous equivalent continuum have been evaluated for increasing values of the Young modulus of the bricks ($E_b = 10 \div 10^3 E_m$) in order to appreciate the effect of mismatch in the elastic moduli of the constituents. The mass density for bricks and mortar are $\rho_b = 1600 \text{ kg/m}^3$ and $\rho_m = 1500 \text{ kg/m}^3$ respectively. The mass density at the macro-scale ρ_M and the inertia tensor components J_{11} , J_{22} take the following values: $\rho_M = 1585 \text{ kg/m}^3$, $J_{11} = 1406 \text{ mm}^2$, $J_{22} = 1410 \text{ mm}^2$. The elastic moduli \mathbb{C} obtained by the standard first-order (Cauchy) homogenization (first step of the homogenization) are given in Table 1. The elastic moduli \mathbb{S} , obtained in the second step of the homogenization for the second order continuum are given in Table 2.

The characteristic lengths associated to the shear and to extensional strain along directions z_1 and z_2 take the form

$$\begin{aligned} \lambda_{Sh-1} &= \lambda_1^2 = \sqrt{\frac{S_{211211}}{C_{1212}}}, \quad \lambda_{Sh-2} = \lambda_2^1 = \sqrt{\frac{S_{122122}}{C_{1212}}}, \\ \lambda_{Ext-1} &= \lambda_1^1 = \sqrt{\frac{S_{111111}}{C_{1111}}}, \quad \lambda_{Ext-2} = \lambda_2^2 = \sqrt{\frac{S_{222222}}{C_{2222}}}, \end{aligned} \quad (19)$$

respectively, and the numerical values for the considered unit cell are given in Table 3. In Table 3 it is observed that when decreasing the stiffness mismatch between the brick and mortar E_b/E_m , the characteristic lengths associated with one-dimensional shear and extensional problems tend to zero.

Tab.3 Characteristic lengths (mm) of the homogeneous second-order model.

The shear dispersive waves along directions \mathbf{e}_β , $\beta = 1, 2$, for $E_b/E_m = 10$ are described in terms of the dispersion functions. The diagrams representing the dimensionless dispersion $\omega d / \hat{c}_1^2$ as a function of the dimensionless wavenumber kd are shown in figure 4 (red line \mathbf{e}_1 propagation, blue line \mathbf{e}_2 propagation) and compared with the corresponding one referred to the first-order continuum (black straight line). The group velocity $c_{g-\beta}^\alpha / \hat{c}_1^2$ and the phase velocity $c_\beta^\alpha / \hat{c}_1^2$ as functions of the wavelength are shown in figure 5, respectively. Unlike the first order continuum (Cauchy), where the frequency is proportional to the wave number, dispersive waves propagate in the second-order equivalent continuum with phase velocity c_β^α and group velocity $c_{g-\beta}^\alpha = \frac{d\omega}{dk}$ which differ at different wave numbers. In the Running bond pattern an appreciable difference between the results provided by the equivalent second-order continuum and the corresponding ones by the standard Cauchy continuum are observed in the diagrams of figures 4 and 5. For wavelength $\lambda = 5d$ from the diagrams in figure 5 one obtains $c_{g-1}^2 \approx 0.85 \hat{c}_1^2$ and $c_1^2 \approx 0.94 \hat{c}_1^2$.

5.2 English bond masonry

The English bond masonry having the rectangular unit cell shown in figure 6, with sides $d_1 = 260\text{mm}$, $d_2 = 140\text{mm}$, is considered. The brick dimensions are $250\text{mm} \times 120\text{mm} \times 60\text{mm}$ and the mortar thickness is 10mm . The constituents are assumed isotropic, perfectly bonded and in plane stress condition; the Young modulus $E_m = 500\text{MPa}$ is assumed for the mortar and equal Poisson ratio is assumed $\nu_m = \nu_b = 0.1$ for both the constituents. The elastic moduli of the homogeneous equivalent continuum have been evaluated for increasing values of the Young modulus of the bricks ($E_b = 10 \div 10^3 E_m$). The mass density for bricks and mortar are $\rho_b = 1600 \text{ kg/m}^3$ and $\rho_m = 1500 \text{ kg/m}^3$ respectively. The mass density at the macro-scale ρ_M and the inertia tensor components J_{11} , J_{22} take the following values: $\rho_M = 1581 \text{ kg/m}^3$, $J_{11} = 5625 \text{ mm}^2$, $J_{22} = 1638 \text{ mm}^2$. The elastic moduli \mathbb{C} obtained by the standard first-order (Cauchy) homogenization (first step of the homogenization) are given in Table 4. The elastic moduli \mathbb{S} , obtained in the second step of the homogenization for the second order continuum are given in Table 5. Moreover, the characteristic lengths associated to the shear and to extensional strain along directions z_1 and z_2 (see relation (19)) for the considered unit cell are given in Table 6.

$10^3 E_m$	67.7	13.5	8.4	0.11

The diagrams representing the dimensionless dispersion $\omega d_2 / \hat{c}_1^2$ as a function of the dimensionless wavenumber kd_2 are shown in figure 7 for $E_b/E_m = 10$; the group velocity $c_{g-\beta}^\alpha / \hat{c}_1^2$ and the phase velocity $c_\beta^\alpha / \hat{c}_1^2$ as functions of the wavelength are shown in the diagrams of figure 8. From these diagrams a remarkable difference between the results provided by equivalent second-order continuum and the corresponding ones from the standard Cauchy continuum are observed. For wavelength $\lambda = 5d_2$ one obtains $c_{g-1}^2 \approx 0.65\hat{c}_1^2$ and $c_1^2 \approx 0.85\hat{c}_1^2$.

6 CONCLUSIONS

The in-plane static and dynamic response of elastic periodic masonry is analyzed on the basis of a second order homogenization technique that is developed by considering an enhanced representation of the micro-displacement field at the brick scale in terms of the macro-kinematics at the structural scale. This kinematical micro-macro framework guarantees the continuity of the micro-displacement field in the representative unit cell and across the interfaces between adjacent unit cells. A computationally efficient procedure is developed which is applied in two steps: the first step corresponds to the standard homogenization, while the second step, that is based on the results of the first step, completes the second-order homogenization. Moreover, it is shown that in the equivalent second-order model dispersive waves propagate.

Running bond and English bond masonry are analysed in the examples to illustrate the capabilities of the homogenization techniques. The overall elastic moduli and the characteristic lengths of the second-order equivalent continuum are obtained by the computational homogenization carried out by the FE analysis of the unit cell and the effects of the stiffness mismatch between the brick phase and the mortar phase are considered.

Finally, it is shown that for wavelengths shorter than ten times the average brick unit size the propagation of elastic waves in the second-order homogenized model takes place with appreciable differences in the phase and group velocities with respect to the standard Cauchy model.

Abstract. *This work presents an assessment of the behavior of infilled frames. The feasibility of possible immediate implementation of some recent developments both in analysis and design of infilled frames for practical design is investigated. It is now widely recognised that masonry infill panels, used in reinforced concrete (R/C) frame structures, significantly enhance both the stiffness and the strength of the surrounding frame. However, their contribution is often not taken into account because of the lack of knowledge of the composite behaviour of the surrounding frame and the infill panel.*

Currently, Seismic Design Guidelines (EC8 – Part 3, FEMA – 440, ASCE 41-06) contain provisions for the calculation of the stiffness of solid infilled frames mainly by modeling infill walls as “diagonal struts.” However, such provisions are not provided for infilled frames with openings. The present study, based on available finite element results, proposes analytical equations for obtaining the reduction factor, which is the ratio of the effective width of a diagonal strut representing a wall with an opening over that of the solid RC infilled frame. That will allow the calculation of the initial lateral stiffness of infills when an opening is present. The validity of the proposed equations is demonstrated by comparing our results, against work done by various researchers.

1 INTRODUCTION

It has been known for long that masonry infill walls affect the strength and stiffness of infilled frame structures. In seismic areas, ignoring the frame-infill panel interaction is not always on the safe side, since, under lateral loads, the infill walls dramatically increase the stiffness by acting as a compressed diagonal ‘strut/area’, resulting, thus, in a possible change of the seismic demand due to significant reduction in the natural period of the composite structural system [1, 2].

The rationale behind neglecting infill walls in the design process is partly attributed to incomplete knowledge of the behaviour of quasi-brittle materials such as unreinforced masonry (URM), of the composite behaviour of the frame and the infill, as well as due to the lack of conclusive experimental and analytical results to substantiate a reliable design procedure for this type of structures, despite the extensive experimental efforts [3-9], and analytical investigations [10-19] over the past decades. Moreover, due to the large number of interacting parameters, if the infill wall is to be considered in the analysis and design stages, a modelling problem arises because of the many possible failure modes that need to be evaluated with a high degree of uncertainty. Therefore, it is not surprising that no consensus has emerged leading to a unified approach for the design of infilled frame systems in spite of more than five decades of research. However, it is generally accepted that under lateral loads an infill wall acts as a diagonal strut connecting the two loaded corners, an approach that is only applicable to the case of infill walls without openings on the diagonal of the infill panel. The reader is referred to Moghaddam and Dowling [20] and Asteris et al. [21] for an extensive review of research on testing and modeling of masonry infilled frames up to 2010.

In this paper the macro-modeling of infilled frames is briefly presented along with a reduction parameter for the representation of infills with openings. Then some analytical studies are presented which are calibrated on experimental results, to show the effect of the openings on the period of vibration of structures and on interstorey drifts using nonlinear dynamic analysis.

2 MACRO-MODELLING OF MASONRY INFILL

Since the first attempts to model the response of the composite infilled-frame structures, experimental and conceptual observations have indicated that a diagonal strut with appropriate geometrical and mechanical characteristics could possibly provide a solution to the problem (Fig. 1).

Figure 1: Masonry infill frame sub-assembly.

Early research on the in-plane behavior of infilled frame structures undertaken at the Building Research Station, Watford (later renamed Building Research Establishment, and now simply BRE) in the 1950s served as an early insight into this behavior and confirmed its highly indeterminate nature in terms solely of the normal parameters of design [22-24]. On the basis of these few tests a purely empirical interaction formula was later tentatively suggested by Wood [25] for use in the design of tall framed buildings. By expressing the composite strength of an infilled frame directly in terms of the separate strengths of the frame and infill, he short-circuited a mass of confusing detail and he recognized the desirability of a higher load factor where strengths were most dependent on the infills.

2.1 Single-strut models

In the early sixties, Polyakov [26] suggested the possibility of considering the effect of the infilling in each panel as equivalent to diagonal bracing, and this suggestion was later adopted by Holmes [27], who replaced the infill by an equivalent pin-jointed diagonal strut made of the same material and having the same thickness as the infill panel and a width defined by

$$\frac{w}{d} = \frac{1}{3} \quad (1)$$

where d is the diagonal length of the masonry panel. The “one-third” rule was suggested as being applicable irrespective of the relative stiffness of the frame and the infill. One year later, Stafford Smith [28], based on experimental data from a large series of tests using masonry infilled steel frames, found that the ratio w/d varied from 0.10 to 0.25. On the second half of sixties Stafford Smith and his associates using additional experimental data [3][4][29] related the width of the equivalent diagonal strut to the infill/frame contact lengths using an analytical equation, which has been adapted from the equation of the length of contact of a free beam on an elastic foundation subjected to a concentrated load [30]. They proposed the evaluation of the equivalent width λ_h as a function of the relative panel-to-frame-stiffness parameter, in terms of

$$\lambda_h = h \sqrt[4]{\frac{E_w t_w \sin 2\theta}{4EIh_w}} \quad (2)$$

where E_w is the modulus of elasticity of the masonry panel, EI is the flexural rigidity of the columns, t_w the thickness of the infill panel and equivalent strut, h the column height between centerlines of beams, h_w the height of infill panel, and θ the angle, whose tangent is the infill height-to-length aspect ratio, being equal to

$$\theta = \tan^{-1}\left(\frac{h_w}{L_w}\right) \quad (3)$$

in which L_w is the length of infill panel (all the above parameters are explained in Fig. 1).

Based on experimental and analytical data Mainstone [31] proposed an empirical equation for the calculation of the equivalent strut width, given by

$$\frac{w}{d} = 0.16\lambda_h^{-0.3} \quad (4)$$

Mainstone and Weeks [32] and Mainstone [33], also based on experimental and analytical data, proposed an empirical equation for the calculation of the equivalent strut width:

$$\frac{w}{d} = 0.175 \lambda_h^{-0.4} \quad (5)$$

This formula was included in FEMA-274 (Federal Emergency Management Agency 1997) [34] for the analysis and rehabilitation of buildings as well as in FEMA-306 (Federal Emergency Management Agency 1998) [35], as it has been proven to be the most popular over the years. This equation was accepted from the majority of researchers dealing with the analysis of infilled frames.

2.2 Multiple struts models

Crisafulli (1997) [36] in his PhD thesis investigated the influence of different multi-strut models on the structural response of reinforced concrete infilled frames, focusing on the stiffness of the structure and the actions induced in the surrounding frame. Numerical results, obtained from the single, two and three strut models, were compared with those corresponding to a refined finite element. The lateral stiffness of the structure was similar in all the cases considered, with smaller values for two- and three-strut models. It must be noted that, for the multi-strut models, the stiffness may significantly change depending on the separation between struts. The single strut model underestimates the bending moment because the lateral forces are primarily resisted by a truss mechanism. On the other hand, the two-strut model leads to larger values than those corresponding to the finite element model. A better approximation is obtained from the three-strut model, although some differences arise at the ends of both columns. Although the single-strut model constitutes a sufficient tool for the prediction of the overall response and the triple-strut model is superior in precision, Crisafulli adopted the double-strut model approach, accurate enough and less complicated compared to the other models.

More recently, Crisafulli and Carr (2007) [37] proposed a new macro-model in order to represent, in a rational but simple way, the effect of masonry infill panels. The model is implemented as a four-node panel element which is connected to the frame at the beam-column joints. Internally, the panel element accounts separately for the compressive and shear behavior of the masonry panel using two parallel struts and a shear spring in each direction as shown in Fig. 2.

Figure 2: Multi-strut model proposed by Crisafulli and Carr [37] for masonry infill panel (only the struts and the shear spring active in one direction are represented).

This configuration allows an adequate consideration of the lateral stiffness of the panel and of the strength of masonry panel, particularly when a shear failure along mortar joints or diagonal tension failure is expected. Furthermore, the model is easy to apply in the analysis of large infilled frame structures. The main limitation of the model results from its simplicity, since the panel is connected to the beam-column joints of the frame, being thus not able to properly predict the bending moment and shear forces in the surrounding frame.

The proposed model for masonry infill panels was implemented in RUAUMOKO [38], a computer-based analytical tool able to accurately model three dimensional structures whilst providing ancillary design data such as earthquake spectra. The proposed model has been also implemented in the program SeismoStruct [39] and numerical results were compared to experimental data by Smyrou [40] and Smyrou et al. [41], showing the accuracy of the model to evaluate the nonlinear response of the structure. Furthermore, they conducted an interesting sensitivity analysis to evaluate the relative importance of the parameters used in the model to represent the cyclic response of masonry.

2.3 Effect of openings in the lateral stiffness of infill walls

Although infill walls usually have oversized openings, recent research has mainly focused on the simple case of infill wall without openings. Research on infill walls with openings is mostly analytical, restricted to special cases, and as such cannot provide rigorous comparison to actual cases because of its focus on specific materials used and specific types of openings. It is worth noting that the contribution of the infill wall to the frame lateral stiffness is much reduced when the structure is subjected to reversed cyclic loading, as in real structures under earthquake conditions.

In order to investigate the effect of openings in the lateral stiffness of masonry infill walls a finite element technique proposed by Asteris [15][18] has been used in this paper. The basic characteristic of this analysis is that the infill/frame contact lengths and the contact stresses are estimated as an integral part of the solution, and are not assumed in an ad-hoc way.

Figure 3: Deformed meshes of an one-storey one-bay infilled frame using the finite element technique proposed by Asteris [15][18] (Method of Contact Points).

In brief, according to this technique, the infill finite element models are considered to be linked to the surrounding frame finite element models at two corner points (only), at the ends of the compressed diagonal of the infill (points A and B in Fig. 3a). Then, the nodal displacements are computed and checked whether the infill model points overlap the surrounding frame finite elements. If the answer is positive, the neighboring points (to the previous linked)

are also linked and the procedure is repeated. If the answer is negative, the procedure is stopped and the derived deformed mesh is the determined one (Fig. 3b).

Using this technique, analytical results are presented on the influence of the opening size on the seismic response of masonry infilled frames. Fig. 4 shows the variation of the λ factor as a function of the opening percentage (opening area/infill wall area), for the case of an opening on the compressed diagonal of the infill wall (with aspect ratio of the opening the same as that of the infill). As expected, the increase in the opening percentage leads to a decrease in the frame's stiffness. Specifically, for an opening percentage greater than 50% the stiffness reduction factor tends to zero.

Figure 4: Infill panel stiffness reduction factor in relation to the opening percentage.

The findings of the present parametric study using the finite-element method, lead to the following relationship for the infill wall stiffness reduction factor λ :

$$\lambda = 1 - 2\alpha_w^{0.54} + \alpha_w^{1.14} \quad (6)$$

in which α_w is the infill wall opening percentage (area of opening to the area of infill wall).

The above coefficient could be used to find the equivalent width of a strut for the case of an infill with opening by multiplying the results of Eqns 1, 4 and 5 above. It can also be used to modify the equations of the Crisafulli model, which is described below.

3 NUMERICAL EXAMPLE

In order to illustrate the inadequacy of the single strut models to represent the structural response of infill walls with openings in frame structures, a case-study was carried out, employing a reinforced concrete frame, whereby the infill walls are modeled with each of the two approaches. For the multi-strut case the Crisafulli double-strut model has been chosen, since it is satisfactorily precise to represent accurately the local effect between the infill and the frame and less complicated than a triple-strut model. The single-strut model used is a rather 'gross' model that can be employed in commercial packages. It consists of a pair of diagonal elastic struts that are active at all times, each of which has a stiffness of 50% of the calculated infill-wall stiffness.

Figure 5: Elevation view of the infilled frame-Location and dimensions of openings [42].

The relative accuracy of the models is assessed through comparison with experimental results obtained from pseudo-dynamic tests of a full-scale four-storey, three-bay reinforced concrete frame, which was tested at the ELSA reaction-wall laboratory within the framework of the ICONS research programme [42]. The frame was infilled with brick walls that included openings of different dimensions (Fig. 5). It can be regarded as representative of the design and construction practice of the 60's in Southern Europe, designed to withstand only vertical loads, without satisfying the modern seismic-code design-requirements.

The experimental seismic response was obtained with pseudo-dynamic testing, i.e. a step by step integration technique to compute the displacement response of the frame that was subjected to three different, numerically specified seismic records, utilizing the non-linear restoring forces actually developed during the test. The input seismic motions were chosen to be representative of a moderate-high European hazard scenario. The acceleration time-histories were artificially generated [43] and three of increasing return periods of 475, 975 and 2000 years were used for the experiment (only the first two were employed in the present study).

The non-linear structural analysis program SeismoStruct [39] was employed for the analyses. SeismoStruct is an internet-downloadable fiber-based Finite Element package capable of predicting the large displacement behavior of space frames under static or dynamic loading, considering both geometric nonlinearities and material inelasticity and fully accounting for the spread of inelasticity along the member length and across the section depth.

In section 3.1, a comparison is made between the analysis results for the above structure using a single strut and a multi-strut model. This is done to calibrate the model based on expe-

rimental data. Then, the same frame is used but having infills with the same percentage of openings in all the panels at all floors. The analyses are used to examine the influence of openings on the period of the structure and the inter-story drift. The effectiveness of the proposed model to represent the effects of soft-stories ('pilotis') is also examined.

3.1 Single strut model vs multiple struts model

Representative numerical results obtained from the single and multi-strut models are depicted in Figure 6. It can be easily concluded that the multi-strut model provides a very good fit to the experimental results and better approximation with the use of finite elements is hardly justified. However it should be stressed that the correct modeling of the infill required the selection of the value of a significant number of parameters, a difficult and intricate task, which is not always appropriate in everyday practice.

On the contrary, the single-strut model lacks a similar ability to represent adequately the experimental behavior, providing significantly less accurate results. This is entirely attributed to the inability of such over-simplified models to reproduce all the complex aspects of the infill walls' behavior. Similar to the above conclusions have been drawn regarding the displacement and the shear-force profiles along the height of the building.

Figure 6: Comparison of the top displacement of the infill frame and the two structural models (475yrp record).

3.2 Effect of openings on fundamental periods

The infill wall enhances the lateral stiffness of the framed structures, however, the presence of openings within the infill wall will reduce the lateral stiffness. Fig. 7 shows the variation of the fundamental period with the opening percentage. All values are also presented in a tabular form (Table 1), where the mass contribution for the fundamental period is given as well. The fundamental period increases as the opening size increases, as expected, due to reduction in stiffness of the model. Such variation of periods cannot be considered using the formulas proposed by design codes. There is no clear relationship between the opening size and the fundamental period, but the opening size does have an influence on the fundamental period of the structure.

By comparing the fundamental periods of a fully infilled (FI) and a bare frame (BF), a difference of magnitude of roughly 9 is observed, which is in agreement with the literature.

Figure 7: Variation of fundamental period with opening size

Openings a_w [%]	Period [sec]	Mass contribution [%]
0	0.077	59.48
25	0.139	85.76
50	0.153	88.33
75	0.256	87.26
100	0.675	83.17

Table 1: Fundamental periods and mass contributions of various percentage openings

Figure 8: Elastic acceleration spectra for a 475 yrp and the fundamental periods of a fully infilled frame (FI), a partially infilled frame (PI) and a bare frame (BF)

An elastic spectrum according to the standard EC 8 [44] for ground type A was chosen, as can be seen in Fig. 8. In this figure, the periods of the idealized systems representing the fully infilled frame ($T=0.077$ s), a partially infilled frame (with 50% of openings) ($T=0.153$ s) and a bare frame ($T=0.675$ s) are indicated. It can be observed that the spectral acceleration, which corresponds to the bare frame (BF), is only about half of the spectral acceleration, which corresponds to the partially infilled frame (PI) and a bit lower than the corresponding value for a fully infilled frame (FI). It is clear that such a variation of the period of vibration will have a considerable effect on the dimensioning of the infilled-frame members.

3.3 Effect of openings on inter-storey drift ratios

The displacement variation along the building height is a typical way of illustrating the behaviour of a building in each storey. A better representation of the above is the use of the interstorey drift curve given in Fig. 9.

Figure 9: Inter-storey drift after 15 load-cycles (475 yrp)

This figure shows the inter-storey drift ratio after 15 complete load cycles. The ‘weakness’ of the second floor is more pronounced when larger openings in the infill panels are present. Three different cases of openings are illustrated and the resulting inter-storey drift ratio confirms the previous statement. The same conclusion was reached by Dorji et al. [45], who presented the inter-storey drifts ratios for three different opening percentages.

Fig. 10 shows the response-history of the infilled frame for the same percentages of openings as those of Fig. 9. When there are no infill walls ($a_w = 100\%$) the interstorey drifts are considerably larger compared to the ones for the other two cases, when the structure is considerably stiffer. Even in the case when there are 50% openings the interstorey drifts are considerably smaller than those of the bare frame. Another observation is that there is clear distinction in the periods of vibration of the three structures with the bare structure having the larger and the fully infilled the smaller of the three.

Figure 10: Response-history of inter-storey drift of the 1st floor for 0%, 50% & 100% openings (475 yrs)

Figure 11: Inter-storey drift showing the soft-storey effect after 15 load cycles (475 yrs)

The applicability of the proposed procedure for representing the openings in the walls was examined by introducing a ‘pilotis’, which may cause the soft-storey phenomenon during dynamic earthquake loads. This study investigated this problem by comparing two models;

- A structure with fully infilled frames throughout the height of the building.
- A structure which does not have any infill at the first floor but has fully infilled frames in the rest of the floors, representing the presence of a ‘pilotis’.

From Fig. 11, which shows the results at the 15th cycle of the analysis, it can be concluded that there is a strong soft-storey effect, which is captured by the proposed modeling. The drift ratio value at the ground floor for case (b) is increased almost 5 times when compared to case (a).

4 CONCLUSIONS

In this paper the attempts of researchers through many decades to model infill walls are summarized and the most commonly used macromodels are presented. One of the main difficulties to introduce infill walls, which are universally accepted as having a significant influence in the response of frames in the modeling of structures is the absence of a way to represent openings in the infills. In this work, a reduction factor, λ , is proposed that can be used as a multiplication factor on well know equations to calculate the reduced equivalent width of compression struts, so as to be able to model infill walls with openings. The same reduction factor can be use in models of multiple-struts so as to be able to idealize the nonlinear behaviour of infill walls with openings.

Using this approach, a two-strut model, which was calibrated on experimental results, was used to examine the effects of openings on the period of vibration of infilled structures with openings and on interstorey drifts.

It was shown that, as expected, the period of vibration of the structures is largely affected by the presences of openings, which in turn has an effect on the earthquake load that such structures will be subjected to during an earthquake. The period of vibration of the infilled frame was found to be 9 times smaller than that of the bare frame, with the periods of vibration of the frames with openings to be in-between, but without a clear trend.

Regarding the interstory drifts, it is shown that at the beginning of the analysis, when the infill and the structure are still in linear behaviour, the bare frame has interstory drifts of the order of 2 times larger than those of the fully infilled frame (Fig. 9). When the structure moves into more cycles, this difference goes as high as 3 times larger (Fig. 10).

The proposed procedure was also used to study the behaviour of a structure with a soft-storey, and as it is shown in Fig. 11, the interstory drift at the 1st storey has increased dramatically, while a small increase was also introduced in the higher stories.

It can be therefore concluded, that the proposed reduction factor can be used to model infill frames with openings with satisfactory results. Further work needs to be done, using a larger number of ground motions and frame configurations , so as to fully validate this methodology.

Abstract. *In recent years the evaluation of risk levels of existing buildings by Rapid-Visual-Screening (RVS) has become a common tool for seismic hazard assessment. If RVS is applied to buildings of similar type located in a well-defined urban area, it is useful to specify and to adapt existing screening rules and forms to the needs of these buildings. In a research effort presented in this paper the RVS procedure is adapted for the seismic assessment of historic residential brick-masonry buildings located in the City of Vienna, Austria. Considering the consistent building typology the proposed RVS methodology enhances the validity and quality of the seismic hazard assessment of this type of buildings. The evaluation and assessment methodology is based on two parameters, i.e. the damage relevance DR, and the structural parameter SP. Limiting conditions of the damage relevance DR are generated for risk classification to consider human and economic influence of damages on a certain building. The structural parameter SP consists of several indicators to describe the condition of certain structural parts of the building itself. In a large-scale in situ investigation a set of 375 buildings within the 20th district of Vienna has been evaluated by the proposed methodology. The results of this visual investigation are integrated into a local seismic building hazard map.*

1 INTRODUCTION

1.1 Objective

Reliability of existing buildings against seismic collapse is a major issue of a comprehensive seismic hazard assessment. Particularly in urban areas with a huge amount of historic buildings the evaluation and assessment of those buildings is essential. In the city center of Vienna so-called *Gründerzeithäuser*, historic residential brick-masonry structures erected within the building phase between 1840 and 1918, represent the predominant type of building. Mostly, these structures have been retained unchanged without considerable structural improvement for decades, but nevertheless are typically still used as residential buildings. Especially the lack of information and scientific investigations about the material properties, the detailed construction, and the dynamic behavior of those buildings has led to many discussions about their vulnerability under seismic loading.

The main intent of the investigations proposed in this paper is to carry out a comprehensive assessment and evaluation methodology based on visual inspections for historic brick-masonry buildings in Vienna in order to obtain a realistic estimation of the damage potential under seismic loading of this particular building type [1].

1.2 Prevalent Risk Assessment Methodologies

Several different methodologies for the assessment and classification of existing buildings were developed in the last few years [2]. Many of them, so called Rapid-Visual-Screening (RVS) techniques, are based on visual inspection of the buildings using predefined forms. Their main advantage is the fast and elementary implementation, which allows the user to evaluate a huge amount of buildings in a relatively short time period.

Particularly in areas with high seismicity the application of RVS techniques is widespread. One of the basic documents, developed and used in the United States of America, is the RVS technique described in the handbook for seismic evaluation of existing buildings by the Applied Technology Council [3]. This method has already been used for years and is an important foundation for various international techniques. In particular the method is based on a scoring system, whereby different building parameters are classified and benchmarked.

Apart from the RVS procedures in the United States of America several other techniques have been developed in different countries. The Japanese technique [4] is based on the so-called Seismic Index (I_s), which describes the resisting earthquake capacity of a story and is estimated from the strength and ductility of the building, the regularity of the building and a certain time index. In contrast, the RVS procedure in Canada accounts for structural parameters, such as the stiffness and the regularity of the building, as well as for nonstructural parameters including the foundation of the building, building occupancy, importance of the building, and falling hazards. Compared to other countries, India has a very large amount of existing buildings of different types, which led to the development of different RVS procedures in the last few years [5, 6].

Most of the European RVS procedures were developed in Greece [7, 8] and in Turkey [9, 10, 11], whereby the investigated masonry buildings of the high seismicity area of Istanbul [12, 13] are of primary interest for the proposed RVS procedure developed for historic residential brick-masonry buildings in Vienna.

The fundamentals of the procedure described in this paper were developed for historic masonry buildings in Italy [14] and Portugal [15]. On the one hand, the assessment of brick-masonry facades can be directly applied by quantifying the building geometries [1, 14]. On

the other hand the connection of the damage relevance DR with damage grades from EMS-98 [16] according to *Ferreira* [15] gives a reliable estimation of the possible extent of losses.

Among the numerous other RVS procedures methods developed in Germany [17, 18] are of particular interest for the proposed RVS technique in Vienna, as they were applied on similar historic buildings in areas with comparable seismicity.

2 APPLICATION TO HISTORIC RESIDENTIAL BUILDINGS IN VIENNA

2.1 Basic Data

It was necessary to consider historic documents, such as building codes from the 19th century [19, 21, 22, 29] and findings from actual investigations [23, 24, 25], in order to develop a suitable RVS procedure for the historic residential brick-masonry buildings in Vienna. Particularly in the last few years a guideline for the in-situ assessment for existing buildings was developed, mainly focused on the evaluation of the state of preservation of the structural system [24].

2.2 Inspection Form and Rating Methodology

As most of the international RVS procedures are focused on typical construction types, an adopted method with specific parameters for the historic residential buildings in Vienna had to be developed. The fundamentals for the evaluation and assessment methodology are based on two types of parameters to describe

- the damage relevance DR and
- the structural parameter SP of the inspected building,

as shown in [26]. The damage relevance DR includes parameters to evaluate the social and economic influence of damages on a certain building. One of the main parameters of the damage relevance is the number of exposed persons within the inspected object. An overview on the content of the damage relevance DR and the description and quantification of several parameters is presented in Table 1. The structural parameter SP mainly consists of single indicators to describe certain structural parts of the building itself. The most important parameters, which can be directly related to earthquake induced damage, are the regularity of the building in elevation and the state of preservation. The description of the structural parameter SP is given in Table 2.

To categorize and prioritize the buildings the combination of damage relevance DR and structural parameter SP is used to define hazard classes:

Hazard Class <i>I</i> :	$SP < 50$ and $DR < 50$
Hazard Class <i>II</i> :	$80 > SP \geq 50$ and $DR < 100$ or $100 > DR \geq 50$ and $SP < 80$
Hazard Class <i>III</i> :	$140 > SP \geq 80$ and $DR < 150$ or $150 > DR \geq 100$ and $SP < 140$
Hazard Class <i>IV</i> :	$SP \geq 140$ or $DR \geq 150$

The visualization of the conditions to define the hazard classes is illustrated in Figure 1.

Parameter	Description	Benchmarks
D ₀₁ Human exposure	Number of endangered individuals within the inspected object (estimation accepted in case of limited accessibility of the inspected object).	$D_{01} = \text{No. of Individuals}$
D ₀₂ Importance	Importance of the inspected object according to [27], ranging from importance class I to IV.	$D_{02} = 1.0 - 50.0$
D ₀₃ Economic importance	Useable living area ULA multiplied by the potential price per m ² and consideration of the remaining life time RLT of the inspected object.	$D_{03} = \frac{ULA \cdot Price}{100000} \cdot \frac{RLT}{25}$
D ₀₄ Material assets	Consideration of buildings with special purposes ranging from residential use (I), to archives and libraries (II) and museums or churches (III).	$D_{04} = 1.0 - 10.0$
D ₀₅ Neighboring effects	Assessment of possible effects due to collapsed buildings or building parts, ranging from low exposure (I), to medium exposure (II) and high exposure (III).	$D_{05} = 1.0 - 10.0$
Damage Relevance		$DR = \sum_{i=1}^5 D_i$

Table 1: Set of parameters describing the damage relevance DR .

Parameter	Description	Benchmarks
S ₀₁ Seismicity	Evaluation of the seismic zone according to [28].	$S_{01} = 1.0 - 1.5$
S ₀₂ Regularity in plan	Classification of the regularity in plan according to [27] and a defined regularity in plan [1].	$S_{02} = 1.0 - 10.0$
S ₀₃ Regularity in elevation	Consideration of vertical irregularities with special attention on soft stories.	$S_{03} = 1.0 - 100.0$
S ₀₄ Type of construction	Evaluation of steel ties, masonry ceilings, etc. [1].	$S_{04} = 1.0 - 25.0$
S ₀₅ Local failure	Potential local failure mechanism of the facades of the inspected buildings [1] according to [14].	$S_{05} = 1.0 - 20.0$
S ₀₆ Secondary structures	Evaluation of exposed secondary structures [1] (chimneys, sculptures and statues of the façade, etc.).	$S_{06} = 0.0 - 20.0$
S ₀₇ Soil conditions	Assessment of the local soil conditions classified according to [27].	$S_{07} = 1.0 - 10.0$
S ₀₈ Foundation	Classification of the foundation of the inspected building [1].	$S_{08} = 1.0 - 10.0$
S ₀₉ State of preservation	Evaluation of the state of preservation of the structure [1] (ceilings, columns, brick-masonry, etc.).	$S_{09} = 0.0 - 30.0$
Structural Parameter		$SP = \sum_{i=1}^9 S_i$

Table 2: Set of parameters describing the structural parameter SP .

To simplify the visual screening of the building on-site a short inspection form was generated [1]. The form should give the surveyor a step-by-step concept and support the inspection. After digitalization of the data several parameters were generated automatically.

Figure 1: Visualization of the conditions to define the hazard classes.

2.3 Damage Estimation

The outcome of post-earthquake assessment reports was used to correlate the evaluated results from the proposed RVS technique for historic residential brick-masonry buildings in Vienna with a possible damage behavior under seismic action. This method can be used if no particular vulnerability curves of the inspected buildings are available [15].

In a first step an earthquake event with similar characteristics like it is predicted for the Vienna basin area [29] related to magnitude, focal depth and site properties as well as adequate building stock was selected. From the past earthquakes the 2009 Earthquake, which hit the city of L'Aquila in the Abruzzo region in Italy, was chosen [30]. The description of damages occurred to historic residential masonry buildings after this event can be found in [30, 31]. The main outcome of the post-earthquake reports was that some of the proposed structural parameters for historic residential brick-masonry buildings in Vienna can be directly related to seismic damage. The most important ones apparently are the regularity in elevation, soft stories and the detailed design of connections between timber ceilings and bearing walls and of course the state of preservation of the affected building structure.

The comparison between damages occurred in L'Aquila [30, 31], the damage description of the EMS-98 Scale [16], which are given in Table 3, and the outcome of the RVS technique for historic residential brick-masonry buildings in Vienna led to the relations listed in Table 4.

Grade	Description of Damage	Visualization
Negligible to slight damage (no structural damage, slight non-structural damage)		
1	<ul style="list-style-type: none"> - Hair-line cracks in very few walls - Fall of small pieces of plaster only - Fall of loose stones from upper parts of buildings in very few cases. 	
Moderate damage (slight structural damage, moderate non-structural damage)		
2	<ul style="list-style-type: none"> - Cracks in many walls - Fall of fairly large pieces of plaster - Partial collapse of chimneys 	
Substantial to heavy damage (moderate structural damage, heavy non-structural damage)		
3	<ul style="list-style-type: none"> - Large and extensive cracks in most walls - Roof tiles detach - Chimneys fracture at the roof line - Failure of individual non-structural elements (partitions, gable walls). 	
Very heavy damage (heavy structural damage, very heavy non-structural damage)		
4	<ul style="list-style-type: none"> - Serious failure of walls - Partial structural failure of roofs and floors 	
Destruction (very heavy structural damage)		
5	<ul style="list-style-type: none"> - Total or near total collapse 	

Table 3: Classification of masonry buildings according to EMS-98 [16].

Therein several values of the assessment results, which were interpreted as boundary conditions for the proposed hazard classes, were related to predicted damage grades according to EMS-98 [16] and relevant structural conditions, which have to be fulfilled by the inspected object. It is obvious that buildings with high regularity in plan and elevation and a very good state of preservation, which were classified in hazard class *I*, should resist an earthquake similar to the one occurred in L'Aquila [30] with moderate damages. On the other hand building structures with high irregularity in elevation and potential soft stories, which are generally in a poor state of preservation and therefore were classified in hazard class *IV*, might be predicted to show very heavy damages up to total destruction of the building under the exposure of the proposed earthquake. In between the buildings with slight or moderate irregularity in plan and elevation and moderate up to good state of preservation, which were classified into hazard classes *II* or *III* respectively, were predicted to show different grades of damage according to EMS-98 [16], ranging from moderate to very heavy damage.

Hazard Class	Assessment requirements Structural Parameter SP Damage Relevance DR	Predicted Damage Grade based on EMS-98	Relevant Structural Conditions
<i>I</i>	$SP < 50$ and $DR < 50$	2	High regularity in plan and elevation; excellent state of preservation
<i>II</i>	$80 > SP \geq 50$ and $DR < 100$ or $100 > DR \geq 50$ and $SP < 80$	2-3	Slight irregularity in plan and elevation; good state of preservation
<i>III</i>	$140 > SP \geq 80$ and $DR < 150$ or $150 > DR \geq 100$ and $SP < 140$	3-4	Moderate irregularity in elevation; subsequently removed bearing elements; moderate state of preservation
<i>IV</i>	$SP \geq 140$ or $DR \geq 150$	4-5	High irregularity in elevation; soft-story; in general poor state of preservation

Table 4: Set of parameters describing the structural parameter SP .

3 APPLICATION

The developed RVS technique for historic residential brick-masonry buildings in Vienna has been calibrated by application to a set of buildings with very well known construction type, material behavior, and socio-economic parameters. These 18 buildings distributed across the historic city center of Vienna should represent a wide range of evaluation parameter possibilities. A comprehensive description of those buildings, the results of the RVS technique application and outcome of the calibration are shown in [1].

After the calibration of the technique a large scale experimental investigation was performed. Therefore an adequate test area was chosen in the 20th district of Vienna with a set of 375 historic residential brick-masonry buildings. A site plan of the test area is shown in Figure 2 with the inspected objects highlighted in red. It can be seen that the historic residential brick-masonry buildings are the predominant building type within the test area. In particular, whole blocks of buildings remained homogeneous since their erection in the 19th century.

3.1 Results

According to the developed RVS technique an engineer was trained on the characteristics of the methodology. The inspection of the buildings was performed continuously within a time period of three months. Besides the in-situ completed inspection forms where digitalized and analyzed. The comprehensive results of each inspected building and any evaluated parameter can be found in [1]. In Figure 3 the results of the damage relevance DR plotted against the structural parameter SP of the large scale application is shown.

Figure 2: Map of the test area in Vienna; inspected historic residential buildings (highlighted in red).

Figure 3: Results of the damage relevance DR plotted against the structural parameter SP of the large scale application.

It can be seen from Figure 3 that the results of the large scale experiment show a precise separation of hazard classes *III* and *IV* either in terms of the damage relevance *DR* or the structural parameter *SP*. Hence inspected objects classified in hazard class *IV* either have a comparatively high damage relevance *DR*, predominantly caused by the high number of exposed persons within the building, or have a very high structural parameter *SP*, which can be only generated by an irregularity in elevation.

According to Figure 3 most of the inspected objects were classified in hazard classes *II* or *III*, whereby no precise separation between those classes can be observed. The main reason for that is the high number of different parameters and hence the benchmarks of a single parameter at a specific building may vary a lot.

The previously proposed methodology was used to correlate the results of the RVS assessment with predicted building damage, see section 2.3. In a first step the inspected objects were classified according to their structural parameter *SP*. Hence the damage grades according to EMS-98 [16] were correlated with the inspected buildings considering the scheme from Table 4, see Figure 4. It can be seen that the separation between damage grades 3 and 4 according to EMS-98 does not exactly correspond to the classification of the hazard classes *II* and *III* from Table 4. The reason therefore is that the frequency distribution of the structural parameter *SP* of the inspected buildings gives a better separation at $SP = 100$, instead of $SP = 80$ from Table 4. In general the direct correlation between hazard classes and damage grades according to EMS-98 seems to be problematic, as the damage distribution of different buildings within a certain hazard class may vary, as already shown in Table 4. Nevertheless the correlation of the results from the RVS technique with EMS-98 damage grades offers a comprehensive and fast prediction of the possible consequences of a certain earthquake. An illustrative presentation of the results from the investigated test area is shown in Figure 5.

Figure 4: Correlation between damage grades according to EMS-98 [16] and the structural parameter of the inspected buildings.

4 CONCLUSIONS

The Rapid-Visual-Screening (RVS) technique is a fast and widespread method for seismic hazard assessment of existing buildings. During the last few years a RVS technique for historic residential brick-masonry buildings in Vienna was adopted, due to the fact that those buildings represent the predominant type of constructions in the city center of Vienna and so far there was no information about their resistance against seismic actions.

The developed methodology to assess historic brick-masonry buildings consists of a visual inspection form and the subsequent evaluation of several parameters to capture the effects of possible damages to the environment and to describe and rate the structural behavior of the building. Furthermore the buildings were classified into certain hazard classes to prioritize the building stock by using the evaluated parameters.

Post-earthquake assessments from adequate past earthquake events have been used to correlate the results of the RVS technique with realistic seismic damages and hence EMS-98 damage grades were predicted.

In a large-scale investigation a set of 375 historic brick-masonry buildings were evaluated by the proposed methodology. The results of these tests could be integrated into a local seismic building hazard map.

The outcome of the proposed methodology supplies a good prediction of the damage distribution within the test area. The evaluated hazard maps give useful information for emergency and evacuation planning as well as for identification of critical objects and further investigations.

ACKNOWLEDGEMENT

The investigations described were performed within the Austrian research project SEISMID [32], which aims among others to develop a methodology to assess the actual seismic bearing capacity of historic buildings. SEISMID is funded by the ZIT Center for Innovation and Technology, which is a subsidiary of the Vienna Business Agency (WWFF). This support is gratefully acknowledged.

Keywords: Confined masonry wall, DIANA, Pushover, Tie elements, Confinement.

Abstract. *In this study the nonlinear finite element analysis has been employed to find out how the properties of ties, either vertical or horizontal, affect the seismic behavior of confined masonry walls. For this purpose the DIANA software (Version 9.3), which is powerful tool for numerical modeling of such structures, has been used. Among the parameters, which are believed to be effective in the confined wall seismic behavior, four ones relate to the ties. These include compressive strength of concrete used in tie elements, cross sectional area of ties, the amount of longitudinal reinforcement in vertical ties, and finally the rigidity of connections between horizontal and vertical ties. With regard to the amounts of the four mentioned parameters, the values recommended by the National Iranian Code of Practice for Seismic Design of Buildings (Iranian Standard No. 2800) were used as the bench mark values. The type of analysis conducted for the wall numerical samples was Push-Over Analysis (POA) and in all cases some reasonable value was considered for the amount of surcharge imposing on the confined wall due to the dead load of the corresponding floor. The results of POA were obtained by assigning various values, from very low to very high, to the four mentioned parameters, and the lateral force – displacement curves were plotted for each set of values. Numerical results show that with variations of the four parameters, considered for the ties' properties, between some limits the global behavior of wall changes slightly, however, if some of these four parameters get values beyond some limits the wall behavior changes drastically from one state to another.*

1 INTRODUCTION

It is more than 100 years that confined masonry structures are used in construction. This type of structure is consisted of masonry walls and confining elements (horizontal and vertical ties), located at four sides of the wall panel. The confining elements are usually made of reinforced concrete (R/C), steel profile, or timbers. Therefore, the features of the confined walls are a combination of those of un-reinforced masonry walls and reinforced concrete or other used frames. It should be noted that the performance of confining elements is not similar to the performance of common R/C beams and columns, and is basically for creating the following features in the confined wall [1]:

- a) Increasing the stability and integrity of the wall against seismic in-plane and out-of-plane forces,
- b) Increasing the strength of the wall,
- c) Decreasing the brittleness of the wall.

These features all together lead to better seismic performance of the wall. The major difference between these walls and the R/C frame with infill walls is that the infill walls do not act as the load bearing elements, while the Confined Masonry Wall (CMW) is basically a load bearing element. The purpose of this research is studying the effect of confining elements on the behavior of confined masonry walls. These effects consists of compressive strength of concrete used in tie elements, cross sectional area of ties, the amount of longitudinal reinforcement in vertical ties, and finally the rigidity of connections between horizontal and vertical ties. For the four mentioned parameters the values recommended by the National Iranian Code of Practice for Seismic Design of Buildings (Iranian Standard No. 2800) were used as the bench mark values and then the change of these values was studied on the behavior of CMW's in the form of capacity curve and fracture mechanism. Non-homogeneity and anisotropy of the wall materials has made its modeling very difficult, particularly when post-cracking analysis is concerned. Lourenco has presented a constitutive behavior model for the unreinforced masonry walls [2]. In that method, masonry wall is modeled as a continuous homogenous and anisotropic medium, and Rankine-type's criterion is used as the yielding criteria in tension and Hill-type's criterion in compression. In the detailed analyses, performed by DIANA (version 9.3) computer program in this study, Lourenco model [2] was used for the nonlinear behavior of wall. It takes into account the different strengths in directions parallel and perpendicular to bricks interfaces with mortar. In the detailed models, considered for analyses, cracking in ties concrete, interaction between ties and wall, and interaction between walls and its foundation, reinforcing steel bars in ties and orthotropic behavior in masonry wall were considered. The type of analysis was nonlinear static analysis (pushover) based on displacement control and in all of the analysis the weight of components and surcharge were considered.

2 STATING THE PROBLEM

The purpose of this research is to evaluate the effect of properties of the tie columns and beams on the behavior of CMW. In the codes and guidelines of confined masonry structures the properties of confinement elements are prescribed and nominal. For example, in the National Iranian Code of Practice for Seismic Design of Buildings (Iranian Standard No. 2800) horizontal and vertical ties are in the form of reinforced concrete with dimensions of 20×20 cm for vertical ties, and 20×20 and 20×35 cm for horizontal ties, corresponding to 22 and 35 cm wall thickness respectively. Reinforcement inside ties was assumed to be consisted of 4 steel bars of 10mm diameter with yielding strength 300MPa and Compression strength of concrete was also assumed to be 15MPa. In this research these values were

considered as the bench mark values and the effect of change of these parameters was evaluated on the behavior of CMW. In modeling the properties of masonry wall was fixed and the geometrical and mechanical properties were assumed to be the same for all cases. The thickness of wall was assumed 22 cm, the length and height of wall was considered as 3 meters and the surcharge was 23.2 N/mm. The tensional and compressional strengths of masonry unit were equal to 0.25 and 6.23 MPa, respectively. In addition to benchmark values for tie elements the compression strength of concrete was assumed as 10 and 20 MPa, cross sectional area of ties 10×10, 15×15, and 25×25 cm, assuming that the width of horizontal tie as 20 cm for all cases. The amount of longitudinal reinforcement in vertical ties was 4φ6, 8, 14. For studying the effect of connection's rigidity between horizontal and vertical tie elements the type of tie elements was changed, such that in case of rigid connection the beam elements was used for ties, and in case of hinge connection the truss element was used. Using the aforementioned quantities and taking into account the wall weight in loading process, and assuming the boundary conditions of wall as a cantilever, the pushover analysis in displacement control state were performed with a target displacement of 30 mm (0.01h) [3], and the capacity curves for all of the numerical models were developed.

3 MODELING

For modeling the masonry walls in DIANA (version 9.3) software, the Continuum Finite Element method (macro-model method) was used, which has relatively high precision and is also more appropriate for studying the general behavior of walls, and enormous analysis cases [2]. In this method, masonry wall is simulated in the form of a continuous homogenized environment and Rankin-type's criterion and Hill-type's criterion are used for expressing the inelastic behavior in tension and compression respectively. These models also take into account the orthotropic behavior. The value of fracture energy in compression and tension were considered as common values in clay brick materials, which are in the vertical direction, respectively, 0.018N/mm in tension and 15N/mm in compression. Furthermore, the combined crack-shear-crush interaction model is believed to be suitable for the simulating fracture caused by tension, fractional slide caused by shear and crush resulted from compression [4]. Regarding the existence of friction between the wall and its foundation after cracking, this model was also considered to be suitable for simulating wall-foundation interaction [5].

For wall-ties-interaction the discrete crack model was used [6]. Normal and shear stresses are functions of total relative displacement, i.e. width and slide of crack. Tension and shear strengths and stiffness after crack between tie and wall were neglected and the behavior of element was considered in brittle type without softening. To avoid the penetration of wall and tie elements into each other, a large value was considered for the axial stiffness in compression. For the numerical stability of interaction element, sliding, with initial shear stiffness, is likely. Beam elements with moment resisting connections were used in order to model the confining elements in the software. For modeling the concrete material of ties the Total Strain Rotating Crack was used [6]. In this model, stresses were defined based on the strain-stress relation, and the average principal strain rate was calculated and transferred to the global system of coordinates of the element [7]. Stress-strain relation defined in modeling for the tensile stress was the Maekawa model [8], and for the compression stress was the perfect elasto-plastic considering 28-day compression strength of concrete. Finally, for modeling the reinforcement of ties the longitudinal bars were assumed to have full bond with concrete around them and follow von Mises Criteria with perfect elastoplastic flow criteria [6].

4 VERIFICATION OF NUMERICAL MODELING

For verifying the numerical modeling, those developed based on the behaviors explained in the previous section were compared with some experimental models. These models include a double-storey concrete frame without infill walls for verifying the ties modeling [9], one masonry wall without confinement for verifying masonry wall modeling [10], and also one confined masonry walls for verifying the modeling of the compound system of masonry wall and ties [11]. Lateral loading was monolithically applied to the numerical models, and at first the vertical loading and after that the lateral loading was applied. Figures 1 to 3 shows comparisons between the experimental results and those obtained by the developed numerical models in this study.

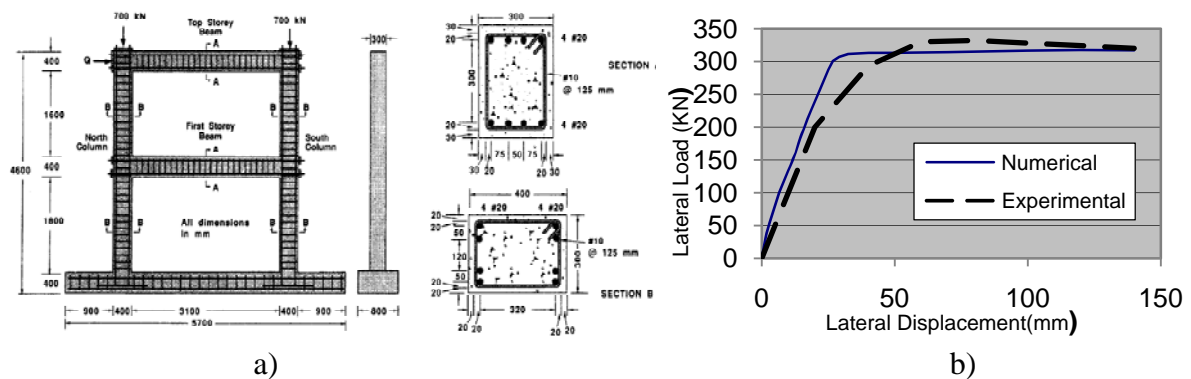

Figure 1. Comparison between experimental and numerical models related to the 2-storey concrete frame [9]: a) the 2-story frame and its features, b) the capacity curves

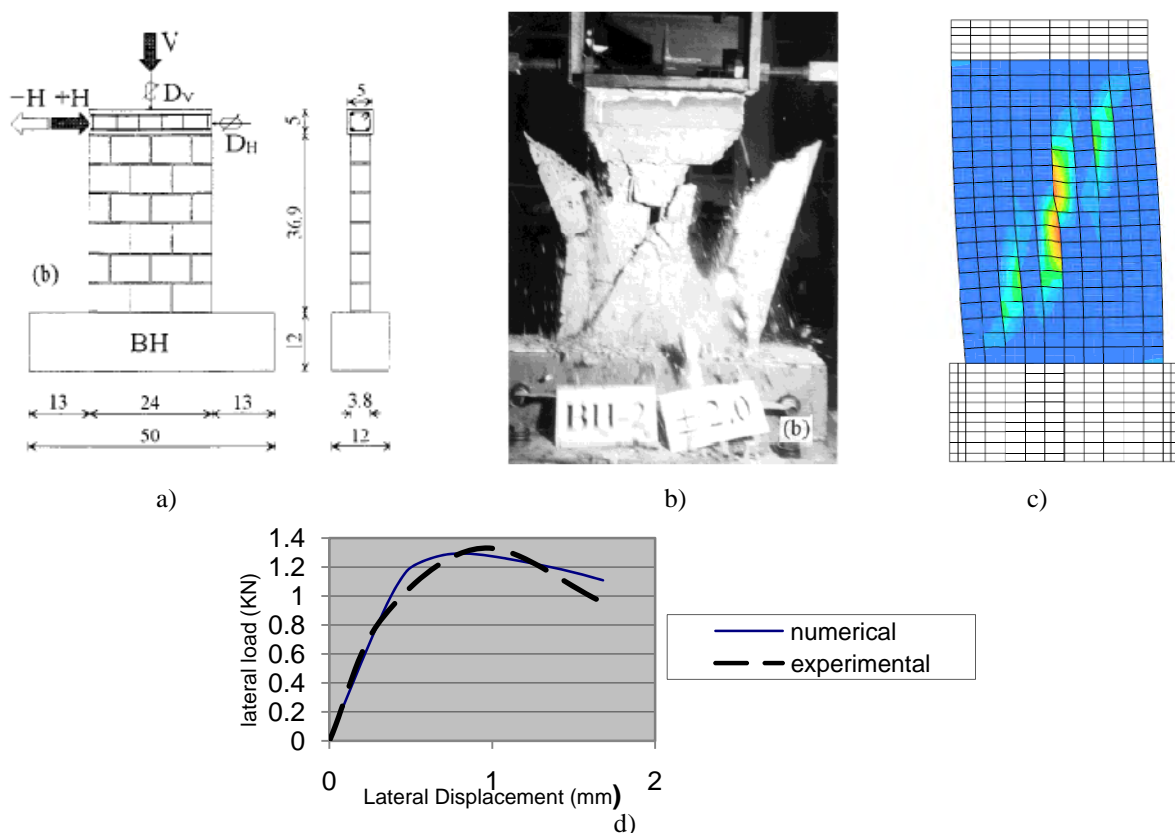

Figure 2: Comparison between experimental and numerical models related to the masonry wall without Confinement [10]: a) the experimental model, b) the experimental fracture mechanism, c) the fracture mechanism obtained by DIANA, d) the capacity curves

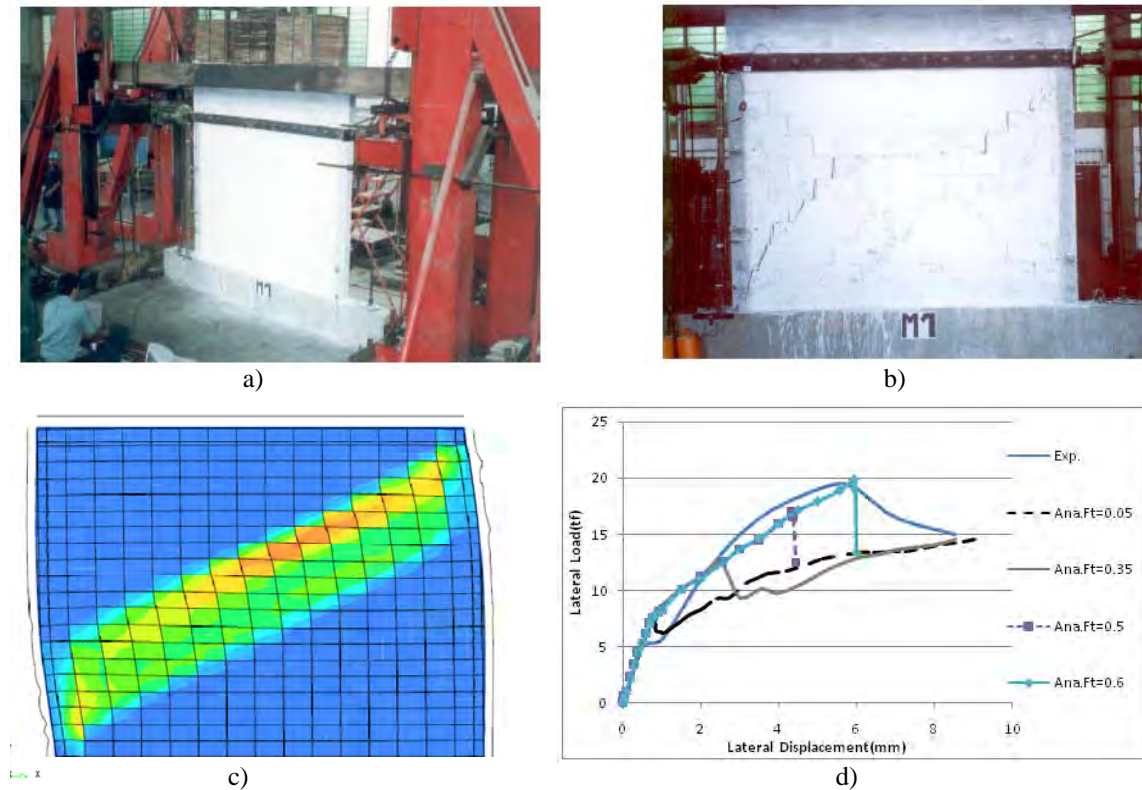

Figure 3: Comparison between experimental and numerical models related to the masonry wall with confinement [11]: a) the experimental model, b) the experimental fracture mechanism, c) the fracture mechanism obtained by DIANA, d) the experimental and numerical capacity curves

It is seen that in cases of the 2-storey concrete frame without infill walls and the masonry wall without confinement there are good agreement between the numerical and experimental results. For the cases of confined masonry walls, since the tensile strength of the masonry (f_t) was not reported, various values between 0.3 to 0.9 MPa were tried, based on Tomazevic recommendation. Figure 3 shows that with a value of 0.6 MPa a good agreement between the numerical and experimental results is achieved.

5 THE EFFECT OF COMPRESSIVE STRENGTH OF THE CONCRETE

In order to study of the effect of compressive strength of the concrete 3 levels of 100, 150, and 200 kgf/cm² were considered for it. Accordingly, with change of compressive strength of the concrete its tensile strength and modules of elasticity were also changed (see Figure 4).

Figure 4: Variation of the tensile strength of concrete based on its compressive strength [8]

All three levels of strength were employed in DIANA software, and the results of analyses are presented in Figure 5.

Figure 5: The CMW capacity curves based on the change of compressive strength of the concrete

It is seen in Figure 5 that increase of the concrete compressive strength has minor effect on the wall's capacity curve. Just a little increase in elastic limit strength and also maximum strength is observed. It is also worth mentioning that the fracture mechanism is the same for the three models, and is of the form of shear fracture with diagonal cracks.

6 THE EFFECT OF CROSS SECTIONAL AREA OF TIES

In order to study of the effect of cross sectional area of ties 4 sections of 10×10 , 15×15 , 20×20 , and 25×25 cm² were considered for the vertical tie elements, but the width of the horizontal tie element was considered to be 20cm in all cases to match with the thickness of masonry wall. The corresponding results are presented in Figure 6.

Figure 6: The CMW capacity curves based on cross sectional area of ties

It is observed from Figure 6 that with cross sectional area of 10×10 cm² for tie elements, elastic limit, ultimate, as well as residual strength, and also the ductility of the wall are all very low. These values increase as the cross sectional area of tie elements increases. In other words, with decreasing the cross sectional area of tie elements, the behavior of confined masonry wall tends to unconfined masonry wall, in both aspects of resistance and ductility. However, the wall initial stiffness does not change with the tie cross sectional area. The increased resistance and ultimate ductility is due to increased effect of confinement resulted

from tie elements on the masonry wall and its increased frame action. In the level of $25 \times 25 \text{ cm}^2$ it is seen that the elastic limit strength increases but ductility corresponding to maximum strength decreases and maximum strength does not change considerably. The decrease of ductility could be due to increase of pressure resulted from interaction between ties and wall because of increased stiffness and frame action in tie elements, which results to brittle behavior in confined masonry wall. It should be mentioned the fracture mechanism is again the same for all models, as is of the form of shear fracture with diagonal cracks.

7 THE EFFECT OF LONGITUDINAL REINFORCEMENT IN VERTICAL TIES

In order to study of the effect of the amount of longitudinal reinforcement in vertical ties on the CMW's behavior four levels of reinforcement in vertical ties were considered, including 4 bars with diameter of 6, 8, 10, and 14 mm. The results of numerical model are presented in Figure 7.

Figure 7: The CMW capacity curves based on the amount of longitudinal reinforcement in vertical ties

It is seen in Figure 7 that with increasing the amount of longitudinal reinforcement in vertical ties, the elastic limit, and maximum and residual strengths increase, but ductility corresponding to maximum strength decreases. With increasing reinforcement from $4\Phi 10$ to $4\Phi 14$ the maximum strength does not change but elastic limit and residual strength increases, but the wall ductility decreases, which can be due to increasing of frame action of tie elements. With decreasing reinforcement from $4\Phi 8$ to $4\Phi 6$, the fracture mechanism changes from shear to flexural fracture.

Figure 8: Capacity curve for model with $4\Phi 6$ reinforcement

It is useful to pay attention to the correspondence of the CMW fracture mechanism to the variations of its capacity curve. For this purpose the capacity curve of the model with 4 Φ 6 reinforcement in vertical ties on which various stages of the wall fracture are indicated by point A to C is presented in Figures 8. As shown in this figure, point “A” on the curve is corresponding to the first observable stiffness degradation, and the start of transverse cracking at the upper end of vertical tie, as shown in Figure 9.

Figure 9: The start of transverse cracking at the upper end of vertical tie

Figure 10: The yielding of reinforcement in lower and upper ends of tensile vertical tie

By increasing the top displacement of the wall and reaching 10 mm, corresponding to the point “B” on the curve, reinforcement in the connection zones of the vertical tie yields in tension, as shown in Figure 10. After this stage the CMW gradually reaches its maximum strength and diagonal cracks appear in the wall. This stage corresponds to point “C” on the curve. After this stage the wall’s strength drops to its residual strength.

Figure 11: The start of diagonal cracking in masonry wall

It should be mentioned in models with $4\Phi 8$ to $4\Phi 14$ the fracture mechanism is shear fracture, since the reinforcement does not yield before maximum strength.

8 THE EFFECT OF RIGIDITY OF CONNECTIONS BETWEEN HORIZONTAL AND VERTICAL TIES

One of effective parameters in the behavior of CMW is the detailing and the amount of rigidity in the ties' connections. Past earthquakes (Indonesia earthquake, 2007) [1], have shown that inadequacy of connection in ties could resulted in vulnerability of the CMW. With decreasing the rigidity of connections in the tie elements and change of its rigidity from fully rigid to hinge, the behavior of CMW is changed to a truss, as shown in Figure 12.

Figure 12: Replacement of CMW by a truss due to lack of rigidity in its tie connections

In order to study the effect of the rigidity of connections between horizontal and vertical ties, the experimental model of Marinilli [11], shown in Figure 4, was modeled as a vertical truss, by replacing the beam elements of ties by truss elements. Analysis results show that the initial stiffness and the ultimate resistance of the truss model is almost the same as that of the beam model, however, the ductility of truss model increases to some extent, in comparison of unconfined masonry wall, with ties modeled as beam elements. On the contrary, with increasing the rigidity of ties connections and reaching the fully rigid state, both resistance and ductility of the CMW increase in comparison with those of the unconfined masonry wall. This is due to the creation of frame behavior in tie elements. The capacity curve for confined masonry wall with truss confining elements (CMWT) along with its fracture mechanism corresponding to different state in capacity curve are presented in Figures 13 to 19. Also for comparison, the capacity curve of the confined masonry wall with beam confining elements (CMWB) along with its fracture mechanism corresponding to different state in capacity curve are presented in Figures 20 to 23.

Figure 13: The capacity curve of the modeled CMWT

Figure 14: The start of cracking in the region between masonry and horizontal tie (corresponding to point A)

Figure 15: The start of cracking in the vertical tie (corresponding to point B)

Figure 16: Development of cracks in the region between masonry wall and horizontal tie (corresponding to the part of capacity curve between points B and C)

Figure 17: Development of cracks in the vertical ties (corresponding to point C)

Figure 18: Development of cracks in masonry wall (corresponding to point C)

Figure 19: Development of widespread cracks in masonry wall (corresponding to point D)

Figure 20: The capacity curve of the modeled CMWB

Figure 21: The start of cracking in the tie-column (corresponding to point A)

Figure 22: Diagonal cracks in masonry wall (corresponding to point B)

Figure 23: Development of diagonal cracks in masonry wall (corresponding to point C)

In the CMWB ties are of 22 cm thickness, 3.0 m height, and 0.25 MPa tensile strength, and the amount of surcharge on the wall is 23.2 N/mm. It should be mentioned the load was applied from right to left. It can be observed from Figures 13 to 23 that the fracture mechanism in the CMWB is different from the CMWT. As it is shown in Figures 13 to 19 in case of CMWT the onset of cracking is in the masonry wall, while in case of CMWB cracking starts in the horizontal tie. This difference is believed to be due to the fact that in CMWT, initially the masonry wall panel resists the lateral load, and the confining elements do not play any significant role in load bearing, while in the CMWB initially the ties resist against the lateral loads but because of their frame action. Also the values of initial stiffness, maximum and residual strength, as well as ductility are quite different in CMWT and CMWB. The initial stiffness of the CMWB is less than 1.5 times of that of the CMWT, while its maximum and residual strength is more than two times of the CMWT. The failure mechanism of the CMWB is also different from that of the CMWT. It can be said that the CMWT behaves similar to the unconfined masonry wall, as expected, while the CMWB behaves similar to the infilled frame.

9 CONCLUSIONS

In this study based on the nonlinear finite element analysis (by using DIANA software), the effect of ties' specifications, including compressive strength of concrete used in tie elements, cross sectional area of ties, the amount of longitudinal reinforcement in vertical ties, and finally the rigidity of connections between horizontal and vertical ties, in the seismic behavior of confined masonry walls were studied. With regard to the amounts of the four mentioned parameters, the values recommended by the National Iranian Code of Practice for Seismic

Design of Buildings (Iranian Standard No. 2800) were used as the bench mark values. Then some changes were applied to those bench mark values to find out the effects of the aforementioned parameters. The results of analyses are as follow:

- The changes of the mentioned parameters do not affect so much the initial stiffness of confined masonry wall, and it was shown that basically the masonry wall provides the initial stiffness in the confined masonry wall.
- With little changes in compressive strength of concrete in tie elements related to bench mark value (15 MPa), due to decrease or increase of tensile strength of concrete, only elastic limit strength decreases or increases respectively and other indices in capacity curve do not change considerably, also fracture mechanism does not change.
- It is believed that the $20 \times 20 \text{ cm}^2$ (bench mark) for cross sectional area in tie elements, is an optimal case, so that with decrease of mentioned value, the behavior of confined masonry wall tends to unconfined masonry wall, and on the other hand, with increase in that some considerable change in the behavior was observed. However, the fracture mechanism is almost the same for all models.
- It is believed that the $4\Phi 10$ (bench mark) for vertical reinforcement in tie-columns, is an optimal value, so that with decrease in that the ductility corresponding to the maximum strength increases and maximum strength itself decreases. It should be mentioned with $4\Phi 6$ in tie columns the fracture mechanism changes from shear to flexural failure. On the other hand, it was observed that by using $4\Phi 14$ in tie-columns, not only the maximum strength does not increase, but the ductility corresponding to the maximum strength decreases.
- It is believed that, with decreasing rigidity in the connections of ties elements, the surcharge resulted from confinement decreases, and the behavior of the confined wall approaches that of the unconfined wall.

Keywords: FRP, Composite Materials, Carbon Fibres, Structural Reinforces, Retrofitting, Structural Retrofitting.

Abstract. *Application of composite materials to construction started in Italy at beginning of the ,90's and was generally accepted as one of the most important technologies for retrofitting and structural recovery of buildings. In 2004 the Italian National Research Council (CNR) issued the guideline for design and applications of composite materials in constructions and in 2009 it has been officially adopted for reconstruction at "L'Aquila" after the earthquake of April 6, 2009.*

The big advantage offered by Composites, mainly based on carbon fibres, is attributed to the special properties of the reinforcing fibres. Applications of composites range from concrete structures to masonry, bricks, steel and wood structures and more specifically reinforcement of beams, columns, vaults, arches, walls, concrete slabs, floors and total building belting.

Since 1993 many important original solutions and know how on materials, design and applications have been developed: reinforcing fabrics produced by an original patented process of thermo welding; connection systems based on Ardfix innovative technology, to prevent delamination; technology for wood beams reinforcements; cables technology and anchoring systems, new water base matrix systems with high fire resistance and good permeability to humidity and water.

A large experience in new solutions, and an important know how in applications has been developed.

New thermo welded meshes produced with alkali resistant zircon glass fibres, have been developed for direct application in concrete or calcium based mortar matrices. This special mesh grade is produced avoiding traditional induction process with plastic coating, leaving the surface of the fibre free from polymer and preserving the good capacity of adhesion to cement or calcium.

Many applications example of the above concept are reported, mainly related to retrofitting historical building.

1-INTRODUCTION

Application of composite materials in construction started in Italy in 1993 with laboratory tests at University of Bologna , and in just ten years reached a very large diffusion and was generally accepted as one of the most important technologies for retrofitting and structural recovery of buildings [1]. The important role of this technology has been generally recognized. In 2004 the Italian National Research Council (CNR) issued the guideline for design and applications of composite materials in construction [2–4] and in 2009 it was officially adopted as one important technology for rehabilitation and recovery of buildings damaged by earthquakes and largely used in seismic situation like in “L’Aquila” after the earthquake of April 6, 2009.

It is well known that the great advantage offered by composites , mainly based on carbon fibres is attributed to the special properties of the reinforcing fibres: very high mechanical properties, high chemical resistance, low weight, low thickness and low invasiveness.

Properties of Composites

- **High mechanical properties:** Carbon fibers are five time more resistant compared to steel.
 - **Lightness:** Carbon fiber density is 1,8g/cm³, steel density is 8 g/cm³.
 - **No invasive:** Reinforcements are generally applied externally, in very low thickness , easily covered by plaster in final coating.
 - **No corrosion and high environmental resistance:** no maintenance in the time.
 - **High fatigue resistance:** Vibration dumping.
 - **Reversibility of the application:** External applications are easily removed.
 - **Easy application:** Very simple application technology without need of important equipments
-

Tab. 1- Main Properties of Composites Applications in Constructions

Reinforcement effect is obtained without addition of mass and rigidity, that means a big advantage in seismic zone applications.(Tab.1)

Technology Solutions of Composite Materials

- **Fibers:** *Carbon, Aramid, LCP, Glass, AR-Glass.*
 - **Reinforcement Grade:**
 - *Textile : Unidirectional , Biax-fabrics, Multiax, Net - fabrics.*
 - *Preimpregnated reinforcements : Pultruded lamina, Bars and Rods or Special shapes, properly designed.*
 - **Application Technologies :** *External Lamination of dry textile, External Adhesion of pultruded lamina, Internal reinforces by Pultruded Bars, Lamina and Cables*
 - **Delamination and failure mode control - Connectors**
-

Tab.2 - FRP- Technical Possible Solutions

Applications of composites range from concrete, masonry, brick, steel and wood and more specifically reinforcement of : beams, columns, vaults, arches, walls, concrete slabs, floors and total building belting.

The large development of technology leads to many different solutions in terms of fibre type and variety of applications. Engineering and architectural criteria to select the appropriate technology among different possibilities should be considered. Products, material and technology optimization is also an important consideration for designers, applicators and end users (Tab.2).

2-FRP: MATERIALS AND TECHNOLOGY DESIGN

In our work, taking advantage of a large experience in composite applications on construction, starting in 1993, many important innovative solutions and „know how’ on materials, design and applications have been developed. In the following paragraphs several criteria for structural reinforcement design and solution selection, among the different opportunities offered by the market are presented [5–9] .

2.1 - Fibre Selection

Carbon Fibres: They are the most important fibres used in construction. The high level of crystallinity, over 99 %, and the high packed crystal structure of graphite makes this fibre very stable in respect to corrosion, even in high alkaline conditions, chemically stable at pH variations and with high thermal resistance, even over 1000° C. (Fig. 1). Besides the high mechanical properties, the special structure and morphology of this fibre make carbon fibres the most stable and safe with respect to environmental durability and for applications under severe conditions. Creep is also an important property when the reinforced structure is subjected to permanent loads. It is well known that carbon fibres show no significant creep under permanent loads.

Fig. 1- The packed crystal structure of carbon fiber under thermal treatment process, in production [10].

Aramid Fibres: aramid fibres, are based on organic polymers, characterized by high mechanical properties, thermal resistance , and unusual capacity of vibration energy absorption

However this fibre lacks in resistance to humidity, to pH variation and UV radiation. Creep resistance of the fibre may be a property that designers should take in consideration with attention.

The high capacity of vibration dumping of Aramid fibre make this material very attractive to apply to earthquake rehabilitation construction, or application to constructions near high traffic roads, in order to prevent vibrations. A combination of aramid fibres as vibration energy dumping elements and carbon fibres as perfectly elastic elements can be a very good solution with excellent synergistic effects.

In practice, when aramid fibres are used, a good protection of the fibre, to humidity, environmental corrosion and UV radiation, should be warranted by the impregnation of resins.

Glass Fibres: glass fibres, largely used in traditional composites applications for a long time, are very cheap products, but they lack in terms of mechanical properties and weight (fibre density is 2,5g/cm³). For this reason the use of this fibre is usually limited to large surface applications when the role of the mechanical properties are not very important.

AR- Glass Fibres: AR- glass fibres nets are easily found in the market and used directly in combination with mortar, mainly for masonry or brick walls reinforcement. This special glass grade is based on composition containing a minimum amount (16%) of zirconium oxide, that provides superior performance under alkaline conditions.

Commercial glass nets based on A.R. fibres, are obtained by traditional waving process which includes an induction process with plastic coating to fix the fibre. So any adhesion between the fibre and the mortar is prevented, adhesion is extremely poor and generated only by mechanical bonds.

2.2- Reinforcements alternatives

The **market** of fibre reinforcements offer a variety of solutions that can be selected by designers. Several alternatives are listed in Table 3.

Fibre Reinforcement
<ul style="list-style-type: none"> ▪ Woven fabrics : Unidirectional tape , Biax and Multiax Fabrics and Biax-Nets for in situ lamination : very simple application , may be easily adapted to the shape of support, it is the only solution for columns wrapping. ▪ Pultruded Lamina : important fibre sections may be applied in only one shot . Lamina cannot permit bending and wrapping. ▪ Pultruded Rods and Connectors: for inside concrete reinforce and connections. ▪ Cables : building belting, connections and walls reinforcement.

Tab.3- Different reinforcement solutions are available

Fabrics and woven tapes can permit an easy application by direct lamination. Woven fabrics are characterized by very good draping properties and reinforcement may take any shape and perfectly follow the substrate profile, for example when the reinforcement should be applied to columns by wrapping to increase confinement

Betontex reinforcing fabrics (Fig.2) are produced by an original patented process of thermo-welding, with high efficiency in reinforcement effects [5]. This special process has been developed by Ardea technology and comprise the use of a special thermo welding of the warp and the weft by means of a thin glass fibre coated by a hot melted adhesive [5, 6].

Fig.2- Thermo welded carbon reinforces based on Betontex® technology.

Industrial production comprise unidirectional tapes, thermo welded biax- fabrics and nets, using different fibres, and weights and different fibre orientation. Reinforcements produced with this technology present very good handling properties, very good impregnation capability and perfect linearity of the fibre. Betontex reinforcements are easily applicable using optimized epoxy resins systems in all different conditions.

Fig.3. Betontex Thermo welded Net produced with AR- glass. Without plastic coating over the fiber.

Fig.4. SEM view of interface between AR- .glass fiber surface and concrete, adhesion of the fiber is improved by Betontex IPN promoter.

New thermo welded nets produced with high zircon A.R. glass fibres, have been developed for direct application in concrete or in calcium based mortar matrices.

This special net grade is produced avoiding traditional induction plastic process, leaving the surface of the fibre free from polymer coating and preserving the good capacity of the fibre

surface of adhesion to cement or calcium matrices. The free surface of the fibre can develop a good interaction with the concrete by direct physicochemical bonds formation (Fig.3-4).

In order to improve adhesion properties a special adhesion promoter has also been developed. This special adhesive system is based on a new concept of matrices with an IPN (Interpenetrated Polymer Network) structure, derived by a combination of two water based resins, one of which is supported over an active inorganic matrix. In fig.4 a view of the interaction between the fibre and the concrete is clearly shown.

Lamina may be used mainly in beam reinforcements when a significant amount of fibre sections should be applied, instead of using many layers of woven fabrics. Banding is a limitation in lamina applications thus, they are generally used only as beam reinforcements for straight on linear shape.

Pultruded rods, generally based on E-glass fibres and vinyl ester resins are very low prices materials, traditionally used for internal reinforcement of concrete.

Pultruded rods made of carbon fibres are primarily used to enhance mechanical properties in many cases and when there is a need to improve adhesion of carbon fibre reinforcements to the structure.

Fig.5. Schematic drawing of Ardfix connection system: a carbon bar push inside the wall a strip of unidirectional carbon fabric.

Connectors are very important for the general technology of composite materials applications in construction. The use of connectors made of carbon rods is extending and many alternative solutions have been proposed. In our research we have developed a very effective and easy to apply connection system that combine the application of carbon rods and unidirectional carbon strips.

Fig. 6. Ardfix connecting the two faces of a wall. Loads are transferred through a net work structure.

Connectors should be used to improve adhesion of reinforcement to substrate, and are recommended when the quality of concrete or substrate is very poor.

Connectors may be very useful to prevent delamination, to transfer the tension from the reinforcement to the substrate and, also, to create a connection between the two sides of a structure, as in slabs or walls.

The use of high performance connectors, removes uncertainties related to substrate quality in terms of delamination resistance and allow designers to use the complete strength properties of the reinforcement without limitations induced by delamination phenomena.

The connection system, optimized in our work and described in reference [7], combines the application of a carbon fibre rod with a strip of tape and is represented in Fig.5 and 6. This system, after its introduction in the market with the name of Ardfix®, has been widely applied in many diverse applications.

Fig.7. Application of Ardfix connectors on the intrados side of a concrete beam .After application of unidirectional reinforcing tapes, the beam is subjected to a flexural four points test.

A large number of laboratory tests have been carried on concrete beams reinforced with unidirectional carbon fibre, using Ardfix connectors. In fig.7 a beam reinforced with Ardfix connectors and unidirectional reinforcements is shown.

Fig.8a. Four point Flexion test on a concrete beam reinforced with n°3 layer of 300g/m² of high modulus ($E=390$ GPa) carbon fibre. No delamination has been detected during test.

Regarding the application, connectors are applied first, then, over connectors terminations, a unidirectional carbon tape is applied to reinforce the intrados of the beam.

With the Ardfix in all four-point flexural tests (Fig. 8a), no delamination of the reinforcement was observed and, at the ultimate load, the beam collapsed following the breaking of the carbon fibre at the centre of the beam, at the maximum moment (Fig.8b). Under such conditions, the ultimate bending resistance of the beam is governed by the ultimate tensile strength of the fiber.

Fig.8b. Breaking of carbon fibre at the centre of the beam at the ultimate strength, without delamination. Calculated tension on the fibre at break was equal to 3500 MPa.

The calculated values of strength for the carbon fibre, detected at the ultimate braking load of the beam, was equal to 3500 MPa, compared to the nominal tensile strength of 4200 MPa of the original fibre, Tenax HM grade.

Cables made of high modulus fibres, can be successfully used to many construction rehabilitation applications. Cables, based on a combination of aramid, glass and carbon fibres are new products developed by Ardea research, and can be used in connections, as ties, walls reinforcement, building belting and pre-stressing.

Fig.9. Application of Betontex Aramid Tie 85 HM on the tambour of “Anime Sante” Cathedral, L’Aquila, damaged by earthquake of 2009. The Tambour was put in security to proceed with further works.

An interesting application of aramid-carbon cable was the securing of the tambour of the Cathedral of “Anime Sante” -L’Aquila, damaged by earthquake of April 2009.

Cables made on aramid fibre, with a weight of 85 g per linear meter and a tensile resistance over 12 tons, were applied by specialized technicians, lowered by an helicopter around the damaged tambour (Fig.9). An important task was the connection at the ends of the cable in order to apply the desired tension. In order to do that, a special ring coated with Dynema fibres was prepared at the ends of each cable. The 38 m long cables were pre-stressed by standard jacks.

A new and challenging application of cables is the reinforcement of historical walls or façades made of either stones or bricks, when the external old appearance should be preserved. Cables may be introduced in very thin slits applied in courses of breaks or stones, avoiding any modification of the external surface.

Fig.10. Historical City Walls in stones (Bassano- Italy), reinforced with hybrid aramid – carbon fibres cable, prestressed and impregnated with epoxy resins. Courses among stones will be filled by traditional mortar.

Fig.11. Bricks walls reinforced with carbon fibres cable coated with aramid fibres, prestressed and impregnated with epoxy resins. Courses among bricks will be closed by traditional plaster.

Figures 10 and 11 show the cable application on stones and bricks walls. The examples refers to the City Walls of Bassano (Italy) and to a facade wall of an historical Cathedral in Bologna. In both cases cables have been pre-stressed and impregnated with special high fluidity epoxy resins and filled with traditional mortar.

2.3- Wood rehabilitation.

Wood-beam retrofitting is an important task that may be easily resolved by using FRP. Many different solutions have been proposed and described in literature [4] using: lamina , rods and unidirectional fabrics. However, all these solutions lack of a good reinforcing effect.

The low external surface compression resistance of wood, compared to the high tensile force of composites at internal surface, is a strong limitation on the strengthening effect.

Fig.12-a. Ardwood, a wood element confined by carbon fibre net. Application of confined element to the extrados of wood beam.

This problem was resolved by applying a parallelepipedon of wood of square section, confined by a carbon fibre net, on the upper part (external surface) of the beam. This phase is followed by the application of carbon unidirectional fabrics or a lamina at the internal surface side of the beam.

Fig.12-b. Ardwood application on a beam, lateral view and section. Connection between Ardwood element and beam is made with Ardfix connectors. The intrados of the beam is reinforced with a carbon fibre lamina or a fabric.

The confined wood at the external surface of the beam be subjected to compression forces, equilibrating the high tensile force of the carbon fibre at internal surface side.

The system has been used for many years with the trade name Ardwood [8]. The schematic drawing of the Ardwood system for the rehabilitation of wood beams is shown in Fig 12(a-b).

3-MATRICES

Matrices are the second components of composite systems, the first being fibres. Matrices play a very important role in composite applications: impregnate the fibres, give shape to the reinforcement element, create a good adhesion to the building structure and transfer stresses from the structural element to the fibres

3.1 – Epoxy Matrices

Many types of matrices can be used in composite technology ranging from polymeric to ceramic and metal matrices.

Resin Grade	RC01	RC02	RC02/3 Tixo	RC30	RC30/3 Tixo
Functionality	Primer, surface preparation	Tixotropic Impregnating and adhesive	High tixotropic Impregnating and adhesive.	Tixotropic epoxy mortar	High tixotropic epoxy mortar
Resin A / Catalyst B ratio	2:1	2:1	2:1	4:1	4:1
Mixing ratio by weight	100:50	100:50	100:50	100:25	100:25
Gel Time at 20°C	50-60 (min.)	50-60 (min.)	50-60 (min.)	40-45 (min.)	40-45 (min.)
Hardening Time at 20°C	180-240 (min)	180-240 (min)	180-240 (min)	120-180 (min)	120-180 (min)
Total Hardening Time at 20 °C	14-16 (hrs)	14-16 (hrs)	14-16 (hrs)	12-14 (hrs)	12-14 (hrs)
Application Temperature range (°C)	From +5°C to 30°C	From +5°C to 30°C	From +5°C to 30°C	From +5°C to 30°C	From +5°C to 30°C

Tab. 4- Betontex Two Components Epoxy Resins Systems

(*) with concrete delamination

Tab. 5- Betontex Two Components Epoxy Resins Systems : Mechanical Properties.

In most structural applications a two component epoxy resin system is used, they are formulated at different viscosity grades: *primer resin*: a low viscosity resins for surface preparation, *impregnation and adhesion resin*: a medium viscosity resin to impregnate fibres, *epoxy resins mortar*: a high viscosity resin, for surface adjustment, and for lamina and Ardfix bar application (tab.4)

Epoxy resins show the best properties (Tab.5) for application of composites to constructions in terms of mechanical properties, aging resistance, and durability in every condition. In construction epoxy resins have been introduced many years for applications of steel bars and plates, as “*beton plaque*”, and engineers are familiar and confident with their use. Nevertheless some caution should be taken regarding: the distortion temperature (HDT) (Tab.5), a property strictly related to the second order transition temperatures T_g , which is in the range between 90-100 °C. In general applications the usual coating with traditional plasters or protective paints may be sufficient to protect FRP. In case of high temperature applications or when fire resistance is required, a protective coating should be applied, as for steel structures.

3.2 – Concrete matrices,

Some applications of carbon fibre fabrics reinforcements, directly dipped in special cement mortar, have been reported in the market. These systems may have the advantage to partially overcome some lack of properties of epoxy resins, but also exhibit some other problems that should be considered.

Carbon yarn, used in waving, is generally composed by a number of basic fibre ranging from 3.000 to 24.000. Polymeric matrices have the capacity to impregnate the single basic fibres, that is to enter inside the yarn, between the single fibres, generating a real “*composite material*”. Cement particles do not have the capability to impregnate the single fibres, but can only coat the yarn externally, leaving the single basic fibres unbounded. For this reason the carbon fibre, in terms of strength, develop very low results, ranging between 25-40 % of the strength of composites impregnated with epoxy resins.

Furthermore there is no bond formation between carbon fibre, surface and cement, so the incorporation of carbon fibres in cement matrices do not generate a “*composite material*” but only a mechanical blend with poor mechanical properties.

3.3- New water based resin system.

Considering the above described problems related to matrices, both of epoxy type or

Fig.13 –IPN resins concept

cement mortar based matrices, we have investigated and optimized new resins system based on the IPN (Interpenetrated Polymer Network) concept, commercialized with the trade name of Betontex IPN Resins (Fig.13).

This type of matrices is based on a new formulated resin in water solution or dispersion, supported over special micronized mineral filler. After mixing and hardening the two components, an IPN structure is obtained.

Similar to epoxy resins, this new type of resins is used in different grades as: IPN primer of low viscosity, IPN impregnation resins of medium viscosity, or IPN mortar of high viscosity.

Fig. 14- Interface between IPN matrix and the reinforcing fibre, SEM x 2000 view ..

Betontex IPN resins may be used to applications with carbon fibres nets or AR Zirconglass nets, over concrete or over bricks or stone masonry structures.

The resins show very good adhesion capacity and very good mechanical properties; in tensile tests with carbon fibres 70-80% of epoxy resin properties are reached.

Temperature resistance is very good, no thermodynamic transition is observed until 180 °C, and degradation temperature may be observed over 300 °C, without melting.

Betontex IPN resins show a good burning resistance (class 1; following UNI 9176 D), can permit water vapour transmission, may be used over humid surfaces without any problem, and demonstrate very good aging properties even under also in severe conditions.

Many applications have been successfully carried out for reinforcement of walls and vaults and new tests are in progress for beam and plate reinforcement with unidirectional fabrics

4-APPLICATIONS EXAMPLES AND CONCLUSIONS.

Many application examples of the described technology are reported.

The most important are related to historical building retrofitting, among them we will refer to:
a) “Venaria Reale”, a Royal Palace in Venaria near Turin.

In Venaria the large arcades were reinforced with unidirectional hybrid carbon-aramid fibres, partially overlapped in the central area of the arcades to increase the fibre section.

b) Basilica of S. Antonio in Padua where the Vaults of convent were reinforced with aramid and carbon unidirectional strips. The walls of the tympanum of Library, were

Fig. 15- Venaria Royal Palace –Turin.

Fig. 16- Intrados reinforcement of arcades - Venaria Royal Palace –Turin. (1999)

reinforced with unidirectional carbon and hybrid carbon-aramid fibres in both sides of the walls and connected by Ardfix connectors in order to create a tridimensional network structure.

Fig.17 – The Basilica f S. Antonio in Padova- Italy (2001-2004).

Fig.18 – The Basilica f S. Antonio in Padova- Italy . Vaults reinforcement of monastery cells.

Fig. 19 -Outside walls reinforcement of Tympanum of Library .

Fig. 20 -Inside walls reinforcement of Tympanum of Library.

We can also mention many other important churches and basilicas such as: Basilica of Vico-forte and Alba near Cuneo, Basilica of S. Petronio and S. Pietro in Bologna that have been subjected to rehabilitation works by using carbon fibres strips with the design and technology concepts described in this paper.

Fig.21- Example of extrados vaults reinforcement by carbon fibres tapes, (S. Giorgio Church, near Bologna-Italy)

Fig.22- Example of walls reinforcement using Ard-fix connectors, at Alba Cathedral in Cuneo- Italy.

A representative example of carbon fibre application with unidirectional strips, at the exterior of church vaults, is shown in figure 21. This reinforcement configuration presented is generally applied to many retrofitting works of old historical buildings and churches in Italy.

Application of connectors on the sides walls of the Alba Cathedral (Cuneo-Italy) is presented in photo 22. Over the connector ends two strips of unidirectional carbon fibre reinforcement is applied in orthogonal direction to the fibres (shown in the picture) and over them, a unidirectional reinforcement strip is placed. All laminations are made using, fresh resins at the same time. In such a way a connection of superior behavior is obtained. Applications on old concrete buildings, retrofitting of bridges and old industrial building have been performed from many years and are now widely applied.

Fig.23- Example of old concrete rehabilitation using thermo welded Betontex unidirectional carbon reinforces.

Picture 23 shows the rehabilitation of an old concrete structure. The Beams are reinforced to increase shear and flexure, while columns are reinforced for bending, compression by confinement and shear. Connectors are used to avoid debonding.

New solutions have been developed for seismic zones. In picture 24 an example of internal belting of an old Villa, damaged by earthquake of 1996 in Reggio Emilia, is shown. A similar reinforcement was applied at the external side of the wall. The strengthening is applied to avoid both out of plane and in plane failure of the masonry walls. Both sides have been connected with Ardfix.

Fig.24- Example of building complete belting (inside and outside) , at Villa Bertani- Reggio Emilia damaged by earth quake of 1996 , using thermo welded Betontex unidirectional carbon reinforces.

Fig.25a-25b- Concrete rehabilitation in a civil building at L'Aquila- Italy, damaged by earthquake of April 2009. Joint Column-Beam reinforcement. and Columns confinement.

Recent reinforced concrete industrial constructions damaged by the “L'Aquila-Italy” earthquake in April 2009 have been rehabilitated using Betontex carbon fibre reinforcements (Fig.25a-b). Reinforcement of old traditional bricks and masonry buildings, damaged by the same earthquake, are in progress, following the technical solutions and using the design concepts and materials reported in this paper.

Keywords: Reliability, Sensitivity Analysis, Gaussian Stochastic Process, First Excursion Probability.

Abstract. *Probability theory offers an appropriate framework for quantifying the level of safety of a structural system. Thus, it is possible to evaluate the chances that a structure fulfills prescribed performance criteria during its lifetime due to uncertainties in loadings, deterioration processes, etc. The aforementioned chances are usually termed as the reliability associated with a structure. Although reliability constitutes a fundamental metric of safety, knowledge on the sensitivity of the reliability with respect to variables such as material properties, cross section of structural members, etc. is also of paramount importance. The information on reliability sensitivity is most valuable as it allows, for example, taking decisions on the final design of a structure such that its level of safety is relatively invariant in case unexpected changes occur. Within the aforementioned framework, this contribution presents a novel approach for estimating the reliability sensitivity of a particular type of structures, namely linear structural systems subject to dynamic loading modeled as a Gaussian stochastic process. The sensitivity is computed with respect to deterministic variables that affect the structural performance (such as stiffness, cross section of structural members, etc.). The proposed approach is based on an efficient simulation technique and local approximations of the functions used to model the structural performance. The reliability measure is expressed in terms of the first excursion probability, which is a criterion widely used in stochastic structural dynamics. In addition, the error associated with the estimator of the reliability sensitivity is computed by means of the Bootstrap method.*

1 INTRODUCTION

One of the key issues for the analysis and design of civil engineering systems is the appropriate identification of the actions (such as water wave loading, wind loading, ground acceleration, etc.) that affect the structural performance during the life time. In most cases, such actions cannot be characterized deterministically due to inherent uncertainties [14]. Probability theory offers an appropriate framework for accounting for these uncertainties by means of, e.g. stochastic processes [28]. In this way, it is possible to generate a metric of the level of safety of a structural system. This metric refers to the reliability, i.e. the probability that a structure fulfills certain performance requirements during its lifetime. The complement of the reliability is the probability of failure (P_F), i.e. the probability that a structure violates prescribed performance criteria.

Besides determining the level of safety associated with a particular structural system, it is also of interest analyzing the sensitivity of the reliability with respect to variations in the properties of the structure [1, 6, 9, 21]. For example, the determination of the variation in the reliability due to a change in the size of a structural member can provide useful information to increase the safety level or to identify the most influential design parameters.

In cases of practical interest, the quantification of the reliability of a structure is an extremely challenging task, as it requires evaluating integrals in high dimensional spaces involving implicit domains [25]. In consequence, the evaluation of the sensitivity of the reliability with respect to system parameters will be usually even more involved than the reliability assessment. In view of this issue, this contribution proposes a novel approach for estimating reliability sensitivity for a particular class of structural systems, namely linear structures subject to dynamic loading modeled as a Gaussian stochastic process. The sensitivity is computed with respect to deterministic variables that affect the structural performance (such as mass, stiffness, cross section of structural members, etc.). The proposed approach is based on an efficient simulation technique and local approximations of the functions used to model the structural performance. The reliability measure is expressed in terms of the first excursion probability, which is a criterion widely used in stochastic structural dynamics. In addition, the error associated with the reliability sensitivity estimator (computed using simulation) is evaluated efficiently applying the Bootstrap method [10, 11].

The subject of efficient reliability sensitivity analysis has been considered several times in the literature. For example, sensitivity analysis of reliability estimates generated using approximate methods such as the First- and Second-Order Reliability Methods (FORM and SORM, respectively; see, e.g. [9]) has been thoroughly studied in the literature for problems involving component or system reliability, see e.g. [6, 12, 13, 18]. These approaches take advantage of the so-called design point associated with a particular reliability problem and eventual correlations between different individual failure modes in order to estimate the sought sensitivity efficiently. Reliability sensitivity analysis has also been studied within the framework of simulation methods. For example, in [22], a method combining Monte Carlo Simulation (MCS) with a linear approximation scheme allows estimating the sought sensitivity. In [30], an estimator for the sensitivity based on Importance Sampling (IS) is proposed. A common aspect of the two aforementioned approaches based on simulation is that they are applicable whenever sensitivity is estimated with respect to a parameter characterizing the random variables of the reliability problem, such as the mean or standard deviation. However, these approaches are not directly applicable in case one seeks to estimate the sensitivity with respect to a deterministic variable. Thus, alternative approaches have been developed to address this case. For example,

in [24], an algorithm for estimating the gradient of the failure probability using either MCS or IS is presented. This algorithm requires solving equations characterizing the structural performance either analytically or numerically; however, this can be an involved task. An alternative approach for reliability sensitivity analysis was introduced in [1]. The key issues of this approach are the association of an *instrumental variability* with the deterministic design variables involved in the sensitivity analysis and the application of the Bayes' theorem. Nonetheless, the range of applicability of this approach is limited as no more than 3 or 4 design variables can be considered simultaneously when performing sensitivity analysis [19]. A different strategy for estimating reliability sensitivity within the context of non linear structural dynamics was introduced in [16, 29]. The main aspect of this strategy is the introduction of a series of approximation concepts both at the level of reliability estimation and the functions modeling the structural performance. This approach has been tested successfully in problems involving up to 10 design variables.

In this contribution, the strategy developed in [16, 29] is applied in order to estimate the reliability sensitivity of linear systems subject to dynamic Gaussian excitation. Novel aspects explored herein are the integration of the aforementioned strategy with an efficient IS scheme developed in [3] and an efficient means for generating approximations of functions related with the structural performance based on the sensitivity analysis of the spectral properties of the linear system under study, following the method proposed in [23]. These two novel aspects lead to a considerable reduction in the numerical costs associated with reliability sensitivity estimation when compared with the case of non linear structural systems. Finally, the error associated with the reliability sensitivity estimator is estimated most efficiently by applying the Bootstrap method introduced in [10].

The structure of this paper is as follows. Section 2 presents the details on the problem studied in this contribution. The approach for evaluating the structural response considering uncertainties in the excitation is discussed in Section 3. Then, Section 4 addresses an efficient simulation technique introduced in [3] for reliability evaluation of linear systems subject to Gaussian excitation. The proposed approach for reliability sensitivity estimation is discussed in Sections 5 and 6. Section 7 addresses the issue of quantifying the error of the estimator for reliability sensitivity developed in the two previous Sections by applying the Bootstrap method. A numerical example demonstrating the properties of the proposed approach is presented in Section 8. Finally, the paper closes with some final remarks and outlook.

2 GENERAL FORMULATION OF THE PROBLEM

Consider a structural system subject to a stochastic excitation of duration T . Let this excitation be represented by a random variable vector $\mathbf{z} \in \Omega_z \subset \mathbb{R}^{n_z}$ of dimension n_z characterized by a probability density function $p(\mathbf{z})$. Moreover, consider a set of responses of interest r_i , $i = 1, \dots, n_r$ of the system modeling the structural performance due to the stochastic excitation such as, e.g. displacements. As the excitation acting over the structure is uncertain, the responses of interest will be uncertain as well. In addition, suppose there is a set of design variables grouped in a vector \mathbf{y} of dimension n_y modeling properties of the system (such as cross section of structural members, material properties, etc.) that can be changed in order to alter the responses of interest. Clearly, the aforementioned responses of interest will be a function of both the design variable vector \mathbf{y} and the random variable vector \mathbf{z} characterizing the excitation. As this last vector also depends on time t , the responses will be also a function of time, i.e. $r_i = r_i(t, \mathbf{y}, \mathbf{z})$, $i = 1, \dots, n_r$, $t \in [0, T]$.

For design purposes, the responses of interest r_i , $i = 1, \dots, n_r$ are compared against accept-

able threshold levels r_i^* , $i = 1, \dots, n_r$. Within a deterministic framework, the objective would be ensuring that these responses do not exceed their prescribed thresholds. However, when uncertainties are considered, the aforementioned condition can be fulfilled only in a fraction of the possible cases, i.e. there is a probability that the responses do exceed their prescribed thresholds. Thus, reliability offers the means for quantifying the level of safety associated with a structural system. A criterion widely used to characterize the level of safety of a structure is the first excursion probability (see, e.g. [28]). This probability measures the chances that the uncertain responses exceed in magnitude the prescribed thresholds within a specified time interval. In other words, this probability measures the chances of occurrence of the following *failure event* F .

$$F = \left\{ \mathbf{z} \in \Omega_z : \max_{i=1, \dots, n_r} \left(\max_{t \in [0, T]} \left(\frac{|r_i(t, \mathbf{y}, \mathbf{z})|}{r_i^*} \right) \right) \geq 1 \right\} \quad (1)$$

It is important to remark that *failure* does not necessarily imply collapse. In fact, the criterion proposed in eq. (1) may refer to, e.g. partial damage states or unacceptable system performance. Alternatively, the failure event defined in eq. (1) can be expressed in terms of the so-called *normalized demand* $D_N(\mathbf{y}, \mathbf{z})$ [2]:

$$F = \{ \mathbf{z} \in \mathbb{R}^{n_z} : D_N(\mathbf{y}, \mathbf{z}) \geq 1 \} \quad (2)$$

where:

$$D_N(\mathbf{y}, \mathbf{z}) = \max_{i=1, \dots, n_r} \left(\max_{t \in [0, T]} \left(\frac{|r_i(t, \mathbf{y}, \mathbf{z})|}{r_i^*} \right) \right) \quad (3)$$

Once the failure event has been defined, it is possible to express its probability of occurrence by means of the following classical probability integral.

$$P_F(\mathbf{y}) = \int_{D_N(\mathbf{y}, \mathbf{z}) \geq 1} p(\mathbf{z}) d\mathbf{z} = \int_{\mathbf{z} \in \Omega_z} I_F(\mathbf{y}, \mathbf{z}) p(\mathbf{z}) d\mathbf{z} \quad (4)$$

In the last equation, $P_F(\mathbf{y})$ denotes the probability of failure (i.e. probability of occurrence of the event F) and $I_F(\mathbf{y}, \mathbf{z})$ is the indicator function which is equal to 1 in case the normalized demand is equal or larger than 1 and 0 otherwise.

As indicated in eq. (4), the probability of failure depends on the design variable vector \mathbf{y} . This has a clear physical interpretation: modifications on this vector (such as an increase in mass or stiffness) will certainly alter the response of the structure and also the probability of exceeding the prescribed thresholds. Thus, for design purposes, it is important to know not only the probability of failure $P_F(\mathbf{y})$ but also the change that this probability experiments due to changes in the design vector, as this allows determining the most influential design variables. This is denoted as the reliability sensitivity. A classical measure for sensitivity is calculating the gradient of the quantity of interest. However, within the context of linear dynamics, the estimation of the gradient of a probability may not be feasible as the gradient may not exist due to the non smooth normalized demand (see, e.g. [17]). Therefore, in this contribution, an approximate representation of the failure probabilities that is differentiable is constructed and then, the gradient of this approximation is estimated. Details on this strategy are described in Sections 5 and 6.

3 STRUCTURAL RESPONSE EVALUATION

3.1 Mechanical Model

The first step for assessing reliability and its sensitivity is characterizing the structural response. The differential equation describing the motion of a linear structure of n degrees of

freedom excited by a dynamical excitation is given by (see, e.g. [7]):

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{G}\mathbf{f}(t) \quad (5)$$

where $\mathbf{x}(t)$ is the displacement response vector of dimension n ; \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness matrices of dimension $n \times n$; $\mathbf{f}(t)$ is a vector of dimension n_f modeling the excitations acting over the structure; and \mathbf{G} is a $n \times n_f$ dimensional matrix that couples the excitation components of the vector $\mathbf{f}(t)$ with the degrees of freedom of the structure. Note that the excitation vector $\mathbf{f}(t)$ depends on the vector of random variables \mathbf{z} described in Section 2; the detailed relation between these vectors is discussed in Section 3.2. The responses of interest r_i , $i = 1, \dots, n_r$ associated with a particular set of values of \mathbf{y} can be evaluated using a convolution integral including the so-called impulse response functions $h_{i,j}(t, \mathbf{y})$, $i = 1, \dots, n_r$, $j = 1, \dots, n_f$, as indicated below.

$$r_i(t, \mathbf{y}, \mathbf{z}) = \sum_{j=1}^{n_f} \int_0^t h_{i,j}(t - \tau, \mathbf{y}) f_j(\tau) d\tau \quad (6)$$

In the last equation, $f_j(t)$ is the j -th component of the excitation vector and $h_{i,j}(t, \mathbf{y})$ is the impulse response function for the response function r_i at time t due to a unit impulse applied at the j -th input at time 0, where zero initial conditions have been assumed without loss of generality. It is noted that the dependence of the response function r_i on the vector of random variables \mathbf{z} is due to the characterization of the stochastic excitation $\mathbf{f}(t)$. In case the response function of interest is given, for example, as a linear combination of the components of the displacement vector, that is, $r_i = \gamma_i^T \mathbf{x}(t)$ and if the system possesses classical damping, the corresponding impulse response function is given by:

$$h_{i,j}(t, \mathbf{y}, \mathbf{z}) = \sum_{r=1}^n \alpha_r^{i,j} \frac{1}{\omega_{d,r}} e^{-\zeta_r \omega_r t} \sin(\omega_{d,r} t), \quad \alpha_r^{i,j} = \frac{\gamma_i^T \phi_r \phi_r^T \mathbf{g}_j}{\phi_r^T \mathbf{M} \phi_r} \quad (7)$$

where $\alpha_r^{i,j}$, $r = 1, \dots, n$, $i = 1, \dots, n_r$, $j = 1, \dots, n_f$ are mode factors, ϕ_r , $r = 1, \dots, n$ are the eigenvectors associated with the eigenproblem of the undamped equation of motion, ω_r , $r = 1, \dots, n$ are the natural frequencies of the system, ζ_r , $r = 1, \dots, n$ are the corresponding damping ratios, $\omega_{d,r} = \omega_r \sqrt{1 - \zeta_r^2}$, $r = 1, \dots, n$ are the damped frequencies and \mathbf{g}_j is the j -th column of the \mathbf{G} matrix. The last equation can be interpreted as the modal superposition formula for the impulse response functions. One advantage of this representation is that in general only a relatively small number of modes m will be required for performing dynamic analysis, i.e. $m \ll n$. Eventually, the contribution of the remaining modes can also be considered in the formulation by using the static solution of the structural modes of higher order [4].

3.2 Stochastic Excitation

Stochastic processes offer an adequate means for describing quantities fluctuating randomly in time such as earthquake ground motion, water wave loading, etc. In particular, a Gaussian process X_t , $t \in [0, T]$ is such that for every finite set $\{t_1, t_2, \dots, t_{n_T}\} \in [0, T]$, the random variables $X_{t_1}, X_{t_2}, \dots, X_{t_{n_T}}$ are jointly normally distributed (see, e.g. [28]). A quite general means for representing Gaussian processes is by applying the Karhunen-Loève (K-L) expansion of the corresponding covariance function (see, e.g. [20]). This representation is applicable to

stationary as well as to non stationary stochastic processes. In order to apply this representation for the excitation vector $\mathbf{f}(t)$ acting over a particular structural system (see eq. (5)), consider a discrete representation of time such that $\Delta t = T/(n_T - 1)$ where T is the duration of the excitation and n_T the number of time points so that the time instants of analysis are $t_k = (k - 1)\Delta t$, $k = 1, \dots, n_T$. Thus, the discrete K-L representation of the j -th component of $\mathbf{f}(t)$ is the following.

$$f_j(t_k) \approx f_j^0(t_k) + \sum_{s=1}^{n_{KL}} f_j^s(t_k) z_s^j, \quad k = 1, \dots, n_T, \quad j = 1, \dots, n_f \quad (8)$$

In the equation above, z_s^j , $s = 1, \dots, n_{KL}$ are independent, identically distributed standard Gaussian random variables, $f_j^0(t_k)$ and $f_j^s(t_k)$ denote the mean function and the s -th K-L component of $f_j(t_k)$, respectively, and n_{KL} is the order of truncation of the series expansion. The K-L vectors are determined by solving an eigenproblem of the corresponding covariance matrix of the discrete process. In the remaining part of this contribution, it is assumed – without loss of generality – that the excitation is a zero-mean process, i.e. $f_j^0(t_l) = 0$, $l = 1, \dots, n_T$. Considering the characterization of the components of the excitation vector described above and considering the convolution integral in eq. (6), the dynamic response of interest evaluated at time t_k can be written as:

$$r_i(t_k, \mathbf{y}, \mathbf{z}) = \Delta t \sum_{j=1}^{n_f} \sum_{s=1}^{n_{KL}} \left(\sum_{l=1}^k \epsilon_l h_{i,j}(t_k - t_l, \mathbf{y}) f_j^s(t_l) \right) z_s^j \quad (9)$$

where ϵ_l is a coefficient depending on the numerical integration scheme used in the evaluation of the convolution integral.

4 RELIABILITY ANALYSIS

4.1 Characterization of Elementary Failure Events

According to the definition in eq. (1), failure takes place whenever the absolute value of any of the responses exceeds the prescribed thresholds at any time within the duration of the stochastic excitation. Considering the discretization scheme proposed above, the occurrence of the failure event reduces to comparing the value of the n_r responses during the n_T discrete time steps against the prescribed thresholds. Thus, the failure event F can be expressed as the union of *elementary failure events* $F_{i,k}$, $i = 1, \dots, n_r$, $j = 1, \dots, n_T$, i.e.:

$$F = \bigcup_{i=1}^{n_r} \bigcup_{k=1}^{n_T} F_{i,k} \quad (10)$$

where:

$$F_{i,k} = \left\{ \mathbf{z} \in \Omega_z : \frac{|r_i(t_k, \mathbf{y}, \mathbf{z})|}{r_i^*} \geq 1 \right\} \quad (11)$$

Based on eq. (10), it is clear that the probability of failure is actually the probability of the union of a number of elementary failure elements. According to eq. (11), the elementary failure regions are defined as the region in the random variables space which cause a barrier crossing at instant t_k due to the i -th response function. Then, it is seen that the evaluation of $P_F(\mathbf{y})$ corresponds to a reliability problem of a series system of $n_r \times n_T$ failure elements. Using the linear

relations between input and response in terms of the Gaussian random variables \mathbf{z} (see eq. (9)), the so-called design points can be established in a straightforward manner defining uniquely the elementary failure regions $F_{i,k}$, $i = 1, \dots, n_r$, $j = 1, \dots, n_T$, see e.g. [8, 9]. It is reminded that the design point associated with the (i, k) -th elementary failure domain – which is denoted as $\mathbf{z}_{i,k}^*$ – can be defined using two equivalent criteria [14]. According to the geometrical criterion, the design point is the realization in the standard normal space that belongs to $F_{i,k}$ with the minimum Euclidean norm with respect to the origin. According to the probabilistic interpretation, the design point is the point belonging to $F_{i,k}$ with highest probability density $p(\mathbf{z})$.

Once the design point $\mathbf{z}_{i,k}^*$ has been established, the calculation of the probability of occurrence of the elementary failure events is straightforward. In particular, this probability is equal to $2\Phi(-\beta_{i,k}(\mathbf{y}))$, where $\Phi(\cdot)$ is the cumulative distribution function of the standard Gaussian distribution, and $\beta_{i,k}(\mathbf{y})$ is the so-called reliability index. Note that this reliability index is the norm of the corresponding design point, i.e. $\beta_{i,k}(\mathbf{y}) = \|\mathbf{z}_{i,k}^*\|$. For the particular case under study, the expression for calculating the reliability index associated with the i -th response and k -th discrete time is the following (see, e.g. [8]).

$$\beta_{i,k}(\mathbf{y}) = \|\mathbf{z}_{i,k}^*\| = \frac{r_i^*}{\Delta t \sqrt{\sum_{j=1}^{n_f} \sum_{s=1}^{n_{KL}} \left(\sum_{l=1}^k \epsilon_l h_{i,j}(t_k - t_l, \mathbf{y}) f_j^s(t_l) \right)^2}} \quad (12)$$

Additionally, the (s, j) -th component of the vector $\mathbf{z}_{i,k}^*$ is equal to:

$$(z_{i,k}^*)_j^s = \frac{r_i^* \left(\sum_{l=1}^k \epsilon_l h_{i,j}(t_k - t_l, \mathbf{y}) f_j^s(t_l) \right)}{\Delta t \sum_{j=1}^{n_f} \sum_{s=1}^{n_{KL}} \left(\sum_{l=1}^k \epsilon_l h_{i,j}(t_k - t_l, \mathbf{y}) f_j^s(t_l) \right)^2}, \quad s = 1, \dots, n_{KL}, \quad j = 1, \dots, n_f \quad (13)$$

4.2 Simulation Strategy

As the elementary failure regions are fully described by the design points, Importance Sampling (IS) arises as an option for evaluating the probability of occurrence (see, e.g. [26]). Thus, the probability integral in eq. (4) is estimated as:

$$P_F(\mathbf{y}) = \int_{\mathbf{z} \in \Omega_z} I_F(\mathbf{y}, \mathbf{z}) \frac{p(\mathbf{z})}{p_{IS}(\mathbf{z})} p_{IS}(\mathbf{z}) d\mathbf{z} \approx \frac{1}{N} \sum_{v=1}^N I_F(\mathbf{y}, \mathbf{z}^{(v)}) \frac{p(\mathbf{z}^{(v)})}{p_{IS}(\mathbf{z}^{(v)})} \quad (14)$$

where $p_{IS}(\mathbf{z})$ is the Importance Sampling density (ISD) function and $\mathbf{z}^{(v)}$, $v = 1, \dots, N$ are samples of the vector of uncertain parameters simulated according to $p_{IS}(\mathbf{z})$. The key issue for the application of the IS scheme described in eq. (14) is the design of an appropriate ISD function ensuring a low variability of the estimator of the probability. In particular, the ISD function proposed in [3] is applied here. This importance sampling density is defined as a weighted sum of probability density functions conditioned on the elementary failure events described previously, that is:

$$p_{IS}(\mathbf{z}) = \sum_{i=1}^{n_r} \sum_{k=1}^{n_T} \omega_{i,k}(\mathbf{y}) p_{IS}(\mathbf{z}/F_{i,k}) \quad (15)$$

where $\omega_{i,k} \geq 0$ is the weight associated with the elementary failure domain $F_{i,k}$ and it is defined such that:

$$\omega_{i,k}(\mathbf{y}) = \frac{\Phi(-\beta_{i,k}(\mathbf{y}))}{\sum_{l=1}^{n_r} \sum_{s=1}^{n_T} \Phi(-\beta_{l,s}(\mathbf{y}))} \quad (16)$$

Additionally, the distribution of \mathbf{z} conditioned on the elementary failure domain $F_{i,k}$ is defined as (according to Bayes' theorem):

$$p_{IS}(\mathbf{z}/F_{i,k}) = \frac{p(\mathbf{z})I_{F_{i,k}}(\mathbf{y}, \mathbf{z})}{2\Phi(-\beta_{i,k}(\mathbf{y}))} \quad (17)$$

where $I_{F_{i,k}}(\mathbf{y}, \mathbf{z})$ is an indicator function equal to one in case the (i, k) -th failure event takes place and zero, otherwise. Replacing the expressions in eqs. (15), (16) and (17) into eq. (14) yields the following estimator for the failure probability:

$$P_F(\mathbf{y}) \approx \hat{P}_F(\mathbf{y}) = \frac{2}{N} \left(\sum_{i=1}^{n_r} \sum_{k=1}^{n_T} \Phi(-\beta_{i,k}(\mathbf{y})) \right) \sum_{v=1}^N \frac{1}{\sum_{i=1}^{n_r} \sum_{k=1}^{n_T} I_{F_{i,k}}(\mathbf{y}, \mathbf{z}^{(v)})} \quad (18)$$

where $\hat{P}_F(\mathbf{y})$ denotes an estimator of the failure probability. It should be noted that in the estimator in eq. (18), the indicator function $I_F(\mathbf{y})$ is set equal to one, as the generation of samples of \mathbf{z} conditioned on an elementary failure event ensures that the failure events occurs. In summary, the estimation of the failure probability using the estimator in eq. (18) requires the characterization of the elementary failure domains through the design points and reliability indexes. Samples of the vector \mathbf{z} conditioned on the elementary failure events are required as well. These samples can be generated according to the technique proposed in [3]. Finally, the structural response associated with each of the samples of \mathbf{z} must be evaluated and compared with the threshold levels in order to compute the indicator function $I_{F_{i,k}}(\mathbf{y}, \mathbf{z})$.

5 FRAMEWORK FOR ESTIMATING RELIABILITY SENSITIVITY

As already mentioned above, the sought sensitivity of the probability of failure is expressed as the gradient of an approximate representation of the probability. This approximation is continuous and smooth, ensuring differentiability. In particular, consider the following approximate representation of the normalized demand function:

$$D_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z}) \approx \tilde{D}_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z}) = D_N(\mathbf{y}, \mathbf{z}) + \sum_{q=1}^{n_y} a_q \Delta y_q \quad (19)$$

where $\Delta\mathbf{y}$ is a certain perturbation of the design variable vector and a_q , $q = 1, \dots, n_y$ are real coefficients (the issue on how to compute these coefficients is discussed in Section 6). Now, consider the following limit, expressing the derivative of the approximate failure probability $\tilde{P}_F(\mathbf{y})$ with respect to y_q , $q = 1, \dots, n_y$.

$$\frac{\partial \tilde{P}_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{\tilde{P}_F(\mathbf{y} + \mathbf{v}(q)\Delta y_q) - \tilde{P}_F(\mathbf{y})}{\Delta y_q} \quad (20)$$

$$= \lim_{\Delta y_q \rightarrow 0} \frac{P[\tilde{D}_N(\mathbf{y} + \mathbf{v}(q)\Delta y_q, \mathbf{z}) \geq 1] - P[\tilde{D}_N(\mathbf{y}, \mathbf{z}) \geq 1]}{\Delta y_q} \quad (21)$$

where $P[\cdot]$ denotes the probability of occurrence of the event between brackets and where $\mathbf{v}(q)$ is a vector of length n_y with zero entries, except by the q -th entry, which is equal to one. Introducing the approximation of the normalized demand function of eq. (19) in eq. (21) yields the following result.

$$\frac{\partial \tilde{P}_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{P[D_N(\mathbf{y}, \mathbf{z}) \geq 1 - a_q \Delta y_q] - P[D_N(\mathbf{y}, \mathbf{z}) \geq 1]}{\Delta y_q} \quad (22)$$

To evaluate the limit in eq. (22), it is necessary to estimate the probability that the normalized demand (for a given design \mathbf{y}) exceeds two different threshold levels. That is, it is necessary to estimate $P[D_N(\mathbf{y}, \mathbf{z}) \geq b]$ for the values $b = 1$ and $b = 1 - a_q \Delta y_q$. Numerical experience has shown that this relation can be approximated by means of an exponential function [15], i.e.:

$$P[D_N(\mathbf{y}, \mathbf{z}) \geq b] \approx e^{\psi_0 + \psi_1(b-1)}, \quad b \in [1 - \epsilon, 1 + \epsilon] \quad (23)$$

where ϵ is a small constant, e.g. $\epsilon = 0.02$ and where ψ_0, ψ_1 are real coefficients (the details on the calculation of these coefficients are discussed in Section 6). After introducing eq. (23) in (22), an expression for computing the probability sensitivity can be obtained, as shown below.

$$\frac{\partial \tilde{P}_F(\mathbf{y})}{\partial y_q} = \lim_{\Delta y_q \rightarrow 0} \frac{e^{\psi_0 - \psi_1 a_q \Delta y_q} - e^{\psi_0}}{\Delta y_q} = -\psi_1 a_q e^{\psi_0} = -\psi_1 a_q \hat{P}_F(\mathbf{y}) \quad (24)$$

It is most interesting to note that the expression for estimating the derivative of the failure probability in eq. (24) depends on the estimate of the failure probability $\hat{P}_F(\mathbf{y})$, the coefficient ψ_1 and on a_q , $q = 1, \dots, n_y$. While the estimate of the failure probability can be computed with the procedure outlined in Section 4, the remaining coefficients are obtained using the procedure outlined in the following Section.

6 IMPLEMENTATION OF RELIABILITY SENSITIVITY ANALYSIS

6.1 Exponential Approximation of Probability

As discussed in the previous Section, the implementation of the proposed strategy for reliability sensitivity requires the generation of an exponential approximation of the probability that the normalized demand exceeds a threshold b . The procedure for reliability estimation described in Section 4 allows estimating the probability that the normalized demand exceeds 1. However, this procedure can be easily extended for estimating the required relation. As this required relation must be estimated for a range $b \in [1 - \epsilon, 1 + \epsilon]$, the definition of the elementary failure domains is slightly altered. In particular, the reliability indexes and design points defined in eqs. (12) and (13) are modified as follows: the term that denotes the threshold level r_i^* is replaced by $r_i^*(1 - \epsilon)$. This change ensures that the samples of \mathbf{z} are such that the values of the associated normalized demands are equal or larger than $(1 - \epsilon)$. In the second place, an indicator function $I_{F,b}(\mathbf{y}, \mathbf{z})$ is introduced in the estimator of eq. (18). This indicator function is defined such that:

$$I_{F,b}(\mathbf{y}, \mathbf{z}) = \begin{cases} 1 & \text{if } D_N(\mathbf{y}, \mathbf{z}) \geq b \\ 0 & \text{if } D_N(\mathbf{y}, \mathbf{z}) < b \end{cases} \quad (25)$$

The indicator function in the equation above is dependent on the threshold level b . This function is then included in the probability estimator of eq. (18) as shown below.

$$\hat{P}[D_N(\mathbf{y}, \mathbf{z}) \geq b] = \frac{2}{N} \left(\sum_{i=1}^{n_r} \sum_{k=1}^{n_T} \Phi(-\beta_{i,k}(\mathbf{y})) \right) \sum_{v=1}^N \frac{I_{F,b}(\mathbf{y}, \mathbf{z}^{(v)})}{\sum_{i=1}^{n_r} \sum_{k=1}^{n_T} I_{F,i,k}(\mathbf{y}, \mathbf{z}^{(v)})} \quad (26)$$

The estimator above can be used directly to estimate the probability that the normalized demand exceeds a certain threshold level. Thus, the estimator is applied as follows. Firstly, samples of the vector \mathbf{z} conditioned on the modified elementary failure events are generated. Then, response and normalized demand associated with each of these samples is computed. In the next step, the probability that the normalized demand exceeds a threshold level is computed over a suitable grid $b \in [1 - \epsilon, 1 + \epsilon]$. This allows generating pairs $(b, \hat{P}[D_N(\mathbf{y}, \mathbf{z}) \geq b])$. Finally,

the coefficients ψ_0, ψ_1 of the exponential approximation proposed in eq. (23) are calculated on a least square sense using the aforementioned pairs.

An important feature of the approach proposed above for calculating the coefficients ψ_0, ψ_1 is that it requires a single run of the simulation algorithm. Moreover, it should be noted that only minor modifications are introduced to the original approach for estimation the probability of failure presented in [3] and described in Section 4 of this contribution.

6.2 Linear Approximation of Normalized Demand Function

The expression in eq. (19) is as a *linear* expansion of the normalized demand function with respect to a perturbation in the design variable vector. In most cases, this expansion will not be exact, as changes in the normalized demand function due to perturbations in the design variables are non linear, implicit functions. Nonetheless, as long as the coefficients $a_q, q = 1, \dots, n_y$ are calibrated appropriately, it could be expected that $\tilde{D}_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z})$ can approximate $D_N(\mathbf{y} + \Delta\mathbf{y}, \mathbf{z})$ reasonably well. For a better understanding of the last point, consider the definition of normalized demand function in eq. (3). As this function includes the $\max(\cdot)$ operator, several elementary failure domains may be relevant in the calculation of $P_F(\mathbf{y})$. The sensitivity of each these elementary domains with respect to the design variables will be – in general – different. Thus, the linear expansion shown in eq. (19) will not capture those individual sensitivities. However, the coefficients a_q represent an *average sensitivity*, i.e. they are an approximate representation of the sensitivity of the individual elementary failure domains.

In view of the issues discussed above, the proposed approach for calibrating the coefficients a_q consists in two steps. In the first one, samples of the vector modeling the uncertain excitation \mathbf{z} are generated such that they lie precisely in the boundary of the failure event. The second step consists in calculating the sensitivity of the normalized demand function with respect to the design variables at the samples generated at the previous step. Thus, the sought coefficients can be calculated as the average of the sensitivities calculated for each sample.

From the two steps described above, the first one can be easily achieved by scaling the samples of \mathbf{z} generated at the reliability analysis step. Suppose that for a particular sample \mathbf{z}^* , the associated normalized demand function is equal to $D_N(\mathbf{y}, \mathbf{z}^*) = b^*$. Then, the required sample is equal to the original sample multiplied by the reciprocal of b^* , i.e. $D_N(\mathbf{y}, (1/b^*)\mathbf{z}^*) = 1$. This property holds due to the linearity of the equation of motion with respect to the excitation (see eq. (5)).

The second step of the proposed approach for calibrating the coefficients a_q consists in estimating the sensitivity of the normalized demand function with respect to the design variables at the sample point \mathbf{z}^* . Suppose that the sample \mathbf{z}^* lies in the boundary of the (i^*, k^*) -th elementary failure domain. That means that the failure event is reached because the i^* -th response achieved the threshold value $r_{i^*}^*$ at the k^* -th discrete time step. Thus, the sensitivity of the associated normalized demand function can be approximated by considering the derivatives of corresponding response at that particular time, i.e.:

$$\frac{\Delta D_N(\mathbf{y}, (1/b^*)\mathbf{z}^*)}{\Delta y_q} \approx \frac{1}{r_{i^*}^*} \text{sgn}(r_{i^*}(t_{k^*}, \mathbf{y}, (1/b^*)\mathbf{z}^*)) \frac{\partial r_{i^*}(t_{k^*}, \mathbf{y}, (1/b^*)\mathbf{z}^*)}{\partial y_q}, \quad q = 1, \dots, n_y \quad (27)$$

In the last equation, $\text{sgn}(\cdot)$ is the sign function. The derivative of the response function r_i at the k -th time can be computed by calculating the derivative of the impulse response function with respect to the design variables. Thus, considering the expression for calculating the response of

interest in eq. (9), the expression for estimating the sensitivity of the response is as follows.

$$\frac{\partial r_i(t_k, \mathbf{y}, \mathbf{z})}{\partial y_q} = \Delta t \sum_{j=1}^{n_f} \sum_{s=1}^{n_{KL}} \left(\sum_{l=1}^k \epsilon_l \frac{\partial h_{i,j}(t_k - t_l, \mathbf{y})}{\partial y_q} f_j^s(t_l) \right) z_s^j \quad (28)$$

In the equation above, $\partial h_{i,j}(t_l, \mathbf{y})/\partial y_q$ represents the derivative of the impulse response function with respect to the q -th design variable. Moreover, it is assumed that the coefficients of the K-L expansion of the stochastic excitation do not depend on the design variable y_q , $q = 1, \dots, n_y$.

The calculation of the derivative of the impulse response function implies calculating the derivative of the spectral properties (frequencies and eigenvectors associated with the eigenproblem of the undamped equation of motion). In this contribution, an efficient procedure for determining eigenvector derivatives developed in [23] is used. In that procedure the calculation of the derivatives of a given eigenvector requires only eigendata associated with that eigenvector. The simplified procedure is much more efficient than standard methods in which eigenvector derivatives are expressed in terms of all eigenvectors.

Once the sensitivities of the responses are calculated according to eq. (28), the sought coefficients a_q are calculated taking the average of the sensitivities calculated for all the samples generated.

$$a_q = \frac{1}{N} \sum_{v=1}^N \frac{\Delta D_N(\mathbf{y}, (1/b^{*,(v)}) \mathbf{z}^{*,(v)})}{\Delta y_q} \quad (29)$$

An interesting feature of the approach proposed above is that it requires a single sensitivity analysis of the spectral properties. The numerical costs associated with this analysis can be considerably lower than solving the eigenproblem for perturbed values of the design variables.

7 VARIABILITY OF RELIABILITY SENSITIVITY ESTIMATOR

The approach for evaluating the sensitivity of a reliability metric with respect to design variables described in Sections 5 and 6 is based on the information provided by N samples of the uncertain parameters generated through IS. More specifically, some local approximations involving these samples and the sensitivity of the normalized demand associated with them is used to compute an approximate measure of the sought quantity, as shown in eq. (24). In mathematical terms, this dependence of the estimator on the samples is represented as shown below.

$$\frac{\partial \tilde{P}_F(\mathbf{y})}{\partial y_q} = m_S(\mathbf{y}, q, \mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_N) \quad (30)$$

In the equation above, $m_S(\cdot)$ denotes the (nonlinear) function that allows estimating the sensitivity based on N samples of the uncertain parameters, q is the index associated with the q -th design variable and \mathbf{z}_v , $v = 1, \dots, N$ represents a random variable vector distributed according to the prescribed probability density function associated with the simulation method being used to estimate reliability; in this case, $\mathbf{z}_v \sim p_{IS}(\mathbf{z})$, $v = 1, \dots, N$. From eq. (30), it is clear that the estimator of the sensitivity is subject to variability, as it is a function of a finite sample N . Therefore, besides assessing the estimator of the sensitivity considering the aforementioned approach, it is also important to assess the variability of this estimator, as this allows gaining insight on its error. This error can be quantified by means of the standard deviation of the estimator:

$$\sigma_{\partial \tilde{P}_F / \partial y_q} = \sqrt{V[m_S(\mathbf{y}, q, \mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_N)]} \quad (31)$$

where $\sigma_{\partial \tilde{P}_F / \partial y_q}$ is the standard deviation of the sensitivity of probability w.r.t. the q -th design variable and $V[\cdot]$ represents the variance. It should be noted that assessing the standard deviation $\sigma_{\partial \tilde{P}_F / \partial y_q}$ analytically can be a challenging task, as $m_S(\cdot)$ is an involved nonlinear function. Thus, some alternative approach must be applied in order to assess the sought standard deviation.

A simple means for assessing $\sigma_{\partial \tilde{P}_F / \partial y_q}$ would be simply generating N_R estimates of the probability sensitivity and then calculating the sample standard deviation, i.e.:

$$\sigma_{\partial \tilde{P}_F / \partial y_q} \approx \hat{\sigma}_{\partial \tilde{P}_F / \partial y_q} = \sqrt{\frac{1}{N_R - 1} \sum_{w=1}^{N_R} \left(\frac{\partial \tilde{P}_F^{(w)}(\mathbf{y})}{\partial y_q} - \frac{\partial \bar{\tilde{P}}_F(\mathbf{y})}{\partial y_q} \right)^2} \quad (32)$$

where

$$\frac{\partial \bar{\tilde{P}}_F(\mathbf{y})}{\partial y_q} = \frac{1}{N_R} \sum_{w=1}^{N_R} \frac{\partial \tilde{P}_F^{(w)}(\mathbf{y})}{\partial y_q} \quad (33)$$

and $\partial \tilde{P}_F^{(w)}(\mathbf{y}) / \partial y_q$, $w = 1, \dots, N_R$ is the w -th estimate of the sensitivity. Although this approach can be implemented, it is highly inefficient from a numerical point of view, as for generating one estimate of the sensitivity (out of the N_R required) it is necessary to compute the dynamical response of the structural system N times. An alternative approach that allows calculating the sought standard deviation and that avoids the repeated simulation of the dynamical response is the so-called Bootstrap method [10]. Bootstrap consists in estimating a particular property of an estimator (such as the standard deviation) based on samples distributed according to an empirical probability distribution. This empirical distribution is constructed based on the very same sample pool used for calculating the estimator. Thus, applying resampling over this pool it is possible to generate a sample set of the estimator and then, calculate the sought property directly from the latter sample set. Algorithmically, this procedure is implemented as described below. For further details on the implementation of the Bootstrap method and its convergence it is referred to, e.g. [5, 10, 11, 27]

1. Generate N samples of the uncertain parameter vector (ground acceleration) and group them in a set C , i.e. $C = \{\mathbf{z}^{(1)}, \mathbf{z}^{(2)}, \dots, \mathbf{z}^{(N)}\}$. Note that the samples generated at this step are the same samples generated for estimating the probability of failure and its sensitivity.
2. Draw a bootstrap sample $C^* = \{\mathbf{z}^{*,(1)}, \mathbf{z}^{*,(2)}, \dots, \mathbf{z}^{*,(N)}\}$ by making independent random sampling from C . Note that this sampling considers replacement and the relative weight of each member of set C is equal to $1/N$. Estimate the reliability sensitivity for the sample set C^* considering the nonlinear mapping function $m_S(\cdot)$, i.e.:

$$\frac{\partial \tilde{P}_F^*(\mathbf{y})}{\partial y_q} = m_S(\mathbf{y}, q, \mathbf{z}^{*,(1)}, \mathbf{z}^{*,(2)}, \dots, \mathbf{z}^{*,(N)}) \quad (34)$$

3. Repeat step 2 a total of N_R times in order to obtain bootstrap replications $\partial \tilde{P}_F^{*,(1)}(\mathbf{y}) / \partial y_q$, $\partial \tilde{P}_F^{*,(2)}(\mathbf{y}) / \partial y_q$, \dots , $\partial \tilde{P}_F^{*,(N_R)}(\mathbf{y}) / \partial y_q$. Estimate $\sigma_{\partial \tilde{P}_F / \partial y_q}$ based on the sample standard deviation of the bootstrap replications.

Provided that N_R is chosen sufficiently large, the procedure described above can produce accurate estimates of the sought standard deviation. For the particular case of this contribution, it

Figure 1: Example - 2-DOF shear beam model

has been found that the Bootstrap method is a very convenient approach for estimating the error of the reliability sensitivity estimator, as no additional computations of the dynamical response are required once the estimator has been calculated. This is a crucial point, as the assessment of the dynamical response can be numerically demanding due to the duration of the stochastic excitation and also due to the size of the matrices associated with the structural model.

8 NUMERICAL EXAMPLE

8.1 Description

A 2-DOF linear shear beam model is considered in the example. The model is depicted in fig. (1). The system is excited by a horizontal ground acceleration $g_A(t)$ of 15 [s] duration, which is modeled as a discrete white noise. The responses of the system to be controlled involve the displacements of each floor due to the ground acceleration. These responses are compared with prescribed thresholds in order to define whether or not failure occurs. The objective is estimating the sensitivity of the probability of failure with respect to the stiffnesses of each of floor.

As shown in fig. (1), each floor of the model is supported by two columns. It is assumed that the columns are perfectly clamped and axially very stiff. Thus, each column can be described by its lateral stiffness $k_i/2 = 9 \times 10^6$ [N/m], $i = 1, 2$. The mass of each floor of the model is equal to $m_1 = m_2 = 30 \times 10^3$ [kg]. It is assumed that the damping associated with the structure is classical with modal damping ratios equal to 4% for each vibration mode. The external force vector is defined as $\mathbf{f}(t) = -\mathbf{M}g_A(t)$, where \mathbf{M} is the mass matrix and $g_A(t)$ is a horizontal ground acceleration, which is modeled as a discrete white noise of 15 [s] duration. A time discretization step equal to $\Delta t = 0.01$ [s] is used to model the ground acceleration. The discrete representation of the white noise signal is such that the coefficients of the K-L expansion of the ground acceleration g_A are equal to:

$$f^s(t_k) = \begin{cases} \sqrt{\frac{2\pi S}{\Delta t}} & \text{if } s = k \\ 0 & \text{if } s \neq k \end{cases}, \quad k = 1, \dots, 1501 \quad (35)$$

In the above equation, $S = 10^{-4}$ [m²/s³] is the power spectral density of the white noise. Note that a total of 1501 random variables are involved in the characterization of the excitation.

The failure event is formulated as a first passage problem during the time of analysis. The structural responses to be controlled are the 2 interstorey drift displacements and the roof displacement. The threshold values are chosen equal to 6×10^{-3} [m] for each of these three responses. In addition, the design variable vector \mathbf{y} groups the stiffnesses of the columns of

each floor, i.e. $\mathbf{y} = \langle k_1, k_2 \rangle^T$. Thus, the reliability problem is formally defined as:

$$P_F(\mathbf{y}) = \int_{D_N(\mathbf{y}, \mathbf{z}) \geq 1} p(\mathbf{z}) d\mathbf{z} \quad (36)$$

where:

$$D_N(\mathbf{y}, \mathbf{z}) = \max_{i=1,2,3} \left(\max_{k=1,\dots,1501} \left(\frac{|r_i(\Delta t(k-1), \mathbf{y}, \mathbf{z})|}{r_i^*} \right) \right) \quad (37)$$

8.2 Results

Before reporting on the results of reliability sensitivity, the results of reliability are presented for the sake of completeness. Applying the simulation strategy described in Section 4 considering a total of 200 samples of the stochastic ground acceleration, it is determined that the probability of failure related with the system described above is equal to $P_F = 4 \times 10^{-4}$. Moreover, the associated coefficient of variation (CoV) of this estimator is equal to 6.5%. Recall that the coefficient of variation is defined as the ratio between the standard deviation of the estimator and the mean value of the estimator. It should be noted that the probability of failure of the system is quite low, thus precluding the possibility of using direct Monte Carlo Simulation for its estimation because of high numerical costs associated.

Next, in order to estimate the reliability sensitivity of the failure probability in eq. (36) with respect to the stiffnesses, two different approaches are considered, namely:

- **Approach 1:** the sensitivity is estimated by performing finite differences, i.e.:

$$\frac{\Delta \hat{P}_F(\mathbf{y})}{\Delta y_q} = \frac{\hat{P}_F(\mathbf{y} + \mathbf{v}(q)\Delta y_q) - \hat{P}_F(\mathbf{y} - \mathbf{v}(q)\Delta y_q)}{2\Delta y_q}, \quad q = 1, 2 \quad (38)$$

In the estimator of the equation above, the perturbation introduced is such that $\Delta y_q/y_q = 0.1\%$. As it can be noted from the formula, two reliability analyses are required for estimating the sensitivity with respect to one design variable. For each of these reliability analyses, a total of 200 samples of the vector modeling the excitation are generated. As the sensitivity metric in eq. (38) may be affected by the variability of the probability estimator $\hat{P}_F(\mathbf{y})$, a total of 200 independent estimations of the sensitivity are performed and then, an average result is considered. Thus, the estimate of the sensitivity generated using this procedure is considered as a reference.

- **Approach 2:** the sensitivities are estimated using the approach proposed in Sections 5 and 6. A total of 200 independent runs of this approach are performed, in order to assess the variability of the estimates. Each individual simulation involves generating 200 samples of the vector modeling the stochastic excitation.

The results obtained are shown in figs. (2) and (3), respectively. Figure (2) shows the estimates of probability sensitivity in the form of arrows indicating the magnitude of the sensitivity; the results obtained with the proposed approach are presented with gray, thin line (only ten simulations were plotted for the sake of clarity) and the reference result with black, thick line. It can be observed that the estimates generated with the proposed approach present very little dispersion. Moreover, on the average, they tend to converge to the reference result. Figure (3) also shows the probability sensitivity estimates for the two approaches described above. Note that this figure includes the results for the proposed approach in terms of the mean plus/minus one

Figure 2: Sensitivity Analysis - 10 independent estimations using proposed approach (gray, thin line) compared to reference solution (black, thick line)

Figure 3: Sensitivity Analysis - mean \pm std. deviation using results of proposed approach compared to reference solution

standard deviation. As it can be observed, the variability of the proposed approach is quite low, producing accurate estimates of the probability sensitivity. Finally, in order to assess the error associated with the reliability sensitivity estimators, the Bootstrap method described in Section 7 is applied. In particular, the number bootstrap replications of the sensitivity metric that are generated is selected such that $N_R = 1000$. It is found that this number ensures sufficient accuracy for estimating the standard deviation of the reliability sensitivity estimator. Recall that the numerical cost associated with the generation of bootstrap replications is negligible, as no additional dynamic analysis are required. The results obtained are presented in Table 1. In this table, the standard deviations of the estimators of reliability sensitivity calculated with the Bootstrap method are compared with the results obtained through approach 2 described above. Note that the latter approach for calculating the aforementioned standard deviations is numerically demanding; however, these results are included here as they constitute a reference. In addition, Table 1 also summarizes the coefficients of variation of each estimator (indicated in parenthesis). It can be seen that the results obtained with Bootstrap are in excellent agreement with the reference results.

Method	$\sigma_{\partial \tilde{P}_F / \partial K_1}$ $\left(\text{CoV}_{\partial \tilde{P}_F / \partial K_1} \right)$	$\sigma_{\partial \tilde{P}_F / \partial K_2}$ $\left(\text{CoV}_{\partial \tilde{P}_F / \partial K_2} \right)$	Number of Dynamic Analyses

9 CONCLUSIONS AND OUTLOOK

This contribution has presented an approach for estimating reliability sensitivity of linear structures subject to Gaussian stochastic excitation. The approach is based on a general framework that was proposed for non linear systems. Taking advantage of the linearity of the problem studied here, this general framework was modified appropriately.

The key issue of the proposed approach is replacing the original reliability problem by one that is differentiable. Thus, the sought sensitivities are calculated by combining an efficient simulation technique with two approximation concepts. The first of these approximations involves the construction of an exponential function modeling the probability that the normalized demand exceeds a prescribed threshold. This approximation can be constructed using the information generated by the simulation technique when estimating reliability. The second approximation involves the sensitivity analysis of the responses of interest of the structural system with respect to design variables. This sensitivity analysis can be performed most efficiently by applying a specific procedure for computing the sensitivity of spectral properties.

A salient feature of the proposed approach for reliability sensitivity is that it can be very efficient from a numerical point of view. The same samples generated for reliability sensitivity can be employed for constructing the aforementioned exponential approximation. In addition, the second approximation mentioned above requires a sensitivity analysis of the spectral properties, which is a problem that is numerically inexpensive when compared to solving a full eigenproblem for perturbed values of the design variable vector. Besides these two approximations, the

application of the Bootstrap method allows estimating the error of the estimator most efficiently, as no additional dynamic analyses are required.

Future research efforts aim at testing the proposed approach in examples involving a larger number of design variables, subject not only to white noise but also to other types of Gaussian processes.

Keywords: Approximation strategies, Base-isolated systems, Simulation, Reliability-based design.

Abstract. *The development of a general framework for reliability-based design of base-isolated structural systems under uncertain conditions is presented. The uncertainties about the structural parameters as well as the variability of future excitations are characterized in a probabilistic manner. Nonlinear elements composed by hysteretic devices are used for the isolation system. The optimal design problem is formulated as a constrained minimization problem which is solved by a sequential approximate optimization scheme. First excursion probabilities that account for the uncertainties in the system parameters as well as in the excitation are used to characterize the system reliability. The approach explicitly takes into account all non-linear characteristics of the combined structural system (superstructure-isolation system) during the design process. Numerical results highlight the beneficial effects of isolation systems in reducing the superstructure response.*

1 INTRODUCTION

There has been a growing interest during the last years in the application of base isolation techniques in order to improve the earthquake resistant performance of civil structures such as buildings, bridges, nuclear reactors, etc. [8, 10, 23, 34]. In fact, the potential advantages of seismic isolation and the recent advancements in isolation-system products have lead to the design and construction of an increasing number of seismically isolated structural systems. Also, seismic isolation is extensively used for seismic retrofitting of existing structures [11, 27]. One of the difficulties in the design of base-isolated structural systems is the explicit consideration of the nonlinear behavior of the isolators during the design process. Similarly, the consideration of uncertainty about the structural model and the potential variability of future ground motions is a major challenge in the analysis and design of these systems. The goal of this work is the development of a general framework for reliability based design of base-isolated systems under uncertain conditions. In particular, base-isolated building structures subject to earthquake excitation are considered in this study. A probabilistic approach is adopted for addressing the uncertainties about the structural model as well as the variability of future excitations. The uncertain earthquake excitation is modeled as a non-stationary stochastic process with uncertain model parameters. Specifically, a point-source model characterized by the moment magnitude and epicentral distance is adopted in this formulation [6]. Isolation elements composed by hysteretic devices are used for the isolation system and they are characterized by the Bouc-Wen type model [5]. The model provides general parametric hysteresis rules that gives a smooth transition of the change of stiffness as the deformation of the nonlinear elements changes. The reliability-based optimization problem is formulated as the minimization of an objective function subject to multiple design requirements including reliability constraints. First excursion probabilities are used as measures of system reliability. Such probabilities are estimated by an adaptive Markov Chain Monte Carlo procedure [4]. A sequential optimization approach based on global conservative, convex and separable approximations is implemented for solving the optimization problem [14, 18, 21]. The approach explicitly takes into account all non-linear characteristics of the structural response in the design process and it allows for a complex characterization of structural systems and excitation models. The solution of the equation of motion of the combined system (superstructure-isolation system) required during the simulation process is computed by a modified Runge-Kutta scheme of fourth-order. A numerical example is presented in order to illustrate the applicability and effectiveness of the proposed framework for reliability-based design of a base-isolated building.

2 RELIABILITY-BASED DESIGN PROBLEM

The optimal design problem is defined as the identification of a vector $\{\phi\}$ of design variables that minimizes an objective function, that is

$$\text{Minimize } f(\{\phi\}) \quad (1)$$

subject to design constraints

$$h_j(\{\phi\}) \leq 0 \quad , \quad j = 1, \dots, n_c \quad (2)$$

and side constraints

$$\phi_i^l \leq \phi_i \leq \phi_i^u \quad ; \quad i = 1, \dots, n_d \quad (3)$$

The objective function is defined in terms of quantities such as initial, construction, repair, or downtime costs. On the other hand, the design constraints are given in terms of reliability constraints and/or constraints related to deterministic design requirements. In a stochastic setting the reliability constraints are usually defined in terms of failure probabilities. These probabilities provide a measure of the plausibility of the occurrence of unacceptable behavior (failure) of the system, based on the available information. The probability of failure $P_{F_j}(\{\phi\})$ corresponding to a failure event F_j evaluated at the design $\{\phi\}$ can be expressed in terms of the multidimensional probability integral [13, 15]

$$P_{F_j}(\{\phi\}) = \int_{\Theta} I_{F_j}(\{\phi\}, \{\theta\}) q(\{\theta\}) d\{\theta\} \quad (4)$$

where $I_{F_j}(\{\phi\}, \{\theta\})$ is the indicator function for failure, which is equal to one if the system fail and zero otherwise, and $\{\theta\}, \theta_i, i = 1, \dots, n_u$ is the vector that represents the uncertain system parameters involved in the problem (structural parameters and excitation). The uncertain system parameters $\{\theta\}$ are modeled using a prescribed probability density function $q(\{\theta\})$ which incorporates available knowledge about the system. Note, that the failure probability function $P_{F_j}(\{\phi\})$ accounts for the uncertainty in the system parameters as well as the uncertainties in the excitation. A model prediction error, that is, the error between the response of the actual system and the response of the model, can also be considered in the formulation [12, 31]. In this case the prediction error may be modeled probabilistically by augmenting the vector $\{\theta\}$ to form an uncertain parameter vector composed of both the structural and excitation model parameters as well as the model prediction-error. The failure domain $\Omega_{F_j}(\{\phi\})$ corresponding to the failure event F_j evaluated at the design $\{\phi\}$ is typically described in terms of a performance function g_j as

$$\Omega_{F_j}(\{\phi\}) = \{\{\theta\} \mid g_j(\{\phi\}, \{\theta\}) \geq 0\} \quad (5)$$

Then, the probability of failure can also be expressed in terms of the failure domain in the form

$$P_{F_j}(\{\phi\}) = \int_{\Omega_{F_j}(\{\phi\})} q(\{\theta\}) d\{\theta\} \quad (6)$$

With the previous notation, a reliability constraint can be written as $h_j(\{\phi\}) = P_{F_j}(\{\phi\}) - P_{F_j}^* \leq 0$, where $P_{F_j}^*$ is the target failure probability. The last inequality expresses the requirement that the probability of system failure must be smaller than an appropriate tolerance. It is noted that in the context of stochastic design a system that corresponds to a feasible design can not be certified with complete certainty, but with a tolerance $P_{F_j}^*$. In other words, the system will operate safely within the pre-specified probability of failure tolerance.

3 STRUCTURAL MODEL

In general, base-isolated buildings are designed such that the superstructure remains elastic. Hence, the structure is modeled as a linear elastic system in the present formulation. The base and the floors are assumed to be infinitely rigid in plane. The superstructure and the base are modeled using three degrees of freedom per floor at the center of mass. Each nonlinear isolation element is modeled explicitly using the Buoc-Wen model. Let $\{x_s(t)\}$ be the n -th dimensional vector of absolute displacements for the superstructure with respect to the base, and $[M_s]$, $[C_s]$, and $[K_s]$ be the corresponding mass, damping and stiffness matrices. Also, let $\{x_b(t)\}$ be the vector of base displacements with three components and $[G_s]$ be the matrix

of earthquake influence coefficients of dimension $n \times 3$, that is, the matrix that couples the excitation components of the vector $\{\ddot{x}_g(t)\}$ to the degrees of freedom of the superstructure. The schematic representation of the base-isolated structural system as well as the displacement coordinates are shown in Figure (1). The equation of motion of the elastic superstructure is then expressed in the form

$$[M_s]\{\ddot{x}_s(t)\} + [C_s]\{\dot{x}_s(t)\} + [K_s]\{x_s(t)\} = -[M_s][G_s](\{\ddot{x}_b(t)\} + \{\ddot{x}_g(t)\}) \quad (7)$$

where $\{\ddot{x}_b(t)\}$ is the vector of base accelerations relative to the ground. On the other hand, the equation of motion of the base can be written as

$$([G_s]^T[M_s][G_s] + [M_b])(\{\ddot{x}_b(t)\} + \{\ddot{x}_g(t)\}) + [G_s]^T[M_s]\{\ddot{x}_s(t)\} + \{f_{is}\} = \{0\} \quad (8)$$

where $[M_b]$ is the diagonal mass matrix of the rigid base, and $\{f_{is}\}$ is the vector containing the nonlinear isolation elements forces (three components). The characterization of such forces is treated in a subsequent Section. Rewriting the previous equations, the combined equation of motion of the base-isolated structure system can be formulated in the form

$$\begin{bmatrix} [M_s] & [M_s][G_s] \\ [G_s]^T[M_s] & [M_b] + [G_s]^T[M_s][G_s] \end{bmatrix} \begin{Bmatrix} \{\ddot{x}_s(t)\} \\ \{\ddot{x}_b(t)\} \end{Bmatrix} + \begin{bmatrix} [C_s] & [0] \\ [0]^T & [0] \end{bmatrix} \begin{Bmatrix} \{\dot{x}_s(t)\} \\ \{\dot{x}_b(t)\} \end{Bmatrix} + \begin{bmatrix} [K_s] & [0] \\ [0]^T & [0] \end{bmatrix} \begin{Bmatrix} \{x_s(t)\} \\ \{x_b(t)\} \end{Bmatrix} = - \begin{bmatrix} [M_s][G_s] \\ [M_b] + [G_s]^T[M_s][G_s] \end{bmatrix} \{\ddot{x}_g(t)\} - \begin{Bmatrix} \{0\} \\ \{f_{is}(t)\} \end{Bmatrix} \quad (9)$$

It is noted that elastic and viscous isolation elements can also be incorporated in the isolation model. Also, the above formulation can be directly extended to more complex cases, for example to nonlinear models for the superstructure.

4 EARTHQUAKE EXCITATION MODEL

The ground acceleration is modeled as a non-stationary stochastic process. In particular, a point-source model characterized by the moment magnitude M and epicentral distance r is considered here [3, 6]. The model is a simple, yet powerful means for simulating ground motions and it has been successfully applied in the context of earthquake engineering. The time-history of the ground acceleration for a given magnitude M and epicentral distance r is obtained by modulating a white noise sequence by an envelope function and subsequently by a ground motion spectrum through the following steps: 1) generate a discrete-time Gaussian white noise sequence $\omega(t_j) = \sqrt{I/\Delta t} \theta_j$, $j = 1, \dots, n_T$, where $\theta_j, j = 1, \dots, n_T$, are independent, identically distributed standard Gaussian random variables, I is the white noise intensity, Δt is the sampling interval, and n_T is the number of time instants equal to the duration of the excitation T divided by the sampling interval; 2) the white noise sequence is modulated by an envelope function $h(t, M, r)$ at the discrete time instants; 3) the modulated white noise sequence is transformed to the frequency domain; 4) the resulting spectrum is normalized by the square root of the average square amplitude spectrum; 5) the normalized spectrum is multiplied by a ground motion spectrum (or radiation spectrum) $S(f, M, r)$ at discrete frequencies $f_l = l/T, l = 1, \dots, n_T/2$; 6) the modified spectrum is transformed back to the time domain to yield the desired ground acceleration time history. Details of the characterization of the

Figure 1: Schematic representation of the base-isolated structural model

envelope function $h(t, M, r)$ and the ground acceleration spectrum $S(f, M, r)$ are provided in the subsequent sections. The probabilistic model for the seismic hazard at the emplacement is complemented by considering that the moment magnitude M and epicentral distance r are also uncertain. The uncertainty in moment magnitude is modeled by the Gutenberg-Richter relationship truncated on the interval $[6.0, 8.0]$, which leads to the probability density function [25]

$$p(M) = \frac{b e^{-bM}}{e^{-6.0b} - e^{-8.0b}} \quad , \quad 6.0 \leq M \leq 8.0 \quad (10)$$

where b is a regional seismicity factor. For the uncertainty in the epicentral distance r , a log-normal distribution with mean value \bar{r} (km) and standard deviation σ_r (km) is used. The point source stochastic model previously described is well suited for generating the high-frequency components of the ground motion (greater than 0.1 Hz). Low-frequency components can also be introduced in the analysis by combining the above methodology with near-fault ground motion models [26].

4.1 Envelope function

The envelope function for the ground acceleration is represented by [29, 6]

$$h(t, M, r) = a_1 \left(\frac{t}{t_n} \right)^{a_2} e^{-a_3 \left(\frac{t}{t_n} \right)} \quad (11)$$

where

$$a_2 = \frac{-0.2 \ln(0.05)}{1 + 0.2(\ln(0.2) - 1)} \quad , \quad a_3 = \frac{a_2}{0.2} \quad , \quad a_1 = \left(\frac{e^1}{0.2} \right)^{a_2} \quad (12)$$

The envelope function has a peak equal to unity when $t = 0.2 t_n$, and $h(t, M, r) = 0.05$ when $t = t_n$, with $t_n = 2.0 T_{gm}$, where T_{gm} is the duration of ground motion, expressed as

a sum of a path dependent and source dependent component $T_{gm} = 0.05\sqrt{r^2 + h^2} + 0.5/f_a$, where r is the epicentral distance, and the parameters h and f_a (corner frequency) are moment dependent given by $\log(h) = 0.15M - 0.05$ and $\log(f_a) = 2.181 - 0.496M$ [3]. As an example Figure (2) shows the envelope function for $r = 20$ km, and $M = 5$ and $M = 7$. Note that increasing the moment magnitude increases the duration of the envelope function, as expected.

Figure 2: Envelope function for epicentral distance $r = 20$ km and moment magnitudes $M = 5$ and $M = 7$

4.2 Ground motion spectrum

The total spectrum of the motion at a site $S(f, M, r)$ is expressed as the product of the contribution from the earthquake source $E(f, M)$, path $P(f, r)$, site $G(f)$ and type of motion $I(f)$, i.e.

$$S(f, M, r) = E(f, M) P(f, r) G(f) I(f) \quad (13)$$

The source component is given by

$$E(f, M) = C M_0(M) S_a(f, M) \quad (14)$$

where C is a constant, $M_0(M) = 10^{1.5M+10.7}$ is the seismic moment, and the factor S_a is the displacement source spectrum given by [3]

$$S_a(f, M) = \frac{1 - \varepsilon}{1 + \left(\frac{f}{f_a}\right)^2} + \frac{\varepsilon}{1 + \left(\frac{f}{f_b}\right)^2} \quad (15)$$

where the corner frequencies f_a and f_b , and the weighting parameter ε are defined, respectively, as $\log(f_a) = 2.181 - 0.496M$, $\log(f_b) = 2.41 - 0.408M$, and $\log(\varepsilon) = 0.605 - 0.255M$. The constant C is given by $C = UR_\Phi VF/4\pi\rho_s\beta_s^3R_0$, where U is a units dependent factor, R_Φ is the radiation pattern, V represents the partition of total shear-wave energy into horizontal components, F is the effect of the free surface amplification, ρ_s and β_s are the density and shear-wave velocity in the vicinity of the source, and R_0 is a reference distance.

Next, the path effect $P(f, r)$ which is another component of the process that affect the spectrum of motion at a particular site it is represented by functions that account for geometrical spreading and attenuation

$$P(f, r) = Z(R(r)) e^{-\pi f R(r)/Q(f)\beta_s} \quad (16)$$

where $R(r)$ is the radial distance from the hypocenter to the site given by $R(r) = \sqrt{r^2 + h^2}$. The attenuation quantity $Q(f)$ is taken as $Q(f) = 180f^{0.45}$ and the geometrical spreading function is selected as $Z(R(r)) = 1/R(r)$ if $R(r) < 70.0$ km and $Z(R(r)) = 1/70.0$ otherwise [3]. The modification of seismic waves by local conditions, site effect $G(f)$, is expressed by the multiplication of a diminution function $D(f)$ and an amplification function $A(f)$. The diminution function accounts for the path-independent loss of high frequency in the ground motions and can be accounted for a simple filter of the form $D(f) = e^{-0.03\pi f}$ [2]. The amplification function $A(f)$ is based on empirical curves given in [7] for generic rock sites. An average constant value equal to 2.0 is considered. Finally, the filter that control the type of ground motion $I(f)$ is chosen as $I(f) = (2\pi f)^2$ for ground acceleration. The particular values of the different parameters of the stochastic ground acceleration model are given in Table (1) (see Application Problem Section). For illustration purposes Figure (3) shows the ground acceleration spectrum for a nominal distance $r = 20$ km, moment magnitudes $M = 5$ and $M = 7$, and model parameters given in Table (1). As the moment magnitude increases, the spectral amplitude increases at all frequencies, with a shift of dominant frequency content towards the lower frequency regime, as anticipated.

Figure 3: Ground acceleration spectrum for epicentral distance $r = 20$ km and moment magnitudes $M = 5$ and $M = 7$

5 ISOLATION MODEL

Several isolation elements can be used to model isolation systems. They include elastic, viscous, nonlinear fluid dampers, hysteretic (uniaxial or biaxial) elements for bilinear elastomeric bearings, hysteretic (uniaxial or biaxial) elements for sliding bearings, etc. Uniaxial bilinear elastomeric bearings with hysteretic behavior, such as lead rubber bearings, are used in the

present implementation. They are modeled using the Buoc-Wen model as [5]

$$U^y \dot{z}(t) = \begin{cases} \dot{x}_b(t)[\alpha - z^n(t)(\gamma \operatorname{sgn}(\dot{x}_b(t)z(t)) + \beta)] & \text{if } n \text{ is even} \\ \dot{x}_b(t)[\alpha - z^n(t)(\gamma \operatorname{sgn}(\dot{x}_b(t)) + \beta \operatorname{sgn}(z(t)))] & \text{if } n \text{ is odd} \end{cases} \quad (17)$$

where $z(t)$ is a dimensionless hysteretic variable, α , β , and γ are dimensionless quantities, U^y is the yield displacement, $x_b(t)$ and $\dot{x}_b(t)$ represent the base displacement and velocity, respectively, and $\operatorname{sgn}(\cdot)$ is the sign function. The forces activated in the elastomeric isolation bearing are modeled by an elastic-viscoplastic model with strain hardening

$$f_{is}(t) = k_p x_b(t) + c_v \dot{x}_b(t) + (k_e - k_p) U^y z(t) \quad (18)$$

where k_e is the pre-yield stiffness, k_p is the post-yield stiffness, c_v is the viscous damping coefficient of the elastomeric bearing, and U^y is the yield displacement. If the post-yield stiffness is written as $k_p = \alpha_L k_e$, where α_L is a factor which defines the extent to which the force is linear, the isolator forces can be expressed as

$$f_{is}(t) = \alpha_L k_e x_b(t) + c_v \dot{x}_b(t) + (1 - \alpha_L) k_e U^y z(t) \quad (19)$$

6 SEQUENTIAL APPROXIMATE OPTIMIZATION

The solution of the reliability-based optimization problem given by Eqs. (1-3) is obtained by transforming it into a sequence of sub-optimization problems having a simple explicit algebraic structure. Thus, the strategy is to construct successive approximate analytical sub-problems. To this end, the objective and the constraint functions are represented by using approximate functions dependent on the design variables. In particular, a hybrid form of linear, reciprocal and quadratic approximations is considered in the present formulation [28, 14, 20]. The approximate discrete sub-optimization problems takes the form

$$\text{Minimize } \tilde{f}_k(\{\phi\}) \quad (20)$$

subject to

$$\tilde{h}_{jk}(\{\phi\}) \leq 0 \quad , \quad j = 1, \dots, n_c \quad (21)$$

with side constraints

$$\phi_i^l \leq \phi_i \leq \phi_i^u \quad ; \quad i = 1, \dots, n_d \quad (22)$$

where \tilde{f}_k and \tilde{h}_{jk} , $j = 1, \dots, n_c$ represent the approximate objective and constraint functions at the current point $\{\phi^k\}$ in the design space, respectively. The approximate objective function is obtained as

$$\tilde{f}_k(\{\phi\}) = f_{1k}(\{\phi\}) + f_{2k}(\{\phi\}) + f_{3k}(\{\phi\}) \quad (23)$$

where $f_{1k}(\{\phi\})$ is a linear function in terms of the design variables, $f_{2k}(\{\phi\})$ is a linear function with respect to the inverse of the design variables, and $f_{3k}(\{\phi\})$ is a quadratic function of the design variables. They are given by

$$f_{1k}(\{\phi\}) = \sum_{(i^+)} \frac{\partial f(\{\phi^k\})}{\partial \phi_i} \phi_i, \quad f_{2k}(\{\phi\}) = - \sum_{(i^-)} \frac{\partial f(\{\phi^k\})}{\partial \phi_i} \frac{(\phi_i^k)^2}{\phi_i} \quad (24)$$

$$f_{3k}(\{\phi\}) = -2\chi^f \sum_{(i^-)} \frac{\partial f(\{\phi^k\})}{\partial \phi_i} \phi_i \left(\frac{\phi_i}{\phi_i^k} - 2 \right) \quad (25)$$

where (i^+) is the group that contains the variables for which the partial derivative of the objective function is positive, (i^-) is the group that includes the remaining variables, and χ^f is a user-defined positive scalar that control the conservatism of the approximation [17, 18]. On the other hand, the constraint functions involving reliability measures (reliability constraints) are first transformed as $h_j^t(\{\phi\}) = \ln[P_{F_j}(\{\phi\})]$. Then the transformed constraint functions are approximated in the form

$$\tilde{h}_{jk}^t(\{\phi\}) = h_{j1k}^t(\{\phi\}) + h_{j2k}^t(\{\phi\}) + h_{j3k}^t(\{\phi\}) + \bar{h}_{jk}^t(\{\phi^k\}) \quad (26)$$

where

$$h_{j1k}^t(\{\phi\}) = \sum_{(i_j^+)} \frac{\partial h_j^t(\{\phi^k\})}{\partial \phi_i} \phi_i, \quad h_{j2k}^t(\{\phi\}) = - \sum_{(i_j^-)} \frac{\partial h_j^t(\{\phi^k\})}{\partial \phi_i} \frac{(\phi_i^k)^2}{\phi_i} \quad (27)$$

$$h_{j3k}^t(\{\phi\}) = 2\chi^{h_j^t} \sum_{(i_j^-)} \frac{\partial h_j^t(\{\phi^k\})}{\partial \phi_i} \phi_i \left(\frac{\phi_i}{\phi_i^k} - 2 \right) \quad (28)$$

$$\begin{aligned} \bar{h}_{jk}^t(\{\phi^k\}) &= h_j^t(\{\phi^k\}) - \sum_{(i_j^+)} \frac{\partial h_j^t(\{\phi^k\})}{\partial \phi_i} \phi_i^k \\ &\quad - (2\chi^{h_j^t} - 1) \sum_{(i_j^-)} \frac{\partial h_j^t(\{\phi^k\})}{\partial \phi_i} \phi_i^k \end{aligned} \quad (29)$$

where $\sum_{(i_j^+)}$ and $\sum_{(i_j^-)}$ mean summation over the variables belonging to group (i_j^+) and (i_j^-) , respectively, and $\chi^{h_j^t}$ is as before a user-defined positive scalar that control the conservatism of the approximations. Group (i_j^+) contains the variables for which $\partial h_j^t(\{\phi^k\})/\partial \phi_i$ is positive, and group (i_j^-) includes the remaining variables. The same type of approximations can be applied to the deterministic constraint functions. The explicit discrete sub-optimization problems (20-22) are solved by standard methods that treat the problem directly in the primal design variable space such as branch and bound techniques, combinatorial methods, evolution-based optimization techniques, etc. [16, 24, 32]. The level of effectiveness of the above sequential optimization scheme depends on the degree of convexity of the functions involved in the optimization problem. For example, if the curvatures are not too large and relatively uniform throughout the design space the proposed algorithm converges within few iterations [9, 21, 30]. For more general cases methods based on trust regions and line search methodologies are more appropriate [1, 19, 22].

7 RELIABILITY AND SENSITIVITY ASSESSMENT

The characterization of the sub-optimization problems (20-22) requires the estimation of first excursion probabilities and their sensitivities. In order to estimate the excursion probabilities at a given design high-dimensional integrals need to be evaluated. This difficulty favors the application of Monte Carlo Simulation as fundamental approach to cope with the probability integrals. However, in most engineering applications the probability that a particular system fails is expected to be small, e.g. between $10^{-4} - 10^{-6}$. Direct Monte Carlo is robust to the type and dimension of the problem, but it is not suitable for finding small probabilities. Therefore, advanced Monte Carlo strategies are needed to reduce the computational efforts. In particular a generally applicable method, called subset simulation, is implemented in this work [4]. On the other hand, the sensitivity of the failure probability functions with respect to the design variables is estimated by an approach recently introduced in [33]. The approach is based on the approximate local representation of two different quantities. The first approximation involves the performance functions that define the failure domains while the second includes the probability of failure in terms of the maximum response levels for safe system operation. For a detailed discussion of the approach the reader is referred to [22, 33].

8 APPLICATION PROBLEM

8.1 Description

A four-story building with a base-isolation system under earthquake motion is considered as an application problem. The plan view, as well as the dimensions for each floor are shown in Fig. (4), and the elevation of one resistant element (A -axis) is illustrated in Fig. (5). Each of the four floors is supported by 80 columns of square cross section. The first floor has a height equal to 3.5 m while the other floors have a constant height equal to 3.0 m, leading to a total height of 12.5 m.

Figure 4: Plan view of the structural model

As previously pointed out (see Structural Model Section) each floor is represented by three degrees of freedom, i.e. two translational displacements in the direction of the x axis and y axis,

Figure 5: Elevation view of axis A

and a rotational displacement. The associated active masses in the x and y direction are taken constant for the first three floors and equal to 2.50×10^6 kg and 1.50×10^6 kg for the last floor. The corresponding mass moments of inertia are taken as 2.10×10^9 kg-m² and 1.20×10^9 kg-m², respectively. On the other hand, the mass of the base is equal to 6.0×10^6 kg, and its mass moment of inertia 5.00×10^9 kg-m². The Young's modulus and the modal damping ratios are treated as uncertain system parameters. The Young's modulus is modeled by a truncated normal random variable with most probable value $\bar{E} = 2.50 \times 10^{10}$ N/m² and coefficient of variation of 20%. Moreover, the damping ratios are modeled by independent Log-normal random variables with mean value $\bar{\zeta} = 0.03$ and coefficient of variation of 40%. The base isolation system is composed of 80 uniaxial bilinear lead rubber bearings with hysteretic behavior. The nonlinear behavior of these devices is modeled using the equations described in Section 5 with model parameters $n = 1$, $\alpha = 1.0$, $\beta = -0.65$, $\gamma = 0.5$, $U^y = 0.5$ cm, $\varepsilon = 0.1$, $k_e = 3 \times 10^6$ N/m, and $c_v = 0.0$. Figures (6) and (7) show a schematic representation of a lead rubber bearing and a typical displacement-restoring force curve of the isolation element, respectively. The structural system is excited horizontally by a ground acceleration applied in the y direction. The induced ground acceleration is characterized as in Section 4, with model parameters listed in Table 1.

Parameter	Numerical Value	Parameter	Numerical Value
\bar{r} (km)	20.0	σ_r (km)	9.0
b	1.8	U	10^{-20}
ρ_s (gm/cc)	2.8	β_s (km/s)	3.5
V	$1/\sqrt{2}$	R_Φ	0.55
F	2.0	R_0 (km)	1.0
T (s)	20.0	Δt (s)	0.01

Table 1: Parameters for the stochastic ground acceleration model.

8.2 Optimal design problem

The objective function f is defined as the volume of the column elements of the structural system. The design variables $\{\phi\}$ are chosen as the dimensions of the columns throughout

Figure 6: Lead rubber bearing

Figure 7: Typical displacement-restoring force curve of the isolation element (lead rubber bearing)

the height, grouped in four design variables, i.e. the dimensions of the columns of each floor constitute each of the design groups. The failure event is formulated as a first passage problem during the duration of the ground acceleration. The structural responses to be controlled are the 4 interstorey drift displacements. The threshold value is chosen equal to 0.2% of the floor height for the interstorey drift displacements. Thus, the failure domains evaluated at the design $\{\phi\}$ are given by

$$\Omega_{F_j}(\{\phi\}) = \{\{\theta\} \mid \max_{t_k, k=1, \dots, 2001} |\delta_j(t_k, \{\phi\}, \{\theta\})| - \delta^* \geq 0\} \quad , \quad j = 1, \dots, 4 \quad (30)$$

where $\delta_j(t_k, \{\phi\}, \{\theta\})$ is the relative displacement between the $(j - 1, j)$ -th floor evaluated at the design $\{\phi\}$, t_k are the discrete time instants, δ^* is the critical threshold level and equal

to 0.006 m, and $\{\theta\}$ is the vector that represents the uncertain system parameters (structural parameters and excitation). Note that more than two thousand random variables are involved in the characterization of the uncertain model parameters. The reliability-based optimization problem is defined as

$$\text{Min } f(\{\phi\})$$

subject to

$$\begin{aligned} P_{F_j}(\{\phi\}) &\leq P_F^*, \quad j = 1, 2, 3, 4 \\ 0.30 &\leq \phi_i \leq 1.10, \quad i = 1, \dots, 4 \end{aligned} \quad (31)$$

Two target failure probabilities are considered: $P_F^* = 10^{-2}$ and $P_F^* = 10^{-4}$. The first case can be interpreted as a design problem with a moderate level of reliability while the second case corresponds to a high level of reliability. In what follows the first case will be referred as Problem 1 while the second case as Problem 2.

8.3 Results

The initial and final designs of Problems 1 and 2 are given in Table (2). The results of the optimization process are presented in Figs.(8), (9) and (10) in terms of the evolution of the objective function and failure probabilities, respectively.

Figure 8: Iteration history in terms of the objective function. Problem 1: moderate level of reliability . Problem 2: high level of reliability

The objective function is normalized by its value at the initial design. It is observed that only a few optimization cycles are required for obtaining convergence. Moreover, most of the improvement of the objective function takes place in the first 3 iterations. It is also seen that the method generates a series of steadily improved feasible designs that move toward the optimum. The results indicate that the value of the objective function at the final design of Problem 2 is greater than the corresponding value of Problem 1. This in turn implies that the structural components (columns) at the final design of Problem 2 are bigger than the corresponding components of Problem 1, as expected. The beneficial effects of the base isolation system are shown

Figure 9: Iteration history in terms of the reliability constraints. Problem 1

Figure 10: Iteration history in terms of the reliability constraints. Problem 2

in Table (3). This table shows the value of the objective function at the final design of Problems 1 and 2 for models with and without the isolation system. The effect of the isolation system is clear from these results. The difference between the values of the objective functions is almost 40% in both Problems.

Finally, the effect of the base isolation system can also be observed from a constraint violation viewpoint. Table (4) shows the probability of occurrence of the failure events associated with the final design of Problem 2 (see Table (2)) for the case where no base isolation is considered. The probability is normalized by the target failure probability $P_F^* = 10^{-4}$. It is seen for example that the probability of occurrence of failure event F_1 is more than 100 times greater than the target failure probability. Once again, the effect of the isolation system is evident from these results.

Design variable	Initial design	Final design	
		Problem 1	Problem 2
ϕ_1 (m)	0.90	0.68	0.85
ϕ_2 (m)	0.80	0.59	0.75
ϕ_3 (m)	0.75	0.57	0.72
ϕ_4 (m)	0.70	0.51	0.64
Normalized objective function	1.00	0.56	0.88

Table 2: Initial and final designs.

Model	Normalized objective function	
	Problem 1	Problem 2
With base isolation system	0.56	0.88
Without base isolation system	0.78	1.21
Difference	39 %	38 %

Table 3: Objective function value of models with and without the base isolation system.

Problem 2	
P_{F_1}/P_F^*	103
P_{F_2}/P_F^*	55
P_{F_3}/P_F^*	20
P_{F_4}/P_F^*	2
$P_F^* = 10^{-4}$	

Table 4: Constraint violations.

9 CONCLUSIONS

A general framework for reliability-based design of base-isolated buildings under uncertain conditions has been presented. The reliability-based design problem is formulated as an optimization problem with a single objective function subject to multiple reliability constraints. First excursion probabilities that account for the uncertainties in the system parameters as well as in the excitation are used to characterize the system reliability. The high computational cost associated with the solution of the optimization problem is addressed by the use of approximate reliability analyses during portions of the optimization process. The proposed approach takes into account all nonlinear characteristics of the structural response in the design process and it allows for a complex characterization of structural systems and excitation models. At the same time, uncertainty in structural and excitation model parameters are considered explicitly during the design process. The numerical results and additional validation calculations highlight the beneficial effects of base-isolation systems in reducing the superstructure response. This in turn implies more robust and safer designs.

Keywords: Orthogonal Expansion, Nonlinear, Random Vibration.

Abstract. *A major challenge in stochastic dynamics is to model nonlinear systems subject to general non-Gaussian excitations which are prevalent in realistic engineering problems. In this work, an n -th order convolved orthogonal expansion (COE) method is proposed. For linear vibration systems, the statistics of the output can be directly obtained as the first-order COE about the underlying Gaussian process. The COE method is next verified by its application on a weakly nonlinear oscillator. In dealing with strongly nonlinear dynamics problems, a variational method is presented by formulating a convolution-type Lagrangian and using the COE representation as trial functions.*

1 INTRODUCTION

To evaluate probabilistic response of a structural dynamic system subject to parametric and external excitations, there are generally two approaches. The first approach uses Fokker-Planck-Kolmogorov (FPK) equation to directly find probability density function (pdf) by assuming a white noise excitation. To solve FPK equation especially for nonlinear systems, various techniques have been proposed, including weighted residual, path integral, etc, which however are all limited to systems of low dimension (up to 4). The second approach includes perturbation method, moment closure method, and statistical equivalent techniques. While the perturbation method is limited to weak nonlinearity, the accuracy of moment closure method and statistical equivalent techniques on highly nonlinear problems remains an open question.

A major deficiency of the existing approaches is their incapability in dealing with general non-Gaussian excitations which are prevalent in realistic engineering problems [5]. The marginal pdf and power spectral density of a loading process play a major role in determining the response of systems, e.g. seismic wave in earthquake engineering. Therefore, a new approach to model dynamic systems subject to non-Gaussian excitations is highly desired.

A novel stochastic computation method based on orthogonal expansion of random fields is recently proposed [6]. In this study, the idea of orthogonal expansion is extended to the so-called n -th order convolved orthogonal expansions (COE) especially in dealing with nonlinear dynamics. For linear vibration systems, the statistics of the output can be directly obtained as the first-order COE about the underlying Gaussian process. The COE is next verified by its application on a weakly nonlinear oscillator. In dealing with strongly nonlinear dynamics problems, a variational method is presented by formulating the convolution-type Lagrangian and using the COE representation as trial functions [7]. Theoretically, substitution of the trial response function into the Lagrangian will lead to the optimal solution. The effect of using different trial functions (COE of different orders) on the accuracy and efficiency of the proposed approach will be examined in a forthcoming paper.

2 CONVOLVED ORTHOGONAL EXPANSIONS

2.1 The zero-th order convolved orthogonal expansion

An underlying stationary Gaussian excitation $h_1(t, \mathcal{G})$ is characterized with the autocorrelation function $\rho(t)$ and unit variance, where $\mathcal{G} \in \Theta$ indicates a sample point in random space. Based on the so-called diagonal class of random processes [1], the zero-th order convolved (or memoryless) orthogonal expansion of $h_1(t, \mathcal{G})$ is proposed as [6]

$$u(t, \mathcal{G}) = \sum_{i=0}^{\infty} u_i(t) h_i(t, \mathcal{G}) \quad (1)$$

where the random basis function h_i corresponds to the i -th degree Hermite polynomial with $h_0 = 1$. According to the generalized Mehler's formula [4] the correlations among the random basis functions are given as

$$\begin{aligned} R_{s_1 s_2 \dots s_n}(t_1, t_2, \dots, t_n) &= \overline{h_{s_1}(t_1, \mathcal{G}) \dots h_{s_n}(t_n, \mathcal{G})} \\ &= \sum_{v_{12}=0}^{\infty} \dots \sum_{v_{n-1,n}=0}^{\infty} \delta_{s_1 r_1} \dots \delta_{s_n r_n} \prod_{j < k} \frac{\rho^{v_{jk}}(t_j - t_k)}{v_{jk}!} s_1! \dots s_n! \end{aligned} \quad (2)$$

where $r_k = \sum_{j \neq k} \nu_{jk}$, $\nu_{jk} = \nu_{kj}$, $\delta_{s_k r_k} = \begin{cases} 1 & s_k = r_k \\ 0 & s_k \neq r_k \end{cases}$, and the overbar denotes ensemble average.

Following Eq. (2), the two-point and three-point correlation functions are specifically obtained as

$$R_{ij}(t_1 - t_2) = \overline{h_i(t_1, \mathcal{G})h_j(t_2, \mathcal{G})} = \delta_{ij} i! \rho^i(t_1 - t_2) \quad (3)$$

$$\begin{aligned} R_{ijk}(t_1 - t_2, t_1 - t_3, t_2 - t_3) &= \overline{h_i(t_1, \mathcal{G})h_j(t_2, \mathcal{G})h_k(t_3, \mathcal{G})} \\ &= \frac{i!j!k!}{i'!j'!k'!} \rho^{k'}(t_1 - t_2) \rho^{j'}(t_1 - t_3) \rho^{i'}(t_2 - t_3) \\ i' &= \frac{j+k-i}{2}, j' = \frac{i+k-j}{2}, k' = \frac{i+j-k}{2} \end{aligned} \quad (4)$$

where i', j', k' must be non-negative integers, otherwise $R_{ijk} = 0$.

The correlation relations can be extended to the derivatives of the random basis functions, e.g.

$$\begin{aligned} R_{ij,pq}(t_1 - t_2) &= \overline{h_{i,p}^{(0)}(t_1, \mathcal{G})h_{j,q}^{(0)}(t_2, \mathcal{G})} = \delta_{ij} i! \frac{\partial^{p+q}}{\partial t_1^p \partial t_2^q} \rho^i(t_1 - t_2) \\ &= \delta_{ij} (-1)^q i! \frac{\partial^{p+q}}{\partial \tau^{p+q}} \rho^i(\tau) \end{aligned}$$

where $\tau = t_1 - t_2$, and the subscripts p, q denote p -th and q -th derivatives. Similarly, the derivations can be made for the convolution of the random basis functions, e.g.

$$\begin{aligned} C_{ij} &= \overline{h_i(t_1, \mathcal{G}) * h_j(t_2, \mathcal{G})} = \delta_{ij} i! \int_{-\infty}^{\infty} \rho^i(t_1 - 2t_2) dt_2 = \delta_{ij} i! \tau_i \\ C_{ij,11} &= \overline{h_{i,1}(t_1, \mathcal{G}) * h_{j,1}(t_2, \mathcal{G})} = \delta_{ij} i! \int_{-\infty}^{\infty} \frac{\partial^2}{\partial t_1 \partial t_2} \rho^i(t_1 - 2t_2) dt_2 = 0 \end{aligned} \quad (5)$$

where $\tau_i = \int_{-\infty}^{\infty} \rho^i(t) dt$ is the correlation time.

2.2 n -th order convolved orthogonal expansion

The idea of the memoryless orthogonal expansion presented above can be generalized to an n -th order convolved orthogonal expansion (COE) for representation of nonlinear output processes

$$u(t, \mathcal{G}) = \sum_{n=0}^{\infty} \sum_{i=0}^{\infty} u_i^{(n)}(t) h_i^{(n)}(t, \mathcal{G}) \quad (6)$$

$$h_i^{(n)}(t, \mathcal{G}) = \overbrace{g * g * \dots * g}^n * h_i = g^{*n} * h_i \quad (7)$$

where g is a given kernel, and the symbol $*$ denotes the convolution operator. For notational simplicity, the superscript (0) of the zero-th order COE is usually dropped throughout the paper. The memoryless orthogonal expansion thus corresponds to the zero-th order COE with $n=0$ in (6). The correlation functions of the n -th order basis functions are therefore obtained as

$$\begin{aligned} R_{s_1 \dots s_n}^{m_1 \dots m_n}(t_1, t_2, \dots, t_n) &= \overline{h_{s_1}^{(m_1)}(t_1, \mathcal{G}) \dots h_{s_n}^{(m_n)}(t_n, \mathcal{G})} \\ &= \sum_{\nu_{12}=0}^{\infty} \dots \sum_{\nu_{n-1,n}=0}^{\infty} \delta_{s_1 r_1} \dots \delta_{s_n r_n} \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} g^{*m_1}(t_1, \tau_1) \dots \\ &\quad g^{*m_n}(t_n, \tau_n) \prod_{j < k} \frac{\rho^{\nu_{jk}}(t_j - t_k)}{\nu_{jk}!} s_1! \dots s_n! d\tau_1 \dots d\tau_n \end{aligned} \quad (8)$$

with the two-point correlations

$$\begin{aligned} R_{ij}^{mn}(t_1 - t_2) &= \overline{h_i^{(m)}(t_1, \mathcal{G}) h_j^{(n)}(t_2, \mathcal{G})} \\ &= \delta_{ij} i! \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g^{*m}(t_1, \tau_1) g^{*n}(t_2, \tau_2) \rho^i(\tau_1 - \tau_2) d\tau_1 d\tau_2 \end{aligned} \quad (9)$$

The derivatives of the n -th order basis functions can be similarly obtained, e.g.

$$\begin{aligned} R_{ij,pq}^{mn}(t_1 - t_2) &= \overline{h_{i,p}^{(m)}(t_1, \mathcal{G}) h_{j,q}^{(n)}(t_2, \mathcal{G})} \\ &= \delta_{ij} i! \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g^{*m}(t_1, \tau_1) g^{*n}(t_2, \tau_2) \frac{\partial^{p+q}}{\partial \tau_1^p \partial \tau_2^q} \rho^i(\tau_1 - \tau_2) d\tau_1 d\tau_2 \end{aligned} \quad (10)$$

By letting $U = \Phi(u)$, $H = \Phi(h)$, $S = \Phi(R)$, $G^n = \Phi(g^{*n})$ and $S^{*i} = \Phi(\rho^i)$, with Φ being the Fourier transform operator, we specially rewrite the two-point correlation functions of the COE basis functions in frequency domain

$$S_{ij}^{mn}(\omega) = \overline{H_i^{(m)}(\omega, \mathcal{G}) \tilde{H}_j^{(n)}(\omega, \mathcal{G})} = \delta_{ij} i! G^m(\omega) \tilde{G}^n(\omega) S^{*i}(\omega) \quad (11)$$

$$\begin{aligned} S_{ij,pq}^{mn}(\omega) &= \left(\omega \sqrt{-1}\right)^{p+q} \overline{H_{i,p}^{(m)}(\omega, \mathcal{G}) \tilde{H}_{j,q}^{(n)}(\omega, \mathcal{G})} \\ &= \delta_{ij} i! \left(\omega \sqrt{-1}\right)^{p+q} G^m(\omega) \tilde{G}^n(\omega) S^{*i}(\omega) \end{aligned} \quad (12)$$

where the tilde denotes complex conjugate. Note that in the cases of stationary correlation functions, it specially follows

$$\begin{aligned} \overline{H_{i,p}^{(m)}(\omega_k, \mathcal{G}) \tilde{H}_{j,q}^{(n)}(\omega_l, \mathcal{G})} &= \delta_{kl} S_{ij,pq}^{mn}(\omega) \\ \overline{H_{i,p}^{(m)}(\omega_k, \mathcal{G}) H_{j,q}^{(n)}(\omega_l, \mathcal{G})} &= \delta_{kl} \delta_{ij} i! \left(\omega \sqrt{-1}\right)^{p+q} G^m(\omega) \tilde{G}^n(\omega) \tau_i \end{aligned} \quad (13)$$

Remark: The advantage of the n -th order COE (6) can be demonstrated by comparing it with the classical Volterra series expansion

$$u(t, \mathcal{G}) = \sum_{n=0}^{\infty} \frac{1}{n!} \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} k^{(n)}(t_1, t_2 \cdots t_n) h(t-t_1, \mathcal{G}) h(t-t_2, \mathcal{G}) \cdots h(t-t_n, \mathcal{G}) dt_1 dt_2 \cdots dt_n \quad (14)$$

The Volterra representation typically suffers from severe difficulties in solving for the unknown kernels $k^{(n)}$. In the COE representation, the kernels are all explicitly given, and the problem is significantly reduced to solving of the unknown coefficients $u_i^{(n)}$.

3 THE COE METHOD ON RANDOM VIBRATION

3.1 Linear oscillators

Suppose the linear oscillator

$$\begin{aligned} \ddot{u} + 2\zeta\omega_n\dot{u} + \omega_n^2 u &= f \\ u(0) = \dot{u}(0) &= 0 \end{aligned} \quad (15)$$

is subjected to a non-stationary non-Gaussian translation input, i.e.

$$f(t, \mathcal{G}) = \sum_{i=0}^{\infty} f_i(t) h_i(t, \mathcal{G}) \quad (16)$$

By using the Green function

$$\begin{aligned} g(t) &= \frac{1}{\omega_d} e^{-\zeta\omega_n t} \sin(\omega_d t) \\ \omega_d &= \omega_n \sqrt{1 - \zeta^2} \\ G(\omega) &= \frac{1}{\omega_n^2 - \omega^2 + \sqrt{-1} 2\zeta\omega\omega_n} \end{aligned} \quad (17)$$

the first three correlations of the non-stationary output u can be directly calculated from

$$\bar{u}(t) = \int_0^t g(t-\tau) f_0(\tau) d\tau \quad (18)$$

$$\begin{aligned} R_{uu}(t_1, t_2) &= \int_0^{t_2} \int_0^{t_1} g(t_1 - \tau_1) g(t_2 - \tau_2) \sum_{i=0}^{\infty} i! \\ &\quad \rho^i(\tau_1 - \tau_2) f_i(\tau_1) f_i(\tau_2) d\tau_1 d\tau_2 \end{aligned} \quad (19)$$

$$\begin{aligned} R_{uuu}(t_1, t_2, t_3) &= \int_0^{t_3} \int_0^{t_2} \int_0^{t_1} g(t_1 - \tau_1) g(t_2 - \tau_2) g(t_3 - \tau_3) \\ &\quad \sum_{i,j,k=0}^{\infty} R_{ijk}(\tau_1 - \tau_2, \tau_1 - \tau_3, \tau_2 - \tau_3) d\tau_1 d\tau_2 d\tau_3 \end{aligned} \quad (20)$$

where R_{ijk} is given in Eq. (4).

When the excitation in Eq. (15) is stationary, the output can be directly given as

$$u(t, \mathcal{G}) = \sum_{i=0} f_i h_i^{(1)}(t, \mathcal{G}) \quad (21)$$

which is a special case of the COE representation (6). Note that, with the Green function g and the underlying Gaussian process being given, the stationary probability density function (pdf) of the output in Eq. (21) can be rapidly estimated by using Monte Carlo method in the frequency domain.

A numerical example for application of the COE on linear oscillator is given in [6]. With regard to the multi-degree-of-freedom linear systems, the oscillator equations given above can be directly applied by using the modal decomposition as shown in [8].

3.2 Weakly nonlinear oscillators

A Duffing oscillator subjected to a Gaussian white noise excitation with intensity D is considered

$$\ddot{u} + 2\zeta\omega_n\dot{u} + \omega_n^2(u + \alpha u^3) = W \quad (22)$$

The Gaussian response of the linear filter can be given as $u_0 = \sigma_0 h_1$, and h_1 is characterized by unit variance and power spectral density (PSD)

$$S = \frac{D}{\sigma_0^2} |G(\omega)|^2 \quad (23)$$

$$\sigma_0^2 = D \int_{-\infty}^{\infty} \left| \frac{1}{\omega_n^2 - \omega^2 + \sqrt{-12\zeta\omega\omega_n}} \right|^2 d\omega = \frac{D\pi}{2\zeta\omega_n^3} \quad (24)$$

For small α , the nonlinear output of Eq. (22) can be approximated as

$$u = \sigma_0 h_1 - \alpha \omega_n^2 \sigma_0^3 g * h_1^3 + 3\alpha^2 \omega_n^4 \sigma_0^5 g * (h_1^2 g * h_1^3) + O(\alpha^3) \quad (25)$$

By noting $h_1^3 = h_3 + 3h_1$ and $h_1^2 = h_2 + 1$, Eq. (25) can be rewritten in terms of the random basis functions

$$u = \sigma_0 h_1 - \alpha \omega_n^2 \sigma_0^3 g * (h_3 + 3h_1) + 3\alpha^2 \omega_n^4 \sigma_0^5 g * [(h_2 + 1)g * (h_3 + 3h_1)] + O(\alpha^3) \quad (26)$$

$$U = \sigma_0 H_1 - \alpha \omega_n^2 \sigma_0^3 G(H_3 + 3H_1) + 3\alpha^2 \omega_n^4 \sigma_0^5 G[(H_2 + \delta(0)) * G(H_3 + 3H_1)] + O(\alpha^3) \quad (27)$$

By using the correlations of Eqs. (3)-(4) and (11), it follows that the stationary mean

$$\bar{u} = O(\alpha^3) \quad (28)$$

and the stationary PSD

$$S_{UU} = \overline{U\tilde{U}} = \sigma_0^2 S - 3\alpha \omega_n^2 \sigma_0^4 (G + \tilde{G})S + \alpha^2 \omega_n^4 \sigma_0^6 [9S(|G|^2 + G^2 + \tilde{G}^2) + 6|G|^2 S^{*3}] + O(\alpha^3) \quad (29)$$

Since

$$\int_{-\infty}^{\infty} \frac{2(\omega_n^2 - \omega^2)}{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega\omega_n)^2} \left| \frac{1}{\omega_n^2 - \omega^2 + \sqrt{-12\zeta\omega\omega_n}} \right|^2 d\omega = \frac{\pi}{2\zeta\omega_n^5} \quad (30)$$

the variance calculated from the first two terms of Eq. (29) is simply obtained as

$$\sigma^2 = \sigma_0^2(1 - 3\alpha\sigma_0^2) \quad (31)$$

which is identical to the result obtained using other approaches, e.g. [2,3]. In addition to serving as verification to the COE method, this example shows simplicity and efficiency of the orthogonal expansions in nonlinear problems.

3.3 Strongly nonlinear oscillators

For strongly nonlinear systems, the perturbation method is inapplicable. In this part, a variational method will be presented following the variational principles formulated for random media elastodynamics [7]. The variational functional, or Lagrangian, of a nonlinear oscillator

$$\ddot{u} + 2\zeta\omega_n\dot{u} + \omega_n^2(u + g(u, \dot{u})) = f \quad (32)$$

can be formulated by using the convolution form

$$\delta\ell = \delta u * [\ddot{u} + 2\zeta\omega_n\dot{u} + \omega_n^2(u + g(u, \dot{u})) - f] = 0 \quad (33)$$

For a Duffing oscillator $g(u, \dot{u}) = \alpha u^3$, the Lagrangian is derived from Eq. (33) as

$$\begin{aligned} \ell(u) = & \frac{1}{2} \dot{u} * \dot{u} + \zeta u * \dot{u} + \frac{1}{2} \omega_n^2 u * u \\ & + \alpha \omega_n^2 (u^3 * u - \frac{3}{4} u^2 * u^2) - f * u + \dot{u}(0)u \end{aligned} \quad (34)$$

where any trial function u satisfies the specified initial condition $u(0)$. To the authors' knowledge, the convolution Lagrangian (34) is the first variational form formulated for nonlinear dissipative systems. It is especially noted that the classical point-wise Lagrangian form does not work on the dissipative term.

For nonlinear random vibrations, the stochastic Lagrangian is directly obtained by taking ensemble average of Eq. (34), i.e.

$$\overline{\delta\ell} = 0 \quad (35)$$

with the trial function u based on the COE representation (6).

For stationary solutions, Eq. (35) can be rewritten in frequency domain as

$$\begin{aligned} \overline{\delta L}(U) = & 0 \\ \overline{L}(U) = & \left(-\frac{1}{2} \omega^2 + \sqrt{-1} \omega \zeta + \frac{1}{2} \omega_n^2 \right) \overline{U^2} + \\ & \alpha \omega_n^2 \left[\overline{(U * U * U)U} - \frac{3}{4} \overline{(U * U)^2} \right] - \overline{FU} \end{aligned} \quad (36)$$

Suppose the excitation is stationary

$$f(t, \mathcal{G}) = \sum_{i=0} f_i h_i(t, \mathcal{G}) \quad (37)$$

and choose the zeroth-order COE

$$u(t, \mathcal{G}) = \sum_{i=0} u_i h_i(t, \mathcal{G}) \quad (38)$$

as the trial function for the stationary solution. By substituting Eq. (38) into Eqs. (34)-(35) and taking derivative with respect to u_i , it leads to a series of equations to solve for u_i

$$\frac{\partial \bar{\ell}}{\partial u_i} = 0 \quad (39)$$

Similarly the first- or higher-order COE can be chosen as the trial function. The detail of numerical examples and investigation of accuracy and computational efficiency of the different trial functions will be provided in a forthcoming paper.

4 CONCLUDING REMARK

By developing a diagonal class of random fields/stochastic processes to represent high-dimensional uncertainty, the proposed convolved orthogonal expansion method opens a new direction to deal with nonlinear stochastic dynamics. The advantage is especially noted for its efficiency in computing of large and nonlinear dynamical systems, in comparison with the classical Volterra series representation and the recently developed random variable based polynomial chaos expansions.

Keywords: Reliability; Calibration; Enhanced Monte Carlo; System failure probability.

Abstract. *This paper extends the recently developed enhanced Monte Carlo approach to the problem of reliability-based design. The objective is to optimize a design parameter(s) so that the system, represented by a set of failure modes or limit states, achieves a target reliability. In a large majority of design and/or calibration contexts, the design parameter α itself can be used to parameterize the system safety margin $M(\alpha)$. The lower tail of this random variable behaves in a regular way and is therefore amenable to straightforward parametric analysis. In contrast to the original Naess et al. method [1], the intention is to estimate the value α_T that corresponds to a (very) small target system failure probability p_{fT} . Monte Carlo sampling occurs at a range of values for α that result in larger failure probabilities, and so the design problem essentially amounts to a statistical estimation of a high quantile. Bounds for α_T can easily be constructed. Several examples of the approach are given in the paper.*

1 INTRODUCTION

A new Monte Carlo (MC) based method for estimating system reliability was recently developed in [1]. The aim of this method is to reduce computational cost while maintaining the advantages of crude MC simulation, specifically, its ease in dealing with complex systems. The key idea is to exploit the regularity of tail probabilities to enable an approximate prediction of far tail failure probabilities based on small Monte-Carlo sample results obtained for much more moderate levels of reliability. The motivation behind this approach is that systems with multiple and complex failure modes or limit states are often exceedingly difficult to analyze using traditional methods of structural reliability. While direct MC does not suffer from this problem, it is computationally burdensome for small probabilities. Hence originates the idea of sampling in a different less reliable range and performing a statistical extrapolation unto the tail. A similar but somewhat different idea is presented in [2].

The fundamentals of the method proposed in [1] are as follows. A safety margin $M = G(X_1, \dots, X_n)$ expressed in terms of n basic variables, is extended to a parameterized class of safety margins using a scaling parameter λ ($0 \leq \lambda \leq 1$):

$$M(\lambda) = M - (1 - \lambda)\mu_M. \quad (1)$$

The failure probability is then assumed to behave as follows:

$$p_f(\lambda) = \text{Prob}(M(\lambda) \leq 0) \underset{\lambda \rightarrow 1}{\approx} q(\lambda) \exp \{ -a(\lambda - b)^c \}, \quad (2)$$

where the function $q(\lambda)$ is slowly varying compared with the exponential function $\exp\{-a(\lambda - b)^c\}$. It may be pointed out that the assumed behaviour of the failure probability applies to any safety margin for which FORM or SORM approximations can be used, but actually its range of applicability is much wider than that.

Clearly, the target failure probability $p_f = p_f(1)$ can be obtained from values of $p_f(\lambda)$ for $\lambda < 1$. It is now far easier to estimate the (larger) failure probabilities $p_f(\lambda)$ for $\lambda < 1$ accurately than the target value itself, since they are larger and hence require less simulations. Fitting the parametric function given by Eq. (2) for $p_f(\lambda)$ to the estimated values would then allow us to provide an estimate of the target value by extrapolation. The viability of this approach is demonstrated by both analytical and numerical examples in [1] and [3].

In the next sections, the Naess et al. [1] approach is extended to reliability-based design and calibration.

2 USING ENHANCED MONTE CARLO TO OPTIMIZE A DESIGN PARAMETER

First consider a typical component design, the reliability of which is governed by the safety margin:

$$M(\alpha) = G(X_1, \dots, X_n; \alpha) \quad (3)$$

with

$$p_f(\alpha) = \text{Prob}(M(\alpha) \leq 0), \quad (4)$$

where α acts as a design factor which "controls" the reliability of the component. The objective is now to determine the (assumed to be unique) value of $\alpha = \alpha_T$ that corresponds to a specified (target) component failure probability p_{fT} , i.e.:

$$\alpha_T : \text{Prob}(M(\alpha_T) \leq 0) = p_{fT}, \quad (5)$$

This assumes that the function $p_f(\alpha)$ is a monotonic function, that is, that the safety of the system either strictly increases or strictly decreases as the design factor α increases and approaches α_T . In practical design situations, α may represent a safety factor, a partial load or resistance factor, or some exceedance level and, the condition of monotonicity is generally speaking satisfied, unless the problem relates to a poor or an unfeasible design.

A more general situation, typical in the context of calibration of design specifications, consists of having the safety margin controlled by a design check function $c(\alpha) = c(x_{1c}, \dots, x_{nc}; \alpha)$ involving characteristic values x_{ic} of each basic variable X_i . Admissible design are such that $c(\alpha) \leq 0$. Minimal acceptable designs are marked by $c(\alpha) = 0$, an assumption which is made throughout this paper. Often the design check function $c(\alpha)$ is selected to be the same mathematical function as G but this is not required - all that matters is that the resulting safety margin $M(\alpha) = G(X_1, \dots, X_n | c(x_{1c}, \dots, x_{nc}; \alpha) = 0)$ is monotonic with respect to α in its approach to the target α_T . Hence the objective is to determine α_T as follows:

$$\alpha_T : \text{Prob}\left(G(X_1, \dots, X_n | c(x_{1c}, \dots, x_{nc}; \alpha_T) = 0) \leq 0\right) = p_{fT}. \quad (6)$$

Typically, p_{fT} is a very small target probability and hence the behavior of p_f as a function of α is similar to a deep tail estimation problem so that it is reasonable to assume that:

$$p_f(\alpha) \underset{\alpha \rightarrow 1}{\approx} q(\alpha) \exp \left\{ -a(\alpha - b)^c \right\}, \quad (7)$$

where $q(\alpha)$ is slowly varying compared to the exponential expression.

To illustrate this premise, consider a basic load and resistance safety margin $M(\alpha) = R(\alpha) - S$ controlled by a design check function $c(\alpha) = (r_c(\alpha)/\alpha) - s_c$, where r_c and s_c are characteristic values of a resistance R and a load S , and α acts as a partial resistance factor ($\alpha > 1$). Assume the load S is Weibull distributed with exponent d and scale parameter s_0 , then the characteristic load s_c at its $(1 - \theta)$ quantile, is equal to $s_c = (-\ln \theta)^{1/d} s_0 = k s_0$ where k is a known positive constant > 1 . First consider the limiting case where the variance of R is zero, $\sigma_R^2 = 0$, hence $r_c(\alpha) = \alpha s_c$ such that $p_f(\alpha) = \text{Prob}(M(\alpha) \leq 0) = \exp(-(\alpha k)^d)$ which is fully consistent with Eq. (7) above. If the variance of $R(\alpha)$ now increases, then the mean resistance will shift even further down the tail since $r_c(\alpha)$ is a small quantile of R . But, the function $p_f(\alpha)$ will only be slightly "contaminated" by a much slower varying function of α ; however, and this is certainly valid in the tail area as $\alpha \rightarrow \alpha_T$, the general form in Eq. (7) will persist and it is amenable to be fitted to data pairs $(p_f(\alpha), \alpha)$ obtained for (much) higher failure probabilities.

Once a satisfactory fit is achieved, the target value α_T corresponding to p_{fT} needs to be estimated, a problem which is similar to a high quantile estimation.

3 EXTENSION TO SYSTEM RELIABILITY

Using Monte Carlo methods for system reliability analysis has several attractive features, the most important being that the failure criterion is relatively easy to check almost irrespective of the complexity of the system. In order to limit the amount of computational effort that may be involved, it is useful to extend the above approach to systems.

Let $M_j(\alpha) = G_j(X_1, \dots, X_n, \alpha)$, $j = 1, \dots, m$ be a set of m given safety margins expressed in terms of n basic variables and a single design parameter α . The series system reliability expressed in terms of the failure probability can then be written as,

$$p_f(\alpha) = \text{Prob}\left(\bigcup_{j=1}^m \{M_j(\alpha) \leq 0\}\right), \quad (8)$$

while for the parallel system,

$$p_f(\alpha) = \text{Prob}\left(\bigcap_{j=1}^m \{M_j(\alpha) \leq 0\}\right). \quad (9)$$

In general, any system can be written as a series system of parallel subsystems. The failure probability would then be given as,

$$p_f(\alpha) = \text{Prob}\left(\bigcup_{j=1}^l \bigcap_{i \in C_j} \{M_i(\alpha) \leq 0\}\right), \quad (10)$$

Here each C_j is a subset of $1, \dots, m$, for $j = 1, \dots, l$. The C_j s denote the index sets defining the parallel subsystems.

We then make the assumption that $p_f(\alpha)$ can also be represented as in Eq. (7) for the system reliability problems. Again, the objective is to determine the value α_T that achieves a stated overall system reliability.

4 IMPLEMENTATION

The method to be described in this section is based on the assumption expressed by Eq. (7). For practical applications it is implemented in the following form:

$$p_f(\alpha) \approx q(\alpha) \exp\{-a(\alpha - b)^c\}, \text{ for } \alpha_0 \leq \alpha \leq \alpha_T, \quad (11)$$

for a suitable value of α_0 . An important part of the method is therefore to identify a suitable range for α so that the right hand side of Eq. (7) represents a good approximation of $p_f(\alpha)$ for $\alpha \in [\alpha_0, \alpha_T]$.

For a sample of size N of the vector of basic random variables $\mathbf{X} = (X_1, \dots, X_n)$, let $N_f(\alpha)$ denote the number of outcomes of the random vector in the failure domain of $M(\alpha)$. The estimate of the failure probability is then

$$\hat{p}_f(\alpha) = \frac{N_f(\alpha)}{N}. \quad (12)$$

The coefficient of variation C_v of this estimator is

$$C_v(\hat{p}_f(\alpha)) = \sqrt{\frac{1 - \hat{p}_f(\alpha)}{\hat{p}_f(\alpha)N}}. \quad (13)$$

A fair approximation of the 95% confidence interval for the value $\hat{p}_f(\alpha)$ can be obtained as $\text{CI}_{0.95} = (C^-(\alpha), C^+(\alpha))$, where

$$C^\pm(\alpha) = \hat{p}_f(\alpha)(1 \pm 1.96C_v(\hat{p}_f(\alpha))). \quad (14)$$

Assuming now that we have obtained empirical Monte Carlo estimates of the failure probability, the problem then becomes one of optimal use of the information available. By plotting $\log |\log \hat{p}_f(\alpha)/q(\alpha)|$ versus $\log(\alpha - b)$, it is expected that an almost perfectly linear tail behavior will be obtained according to Eq. (11). Recalling that the function $q(\alpha)$ was assumed to be slowly varying compared with the exponential function $\exp\{-a(\alpha - b)^c\}$ for values of α close to α_T , it is now tentatively proposed to replace $q(\alpha)$ by a suitable constant value, q say, for tail

values of α , say $\alpha > \alpha_1 (\geq \alpha_0)$. Hence, we will investigate the viability of the following simpler version of Eq. (11):

$$p_f(\alpha) \approx q \exp \{ -a(\alpha - b)^c \}, \text{ for } \alpha_1 \leq \alpha \leq \alpha_T, \quad (15)$$

for a suitable choice of α_1 .

The problem of finding the optimal values of the parameters a, b, c, q is carried out by optimizing the fit on the log level by minimizing the following mean square error function with respect to all four arguments [4],

$$F(a, b, c, q) = \sum_{j=1}^M w_j (\log \hat{p}_f(\alpha_j) - \log q + a(\alpha_j - b)^c)^2, \quad (16)$$

where $\alpha_1 < \dots < \alpha_M$ denotes the set of α values where the failure probability is empirically estimated. The w_j denote weight factors that put more emphasis on the more reliable data points, alleviating the heteroscedasticity of the estimation problem at hand. The choice of weight factor is to some extent arbitrary. In this paper, we use $w_j = (\log C^+(\alpha_j) - \log C^-(\alpha_j))^{-\theta}$ with the values $\theta = 1$ and 2 , combined with a Levenberg-Marquardt least squares optimization method [5]. Note that the form of w_j puts some restriction on the use of the data. Usually, there is a level α_j beyond which w_j is no longer defined. Hence, the summation in Eq. (16) has to stop before that happens. Also, the data should be preconditioned by establishing the tail marker α_1 in a sensible way.

Although the Levenberg-Marquardt method as described above generally works well, it may be simplified by exploiting the structure of F . It is realized by scrutinizing Eq. (16) that if b and c are fixed, the optimization problem reduces to a standard weighted linear regression problem. That is, with both b and c fixed, the optimal values of a and $\log q$ are found using closed form weighted linear regression formulas in terms of $w_j, y_j = \log \hat{p}_f(\alpha_j)$ and $x_j = (\alpha_j - b)^c$.

It is obtained that the optimal values of a and q are given by the relations,

$$a^*(b, c) = - \frac{\sum_{j=1}^M w_j (x_j - \bar{x})(y_j - \bar{y})}{\sum_{j=1}^M w_j (x_j - \bar{x})^2}, \quad (17)$$

and

$$\log q^*(b, c) = \bar{y} + a^*(b, c) \bar{x}, \quad (18)$$

where $\bar{x} = \sum_{j=1}^M w_j x_j / \sum_{j=1}^M w_j$, with a similar definition of \bar{y} .

The Levenberg-Marquardt method may now be used on the function $\tilde{F}(b, c) = F(a^*(b, c), b, c, q^*(b, c))$ to find the optimal values b^* and c^* , and then the corresponding a^* and q^* can be calculated from Eq. (17) and (18).

For estimation of the confidence interval for the predicted target quantile α_T provided by the optimal curve, the empirical confidence band is reanchored to the optimal curve. The range of fitted curves that stay within the reanchored confidence band will determine an optimized confidence interval of the predicted value.

5 NUMERICAL EXAMPLES

The examples in the following two sections all have simple explicit limit state functions in terms of the basic random variables. The computational issue is therefore minor and no effort has been made to investigate the possibility of implementing more effective sampling strategies.

If the proposed method were to be used in combination with computationally demanding procedures involving e.g. a FE method for calculating the sample, it would be necessary in general to use more effective sampling strategies than the brute force procedure used here.

5.1 Component load factor calibration

In this first example, the 10-bar truss structure shown in Fig. 1 is studied. An enhanced Monte-Carlo reliability analysis of this truss is given in [1]. Here a load factor for a transversal load P is calibrated in order to achieve a target reliability of (10^{-6}) with respect to the horizontal sway of the truss. The ten truss members are cut from three different aluminum rods with cross-sectional areas A_1 , A_2 and A_3 , as shown in Fig. 1. The structure is subjected to external loads P as shown in Fig. 1. The horizontal displacement D at the upper right hand corner of the truss structure can be written as [6]:

$$D = \frac{BPL}{A_1 A_3 E} \left\{ \frac{4\sqrt{2}A_1^3(24A_2^2 + A_3^2) + A_3^3(7A_1^2 + 26A_2^2)}{D_T} + 4A_1 A_2 A_3 \frac{20A_1^2 + 76A_1 A_2 + 10A_3^2}{D_T} + 4\sqrt{2}A_1 A_2 A_3^2 \frac{25A_1 + 29A_2}{D_T} \right\} \quad (19)$$

where $D_T = 4A_2^2(8A_1^2 + A_3^2) + 4\sqrt{2}A_1 A_2 A_3(3A_1 + 4A_2) + A_1 A_3^2(A_1 + 6A_2)$ and E is Young's modulus. The random variable B accounts for model uncertainties. It is assumed that A_1, A_2, A_3, B, P, E are independent basic random variables. Their properties are summarized in Table 1. Also shown are the characteristic values used in the design check Eq. (21).

and the design check constraint is

$$c(\alpha) = d_0 - D(A_{1c}, A_{2c}, A_{3c}, B_c, E_c, \alpha P_c(\alpha)), \quad (21)$$

where α represents the transversal load factor.

Figs. 2 and 3 show the optimized fitted parametric curve to the empirical data in a log plot for sample size 10^5 and for weighted regression coefficients $\theta = 2$ and $\theta = 1$, respectively. The difference between the two tail extrapolations is minimal. Applying the proposed procedure with a sample of size 10^5 gives the estimated value for α_T with the 95% confidence interval shown in Table 2 for both $\theta = 2$ and 1. Note that a crude Monte Carlo simulation verification of $(\alpha_T = 1.46, p_{fT} = 10^{-6})$ using $3 \cdot 10^9$ samples to within 2.5% at 95% confidence requires a computation time of about 24h on a laptop computer. The CPU time for the results shown in Table 2 was only about 40 seconds on a standard laptop.

5.2 Design resistance safety factor in a series system

This example concerns the maximum internal forces in the members of a statically determinate 13-member truss structure subjected to external loading. The structure is shown in Fig. 4, which also displays the numbering of the truss elements from 1 to 13. The external loads P_1, P_2, P_3 which are acting on the structure as shown in Fig. 4, are modelled as independent Gaussian variables. The capacity for axial stress of truss element number j is expressed as $R_j = \sigma_{yj} A_j$ where σ_{yj} = the yield stress (MPa) and A_j = the cross-sectional area of this element (cm^2), and α is a resistance safety factor > 1 used as a division factor in the design check equation below. It is assumed that $A_1 = A_7 = 18.7$, $A_2 = A_8 = 13.1$, $A_3 = A_9 = A_{12} = A_{13} = 11.7$, $A_4 = A_{10} = 11.3$, $A_5 = A_{11} = 3.3$, $A_6 = 8.0$. The 13 yield stresses are assumed to be independent Gaussian variables. The 16 basic random variables in this problem are listed in Table 3.

	Mean Value	Coef. of Var.	Prob. distr.	Char. value in Eq. (22)
$P_j, j = 1, 2, 3$	89 kN	0.15	Normal	99% quantile
$\sigma_{yj}, j = 1, \dots, 13$	based on Eq. (23)	0.15	Normal	5% quantile
L	2.54 m	-	-	-

Table 3: The 16 basic variables.

 M_{13} &= R_{13} - 0.1768P_1 - 0.3536P_2 - 0.5303P_3
 \end{aligned} \tag{22}$$

The 13 design check equations have the same mathematical set of 13 equations except that the deterministic characteristic values of Table 3 are used and a resistance safety factor is involved. The most severe constraint is the compressive stress in members 1 and 7 which therefore governs the design of the system as a whole:

$$\frac{\sigma_{yc}(\alpha)A_1}{\alpha} - 1.8372P_c = 0, \tag{23}$$

The objective is to find the value α_T such that the series system failure probability given by Eq. (8) is equal to a target $p_{fT} = 10^{-5}$. The log plot of $p_f(\alpha)$ versus α is shown in Figures 5 and 6 for $\theta = 1$ and for samples of size 10^4 and 10^5 , respectively. The estimated α_T corresponding to $p_f = 10^{-5}$ together with their CIs are shown in Table 4. A Winbugs script runs the entire analysis in under 1min for 10^5 samples. As a contrast, crude Monte Carlo simulation with $5 \cdot 10^9$ samples confirms ($\alpha_T = 1.89, p_f = 10^{-5}$) for the series system accurate to within about 0.5% with 95% confidence, but requires a computation time of about 24h on a laptop computer.

	$N = 10^4$	$N = 10^5$
higher 95% CI	1.95	1.92
α_T	1.85	1.88
lower 95% CI	1.69	1.80

Table 4: Optimal resistance safety factor α_T corresponding to a system $p_{fT} = 10^{-5}$ using sample size 10^4 and 10^5 with $\theta = 1$.

Figure 6: Sample size 10^5 — weighted regression with $\theta = 1$.

6 CONCLUSIONS

In this paper, we have described a Monte Carlo based method for a reliability-based calibration of design parameters such as load/resistance factors, safety factors or specification levels of structural systems. It has been shown that the method may provide good estimates of design factors for structural systems with a moderate computational effort. It has been pointed out that the use of Monte Carlo methods for system reliability analysis has several very attractive features, the most important being that the failure criterion is usually relatively easy to check almost irrespective of the complexity of the system and the number of basic random variables.

Keywords: non-synchronous sensing, wireless sensor network, modal identification.

Abstract. *Structural health monitoring (SHM) employing wireless sensor networks (WSN) is becoming increasingly popular in recent years. Accurate synchronized sensing amongst wireless sensors is a key issue enabling the implementation of such smart systems for SHM based on vibration measurements. However, perfect synchronized sensing is unachievable in WSN. The effect of non-synchronous sensing when using wireless sensors on structural modal identification is addressed and a methodology for correcting such errors is proposed herein. This paper first discusses the potential sources causing non-synchronous sensing and estimates their extents based on data samples collected from Imote2 sensors, and then investigates the impact of synchronization errors in the measured output response on modal identification using numerical simulations. The simulation results show that even small synchronization errors in the output response can distort the identified mode shapes. A new methodology is proposed herein for eliminating such errors. This methodology estimates the power spectral densities (PSDs) of output responses using non-synchronous samples directly based on a modified FFT. As long as the corrected PSDs are obtained, the correlation functions can also be easily obtained by IFFT. Then these corrected PSDs or correlation functions can be fed into various output-only modal identification algorithms. The proposed methodology is validated using numerical simulations. It is found that the simulation results closely match the identified parameters based on synchronous data.*

1 INTRODUCTION

In recent years, the emerging wireless sensor networks (WSN) for structural health monitoring (SHM) have attracted a lot of attention from both the academic and industrial communities [1]. A wireless sensor network consists of a group of sensors using wireless links to perform distributed sensing and processing tasks. Compared with traditional wired sensor monitoring systems, there is no extensive wiring between sensors and data acquisition system involved, resulting in fast and flexible deployment, easier maintenance and cost reduction. In addition, wireless sensing technology allows sensor data to be processed locally at each sensor node, which can reduce the amount of data that needs to be transmitted and distribute the computing burden across the network. Inspired by these advantages, WSN are becoming even more popular in structural health monitoring applications.

Though WSN have the potential to improve SHM dramatically, a number of issues need to be addressed before wireless sensors can be utilized in SHM [2]. Time synchronization in WSN has been an important concern that has restricted the application of these networks since vibration-based SHM needs synchronous measured data. However, each wireless sensor in the network has its own intrinsic clock, and these clocks on the sensors have to be frequently synchronized with each other to maintain a consistent global time. For clock synchronization, several methods have been developed and tested [3]. The flooding time synchronization protocol (FTSP) [4] is adopted in our network, which is capable of clock synchronization with errors estimated to be about $10\mu\text{s}$ [5]. The clock synchronization is periodically performed to eliminate the clock offsets and skews. Thus, accurate clock synchronization among sensor nodes has been shown to be achievable.

However, even when the clocks on all sensor nodes are precisely synchronized, the measured signals may not be synchronized with each other due to the decentralized nature of WSN and resource limitations in each wireless sensor. In the following sections the potential sources causing non-synchronous sensing are first discussed and their extents are estimated using data collected from Imote2 sensors [6]. Then, the impact of non-synchronous sensing on modal identification is investigated by numerical simulations. A new methodology for eliminating such errors is proposed. Finally, the proposed methodology is validated by an illustrative example using simulated data.

2 SOURCES CAUSING NON-SYNCHRONOUS SENSING

Sensing on Imote2 sensors is performed in the following way. Prior to sensing, clock synchronization is conducted to convert the local clock times to global clock time using the estimated offsets and skews between local clocks and reference clock. Next the base station node sends sensing parameters such as sampling frequency and number of data points to remote nodes. When the prescribed start-sensing time arrives, sensing tasks are posted on the remote nodes. Once the sensing driver is ready, sensing starts. The sensing tasks continue running until the predetermined amount of data is acquired. During sensing, the acquired data points are first stored in a buffer. Every data point or every several data points can be marked with a local time stamp. When the buffer is filled, the data is passed to the sensing application for possible processing and/or transmission, and the emptied buffer becomes available for the next block of data. By examining the above sensing procedures, potential sources causing non-synchronous sensing are summarized below. A schematic diagram depicting these errors is shown in Figure 1.

(a). Clock synchronization error: for FTSP in Imote2 platform, this error is less than $10\mu\text{s}$ most of the time, with the maximum observed value being $80\mu\text{s}$ [5]. This error is comparatively small for SHM applications.

(b). Non-simultaneity in sensing start-up: starting sensing on all imote2 nodes simultaneously is challenging. Even if the time of start of sensing is set to be the same global time, the real execution time may have different delays in each node, and thus sensing may not start simultaneously.

(c). Differences in sampling frequency among sensor nodes: the actual sampling frequency may differ from the nominal value by at most 10 percent for the Imote2 Basic Sensor Board [7].

(d). Non-uniform sampling interval over time: a non-uniform sampling interval is observed in the Imote2 sensor boards. The coefficient of variation (COV) of the sampling interval is about 0.01~0.02%, which is relative small.

Figure 1: Illustration of non-synchronous sensing.

Ideally, the signal is sampled uniformly (with a constant sampling interval T_s) and synchronously (all the sensors start sensing at the same global time). The time at $(k+1)^{\text{th}}$ sampling instant is:

$$t_k = kT_s \quad (1)$$

Due to the reasons mentioned above, the $(k+1)^{\text{th}}$ data point is actually sampled at a different time instant:

$$t'_k = kT_s + \delta + ck + \varepsilon(k) \quad (2)$$

where, δ is a constant time shift, coming from sources (a) and (b); because the clock synchronization error is relatively small, only sensing start-up time delay is considered here; ck is a linear time shift, coming from source (c); the coefficient c is the difference between real sampling interval and nominal sampling interval; $\varepsilon(k)$ is a random time shift, coming from source (d), and these time jitters result in non-uniform sampling.

3 ERROR ESTIMATION

3.1 Test of non-synchronous sensing when using Imote2's

The extent of non-synchronous sensing when using Imote2's is evaluated using time stamps marked with data points when sampling. To evaluate these non-synchronous sensing errors, a group of ten Imote2 sensors were programmed with a sensing application. The sensing application was modified slightly from Illinois SHM Project (ISHMP) Services Toolsuite [8]. The sensor boards used are Imote2 basic sensor board ITS400B [6]. One sensor serves as base station node, the other nine sensors serve as remote nodes. After the base station node sends sensing parameters to these nine remote nodes, they start to sample at the same set time

and also record the time stamps of every data point. Processing these time stamps, we can estimate the non-synchronous sensing effect on Imote2 sensors. The statistical properties of the sampling times are listed in Table 1, and the differences of the start-sensing time among sensors are listed in Table 2.

node ID	mean sampling frequency (Hz)	mean sampling interval (μ s)	% error $(\bar{\Delta t}_i - \Delta t_i) / \Delta t_i$	standard deviation of sampling interval	COV of sampling interval
3	38.64	25878	3.51%	3.0	0.01%
32	39.09	25584	2.33%	3.8	0.01%
98	38.20	26179	4.71%	3.7	0.01%
99	39.84	25099	0.40%	2.5	0.01%
101	40.50	24690	-1.24%	2.9	0.01%
102	40.47	24711	-1.16%	4.1	0.02%
104	39.22	25499	1.99%	4.6	0.02%
105	39.98	25011	0.04%	3.0	0.01%
113	38.77	25791	3.16%	5.2	0.02%

Notes: $\bar{\Delta t}_i, \Delta t_i$ are the actual mean sampling interval and the nominal sampling interval, respectively

Table 1: Statistics of sampling time (40Hz, 1000 points)

Node ID	3	32	98	99	101	102	104	105	113
relative time delay δ_i (μ s)	14942	14160	16582	16582	8601	910	17908	10484	0
fractional time delay $\delta_i / \Delta t_i$	0.60	0.57	0.66	0.66	0.34	0.04	0.72	0.42	0

Table 2: Differences of the start-up time (Node 113 as reference)

From Table 1, we can see that the sampling frequencies of the accelerometers on the Imote2 sensor boards have various non-negligible deviations from the nominal value (40Hz), with a maximum of 4.71% error in Node #98. Differences in the sampling frequencies among the sensor nodes will result in inaccurate estimation of modal parameters unless appropriate post-processing is performed. From the last column in Table 1 we can see that the time intervals fluctuate about 0.01~0.02%, which is quite small, thus the non-uniform sampling effect (random shift term $\varepsilon(k)$) can be neglected. From Table 2 we can see that sensing start-up at all Imote2 sensor nodes is not simultaneous. Some of them start earlier and some later. Node #113 is the first one to start sensing, while Node #104 is the last one. Another observation is that these differences are all less than one sampling time interval. The maximum difference is 0.72 time step observed in Node #104. Although the commands to start sensing are set at exactly the same time, the execution times of the commands are different in different sensor nodes.

3.2 Effect of non-synchronous sensing on modal identification

The effect of time synchronization error on modal identification has been studied by Krishnamurthy et al. [12] and it was found that these errors affect the identified mode shape results. However, Krishnamurthy considered that these errors only come from clock synchronization errors and these errors have been overestimated. In reality, clock synchronization errors are comparatively small compared with other errors in Imote2 sensors.

To study the impact of synchronization errors on modal identification, we simulate a 2-DOF shear structural model subjected to white noise excitation. The 2-storey shear building model and the theoretical modal parameters (natural frequencies, modal shapes) are shown in Figure 2. In order to study the non-synchronous sensing effect, three cases of output response are considered: no time shift, constant time shift and linear time shift. According to the extent

of synchronization errors showed in section 3.1, the simulations of non-synchronous sensing are done using three scenarios: 1) Baseline (no time shift): both of the sampling frequencies are 40Hz; 2) Case1 (constant time shift): both of sampling frequencies are 40Hz, but channel #2 has 20000 μ s time delay; 3) Case2 (linear time shift): The sampling frequencies of channel #1 & #2 are 39.8406Hz & 40.4858Hz, respectively.

Table 5: Comparison of identified modal parameters using NExT/ERA method

After obtaining the output response data of the structure, various modal identification algorithms can be applied to identify the modal parameters. In this study three popular output-only modal identification algorithms are utilized: Peak-Picking (PP) [9], Frequency Domain Decomposition (FDD) [10] and Natural Excitation Technique in conjunction with Eigensystem Realization Algorithm (NExT/ERA) [11]. The identified results are summarized and compared in Table 3, 4 & 5. It can be seen that all these three algorithms suffer from errors when using the non-synchronous samples directly. These errors affect only slightly the identified frequencies but affect the mode shapes considerably. The constant time shift error almost only affects the phase information of the mode shape. The linear time shift error has more influence on the modal parameters, especially the mode shapes, of which both the magnitude and phase suffer big errors. For these three output-only modal identification algorithms, FDD and NExT/ERA are more susceptible to synchronization errors, especially for linear time shift errors.

4 ERROR ELIMINATION

4.1 Proposed algorithm

In order to eliminate the synchronization errors, direct intuition suggests reconstructing the synchronous samples from measured non-synchronous ones. This is so called signal reconstruction, and some work has been done for this purpose such as interpolation based approach [13] and resampling based approach [5]. Nevertheless, such approaches can be computationally extensive. Rather than reconstructing the signal in the time domain, we develop a correction approach to recover the true spectral density using non-synchronous samples in the frequency domain. This approach is based on the spectral relationship of synchronous data and non-synchronous data. Because only spectral densities or correlation functions are needed for most of modal identification algorithms and raw synchronous time histories are not needed, reconstruction of the signal in the time domain is unnecessary. As long as we are able to obtain the corrected spectral densities, the correlation functions can also be easily obtained by IFFT.

4.1.1 Constant time shift

Consider two time histories $\{x_\alpha(0), x_\alpha(\Delta t), \dots, x_\alpha((N-1)\Delta t)\}^T$ and $\{x'_\beta(\delta), x'_\beta(\Delta t + \delta), \dots, x'_\beta((N-1)\Delta t + \delta)\}^T$, i.e., \mathbf{x}'_β has a constant time shift δ . The discrete Fourier transform (DFT) for \mathbf{x}_α is given by

$$X_\alpha(\omega_k) = \sum_{n=0}^{N-1} x_\alpha(n\Delta t) e^{-j\omega_k n\Delta t} \quad (3)$$

where $\omega_k = k\Delta\omega$, $\Delta\omega = \frac{2\pi}{N\Delta t}$, $k = 0, 1, \dots, \text{int}(N/2)$. The DFT for the shifted signal \mathbf{x}'_β is given by

$$X'_\beta(\omega_k) = e^{j\omega_k \delta} \cdot X_\beta(\omega_k) \quad (4)$$

where $X_\beta(\omega_k)$ is the DFT of the original signal. Therefore,

$$X_\beta(\omega_k) = X'_\beta(\omega_k) \cdot e^{-j\omega_k \delta} = X'_\beta(\omega_k) \cdot \left(e^{-j\frac{2\pi}{N} \frac{\delta}{\Delta t}} \right)^k \quad (5)$$

Then, the true cross spectral density estimate can be obtained by

$$S_{x_\alpha x_\beta}(\omega_k) = \frac{\Delta t}{N} E[X_\alpha(\omega_k) X_\beta^*(\omega_k)] \quad (6)$$

where $(\cdot)^*$ denotes the complex conjugate operation.

4.1.2 Linear time shift

Consider two time histories $\{x_\alpha(0), x_\alpha(\Delta t_\alpha), \dots, x_\alpha((N_\alpha - 1)\Delta t_\alpha)\}^T$ and $\{x_\beta(0), x_\beta(\Delta t_\beta), \dots, x_\beta((N_\beta - 1)\Delta t_\beta)\}^T$, having different sampling frequencies, i.e. $\Delta t_\alpha \neq \Delta t_\beta$, with corresponding sampling time lengths $T_\alpha = N_\alpha \Delta t_\alpha$ and $T_\beta = N_\beta \Delta t_\beta$, respectively. In discrete Fourier transform, we know that $\omega_k = k\Delta\omega$ and $\Delta\omega = 2\pi/T = 2\pi/N\Delta t$. In order to ensure that $X_\alpha(\omega_k)$ and $X_\beta(\omega_k)$ correspond to the same discrete frequency when calculating the cross spectral density, their frequency resolutions should be identical, i.e., $\Delta\omega_\alpha \equiv \Delta\omega_\beta$, thus their duration time should be the same, i.e.,

$$N_\alpha \Delta t_\alpha = N_\beta \Delta t_\beta, \quad \frac{N_\alpha}{N_\beta} = \frac{\Delta t_\beta}{\Delta t_\alpha} \quad (7)$$

Based on this relationship, the cross spectral density can be estimated by

$$S_{x_\alpha x_\beta}(\omega_k) = \frac{\Delta t_\beta}{N_\alpha} E[X_\alpha(\omega_k) X_\beta^*(\omega_k)] = \frac{\Delta t_\alpha}{N_\beta} E[X_\alpha(\omega_k) X_\beta^*(\omega_k)], \text{ when } N_\alpha, N_\beta \rightarrow \infty \quad (8)$$

where $\omega_k = k\Delta\omega$, $\Delta\omega = \frac{2\pi}{N_\alpha \Delta t_\alpha} = \frac{2\pi}{N_\beta \Delta t_\beta}$, $k = 0, 1, \dots, \min\{\text{int}(N_\alpha/2), \text{int}(N_\beta/2)\}$.

4.1.3 Summary of proposed procedure

In reality, the time shifts of non-synchronous data are a combination of constant time shifts and linear time shifts. The most popular FFT-based method for power spectral density estimation is Welch's refined periodogram approach [14]. The procedures for computing the true power spectral density estimate from non-synchronous data in WSN are as follows:

- (1) Calibrate the sampling frequencies of each sensor board before sensing experiment.
- (2) Perform sensing experiment, and make sure the time stamps are also recorded when sampling.
- (3) Set one sensor as reference and partition the data into several segments. Each segment has a length of N_r data points.
- (4) Partition the data in other sensors into several segments as well. The first data point of each segment is chosen as close as possible to the first data point of the corresponding segment in the reference sensor data by comparing their time stamps. The length N_i of each segment is chosen such that the Eq. (7) holds approximately.
- (5) Calculate the Fourier transform of each segment and correct it using Eq. (5).
- (6) Calculate the cross spectral density using Eq. (8).

4.2 Numerical example

The structural system used is the same as before in section 3.2. The i^{th} sampling instant is chosen as follows: $t_1(i) = 0.0250 \times (i-1)$, $t_2(i) = 0.0247 \times (i-1) + 0.0200$, i.e. sensor #1 has a sam-

pling frequency 1/0.0250 (40) Hz, while sensor #2 has a slightly different sampling frequency 1/0.0247 (40.4858) Hz and a time delay 0.02 sec. The measurement noise for the response is taken to be 10 percent, i.e. the RMS of the measurement noise for a particular channel is equal to 10 percent of the RMS of the noise-free response at the corresponding channel.

The identified modal parameters using PP, FDD and NExT/ERA methods are summarized and compared in Table 6, 7 & 8. It can be seen that the modified methods using the proposed corrected spectral densities or correlation functions can achieve better accuracy than the original methods.

5 CONCLUSIONS

The purpose of this paper is to address the problem of non-synchronous sensing on modal identification when using wireless sensor networks. The potential sources causing non-synchronous sensing are first discussed and their extents are estimated based on data collection from Imote2 sensors. Among these error sources the dominant ones are non-simultaneity in sensing start-up and differences in sampling frequency among sensor nodes. According to

numerical simulations, these errors can distort the identified results of the mode shapes. A new methodology is proposed for eliminating such errors. This methodology estimates the power spectral density (PSD) of output responses using non-synchronous samples based on a modified FFT. As long as we obtain the corrected spectral density, the correlation functions can also be easily obtained by IFFT. Then, these corrected PSDs or correlation functions can be fed into various output-only modal identification algorithms. Comparing with other existing methods of raw synchronous time history reconstruction, this methodology is simple and computationally efficient. The proposed methodology is validated using numerical simulations. The simulation results closely match the identified parameters based on synchronous data.

7 APPENDIX A – DERIVATION OF EQ(4)

The discrete Fourier transform for shifted \mathbf{x}'_β is given by

$$\begin{aligned} X'_\beta(\omega_k) &= \sum_{n=0}^{n=N-1} x'_\beta(n\Delta t + \delta) e^{-j\omega_k n\Delta t} = \sum_{n=0}^{n=N-1} x'_\beta(n\Delta t + \delta) e^{-j\omega_k (n\Delta t + \delta)} \cdot e^{j\omega_k \delta} \\ &= e^{j\omega_k \delta} \cdot \sum_{n=0}^{n=N-1} x'_\beta(n\Delta t + \delta) e^{-j\omega_k (n\Delta t + \delta)} = e^{j\omega_k \delta} \cdot X_\beta(\omega_k) \end{aligned} \quad (9)$$

8 APPENDIX B – DERIVATION OF EQ(8)

The cross spectral density function between \mathbf{x}_α and \mathbf{x}_β is defined by [15]

$$\begin{aligned} S_{x_\alpha x_\beta}(\omega_k) &= \lim_{T \rightarrow \infty} \frac{1}{T} E \left[X_\alpha(\omega_k, T) \cdot X_\beta^*(\omega_k, T) \right] \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} E \left[\int_0^T x_\alpha(t) e^{-j\omega_k t} dt \cdot \left(\int_0^T x_\beta(t) e^{-j\omega_k t} dt \right)^* \right] \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} E \left[\int_0^T x_\alpha(t) e^{-j\omega_k t} dt \cdot \int_0^T x_\beta(t) e^{j\omega_k t} dt \right] \\ &= \lim_{N_\alpha \rightarrow \infty} \frac{1}{N_\alpha \Delta t_\alpha} E \left[\Delta t_\alpha \sum_{n_1=0}^{N_\alpha-1} x_\alpha(n_1 \Delta t_\alpha) e^{-j\omega_k n_1 \Delta t_\alpha} \cdot \Delta t_\beta \sum_{n_2=0}^{N_\beta-1} x_\beta(n_2 \Delta t_\beta) e^{j\omega_k n_2 \Delta t_\beta} \right] \quad (10) \\ &= \lim_{N_\alpha \rightarrow \infty} \frac{\Delta t_\beta}{N_\alpha} E \left[\sum_{n_1=0}^{N_\alpha-1} x_\alpha(n_1 \Delta t_\alpha) e^{-j\omega_k n_1 \Delta t_\alpha} \cdot \sum_{n_2=0}^{N_\beta-1} x_\beta(n_2 \Delta t_\beta) e^{j\omega_k n_2 \Delta t_\beta} \right] \\ &= \lim_{N_\alpha \rightarrow \infty} \frac{\Delta t_\beta}{N_\alpha} E \left[X_\alpha(\omega_k) X_\beta^*(\omega_k) \right] \end{aligned}$$

Keywords: Time-varying risk, aftershock hazard, fragility curves, damaged structure, bridges.

Abstract. *A critical issue in the emergency management after the earthquake is the functionality of the main infrastructure (hospitals, road network, etc.) and the decision on their usability just after the main shock. At present, a decision is taken on the basis of a structure in-situ inspection; an analytical assessment is in contrast with the lack of time and data. For this reason in this paper a method that rationally combines information from the analytical approach and the in situ inspection is proposed. In particular an effective tool to speed-up the decision making phase concerning the evaluation of the seismic risk of mainshock-damaged structures due to aftershocks has been proposed. The risk is calculated combining the aftershock hazard using the Omori law and the fragility curves of the structure calculated using IDA technique and updated using in-situ inspection data. The procedure has been applied to a highway r.c. bridge. The results have highlighted a high sensitivity to the Bayesian updating especially when the damage predicted by the numerical analysis does not correspond to the real damage. The mean annual rates of collapse provided by the method has shown that the risk structure change dramatically when an aftershock sequence strike the bridge and this risk decreases with time allowing the authorities to decide if and when re-open the bridge to traffic.*

1 INTRODUCTION

The earthquakes, as well known, are cluster phenomena: thus the sequence of a seismic event is non-poissonian. In order to simplify the model, the phenomenon is usually represented by a superposition of two different phenomena: the mainshock, considered as stationary, that is the major intense event of each cluster; the second one (aftershock), strongly non-stationary, follows the mainshock event. Although the mainshock may be preceded by precursor events (foreshocks), usually these latter are low-intensity shocks, whereas, the sequence of the aftershocks due to a high magnitude event is made of numerous earthquakes, some of which may have an intensity similar to the mainshock one.

For a long time, the evaluation of the seismic risk was based on mainshocks. This is justified by the fact that a mainshock is usually the most violent event, capable to induce relevant damages to the building and to catch the people inside the buildings, and in case of collapse, to provoke the most number of victims. Aftershocks, although as much violent, act on empty buildings, and their potentiality in terms of victims is much lower. Nevertheless, the aftershock risk is relevant for two aspects: a) in the estimation of the risk based not only on the human life preservation, but also on the direct and indirect economic consequences of an earthquake, the damages induced by aftershocks may increase highly the cost of a seismic event; b) in assuming decisions about the feasibility of buildings and transitability of the streets, the aftershock risk represents the main parameter.

Usually, these decisions are taken in the field, on the basis of simple vision inspections and on a synthetic evaluation of the situation, based on the experience of the inspector, often not so wide given that the seismic events are likely rare events.

The decision about the feasibility of a construction, in a post-earthquake scenario, has relevant consequences, because if an imprudent choice can produce further victims, a conservative choice may produce a social inconvenience and useless costs for the housing of the displaced persons or for the interruption of the productive activities.

For some years some researcher and institutions [1, 2, 3, 4, 5, 6, 7] have suggested a more rational and analytical approach to the problem of the feasibility of the seismically damaged constructions, in particular in the period immediately after the mainshock.

The application of analytical methods, for a rapid estimation of the feasibility of buildings, introduces so many difficulties that the final decision cannot ignore the judgment of the detector; in fact, the buildings are numerous and complex structure for which is difficult to define general damage levels that account for the behavior of non-structural elements (partitions, ceilings, etc..), as well as the risk related to the surrounding situation (e.g. collapse of adjacent buildings). More affordable seems to be a rational and analytical procedure to manage the decisions about the transitability of bridges; in fact, bridges are more simple structures and less numerous, for which appears more plausible to organize a customized procedure to use in emergency situations.

The bridges are strategic structures because their unavailability can cause the interruption of the road ways, prevent the ordinary means to reach the zone struck by the seismic event. This condition becomes particularly penalizing during the post-earthquake emergency, when high amount of transportation means have to be employed for the rescue operations. The decision to close to the traffic a bridge of an important roadway, which connect the most struck zones, is therefore very delicate, and it should be taken on the basis of the most possible rational and objective criteria. In a recent paper [8] some authors have studied the problem to correlate the intensity of the event with the vertical load carrying capacity (traffic) of the bridge. The results are given in terms of fragility curves for different percentages of traffic reduction. Nevertheless the correlation of the residual vertical load carrying capacity with the seismic

damage is very difficult and uncertain, both for the limits of the current models and because the live loads often represent a limited fraction of the bridge weight.

More promising seems to be the way proposed by [9, 10] to relate the decision of the usability of a bridge to the risk due to aftershocks. For this purpose, is necessary to perform an After-shock Probabilistic Seismic Hazard Analysis (APSHA) [3]; as soon as the magnitude and position of the main event is known, this analysis, as similar as the ordinary Probabilistic Seismic Hazard Analysis (PSHA), provides the probability that, in the unit time, an earthquake occurs with an intensity greater than a given one.

The analysis is completed with a convolution between the hazard and the vulnerability of the structure; in the post-earthquake the structures will be probably damaged, therefore fragility curves depending on the damage induced by the mainshock have necessary to build.

A relevant difficulty consists in the evaluation of the damage level suffered by the structure. In fact, an inspection will allow to detect only some visible effects due to the seismic action (e.g. cracks, spalling of concrete cover, buckling of reinforcement, etc..). These observations are certainly correlated with the damage suffered the structure but with a high dispersion.

Alternatively, it is possible to proceed analytically; being known position and magnitude of the event, the seismic intensity of the site is determined (e.g. the median spectrum) using an attenuation law; however, also in this case the dispersion of the intensity, of the shape of the spectra and the reliability of the model render the estimation of the suffered damage very uncertain; furthermore, the result of a predictive model based on the analysis cannot to conflict with the observation.

In a recent work [10], the authors use both the methods synergically. The predicted damage, on the basis of the attenuation curves and the fragility curves of the undamaged structure, is used as prior estimation of the probability, which are updated on the basis of the observed damage, using as likelihood function the probability function conditioned to the observed one; this function can be built using numerous experimental tests [11].

Another difficulty regards the use of the results in the decision process about the usability of the structure (e.g. the functionality of the bridge). In fact, differently from the mainshock, the aftershock process is strongly non-stationary, therefore, the hazard (and then the risk) vary day by day, decreasing rapidly with the time, measured starting from the mainshock event.

The risk threshold under which is possible to use the construction has been highly discussed. A reasonable criteria is based on the comparison between the prior risk of the undamaged structure, due to the mainshock, with the aftershock risk, but the non-stationarity of the aftershock process renders very problematic the comparison.

Different proposals have been done to make comparable the above two quantities. Yeo and Cornell [12] compare the cost (discounted) required to save a human life with respect to the mainshock risk (in an infinite time) with the same cost associated with the aftershock; with some approximations the conversion factor is the social discount factor (3-5%). More simply, Pinto and Franchin [9] compare the average risk (annualized) in the residual time between the data of the decision and the end of the aftershock sequence. Both the criteria will be applied and compared.

2 DESCRIPTION OF THE METHOD

In this section a rational method for probabilistic aftershock risk evaluation of damaged bridges is presented. Basically, the procedure consists of the following four steps:

- Evaluation of the fragility curves of damaged and undamaged bridge
- Damage evaluation phase

- Aftershock hazard analysis
- Evaluation of the aftershock risk

The main goal of the method is to provide the mean annual rate of collapse for aftershocks of a mainshock-damaged bridge. The method, already proposed by the authors [10], is here improved introducing a new technique for the evaluation of the fragility curves, which is based on the Latin Hypercube Sampling technique. All the relevant aspects of the proposed procedure is illustrated in the following sections.

2.1 Evaluation of the fragility curves

The first phase of the procedure, to be carried out before the earthquake occurs, consists of evaluating the fragility curves of undamaged and damaged structure. A parameter of damage measure has to be adopted (in the following the maximum drift will be adopted) and a series of dynamic analysis on a proper structural model has to be executed in order to calculate the probabilities functions $\bar{F}_{\phi,y}(\phi_i, y)$ of the damage ϕ_i , versus the local intensity y_i of the earthquake. The IDA procedure [13] is the most used method for the evaluation of the fragility curves.

Following this method a series of increasing damage levels is established (ϕ_1, ϕ_2, \dots) and a wide sample of accelerograms are chosen together with the representative parameter of the local intensity (e.g. PGA or spectral ordinate).

Nonlinear dynamic time-history analysis are performed using the selected set of ground motions, scaling each record, in an iterative procedure, until the intensity that causes precisely the damage level ϕ_i is found.

It is now possible, for each accelerogram, to induce in the structure the damage level j^{th} , and then, starting from that point, to apply another series of accelerograms with increasing intensity, in order to simulate the effects of the aftershocks. It is necessary to repeat the IDA procedure for a number of times equal to the product between the number of damage levels and the number of the accelerograms selected for simulate the mainshock. Altogether, the required number of analysis is rather large and significantly increase when the probability $\bar{F}_D(\phi_i | \phi_j, y)$ that the structure, with an initial damage level ϕ_j , reaches or exceeds the damage level ϕ_i caused by an aftershock, has to be evaluated; the latter is given by $n_{an} = n_{dl} \times n_{am} \times n_{aa} \times n_{il}$, in which n_{dl} is the number of the considered damage levels, n_{am} is the number of the accelerograms used for the mainshock, n_{aa} is the number of the accelerograms used for the aftershocks and n_{il} is the number of the intensity levels considered in the IDA procedure.

Therefore the IDA technique can only be applied to simple structural schemes for which the time of calculation remains acceptable; the extension to more complex structures will require a more efficient procedure.

With the aim of extending the procedure to more complex structures, the regression analysis is here used to evaluate the fragility curves, significantly reducing the number of analysis and, consequently, the computation time. A set of accelerograms is selected together to a range of variation of the PGA and the Latin Hypercube Sampling technique (LHS) is applied to select the sample used for the structural analysis.

This technique uses a stratified sampling scheme that generates a sample containing n values on each of p variables; these are obtained by dividing the range of variation of each variable into n equiprobable and non-overlapping intervals; the values are randomly distributed

with one from each interval $(0,1/n)$, $(1/n,2/n)$, ..., $(1-1/n,1)$, and then they are randomly permuted.

The LHS technique is used to extract a significant sample of variables on which to perform the analysis and then the regressions. In particular, in order to determine the fragility curves of the undamaged structure, n_m couples of variables (accelerogram, intensity y_i) are extracted and the damage level ϕ_i , obtained in the analysis, is used to build n_m couples (y_i, ϕ_i) .

To obtain the “fragility surface” of the damaged structure, n_a quadruples of variables $(A_{mi}, y_{mi}, A_{ai}, y_{ai})$ are extracted, where A_{mi} and A_{ai} indicate the i^{th} mainshock and the i^{th} aftershock accelerogram respectively, whereas y_{mi} and y_{ai} are the corresponding intensities. From the analysis of the structure subjected to this couple of accelerograms, the corresponding two levels of damage ϕ_{mi} and ϕ_{ai} are recorded, on condition that $\phi_{ai} \geq \phi_{mi}$. Consequently the following n_a triples $(y_a, \phi_{mi}, \phi_{ai})$ are obtained. The objective is to find the distribution function of the damage ϕ_i caused to the undamaged structure by the mainshock and then the distribution function of the damage $\phi_{ai} | \phi_{mi}, y_{ai}$ caused by the aftershock to the structure with a pre-existing damage level ϕ_{mi} .

For both the analyses the following polynomial regression model is used:

$$\log \phi = \mathbf{X}\boldsymbol{\beta} + \varepsilon \quad (1)$$

where $\mathbf{X} = \begin{bmatrix} 1 & x_1 & x_2 & \dots & x_1^2 & x_1x_2 & \dots \end{bmatrix}$ is the vector $(1 \times m)$ of the polynomial variables, whereas $\boldsymbol{\beta}$ is the coefficient vector and ε is a random variable.

The use of the logarithms of ϕ depends on hypothesis that this quantity (non-negative) is better described by a lognormal random variable. The random variable ε is instead Gaussian.

In the examined case the variables in \mathbf{X} are the intensity y_m in the first analysis and the pairs (y_a, ϕ_m) of the intensity of the aftershock and the initial damage.

If $\hat{\boldsymbol{\Phi}}$ is a vector $(n_a \times 1)$ built using the logarithms of the calculated damages and $\hat{\mathbf{X}}$ is the matrix $(n_a \times m)$ of the polynomial variables calculated in the sample points, it found, by the regression analysis, that $\log \phi$ is a random variable with mean:

$$E[\log \phi] = \hat{\mathbf{X}}\boldsymbol{\beta} \quad (2)$$

with

$$\boldsymbol{\beta} = (\hat{\mathbf{X}}^T \hat{\mathbf{X}})^{-1} \hat{\mathbf{X}}^T \hat{\boldsymbol{\Phi}} \quad (3)$$

and variance

$$\sigma_{\log \phi}^2 = s^2 \frac{\|\hat{\mathbf{X}}^T \hat{\mathbf{X}} + \mathbf{X}^T \mathbf{X}\|}{\|\hat{\mathbf{X}}^T \hat{\mathbf{X}}\|} \quad (4)$$

where

$$s^2 = \frac{(\hat{\boldsymbol{\Phi}} - \hat{\mathbf{X}}\hat{\boldsymbol{\beta}})^T (\hat{\boldsymbol{\Phi}} - \hat{\mathbf{X}}\hat{\boldsymbol{\beta}})}{\nu - 2} \quad (5)$$

The term $\log \phi$ follows the t-Student distribution with $\nu = n - m$ degrees of freedom. It is observed that if the dimensions m of the sample are high, the t-student distribution approximates the Gauss distribution, so ϕ becomes lognormal.

2.2 Damage evaluation

After a seismic event, the magnitude m_0 and the position r of the epicenter are quickly available; with such a data and using a proper attenuation law [14], 15, 16] it is possible to find the average value and the standard deviation of the selected parameter of local intensity as function of the magnitude and the epicentral distance (or minimum distance from the fault). Assuming for y a log-normal distribution, the conditional probability density of the intensity y is:

$$f_{Y|IM,R}(y|m_0, r_0) = \frac{1}{\sqrt{2\pi}\zeta_{0,y}} \exp\left[-\frac{(\ln y - \mu_0)^2}{2\zeta_0^2}\right] \quad (6)$$

in which $\zeta_0 = \sqrt{\ln(1 + (\sigma_y / \bar{y})^2)}$ and $\mu_0 = \ln \bar{y} - \zeta_0^2 / 2$.

Consequently the probability of exceeding the damage level ϕ_i conditioned to the occurrence of an event of magnitude m_0 and distance r_0 can be calculated by integrating the product between seismic hazard and fragility:

$$\bar{F}_\Phi(\phi_i | m_0, r_0) = \int_0^\infty \bar{F}_{\Phi|Y}(\phi_i | y) f_{Y|IM,R}(y | m_0, r_0) dy \quad (7)$$

This (probabilistic) damage estimation does not account for what is really occurred in the structure. As stressed above, the post-earthquake observation of the damage does not allow, at least for moderate intensity events, to evaluate the damage index ϕ_i used in the analytical model without a permanent instrumentation placed on the structure.

To evaluate the CDF of the damage index ϕ conditioned to the observed damage θ_k , $F_\phi(\phi | \theta_k)$, a relationship between the two variables must be known; on the basis of laboratory tests, Berry and Eberhard [11] have developed relationships that provides, as function of the characteristics of the reinforced concrete element (normal force, sectional area, length, percentage of reinforcement, etc.), the average value and the coefficient of variation of the damage index ϕ_i (drift) corresponding to the observed damage θ_k , ($k=1,2,3$), where θ_1 = spalling, θ_2 = buckling of the steel bars, θ_3 = failure of the steel bars.

Assuming that the probability of ϕ conditioned to the damage θ_k can be expressed as lognormal, the previous data permit to determine the CDF of the drift ϕ conditioned to θ_k , $F_\phi(\phi | \theta_k)$. The probability $p(\theta_k | \phi)$ can be obtained observing that, if ϕ_k is the drift for the damage level θ_k , then $\phi < \min_k(\phi_k) = \text{no damage}$, $\phi_1 \leq \phi < \min(\phi_2, \phi_3) = \text{damage } \theta_1$, $\max(\phi_1, \phi_2) \leq \phi < \phi_3 = \text{damage } \theta_2$, and finally $\max_k(\phi_k) \leq \phi = \text{damage } \theta_3$. Consequently, if θ_0 stands for no damage condition, we can assume:

$$\begin{aligned} p(\theta_0 | \phi) &= \Pr\left[\min_k(\phi_k) > \phi\right] = \prod_{k=1}^3 [1 - F_{\phi_k}(\phi | \theta_k)] \\ p(\theta_i | \phi) &= \prod_{j=1}^i F_{\phi_j}(\phi | \theta_j) \prod_{k=i+1}^3 [1 - F_{\phi_k}(\phi | \theta_k)] \quad (i=1,2) \\ p(\theta_3 | \phi) &= \Pr\left[\max_k(\phi_k) \leq \phi\right] = \prod_{k=1}^3 F_{\phi_k}(\phi | \theta_k) \end{aligned} \quad (8)$$

where $p(\theta_k | \phi)$ is the probability of the observed damage θ_k conditioned to the drift ϕ . If we consider $p_0(\phi) = f_\Phi(\phi | m_0, r_0)$ a prior probability distribution, estimated before the direct observation of the damage, and θ_k is the level of the real observed damage, applying the Bayes theorem using $p(\theta_k | \phi)$ as likelihood function, the updated estimation of the probability can be obtained as:

$$p(\phi | \theta_k) = \frac{p(\theta_k | \phi) p_0(\phi)}{\int p(\theta_k | \phi) p_0(\phi) d\phi} \quad (9)$$

This probability function of the damage index ϕ combines the results of a predictive analysis carried out on the numerical model of the structure with the information gathered from the visual observation of the residual damage of the structure.

2.3 Aftershock hazard analysis

Since it is supposed that the main event has occurred and then magnitude, epicentral distance and (possibly) fault line and position are known, it is possible to carry out an Aftershock Probabilistic Hazard Analysis (APSHA), similarly to the procedure illustrated in [2].

In this paper we will suppose that the length of the rupture zone (L_R), if not directly known, can be estimated as function of the magnitude as indicated in [17]:

$$L_R = 10^{(a+bm_0)} \quad (10)$$

where a and b are parameters depending on the fault rupture type and L_R is expressed in Km.

Unlike the standard hazard analysis (PSHA), in which the seismic events is assumed Poissonian and stationary, the aftershocks process is highly non-stationary; the mean instantaneous daily rate of events at time t with magnitude greater or equal to m following a mainshock of magnitude m_m , is given by the “modified Omori Law” [18].

$$\gamma(t, m, m_m) = \frac{10^{a+b(m_m-m)}}{(t+c)^p} \quad (11)$$

where a, b, c , and p are regional parameters that can be estimated on the basis of the past seismic events [19].

Moreover, by introducing a truncation of the magnitude m such that $m_l < m < m_m$, the average number of daily events with intensity greater than m is given by [2]:

$$\gamma(t, m, m_m) = \gamma_0(t, m_l, m_m) \frac{e^{-\beta m} - e^{-\beta m_m}}{e^{-\beta m_l} - e^{-\beta m_m}} = \gamma_0(t, m_l, m_m) [1 - F_M(m)] \quad (12)$$

where $\beta = b \ln 10$ and $\gamma_0(t, m_l, m_m)$ is the average number of the daily events at time t with magnitude $m_l < m < m_m$ and

$$\gamma_0(t, m_l, m_m) = \frac{10^{a+b(m_m-m_l)} - 10^a}{(t+c)^p} \quad (13)$$

The mean number of aftershocks with magnitudes m such that $m_l < m < m_m$ in the time interval $[t; t+T]$ following a mainshock of magnitude m_m is given by:

$$\gamma(t, T; m_m) = \int_t^{t+T} \gamma_0(\tau, m_1, m_m) d\tau = \frac{10^{a+b(m_m-m_1)} - 10^a}{p-1} \left[(c+t)^{1-p} - (c+t+T)^{1-p} \right] \quad (14)$$

For an aftershock of magnitude m and epicenter P , the local intensity at the site is deduced by the attenuation law: $\log y = \psi(r, m) + \varepsilon$, in which ψ is a function of the magnitude m and of the distance r between the structure and the epicenter (or the minimum distance from the fault), whilst ε is a zero-mean Gaussian variable with standard deviation σ_ε . The probability density of Y for a given event conditioned to m and r is then:

$$f_{Y|R}(y | r, m) = \frac{1}{y} \varphi\left(\frac{\ln y - \psi(r, m)}{\sigma_\varepsilon}\right) \quad (15)$$

where $\varphi(\cdot)$ is the standard normal PDF.

In order to obtain the probability of Y unconditioned with respect to the magnitude, the equation (15) must be multiplied by the PDF of the magnitude of the aftershocks, $f_M(m) = dF_M(m)/dm = \beta e^{-\beta m} / (e^{-\beta m_1} - e^{-\beta m_m})$ and integrated over m :

$$f_{Y|R}(y | r) = \frac{1}{y} \int_{m_1}^{m_m} \varphi\left(\frac{\ln y - \psi(r, m)}{\sigma_\varepsilon}\right) f_M(m) dm \quad (16)$$

As frequently occurs, when the attenuation law is a linear function of m , $\log y = \psi(r) + qm + \varepsilon$, the integral (16) can be developed in closed form [25]:

$$\begin{aligned} f_{Y|R}(y | r) &= \frac{1}{\sqrt{2\pi}\sigma_\varepsilon y} \int_{m_1}^{m_m} \exp\left(-\frac{(\ln y - \psi(r) - qm)^2}{2\sigma_\varepsilon^2}\right) \frac{\beta e^{-\beta m}}{e^{-\beta m_1} - e^{-\beta m_m}} dm = \\ &= \frac{e^{\beta(m_1+m_m+\psi(r)/q+\sigma_\varepsilon^2\beta/q^2)}}{2(e^{-\beta m_1} - e^{-\beta m_m}) y^{\beta/q+1} q\beta} \left[\operatorname{erf}\left(\frac{-\beta\sigma_\varepsilon^2 - q[qm_1 - \ln(y) + \psi(r)]}{\sqrt{2}\sigma_\varepsilon q}\right) + \right. \\ &\quad \left. - \operatorname{erf}\left(\frac{-\beta\sigma_\varepsilon^2 - q[qm_m - \ln(y) + \psi(r)]}{\sqrt{2}\sigma_\varepsilon q}\right) \right] \end{aligned} \quad (17)$$

If R denotes the region where the aftershocks may occur (in the following it will be assumed that coincides with the length of mainshock fault, similarly to [2]), and $f_R(r)$ is the probability density function of the distances r from the site, the probability density of an event with intensity y , conditioned to the occurring of the event, is:

$$f_Y(y) = \int_R f_{Y|R}(y | r) f_R(r) dr \quad (18)$$

2.4 Evaluation of the aftershock risk

The functions $\bar{F}_D(\phi_i | \phi_j, y)$ and $p(\phi_j | \theta_k)$ previously defined have the following meaning; the first one provides the probability that the structure, stricken by the mainshock with a damage level ϕ_j , could exceeds the damage level $\phi_i \geq \phi_j$ because of an aftershock, while the second one is the probability that the structure, stricken by the mainshock, has suffered the damage ϕ_j .

Therefore, if an aftershock occurred, the probability that a damage $\phi \geq \phi_i$ is:

$$Pr(\phi \geq \phi_i) = \int_0^{\phi_i} \int_0^{\infty} \bar{F}_D(\phi_i | \phi_j, y) f_Y(y) p(\phi_j | \theta_k) dy d\phi_j \quad (19)$$

At time t , the daily mean number of the shaking that induce in the structure a level of damage greater or equal to ϕ_i is therefore $\gamma(\phi_i | t) = \gamma_0(t, m_1, m_m) Pr(\phi \geq \phi_i)$. If an aftershock cluster is represented by a Poisson process, the probability (risk) that the damage is exceeded in the time $[t, t+T]$ is:

$$Pr(\phi \geq \phi_i | t, T) = 1 - e^{-N_a(\phi_i, t, T)} \quad (20)$$

where:

$$\begin{aligned} N_a(\phi_i, t, T) &= \int_t^{t+T} \gamma(\phi_i | \tau) d\tau = \\ &= \int_t^{t+T} \gamma_0(\tau, m_1, m_m) Pr(\phi \geq \phi_i) d\tau = Pr(\phi \geq \phi_i) \int_t^{t+T} \gamma_0(\tau, m_1, m_m) d\tau = \\ &= Pr(\phi \geq \phi_i) \frac{10^{a+b(m_m-m_1)} - 10^a}{p-1} \left[(c+t)^{1-p} - (c+t+T)^{1-p} \right] \end{aligned} \quad (21)$$

is the mean number of the events that produce the damage ϕ_i in the time interval $[t, t+T]$.

3 DECISION-MAKING ANALYSIS

The probability evaluated with equation (20) represents the risk, due to an aftershock, that a damage level ϕ_i in the structure is exceeded during the time interval T , starting from the time t ; in the following, ϕ_i will be assumed as collapse condition. This data is useful to assume a rational decision on the usability of the construction (e.g. the functionality of a bridge). A reasonable criterion to orient such a decision consists of comparing the risk due to the aftershocks (provided by eq. (17)) with the risk due to the mainshock. Nevertheless, this comparison introduces considerable conceptual difficulties.

In fact, in the Probabilistic Seismic Risk Analysis (PSRA), the process of the events is assumed to be stationary, therefore the mean number of the events that produce the damage ϕ_i in the time T is simply, $\gamma_m(\phi_i)T$, where $\gamma_m(\phi_i)$ is the mean number of events in the unit time (generally one year). The comparison among these two risks can simply be done comparing the frequencies, independently from the used time unit, because of the simple proportionality with the time T . In case of aftershocks, the Omori law shows that the process is strongly non-stationary, and the average frequency decays as $\sim 1/t$; for instance, using the values of the coefficients of the Omori law obtained by [20] for the Italian earthquakes, after 7 days the activity is reduced to less than the 17% of that of the first day, while after one month it is a little bit more than 4%. Similar results, but even more pronounced, are found using the values of Reasenberg and Jones for the southern California.

The dependency of the aftershocks risk from the initial time t can be employed for establishing a date over which the risk decrease up to a level comparable with the mainshock risk and therefore considered as acceptable; for this purpose the problem of establishing for what time T the risk has to be measured, must be overcome. For instance, it may be assumed $T=1$ year in order to make N_a directly comparable with the annual frequency of collapses due to mainshocks. But if a lower value of T is assumed (e.g. 6 months), N_a is reduced, at least in the first ten days, less than 20% (Lolli and Gasparini data [20]), while the expected mean number

of the mainshocks halves. The choice of $T=1$ year appears therefore arbitrary and related only to common criteria.

More realistic appears the approach proposed by [9] consisting in using the maximum duration of the aftershocks sequence expressed as $t_u = 60 + 60(m_m - 4)$ days [20]. In this way however the duration of the time period $T = t_u - t$ varies with t . For a direct comparison between this quantity and the annual stationary frequency, an "equivalent" annual frequency expressed as: $[365/(t_u - t)]N_a(\varphi_i, t, t_u - t)$ has to be calculated. Another interesting approach is that carried out from Yeo and Cornell [12]; in this work the authors assume as equivalence criteria the condition that the expected investment into life-safety technologies for saving an arbitrary building occupant in the future is the same for both cases. As result, an equivalent, time-independent collapse rate is obtained multiplying the total number of collapses in the interval $(t - \infty)$ by the "inflation-adjusted discount rate".

4 INCREMENTAL DYNAMIC ANALYSIS AND REGRESSION METHODS FOR THE EVALUATION OF FRAGILITY CURVES

To validate the application of the regression method for fragility curves evaluation the results obtained on a case study have been compared with those obtained by the IDA procedure.

In a previous author's work [9] the developed procedure with IDA has been applied to a simply supported highway viaduct (Vallone del Duca) of the A16 Napoli-Canosa highway, composed by two independent roadways, each one composed by three simply supported reinforced concrete beams with a span of 32 m.

For the fragility calculation, a set of 10 ground motion records has been selected from the *PEER* database; the same set of records has been used to represent the mainshocks and aftershocks.

A first cycle of analysis (*IDA*), representing the mainshock event, has been carried out to evaluate the fragility curves for the undamaged structure and the PGA leading to predefined damage levels; 350 analysis have been executed: 10 accelerograms \times 35 intensity levels.

A second cycle of analysis (*IDA*) has been performed to evaluate the fragility curves of the damaged structure due to the aftershocks leading to collapse; in this cycle 56000 analysis have been executed combining 16 mainshock damage level for each of the 10 accelerograms with 35 intensity levels for each of the 10 aftershock records. The regression significantly reduces the analysis number; in this case 160 analysis have been performed for the mainshock fragility evaluation and 1600 for the aftershock ones.

Figure 1 and Figure 2 show the comparison between the mainshock and aftershock fragility curves obtained by IDA and those obtained by the regression method; it can be noticed that the IDA curves presents some differences with respect to approximate curves obtained with a small size sample; therefore IDA curves can be well approximated using the regression.

Figure 3 shows the comparison between the mean annual frequency of collapse due to mainshocks and to aftershocks evaluated by the two methods; for the aftershocks the risk has been evaluated as mean daily rate, calculated using equation (21) and assuming $T = 1$ day. Then, it is transformed in annual rate multiplying by 365. The comparison shows a good agreement from the results of two methods, with the clear advantage, for regression method, of a substantial reduction of the computational time.

5 APPLICATION

The bridge object of this study is an old reinforced concrete viaduct consisting of a thirteen-span bay deck with two independent roadways sustained by 12 couples of portal frame piers (Figure 4), each composed of two solid or hollow circular columns of variable diameter (120-160 cm), connected at the top by a cap-beam and at various heights by one or more transverse beams of rectangular section.

The height of the piers varies between 13.8m, near the abutments, to 41 m, at the center of the bridge. The deck is realized by two Π reinforced concrete beams 2.75m high, which are interrupted by some Gerber saddles placed at the second, seventh and twelfth bay respectively. The deck is connected to the piers by two steel bars inserted in the concrete.

The linear distributed weight of the deck is approximately 200 kN/m for each road-way. This means that to each pier receives a vertical load varying between 6600 kN and 8400 kN, while the length of the bays varies between 33 and 42 m.

Figure 4: The Rio Torto highway viaduct

The examined pier (Figure 5) has a total height of 25.14 m and it is composed by two columns with hollow section of external and internal diameter equal to 160 cm and 120 cm respectively. The longitudinal and transverse reinforcement consists respectively of 16 steel bars $\phi 20$ mm and spiral stirrups $\phi 6$ mm with spacing $s=14$ cm. The transverse beam has a rectangular section 40×130 cm with a symmetrical longitudinal reinforcement realized with $\phi 24$ and $\phi 20$ mm and stirrups $\phi 8$ mm with variable spacing ($s=10$ cm at nodes and $s=14$ cm in the middle). The cap-beam presents a U-shaped section with longitudinal reinforcement $4\phi 24+8\phi 20$ mm and stirrups $\phi 8$ mm with variable step.

The average strengths of the material, specified in original design drawings and report, are: concrete compressive strength $f_c=26$ MPa and steel yield strength $f_y=360$ MPa. The deck weight of 200kN/m correspond to a frame load of 6600kN divided over the two columns.

The dynamic analysis have been performed using Opensees software [21]. The pier have been modeled as 2D-frame composed of nonlinear beam column elements, including uniaxial bending and axial force modeled by a fiber-discretized section; the P-delta effect is also included.

The axial/flexural response of transverse beams have been coupled at each integration point, by the section aggregator command, with the shear response modeled by an uniaxial hysteretic law. The shear force-deformation law is represented in Figure 7. The envelope is multilinear with characteristic points at cracking, peak and residual strength given evaluated according to [22].

The typical cyclic response, for a given axial force, here assumed as constant, is shown in Figure 6; Figure 7 shows the cyclic shear response of the end section of a transverse beam.

The viaduct here analyzed has been realized in a zone with moderate-to-high seismic activity. The seismogenic zone (913) in which the bridge is placed is indicated in Figure 8. The return period for the life safety condition is about 2000 years. The associated shaking map (from INGV) shows (Figure 9) that the expected PGA ranges between 0.23g and 0.25g, whereas considering the collapse prevention condition (probability of 2% in 50 years) PGA ranges between 0.30g and 0.35g.

In order to evaluate the aftershock hazard of the site, two mainshocks have been here considered, with epicenter placed at a distance $R = 10$ km from the site and magnitude $M = 6.5$ and $M = 6$. These latter have been adopted taking into account that the maximum value of the magnitude associated with an event within 20 km from the site in the parametric catalogue of damaging earthquakes in the Italian area [23] is $M = 6.0$; this value is compatible with a value of the pga corresponding to an average return period equal to 2475 (0.34g), resulting from a conventional PSHA analysis [23] and evaluated using the most recent data for seismogenic zones for the Italian territory [24].

For the evaluation of the aftershock rate (eq.(10)), the parameters suggested by Lolli and Gasperini [20] are here adopted: $a = -1.676$, $b = 0.96$, $c = 0.0295$, $p = 0.93$ and $m_1 = 4.5$; moreover, the fault length has been calculated as function of the magnitude m using eq. (10) as suggested in [17].

A Montecarlo simulation, using 1000 samples, has also been used for the integration over the distance R .

For the evaluation of the fragility curves, a set of 10 ground motion records has been selected from the *PEER* database, with the following parameters: $6 \leq \text{Magnitude} \leq 7$, Source-Site distance ≤ 25 km; the records have been normalized to the peak ground acceleration and scaled according to target spectrum provided by the Italian Code for an average return period of 2475 years. In this work the same set of records used to represent the mainshocks has also been used for the aftershocks.

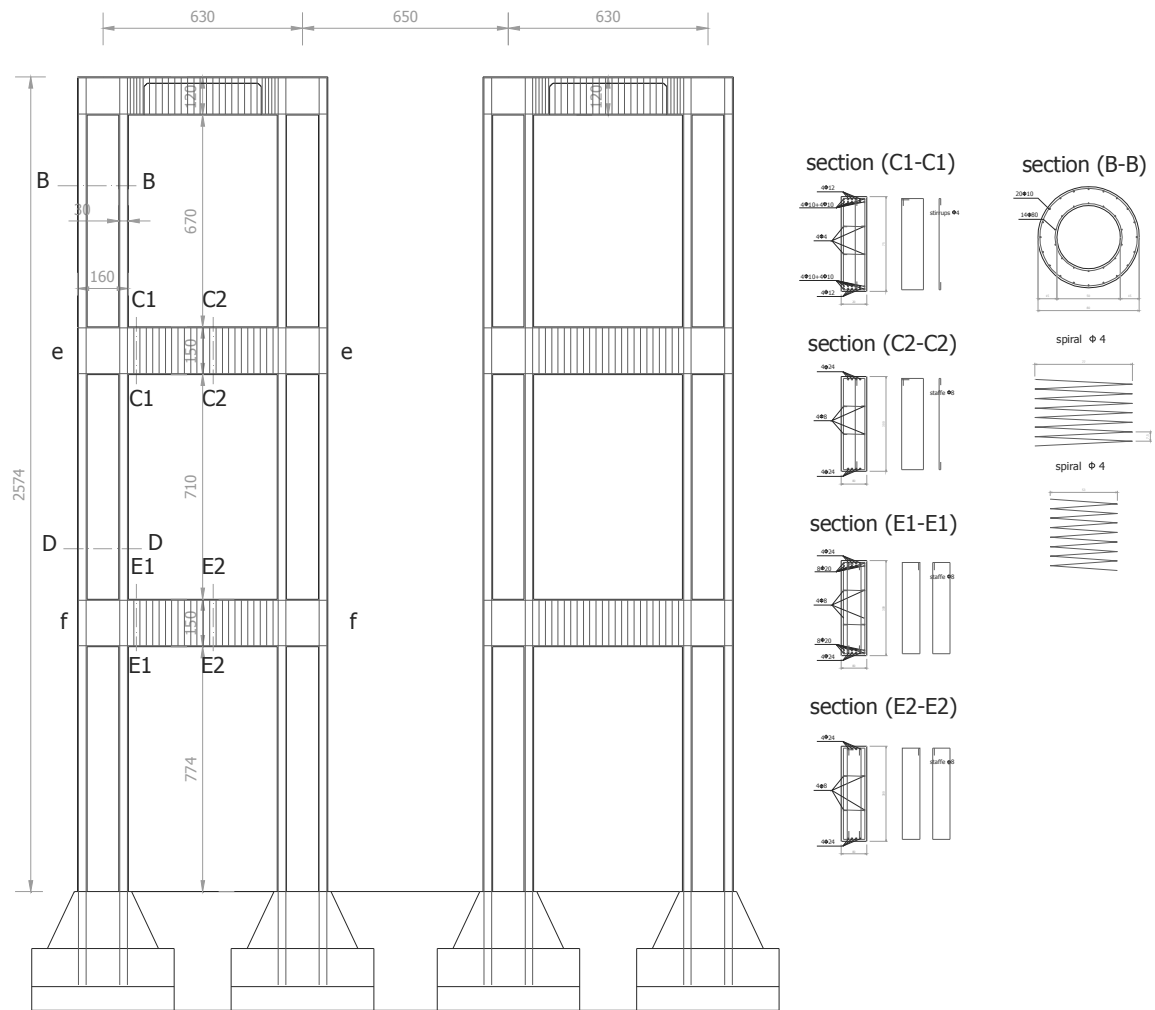

Figure 5: Geometry and reinforcement details of pier n. 9

Figure 6: Cyclic behaviour of the pier

Figure 7: Cyclic shear force-deformation of a transverse

Figure 8: ZS9, Seismogenetic area for Italian territory.

Figure 9: Seismic hazard for the probability of exceedance of the 2% in 50 years (mean return period 2475 years) [26].

In Figure 10 the daily rate of exceeding site PGA of the aftershocks is illustrated for different level of PGA as a function of the elapsed time from the initial rupture t (1, 5, 10, 15 days from the mainshock).

To calculate the fragility curve of the intact structure subjected to a mainshock, 160 non-linear time history analysis have been carried out, by selecting, with the LHS technique, the records and the relevant PGA in the range $0.5g \div 1.5g$. The lower limit of $0.5g$ on the PGA has been adopted taking into account that only the drifts that cause structural damage are considered.

To calculate the fragility curve of the mainshock-damaged structure, subjected to an aftershock that causes collapse (corresponding to a drift $\phi_u = 0.025$), a second cycle of 1600 analysis has been performed by selecting, with the LHS technique, the records of the mainshock and the aftershock and the relevant PGA in the range $0.1g \div 1.5g$.

Figure 11 shows the fragility curves of the undamaged structure due to the mainshock $p_0(\phi) = f_\phi(\phi | m_0, r_0)$, estimated before the direct observation of the damage, in comparison with fragility curves due to aftershocks $\bar{F}_D(\phi_i | \phi_j, y)$, for three levels of damage caused by mainshock ($\phi_1 = 0.003$, $\phi_2 = 0.01$, $\phi_3 = 0.02$). The effect of the initial damage on the probability of failure due to an aftershock generally increases the probability of failure for each value of PGA.

Figure 10: Daily rates of exceeding site PGA

Figure 11: Fragility curves of the pier undamaged and for three levels of damage

The three level of damage considered in this work have been evaluated by experimental tests performed by some of the authors [27] in the laboratory of the Department of Structures of the University of Roma Tre. The tests consist of cyclically imposed displacement to a 1:4 scale of one of the piers; they have shown that the shear behaviour of the pier is extremely relevant; in particular, the shear failure of the transverse beam has a strong influence on global cyclic behaviour of the specimen, with a pronounced pinching effect that reduces the dissipation capability of the pier. The assumed drift values ($\phi_1 = 0.003$, $\phi_2 = 0.01$, $\phi_3 = 0.02$) correspond to the shear cracking of the transverse beam and flexural cracking at the base of the column.

In 12 the effect of the Bayesian updating on the probability function of the damage (drift) produced by the mainshock is shown; the continuous curve is the CDF of the drift due to the seismic event, evaluated using the attenuation law and the fragility curve of the undamaged structure (eq. (7)). The dashed curves represent the updated function [eq. (9)] assuming two different observed damages θ_1 and θ_2 with the relevant drift mean value from tests and assuming a lognormal distribution. A high sensitivity to the Bayesian updating, considering the limited level of damage here adopted, can be noticed. In particular, an event with magnitude $M = 6.0$ causes a calculated median drift of 0.52% that undergoes a small variation if a damage θ_1 is observed, but moves to 0.97% if a damage θ_2 is observed; an event with magnitude $M = 6.5$ causes drift with a median value of 0.65% that undergoes reduces to 0.6% or moves to 1.1% if a damage θ_1 or θ_2 , respectively, are observed. This result shows as the Bayesian updating can strongly modify the damage curve, when the damage predicted by the numerical analysis does not correspond to the in-situ one, although the high dispersion of the observed damages.

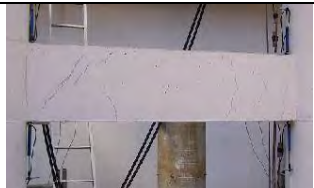

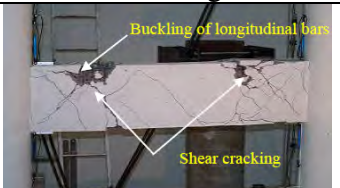

Observed damage	θ_1	θ_1	θ_1
Drift mean value	0.003	0.01	0.02
Correlation coefficient	0.35	0.25	0.2
Physical description	Hairline cracks	Onset of concrete spalling - development of shear cracks	Wide-cracks widths - longitudinal bars buckling
			

Table 4.1. Mean value and correlation coefficient of the drift

Figure 3 shows the results of the analysis in terms of risk for the two assumed values of the mainshock magnitude. The continuous lines represent the mean daily rate of collapse, calculated using equation (20) assuming $T = 1$ day, transformed in annual rate multiplying by 365; the dashed lines represent the equivalent mean annual rate of collapse, computed using the variable observation time $T = t_u - t$ (in this equation t_u is the time duration of the aftershocks [20]). In the same graph the lines with markers represent the equivalent rates of collapse evaluated applying a discount rates of 2.5% .

Figure 12: CDF of the drift for different observed damages θ_k

Figure 13: Mean annual frequency of collapse as a function of time elapsed from the mainshock

The equivalent mean annual rate of collapse computed with the first two criteria is much larger than the mean annual rate due to mainshock; in practice this curves intersect the mainshock level only at the end of the aftershock sequence. The criteria proposed in [12], instead, make the two risk comparable, and, for moderate earthquakes, the crossing time is shorter than the duration of the aftershocks sequence.

1. CONCLUSIONS

A critical issue in the emergency management after the earthquake is the functionality of the main infrastructure (hospitals, road network, etc.) and the decision on their usability just after the main shock. At present, a decision is take on the basis of a structure in-situ inspection; an analytical assessment is in contrast with the lack of time and data. For this reason in this paper a method that rationally combines information from the analytical approach and the in situ inspection is proposed. In particular an effective tool to speed-up the decision making phase concerning the evaluation of the seismic risk of mainshock-damaged structures due to aftershocks has been proposed. The risk is calculated combining the aftershock hazard using the Omori law and the fragility curves of the structure calculated using IDA improved by using LHS technique and updated with in-situ inspection data. The procedure has been applied to a highway r.c. bridge. The results has highlighted a high sensitivity to the Bayesian updating especially when the damage predicted by the numerical analysis does not correspond to the real damage. The mean annual rates of collapse provided by the method has shown that the risk structure change dramatically when an aftershock sequence strike the bridge and that this risk decreases with time allowing the authorities to decide if and when re-open the bridge to traffic.

AKNOWLEDGEMENT

The work presented in this paper has been partially funded by a grant of Italian Ministry of University and Research (MIUR) in the scope of Research Programs of National Interest (PRIN 2007).

Abstract.

Resilience is defined as the ability to mitigate hazards disposing a prompt strategy for recovering activities. Many papers are available in literature describing community resilience performances, but very few describe how to quantitative measure this index and which tools to use. The paper presents a software for evaluating community resilience index using the PEOPLES framework methodology. A critical comparison with similar softwares already available in literature is given emphasizing strengths and weakness with respect to the new proposed software, that has a user friendly graphical interface in Google earth environment. Finally the program and the methodology are tested using the case study of the 2009 Italian earthquake in L'Aquila that mainly affected historical monumental buildings in downtown L'Aquila. Four different scenario events are assumed to describe the reconstruction phase (recovery) and compared using the proposed platform.

1 INTRODUCTION

In recent years, we have seen how important is planning after disasters (e.g., L'Aquila and Haiti earthquake, Hurricane Katrina, September 11th terrorist attack, etc.), so the concept of resilience, that is the ability of social units (e.g., organizations, communities) to mitigate hazards, contain the effects of disasters, and carry out recovery activities in ways that minimize social disruption, has gained attention recognizing the fact that not all threats or disasters can be averted.

The community planning is affected by physical, social, and economic components of urban or rural communities. The main goal of this research is to develop tools that allow communities to reduce vulnerabilities while enhancing their overall resilience against extreme events and enabling sustainable development. When considering small communities such as rural communities, their residents are faced with multiple conflicting decisions when responding to natural and man-made hazards. Hazard mitigation practices of rural communities include best management practices in soil and water conservation to reduce soil erosion and flooding.

Resilience has been defined as a measure of geospatial and temporal functionality, its decay and recovery, in face of various hazards [1]. The functionality and resilience of a community depend on numerous components and dimensions. In previous research [2][3], seven dimensions of community resilience were identified and represented in the holistic, interdisciplinary framework with the acronym PEOPLES: *Population and Demographics, Environmental/Ecosystem, Organized Governmental Services, Physical Infrastructure, Lifestyle and Community Competence, Economic Development, and Social-Cultural Capital*. The PEOPLES Resilience Framework provides the basis for development of quantitative and qualitative models that measure the resilience of communities against extreme events in any or a combination of the above-mentioned dimensions, using risk assessment, loss estimation and recovery tools. The methodology has been implemented in software and the first release of it is presented for the first time in this paper. In the current version only the physical and infrastructure dimension has been developed, while other resilience dimensions have been set up in the graphical user interface waiting for approval from the scientific team of the PEOPLES framework developers. A case study of an Italian region recently affected by an earthquake has been used to prove the applicability of the developed software.

2 CRITICAL REVIEW OF CURRENT RESEARCHES

Several methods are available in literature for loss estimation methodologies. Among all the most famous is HAZUS [4], a software that was developed by the National Institute of Building Sciences (NIBS). The model uses and works on inventory of the classification of various components like population, building, transport system, lifeline utilities and hazardous materials. The building inventory is made for groups of buildings, with similar characteristic. The buildings are divided by groups of pre-defined building classes. There are 36 different *structural classes* that depend by construction, material, and structural type, while the *occupancy inventory* of the general building stock in the HAZUS methodology is prepared on the basis of its general and specific building occupancy. The building and occupancy type inventory are used, respectively, for the building risk assessment and to evaluate the potential economic losses. It is important to mention that this methodology evaluates only building risk assessment without any evaluation of the recovery plan and only a gross estimation of the recovery time.

More recently another software has been developed called *ResilUS* that is a prototype simulation model for community resilience to disasters [5][6][7]. *ResilUS* uses a macro-subdivision of area, like the neighborhoods subdivision, where are contained within a broader community. The model represents damage and recovery associated with a hazard event into three elements of community capital (economic, technological and human or, for businesses, individual), which is limited to buildings and lifelines (transportation network, electrical network, water network and critical facilities). *ResilUS* relies on two generic indicators of resilience that are the ability to perform and opportunity to perform associated with each hierarchical scale (community, neighbourhood, agent). Resilience, of agents, infrastructure, or communities, is measured in terms of some indicator of performance (e.g. level of service, building stock, income, or gross regional product). The model has four recovery curves, but currently the software *ResilUS* uses only one curve, that brings back to pre-disaster conditions.

In Europe another software package has been developed that is called *SELENA-RISe* open risk package [8][9], which was developed by the international centre for geohazards (ICG), through NORSAR (Norway) and the University of Alicante (Spain). It consists of the two separate software tools *SELENA* (Seismic Loss Estimation using a Logic Tree Approach) and *RISe* (Risk Illustrator for *SELENA*). *SELENA* is the computational platform that evaluates the building risk and potential losses (economic and casualties), while *RISe* converts the output files of *SELENA*, in order to plot on Google Earth. The software uses the HAZUS methodology to evaluate damage of the general building stock and the economic and human losses related to these physical damages. *SELENA* uses different building codes and models (e.g. EC8 [10], IBC-2006 [11], IS 1893 [12], CSM [13] [14], etc. The limitation of the software consists in extensive data input requirements, without a user friendly graphical interface, because it has two separate softwares, both running in MATLAB environment.

Based on the above observation there is need for a new software that takes in account the time dimension of the disaster and the entire recovery process.

3 PEOPLES FRAMEWORK

Disaster resilience is often analyzed considering technological and social units, but also considering the spatial scale of analysis, (e.g. single buildings, towns, communities, regions, country etc.). Technological aspects mainly focus on performances and interdependencies of different networks and systems. The human component is also central, because resilience depends first on the actions of people operating at the individual and neighborhood scale. Community resilience also depends heavily on the actions of different levels of government and its agencies at the local and regional scales when a disruptive extreme event occurs.

The PEOPLES Resilience Framework is built on, and expands, previous research at MCEER linking several previously identified resilience dimensions (i.e., technical, organizational, societal, and economic) and resilience properties (i.e., R^4 : robustness, redundancy, resourcefulness, and rapidity) [15][16][17]. In detail, the methodology subdivides the community resilience in seven dimensions, which are listed below:

- **P**opulation and Demographics (Composition, Distribution, Socio-Economic status, etc.);
- **E**nvironmental/Ecosystem (Air quality, Soil, Biomass, Biodiversity, etc.);
- **O**rganized Governmental Services (Legal and security services, Health services, etc.);
- **P**hysical Infrastructure (Facilities, Lifeline, etc.);

- **L** ifestyle and Community Competence (Quality of Life, etc.);
- **E** conomic Development (Financial, Production, Employment distribution, etc.);
- **S** ocial-Cultural Capital (Education services, Child and elderly care services, etc.).

All dimensions are measured by functionality indices that measure the performances, so the PEOPLES Resilience Framework defines components of functionality using a geospatial-temporal distribution within its geographical influence boundaries. Interdependencies between and among these components are key to determining the resilience of communities (recovery plan). The resilience can be considered as a dynamic quantity that changes over time and across space. The PEOPLES Resilience Framework requires the combination of qualitative and quantitative data sources at various temporal and spatial scales, and as a consequence, information needs to be aggregated or disaggregated to match the scales of the resilience model and the scales of interest for the model output.

4 SOFTWARE DESCRIPTION

A software that uses the methodology of PEOPLES Resilience Framework (ArciRasili-ence1.0) to measure the Resilience index at the Community Scale was created.

Firstly, our interest was focused in “Physical Infrastructure” dimension, in particular in building structures, like Facilities or Health Care. The software is divided in five parts:

1. *Input data collection (e.g. building network characteristics, etc.);*
2. *Damage State Probability Analysis;*
3. *Resilience analysis;*
4. *Output data;*
5. *Decision making;*

4.1 Input data collection

Data input of physical infrastructures will be collected in a database in a central server through the access to the website of the project (www.polito.it/ICRED). The access to submit the input data from users will be controlled by a username account with password. The input data required by the program are the following:

- *Infrastructure Localization and Geometry parameters;*
- *Physical Infrastructure parameters;*
- *Damage parameters (e.g. capacity curve, damping ratio, occupancy class, construction building times, functionality losses, etc.);*

While, the services data, that are available inside the software, are the parameters that define the seismic action according to Italian Seismic Standard [18] (PGA, F_0 and T^*_c) and some parts of HAZUS database [4].

Figure 4-1: Data input interface for Localization and Geometry of Infrastructure.

Figure 4-1 shows how the geometry of the infrastructure is drawn using the Google Maps interface, while the physical infrastructure characteristics are defined using the classification given in the PEOPLES Resilience Framework [1] that will be used to evaluate the corresponding fragility curves as shown in Figure 4-2.

Figure 4-2: Data input interface for Damage features.

The building response is evaluated using the capacity spectrum method (CSM) rather than nonlinear time history analysis, because it is faster when several building performances need to be evaluated in a given region. When evaluating seismic response the software uses the capacity curves provided by HAZUS database [4], but they can also be assigned directly from

the users. Seismic demand is evaluated using the information provided in the Italian seismic standard, given the soil category and the topographic characteristics of the site. In the near future also the seismic demand according to the US seismic standard will be provided.

Another parameter assigned as input to evaluate the seismic response of the buildings is the damping ratio that can be assigned manually or using the default values recommended by HAZUS database [4]. The over strength factor (q) can also be assigned manually or directly evaluated according to the Italian seismic standard [18]. Also fragility curves associated to a given building typology are evaluated using the HAZUS database or assigned manually from the user. Other parameters necessary to evaluate resilience are the occupancy class, the total occupancy area, the full replacement costs, the construction building times, the recovery costs and the functionality losses (Figure 4-3).

Perc.	Cod.	Occupancy Class	Sub-Category	Info
	RES1	Single Family Dwelling	-

Repair Cost [\$]	0	336...	168349...	695285...	16834...	<input checked="" type="checkbox"/>

Figure 4-3: Data input interface for Resilience features.

The general building stock is also classified according to the occupancy class of HAZUS, but it is divided into general occupancy and specific occupancy classes. The general occupancy classification system consists of seven groups (*residential, commercial, industrial, religion/nonprofit, government, education and lifelines*). There are 33 specific occupancy classes. While the total occupancy area is the sum of the all occupancy areas used by the respective occupancy classes presented inside the building.

Another feature is the building time for each damage state that is defined as the sum of the time spent for building cleanup and repair. If using the HAZUS database [4] these values are function of occupancy classes inside the building. The recovery costs, instead, are defined as the building repair costs due to each damage state (slight, moderate, extensive and complete). In HAZUS these values are function of full replacement cost and of the occupancy classes inside the building. Finally, the functionality losses are the percentages of the building functionality loss at a given damage state (e.g. 1% none; 5% slight; 10% moderate; 24% extensive; 60% complete). If using the internal database these values depend on the occupancy classes inside the building.

4.2 Damage State Probability Analysis

The disaster induces a different damage state for each building. The problem is to predict how the damages will be distributed in the control area. The software provides the damage state due to earthquakes, in the buildings presented in the control area. The damage state probability for each building is calculated using the following steps:

- Evaluate the response spectrum of the building;
- Calculate the peak displacement response of the building;
- Evaluate the damage states probabilities (slight, moderate, extensive and complete) of the building;
- Calculate the construction building time, repair cost and the functionality of the building after disaster.

The response spectrum of the building is evaluated according to the Italian Seismic Standard [18] in the centroid of the building perimeter. In the next version of software, it will be possible using Ambraseys AR. To evaluate the peak displacement response of the building, the software takes the data obtained from the response spectrum (function of PGA and period of the structure) and transforms them to obtain a curve function of the pseudo spectral acceleration and the pseudo spectral displacement. The peak displacement response is defined as the abscissa of intersection point between the demand spectrum curve and the capacity curve of the building.

The damage states probability (slight, moderate, extensive and complete) are the values obtained from the four fragility curves of the building substituting the peak displacement response as parameter (see Figure 4-4).

Figure 4-4: The probabilities of damage states.

The last step of damage state probability analysis is to evaluate the construction building time (which is the time spends on building cleanup and repair), the repair cost and the functionality of the building after the disaster. For the first two parameters (K_{TOT}), the software will use the same procedure of HAZUS, which consists in a summation of products between damage state probability (PDS_i) and the relative parameter (k_i) (construction buildings times or repair costs)(see Equation 1).

$$K_{TOT} = \sum_{i=1}^4 PDS_i \cdot k_i \quad (1)$$

While for the building functionality, before the software evaluates the discrete probabilities of damage states ($DPDS_i$) (see Equation 2 and Figure 4-5) and after it uses the previous procedure (Equation 2) replacing the damage state probability with the discrete probability.

$$\begin{cases} DPDS_i = 1 - PDS_{i+1} & i = 0 \\ DPDS_i = PDS_i - PDS_{i+1} & i = 1, 2, 3 \\ DPDS_i = PDS_i & i = 4 \end{cases} \quad (2)$$

Figure 4-5: The discrete probabilities of damage states.

4.3 Resilience analysis

Resilience of the building (R_i) is defined as a function indicating the capability to sustain a level of functionality or performance for a given building, bridge, lifeline networks, or community, over a control period T_{LC} ($[T_A; T_B]$), that is chosen by user. This quantity is defined graphically as the normalized area underneath the functionality function $Q_i(t)$ of the building (internally integrated with a discrete Simpson integral) and is defined analytically as follows:

$$R_i = \frac{\int_{T_A}^{T_B} Q_i(T) dt}{T_B - T_A} \quad (3)$$

Where the functionality $Q_i(t)$ ranges from 0 to 100% (where 100% mean no reduction in performance, while 0% means total loss).

Figure 4-6: An example of recovery function.

The functionality function $Q_i(t)$ of the building is a function composed by two parts. The first part is constant, while the second one is lognormal (see Figure 4-6). The function is analytically defined as follows:

$$\begin{aligned} Q_i(T) &= 1 & T < T_{Dis} \\ Q_i(T) &= F_s & T_{Dis} \leq T < T_{Ad} \\ Q_i(T) &= F_s + (1 - F_s) \cdot \Phi\left(\frac{\ln(T) - \mu}{\sigma}\right) & T_{Ad} \leq T \end{aligned} \quad (4)$$

Where F_s = is the functionality of the building after disaster; Φ = is the lognormal function; σ and μ , are respectively the standard deviation and average value of the lognormal distribution; T_{Ad} and T_{Dis} , are the administrative and disaster times.

The length of the constant function is equal to the administrative time (that will be discussed in the following paragraph). While, the two coefficients of the lognormal function depend essentially from the type of infrastructure (for the μ value), the K value (ratio between construction building time CBT and average time μ) and the functionality value after building time (for σ value; see Equation 5).

$$\sigma = A \cdot \ln(K) = 0.384 \cdot \ln\left(\frac{CBT}{\mu}\right) \quad (5)$$

In finally, the resilience at the community scale of selected area (called community resilience R_C) is evaluated by a weighted average of all buildings resilience R_i , analytically defined as follows:

$$R_C = \frac{\sum_i R_i \cdot W_i}{\sum_i W_i} \quad (4-7)$$

where, the weight coefficients W_i depend by the type of infrastructure.

4.4 Decision making

The software can be used as decision making tools for communities to evaluate the effect of different recovery plans in terms of resilience. The software tests each possible combination of recovery processes (in agreement to the maximum possible number of simultaneous building sites in the selected area and the economic availability of the community) modifying the administrative times of each building (the administrative time is the time elapsed from the disaster to the start of repair works of the building). The software identifies as the better solution the one that has the major recovery velocity in each point of the functionality function (the recovery velocity is expressed as the value of the derivate of the functionality function). It also evaluates resilience and functionality of the buildings and the community (see Figure 4-7).

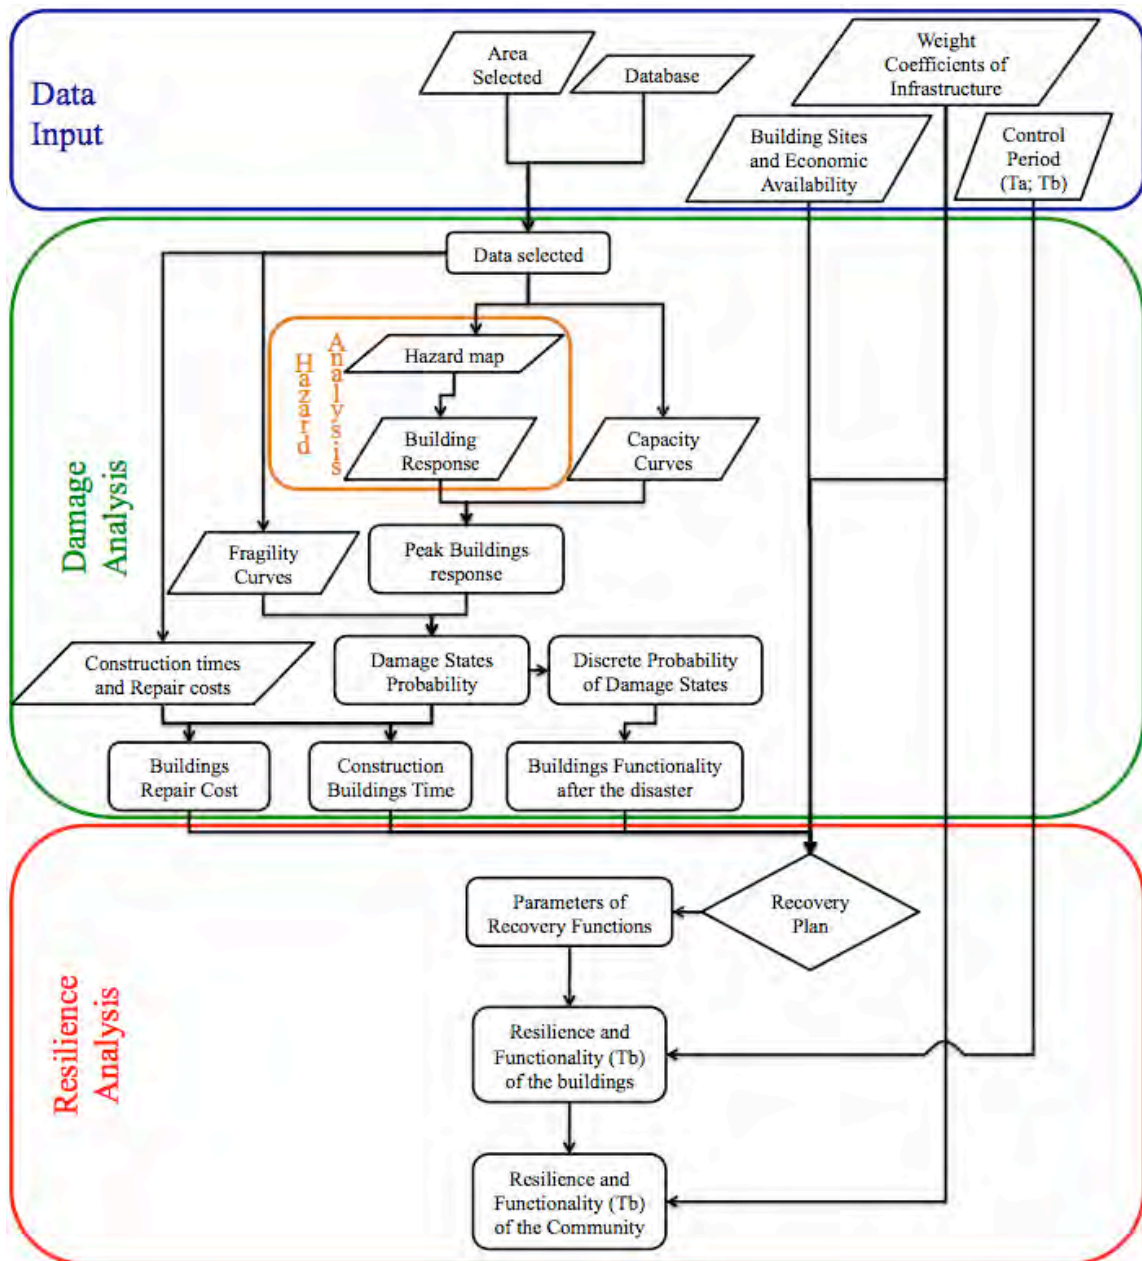

Figure 4-7: Flowchart of all steps to follow to evaluate the global resilience.

5 CASE STUDY

The software has been tested using as case study 10 buildings inside l'Aquila downtown (see Figure 5-8).

Figure 5-8: The ten buildings selected inside the city center of L'Aquila and in the high left corner there is the software interface for selected area.

The ten buildings selected have the follow features (Table 5-1; Table 5-2 and Table 5-3):

NAME		TYPE OF INFRASTRUCTURE		
N°	Name	PEOPLES Classification		
1	Building 1	Facilities	Residential	Housing Units
2	Building 2			
3	Building 3			
4	Building 4		Commercial	Office Buildings
5	Building 5			
6	Building 6			
7	Building 7		Residential	Housing Units
8	Building 8			
9	Building 9		Commercial	Hotels - Accommodations
10	Building 10		Residential	Housing Units

RESILIENCE FEATURES

N°	Occupancy Class	Description	Sub-category	Total Occupancy Area [m ²]
1	100% RES3b	Multi Family Dwelling – small	Triplex/Quads	2.140,08
2				6.641,45
3	67% RES3a 33% COM1	Multi Family Dwelling – small Retail Trade	Duplex Dept Store, 1 st	4.952,12
4	100% COM4	Prof./Tech./Business Services	Office, Small	3.841,74
5				4.392,80
6				2.702,28
7	75% RES3a 25% COM1	Multi Family Dwelling – small Retail Trade	Duplex Dept Store, 1 st	1.213,80
8	100% RES3b	Multi Family Dwelling – small	Triplex/Quads	6.628,45
9	100% RES4	Temp. Lodging	Hotel, medium	4.850,70
10	100% RES3b	Multi Family Dwelling – small	Triplex/Quads	4.719,35

Table 5-3: Data input for Resilience features.

The test evaluates four different recovery plans having the same limit state characteristics but different site availability - i.e. number of construction sites that might fall within the considered area.

The first and fourth scenarios have, respectively, the maximum and minimum availability, that consists having respectively a maximum of 10 and 0 building construction sites per day inside the selected area (there is not limitation for simultaneous start of construction sites). The second scenario has the maximum limit of five construction building sites per day and of four simultaneous starts of construction building sites. While, the third scenario has the limit of one building site per day (no-limit for simultaneous starts of building sites). In all cases there is no-limit on economic budget. It was found the following results that are summarized in the tables below assuming a return period for the earthquake of 2475 years and a control period of 2 years.

GLOBAL RESILIENCE OUTPUT DATA

	Case:	I	II	III	IV
Community Resilience (Ta; Tb) [%]:		98,3	95,0	74,8	58,2
Community Functionality (Tb) [%]:		100,0	100,0	88,6	58,2

Table 5-4: Output data of Global Resilience for each case.

DAMAGE OUTPUT DATA FOR EACH BUILDING

Building N°	S _d [m]	S _a [g]	PDS-s	PDS-m	PDS-e	PDS-c	DPDS-n	DPDS-s	DPDS-m	DPDS-e	DPDS-c	CBT [days]	SF [%]	RC [\$]

10	0,548	0,069	87	45	4	0	13	42	41	4	0	19	89,2	242968

Table 5-5: Output Damage data for each building.

Table Legend:

N°: Infrastructure number [-];

S_d: Peak displacement response [m];

S_a: Peak acceleration response [g];

PDS-: Probabilities of damage state (s: slight, m: moderate, e: extensive and c: complete) [%];

DPDS-: Discrete probabilities of damage state (n: none, s: slight, m: moderate, e: extensive and c: complete) [%];

CBT: Construction building time [days];

SF: Start functionality value [%];

RC: Recovery cost [\$].

Figure 5-9: Histogram of discrete probability of damage states.

From the Table 5-5 and Figure 5-9 it is possible to see how are distributed the damage states in all buildings presented in the selected area. The buildings that have the higher damages are the buildings 1, 2 and 9. This result was easy to predict because the three buildings are designed with low seismic design level (low code). Instead Figure 5-10 shows the contour plot of functionality immediately after the disaster. In this case, the lower values of functionality are near buildings 1 and 2 in the plot, because the functionality is diffused through the weighted average.

Figure 5-10: Contour plot of functionality.

RESILIENCE OUTPUT DATA FOR EACH BUILDING								
Case:	I	II	III	IV	I	II	III	IV
Building N°	AT [days]				RES [%]			
1	0	133	152	inf.	95,6	82,1	80,2	45,2
2	0	91	336	inf.	96,0	87,2	63,8	48,1
3	0	0	0	inf.	99,6	99,6	99,6	84,9
4	0	0	51	inf.	99,4	99,4	97,5	82,5
5	0	34	843	inf.	98,7	96,9	61,3	74,3
6	0	51	744	inf.	98,7	96,0	61,3	74,3
7	0	34	643	inf.	98,6	96,6	61,7	74,1
8	0	0	942	inf.	98,9	98,9	64,3	77,8
9	0	66	511	inf.	97,7	93,0	61,4	67,4
10	0	0	118	inf.	99,8	99,8	97,2	89,2

Table 5-6: Output data of Resilience features for each building and each case.

Table Legend:

AT: Administrative time [days];

RES: Resilience over the control period [%].

Table 5-6 shows the administrative time, the resilience over the control period and the rank in recovery plan for each building.

Figure 5-11: The number of building sites per day for each case.

As mentioned above, the only difference between various cases is the buildings sites availability (men / day), which is shown on Figure 5-11. Case I requests immediately an higher number men per day, while cases III, IV and II (more realistic and efficient) have a constant or homogeneous distribution in the time.

Figure 5-12: Recovery function for each case

From the Figure 5-12, that shows the four functionality functions for each case, it is possible to observe that the case I is the most resilient, while the case IV has the smallest values of resilience. The case III is like a cumulative sum of all functionality functions of the buildings, because the works follow each other sequentially.

RESILIENCE INDEX

Case:	I	II	III	IV
Community Resilience index [%]:	92,0	87,6	80,6	58,2
Time of completion of work, T_{CW} [days]:	183,9	316,8	1033,0	inf.

Table 5-7: Output data of Global Resilience for each case.

The resilience index in Table 5-7 is defined as the value of community resilience from the disaster time T_{Dis} to the time of completion of the works T_{CW} (at this time the functionality will be equal to 100% or highest value). This index decreases with decreasing of the velocity of recovery, so it is a good parameter to evaluate the performance of the community and of the chosen recovery plan.

6 CONCLUSIONS

This paper presents a software able to evaluate the disaster resilience of communities and systems in general using the PEOPLES framework methodology. The main advantage with respect to the other software already available is the simple graphical interface that uses the Google earth visualization. This platform can be used both for data input, but also for output visualization. The output file are available both in a excel format and in a KML file readable by Google Earth.

The PEOPLES framework developed in the software integrates the information from different fields in a unique function that reach results that are unbiased by uninformed intuitions or preconceived notions of how large or how small the risk is.

Finally the program and the methodology are tested using the case study of the 2009 Italian earthquake in L'Aquila. Four different scenario events are assumed to describe the reconstruction phase (recovery) and compared using the proposed platform.

Some assumptions that are made for one case can not be so important for others, so engineers and decision makers during the calculation of the community resilience index should focus on the assumptions that most influence the problem at hand.

Abstract. *After the occurrence of a natural (e.g. earthquake, hurricane, flood, fire) or technological (e.g. explosion, terrorist attack) extreme event, the distributed infrastructure systems and their individual structural components are likely to be significantly damaged. For the emergency response and the quick socio-economic recovery of the region, transportation networks, lifelines, and infrastructure in general play a role of utmost importance. For this reason, the so called “disaster management” has always to be focused on restoring as quickly as possible the proper functionality of the infrastructure under limited financial resources and other logistic constraints. The main focus of the present paper is to address this problem and provide a general framework to assist the decision making process in these critical situations. In fact, the main issue in these scenarios is to have a practical and robust way to collect and analyze data with a fast and reliable tool that can lead to quick but informed decisions.*

Several decision support systems for emergency and/or disaster management have been proposed in the last decades. The proposed approach is based on the holistic concept of resilience, which is gaining momentum as metric for the evaluation of the efficiency of the restoration activities. Resilience is used in this paper as one of the optimization criteria for the rehabilitation planning.

An illustrative example is presented to clarify the applicability of the proposed approach to transportation networks.

1 INTRODUCTION

Lately, the concept of resilience and the interest on its possible practical applications is gaining a lot of momentum. “Resilience” has become a very popular keyword for articles, symposia, workgroups, special sessions, research projects, and, in general, in the press. In civil engineering, the use of resilience is associated with disaster loss mitigation and disaster management [1, 2], especially for analyses of distributed civil infrastructure systems [3, 4] and lifelines [5].

This paper promotes a novel paradigm for the resilience-driven disaster management of civil infrastructure, with application to bridge networks. A multi-criteria perspective is proposed as optimal way to develop a framework for the quantitative assessment of resilience and its use for assisted decision making in the disaster management practice [6].

In the past years, several *systemic* definitions of resilience and frameworks for its use have been proposed. Some of the most comprehensive can be found in [7, 8, 9, 10, 11], while Rose [12] presents an interesting review of possible definitions. Section 2 focuses on the *analytical* definitions of resilience, with particular emphasis on the family of the formulation that is used in this paper. Section 3 describes the proposed multi-objective approach. Section 4 presents an illustrative example involving the post-disaster restoration of a bridge network. Finally, Section 5 collects the concluding remarks.

2 ANALYTICAL DEFINITIONS OF RESILIENCE

In the literature, several analytical definitions of resilience have been proposed and applied. Zhou et al. [13] have collected a list where the first definition of resilience dates back to 1973 [14]. The first seed of the definition of resilience that is most popular nowadays can be found in [15]: “Resilience is the ability of human communities to withstand external shocks or perturbations to their infrastructure and to recover from such perturbations”. Along the decades, several authors have focused on one or more aspects of resilience, such as the ability of a structure or system to withstand an extreme event (better called “capacity” for structural applications) or the time required to recover the original functionality (sometimes referred to as “rapidity”). In 2003, a large group of researchers introduced the concept of “resilience triangle”, to combine the various aspects associated with resilience [16]. The resilience triangle was originally used to describe the “loss of resilience” and was associated with the equation:

$$R_1 = \int_{t_0}^{t_r} [100 - Q(t)] \, dt \quad (1)$$

where R_1 is the loss of resilience experienced by the system, t_0 is the time instant when the extreme event occurs, t_r is the time when the functionality of the infrastructure is fully restored, Q is the percentage “functionality” (or “quality”, or “serviceability”) of the system, and t is time. Figure 1 shows a graphical interpretation of the resilience triangle and of the resilience loss R_1 in Eq. (1). The definition in Eq. (1) has the merit of connecting analytically the concepts of resilience and functionality and has been used in several subsequent articles [17, 18, 19].

Cimellaro et al. [20, 21] proposed a different analytical formulation that focused on resilience itself, rather than on its loss:

$$R_2 = \int_{t_0}^{t_r} Q(t) \, dt \quad (2)$$

Figure 1: Resilience triangle (shaded) and resilience loss R_1 (diagonal pattern)

Figure 2: Resilience according to Eq. (2). The faster recovery path (dashed) yields a lower value of resilience (area with diagonal pattern) than the slower recovery path (solid).

This definition branches out from the resilience triangle and has the advantage of being able to take into account restoration patterns that bring the final functionality to a level different (i.e. lower or even higher) from 100%. However, Eq. (2) has a drawback that makes it inappropriate for some applications. In fact, the integral is computed between t_0 and t_r and this can result in low values of resilience for fast restoration strategies (see Figure 2).

To overcome the mentioned issue, Bocchini and Frangopol [22] proposed to modify the

Figure 3: Resilience according to Eq. (3). The faster recovery path (dashed) correctly yields a higher value of resilience (area with diagonal pattern) than the slower recovery path (solid).

analytical definition of resilience, focusing on a fixed time horizon t_h :

$$R_3 = \int_{t_0}^{t_0+t_h} Q(t) dt \quad (3)$$

Figure 3 shows that this definition correctly provides higher (i.e. better) values of resilience for the faster (i.e. better) recovery paths. The definition in Eq. (3) can be used to compare, rank, and optimize [22] the various disaster management strategies. The investigated time horizon t_h does not need to be chosen larger than the longest recovery time. In fact, if the recovery is not complete at $t = t_0 + t_h$, Eq. (3) is still applicable and yields, as expected, a small value of resilience. Unfortunately, R_3 still shares a shortcoming with R_1 and R_2 : in all these cases resilience is measured in units of time, since $Q(t)$ is non-dimensional. Despite the fact that Eq. (3) computes correct values of resilience, these values expressed in units of time can be difficult to interpret and communicate to decision makers.

For this reason, a normalization factor was later introduced [4, 23]:

$$R_4 = \frac{\int_{t_0}^{t_0+t_h} Q(t) dt}{t_h} \quad (4)$$

The numerator of Eq. (4) represents the area underneath the recovery path $Q(t)$; the denominator represents the value of resilience in case the event did not occur or had no effects on functionality (i.e. $100\% \cdot t_h = t_h$). Figure 4 provides a graphical interpretation of Eq. (4).

Depending on the general frameworks and applications where the analytical definitions of resilience in Eqs. (1)–(4) are used, each of them can be appropriate. However, R_4 is the most versatile and easy to use for decision makers.

Figure 4: Resilience according to Eq. (4). The numerator of Eq. (4) is the shaded area, the denominator is the area of the large rectangle (area with diagonal pattern).

3 MULTI-CRITERIA PERSPECTIVE

Resilience is a concept that intrinsically includes several metrics. For instance, Bruneau et al. [16] define the four “properties” of resilience (i.e. “robustness”, “rapidity”, “redundancy”, and “resourcefulness”) and the four “dimensions” of resilience (i.e. “technical”, “organizational”, “social”, and “economic”). The need of capturing all these aspects has led researchers to pursue two conflicting objectives: (i) on one hand the desire of having a synthetic, scalar index of resilience, for immediate comparison and ranking of different strategies; (ii) on the other hand the goal of representing, within a single concept, a broad set of “properties” and “dimensions”. In this paper, it is proposed to reconcile these two conflicting objectives by means of a multi-criteria analysis and Pareto optimization.

Chang and Shinozuka [5] combined the concept of the resilience triangle with a probabilistic approach. To do this, they had to deviate from the basic definition in Eq. 1 and introduce acceptable thresholds for the post-event functionality $Q(t_0)$ and for the time to complete recovery t_r . This can be interpreted as a first attempt to introduce two criteria in the analysis and treat them as two separate limit states.

Similarly, Zobel [24] criticizes the fact that all the analytical definitions of resilience can yield the same value for very different scenarios in terms of initial loss and time to recovery, and this can be unacceptable or misleading for decision makers. Therefore, Zobel [24] proposes an “adjusted resilience function” that incorporates information on the relative importance of the time to complete recovery and the initial functionality loss, as perceived by decision makers.

The proposed approach consists in leaving the values of the important variables of the problem as separate metrics and combining them in the framework of Pareto optimization. In this way, the term “resilience” can be used to refer to the well-defined indicator R_4 in Eq. (4). Therefore, the search for the best recovery strategy should include resilience as one of its objectives, together with other objectives and constraints. For instance, for the case of disaster management of the civil infrastructure, the conflicting objectives are resilience [22], total cost

of interventions [22], time to reach a target functionality level [25], and time to complete recovery [25]. As expected, resilience should be maximized, while the other values should be minimized. Moreover, Pareto optimization allows to introduce separate constraints and requirements, such as maximum cost of the interventions [22], minimum required functionality at a specific time instant [25], maximum number of simultaneous interventions on the components of a distributed system [23], and additional constraints on the individual restoration parameters. Therefore, given all the required data that depend on the specific application, the general optimization problem can be formulated as:

Find:

$$\text{parameters of the rehabilitation strategy} \quad (5)$$

so that

$$R = \text{maximum} \quad (6)$$

$$C = \text{minimum} \quad (7)$$

$$T_i = \text{minimum} \quad \forall i = 1, 2, \dots, I \quad (8)$$

$$T = \text{minimum} \quad (9)$$

subject to the constraints

$$C \leq C_{max} \quad (10)$$

$$Q(t_h^T) \geq Q_h^T \quad \forall h = 1, 2, \dots, H \quad (11)$$

$$N_{SI}(t) \leq N_{SI\ max} \quad \forall t \in [t_0, t_0 + t_h] \quad (12)$$

$$\text{and constraints on the individual rehabilitation parameters} \quad (13)$$

where R is the resilience of the system, C is the total cost of the restoration interventions, T_i is the time required to reach target functionality level Q_i , T is the time of total recovery, C_{max} is the amount of available funding, Q_h^T is the target functionality level that must necessarily be provided at time t_h^T , N_{SI} is the number of simultaneous rehabilitation interventions applied to the system, and $N_{SI\ max}$ is the maximum allowable number of simultaneous interventions.

4 ILLUSTRATIVE EXAMPLE

The case of the post-disaster restoration of a bridge network is considered as a qualitative example. The functionality of the network $Q(t)$ is defined as its ability to effectively redistribute traffic flows and is a function of the total travel time spent and total travel distance covered by the network users that depart during a fixed peak traffic hour [22]. The rehabilitation strategies consist in the schedules of the interventions on the various bridges and the amount of funding invested on each bridge which, in turn, determines the quality and speed of the restoration [22].

The objectives are the maximization of the resilience R , defined as in Eq. (4), the minimization of the total cost of interventions C , the minimization of the time T_1 required to reach the functionality level $Q_1 = 50\%$, and the minimization of the total recovery time T .

The total restoration cost cannot exceed the maximum amount of funding C_{max} . Moreover, constraints on the minimum functionality level (Q_1^T and Q_2^T) at two time instants (t_1^T and t_2^T) are implemented. Finally, it is assumed that the maximum number of bridges that can undergo simultaneous interventions is $N_{SI\ max} = 5$.

Three restoration strategies are considered (namely, strategy A, B, and C) and their expected recovery paths are represented in Figure 5. All the strategies are associated with similar values

Figure 5: Three possible recovery strategies associated with similar values of resilience

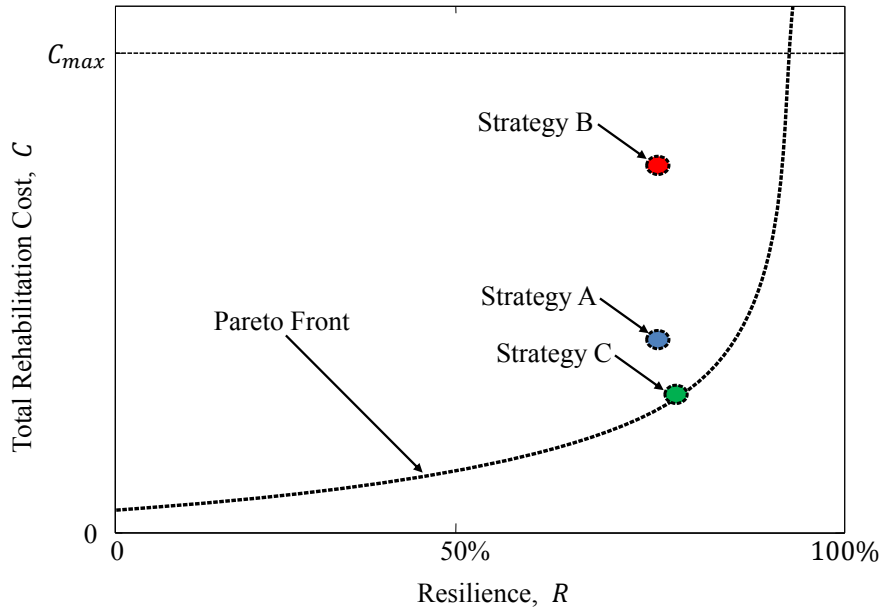

Figure 6: Pareto front in the plane of resilience and cost.

of resilience, defined by Eq. (4). Strategy A is characterized by a reduction of the functionality around time t_2^T . This usually happens when interventions start on some major bridges, requiring a (further) reduction of their flow capacity. It would be desirable to avoid negative slopes in the recovery path, and this can be required adding a constraint on the derivative of $Q(t)$. Nevertheless, strategy A yields a good value of resilience, is compatible with the requirements on the minimum functionality levels at t_1^T and t_2^T , makes the network reach $Q_1 = 50\%$ in a very short time, and the total restoration is completed significantly before the end of investigated time horizon. Strategy B has the same total recovery time as strategy A and a very similar overall

Figure 7: Pareto front in the plane of time to recovery and cost.

resilience. However, strategy B is not compliant with the constraint at time t_1^T (it crosses the dashed line, that represents the minimum required functionality in Figure 5). For this reason, strategy B should be discarded. Strategy C provides a very quick initial phase of the restoration activities and makes the network reach the values $Q_1 = 50\%$ in the shortest time, compared to the other strategies. Strategy C is also compliant with the constraints at t_1^T and t_2^T and provides a value of resilience that is slightly larger than the other strategies. This is achieved despite the fact that adopting strategy C, the network functionality is not entirely restored during the investigated time horizon: $Q(t_0 + t_h) < 100\%$; $T > t_h$.

Figure 6 shows the Pareto front in the space of the two objectives resilience and total rehabilitation cost. A solution is said to be “Pareto-optimal” if there is no other solution that yields an improvement in one of the objectives, without worsening at least another. The front shows that to achieve higher values of resilience, more financial resources are required. All the strategies have a total rehabilitation cost that is lower than the available funding. Strategy C, in particular, requires the lowest investment and is on the Pareto front. It is very common that solutions that do not restore the entire functionality are very economical. In fact, avoiding a few very expensive bridge rehabilitation can determine a significant reduction in the cost, with a very small loss of the overall network functionality.

Figure 7 presents the Pareto front in the space of time to recovery and cost. As already mentioned, strategies A and B have very similar recovery times, while strategy C restores the entire functionality only after the end of the investigated time horizon. In this case both strategies A and C are very close to the Pareto front.

Similar plots in the spaces of the other objectives and of the design variables can be provided. Depending on the relative importance of the various objectives for the specific scenario, decision makers will choose the most convenient solution. For this example, strategy C seems to be the best compromise, for the reasons explained previously.

The procedure presented in this illustrative example can be automated by means of multi-objective genetic algorithms [26]. Numerical applications of the proposed approach to realistic

bridge networks, solved by means of an automated procedure based on genetic algorithms can be found in [22, 23, 25].

5 CONCLUSIONS

A resilience-driven approach to the disaster management of the civil infrastructure has been presented. A new paradigm to the use of resilience is proposed, where resilience is one of the objectives in a multi-criteria analysis aimed at finding the best recovery path and the associated intervention strategy.

In the past, the intrinsic holistic nature of the concept of resilience has created a contrast between its *systemic definitions* (that try to be as comprehensive as possible) and its *analytical definitions* (that pursue a single scalar metric). In the proposed approach, a consistent resilience indicator is used in conjunction with other metrics and constraints that together define the best disaster management strategy. This approach reconciles the two diverging needs mentioned previously.

The framework of multi-criteria Pareto optimization appears to be the perfect paradigm to develop studies on resilience and disaster management within this novel perspective.

Abstract. *Resilient systems present an inherent ability of recovering from a certain damage state reached due to the application of a significant stress. The quantification of a system's resilience is a difficult task to perform because of: a) the system's complexity, b) the uncertain characteristics of the excitation force, c) the lack of specific elements to measure for an accurate assessment of a system's resilience, and d) the lack of robust tools for quantifying a system's resilience. Therefore, a decision maker requires both a methodology and the tools to decide for the most effective risk-response strategy. This paper presents such a methodology for a risk-based decision making for resilient systems. The proposed methodology involves the consideration of the following parameters: i) the variability of impact upon risk occurrence, ii) the available response strategies, and iii) the preference of the decision maker with regard to the criticality of the various impacts upon risk occurrence. The proposed methodology considers the four risk-response strategies defined by the Project Management-Body of Knowledge (5th ed.), namely: a) acceptance, b) mitigation, c) transfer, and d) avoidance. Three criteria are examined, in order to determine the preference margins between these strategies: i) compliance with regulations and specifications, ii) determination based on data elaboration (e.g. statistical, empirical, etc.), and c) subjective judgment. By applying any one of these criteria for a specific risk impact, the decision maker predetermines the boundary values between the risk-response strategies. Once, the value of the impact upon risk occurrence is estimated, the decision maker is capable to decide for the respective risk-response. The proposed methodology, then, integrates the various strategies decided for the various risk impacts to one single strategy that best confronts simultaneously all the different impacts on the system. The application of the proposed methodology is demonstrated through a case study that provides with numerical results. This paper introduces a new approach that successfully incorporates into the risk-based decision making problem, the critical issue of considering margins between damage states of resilient systems for various failures that occur simultaneously under a single stress.*

1 INTRODUCTION

Infrastructure systems are characterized of great interdependencies, which are mostly identifiable, yet difficult to model. Therefore, their efficiency in improving everyday's life for people, as well as their contribution to the economy and societal wealth can only partially be estimated by traditional tools and techniques. These estimations become even more difficult when risks of all kind of nature are considered. Natural hazards like floods become more intensive due to climate changes, while earthquakes still remain difficult to foresee. Infrastructure reliability and functionality are very critical and require appropriate risk response strategies, which can successfully ensure the long-term sustainability of infrastructure systems.

Introducing the concept of resilience for infrastructure systems is a new and evolving approach that provides a different perspective to the design and monitoring of infrastructure systems [1], [2]. Resilience may be, generally, considered as a system property that allows a quick recovery after a major risk occurrence [3], [4]. The recovery can be, generally, defined as a stable system's state that allows operation to a specific service level depending on the system. Therefore, resilience does not imply a full system recovery, but rather the necessary one that ensures continuity of the system's functionality to predetermined and required levels. A comprehensive analysis of the resilience concept can be found in [4].

Measuring resilience is a difficult task, because it requires a good insight of the system's structure and operation [5]. When the system is complex and prone to inherent uncertainties with regard to its function, measuring resilience becomes a, really, rough work to do. On the other hand, while resilience is inherent to the system, there is a definite interaction between the system and the system's environment that renders the process of recovery, not solely dependent on the system's resilience, but also on the actions that aim to alleviate the risk impact, which are normally decided in the framework of a risk response action plan. Therefore, a system's safety against stresses (occurred risks) is a combination between several parameters and hardly a system's property [6].

A complementary approach to resilience measurement for ensuring infrastructure system's functionality is the application of the proper risk-response strategies against anticipated risks. A properly designed and applied risk-response strategy that successfully corresponds to the system's requirements for recovery facilitates and accelerates the system's reaction against the damage from the occurred risk. Risk-response strategies can be decided through various decision making methods. However most of them present two serious limitations when they are considered for application in resilient systems: a) they do not address, in any way, the systems' characteristics to the decision making process and b) they treat systems' complexity in a rather descriptive, than analytic fashion. The following section presents some well-established and widely applied decision making methods and argues about their limitations for resilient systems.

This paper presents a risk-based decision making approach that aims at providing risk-response decision for resilient systems that consider both the systems' characteristics and the complexity. The first feature, i.e. the systems' characteristics, is introduced in an indirect way; a risk analysis that may be performed by any traditional or innovative method produces the values of risks that the system is prone to. However, since the risk value is considered as the expected value of a risk impact and this impact is directly related to the system's characteristics, it is inferred that in an indirect way these characteristics are addressed to the decision making process. The second feature, i.e. the system's complexity, is introduced by the comparison of the best risk-response decisions for different criteria and the homogenization of these decisions to one that optimally responds to all criteria simultaneously. The final output is a single decision for responding to a specific risk that the system faces.

The proposed methodology is presented in section 3 with an application example to facilitate understanding and demonstrate the mode of application.

2 DECISION – MAKING METHODS AND THEIR LIMITATIONS FOR RESILIENT SYSTEMS

Many decision making methods have been developed that present different levels of complexity and suitability for the various decision making problems. From basic methods that apply to everyday life's occasions to more sophisticated ones that are introduced in the cases of complex problems, there are two main approaches in the philosophy of the decision making: a) the decision is made based on the preference of the expected output compared to the expected outputs of other decision alternatives or b) the decision is made based on the problem's analysis that clearly suggests the best treatment for the problem in hand. In the following subsections some well-established methods that constitute the state-of-the-art in decision making are very briefly described, in order to provide the basis for consideration of their efficiency for resilient systems.

2.1 Elementary methods

Elementary methods are mostly applied to relatively simple decision making problems and they do not require either special knowledge or specific skills. "Pros and Cons" and "weighted Pros and Cons" methods rate the advantages and the disadvantages between alternative decisions and the alternative that presents the strongest pros and the weakest cons prevails [7].

Plus/Minus/Interesting method introduces except from pros and cons, the probable impact of the alternative decisions and through simple numerical rating it does not only suggest an optimum decision among alternatives, but also examines whether the selected alternative: a) shall improve the decision situation and b) is applicable or not [8].

Payoff matrices are used in combination with optimistic, realistic or pessimistic criteria (e.g. maximax - minimin, Hurwicz criterion, maximin – minimax) to identify the best tradeoff between a decision and its output [9].

Conjunctive and disjunctive methods evaluate decision alternatives by comparison to a given threshold and only those alternatives that reach a satisfactory level compared to the threshold are acceptable for implementation [10].

The above methods are not designed for complex problems; therefore their structure prevents their application to such problems. With the exception of conjunctive and disjunctive methods, the rest of the others fail to address the system's characteristics to the decision making process in a systematic or quantified way.

2.2 Graphical methods

Graphical methods comprise influence diagrams (fault-trees, event-trees, and cause and effect diagrams) and decision-trees. They incorporate uncertainty by assigning probabilities to the different decision nodes and they can map system's processes. However, there are two major limitations for application to infrastructure systems: a) they are highly impractical for complex systems and b) the system is mapped in a rather deterministic way, i.e. each branch of a tree describes a "road map" from the initial event (decision) to the final output, which is stable and independent from interdependencies and unexpected events. Both limitations render graphical decision making methods inappropriate for application to infrastructure systems' decision situations.

2.3 Multi-Attribute Utility Theory (MAUT) methods

MAUT is a theoretical framework that can deal with complex decision problems that feature a large number of criteria and decision alternatives. MAUT methods are characterized from the use of utility functions that express the preference of the decision maker over the various decision criteria for different decision alternatives. The final decision is selected through a process that utilizes dimensions-free scales that allow for comparison between different, in nature, criteria. A great number of methods and techniques are based on MAUT such as SMART, Generalized means, UTA, AHP, etc. The main limitation of these methods, which is systemic and related to the methodological approach, is that the decision criteria are weighted according to the preference of the decision maker and the final decision is made based on the aggregate of the products between these weights and the expected values of the decision's output for the criteria. This approach overlooks the actual impact of a decision and instead it correlates it with the factual (quantitative) or judgmental (qualitative and mostly subjective) preference of the decision maker. The importance of this limitation can be understood by the following examples:

- Example A: Tom decides to go to the movies and he has to choose between two options (AL_1 and AL_2) based on the criteria of distance from home (DH) and time of the movies start off (TS). According to his preferences by using any MAUT method, the final decision will come up to a problem generally described in the following equations:

$$AL_1 = w_{DH} \times DH_1 + w_{TS} \times TS_1 \quad (1)$$

$$AL_2 = w_{DH} \times DH_2 + w_{TS} \times TS_2 \quad (2)$$

In equations (1) and (2), w_{DH} and w_{TS} are Tom's weights (preferences) for each decision he used. The maximum value between AL_1 and AL_2 indicates the optimum decision for Tom. However, this optimum decision does not, in fact, consider the real values of the criteria (i.e. real distance, real start off time), but, only, some weighted values that reduce or increase the real ones according to Tom's preferences.

- Example B: A public authority decides to take measures to increase the safety of a bridge against earthquake. The appropriate measures result to two options and they are evaluated based on the criteria of bridge functionality and technical reliability (after the application of the measures). In this example, the relativity, which is an inherent feature in decisions drawn through MAUT methods may easily alter the real data and result to doubtful decisions.

The systemic limitation of MAUT methods that has been identified and described above, along with certain other limitations that each one of the methods discretely suffers from, renders them questionable for application to infrastructure systems, where real values of impact from a risk or stress should not be altered for the process of decision making.

2.4 Outranking methods

Outranking methods may also be applied to complex systems and they also use weights for the different decision criteria. However, they are significantly different to MAUT methods. The most important difference is that outranking methods do not evaluate the alternatives based on a maximum score over certain criteria with different preferences, but, instead, they make pair wise comparisons between alternatives based on actual measurements. Outranking methods, such as ELECTRE and PROMETHEE methods, are able to compare any two different alternatives fully or partially, in the case where there are no available data or information for all the criteria used. Application of these methods results to a ranking between them and the first alternative in this ranking is the selected decision. The main limitations of outranking

methods are: a) complexity, b) requirement of a strong mathematical background for application, and c) computational limits, i.e. these methods are not applicable for decision problems with many alternatives. These limitations render outranking methods questionable for application to infrastructure systems.

3 A NEW APPROACH FOR RISK-BASED DECISION MAKING FOR RESILIENT SYSTEMS

In the previous section the current practice in decision making was briefly discussed and the main findings were that for various reasons the existing methods present significant limitations for application to infrastructure systems. Such limitations become more significant when considered for application with regard to the resilience of infrastructure systems. Therefore, a new approach that can be free of these limitations and applicable to these systems is required. In this section such an approach is presented and demonstrated through an application example.

3.1 Risk-based decision making process

Risk – based decision making is a process that should follow certain steps (sub-processes) as illustrated in Figure 1.

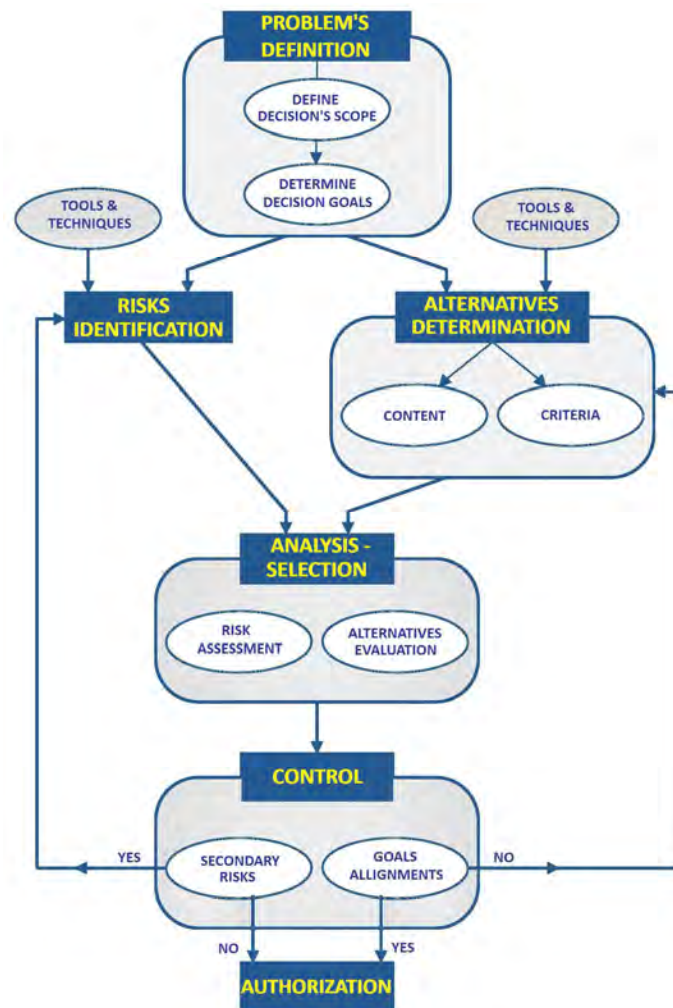

Figure 1: Risk-based decision making process flowchart

The first step is the problem's definition, which includes the clear and concise determination of the involved stakeholders' requirements. Given these requirements, the scope of the decision is defined and the determination of the respective goals to attain is achieved. Once, the decision situation problem is clearly defined, the next steps are to identify both the involved risks and the alternative decisions that can potentially serve the achievement of the goals set in the previous step. The alternative decisions must be well described in terms of their content, i.e. required processes, expected impact, etc., as well as criteria that are, one by one, associated to the predetermined goals. Both processes are performed through appropriate tools and techniques, which are extensively used in risk analysis and scenario analysis (e.g. Delphi method, SWOT analysis, information gathering techniques, etc.). The analysis that considers, simultaneously, the outputs of the previous steps, i.e. the risks and the alternative decisions, results through risk assessment and alternatives evaluation to the selection of the best decision in terms of satisfaction of the stakeholders' requirements. This decision is then checked for goals alignment and secondary risks that may arise upon its application and if the control results are acceptable then it is approved, while if not, the whole process is repeated from step 2, until it reaches acceptance.

In this paper, a new methodology is proposed that complies with the generic risk-based decision making process, as described above, and achieves to integrate the various strategies that are optimum for each different impact upon the occurrence of a specific risk to one single strategy that best confronts simultaneously all the different impacts on the system. In order to facilitate understanding, the methodology is presented through an application example.

3.2 The proposed methodology through an example of application

Suppose an infrastructure system that is of critical importance for the economic and social life of a specific area. Such a system may be a highway road, an airport, a wind farm, a public service building, etc. Infrastructure systems during their life – cycle are prone to several and different risks that can cause severe damages once they occur. Examples of such risks are all the types of failure caused by a natural hazard (earthquake, flood, fire, etc.), material failure, terrorist act, etc. The potential occurrence of one of these risks results to certain damages that are evaluated in a different way among those affected (stakeholders) by the risk event. Therefore, at every stage when a decision is required for the determination of the appropriate risk response strategy, the latter depends on the requirements and specifications set by these stakeholders.

In the case of a power plant, for example, the main priority is set to supply energy with a steady rate through an environmental friendly production process. The achievement of these goals must be ensured against a wide range of risks during the operation of the power plant. An example of one of these risks is recorded in Table 1.

Code	TECH 1.1
Name	Risk of failure due to earthquake
Class	Technical
Factors	Heavy earthquake loads that exceed the facilities' structural strength
Components	Cracks in walls, deformations, production fall
Impact	Repair costs, loss of revenue, injuries, fatalities, pollutants emissions

Table 1: A record of a risk for a power plant

Table 1 presents a hypothetical record in a risk inventory used for risk identification. The identified risk, given in the second row of the table, is classified and analyzed in terms of: a)

the factors that lead to its occurrence, b) the symptoms (components) that are visible in different levels of risk occurrence and c) the impact, which is the result of the risk event upon occurrence. This type of inventory along with certain innovative notions such as the “component” term is based on current research performed by Angelides et al. [11].

The alternative decisions that need to be investigated, in relation to the identified risk, in order to determine the optimum among them that ensures the achievement of the decision’s goals (i.e. constant energy supply in an environmental friendly mode) are: a) risk acceptance, b) risk mitigation, c) risk transfer, and d) risk avoidance. These alternatives are essentially the recommended risk response strategies proposed by the Project Management Body of Knowledge [12], which are apply, in general, to all types of projects or situations. Table 2 provides a detailed description of the alternative decisions in terms of content, required processes, and expected impact adjusted to the example of application.

Alternative decision	Risk acceptance	Risk mitigation	Risk transfer	Risk avoidance
Content Description	A decision that aims at assuming responsibility and liability for the negative impact upon risk occurrence. Recommended for insignificant risks	A decision that aims at the reduction of the risk to an acceptable threshold.	A decision that aims at shifting to a third party, the negative risk impact, along with ownership of the response. Risk transfer only indirectly deals with risk.	A drastic decision that aims to eliminate either the risk factors or the risk impact. It involves even project cancellation. Recommended for very significant risks.
Application mode	A. Establish a contingency reserve to use in case of failure.	A. Simplify the energy supply process. B. Reinforce critical elements of the structure. C. Design an action plan for quick – response.	A. Insurance. B. Performance bonds. C. Guarantees. D. Risk transfer contracts.	A. Establishment of the facilities to a non-seismic area. B. Change of goals.
Expected impact	Undertake the cost for the system’s recovery after the occurrence of the risk	Limit the negative effect to an acceptable level	Ensure compensations from a third party for the harmed stakeholders in case of failure	Eliminate risk

Table 2: Alternative decisions for dealing with the risk of failure due to earthquake for a power plant

The alternative risk response strategies analyzed in Table 2 may be quantified either according to regulations, specifications, and legal frameworks or based on the strategy and policy of the organization that operates the power plant.

The criteria over which the alternative decisions are evaluated need to be consistent with the final decision’s goals. They also need to be of quantitative nature, in order to define the thresholds that will constitute the boundaries of transition between the alternative decisions.

These boundaries, in fact, define the ranges that correspond to the respective risk response strategies or, in other words, all the estimated risks define a range from zero value to a maximum value, which is further divided to smaller ranges that each one of them corresponds to the respective decision alternative. A generic example of the quantified relation between the risks and the risk response strategies is illustrated in Figure 2 (AD: Alternative Decision).

Figure 2: Quantification of the alternative decisions for one decision criterion

For the example under study, the following criteria are set:

- Minimization of the system's recovery cost (SRC). This cost includes maintenance costs, repair/replacement costs, and loss of revenue due to the temporary halt of the energy production and supply process. The quantification of the alternative decisions with regard to the SRC criterion is based on: a) the risk analysis that is conducted by the facility's administration, and b) the attitude towards risks that the facility's administration adopts. Figure 3 illustrates a numerical example for this criterion. In Figure 3, "Ac" stands for "Risk acceptance", "M" stands for "Risk mitigation", "T" stands for "Risk transfer", and "Av" stands for "Risk avoidance". It should be noted that the ranking of the alternatives is consistent with the risk impact. Therefore, it is assumed that the smaller impact is manageable for the decision maker (risk acceptance), while the larger impact is intolerable for both the decision maker and any third party (risk avoidance).

Figure 3: Quantification of the alternative decisions for the SRC decision criterion

Any risk R that has a value R_{C_i} with regard to the SRC criterion results to the respective alternative decision according to the following relations:

$$[0, 10^6] = \Theta^C, C_i \in \Theta^C \quad (3)$$

$$\forall R_{C_i} \in [0, 20.000] \rightarrow \text{Risk acceptance} \quad (4)$$

$$\forall R_{C_i} \in [20.000, 100.000] \rightarrow \text{Risk mitigation} \quad (5)$$

$$\forall R_{C_i} \in [100.000, 250.000] \rightarrow \text{Risk transfer} \quad (6)$$

$$\forall R_{C_i} \in [250.000, 1.000.000] \rightarrow \text{Risk avoidance} \quad (7)$$

- Prevention of human injury or fatality (HIF). The quantification of the alternative decisions with regard to the HIF criterion depends on the legal framework that regulates the health and safety issues in each case. An established approach to evaluate the severity of a non-fatal accident is according to the hours or days of absence from work [13]. Specific thresholds stand to differentiate between non-injuries, light injuries, fair, and

severe injuries. The case of human loss is, of course, the worst scenario and the upper boundary in the HIF criterion. This quantification approach is adopted in the case of the example and Figure 4 illustrates the numerical output for this criterion. The notations in Figure 4 are identical to the respective in Figure 3.

Figure 4: Quantification of the alternative decisions for the HIF decision criterion

Any risk R that has a value R_{HL_i} with regard to the HIF criterion results to the respective alternative decision according to the following relations:

$$[0, 25.000] = \Theta^{HL}, HL_i \in \Theta^{HL} \quad (8)$$

$$\forall R_{HL_i} \in [0, 60] \rightarrow \text{Risk acceptance} \quad (9)$$

$$\forall R_{HL_i} \in [60, 365] \rightarrow \text{Risk mitigation} \quad (10)$$

$$\forall R_{HL_i} \in [365, 5.000] \rightarrow \text{Risk transfer} \quad (11)$$

$$\forall R_{HL_i} \in [5.000, 25.000] \rightarrow \text{Risk avoidance} \quad (12)$$

The intervals in equations 9-12 describe respectively the following situations: a) no injury to light injury, b) light to fair injury, c) fair to severe injury, and d) severe injury to death. Again, as in the case of the SRC criterion, the ranking of the alternatives is consistent with the risk impact. Therefore, it is assumed that the smaller impact is manageable for the decision maker (risk acceptance), while the larger impact is intolerable for both the decision maker and any third party (risk avoidance).

- Prevention of environmental pollution (ENP). The quantification of the alternative decisions with regard to the ENP criterion can be based on regulations and respective legal frameworks. Another approach, which is adopted for the example, is to consider the severity of the pollution with regard to the magnitude of the area which is affected [14]. Figure 5 illustrates a numerical example for this criterion (values refer to acres). The notations in Figure 5 are identical to the respective in figures 3 and 4.

Figure 5: Quantification of the alternative decisions for the ENP decision criterion

Any risk R that has a value R_{E_i} with regard to the ENP criterion results to the respective alternative decision according to the following relations:

$$[0, 10^7] = \Theta^E, E_i \in \Theta^E \quad (13)$$

$$\forall R_{E_i} \in [0, 10^4] \rightarrow \text{Risk acceptance} \quad (14)$$

$$\forall R_{E_i} \in [10^4, 10^5] \rightarrow \text{Risk mitigation} \quad (15)$$

$$\forall R_{E_i} \in [10^5, 5 \times 10^5] \rightarrow \text{Risk transfer} \quad (16)$$

$$\forall R_{E_i} \in [5 \times 10^5, 10^7] \rightarrow \text{Risk avoidance} \quad (17)$$

The same assumption made in the previous two criteria concerning the ranking of the alternatives stands for this criterion as well.

Once, the evaluation criteria of the alternative decisions are determined, the risk-based decision making process steps to the next stage, which is the analysis, based on actual risk estimations and the evaluation of the decision alternatives. It is important to notice that the process assumes the interdependency of the criteria. This assumption, although not always valid, does not reduce the effectiveness of the methodology, since the integration to one decision is independent of the interdependency between the criteria.

Risk quantification can be generally performed by the equation (18).

$$\text{Risk} = E[h] = \int h(\theta) \times p(\theta) d\theta \quad (18)$$

, where θ , denotes the uncertainty that characterizes the risk occurrence, which is expressed by a probability density function $p(\theta)$, while the overall impact upon risk occurrence can be measured by a Risk Consequence Measure $h(\theta)$. Equation (18) expresses the expected value of the risk, which is a well – established approach on the field for risk quantification. This expected value in the case of the example under study must be estimated for the three different criteria. Therefore, the identified risk (Risk of failure due to earthquake) must be quantified in terms of impact to the system's recovery costs, the human losses and the environmental pollution. This quantification is performed by proper adjustment of equation (18). The mathematical expression for each case is given in equations (19) – (21):

$$R_{C_i} = \int h_{C_i}(\theta) \times p(\theta) d\theta \quad (19)$$

$$R_{HL_i} = \int h_{HL_i}(\theta) \times p(\theta) d\theta \quad (20)$$

$$R_{E_i} = \int h_{E_i}(\theta) \times p(\theta) d\theta \quad (21)$$

In equations (19) – (21), h_{C_i} measures in monetary terms the impact of the risk occurrence with regard to the SRC criterion, h_{HL_i} measures the impact of the risk occurrence with regard to the HIF criterion (the measurement is hours), and h_{E_i} measures the impact of the risk occurrence with regard to the ENP criterion (the measurement is acres). Provided that the necessary data to estimate the Risk Consequence Measures for each criterion and the probability of the risk event are available, equations (19) - (21) produce specific values that can be placed in the respective ranges of the previously defined alternative decisions for each criterion. Figure 6 illustrates graphically an example of this step of the process. As shown there, for the example under study, the same risk requires three different decisions, one for each one of the three different decision criteria: a) the proper decision with regard to the SRC criterion is “Risk acceptance”, b) the proper decision with regard to the HIF criterion is “Risk avoidance”, and c) the proper decision with regard to the ENP criterion is, again, “Risk acceptance”. It is obvious that if the analysis would indicate, also, “Risk acceptance” for the HIF criterion, then the decision maker would decide this alternative for the specific risk. However, in this case the decision maker needs to compare the alternative decisions for each criterion and select the most appropriate one that satisfies simultaneously all the criteria. While in the case of the example,

the selection of “Risk avoidance” may be considered “an easy choice”, since preventing human loss is a top priority, the general approach requires an objective way to compare all the alternatives for all the criteria between them. A graphical representation of all possible comparisons between any four decision alternatives for three criteria is illustrated in Figure 7.

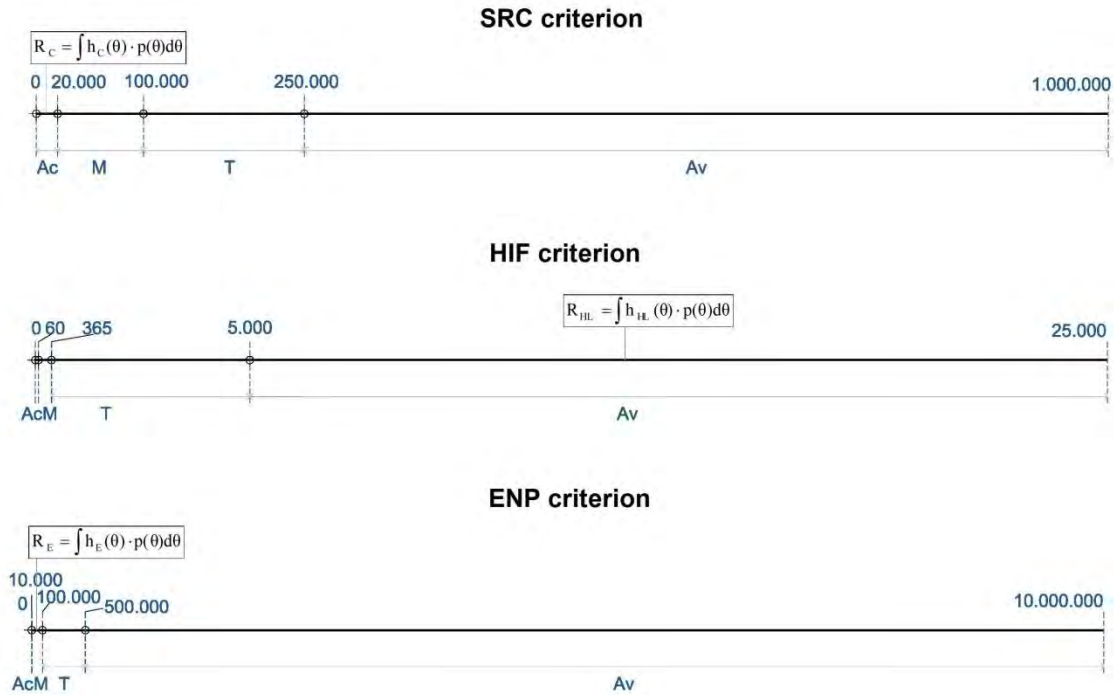

Figure 6: Assignment of risk values to the alternative decisions ranges per criterion

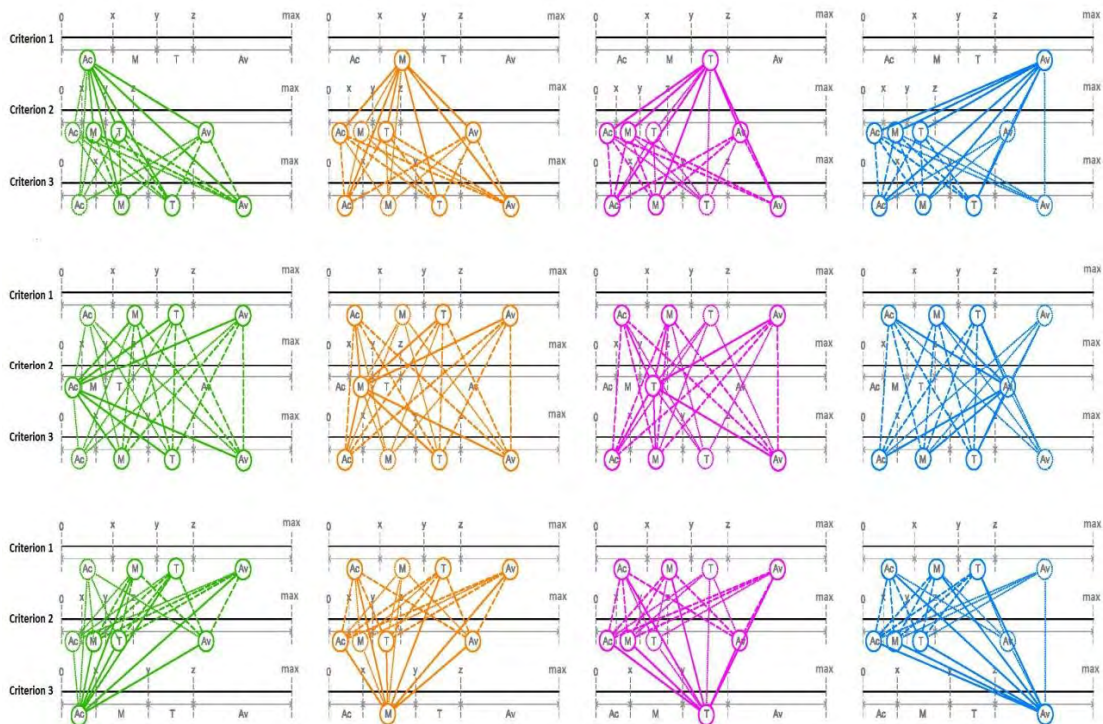

Figure 7: The possible comparisons between the alternative decisions of each criterion to the alternative decisions of the other criteria for the example under study

Due to the fact that different measures are used for each criterion, it is essential to transform the different scales from the three criteria to one single scale, in order to allow comparison between the alternative decisions. This can be easily achieved by dividing the values of the boundaries between the alternative decisions to the maximum value of the risk for each criterion. Essentially, the original scales are transformed to dimensions-free scales in the interval $[0, 1]$, where 0 corresponds to the minimum value of the risk, 1 corresponds to the maximum value of the risk, and the values in between correspond to the boundaries of the alternative decisions. Figure 8 graphically illustrates the dimensions-free scales for each criterion.

Figure 8: The dimensions-free scales for each criterion for the example under study

Another critical issue, which should be considered for the appropriate comparison between the alternative decisions, is the preference of the decision maker for the various alternatives for each criterion. For example, as stated above, it can be, generally, expected that there is a stronger preference to avoid human loss compared to the preference of spending a large amount for maintenance costs to reduce the risk of failure due to earthquake. However, it is not easy to generalize a preference, e.g. of taking measures for environmental protection (risk mitigation for the ENP criterion) compared to a fair amount of equipment replacement costs (risk acceptance for the SRC criterion). Therefore, a systematic way that will denote preference of the decision maker of the alternative decisions evaluated over different criteria is required. The proposed approach is based on the concept of utility, which addresses the preference of the decision maker between different alternative decisions. Utility theory has been used extensively with many variations in the field of decision making [15], [16], [17].

For each criterion of the alternative decisions, the decision maker defines the appropriate utility function that best represents his preference considering the parameter of risk. Figure 9 illustrates a graphical example of such functions that were selected for the example under study.

The utility functions in Figure 9 are defined in the set $[0, 1]$ as they are in concordance with the dimensions – free scales for each criterion. Since the boundaries for each alternative decision are known from the previous steps, the overall preference of each different alternative is calculated by the area defined by the function's curve, the x axis and the utility values for each boundary value of the alternative decision. Figure 10 illustrates a graphical example of this calculation and the numerical results are presented in Table 3.

Figure 9: Utility functions for each decision criterion

Figure 10: Calculations of the utilities of the alternative decisions for each criterion

Criterion	Alternative Decision	Utility
SRC	Risk acceptance	0.00058
	Risk mitigation	0.07361
	Risk transfer	1.13112
	Risk avoidance	7.33324
HIF	Risk acceptance	0.01106
	Risk mitigation	0.08325
	Risk transfer	1.76021
	Risk avoidance	7.98551
ENP	Risk acceptance	0.00001
	Risk mitigation	0.02922
	Risk transfer	0.27364
	Risk avoidance	9.29736

Table 3: Utility values for the alternative decisions for each criterion

The calculation of utilities for each alternative decision per criterion facilitates the comparison of the alternatives and consequently the decision making process for the decision maker. Concerning the example under study, the risk analysis indicated a risk acceptance for the SRC and ENP criteria, and risk avoidance for the HIF criterion (see Figure 6). An objective comparison between the two alternative decisions, which is based on the numerical results that are

presented in Table 3, clearly suggests the “risk avoidance” decision as the most preferable (the one that corresponds to the maximum utility value).

Some interesting observations of the numerical results in Table 3 prove the logical consistency of the approach:

- In the case where each of the three criteria corresponds to a different alternative decision the most risk averse decision of all three always predominates.
- The HIF criterion, compared to the other two criteria consistently presents greater utility values for the same alternative decision. This is not the case only for the “risk avoidance” decision between the HIF and ENP criteria; however it is not unreasonable to consider a human injury or fatality as less important compared to an incident of major environmental pollution with long-term catastrophic effects on every form of life.

4 CONCLUSIONS

Infrastructure systems are very critical for the society and the economy. In a challenging situation with severe risks of different nature and magnitude, it becomes crucial to define those limit states of the systems that will ensure functionality and serviceability right after the occurrence of a risk and a fast system recovery to the operational levels before the occurrence of the risk.

Resilience is a concept that responds to the above requirements. However, due to the high complexity of infrastructure systems and their interdependencies both between the system’s parameters and between the system and its environment, the measurement of resilience becomes a very difficult task to perform. A complementary approach, which indirectly provides estimation for the system’s resilience is the application of the proper risk-response strategies against anticipated risks. Therefore, appropriate decision making is required.

Currently, several decision making methods and techniques exist that are well-established and in some cases, they are very sophisticated, in terms of methodological approach or mathematical background. However, they all present various limitations both in general and for application to infrastructure systems, in particular.

This paper presents a methodology for risk-based decision making that is characterized by the following features:

- It considers the variability of impact upon risk occurrence by using appropriate risk values, which are estimated for each criterion under study. Instead of the traditional approach, that of integrating different risk values to a single one that, allegedly, denotes an overall risk value, the proposed methodology utilizes actual risk values that correspond to the different decision criteria.
- It involves the preference of the decision maker not in a way that alters the evaluation criteria of the decision as is done in MAUT methods, but, rather, in a way that is restricted to the expression of tolerance of certain risk events in case they occur. This means that the boundaries for the alternative decisions with regard to different stresses are predefined and constant, regardless of the risk event and any per case variation of the preference of the decision maker.
- It compares preference of decisions instead of preference of alternatives. This means that the risk analysis that precedes the decision making process provides results that directly indicate the appropriate decision regarding a specific criterion and then these decisions are compared and the most preferred is selected.
- It involves risk-response strategies for which the decision maker has decided that they respond to the system’s requirements for increasing resilience.

The proposed methodology allows the overcoming of some limitations of well-established decision making methods in the problem of deciding the appropriate risk-response strategies for infrastructure systems. In this way, it becomes a potentially valuable tool for an indirect definition of resilience in these highly complex systems, which are prone to various failures that occur simultaneously under a single or multiple stresses.

Abstract. *Over the past years, the concept of resilience has gained attention recognizing the fact that not all threats or disasters can be averted. In fact, communities around the world are turning their attention to efforts and ways that can enhance their resilience against extreme events in any dimensions of life. Resilience is becoming increasingly important for modern societies as states come to accept that they cannot prevent every risk from being realized but rather must learn to adapt and manage risks in a way that minimizes impact on human and other systems. This paper presents a holistic framework for defining and measuring disaster resilience for a community at scales ranging from individual structures (e.g. hospitals) and smaller communities (neighborhoods) to entire regions. Seven dimensions of community resilience have been identified and are represented by the acronym PEOPLES: Population and Demographics, Environmental/ Ecosystem, Organized Governmental Services, Physical Infrastructure, Lifestyle and Community Competence, Economic Development, and Social-Cultural Capital. The PEOPLES Resilience Framework provides the foundation to integrate any quantitative and qualitative models that measures systems' resilience against extreme events (or disasters for that matter) in any or a combination of the above-mentioned seven dimensions. Besides a short-term gap finding analysis, this framework enables communities over the long-term to add and utilize geospatial and temporal decision-support tools that help communities in their planning efforts to assess and to enhance resilience.*

1 INTRODUCTION

Several studies on the disaster resilience of technical systems have been undertaken for quite some time [1] [2], but the societal aspects and the inclusion of various and multiple types of extreme events are new developments. This paper presents a holistic framework for defining and measuring disaster resilience for a community at scales ranging from individual structures (e.g. hospitals) and smaller communities (neighborhoods) to entire regions.

Research by the authors resulted in a) the definition of the quantitative PEOPLES Resilience Framework for communities at various scales that is based on seven distinct dimensions of resilience; b) identification of dimension subcategories and measures of functionality - at the base of resilience measurement - and related spatial-temporal scales, c) identification of gaps in definition and measurement of system functionality to determine indices and sub-indices of community resilience, and d) associated literature review [3] [4].

This new conceptual framework builds on and expands previous research at MCEER (Multidisciplinary Center for Extreme Events Research) linking the resilience dimensions (technical, organizational, societal, and economic [5]) so as to measure the disaster resilience of major components defined by the PEOPLES Resilience Framework. Seven dimensions of community resilience have been identified and are represented by the acronym PEOPLES: **P**opulation and Demographics, **E**nvironmental/Ecosystem, **O**rganized Governmental Services, **P**hysical Infrastructure, **L**ifestyle and Community Competence, **E**conomic Development, and **S**ocial-Cultural Capital.

The PEOPLES Resilience Framework provides the basis for the development of quantitative and qualitative models that already exist or will be adapted to measure continuously the resilience of communities against extreme events or disasters in any or a combination of the above-mentioned dimensions.

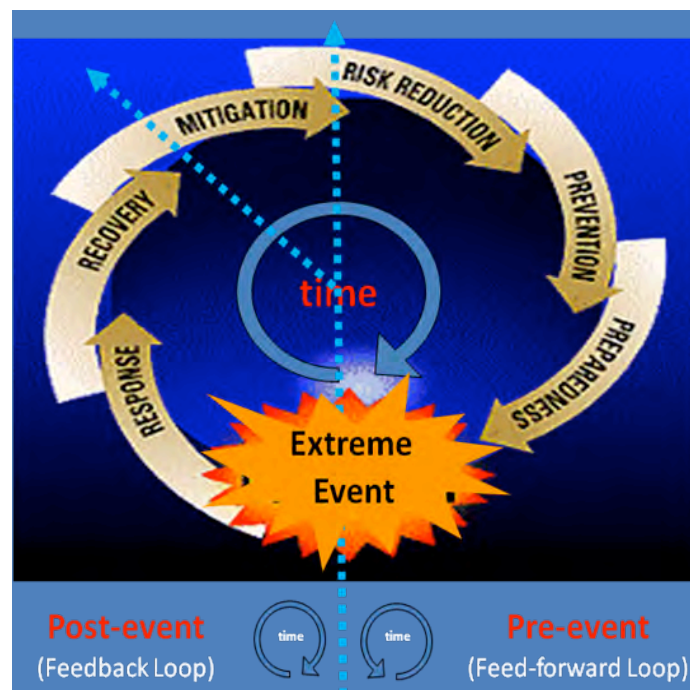

Figure 1: Extreme Events Management Cycle (Renschler et al, 2010)

This framework has been implemented in a decision-support software [6] integrating other disciplines to assess pre and post-disaster response (Figure 1) of communities in a geospatial and temporal scale. Over the longer term the software can be used as a decision support system for engineers and stakeholders as well as by emergency institutions and decision makers in general.

2 METHODOLOGY

Disaster resilience is often divided between technological units and social systems [7]. On a smaller scale, when considering critical infrastructures (for instance the closing of a local hospital), the focus is predominantly on technological and organizational aspects [8]. On a larger scale, when considering an entire community, the focus is broadened to include the interplay of multiple systems – human, environmental, and others – which combine to ensure the healthy, self-organizing functioning of a larger part of society residing in a region. At the community level, the human component is central, because in the case of a major disruptive event, in any of the seven dimensions (Figure 2) resilience depends first on the actions of people operating at the individual and neighborhood scale (Figure 3).

Figure 2: The PEOPLES Resilience Dimensions.

The following describes briefly each of the seven dimensions associated with the PEOPLES Resilience Framework and some potential indicators. The dimensions are neither orthogonal nor synonymous. While they are discussed as distinct dimensions and while we anticipate developing measures that are often independent, the nature of community resilience is such that interdependence between and among the dimensions is expected and necessary. The potential indicators are intended to be illustrative rather than exhaustive. Importantly, the indicators that are identified are those that may be used to describe a community and its resilience at any time, and not simply post-extreme event. Ultimately, the value of the PEOPLES Resilience Framework is that it (a) identifies the distinct dimensions and related key indicators but also (b) aggregates the dimensions in ways that reflect community realities.

2.1 Population and Demographics

A measure of functionality of population and demographics Q_p within a given community could be quantified by using the social vulnerability index (SoVI) proposed by Cutter [9]. Social vulnerability (a counterpart of social resilience) is defined as the inability of people, organizations, and societies to withstand adverse impacts from multiple stressors to which they are exposed. These impacts are due in part to characteristics inherent in social interactions, institutions, and systems of cultural values. Social vulnerability is a pre-existing condition of the community that affects the society's ability to prepare for and recover from a disruptive event. It affects and is affected by both evolutionary occurrences (e.g., slow changes in median age) and transformative events (e.g., wholesale shifts in dominant ethnicity).

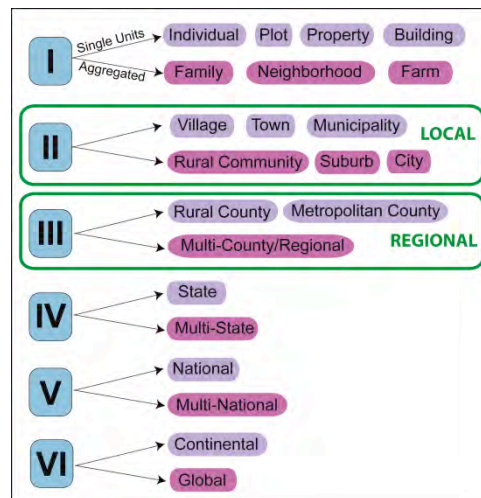

Figure 3: The Peoples Resilience Scales.

2.2 Environment/Ecosystem

Ecological or ecosystem resilience is typically measured by the amount of disturbance an ecosystem can absorb without drastically altering its functions, processes and structures [10], or by the ability of an ecosystem to cope with disturbance. In the context of the PEOPLES Resilience Framework, environmental and ecosystem resources serve as indicators for measuring the ability of the ecological system to return to or near its pre-event state.

2.3 Organized Governmental Services

In contrast to the more or less spontaneous individual and neighborhood responses to extreme events, organized governmental services are designed to allow an orderly response. Organized governmental services include traditional legal and security services such as police, emergency and fire departments and in extreme cases, the military. In this dimension, we also include the services provided by public health and hygiene departments as well as cultural heritage departments. Each of these organized government services plays a key role in sustaining communities both before and after extreme events. A good example of the necessity of a well functioning government may be seen in the devastating January 12, 2010 earthquake in Haiti. In the aftermath, the news media reported a lack of government services and orderly control, and a general perception that the government was not in a position to help its people [11].

2.4 Physical Infrastructure

The physical infrastructure dimension incorporates both facilities and lifelines. Within the category of facilities, we include housing, commercial facilities, and cultural facilities. Within the category of lifelines, we include food supply, health care, utilities, transportation, and communication networks. In terms of housing, key indicators may include proportion of housing stock not rated as substandard or hazardous and vacancy rates for rental housing [12]. In terms of communication networks, key indicators may include adequacy (or sufficiency) of procedures for communicating with the public and addressing the public's need for accurate information following disasters, adequacy of linkages between official and unofficial information sources, and adequacy of ties between emergency management entities and mass media serving diverse populations [12].

2.5 Lifestyle and Community Competence

This dimension reflects the reality that community resilience is not simply a passive “bouncing back” to pre-disaster conditions [13] but rather a concerted and active effort that relies on peoples' ability to creatively imagine a new future and then take the requisite steps to achieve that desired future. It captures both the raw abilities of the community (e.g., ability to develop multifaceted solutions to complex problems, ability to engage in meaningful political networks) and the community's perceptions of its ability to effect positive change. Communities that collectively believe that they can rebuild, restructure, and revive themselves are more likely to be persistent in the face of environmental, governmental, and other obstacles. Communities with positive experience dealing with extreme events may be more likely to possess high degrees of community competence. For example, in the wake of the 2011 earthquake and tsunami that devastated Japan, it is expected that Japan will recover relatively quickly because it has experience dealing with extreme events (e.g., the 1995 Great Hanshin or Kobe earthquake).

2.6 Economic Development

Resilient communities are characterized by their involvement in a diverse array of products and services that are both produced in and available to the community. Diversity in production and employment is linked to a community's ability to substitute goods and services and shift employment patterns as the situation demands. Efficient redundancy in operations and information systems enables relatively swift reopening of critical employers. The PEOPLES Resilience Framework incorporates three illustrative subcategories within this dimension: industry – production, industry – employment distribution, and financial services. Primary indicators of this dimension include the proportion of the population that is employed within the various industries, and the variability that might characterize a community's industrial employment distribution. This dimension is closely interwoven with the Population and Demographics dimension. For example, key indicators of economic development beyond employment and industry distribution include literacy rates, life expectancy, and poverty rates. Disaster-specific indicators related to economic development include extent of evacuation plans and drills for high occupancy structures, adequacy of plans for inspecting damaged buildings following disasters, and adequacy of plans for post-disaster commercial reconstruction [12].

2.7 Social-Cultural Capital

Measuring social/cultural capital requires acquisition of tallies, such as the number of members belonging to various civil and community organizations. It also requires surveys of community leaders and their perceptions (e.g., quality of life surveys). Communities with high degrees of social-cultural capital create “friction to exit” for their members, encouraging people to invest in those activities and organizations that make the community a “good place to live,” and encouraging people to return and reinvest in their communities after an extreme event. Disaster-specific indicators include existence of community plans targeting transportation-disadvantaged populations, adequacy of post-disaster sheltering plans, adequacy of plans for incorporating volunteers and others into official response activities, adequacy of donations management plans, and the community’s plans to coordinate across diverse community networks [12].

3 RESILIENCE COMPONENTS AND SUBCOMPONENTS

The PEOPLES Resilience Framework requires the combination of qualitative and quantitative data sources at various temporal and spatial scales, and as a consequence, information needs to be aggregated or disaggregated to match the scales of the resilience model and the scales of interest for the model output. Table 1 shows the complete list of components and sub-components. In the following sections a detailed description of each component is complemented by attempts of quantification.

4 INTEGRATION

Within the PEOPLES Resilience Framework, each dimension and its indicators or term of functionality and/or service will be represented with a GIS layer of the area of interest as suggested in the example portrayed in Figure 4, where Q_{pop} = functionality of population; Q_{env} = functionality of ecosystems; and so on. Additional terms for subcategories of resilience dimensions can be added, such as functionality of schools, dams, fire stations, oil and natural gas systems, emergency centers, communication towers/antennae, etc.

5 CONCLUSIONS

The seven dimensions of community resilience are identified within the new PEOPLES Resilience Framework as Population and Demographics, Environmental/Ecosystem, Organized Governmental Services, Physical Infrastructure, Lifestyle and Community Competence, Economic Development, and Social-Cultural Capital.

PEOPLES builds on and expands previous research at MCEER linking the four resilience properties (robustness, redundancy, resourcefulness, and rapidity) and resilience dimensions (technical, organizational, societal, and economic) so as to measure the disaster resilience of capital assets (e.g., hospitals) and asset classes (e.g., health care facilities).

The PEOPLES Resilience Framework has been implemented in decision support software to assess pre and post-disaster response of communities. Over the longer term, the software can be used as decision support system for engineers and stakeholders as well as by emergency institutions and decision makers in general. Such a system should enable decision makers to prioritize resource allocations and take the steps needed to enhance community resilience before and after an extreme event.

Keywords: Pipeline, Buckling, Seismic fault, Finite elements, Pipeline integrity.

Abstract. *The present paper investigates the mechanical behaviour of buried steel pipelines, crossing active strike-slip tectonic faults. The fault plane is vertical and crosses the pipeline axis at a certain angle. The interacting soil-pipeline system is modelled rigorously through finite elements, which account for large strains and displacements, nonlinear material behaviour and special conditions of contact and friction on the soil-pipe interface. Steel pipelines of various diameter-to-thickness ratios, and typical steel material for pipeline applications (API 5L grades X65 and X80) are considered. Most of the numerical results in the paper refer to the case where the fault plane crosses the pipeline axis at right angle. In particular, the paper investigates the effects of various soil and pipeline parameters on the mechanical response of the pipeline, with particular emphasis on pipe wall failure due to “local buckling” or “kinking” and pipe wall rupture. The effects of shear soil strength and stiffness are also investigated. Furthermore, the influence of the presence of pipeline internal pressure on the mechanical response of the steel pipeline is examined. Numerical results aim at determining the fault displacement at which the pipeline failure occurs, and they are presented in a graphical form that shows the critical fault displacement, the corresponding critical strain versus the pipe diameter-to-thickness ratio. Furthermore, results for cases where the fault plane crosses the pipeline axis at an angle different that 90-degrees are presented and the corresponding failure modes are identified. It is expected that the results of the present study can be used for efficient pipeline design in cases where active faults are expected to impose significant ground-induced deformation to the pipeline.*

1 INTRODUCTION

Seismic events constitute a threat for buried pipeline structural integrity. In particular, permanent ground deformation applied on the pipeline in a quasi-static manner, and not necessarily associated with high seismic intensity, may cause serious pipeline damages, reported in numerous earthquakes, such as the 1995 Kobe earthquake [1], the 1999 Kocaeli earthquake [2] and the 1999 Chi-Chi earthquake [3].

The present paper focuses on the mechanical response of continuous (welded) buried steel pipelines crossing active strike-slip seismic faults, a particular ground-induced action, associated with axial, shear and bending loads. High stresses and strains are developed in critical locations, which are well into the inelastic range of pipe material and may cause pipeline failure. In particular, high tensile stresses may cause fracture of the pipeline wall, especially at welds or defected locations, whereas high compression stresses may cause buckling, mainly in the form of pipe wall wrinkling, a shell-type instability, referred to as “local buckling” or “kinking”.

Newmark and Hall [4] were the first to attempt prediction of pipeline mechanical response under fault displacement, using a simplified analytical model of a long cable with small displacements. Their work has been extended by Kennedy et al. [5] [6] considering non-uniform friction between the pipe and the surrounding soil, and further enhanced by Wang and Yeh [7] to account for pipeline bending stiffness. Notable analytical works on the subject, based on a beam-type approach for pipeline modelling have been presented by Vougioukas et al. [8], Wang and Wang [9] and Takada et al. [10]. Kokavessis and Anagnostidis [11], presented a finite element methodology to simulate buried pipeline behaviour under permanent ground-induced actions, using contact elements to describe the soil-pipe interaction. Furthermore, Karamitros et al. [12] presented an enhanced analytical beam-type methodology, supported by three-dimensional finite element models, which employed shell elements for describing the pipe and nonlinear springs to simulate soil behavior. Liu et al. [13] presented a numerical simulation of pipelines crossing active faults through a combination of shell elements and springs, similar to the model in [12].

Experimental works on the effects of strike-slip faults on buried polyethylene (HDPE) pipelines have been reported by Ha et al. [14][15] and Abdoun et al. [16], based on centrifuge modelling of pipeline response and examined the influence of the type of faulting, the angle of strike-slip faults on the pipeline mechanical behaviour, as well as the effects of buried depth, pipeline diameter, and moisture content.

The work in the present paper is part of an extensive research effort aimed at investigating the response of buried steel pipelines crossing active faults for various soil conditions, using advanced numerical simulation tools and identifying possible failure modes, with emphasis on site conditions (i.e. the properties of the surrounding soil). The present work follows an integrated approach, which is based on modelling of the soil-pipeline system through nonlinear finite elements, accounting rigorously for (a) the inelastic behaviour of the surrounding soil, (b) the interaction and the contact between the soil and the pipe (including friction contact and the development of gap), (c) the development of large inelastic strains in the steel pipeline, (d) the distortion of the pipeline cross-section and possible local buckling formation, (e) the presence of internal pressure. The pipeline axis is assumed horizontal and crosses the fault plane at right angle. Considering a variety of soil parameters for both cohesive and non-cohesive soils, the influence of soil conditions on the pipeline structural response is examined in detail. Furthermore, the effects of pipeline diameter-to-thickness ratio D/t and steel material on pipeline response are also investigated. The numerical results are employed to develop inter-

action diagrams of the fault displacement causing pipeline failure with respect to the value of pipe diameter-to-thickness ratio D/t , which could be used for practical design purposes.

2 NUMERICAL MODELING

General-purpose finite element program ABAQUS [18] is employed to simulate the mechanical behavior of the steel pipe, the surrounding soil medium and their interaction in a rigorous manner, considering the nonlinear geometry of the soil and the pipe (including the cross-sectional distortions of the pipeline cross-section), through a large-strain description of the pipeline-soil system and the inelastic material behavior for both the pipe and the soil.

Figure 1 shows the elongated prismatic model considered for simulating this permanent ground-induced action, where the pipeline is embedded in the soil. The corresponding finite element mesh for the soil formation is depicted in Figure 1a and Figure 1b, and for the steel pipe in Figure 1c. Four-node reduced-integration shell elements (type S4R) are employed for modeling the pipeline cylinder, whereas eight-node reduced-integration “brick” elements (C3D8R) are used to simulate the surrounding soil. The top surface represents the soil surface, and the burial depth is chosen equal to about 2 pipe diameters, which is in accordance with pipeline engineering practice. A short parametric study demonstrated that a 60-diameter length of the pipeline (in the x direction) is adequate for the purposes of the present analysis. Furthermore, prism dimensions in directions y, z equal to 10 and 5 times the pipe diameter, respectively, are also found to be adequate. The seismic fault plane crosses the pipeline axis at a certain angle and divides the soil in two equal parts (Figure 1a). The analysis is conducted in two steps; gravity loading is applied first and, subsequently, fault movement is imposed. The vertical boundary nodes of the first block remain fixed in the horizontal direction (including the end nodes of the steel pipeline), whereas a uniform horizontal displacement due to fault movement is imposed in the external nodes of the second (moving) block (including the end nodes of the pipeline). A finer mesh was employed for the central part of the pipeline, where maximum stresses and strains are expected, with a total of 54 shell elements around the cylinder circumference in this central part, whereas the size of the shell elements in the longitudinal direction has been chosen equal to $1/26$ of the pipeline outer diameter D .

Figure 2a plots the soil – pipeline system after a seismic fault movement, for a plane perpendicular to the pipeline axis. The fault movement is considered to occur within a narrow transverse zone of width w , to avoid discontinuity at the vicinity of the fault, which sometimes causes numerical problems and corresponds to a more realistic representation of the fault displacement mechanism. Following a short parametric study, the value of w has been considered equal to 0.33 m.

A large-strain J_2 flow (von Mises) plasticity model, with isotropic hardening is employed to describe the mechanical behavior of the steel pipe material, calibrated through an appropriate uniaxial stress-strain curve from a tensile test. Furthermore, an elastic-perfectly plastic Mohr-Coulomb model is considered for the soil behavior, characterized by the soil cohesiveness c , the friction angle ϕ , the elastic modulus E , and Poisson’s ratio ν . The dilation angle ψ is assumed to be equal to zero throughout this study. A contact algorithm is considered to simulate the interface between the outer surface of the steel pipe and the surrounding soil, which takes into account interface friction, which is considered through definition of an appropriate friction coefficient μ . In our analysis, the value of μ is equal to 0.3. Moreover, the interface allows separation of the pipe and the surrounding soil. The analysis proceeds using a displacement-controlled scheme, which increases gradually the fault displacement d . At each increment of the nonlinear analysis, stresses and strains at the pipeline wall are recorded.

3 NUMERICAL RESULTS

Using the above numerical simulation tools, results are obtained for steel pipelines for various values of the diameter-to-thickness ratio, as well as for different soil conditions. In all cases considered in the present paper, the outer pipe diameter of the pipe D is assumed equal to 914.4 mm (36 in), whereas the pipe wall thickness ranges from 6.35 mm ($\frac{1}{4}$ in) to 19.05 mm ($\frac{3}{4}$ in), so that a range of D/t values between 48 and 144 is covered. This range of D/t values is typical for onshore applications (oil, gas or water pipelines). The surrounding soil has dimensions 60m×10m×5m in directions x , y , z respectively.

In sections 3.1, 3.2 and 3.3, the seismic fault plane is perpendicular to the pipeline axis and located at the middle cross-section of the pipeline. Particular emphasis is given on the effects of external pressure on the structural response. Both X65 pipelines and high-strength steel X80 pipelines are analyzed. Finally, in section 3.4, numerical results are obtained for an X65 pipeline where the fault plane crosses the pipeline axis at angles different than 90-degrees, aiming at identifying the corresponding failure modes.

3.1 X65 steel pipelines in cohesive soils

A moderately thick-walled X65 pipeline is considered first, with diameter and thickness equal to 914.4 mm (36 in) and 12.7 mm (0.5 in) respectively, so that $D/t=72$. The API 5L X65 steel material is a typical steel material for oil and gas pipeline applications, with a nominal stress-engineering strain curve shown with solid line in Figure 3a, obtained from a uniaxial tensile test. The yield stress σ_y is equal to 450 MPa (65 ksi) followed by a plastic plateau up to 3% strain and a strain-hardening regime with a hardening modulus equal to about $E_s/300$, where E_s is the Young's modulus of the steel material. Assuming a safety (reduction) factor equal to 0.72 [21], the maximum operating pressure p_{\max} of this pipeline [$p_{\max} = 0.72 \times (2\sigma_y t/D)$] can be readily calculated equal to 9 MPa (90 barr).

The pipeline is assumed to be imbedded in a cohesive soil and to be crossing a fault zone having a width w equal to 0.33 m. At this stage, the internal pressure p is equal to zero, and a soft-to-firm clay is considered, referred to as Clay I, which under “undrained” loading conditions has a cohesion $c = 50$ kPa, friction angle $\phi = 0^\circ$, Young's modulus $E = 25$ MPa and Poisson's ratio $\nu = 0.5$. Figure 4a depicts the shape of the deformed pipeline at fault displacements $d = 1$ m, 2 m, 3 m and 4 m in the area near the fault. Moreover, Figure 4b depicts the shape of the deformed pipeline and the distribution of the longitudinal normal strain ε_x on its outer surface at fault displacement equal to $d = 1$ m and $d = 4$ m. The deformed shape of the pipeline at $d = 1$ m shows a localized deformation at point A, referred to as “local buckling” or “kinking”, whereas point A is the “critical location” of the pipeline, at a distance of 5.45 m from the fault. Due to the skew-symmetry of the problem, a similar local deformation pattern occurs at point B, on the hidden side of the pipeline. Under increasing fault movement, a substantial development of this localized deformation pattern is observed, associated with the distortion of a significant part of the pipeline around this area, as shown in Figure 4b, for a fault displacement of $d = 4$ m. As the pipeline length increases with continued fault movement, it results to higher tensile and smaller compressive strains in the longitudinal direction. Figure 4b, shows that for a fault displacement of $d = 4$ m compressive longitudinal strains are significantly lower than those corresponding to a fault displacement of $d = 1$ m.

Figure 5 shows the deformed shape of the pipeline at fault displacements d equal to 1 m, where a localized buckling pattern develops where the compressive stresses and strains reach a maximum value. It is also important to notice that, upon local buckling formation, the deformation of the pipeline localizes in the vicinity of the buckle, as shown in Figure 5b. The variations of longitudinal compressive and tensile strain ε_x along the two outer (most stressed) generators of the pipe cylinder are shown in Figure 6 and Figure 7 for different values of the fault displacement and for a small segment of the pipeline about the critical area. The results for the compressive strain shown in detail in Figure 6b, indicate that for a value of fault displacement greater than 0.67 m, significant distortion of the cross-section occurs due to the development of a localized wrinkling pattern (local buckling) on the pipe wall, on the compression side of the deformed pipeline. This stage is considered as the onset of local buckling.

One may notice that the value of fault displacement at which onset of localized buckling occurs (d_{cr}), referred to as “critical fault displacement”, can be defined in many ways. In the present work, the onset of local buckling is considered at the stage where outward displacement of the pipe wall starts at the area of maximum compression. At that stage, bending strains due to pipe wall wrinkling develop (Figure 6), associated with significant tensile strains at the “ridge” of the buckle, so that the longitudinal compressive strains at this location at the outer surface of the pipe wall start decreasing, forming a short wave at this location. In the present case, this stage corresponds to a fault displacement equal to 0.67m as shown in Figure 6b.

At the above stage of local buckling onset, the longitudinal strain at the location of the buckle (ε_{cr}) is measured equal to 7.7×10^{-3} . Furthermore, at this critical buckling stage, the maximum tensile strain on the opposite side of the pipe ($\varepsilon_{T,max}$) is 5.2×10^{-3} , which is much less than the strain that would cause tensile failure in the form of rupture in a non-seriously-defected pipeline [22]. It is noted that the formation of a local buckle is undesirable because it is associated with the concentration of strain at the buckled area, which may lead to fatigue cracking under repeated loading [23]. Upon formation of the local buckle, pipe deformation concentrates around the buckled cross-section. However, further continuation of the imposed deformation results in significant tensile strains at the buckled area, decreasing the compressive strains and resulting in high local tensile stresses, on either side of the pipeline cross-section, may lead to local fracture at welds or other locations where minor defects exist.

The effects of internal pressure on pipeline mechanical behavior are investigated by considering internally pressurized pipelines imbedded in the same soil conditions (Clay I). Numerical results corresponding to a pressure level of 50 barr, which is equal to 56% of the maximum operating pressure p_{max} indicate that, despite the fact that the buckled shapes of pressurized cylinders are similar to the buckled shape of Figure 5, the corresponding values of critical fault displacement d_{cr} and the compressive strain along the critical generator of the steel pipeline are somewhat lower than the ones shown in Figure 6b. Those results indicate that, in the case of buried (confined) pipes, the presence of internal pressure results in a decrease of critical fault displacement. The decrease is attributed to the development of additional stresses and strains in the pipeline wall that cause early yielding and lead to a premature local buckling failure. For the case of $p/p_{max}=0.56$, the maximum strain ε_{cr} at buckling (critical strain) is equal to 8.3×10^{-3} , which is similar yet slightly higher than the critical strain for zero pressure.

The numerical results in Figure 8 and in Figure 9 refer to an X65 steel pipeline with D/t ratio equal to 72, buried in stiffer cohesive soil conditions. The values of soil parameters c , E and ϕ are equal to 200 kPa, 100 MPa and 0° , respectively, and correspond to a stiff clay under “undrained conditions”, referred to as Clay II. The width of the fault zone is equal to 0.33 m. The numerical results indicate that pipe bending deformation in the stiff soil occurs within a shorter distance from the fault location, and the critical area is at 3.2 m from the fault. Comparison of those results with the results shown in Figures 6 and 7 demonstrates the significant effect of site conditions on the mechanical behavior of the steel pipeline. In other words, for the same fault displacement d , higher bending stresses and strains occur in the case of a stiff soil than those in the case of a soft soil. The numerical verification of the above observation is offered in Figure 8 and Figure 9, which depict the variation of longitudinal (axial) normal strain along the compression generator. Local buckling occurs when the fault displacement becomes equal to 0.23 m, which is much less than the corresponding critical fault displacement for the case of soft clay (0.67 m). The corresponding maximum compressive strain ε_{cr} that causes local buckling is equal to 7.3×10^{-3} , whereas the maximum tensile strain $\varepsilon_{T,max}$ along the opposite generator at the stage of local buckling onset is equal to 4.8×10^{-3} . The striking difference between softer and stiffer soil conditions is attributed to the fact that a steel pipeline in a softer soil, when subjected to a fault displacement, accommodates itself easier within the deformable soil, resulting in lower bending stresses and strains, which enable the pipeline to sustain larger ground-imposed displacements.

To investigate the effects of the diameter-to-thickness D/t ratio in cohesive soils (Clay I, II), numerical results are obtained for 36-inch-diameter X65 steel pipelines with thickness ranging between $\frac{1}{4}$ -inch and $\frac{3}{4}$ -inch, corresponding to D/t values between 48 and 144.

The numerical results are summarized in Figure 10. In particular, Figure 10a plots the fault critical displacement, d_{cr} , normalized by the pipe diameter D , in terms of the diameter-to-thickness ratio, D/t . The results show a substantial decrease of d_{cr} with increasing value of the D/t ratio, which means that thin-walled pipelines are more prone to buckling and fail at relatively small values of fault displacement. Furthermore, stiff soil conditions result in significantly lower deformation capacity of the pipeline. In Figure 10b the corresponding critical compressive strain at the onset of local buckling, ε_{cr} , is plotted against the value of the diameter-to-thickness ratio, D/t . The results indicate that thinner pipes buckle at smaller critical strain, which is in accordance with test data and numerical results from non-confined pipes [24].

In the above results, no critical displacement or critical strain is shown for $D/t = 44$ and soft soil conditions (Clay I). In this particular case, the numerical results did not indicate local buckling; the pipeline exhibited significant ground-induced deformation without any wrinkling of the pipeline wall for fault displacements that exceed 2.5 m. The significant tensile strains developed in the pipeline due to longitudinal pipeline stretching, after a certain fault movement, are responsible for this behavior.

In Figure 10, the effects of internal pressure are also depicted. The numerical results are obtained for a pressure level equal to 56% of the maximum operating pressure, p_{max} , and show that the presence of internal pressure results to a small decrease of critical fault movement, d_{cr} in Figure 10a, due to the additional stresses and strains in the pipeline wall because of pressure. Furthermore, the corresponding critical strain in the presence of pressure is similar to the corresponding critical strain for the zero pressure case, as shown in Figure 10b.

3.2 X65 steel pipelines in non-cohesive soils

The response of an X65 steel pipeline with $D/t = 72$ embedded in non-cohesive soils is examined, by considering representative results for two frictional soils and comparing them to those obtained for the cohesive soils. First, a granular soil is considered with a friction angle $\varphi = 30^\circ$, Young's modulus $E = 8$ MPa and Poisson's ratio $\nu = 0.3$, corresponding to loose sand and referred to as "Sand I". The relatively small value of the stress-dependent Young's modulus E is justified by the shallow embedment depth of the pipeline. A small amount of artificial cohesion equal to $c = 5$ kPa was also included to prevent numerical difficulties associated with the behavior of a purely frictional material at very small confining stress, such as in the case of a gap opening at the pipe-soil interface. Figure 11 and Figure 12 show the variation of the axial strain ε_x along the compression and tension outer sides, respectively, of the buckled area for Sand I. The critical distance from the fault, corresponding to the point with maximum bending curvature along the pipe, is 6.1 meters. The results for the compressive strain shown in Figure 11 indicate that at a value of fault displacement equal to 0.87 m, local buckling occurs, and beyond this stage, significant distortion of the cross-section occurs due to local buckling on the pipe wall on the compression side of the bent pipeline. The shape of the developing buckling is similar to that of Clay I. The longitudinal strain at the location of the buckle (ε_{cr}) is equal to 9.7×10^{-3} . Furthermore, at the critical buckling stage ($d = 0.87$ m), the maximum tensile strain on the opposite side of the pipe ($\varepsilon_{T,max}$) is 6.8×10^{-3} , which is much less than the strain that would cause tensile rupture. Beyond the formation of the local buckle, pipe deformation concentrates around the buckled cross-section and the localized wrinkling pattern is further developed. Further continuation of the imposed deformation results in pipe-wall folding, which is accompanied by significant local strains (compressive and tensile) at the buckled area. Moreover, the maximum tensile strain on the opposite (tensile) side of the pipe is also significantly increased.

Similar results are obtained for an X65 steel pipeline with $D/t = 72$, embedded in a more dense sand with values of φ and E equal to 40° and 50 MPa, respectively, referred to as "Sand II". The numerical results indicate that pipe bending deformation in Sand II occurs within a shorter distance from the fault location (5.1 m) due to the higher strength of this sand. Comparison of those results with the results in Figure 11 and Figure 12 demonstrates that for the same fault displacement d , higher bending stresses and strains occur in the case of Sand II. Furthermore, local buckling occurs when the fault displacement becomes equal to 0.70 m, which is less than the corresponding critical fault displacement for the case of loose sand (0.87 m). The maximum compressive strain ε_{cr} that causes local buckling is equal to 10.47×10^{-3} , whereas the corresponding maximum tensile strain $\varepsilon_{T,max}$ along the opposite generator is equal to 6.98×10^{-3} .

Finally, the numerical results for the mechanical behavior of X65 pipelines in non-cohesive soils (Sand I and II) are summarized in Figure 13, in terms of the normalized fault critical displacement and the critical corresponding strain at buckling with respect to the diameter-to-thickness ratio, D/t . The results shown in Figure 13a indicate that dense soil conditions (sand II) result in lower deformation capacity of the pipeline.

3.3 Behavior of X80 steel pipelines

The behavior of buried high-strength steel (API X80) pipelines under normal fault-induced deformation is also analyzed, using the numerical tools described in the previous sections.

The nominal uniaxial tensile stress-strain relationship of the X80 material is plotted in Figure 3. The dashed material curve, which has a yield stress of 596 MPa and does not have a plastic plateau, corresponds to a cold expanded (UOE) pipe. The solid material curve with a yield stress of 550 MPa and a plastic plateau up to a strain of 1.48% represents a seamless steel pipe material. Results are obtained for 36-inch-diameter X80 steel pipelines with D/t ratios between 48 and 144. Figure 14a plots the value of the fault critical displacement, d_{cr} , normalized by the pipe diameter D , in terms of the diameter-to-thickness ratio, D/t , for the two types of X80 steel and for cohesive soil conditions (Clay I and II). As in the case of X65, the value of d_{cr} decreases significantly with increasing value of D/t , indicating that thin-walled pipelines are more vulnerable to buckling and may fail at relatively small values of fault displacement. It should be noted that for the softer Clay I material, no values of d_{cr} are given for $D/t = 44$ and 72 , as no wrinkling of the pipeline wall was observed in this case even for fault displacements exceeding 4 m. This is attributed to the beneficial effect of tensile deformation on the mechanical behavior of those relatively thick pipes, as described in the Appendix. Naturally, the values of d_{cr} for the high-strength steel X80 pipes in Figure 14a are higher than those for the X65 pipes given in Figure 10a. Similarly, Figure 14b plots the corresponding critical axial strain, ε_{cr} , versus the diameter-to-thickness ratio, D/t , for zero internal pressure. Comparing the behavior of the two X80 materials, it is evident that both d_{cr} and ε_{cr} are higher for UOE pipe due to both increase of yield strength and higher initial post-yielding tangent modulus. The increase of buckling strength in UOE pipes is in accordance with the test data reported elsewhere [24].

3.4 Effects of the pipeline-fault crossing angle

In this section, a short parametric study is conducted to examine the effects of pipeline-fault crossing angle on the pipeline structural performance, as shown in Figure 15. The crossing angle β is the main parameter of interest; positive values of β correspond to geometries that induce tension in the pipeline, whereas negative values of β are associated with compression of the pipeline. A 36-inch-diameter, $\frac{1}{2}$ -inch-thick X65 pipeline, embedded in soft-to-firm clay soil conditions (Clay I), is examined for various crossing angles.

Figure 16 shows the deformed shape of the above pipeline for a value of β equal to 25 degrees, at a fault displacement $d = 2$ m. At this angle, local buckling does not occur. The deformed shape shows a significant distortion of the pipeline cross-section in the form of ovalization. The amount of ovalization, defined as $ov = \Delta D/D$ (where ΔD is the change of diameter in the plane of bending), reaches a limit value of 0.15 at fault displacement of 1 m, at the area where pipe intersects with the fault. It is noted that this value of 0.15 is specified by NEN 3650 specification, as described in [25]. Under increasing fault movement, this ovalization pattern is further developed resulting in an inversion of the pipeline wall (i.e. a local “concave” deformation pattern on the pipeline wall), for a fault displacement of $d = 2.53$ m. Critical tension strain (3%) appears at a fault displacement $d = 0.64$ m, whereas a maximum tensile strain of 5% occurs at a fault displacement $d = 1.42$ m, at a distance 1.1 m away from fault.

The deformed shape of the above 36-inch-diameter, $\frac{1}{2}$ -inch-thick X65 steel pipeline in Clay I soil conditions, crossing the fault plane at an angle of β equal to 45 degrees, is shown in Figure 17. The amount of ovalization reaches a critical value of 0.15 at fault displacement of 1.08 m, at the area where pipe intersects with the fault. With increasing fault displacement,

this ovalization pattern is further developed. For a fault displacement equal to 4 m no “inversion” of the pipeline wall has been observed. Critical tension strain (3%) is reached at a fault displacement $d = 0.37$ m, whereas a maximum tensile strain of 5% occurs at a fault displacement $d = 1.14$ m, at the point where pipeline crosses the fault plane.

The response becomes quite different if a opposite crossing angle is considered, corresponding to a negative value of β . In this case, fault motion is associated with a decrease of length of the pipeline, resulting in the development of significant compressive stresses and strains, leading to local buckling. In Figure 18, the deformed shape of the above 36-inch-diameter $\frac{1}{2}$ -inch-thick X65 steel pipeline in Clay I soil conditions, crossing the fault plane at an angle of β equal to -10 degrees, is shown. The critical fault displacement has been computed equal to 34 cm. Upon continuation of fault displacement, the buckle pattern is further developed, so that an inversion of the pipeline wall occurs at fault displacement of 75 cm in the same cross-section where buckle appears. The cross-section where maximum deformation occurs is located 7.5 meters away from fault.

4 CONCLUSIONS

Using advanced finite element simulation tools, the mechanical behaviour of buried steel pipelines crossing an active strike-slip fault was investigated. The pipeline is assumed horizontal and normal to the fault plane, an idealized case, which allows for the investigation of several soil and pipe parameters on pipeline deformation and strength. In particular, the effects of various cohesive and non-cohesive soil conditions (expressed through various values of soil cohesion, friction and stiffness parameters (c, ϕ, E)) on the structural response of the pipe are examined, with particular emphasis on pipe wall failure.

For pipelines crossing strike-slip faults at right angle, an extensive parametric study is conducted, and numerical results are obtained for various values of D/t ratio and for X65 and X80 steel pipelines. In the majority of the cases analyzed, it is shown that the formation of local buckling due to excessive compressive strains at the pipeline wall is the governing mode of failure. The numerical results are presented in diagram form for the critical fault displacement d_{cr} and the corresponding critical strain ε_{cr} , and indicate a strong dependence in terms of the pipeline diameter-to-thickness ratio D/t .

It is concluded that, for pipelines crossing strike-slip faults at right angle, in cohesive soils, softer ground conditions result in a large deformation capacity of the pipeline, whereas stiff ground conditions decrease the critical fault displacement. Similarly, in non-cohesive soils, loose sand conditions results in larger values of critical fault displacement than in dense soil conditions. The width of the fault slip zone was found to have non-important effects for the mechanical behaviour of the pipe. It was demonstrated that the presence of internal pressure results in a small decrease of the deformation capacity, due to early yielding of the steel material. It was also concluded that high-strength X80 steel pipelines have a greater deformation capacity than X65 pipelines. Furthermore, cold-formed UOE X80 pipes exhibit better behaviour in terms of buckling than seamless X80 pipes due to strain hardening. Furthermore, the numerical results show that thick-walled pipes may not exhibit buckling; in those pipelines wall fracture may occur due to the development of excessive tensile strains.

Finally, numerical results are obtained for pipelines crossing the vertical fault at angles different than 90-degrees. In “negative” values of the angle, local buckling of the pipeline wall is the dominant mode of failure; local wrinkling increases with increasing fault displacement. On the other hand, for “positive” values of the crossing angle, the behaviour is considerably different. Local wrinkling does not occur; nevertheless the pipeline exhibits a significant dis-

tortion of its cross-section, followed by the development of significant tensile strains that may lead to pipeline rupture.

Abstract. *Elbow components are widely used in industrial facilities as parts of piping/tubing systems. Their performance under severe loading conditions may be critical for the structural integrity of an industrial facility. In the case of an earthquake event in addition to other service loads, such as internal pressure, they are subjected to strong repeated cyclic structural loading. When these elements are subjected to strong repeated loading, they present failure modes associated with cyclic plasticity phenomena (material degradation or cyclic creep). Furthermore, due to their flexibility, significant non-linearities occur and the elbow cross-section shape distorts as cyclic loading takes place resulting at an oval or flatten shape at the end of the loading sequence. Accumulation of plastic strains (cyclic creep or ratcheting) also takes place at the most stressed parts of the element, associated with extensive bulging of the cross-section which is more pronounced in the presence of internal pressure. The present study is numerical, based on a finite element simulation of the elbow, and investigates the elbow component behavior subjected to strong cyclic bending of various amplitudes in the presence of different levels of internal pressure. The material constitutive model has a dominant effect on the elbow response, and this is shown through the use of 3 different plasticity models. The capabilities and drawbacks of each plasticity model regarding the simulation of cyclic plasticity phenomena are discussed in detail.*

1 INTRODUCTION

Pipe elbows constitute essential components of industrial piping systems in chemical plants, refineries and power plants. Because of their flexibility properties, they can accommodate thermal expansions and absorb other externally-induced loading. Under extreme loading conditions, such as seismic loading, elbows exhibit significant cross-sectional distortion (ovalization), associated well beyond the elastic limit of the material, which may cause failure of the piping component. Failure is in the form of excessive cross-sectional ovalization or local buckling. Therefore, their structural performance under earthquake loading conditions may be critical for the structural integrity of an industrial facility [1].

Experimental data on a series of tests on 16-inch 90 deg elbows ($D/t=39$ and $R/t=3$) under in-plane closing moments were reported by Sobel and Newman ([2], [3]) and Dhalla [4], and compared with numerical results from shell elements and simplified elbow elements. Gresnigt et al. ([5], [6], [7]) reported test data on five 30 deg, five 60 deg and one 90 deg steel elbows ($R/r=6$) under bending and pressure. Greenstreet [8] determined experimentally the load-deflection response of 20 carbon/stainless steel pipe elbows, under bending loading conditions, with internal pressure. Hilsenkopf et al. [9] conducted bending tests on thin-walled ($D/t=89.5$) stainless steel elbows and thick-walled ($D/t=13.4$) ferritic elbows, in connection with their functional capability. In-plane bending experiments on 90 deg elbows were reported by Suzuki and Nasu [10] and, more recently, by Tan et al. [11]. In both works, the test results were compared with finite element results. More recently, using a special-purpose “elbow” element of ABAQUS, Shaleby and Younan ([12], [13]) analyzed standalone 90 deg steel elbows ($R/r=3$) for a wide range of diameter-to-thickness ratios ($15.5 \leq D/t \leq 97$), under in-plane bending (opening and closing moments) and internal pressure. This work was extended by Mourad and Younan ([14], [15]) who analyzed pressurized standalone 90 deg steel elbow segments ($R/r=3$) under out-of-plane bending. In those works, only the curved part of the pipe was analyzed, neglecting the effects of the adjacent straight parts. Chattopadhyay et al. [16] employed twenty-node fully-integrated solid elements from a general-purpose program to analyze thick 90 deg elbows ($D/t \leq 25$) under in-plane bending, accounting for the effects of the adjacent straight parts, and proposed simplified formulae were proposed for the collapse (limit) moment capacity in terms of pressure and the bend factor ($h=tR/r^2$). Karamanos et al. ([17], [18]) presented a numerical study of steel elbow response under in-plane bending (opening and closing) and out-of-plane bending, considering internal pressure effects. A good comparison was found between numerical results and test measurements reported by Gresnigt et al. [5]. The numerical work in Karamanos et al. ([17], [18]) was extended by Pappa et al. [19], to include the effects of external pressure on the bending response of elbows, for offshore pipeline applications.

The above works referred to monotonic loading, verifying the highly nonlinear response of steel industrial elbows under ultimate loading conditions. However, in the course of a strong seismic event, the elbows are subjected to strong repeated cyclic structural loading, associated with excursions of steel material in the plastic range. Under those severe cyclic loading conditions together with other service loads (e.g. internal pressure), the elbow may exhibit significant accumulation of plastic strain (“cyclic creep” or “ratcheting”), which eventually may lead to failure. Extensive experimental work on 2-inch pipe elbows under strong cyclic in-plane bending loading conditions has been reported by Yahiaoui et al. [20], focusing on the ratcheting behavior. The schedule of the pipes were SCH40 (Std) and SCH80 (XS), and the specimens included both long ($R=76\text{mm}$) and short ($R=51\text{mm}$) radius elbows. The materials were carbon steel (ASTM A106B) and stainless steel (A312 TP304L). The specimens were first pressurized, then their resonance frequency was determined and, subsequently, they were

shaken under an “increasing input displacement amplitude” loading pattern. It was concluded that ratcheting in the hoop direction was more pronounced than in longitudinal direction. In short radius elbows, some ratcheting was observed at the intrados, in the longitudinal direction. It was also observed that ratcheting for carbon steel elbows initiated with the applied bending moment reached the value of plastic moment. Furthermore, no permanent cross-sectional deformation was observed. This work was continued in Yahiaoui et al. [21] for the case of elbows under out-of-plane bending moments, and similar conclusions were drawn. In a subsequent publication, the authors (Moreton et al. [22]), based on the work by Edmunds and Beer [23] attempted to predict analytically the ratcheting rate, as well as the conditions for ratcheting initiation. Slagis [24] reported experimental testing conducted by EPRI/NRC on carbon/stainless steel pipe elbows. The tests were performed through a shaking-table apparatus, simulating floor response motion, and included both component tests and piping system tests. Extensive experimental work was presented by Fujiwaka et al. [25], through a series of material tests, pipe component tests and piping system tests at room temperature and at 300°C. The specimens comprised bent pipes, tees, and straight pipes, from both carbon and stainless steel material. Finite element simulations were also reported and a criterion was developed for evaluating ratcheting effects on fatigue.

Degrassi et al. [26] performed non-linear time history finite element analysis of piping system with the object of simulating ratcheting responses under seismic excitation. They simulated the seismic responses of the piping systems using the bilinear, multilinear and Chaboche models in ANSYS. Balan and Redektop [27] simulated the response of elbow specimen under cyclic bending and internal pressure with bilinear plasticity model in the finite element code ADINA. They demonstrated that the shakedown phenomenon is simulated by the bilinear model for circumferential strain at the flank. More recently, Rahman & Hassan [28] presented an extensive analytical work on cyclic behavior of steel elbows, supported by 3 experiments on 2-inch SCH10 pipes, aiming at determining the capabilities of several cyclic plasticity models in predicting the ratcheting rate.

All the above works have demonstrated that when steel elbows are subjected to strong repeated loading, they present failure modes associated with cyclic plasticity phenomena (material degradation or cyclic creep). In many instances, it has been noticed that – especially in the case of pressurized elbows – the elbow cross-section shape distorts (ovalization or flattening) or bulges as cyclic loading takes place.

The present study is part of a large European research effort, aimed at investigating the structural safety of industrial equipment structures and components, including industrial elbows. The research presented in the present study is numerical, based on a finite element modeling of 8-inch SCH40 elbows of P355 material according to EN 13480-2 (equivalent to API 5L X52), and it is motivated by the need of developing accurate numerical models for of steel elbow elastic-plastic behavior under strong cyclic bending, in the presence of different levels of internal pressure.

Following a brief presentation of elbow stress analysis and the ultimate capacity under monotonic loading conditions (closing and opening), special attention is given on the constitutive model for describing the cyclic behavior of steel material. In the present paper, linear and nonlinear kinematic hardening models are employed in terms of their capabilities and drawbacks in simulating cyclic plasticity phenomena observed in previous experimental observations. Finally, the numerical results are compared with the provisions of ASME B31.3 [29] and EN 13480-3 [30].

2 DESCRIPTION OF NUMERICAL SIMULATION

General-purpose finite element program ABAQUS is employed in the present study for the parametric study. The analysis considers nonlinear geometry through a large-strain formulation, and inelastic effects, which are accounted for through a J_2 (von Mises) plasticity model. For monotonic loading conditions isotropic hardening is employed, where the uniaxial stress-strain curve from a tensile test is considered for calibration purposes. The yield stress (σ_y) of the material is considered equal to 355 MPa, and hardening of the pipe material is assumed with a hardening modulus of about $E/200$. For cyclic loading conditions, in addition to the isotropic hardening, linear and nonlinear kinematic hardening is also employed. More details on the description and the application of those plasticity models are available in a subsequent section of the present study.

Previous numerical results indicated that pipe elbows may exhibit an unstable post-buckling response (Karamanos et al. ([17], [18])). Therefore, in the case of monotonic loading, a path-follower (Riks) algorithm is employed to trace unstable equilibrium paths and calculate the post-buckling response of the elbow members.

Four-node reduced-integration shell elements (type S4R) are employed for modeling of the pipe-elbow geometry. Several analyses have also been repeated with an eight-node element S8R, and the results were found almost identical with the results obtained through the S4R element [18]. The special-purpose “elbow” elements in ABAQUS, is not considered because of its inadequacy of simulating very accurately buckling and post-buckling elbow configurations.

The thickness of the curved part of the elbow is equal to the thickness of the straight part. Thickness variations due to the manufacturing process are not taken into account in the present analysis geometry.

In the present study, a detailed simulation the scheduled experimental procedure is conducted. In the numerical model, rigid plates are assumed to “cap” end sections A and B (Figure 1). This is achieved through the “kinematic coupling” feature of ABAQUS, which relates the degrees of freedom of the shell nodes in section B with the degrees of freedom of a reference node, which is assumed to be located at the centroid of the end-section. In case of non-zero internal pressure, the corresponding capped-end force is taken into consideration. Capped-end section A is hinged, whereas the other end-section allows for both in-plane rotation and displacement along the x-direction.

3 NUMERICAL RESULTS FOR MONOTONIC LOADING

Under bending loading, pipe elbows, compared with straight pipe segments, undergo very pronounced cross-sectional deformations, in the form of cross-sectional ovalization. This ovalization makes the elbow significantly more flexible, exhibiting considerably higher stresses and strains. A simple energy formulation has been proposed by Rodabaugh and George [32] to describe the mechanical behavior of elastic elbows; assuming uniform cross-sectional deformation along the elbow axis, the total potential energy of the elbow under bending and pressure is formed. Solution is obtained analytically, minimizing the potential energy, and resulted in the so-called flexibility factor, which expresses the ratio of elbow flexibility over the flexibility of a straight pipe of equal length and of the same cross-section. The same solution provides the longitudinal and hoop stresses, and the ovalization of the cross-section, and compares quite well with finite element results. For a thorough presentation of those issues, one may refer to the recent paper of Pappa et al. [19]. Among other conclusions, it is interesting to note that the flexibility factor is higher in the absence of internal pressure and is reduced when internal pressure is raised. Furthermore, the maximum circumferential stress is higher than the maximum longitudinal stress, and that the maximum longitudinal stress is considerably higher than the maximum stress of a straight pipe with the same cross-section, and does not occur at the top or the bottom of the cross-section. The significant ovalization of the elbow cross-section is mainly responsible for this behavior.

The above results refer to linear elastic analysis of standalone elbows, assuming no variation of stress and deformation along the elbow; however, in a real situation, the problem is more complicated. There are straight pipes welded to the elbow ends that influence ovalization along the elbow, whereas the severe deformation of the elbow is associated with significant inelastic deformations. Considering also the significant change of elbow geometry, it is necessary to use numerical (finite element) simulation tools in order to determine the ultimate bending moment capacity of the steel elbow.

Using the finite element simulation described in section 2, the bending response of an 8-inch short-radius SCH40 elbow is analyzed. The bend radius is 328.62 mm (equal to 1.5 times the pipe diameter D), the pipe thickness t is 8.18 mm and the material of the pipe is P355 material as described in the previous section. Each straight part of the piping specimen is 1095.4 mm (equal to 5 times the pipe diameter D).

Elbow with above characteristic is analyzed, for internal pressure levels up to 50% of the fully-plastic pressure p_y . The results focus on the ultimate capacity, the corresponding failure mode and the effects of pressure. In Figure 2, the applied in-plane closing force of thick-walled elbow is plotted in terms of the displacement of end section B. The results depicted in figure demonstrate the beneficial effect of internal pressure on the ultimate capacity of elbow. This is mainly due to the reduction of cross-sectional ovalization of the curved part. Ovalization is expressed in terms of the non-dimensional ovalization parameter (ov) defined as $ov = |D_A - D_B| / 2D_m$, where D_A is the length of the deformed diameter on the plane of bending and D_B is the length of deformed diameter perpendicular to the plane of bending, both measured at the cross-section under consideration. In Figure 4, the ovalized shape of elbow is depicted. In both cases, failure is due to a plastic mechanism with four plastic hinges, which are located at the intrados, the extrados and the two “flank” locations.

Fig. 2: Load versus end-displacement curves for two levels of internal pressure with respect to p_y .

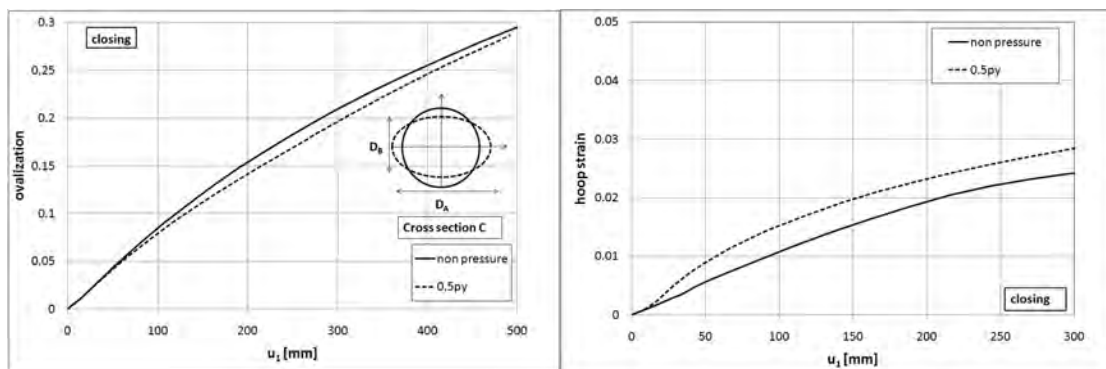

Fig. 3: Ovalization of cross section C and hoop strain of cross section C at “flank” location for two levels of internal pressure under closing bending.

Fig. 4: Deformed three-dimensional elbow shape under closing bending moments; (a) zero pressure; (b) internal pressure 50% of p_y

The response of the elbows under opening bending moments is shown in Fig. 5, for two different pressure levels 0%, and 50% of the yield pressure p_y . In figures 5, 6 and 7, the force-displacement, ovalization–displacement and hoop strain-displacement curves are plot-

ted. Elbows under in-plane opening moments exhibit “negative” ovalization, so that the length of the diameter on the plane of bending increases. It is noted that thick-walled pipe elbows under opening moments and internal pressure exhibit small ovalization. In Figs. 7a and 7b, the buckled shapes of elbows for zero and 50% of the fully-plastic pressure p_y opening moment bending are depicted. It is important to note that the capacity of non pressurized elbows under opening bending moments is significantly greater than the corresponding moment capacity under closing bending moments as shown in the numerical results.

4 MATERIAL MODELING FOR CYCLIC PLASTICITY

For the numerical simulation of the elbow performance under cyclic bending conditions in the presence of internal pressure, several cyclic plasticity models are used. The first and most traditional cyclic plasticity model adopted is a von Mises flow model with isotropic hardening. According to this model, the origin of the Yield Surface remains fixed at the stress space and it is allowed to expand as it is described by the following equation:

$$F = \frac{1}{2} \mathbf{s} \cdot \mathbf{s} - \frac{k^2(\varepsilon_q)}{3} = 0 \quad (1)$$

where \mathbf{s} is the deviatoric stress tensor defined as $\mathbf{s} = \boldsymbol{\sigma} - p\mathbf{I}$ (p is the “hydrostatic” stress and \mathbf{I} is the identity tensor) and k is the parameter that defines the size of the yield surface which is generally a function of the equivalent plastic strain ε_q .

An advancement of the von Mises plasticity model with isotropic hardening that overcomes the drawbacks related to its simplicity is the use of linear and nonlinear kinematic hardening rules. In this case, the Yield Surface is free to move in the stress space while its size remains constant. The yield criterion for kinematic hardening is as follows:

$$F = \frac{1}{2} (\mathbf{s} - \mathbf{a}) \cdot (\mathbf{s} - \mathbf{a}) - \frac{k^2}{3} = 0 \quad (2)$$

where \mathbf{a} is the back stress tensor that expresses the current center of the yield surface in the deviatoric space. The linear kinematic hardening rule is described by the following linear expression:

$$\dot{\mathbf{a}} = C \dot{\boldsymbol{\varepsilon}}^p \quad (3)$$

where C is the kinematic hardening modulus considered as constant and $\dot{\boldsymbol{\varepsilon}}^p$ is the plastic strain rate. In this case the size of the Yield Surface k is constant. When the nonlinear kinematic hardening (Armstrong-Frederick) rule is adopted, the aforementioned hardening rule is modified as:

$$\dot{\mathbf{a}} = C \dot{\boldsymbol{\varepsilon}}^p - \gamma \mathbf{a} \dot{\varepsilon}_q \quad (4)$$

where C is the linear kinematic hardening modulus and γ is the parameter that determines the rate at which the kinematic hardening modulus decreases with increasing plastic deformation. The use of the multilinear kinematic hardening rules significantly improves the capacity of the plasticity model to predict cyclic plasticity related phenomena such as the Bauschinger effect and ratcheting. The special characteristic of the adopted plasticity models have been extensively discussed by Varelis [31].

For the calibration of the above cyclic plasticity model parameters due to the lack of experimental data, the material uniaxial stress strain curve is used. The fitting of the predicted material uniaxial behavior for each plasticity model adopted to the measured values is depicted in Fig.1. The corresponding model parameter values that provide the best fit to the measured stress/strain uniaxial curve are for linear kinematic hardening $C = 1007.137$ and for nonlinear kinematic hardening $\sigma_y = 350 \text{ MPa}$, $C = 1500$, $\gamma = 10$.

Fig. 8: Uniaxial stress-strain curve and cyclic plasticity model predictions

5 CYCLIC RESPONSE OF STEEL ELBOWS

For the examination of cyclic response of steel elbows the numerical model described above has been used. Loading is introduced by applying cyclic displacement at the one end of the elbow specimen in the absence and in the presence of internal pressure. The cyclic displacement ranges considered in the present study are $\pm 150 \text{ mm}$ and $\pm 300 \text{ mm}$ which are well beyond the elastic behavior limit of the elbow as shown in the monotonic curves presented.

The first set of simulations is conducted with zero pressure loading, while in the second simulation set a relatively high pressure of $p = 14.5 \text{ MPa}$ is first applied and subsequently kept constant throughout the cyclic loading application. The pressure value corresponds to about 50 percent of the yield pressure of the elbow $p_y = 2\sigma_y t / D$, where σ_y is the yield strength of the material (equal to 355 MPa), t is the elbow wall thickness equal to 8.179 mm and D is the elbow diameter. The result of the three cyclic plasticity models adopted are presented and discussed in detail in the following paragraphs. The numerical results of interest are the force-displacement curve, the change of the elbow diameter measured at the central cross-section in the horizontal and vertical direction, and the evolution of strain at the elbow flank.

5.1 Cyclic bending in the absence of internal pressure

The elbows are subjected to cyclic loading of alternating sign in the range of ± 150 mm and ± 300 mm without internal pressure. The loading begins with a closing end-displacement and continues with unloading and reverse loading for 10 complete load cycles. In Fig. 9(a) the load versus end-displacement curves for each plasticity model are presented. In Fig. 9(b) the prediction for the first loading cycle is depicted for the three material models.

It is clearly observed that the predictions of the plasticity models vary significantly. The isotropic hardening model, denoted as (ISO), predicts higher required load when reloading takes place. After a few initial load cycles the response for the remaining load cycles appears to stabilize. The models using the linear kinematic hardening rule (LK) and the nonlinear kinematic hardening rule (NLK) predict lower reaction forces compared to the ISO model and similar to each other. This can be attributed to the constantly increasing size of the yield surface assumed by the ISO due to plastic deformation increase. On the contrary, the constant size of the yield surface assumed in the case of LK and NLK model results to lower reaction forces since plastic deformations initiate at lower stress levels. Furthermore, the behavior stabilizes after a few initial load cycles as well, but the stabilized hysteresis loops predicted by the LK and the NLK model have different sizes. This is because in the case of the NLK model, the hardening modulus is continuously decreasing until it reaches a zero value as the equivalent plastic strain increases, whereas for the LK model the hardening modulus remains constant.

The prediction of cross-sectional distortion for each plasticity model is presented in Fig. 10. All three models used predict almost the same distortion values for both the horizontal and the vertical direction. Only minor differences are observed near the end of the cyclic loading history. Greater differences in predictions of the three models are observed for the strain accumulation (ratcheting) at the flank of the elbow as shown in Fig. 11. Near this area the plastic deformations are accumulated resulting to a localization of plastic deformation that might result to fracture. The main reason for the above differences is that each plasticity model predicts a different deformation shape of the elbow at the end of the loading history, as shown in Fig. 12.

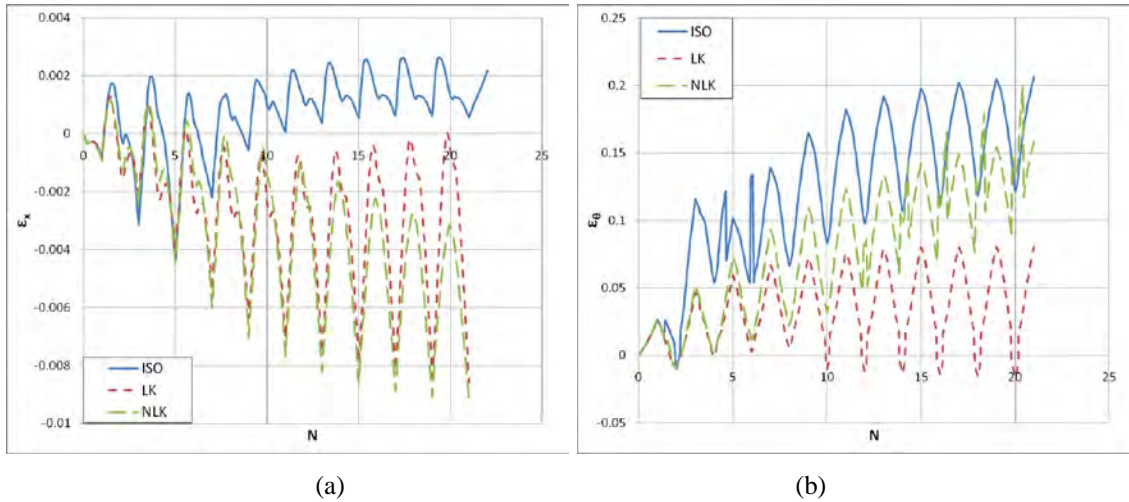

Fig. 11: Strains at the elbow flank: (a) Longitudinal direction, (b) Hoop direction

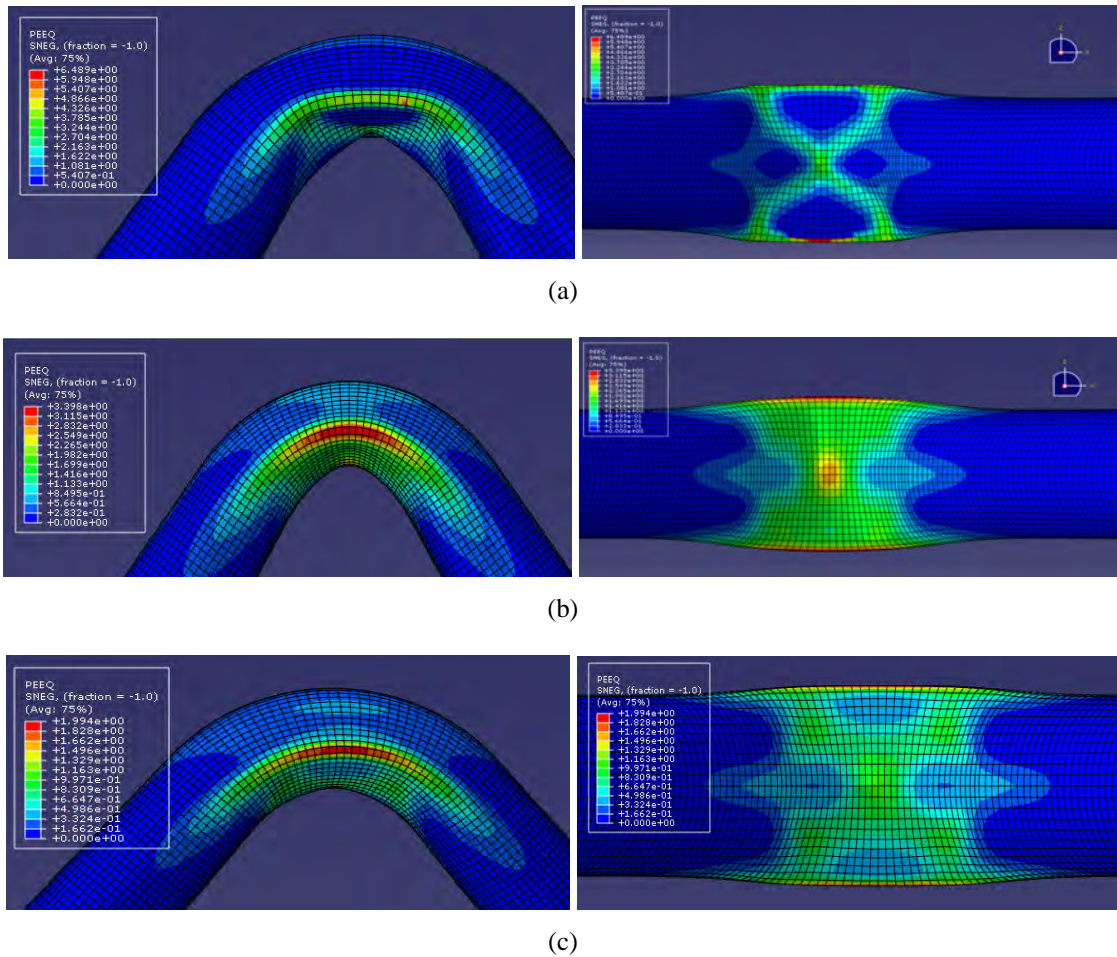

Fig. 12: Plastic deformation distribution at the end of the loading history: (a) ISO, (b) LK and (c) NLK model predictions

The same quantities have been monitored for the ± 300 mm end-displacement loading case and zero pressure. The corresponding load versus displacement curves for the entire loading history and for the first load cycle only are presented in Fig. 13(a) and 13(b) respectively. Again, the ISO hardening model overpredicts the resulting end-reaction

compared to the models that use the LK and the NLK rule. For this loading range as well, the same stabilization trend for the hysteresis loops is observed.

The cross-sectional distortion for the loading range of ± 150 mm is also observed for the loading range of ± 300 mm. The predictions of the three plasticity models presented in Fig. 14 provide close results. In Fig. 15, strain accumulation at the flank region is shown. It is noticeable that the ISO model predicts very high strain values especially near the end of the cyclic loading history, mainly in the hoop direction. It should be noted though that the predicted strain values by all models that lay or exceed the value of 20 percent are far beyond the fracture limit of the material, which indicates that a crack is propable to initiate at this region in the longitudinal direction. Finally, the significant differences observed in the strain accumulation graph of Fig. 15 can be attributed to the different deformation modes predicted by each model, which are very similar to those observed in the case of ± 150 mm loading.

5.2 Cyclic response of internally-pressurized elbows

The presence of internal pressure has significant effects on the elbow structural performance under cyclic loading conditions. The monotonic loading curves presented in a previous paragraph, indicate that due to the existence of internal pressure, the elbow capacity is increased well beyond the elastic limit. For comparison reasons, the same end-displacement ranges of ± 150 mm and ± 300 mm have been considered for these simulations, for a pressure level equal to $p = 14.5$ MPa.

From Fig. 16(a) it is observed that the existence of internal pressure maintains the hysteresis loops in an almost stabilized state throughout the cyclic loading history. The over-prediction of the ISO model compared to the predictions of the other two models (Fig. 16(a) and (b)) can be attributed to the constantly increasing yield surface size. This results to extensive bulging of the elbow section (Fig. 19a) and consequently to significant loss of resistance capacity observed after a few load cycles.

It is interesting to note that the predictions of the LK and NLK models as far as the final deformation state is concerned are significantly different. More specifically, the LK model predicts a local buckle oriented at the extrados of the elbow (Fig. 19(b)), while the NLK predicts a local bulging of the elbow intrados, but significantly smaller compared to the bulging predicted by the ISO model. The aforementioned differences in the deformation modes explain the differences in Figures 18 and 19 with respect to the cross-sectional distortion and the accumulation of strain at the flank region.

(c)

Fig.19: Plastic deformation distribution at the end of the loading history:
(a) ISO, (b) LK and (c) NLK model predictions

Finally, the end-displacement loading of ± 300 mm is conducted in the presence of pressure equal to 14.5 MPa. This is the most severe load combination for the elbow specimen. As illustrated in Fig. 20 to 22, the ISO and the NLK models predict extensive deformation of the material after a few initial loading cycles. The LK model predicts a smaller rate of deformation accumulation. Nevertheless, even in this case the deformation values become significant well before the end of the simulation history.

Similarly to the previous loading case, each model predicts a different deformed geometry. The ISO and the NLK models predict bulging of the elbow cross-section, while the LK model predicts a local buckle at the middle of the elbow specimen and some side buckles at the extrados of the elbow element at the connection of the straight and the curved elbow part (Fig. 23). The cross-sectional distortions as well as the longitudinal and hoop strains at the flank region are considered very high, and the rapidly increasing rate of the accumulated strains indicates the occurrence of fracture at the flank (Fig. 22).

Fig. 22: Strains at the elbow flank: (a) Longitudinal direction, (b) Hoop direction

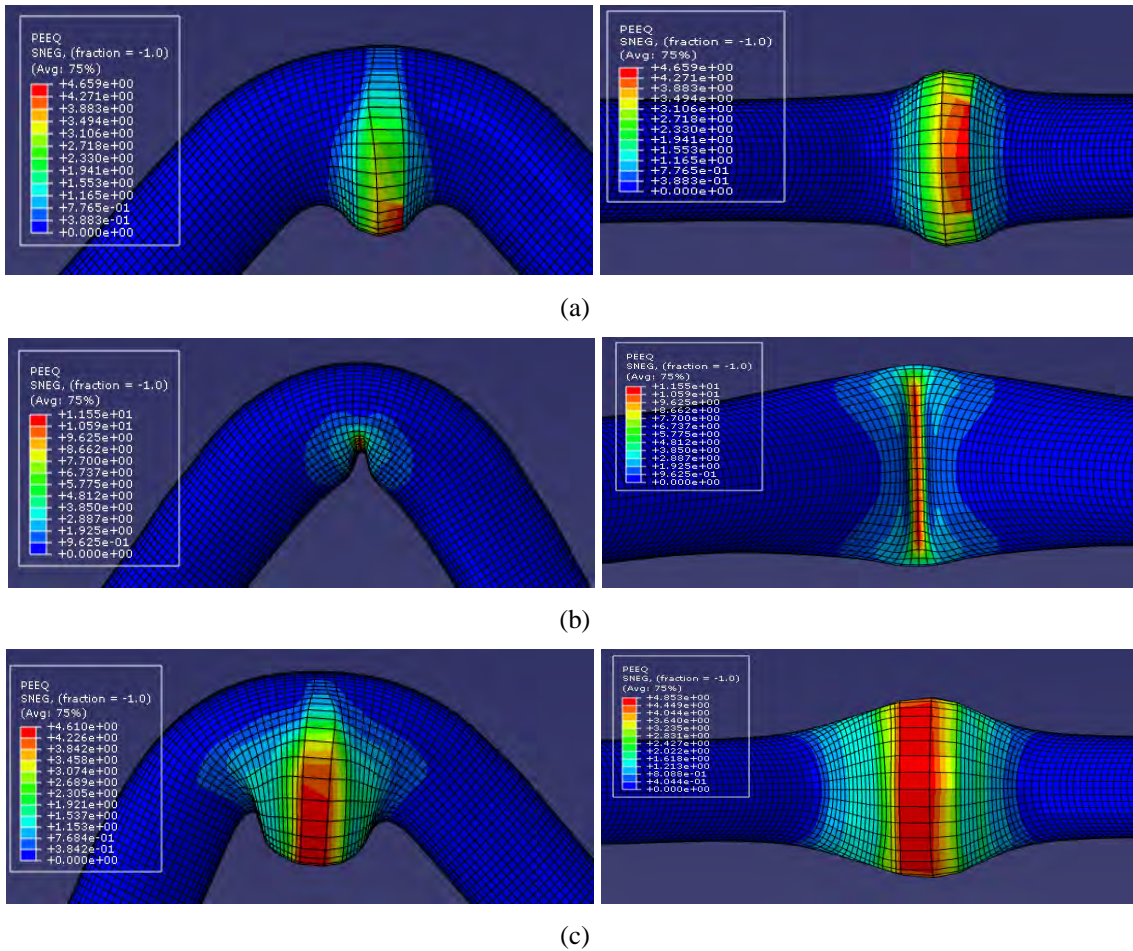

Fig. 23: Plastic deformation distribution at the end of the loading history: (a) ISO, (b) LK and (c) NLK model predictions

Another issue examined by the present numerical simulation is whether the loading sequence influences the total specimen behavior. In all the previously analyses the loading history starts with the application of a closing moment. This sequence is now reversed and the elbow specimen is subjected to an opening moment first. In the followings, the case of ± 300

mm end-displacement without pressure is presented. Similar results and conclusions are valid for the other cases examined

As in Fig. 24 to 26, the elbow performance presents the same characteristics as those presented in Fig. 13 to 15. The direct comparison between these two sets of Figures shows that only minor discrepancies exist mainly in terms of the predicted strain values. The most important one is that the ISO model predicts large strain values in the hoop direction from the first loading cycles instead of the last loading cycles as shown in Fig. 15 (b) and 26 (b). The other results for all the plasticity models adopted are only shifted by the difference in phase of the loading cycles. Finally, the deformation modes predicted by the three models are similar to those presented in Fig. 12.

6 DESIGN IMPLICATIONS

The design of process piping elbows is conducted using ASME B31.3 [29] and EN 13480-3 [30]. In both Standards the loading conditions are categorized as sustained and occasional and different design requirements are applied for each load category. In this section, using appropriate design provisions from B31.3 and EN 13480-3 and employing the numerical results the interaction between pressure and bending moment is determined.

Strong cycling loading conditions are possible to exist when severe earthquakes strike industrial facilities containing elbow specimens as the one analyzed in the present study. Therefore the applied cyclic loading is considered as occasional loading and the corresponding design rules of these two standards should be considered, as follows.

According to the B31.3 standard, in the case of occasional loading acting on an element, the sum of the longitudinal stresses, S_L , due to sustained loads, such as pressure and weight, and of the stresses produced by occasional loads, such as wind or earthquake, may be as much as 1.33 times the basic allowable stress which is given in the relevant Appendix A. In an equation form, this requirement can be written as:

$$S_L + S_{L,Occ.} \leq 1.33S_h \quad (5)$$

S_L can be defined as: $S_L = pD / 4t$ assuming that only pressure loading and no bending loading is applied from the sustained loading case. It is worth-mentioning that there is no given formula in this standard for the calculation of the longitudinal stresses due to pressure loads. The quantity $S_{L,Occ.}$ is defined for in-plane bending as:

$$S_{L,Occ.} = \frac{(i_i M_i)}{Z}, \quad i_i = \frac{0.9}{\left(\frac{tR_1}{r_2^2}\right)^{2/3}}, \quad Z = \frac{\pi(D_o^2 - D_i^2)}{32D_o} \quad (6)$$

where i_i is the intensification factor given in Appendix D, R_1 is the bend radius, r_2 is the elbow mean radius, D_o and D_i are the outer and inner elbow diameter respectively. Finally, the allowable stress value S_h for all the range of the operation temperatures is given in Appendix A equal to 151.68 MPa (22 Ksi).

Similar provisions exist in the EN13480-3 code, where the stresses due to occasional loading conditions are limited by the following equation:

$$\frac{p_c d_o}{4e_n} + \frac{0.75iM_B}{Z} \leq kf_h \quad (7)$$

where p_c is the calculation pressure load, d_o is the outer elbow diameter, e_n is the nominal thickness, i and Z are the intensification factor and the section modulus defined as presented above, f_h is the allowable stress for the design temperature equal to 163.3 MPa and k is a coefficient equal to 1.2 for the design basis earthquake and equal to 1.8 for safe shut-down earthquake. It is noticeable that only the EN13480-3 code has provisions for two seismic levels resulting to a less conservative overall design of the elbow members.

The normalized moment-pressure interaction diagram by the two standards described above is presented in Fig.27. In the same graph, the numerical predictions of the developed model are also presented for the closing bending case, which is considered to be more critical than the opening bending case. The corresponding moment values have been normalized by the plastic moment equal to $M_p = \sigma_y D^2 t$, while the yield pressure $p_y = 2\sigma_y D/t$ has been used to normalize the pressure values. For the simulated range of pressure level, the corresponding allowed moment by both standards is considerably lower compared with the predictions of all models. Moreover, the beneficial effect of the internal pressure acting simultaneously with the bending loading is not recognized by any of the codes examined. This results to a different interaction curve trend. More specifically, according to the allowable stress concept that both codes are based on, as the internal pressure increases, the bending capacity of the elbow decreases. On the contrary, the numerical simulation allows for the precise prediction of the geometry change due to the combination of applied loads which has significant effect on the overall member behavior.

Fig. 27: Moment-pressure interaction diagram. Code provisions and FE analysis results.

7 CONCLUSIONS

In this paper, a numerical simulation of cyclic bending of industrial steel elbows was presented. Both opening and closing moment loads have been considered acting alone or in the presence of internal pressure.

The finite element model predictions regarding the monotonic behavior of the elbow indicate that the application of closing moment governs the elbow structural behavior. Moreover, the numerical results show that the presence of internal pressure increases the moment capacity of the elbow.

The predicted elbow behavior under monotonic loading in the presence of internal pressure has been also compared with the provisions of B31.3 and EN13480-3 standards. Both standards are based on the allowable stress concept and therefore are proved to be over conservative. The numerically developed moment-pressure interaction diagram shows an increase of the elbow moment capacity when internal pressure is applied. This fact contradicts the predictions of the two code provisions reported in this study where the increase of internal pressure results to a reduction of the maximum allowed pressure.

Finally, the elbow behavior under cyclic loading conditions has been extensively presented and the corresponding plasticity model predictions have been reported. The predicted hysteresis loops vary due to the different concepts each plasticity model is based on. Nevertheless, all the model predictions indicate that ratcheting takes place at the critical locations which eventually results to extensive bulging of the member and failure of the elbow.

Keywords: Buried steel pipeline, Active fault, Nonlinear stress analysis, Plastic strains, Pipe-soil interaction

Abstract. *In the present paper the results of the analytical model for a nonlinear stress-strain analysis of buried steel pipelines at active fault crossings are analyzed and discussed versus the numerical finite element results. The analytical model is based on the partition of the pipeline into four segments. The two segments in high curvature zones on both sides of the fault are modeled as beams in bending and tension with direct account for the axial force in the equations of motion. The two other segments are treated as beams-on-elastic foundation. The interaction of the pipeline with the surrounding soil is taken into account in axial and transverse directions using bilinear soil diagrams. The nonlinearity of the pipe steel is introduced on a cross-section level assuming a bilinear stress-strain relationship. The analysis is performed iteratively as a series of elastic solutions using a secant modulus of the pipe steel. The analysis of applicability of the proposed model to various cases of pipeline-fault intersection conditions is performed through the comparison of the results obtained with the analytical model to the results of the numerical simulation of the finite element model in ANSYS. The developed finite element model uses current technology ANSYS pipe elements with account for axial, bending, shear and torsional deformations, material nonlinearity, large displacements and strain nonlinearities. The pipe-soil interaction is modeled by the nonlinear soil spring elements. The analysis of the results allows drawing the conclusion on the applicability of the proposed analytical methodology to a wide range of conditions met in practice, at least for the preliminary assessment. The limitations of the analytical methodology and possible further refinements are also discussed.*

1 INTRODUCTION

The advancement of the gas-transport systems to the regions of high seismic activity reinforces the actuality of the research in the field of seismic analysis and design of main gas pipelines. The research methods in stress-strain analysis of pipelines can be generally divided into analytical and numerical. Giving credit for a progress in numerical finite and boundary element methods, we still have to admit the actuality of analytical models which are well suited for preliminary analysis and provide basis for more advanced numerical techniques.

It is well known that permanent ground deformation caused by relative displacements of adjacent parts of earth's crust along the fault is among the most dangerous earthquake effects and can result in a pipe failure [1]. The first paper considering a fault crossing problem analytically was published by Newmark and Hall [2]. A case of pipeline intersecting a strike-slip fault at an angle $\beta \leq \pi/2$ is studied. The axial strain component is considered to have the major effect on the pipeline. The average axial tensile strains along the effective unanchored length are calculated using the pipeline elongation due to the axial component of the fault movement and due to the second-order effects caused by lateral component of the fault movement. Since the bending stiffness and lateral pipe-soil interaction is neglected and the axial strains are averaged over the unanchored length, the maximal strains are underestimated.

Later, Kennedy et al. [3] extended the methodology proposed in [2]. The bending strains are introduced into the model based on a cable schematization. Given this assumption, adequate results can only be obtained in the case of large fault movements in projection on the axial pipe direction producing substantial axial tensile strain component.

Further advancements to the analytical models for a pipeline crossing strike-slip fault were made by Wang and Yeh [4]. Their model is based on a division of a pipe into four segments. The two segments in high curvature zone on both sides of the fault trace act as circular arcs, while the two other segments are considered as beams-on-elastic-foundation. The most significant shortcoming of the model is that the influence of axial force on the bending stiffness is neglected. Also, according to the model, the critical combination of the axial and bending strains develops at the ends of high curvature zones on each side of the fault. On the contrary, it can be shown [5, 6] that the maximal stresses and strains develop within these zones, closer to the fault intersection point.

Recently, Karamitros et al. [5] introduced a number of substantial refinements to the above mentioned methodology. In the model, the two segments in high curvature zones are considered within the elastic beam theory taking into account the pipe-soil interaction in both axial and transverse directions. The elastoplastic behavior of the pipe steel is considered within a bilinear stress-strain relationship. The analysis is performed iteratively as a series of elastic solutions using a secant modulus of the pipe steel. The results of the developed model show good agreement with the finite element results for strike-slip fault crossings over a range of fault displacements $\Delta = 0 \div 2D$, where D is the pipe diameter, and the intersection angles $\beta = 30^\circ, 45^\circ$ and 60° .

Some essential shortcomings of the previous methodologies are addressed in the paper by Trifonov and Cherniy [6]. In particular, no symmetry condition about the intersection point is used, allowing for different types of fault kinematics to be analyzed; the tension-bending interaction is taken into account directly in the equations of motion of the two segments in high curvature zones on both sides of the fault; the contribution of transverse displacements to the axial elongation is included in calculation of axial stresses and strains. A good agreement was established between the results of the developed analytical model and finite-element model for a strike-slip and normal slip fault crossing problems.

In the present work, the application of model of the paper [6] to a strike-slip fault crossing problem is analyzed in comparison to the finite element results. In the following section the analytical model is briefly discussed. Next, in section 3 the numerical finite element model developed for the verification of the analytical methodology is presented, and the comparison of the analytical to numerical finite element results is performed. The limitations of the analytical model are also discussed. Finally, in section 4 some additional corrections to the analytical model are introduced and discussed in connection with the finite element results.

2 ANALYTICAL MODEL OF A PIPELINE CROSSING ACTIVE FAULT

2.1 Structural model of a pipeline in the fault zone

Following the papers [5, 6], a pipeline is partitioned into four segments shown in figure 1. Point B represents the intersection of the pipeline with the fault trace; points A and C are the closest points of the pipeline axis with zero transverse displacements. Points A' and C' are at a distance from A and C that is sufficient for the attenuation of transverse displacements.

As the pipeline transverse displacements relative to surrounding soil are small on the segments AA' and CC', the pipe-soil interaction can be considered as elastic and a beam-on-elastic foundation theory can be applied. The pipeline transverse displacements $w(x)$ follow the equation

$$EI \frac{d^4 w}{dx^4} + kw = 0 \quad (1)$$

where x is the coordinate measured from the point A (or C), E is the elastic modulus, I is the moment of inertia of the cross-section, k is the stiffness parameter of the elastic foundation. Assuming that soil resistance in considered transverse direction is characterized by a bi-linear diagram with the displacement at yield w_u and corresponding force q_u , the stiffness of the elastic foundation is calculated as $k = q_u / w_u$.

The solution of the Eq. (1) is obtained with the use of the boundary conditions $w = 0$ for $x = 0$ and $w \rightarrow 0$ for $x \rightarrow \infty$:

$$w(x) = Ce^{-\lambda x} \sin \lambda x \quad (2)$$

where $\lambda = (k / 4EI)^{1/4}$.

The segments AB and BC are analyzed as elastic beams loaded with the axial force F and distributed transverse load q . The intensity of the distributed load is equal to the limit value of pipe-soil interaction force per unit length for considered transverse pipe displacement direction relative to surrounding soil. This assumption is valid for the strike-slip fault crossing. In case of normal-slip fault with relatively small displacements an alternative partition accounting for elastic soil behavior on the segment with downward relative pipeline movement gives better results. The details on this case are given in the paper [6]. In the following, we will concentrate on the analysis of a strike-slip crossing problem.

The equilibrium equation for the beam under combined bending-tension can be obtained considering the equilibrium of the differential line element in the deformed configuration loaded with the constant axial force F and uniformly distributed transverse load q :

$$EI \frac{d^4 w}{dx^4} - F \frac{d^2 w}{dx^2} = q \quad (3)$$

Figure 1: Pipeline model at active fault crossing.

The solution of Eq. (3) can be written in the form of initial parameters:

$$w(x) = w(0) + \phi(0) \frac{\sinh \alpha x}{\alpha} + \frac{M(0)}{EI\alpha^2} [\cosh \alpha x - 1] + \frac{V(0)}{EI\alpha^3} [\sinh \alpha x - \alpha x] + \frac{q}{F} [(\cosh \alpha x - 1)/\alpha^2 - x^2/2] \quad (4)$$

where $\alpha^2 = F/EI$. The parameters $\phi(0)$, $M(0)$, and $V(0)$ are the rotation angle, bending moment, and transverse force for the section with $x = 0$.

The unknown parameters in Eq. (2) and (4) written for the corresponding pipe segments together with the unknown length parameters L_1 and L_2 , are found from the boundary conditions on the junction points A, B, and C. The resulting system of nonlinear algebraic equations can be solved numerically as shown in [6]. In the case of a strike-slip fault the pipeline-soil interaction forces acting on the segments AB and BC are identical. The use of symmetry condition in this case simplifies the resulting system of equations which reduces to a single nonlinear equation solved by the Newton-Raphson technique.

After the solution $w(x)$ is obtained, other quantities, such as rotation $\phi(x) = w'(x)$, bending moment $M(x) = EIw''(x)$ and transverse force $V(x) = EIw'''(x) - Fw'(x)$ can be evaluated (here the notation $w' = dw/dx$ is used). Also, the maximum bending moment $|M_{\max}|$ can be derived for each segment. Further details on the structural model and solution procedure can be found in [6].

2.2 Evaluation of the axial stress and strain

The axial force in Eq.(3) is assumed constant and equal to the axial force at the intersection of the pipeline with the fault trace. The latter is calculated by equating the geometrically required and the stress-induced (available) pipeline elongations.

The geometrically required elongation ΔL_{req} results from the fault movement in the axial direction and the pipeline elongation due to bending:

$$\Delta L_{req} = \Delta \cos \beta + \frac{1}{2} \int_x (w')^2 dx \quad (5)$$

where Δ is the fault displacement, β is the fault intersection angle. Integration in the second term in Eq. (5) is performed over the curved segments AB and BC.

The available elongation ΔL_{av} is evaluated by integrating the axial strains $\varepsilon_a(x)$ over the unanchored length L_{anch} , characterized by relative slippage of the pipe and the surrounding soil:

$$\Delta L_{av} = 2 \int_0^{L_{anch}} \varepsilon_a(x) dx \quad (6)$$

In Eq. (6), it is assumed that the elongation on both sides of the fault trace is identical.

Denoting the axial force and axial stress developing at the fault intersection point by F_a and σ_a , the unanchored length L_{anch} can be calculated as:

$$L_{anch} = F_a / t_u = \sigma_a A_s / t_u \quad (7)$$

where A_s is the pipe cross-sectional area, and t_u is the limit pipe-soil interface friction.

The axial strain distribution over the length L_{anch} is obtained from the axial stress distribution

$$\sigma(x) = \sigma_a - t_u x / A_s \quad (8)$$

assuming a bilinear stress-strain relationship for the pipe steel:

$$\varepsilon_a(x) = \begin{cases} \sigma(x) / E, & \sigma(x) \leq \sigma_Y \\ \sigma_Y / E + (\sigma(x) - \sigma_Y) / E_t, & \sigma(x) > \sigma_Y \end{cases} \quad (9)$$

In Eq. (9), E is the elastic modulus, E_t is the hardening parameter (plastic modulus), σ_Y is the yield stress.

Combining Eqs. (6), (8), and (9) and using the condition $\Delta L_{av} = \Delta L_{req}$, the axial stress at the fault intersection can be evaluated as [5, 6]:

$$\sigma_a = \begin{cases} [Et_u \Delta L_{req} / A_s]^{1/2}, & \Delta L_{req} \leq \sigma_Y^2 A_s / (Et_u) \\ \sigma_Y (1 - E_t / E) + [\sigma_Y^2 ((E_t / E)^2 - E_t / E) + E_t t_u \Delta L_{req} / A_s]^{1/2}, & \Delta L_{req} > \sigma_Y^2 A_s / (Et_u) \end{cases} \quad (10)$$

2.3 Modeling of the interaction between the axial and bending strains on sectional level

If the plastic strains develop in the cross-section with the maximum bending moment, the axial and bending strains become interconnected. In particular, axial strains in the vicinity of the corresponding cross-section increase locally, ensuring the equilibrium between the stress-integrated axial force and the applied axial force. To account for this effect, the stress and strain distributions over the cross-section have to be considered [6].

Under the assumption of plane cross-sections, the strain distribution on the cross-section with the maximum bending moment is given by

$$\varepsilon = \varepsilon_a + \varepsilon_b \cos \theta \quad (11)$$

where ε_a is the axial strain, and $\varepsilon_b = M_{\max} D / (2EI)$ is the maximal bending strain, θ is the polar angle of the cross-section measured from the vertical diameter (figure 2).

Figure 2: Stress and strain distribution over the cross-section.

In figure 2 the yield strain is denoted by ε_Y and the angles $\varphi_{1,2}$ define the portions of the cross-section that undergo yielding:

$$\varphi_{1,2} = \begin{cases} \pi, & \frac{\varepsilon_Y \mp \varepsilon_a}{\varepsilon_b} < -1 \\ \arccos\left(\frac{\varepsilon_Y \mp \varepsilon_a}{\varepsilon_b}\right), & -1 \leq \frac{\varepsilon_Y \mp \varepsilon_a}{\varepsilon_b} \leq 1 \\ 0, & 1 < \frac{\varepsilon_Y \mp \varepsilon_a}{\varepsilon_b} \end{cases} \quad (12)$$

Accordingly, the distribution of stresses takes the form:

$$\sigma = \begin{cases} \sigma_Y + E_t(\varepsilon - \varepsilon_Y), & 0 \leq \theta < \varphi_1, \\ E \varepsilon, & \varphi_1 \leq \theta \leq \pi - \varphi_2, \\ -\sigma_Y + E_t(\varepsilon + \varepsilon_Y), & \pi - \varphi_2 < \theta \leq \pi. \end{cases} \quad (13)$$

The axial force and bending moment are evaluated by the stress-integration over the cross-section with the use of Eq. (11) – (13):

$$\begin{aligned} F(\varepsilon_a, \varepsilon_b) &= 2 \int_0^\pi \sigma R_m t d\theta = \\ &= 2 R_m t [E \pi \varepsilon_a - (E - E_t)(\varphi_1 + \varphi_2) \varepsilon_a + (E - E_t)(\varphi_1 - \varphi_2) \varepsilon_Y - \\ &\quad - (E - E_t)(\sin \varphi_1 - \sin \varphi_2) \varepsilon_b], \end{aligned} \quad (14)$$

$$\begin{aligned}
 M(\varepsilon_a, \varepsilon_b) &= 2 \int_0^\pi \sigma R_m t R_m \cos \theta d\theta = \\
 &= \frac{1}{2} R_m^2 t [2E \pi \varepsilon_b - 4(E - E_t)(\sin \varphi_1 - \sin \varphi_2) \varepsilon_a + \\
 &+ 4(E - E_t)(\sin \varphi_1 + \sin \varphi_2) \varepsilon_y - 2(E - E_t)(\varphi_1 + \varphi_2) \varepsilon_b - \\
 &- (E - E_t)(\sin 2\varphi_1 + \sin 2\varphi_2) \varepsilon_b].
 \end{aligned} \tag{15}$$

Here, the notation $R_m = (D - t)/2$ is used.

For the evaluation of the axial strain in the cross-section with the maximum bending moment the equilibrium condition between the applied axial force and the one obtained by the integration over the cross-section is used:

$$F(\varepsilon_a, \varepsilon_b) - F_a = 0 \tag{16}$$

The Eq. (16) can be treated as a nonlinear function of ε_a and solved iteratively.

To satisfy the moment equilibrium condition

$$M(\varepsilon_a, \varepsilon_b) - M_{\max} = 0 \tag{17}$$

an iterative solution is performed using the secant Young's modulus derived from the Eq. (17):

$$E_{\text{sec}} = \frac{M(\varepsilon_a, \varepsilon_b) D}{2I\varepsilon_b} \tag{18}$$

The specified procedure is applied separately to the segments AB and BC, yielding $\varepsilon_{a1}, \varepsilon_{a2}$ and $E_{\text{sec}1}, E_{\text{sec}2}$, which are applied on the next iteration.

2.4 The solution algorithm

The described model can be implemented in a computer program according to the algorithm given below. For a general fault kinematics the algorithm consists of the following steps (superscript k stands for the iteration number):

1. Given the fault kinematics and the intersection angle, calculate the components of fault displacements in projection on the pipe coordinate system Δx and Δy .
2. Using the transverse displacements from the previous iteration $w_1^{(k-1)}(x)$ and $w_2^{(k-1)}(x)$, calculate the elongation due to the pipe transverse displacements, the required elongation $\Delta L_{\text{req}}^{(k)}$ and axial force $F_a^{(k)}$ (section 2.2).
3. Performing the solution of the structural problem (section 2.1) using the appropriate secant moduli $E_{\text{sec}1}^{(k)}$ and $E_{\text{sec}2}^{(k)}$, evaluate the lengths of the segments AB and BC $L_1^{(k)}$ and $L_2^{(k)}$. Evaluate the transverse displacements $w_1^{(k)}(x)$ and $w_2^{(k)}(x)$.
4. Find the maximum absolute values of the bending moments on segments AB and BC $M_{1\max}$ and $M_{2\max}$. Evaluate the corresponding maximum bending strains ε_{b1} and ε_{b2} .
5. Evaluate the maximum axial strains on segments AB and BC ε_{a1} and ε_{a2} performing an iterative solution of Eq.(16) for segments AB and BC.
6. Evaluate bending moments $M_1^{(k)}(\varepsilon_{a1}, \varepsilon_{b1})$ and $M_2^{(k)}(\varepsilon_{a2}, \varepsilon_{b2})$ on segments AB and BC.

7. Check the moment convergence. If the convergence criterion is satisfied, proceed to the next load step or terminate the solution (step 8). Otherwise, calculate secant moduli $E_{\text{sec}1}^{(k+1)}$ and $E_{\text{sec}2}^{(k+1)}$ for segments AB and BC and go to the next iteration (step 2).
8. Output the results and stop the solution.

The initial displacement functions $w_1^{(0)}(x)$ and $w_2^{(0)}(x)$ used on the first iteration ($k = 1$) for calculation of $\Delta L_{\text{req}}^{(1)}$ and $F_a^{(1)}$ are taken as zero, if the total fault displacement is applied in one step, or as the displacements calculated on the previous load step, if the total fault displacement is applied in several steps. The initial values of the secant moduli $E_{\text{sec}1}^{(1)}$ and $E_{\text{sec}2}^{(1)}$ are equal to the elastic modulus E .

The convergence of the described algorithm observed during numerical modeling is rather good for different fault intersection angles and total fault displacements. The number of iterations necessary to meet the convergence criteria ranged from 1 to 7.

3 THE RESULTS OF THE ANALYTICAL MODEL VERSUS FINITE ELEMENT MODEL

3.1 Finite element pipeline model

To analyze the applicability of the analytical model to practical cases of pipeline-fault intersection conditions, a finite element model is developed. The finite element model treats a structural problem of pipeline crossing active fault more rigorously, thus, allowing the assessment of the influence of simplifying assumptions adopted in the analytical model on the stress and strain predictions. The finite element model is implemented in ANSYS 12.1 [7]. A pipeline segment with the length 1000 m is considered. The fault intersection point is placed at the middle of the segment. The pipeline is clamped at the end on the stationary part of the fault and free at the end on the moving part of the fault.

The pipeline segment is meshed by 1000 PIPE288 elements with the concentration of elements in the near-fault zone (taken as 50 m on both sides of the fault). The PIPE288 is a three-dimensional element based on Timoshenko beam theory with axial, bending, shear and torsion deformations included. Large displacements, strains, material nonlinearity are also accounted for.

Figure 3: A fragment of the finite element model.

The pipe-soil interaction is modeled by nonlinear spring COMBIN39 elements oriented in the three orthogonal directions. The element allows for arbitrary nonlinear force-deflection curve to be used. In the analysis, an elastic-perfectly plastic diagrams with characteristics calculated according to ALA-ASCE [8] guidelines were used.

A fragment of the finite element model is depicted in figure 3.

The total fault displacement is applied in 50 steps with automatic substepping and convergence control. The fault displacement components are prescribed to the free ends of the corresponding soil-spring elements on the moving part of the fault, while the soil-spring free ends on stationary part of the fault are fixed. On each step the solution quantities are output into the data files for subsequent analysis.

3.2 Numerical results for the case of strike-slip fault crossing

The numerical examples described in this section are based on the pipeline and soil data used in the papers [5, 6]. A natural gas pipeline with the external diameter $D = 0.9144$ m, wall thickness $t = 0.0119$ m is considered. The pipeline material has the following characteristics: yield stress $\sigma_y = 490$ MPa, elastic Young's modulus $E = 210$ GPa, hardening modulus $E_t = 1.088$ GPa. The pipe-soil interaction is modeled by elastic-perfectly plastic diagrams. The corresponding parameters are calculated according to the ALA-ASCE guidelines [8] for the case of medium-density sand with friction angle 36° , unit weight 18 kN/m³ and pipe burial depth equal to 1.3 m.

The fault intersection angles, taken for numerical simulation in papers [5, 6], ranged from 30° to 60° . A good correspondence of the analytical results to numerical results was observed. But from the practical viewpoint, the case of intersection angle close to 90° is an important one. Therefore, it is desirable to determine the level of accuracy of the results obtained using the proposed analytical methodology in this range of angles. The case of a strike-slip fault will be considered below as practical example.

Probably, the most representative quantity, characterizing the level of correspondence between the finite element and the analytical results, is the maximal strain in the pipe. Also, this parameter is the main characteristic used in the strain-based design procedures. Figure 4 illustrates the evolution of the maximal longitudinal strains with the fault displacement for the two values of the fault intersection angle $\beta = 30^\circ$ (a) and 90° (b). The solid line corresponds to the analytical solution while the dashed line represents the finite element solution.

Figure 4: Comparison of the analytical (solid lines) and finite element (dashed lines) solutions for the two cases of fault intersection.

Figure 5: Distributions of the transverse displacements and bending moments in the near-fault zone.

It is seen that for the case $\beta = 30^\circ$ the results are rather close in the whole range of values of the fault displacements, while for the case $\beta = 90^\circ$ the results substantially differ starting from $\Delta/D = 0.7$. The maximal difference near 40% is observed for $\Delta/D = 2$.

To understand the cause of this discrepancy, other solution quantities were analyzed. The distributions of the transverse displacements and bending moments in the near-fault zone are depicted in figure 5. The correspondence of the finite element (dashed lines) and the analytical results is rather good in both cases.

The distributions of the longitudinal strains are shown in figure 6. Total strain is a more sensitive parameter revealing substantial differences between the rigorous numerical model and approximate analytical model for the case of $\beta = 90^\circ$ (figure 6, b). Surprisingly, the closeness of the results for $\beta = 30^\circ$ (figure 6, a) is good, especially taking into account the approximate character of the analytical model and a rather complex shape of the strain distribution. The sharp drop in strains on analytical results reflects the transition to the segments AA' and CC' considered as beams-on-elastic foundation with the initial Young's modulus.

Figure 6: Distribution of the longitudinal strains in the near-fault zone.

In the case $\beta = 90^\circ$, numerical solution shows a concentration of deformations in relatively narrow zones on both sides of the fault. These zones do not side the fault intersection point but are rather at distance of several meters. As shown in figure 7 representing the finite element solution for plastic strains, the concentration of strains corresponds to the zones of plasticity. These zones are compact and pronounced for $\beta = 90^\circ$ as in this case the bending dominates, while for $\beta = 30^\circ$ a substantial axial component of strain causes a dramatic “stretching” of plastic zones.

In the analytical model the potentially plastic zones (segments AB and BC) are bounded by the fault intersection point and the nearest point with zero relative pipe-soil displacements in transverse direction. Thus, for $\beta = 90^\circ$ plastic deformations in analytical solution are spread over substantially larger length than in numerical solution. Consequently, the equivalent secant modulus is larger than the plastic modulus of the material and the maximal strains are smaller but more evenly distributed.

Figure 7: Distribution of the plastic strains in the near-fault zone (finite element solution).

Hence, in the situations when bending is the prevailing mechanism of deformation, the analytical model would underestimate the maximal strains. On the other hand, in situations when axial strains are significant, the analytical model would give reasonable maximal strain predictions. In the next section a correction of the analytical methodology is suggested and illustrated on numerical examples.

4 AN APPROXIMATE ACCOUNTING FOR THE STIFFNESS VARIATION WITHIN THE PROPOSED ANALYTICAL MODEL

4.1 The stiffness correction method

One of the simple ways to remedy the analytical results for the fault intersection angles close to 90° is based on stiffness correction within the segments AB and BC without performing any changes in the basic methodology.

For the final evaluation of strains, the initial beam is replaced by a beam with varying stiffness $EI = EI(\xi)$, where ξ is a non-dimensional coordinate within the pipeline segment. It is considered that all other loading conditions remain the same, giving an identical moment distribution along the segment. This assumption is supported by relative closeness of the moment distributions for analytical and finite element solutions shown in figure 5. Thus, it seems reasonable to state the equivalence of the bending strain energies of the initial beam with the secant stiffness and the modified beam with varying stiffness:

$$\frac{1}{2} \int_l \frac{M^2(x)}{E_{\text{sec}} I} dx = \frac{1}{2} \int_l \frac{M^2(x)}{EI(x)} dx \quad (19)$$

Next, we adopt the following approximation of the stiffness distribution:

$$EI(\xi) = aE_{\text{sec}} I - \omega(\xi)(aE_{\text{sec}} I - bE_{\text{sec}} I) \quad (20)$$

where the shape function $\omega(\xi)$ is given by

$$\omega(\xi) = \begin{cases} 0, & \xi < 0, \quad \xi > 1 \\ 16(\xi^4 - 2\xi^3 + \xi^2), & 0 \leq \xi \leq 1 \end{cases} \quad (21)$$

and

$$\xi = (x - x_{\text{max}})/l_p + 0.5 \quad (22)$$

Here, l_p is the support of the function $\omega(\xi)$, x_{max} is the position of the maximum bending moment within the segment. Parameter l_p defines the length of the concentration zone.

For $x = x_{\text{max}}$ we have: $\xi = 0.5$, $\omega(\xi) = 1$ and $EI(\xi) = bE_{\text{sec}} I$. For $x = 0$ and $x = L$ (where L is the segment length) under the condition $l_p < L$ we have $\omega(\xi) = 0$ and $EI(\xi) = aE_{\text{sec}} I$. Thus, the amount of stiffness variation is controlled by the parameters a and b .

As the strain concentration is connected to the strain variability within the segment and becomes higher with the strain growth, it is natural to consider the dependence of the parameters a and b on:

- Maximal bending strains within the segment ε_b ;
- The parameter of unevenness taken as the ratio of average bending strains to the maximum bending strains:

$$\zeta = \varepsilon_{b,av} / \varepsilon_b \quad (23)$$

where the average bending strain is calculated as

$$\varepsilon_{b,av} = \frac{1}{L} \int_0^L \varepsilon_b(x) dx \quad (24)$$

The parameter of unevenness is plotted on figure 8, a for various fault intersection angles based on the analytical solution. It is seen that this characteristic helps to differentiate the cases where the concentration is insignificant and the ones with substantial strain concentration for large fault displacements.

Picking out the bounding levels ζ_1 and ζ_2 , the following secondary parameter of unevenness is introduced:

$$C_1 = \begin{cases} a_1 \zeta + b_1, & \zeta < \zeta_1 \\ 1, & \zeta \geq \zeta_1 \end{cases} \quad (25)$$

where

$$a_1 = [C_1(\zeta_1) - C_1(\zeta_2)] / [\zeta_1 - \zeta_2], \quad b_1 = [\zeta_1 C_1(\zeta_2) - \zeta_2 C_1(\zeta_1)] / [\zeta_1 - \zeta_2] \quad (26)$$

Here $C_1(\zeta_1)$ and $C_1(\zeta_2)$ are the values of the parameter C_1 at bounding levels taken as $C_1(\zeta_1) = 1$ and $C_1(\zeta_2) = 2$. The expression (25) is illustrated in figure 8, b.

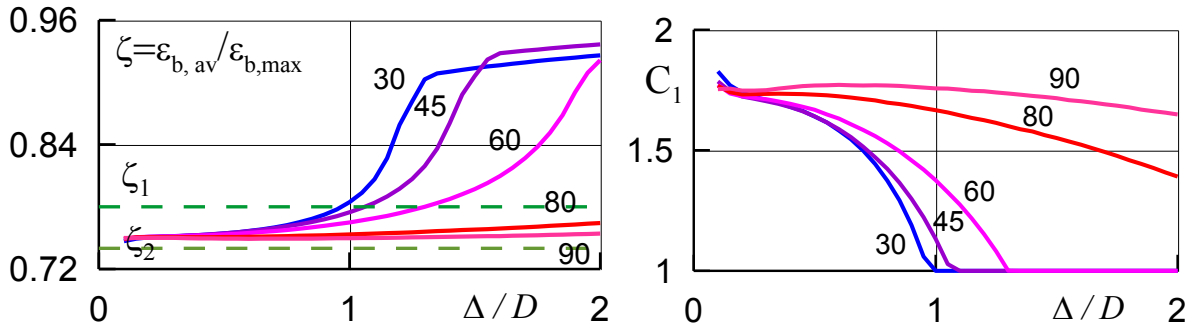

Figure 8: (a) The parameter of unevenness for various fault intersection angles. (b) Secondary parameter of unevenness.

To mitigate C_1 in the range of small strains the following parameter is used:

$$C_2 = \varepsilon_b / \varepsilon_{b,1} \quad (27)$$

where $\varepsilon_{b,1}$ – some normalizing level taken in the following equal to 0.007. The numerical values of ζ_1 , ζ_2 , $C_1(\zeta_1)$ and $C_1(\zeta_2)$ are based entirely on analytical solution. The numerical value of $\varepsilon_{b,1}$ defines the amount of strain concentration. Actually, this is the only parameter which is fitted using the finite element results. Finally, the following characteristic of the strain concentration is derived:

$$C_3 = \begin{cases} C_1 C_2, & C_1 C_2 > 1 \\ 1, & C_1 C_2 \leq 1 \end{cases} \quad (28)$$

The evolution of this characteristic with the fault displacement is shown in figure 9.

Figure 9: The characteristic of the strain concentration.

The application of the obtained strain concentration parameter within the framework of Eq. (20) is given by the relations

$$a = C_3, \quad b = 1/C_3 \quad (29)$$

Thus, in the strain concentration region the original secant stiffness is reduced in C_3 times, while outside this region it is increased in C_3 times. The proposed relations are rather approx-

imate but at least qualitatively represent the character of the actual stiffness distribution. The application of the proposed correction technique is illustrated in the following section.

4.2 Corrected solution for various fault intersection angles

Using the proposed correction procedure, the following steps within the basic solution algorithm must be performed:

1. Given the basic solution for the prescribed fault displacement, the parameters in Eq. (20) – (22) are determined.
2. The corrected distribution of the bending strains is calculated according to the relation

$$\varepsilon_b(x) = \frac{M(x)}{EI(x)} \frac{D}{2} \quad (30)$$

3. The corrected maximal bending and total strains are then evaluated:

$$\varepsilon_b = \frac{M(x_{\max})}{EI(x_{\max})} \frac{D}{2}, \quad \varepsilon_{\max} = \varepsilon_b + \varepsilon_{a,\max} \quad (31)$$

The strain correction procedure was applied to the pipeline-fault intersection analysis of section 3.2. Figure 10 illustrates the corrected stiffness distribution for the case $\beta = 90^\circ$, $\Delta/D = 2$. The lengths of the curved segments AB and BC were $L_1 = L_2 = L = 9.91$ m. The parameters of Eq. (20) – (22) were found to be $C_3 = 2.18$, $l_p = 6.05$ m.

Figure 10: The corrected stiffness distribution on segments AB and BC for $\beta = 90^\circ$, $\Delta/D = 2$.

Figure 11 illustrates the application of the correction procedure to the analytical solution for crossing angles $\beta = 30^\circ$, 45° , 60° , 80° and 90° . The maximal strains obtained with analytical model without correction (curves 1), analytical model with strain correction (curves 2), and finite element model (curves 3) are plotted against the fault displacement. It can be noted that the suggested correction procedure substantially improves the maximal strain assessment for crossing angles close to 90° with slight overestimate for small and moderate crossing angles.

In figure 12 the comparison of the bending strain distributions in the near fault zone is presented for $\Delta/D = 0.5, 1$ and 2 m. The numbering of curves corresponds to the figure 11. It can be concluded that the corrected strain distribution follows the exact (finite element) strain distribution quite closely for all three values of the fault displacement. In particular, for moderate strains the plastic strains are small and strain concentration is not observed. As the plastic strains caused by bending become large, the unevenness of strain distribution also grows and the effect of strain concentration is accounted for.

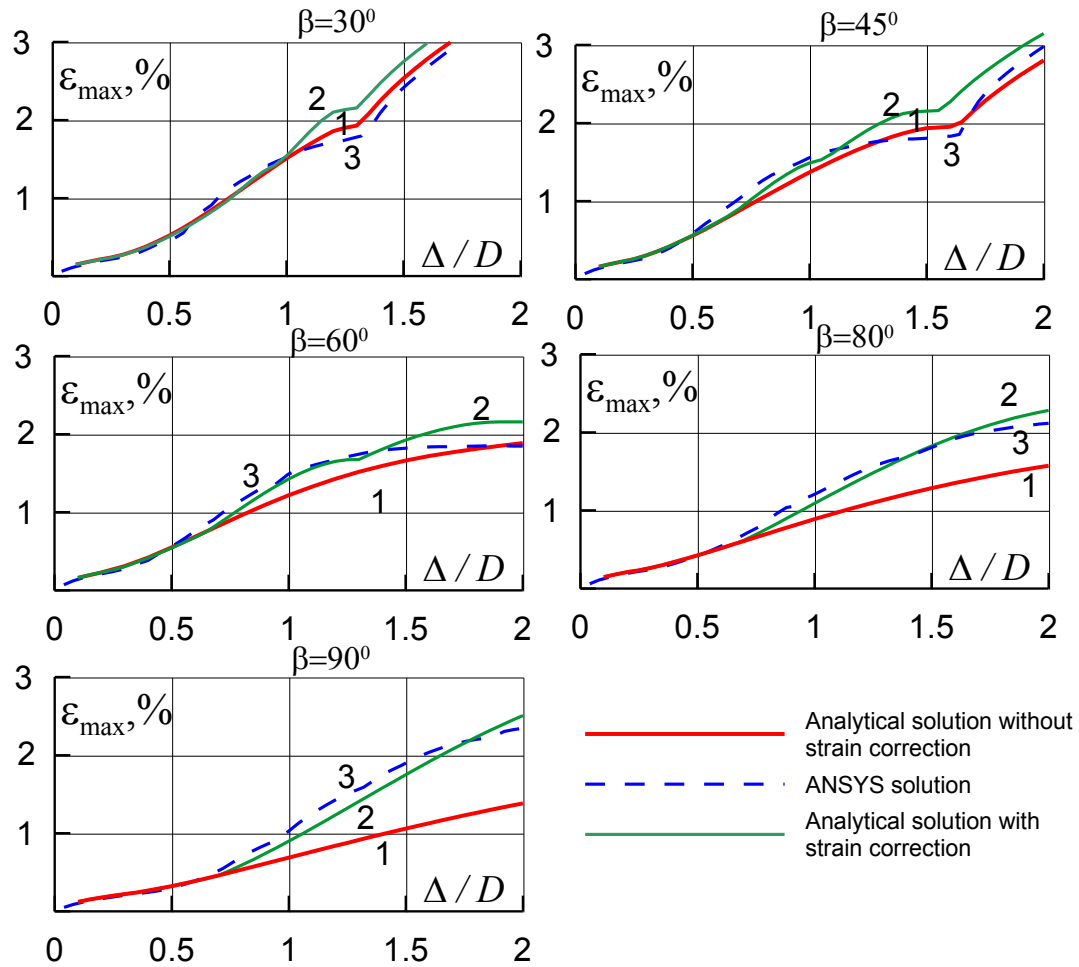

Figure 11: Evolution of the maximal strains with the fault displacement for different fault intersection angles.

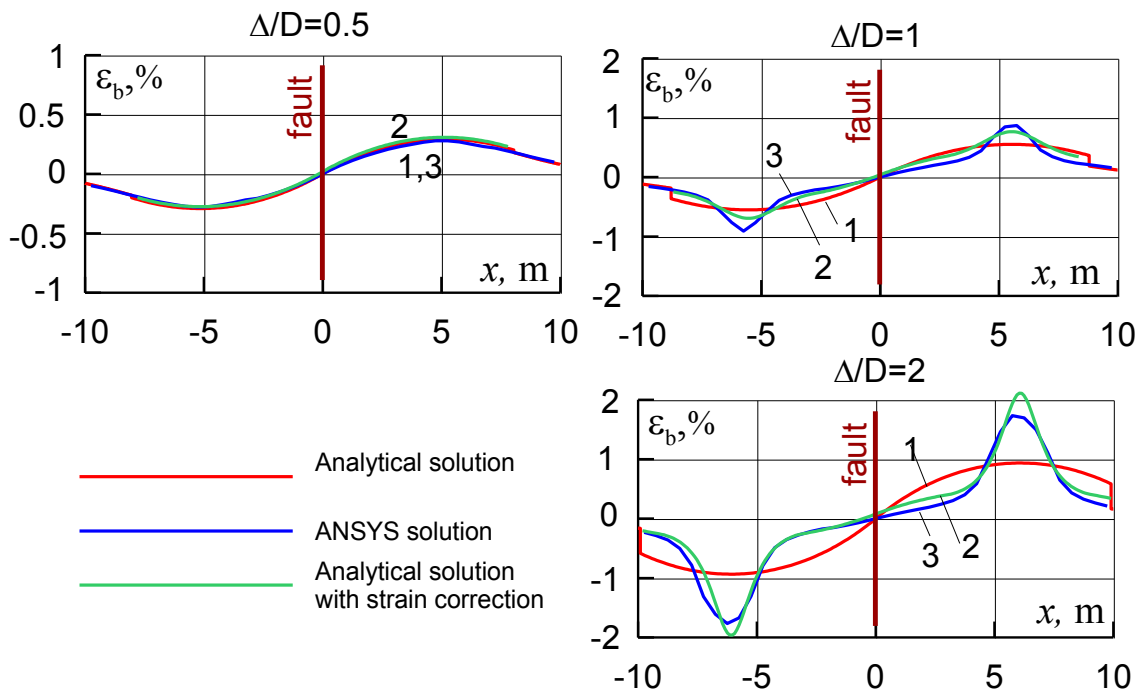

Figure 12: Bending strain distributions in the near fault zone for the case $\beta = 90^\circ$.

5 CONCLUSIONS

The analytical model for stress-strain analysis of pipelines crossing active faults described in paper [6] is outlined. The comparison of the numerical results obtained with the analytical model to the results of a more rigorous finite element model is performed for the case of strike-slip fault crossing at various intersection angles. The detailed analysis of the strain distributions in the near fault zone revealed the limitations of the analytical model. In particular, for the fault crossing angle close to 90^0 the difference in maximal strains is substantial for large fault displacements.

Based on the performed analysis, a strain correction procedure is suggested. The results of the numerical simulation with the use of strain correction show good correspondence with the finite element results in the range of fault intersection angles from 30^0 to 90^0 and fault displacements from 0 to $2D$ (where D is the pipe diameter). Thus, it can be concluded that the suggested procedure of strain correction extends the applicability of the original analytical model to the practically important case of pipeline crossing active fault at an angle close to 90^0 . The main advantage of the proposed procedure is its simplicity and direct applicability to the original pipeline model. The main drawbacks, as they are seen to the authors, are the mostly empirical character of the correction procedure and the need to use an exact numerical solution for preliminary calibration of the strain correction parameters.

Keywords: Unanchored tanks, shell-base connection, cyclic tests, uplifting of tanks.

Abstract. *When an unanchored tank is subjected to strong motion, the impulsive mass of the contained liquid generates a moment which if strong enough could cause partial uplift of the tank's base plate. As the tank undergoes uplifting, the shell-base welded connection is subjected to cycles of rotation which could lead to its failure. To address this issue, the Eurocode and the New Zealand's recommendations limit the rotation amplitude that the shell-base connection of a tank may undergo to 0.2 radians. This limit is obtained from the following two assumptions: (1) a plastic hinge with a length equal to twice the thickness of the base plate forms at the base plate, next to the connecting weld, and (2) the maximum strain that can be sustained by the base plate is 5%. While these two assumptions are reasonable and have been the state of practice for many years, no research work is believed to exist backing these two assumptions and therefore the 0.2 radians limit. For this reason, an experimental research was conducted to determine the real rotational capacity of shell-base welded connections found in tanks. A total of 24 shell-base connections were tested considering the bending and membrane stresses that develop at the base plate when uplift occurs. Constant amplitude tests were carried at different amplitudes of rotation in order to create curves of rotation versus number of cycles to failure. The main finding from this investigation is that the current limit of 0.2 radians is very conservative and that a limit of 0.4 radians would be more realistic.*

1 INTRODUCTION

Unanchored steel tanks are widely used to store water, gasoline and other petroleum-derived liquids. As these tanks are not anchored to the ground, they may be subjected to sliding or rocking motion. Rocking of the tank implies that the wall (shell) uplifts from the ground, causing a rotation at the junction of the shell-base connection. Design codes allow tanks to be unanchored [1, 2], however, they set a limit in the rotation amplitude that the connection may undergo. The Eurocode [1] and the New Zealand's recommendations [2] set the limit to 0.2 radians. This limit is based on two assumptions: (1) a plastic hinge with a length of twice the thickness of the base plate forms at the base plate, next to the shell-base joint, and (2) that the maximum strain at the plastic hinge is 5%. The allowed plastic rotation in the connection, θ_p , is then computed from these two assumptions, by means of equation 1.

$$\theta_p = \int_0^{2t} k \cdot dx = \left(\frac{\varepsilon}{t_{base}/2} \right) \cdot 2 \cdot t_{base} = \left(\frac{0.05}{t_{base}/2} \right) \cdot 2 \cdot t_{base} = 0.2 \text{ rad} \quad (1)$$

where dx is the length of the plastic hinge ($2t_{base}$), k is the curvature of the section ($\varepsilon/(t_{base}/2)$), ε is the maximum strain (5%) and t_{base} is the thickness of the base plate. A typical shell-base connection of a steel tank showing the assumed plastic hinge length and strain distribution is shown in Figure 1.

Figure 1: Shell-base connection.

The New Zealand's recommendations state that the assumptions that lead to a 0.2 radians limit should be conservative for a base plate adjacent to a well prepared weld. While the assumptions are conservative and seem reasonable, no experimental work was done to verify these limits. For that reason, an experimental work was conducted to determine the rotational capacity of the shell-base connection.

This paper summarizes the findings from the experimental work conducted on the shell-base connections. An introduction explaining the development of the current 0.2 radians limit is presented in Section 1. Section 2 presents the specimens used for testing. The loading protocol and the tests matrix are presented in Section 3. The test setup is presented in Section 4. Section 5 presents the results. Section 6 applies the findings from the experiments to estimate the rotational capacity of the connection. The conclusions are presented in Section 7.

2 SPECIMENS

Specimens were fabricated from one old tank built in 1961 and located in the city of Konolfingen, Switzerland. In addition, new specimens were fabricated in order to allow for more parameters (e.g., thickness, condition of specimen) to be tested. The new specimens were fabricated by a steel fabricator well acquainted with the fabrication process of steel tanks. Figure 2 shows two different specimens being tested. Note that the specimens are rotated 90 degrees, thus, the base is vertical and the wall is horizontal. This is explained in Section 4. 24 specimens were tested; these were divided in four types, depending on the shell-base thickness and the condition of the specimen (old vs. new). Table 1 summarizes the specimens used, their base and wall (shell) thickness, the weld size, and their condition.

Figure 2: Specimens being tested; left, view from “inside” of tank; right, view from “below” the tank’s base plate.

Type	No. of specimens	Base thickness, t_{base} [mm]	Wall thickness, t_{wall} [mm]	Weld size [mm]	Condition
1	8	6	10	4	New
2	6	8	12	6	New
3	4	10	15	7	New
4	6	7	8	7	Old

Table 1: Specimens used for experiments.

3 LOADING PROTOCOL AND TEST MATRIX

3.1 Loading protocol

When a tank undergoes uplifting of its base, the rotation induced at the shell-base connection is first resisted by bending at the base, in the region next to the weld. However, if the rotation is sufficiently large and causes yielding, the subsequent uplifting is resisted by membrane action of the base plate. The stress developed by the membrane action is normally less than 10% of the material’s yield strength, for rotations less than 0.5 radians. In addition to bending and membrane loading, circumferential compressive stresses are also developed in the base plate. These stresses may be significant for large deformations, however, that is not

the case during tank uplift. In order to have a realistic scenario, both bending and tensile (membrane) loading were considered for all tests.

Experiments were loaded using two levels of membrane loading, either 10% or 50% of the specimen's base plate yield strength. While the real behavior is expected to be less than 10% of the yield strength, 50% was also studied to observe the behavior of the connection under such conservative scenario. The tests were performed at three different levels of rotation: 0.2, 0.3 or 0.4 radians. All three series were subjected to initial cycles at 0.02, 0.03, 0.05, 0.07 and 0.1 radians as shown in Figure 3. The first series continued with three cycles at 0.2 radians followed by cycles at 0.3 radians until failure. The second series continued with cycles at 0.2 radians until failure. Finally, the third series continued with three cycles at 0.2 radians, 3 cycles at 0.3 radians, and cycles at 0.4 radians until the specimen failed. Failure was achieved when total rupture of the specimen occurred.

Figure 3: Loading protocol.

3.2 Test matrix

Different parameters of interest were studied in the experimental program. Specimens with different thicknesses were used to study how the thickness of the base plate affected the maximum number of cycles resisted by the specimen. The axial load applied to the bottom of the tank (membrane load) was either 10% or 50% of the nominal yield strength. Also, specimens were either newly fabricated or from an old tank. Finally, the amplitude of rotation applied was 0.2, 0.3 or 0.4 radians. The test matrix is shown in Table 2.

No. tests	Specimen condition	Base thickness t_{base} [mm]	Wall thickness t_{wall} [mm]	Tension [% P_y]	θ_p [rad]
2	Old	7	8	10	0.3
2	Old	7	8	50	0.3
2	New	6	10	10	0.3
2	New	6	10	50	0.3
2	New	8	12	10	0.3
2	New	8	12	50	0.3
2	New	10	15	10	0.3
2	New	10	15	50	0.3
2	New	6	10	10	0.2
2	New	8	12	50	0.2
2	New	6	10	10	0.4
2	Old	7	8	10	0.4

Table 2: Test matrix.

4 TEST SETUP

In order to introduce the membrane loading and the uplifting of the shell-base connection at once, a complex setup involving two actuators and a four pin frame (leveling frame) were introduced. Figure 4 shows the test setup in its displaced position. Note that the specimen was rotated 90 degrees counter clockwise, therefore, the membrane load was applied by the vertical actuator and the uplift was applied by the horizontal actuator. The leveling frame's function was to keep the specimen horizontal under all levels of uplift.

Figure 4: Test setup.

5 RESULTS

The parameter which clearly had the most influence in the number of cycles resisted by the specimens was the membrane load applied. Specimens with 50% membrane load endured between 2.5 and 9 cycles, while specimens with 10% membrane load endured between 84 and 200 cycles. In average, specimens with 10% membrane load endured 19 times more cycles than specimens with a 50% membrane load.

The thickness of the base plate was also found to influence the number of cycles resisted by a connection. For tests carried out with a membrane load of 50% of P_y , specimens with a thickness of 10mm endured about 50% more cycles than specimens 8mm thick and 183% more cycles than specimens 6mm thick. For tests carried out with a 10% of P_y membrane load, specimens with a thickness of 10mm endured 36% more cycles than 8mm thick specimens and 41% compared to 6mm thick specimens.

With the number of cycles to failure, N_f , recorded for each test (see [3] for a comprehensive discussion), plots of rotation amplitude vs. number of cycles to failure were created. Figure 5 shows the data points, the 50% confidence level (linear regression) and the 95% confidence level line for all tests carried out at a 10% of P_y membrane load. Note that the initial smaller cycles applied were considered by converting them into equivalent cycles (see [4]). From Figure 5 it can be seen that for the rotation limit of 0.2 radians, the number of cycles that may be resisted is about 342 cycles (using the 95% confidence level). It can also be seen that the connections underwent 64 cycles at 0.3 radians and about 20 cycles at 0.4 radians. Having established the relationship between rotation and number of cycles to failure, only the number of cycles that the tank is likely to undergo (for a given location) is needed to estimate the maximum rotation that the connection will undergo. Figure 5 is used in the next section to estimate a rotation limit.

Figure 5: RN curve for shell-base connections.

6 APPLICATION

The RN curve shown in Figure 5 relates the rotation amplitude to the number of cycles (with same amplitude) that will cause failure at this rotation amplitude. It shows that at the current code limit of 0.2 radians the connection would be able to undergo about 340 cycles of equivalent amplitude. This number of cycles is clearly much greater than the expected number of cycles to which the shell-base connection of a tank would be subjected to during an earthquake. The rotation capacity of this connection can be directly obtained by entering Figure 5 with the number of equivalent cycles that it is likely to undergo for a specific site hazard.

The maximum number of cycles at the shell-base connection was estimated for the highest hazard in Switzerland [5]. To estimate the number of cycles, 2 tanks were modeled in ABAQUS and subjected to 8 ground motions. The number of cycles at the shell-base connection and their magnitude were then obtained for each ground motion. From this analysis, it was estimated that the number of cycles expected at the shell-base connection would be 4 cy-

cles. Entering Figure 5 with this number of cycles is not possible as the range of number of cycles is between about 20 and 400 cycles. It is however clear that at a rotation of 0.4 radians (maximum tested) the tank would be able to undergo about 20 cycles which is much greater than the estimate of 4 cycles. This is a clear indication that the shell-base connection can resist at least 0.4 radians without failure.

As an alternative method for determining the equivalent number of cycles, the cyclic-demand spectrum developed in [4] could be used. The cyclic-spectrum is similar to a response spectrum, but instead of providing the acceleration for a given period of vibration, it provides the number of cycles that the structure will experience, as a function of the fundamental period of the structure. In order to apply the cyclic-demand spectrum, it was assumed that each cycle of displacement of the tank causes a cycle of rotation at the connection. This is a reasonable assumption since cycles in the shell-base connection are directly related to displacement of the tank. For full details on how to develop the cyclic-demand spectrum see [4].

The cyclic-demand spectrum was developed for the city of Sion, Switzerland, for a 2500-year return period and for 2% of critical damping. The equivalent numbers of cycles in the acceleration, velocity and displacement controlled regions (i.e., N_A , N_V and N_D) are 1.7, 1.4 and 1.1 respectively. From this analysis, the expected number of equivalent cycles was found to be about 4 cycles.

Both the time history analysis of tanks [5] and the cyclic-demand spectrum [4] estimated the number of cycles to be around 4 cycles. As mentioned before, 4 cycles is clearly much less than the 20 cycles that the connection is capable of resisting at 0.4 radians. Thus, it becomes clear that the 0.2 radians rotation limit established by the Eurocode and the New Zealand's recommendations is very conservative.

7 CONCLUSIONS

Current Eurocode and New Zealand's recommendations allow a tank to rest on ground, without anchorage, as long as uplift is limited. The uplift limit, given in terms of rotation of the shell-base connection, is set to 0.2 radians. This limit was derived from the assumptions that a plastic hinge with a length equal to twice the thickness of the base plate forms at the base plate, next to the shell, and that the maximum strain allowed in the plastic hinge zone is 5%. While both assumptions seem reasonable and have been the state of the practice for many years, to the knowledge of the authors no experimental work representing the behavior of these connections had been done to back these assumptions. With that in mind, an experimental research was performed to study the rotational capacity of shell-base connections in unanchored steel storage tanks. The experimental work included studies of connections with different shell-base thicknesses, with different amounts of membrane load and cycles at different amplitudes of rotation. In addition, new and corroded specimens were tested. The main conclusions from this experimental study are listed below:

- In average, specimens with a 10% of P_y membrane load endured 19 times more cycles than specimens with a 50% of P_y membrane load.
- The thickness of the base plate was found to influence the number of cycles resisted by a connection. Specimens with a thicker base plate endured more cycles than those with a thinner base plate.
- The main result from the experimental program was the creation of curves of rotation vs. number of cycles, called RN curves.

- The RN curves indicated that the wall-to-base connection of a tank would endure 342 cycles at the rotation limit of 0.2 radians given in the Eurocode and the New Zealand's recommendations (with 95% confidence).
- The number of cycles to which the shell-base connection of a tank will be subjected to was estimated to be about 4 cycles.
- Results from this research suggest that a limit of 0.4 radians, which was the maximum rotation angle tested, would be more realistic than the 0.2 radians limit.

Results from this research suggest that a limit of 0.4 radians would be more realistic, however, it should be noted that the results presented in this paper were drawn from a limited number of tests and therefore should be used with caution.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the financial support provided by CARBURA and the Swiss Federal Office for the Environment. The authors would like to thank Dr. Praveen Malhotra for his aid in developing the cyclic-demand spectrum for the maximum hazard of Switzerland.

Abstract. *In petroleum industries, especially in refineries installations, hundreds of miles of pipes are installed to transfer raw and refined material (fluid and gas) from a point to another of the plant, connecting all the components involved in the transformation process (tanks, distillations columns, furnaces, etc.). Recent seismic events showed a quite high vulnerability of these structures, where damage ranges from the simple failure of joints to the failure of supporting structures. For these reasons, initially the seismic analysis and component design of refinery piping systems is here analysed. A review of the current approaches imposed by European (EN13480:3) and American (ASME B31.3) standards is illustrated by using a proper case study of a piping system on a pipe-rack. The analysis permitted to identify the limits of the design standards and to identify the critical aspects of the problem, i.e., dynamic interaction between pipes and rack, correct definition of the response factor, strain versus stress approach. Finally, the preliminary phases of an experimental investigation on flanged joints are also illustrated.*

1 INTRODUCTION

The piping systems typically found in a refinery complex contain various components and support structures and operate in a broad range of working environments. Some common components usually used in piping systems include straight pipes, elbows, Tee-Joints, various valves, flanged joints, pressure vessels, tanks, strainers and reducers. Depending on the nature of the working fluids, piping systems are designed to work over a wide range of temperature and pressure. A typical piping system is presented in Figure 1.

A pipe-way is the space allocated for routing several parallel adjacent pipelines within process plants. A pipe rack is the structure employed for supporting the pipelines and carrying electrical and instrument trays. The pipe rack is usually made of steel or concrete frames, on top of which the pipeline rests.

Pipe racks are necessary for arranging the process and service pipelines throughout the plant, and they are used in secondary ways; principally to provide a protected location for auxiliary equipment, pumps, utility stations, manifolds, and firefighting and first-aid stations. Lighting and other fixtures can be fitted to the pipe rack columns. Air-cooled heat exchangers are often supported above pipe racks for economy of plot space.

Figure 1 Typical piping layout

Figure 2 : Breakage of a piping flanged connection

Recent seismic events showed a quite high vulnerability of these structures, where damage ranges from the simple failure of joints to the failure of supporting structures [1],[2],[3],[4]. For example, the failure of a bolted flange connection is shown in Figure 2.

Consequences can be characterized by several degrees of severity, depending on the material delivered by pipes. For dangerous liquids or gases, even a simple failure of a joint can represent the trigger of a significant accidental chain, with severe consequences both for the environment and human lives. Unfortunately, few contributions in the literature are available, in order to clarify the seismic requirements that piping systems have to comply with. In addition, aspects like action and structural modelling have not yet been treated in a satisfactory manner. Moreover, current American and European standards do not contain enough rules and details for a proper seismic analysis and design of piping systems.

Along these lines, some problems relevant to seismic analysis criteria of piping systems are addressed in this paper. In a greater detail, several aspects that characterise the problem are treated: 1) modelling of pipes and pipe-racks; 2) selection of the analysis method; 3) definition of the seismic action; 4) dynamic analysis of the system; 5) stress analysis of pipes; 6) definition of the ultimate capacity of pipes and joints between pipes.

To this end a representative case study of an actual piping system was analysed. The requirements of American and European codes were compared and important aspects were hig-

highlighted, like: a) dynamic coupling between pipes and pipe-rack, often erroneously neglected; b) definition of proper restraint conditions between pipes and support structures and between adjacent piping systems; c) evaluation of the ultimate capacity of pipes and joints necessary for a correct design of a structure, as suggested by modern approaches like Performance-based Engineering.

About the aforementioned item c) an experimental campaign is currently undertaken at the University of Trento in order to characterise the cyclic behaviour of flanged joints between pipes, particularly important to avoid leakage of dangerous substances during a severe seismic event. Preliminary information about the testing activity is illustrated and commented.

2 EUROPEAN AND AMERICAN STANDARDS FOR THE SEISMIC DESIGN OF PIPING SYSTEMS

Nowadays, both European and American codes are available for the design of piping systems under seismic events. The main European contribution is chiefly represented by the standard EN13480, dedicated to metallurgy piping systems [5]. The Eurocode 8 - part 4, the European seismic code for industrial components, is also devoted to pipelines, but only of above-ground type, which differs from metallic piping system for many aspects, and then useless.

American experience on piping system is very rich, especially in terms of design standardization and seismic design calculation, and the long list of standards and codes available it is a clear demonstration of it. The main standard is represented by ASME B31.3 [6], but many other contributions and guidelines are also available [7],[8].

The seismic analysis of a piping system involves several basic steps that allow defining the proper seismic action, the suitable numerical model and analysis method and the verification format to be used. The European (EN13480:3-2002) and the American standards (ASME B31.3-2006) for piping systems differ for several of these aspects. Thus, in order to understand these differences and the consequences on the seismic response evaluation, in the following both European and American standards are applied to a representative case study.

It is necessary to stress that the American Standard does not contain explicit indications on the seismic analysis of piping systems, but rather refers to the American standard for seismic analysis of structure ASCE7-05, which includes all the required prescriptions. On the contrary the European Standard contains an entire Annex (A) dedicated to the dynamic and seismic analysis of piping systems, but does not contain explicit quantification of the seismic action. At this end the Eurocode 8 (prEN1998:1 2004) should be used.

3 DESCRIPTION OF A CASE STUDY

The piping system here analysed belongs to a refinery, whose plant view is shown in Fig.3. The supporting steel structure is composed by seven transverse moment resisting frames placed every 6 m, realized with commercial HEA/B steel profiles. In the longitudinal direction it behaves like a truss structure, which is reinforced with 6 braces (see Fig. 4, Fig.5). Horizontal bracings are also installed to avoid excessive relative displacements between the pipe supports.

The piping system presents a typical piping layout with pipes having different diameters. To simplify the analysis, only the structural contribution of 8" pipes has been considered, whose layout is shown in Fig. 6. The remaining pipes are considered only as weight. Several flanged elbows are present within the pipe-rack and at both the ends of the piping system.

Figure 3 – Plan view of the refinery

Figure 4 – The piping system

The fluids contained in the pipes are several, but essentially Amine, cooling water and high to medium pressure steam. The vertical loads corresponding to the weight of the pipes, insulation and fluid are considered as uniformly distributed equal to 12 kN/m. The main characteristics of the piping system are the following:

- Structural steel S-275 JR according to EN 10025 (2005)
- Pipe steel - ASTM A106 Grade B
- pipes with diameter of 8''
- Pressure of the pipes: 0.5÷5 Mpa
- Temperature range 47 °C ÷360 °C.
- Seismic category of Importance $I_p=1.5$, $PGA=0.24$ g, Soil conditions: D

Figure 5 - The analysed piping system

4 MAIN ISSUES IN SEISMIC DESIGN OF PIPING SYSTEMS

The seismic design of a piping system entails many issues. As stated above, they are essentially related to the modelling of the structure, to a correct definition of the seismic action, to a proper analysis method to be applied, and finally, to a appropriate design method to be used. In addition, nowadays, the Load and Resistance Factor Design method (LRFD) is certainly the standard method for designing structures and the allowable stress design method is by now abandoned because often considered too much conservative. Unfortunately, this latter is still the current approach for designing a piping system. This represents a limit to be overcome. But to the purpose, it is firstly necessary to understand the limit of such an approach; and the more direct way is to apply the codes prescriptions to a case study, trying to individuate limits and drawbacks. In doing this, it seems proper to compare European and American experiences, applying both the EN13480:3 and ASME B31.3 to the case study described above along with a comparison of the results regarding all the treated aspects.

4.1 Definition of a numerical model

A synthetic scheme of what European and American standard prescribe for a correct numerical modelling of a piping system and the definition of the seismic conditions is reported in Table 1.

The table clearly shows that the suggested numerical model to use in seismic analysis is always elastic both for EN13480 and ASME B31.3. This choice comes certainly from the old way to evaluate the safety level of a structure: the allowable stress method, still diffused in designing of piping systems. Usually, only the piping system is modelled, using the supporting structure only to evaluate the seismic action at pipes level (e.g., in-structure spectra). The supporting structure (e.g. pipe-tack) is treated as elastic too. The assumption of elastic beha-

behavior would not be a strong limitation if a correct value of the behavior factor were adopted. Some comments on this aspect will be provided afterwards.

Another important aspect, often related to the assumption on the numerical model is the analysis method to be adopted. This ranges from the very simple equivalent static method to the time-history analysis. But, this aspect will be treated in the next section.

A key point in modelling a piping system is the possibility to neglect the interaction (static and dynamic) between the pipes and the supporting structure. EN13480 does not provide any indication about it, whereas ASME B31.3, by means of ASCE-07, prescribes a crude rule based on the ratio WR between the weights of pipes and supporting structure. In particular, if $WR < 25\%$ the interaction can be excluded and the piping system can be considered as a non-building structure, loaded by a seismic action coming from the supporting structure at pipes level.

This rule has been recently analysed by several authors. For example in [9] the rule has been analyzed using time-history analysis. From the results and discussion the author concluded that in some cases this decoupling rule could produce gross errors in the evaluation of the dynamic behavior of piping systems. In particular, it seems that in dynamic assessment of such systems, in addition to the primary-secondary system weight ratio criteria, attention should be paid to other aspects as “end conditions of pipes”, “relative stiffness of supporting structure to piping system” and “relative stiffness of pipes to pipe-supports”, even though only partial conclusions were reached by the authors, that suggested more investigations on this matter. In the literature many works have been dedicated to the problem of dynamic coupling between primary and secondary systems [10],[11],[12], but the results are difficult to be extended to the case of piping systems for several reasons, but mainly because in case of piping systems the secondary system is composed by more sub-systems (pipes with different diameters, different end conditions, different supports, etc.). Therefore, assumption of a single secondary system could lead to gross errors in response prediction of piping systems.

(1) elastic calculation shall be used although some part might exhibit plastic deformations (p. 4.1), (2) SSE=safe shutdown earthquake, DBE= Occasional operation condition, (3) FF=Flexibility Factor, SIF= Stress Intensification Factor, (4) G=ground motion spectra, IS=In-structure spectra.

Code	Model type	Analysis	Seismic condition	Dynamic interaction	Relative motion	Pipe modelling
EN13480:3	Elastic ⁽¹⁾	Equivalent Static Modal (G,IS ⁴) Time-History	SSE ⁽²⁾ OBE	NO	YES	Beam elements (FF and SIF)
ASME B31.3	Elastic	Static Modal Time-History	SSE	YES/NO	YES	Beam elements (FF and SIF) ⁽³⁾

Table 1 – Code prescriptions for numerical modelling as well as seismic conditions

Concerning the case study, applying the weight ratio rule, dynamic interaction has been considered, because $WR > 25\%$. Moreover, for comparison, this rule has also been considered in applying the European standard. In order to evaluate the effectiveness of the weight rule, the behavior of the piping system without pipe-rack has also been analysed.

The pipes are usually connected to the pipe-rack by mechanical supports, often flexible. They are usually designed to accommodate thermal and pressure effects, avoiding excessive stress in the pipes. Unfortunately, no indications on how to model them are provided by European and American standards. Nevertheless, this is an important aspect that have to be treated with particular attention because can cause changes in dynamic behavior of the system.

Dissipative supports can be used instead of traditional ones in order to introduce artificially more damping and reduce the response of the pipes.

The analysed case present a quite stiff support systems, modelled as elastic spring in the transverse direction (Y), leaving free the relative displacements in longitudinal direction (X) and using fix restraints conditions in vertical direction. Moreover, as usual, all the rotations between pipe and pipe-rack have been unrestrained.

Another relevant aspect about modelling of piping systems is the adoption of a proper model for pipes and fittings (elbows, tee-joints, nozzles, etc..). At this regards, usually beam elements with hollow section are used for straight pipes (Fig.7). The fittings are also modelled using beam elements, but modifying the stiffness for the effect of geometry. At this regards both European and American codes define a flexibility factor ($k > 1$) using which the moment of inertia of the pipe is reduced. In addition, to take into account the stress concentration effect, the Stress Intensification Factor (SIF) is used to increase the stress calculated using the beam theory. The value of k and SIF calculated according to EN13480 and ASME B31.3 are very similar.

In presence of high pressure condition the stiffness of the pipe could increase. To account for this effect the flexibility factor k is reduced. Unfortunately, only ASME B313.3 provides an explicit expression of the pressure reducing factor. For the analyzed case and for a pressure of 5 MPa this factor halves the flexibility.

Alternatively, it is possible to use shell elements to model fittings [13]. This approach is appropriate to account for ovalization of the section and stiffening pressure effect. For this reasons this model has been used for the case study and a comparison with beam model has been carried out (Fig. 8). We can anticipate that the numerical simulations have shown a similar behavior of both the models and the reliability of modified beam element, at least for standard fittings, like the one here analyzed. Therefore, in what follows only the results of the more refined one will be shown.

Figure 7 – Beam FEM for an elbow

Figure 8 – Shell FEM for an elbow

A last but not less important aspect regards the boundary conditions of the pipes. In fact, because a piping system is realized by hundreds of miles of pipes, the analysis involves necessarily a limited part of the structure. Consequently proper boundary conditions have to be accurately adopted to simulate the remaining part of the structure. Also for this delicate aspect no indications are provided by the European and American standards. As already shown in literature, the correct boundary conditions may cause important modifications of the dynamics of the piping system but the correct choice depends on the single case [9].

Because one of the aim of this work is to compare European and American standards, it has been decided to limit the possible cases adopting as restraint conditions of the pipe ends only hinges. In this respect, one can look at Fig. 9.

Fig. 9 – Boundary condition in one if the pipe ends

The model of the piping system and the support structure has been realized in the general purpose software MIDAS Gen [14]. It is shown in Fig. 10.

Figure 10 – The FE model of the piping system

4.2 Seismic actions and analysis methods

Both European and American standards assume the following two types of analysis mandatory for the pipes:

- Movements due to inertia effects
- Differential movement of the supports (within the supporting structure or between adjacent pipe-racks)

The first type of analysis is essentially related to the effects of the absolute acceleration on the pipe mass. The second one is due to the relative movements between two supports, within the supporting structure or belonging to adjacent structures. Often the relevant effects are due to the displacement effect rather than acceleration effects.

Concerning the case study, the entire model here considered (pipe + pipe-rack) allow identifying both the effects. On the contrary the model without considering the supporting structure, here also considered, allows identifying only the inertia effect of the pipes, unless a multi-support excitation would be used.

The seismic action for pipe-racks is usually represented by design response spectra or accelerograms (natural records or synthetic accelerograms). For the analysis of pipes only, “In-structure” spectra or “filtered response spectra” are used.

Design response spectrum method

The design spectra are the main representation of a seismic action and usually are defined by the seismic codes in terms of hazard conditions of the site, the level of dissipation capability of the supporting structure and pipes (response or behavior factor), the right level of damping to be employed, and the level of structure reliability to impose, identified by the importance factor.

For what regards the support structure, hazard conditions apart, the damping usually adopted is equal to 5%, as suggested by Eurocode 8 and 3 for steel structures, whereas the behavior factor q depends on the type of structure used for the pipe-rack. While for building-type structure this aspect has been well identified and quantified, for structures like pipe-racks, that may often be considered as non-building structure (ASCE-07:2005), the problem may be quite different.

The current American and European seismic codes provide a q factor for steel racks equal to $3\frac{1}{2}$ and 4 respectively (Tab 2). This choice probably derives from the hypothesis of no-coupling between the rack (primary system) and the pipes (secondary system). In fact, usually the level of dynamic coupling between pipes and rack can be neglected. But in other some cases its influence cannot be excluded a priori [9].

In order to compare the results of EN13480 and ASME B31.3 the same elastic spectrum, has been here adopted defined according to prEN1998:1, and modified using the behavior factor of Tab. 2. It is shown in Fig. 13.

The spectral response of the modal oscillators and then combined to obtain the resultant response of the system. Moreover, the resultant forces and displacements from bi-directional analysis are typically obtained by the square root sum of square of the response in each direction, or by applying the so-called 100-30 rule.

Figure 11 First two vibration modes of the pipe-rack model

In Tab.3 the main dynamic characteristics of the system are shown. As mentioned before, the modal analysis on the entire system allows highlighting the important role of the pipes in realizing structural coupling between the several frames of the pipe-rack. For example in Fig. 11 and 12 the vibration modes of the rack with and without the pipes is shown. They are quite different especially in terms of excited mass. For example, the period of the first mode of the

rack with and without pipes is very similar, whereas the excited mass is higher in the first case, showing the coupling effect of the transverse frames due to the pipes.

All the results here presented have been carried out for the elbows modelled using shell elements. The results using the simpler beam elements (here not presented) are quite close to previous ones, showing their reliability.

Table 3 – First three vibration modes of the entire piping system

In-structure spectra

The in-structure spectra allow a seismic action to be defined for the single pipe at several floors of the pipe-rack, in which the pipe is placed. Both European and American codes give their explicit expressions. They are defined as the spectrum acceleration multiplied by the amplification factor AF shown in Fig. 14. The expression of the amplification factor expressed by EN13480 (EC8) and ASME B31.3 (ASCE-07) differ for the presence of the period

ratio T_a/T_1 , presents only in the seismic European Standard which takes into account the dynamic interaction between pipes (T_a) and pipe-rack (T_1). (see tab. 4).

Figure 13 Eurocode 8-1 free-field elastic spectrum (Soil D)

Figure 14 Amplification factor of in-structure spectra v/s T_a/T_1

In case of piping, because is generally avoided any yielding phenomenon in the pipes, the dissipation capability is generally restricted only to the supporting structure and the relative response modification factor depends on its structural configuration. In some cases dissipation phenomena may have place also in the pipes and a specific behavior factor have to be defined if the elastic analysis with response spectra is used.

The behavior factor provided by the codes, especially by the American one, seems to be overestimated. For example, ASCE-07 prescribes the use of a behavior factor 6 or 12 according to the deformability of the material used. In some cases this hypothesis may not be totally true.

For example Okeil and Tung in 1996 [15] using an idealized piping system have suggested a closed-form formula that provides the reduction factor q as function of the ductility of the support structure, μ , and the ratio f of the piping frequency and the frequency of the seismic action. The reduction q increases with the ductility, μ . Moreover, the stiffer is the piping system (low values of f) the higher is q . In any case q is never greater than 3-4. These results are in contrast with the provisions of ASCE-07.

Code	Expression	note
ASME B31.3 (ASCE-07)	$F_p = I_p \frac{0.4a_p S_{DS} W_p}{R_p} AF$ $AF = \left(1 + 2 \frac{z}{H}\right)$	$a_p = 2.5$ (Tab. 13.6-1) S_{DS} = Maximum spectral acceleration W_p = Weight of the pipe z = height where the pipe is placed H = total height of the pipe-rack I_p = Importance factor R_p = response factor
EN13480:3 (EC8)	$F_a = I_p \frac{a_g S W_p}{R_p} AF$ $AF = \left[\frac{3 \left(1 + \frac{z}{H}\right)}{1 + \left(1 - \frac{T_a}{T_1}\right)^2} \cdot \frac{1}{2} \right]$	a_g = Peak Ground Acceleration S = soil factor T_a = fundamental period of the pipes T_1 = fundamental period of the pipe-rack

Table 4 In-Structure spectra definitions

Other authors reached similar conclusions as well. For example in [16] the authors investigated on the dynamic response of a piping system on a rack with gap and with friction. By using dynamic harmonic analysis on a simple system they found that in presence of nonlinearity (friction between pipes and rack) the reduction of the acceleration with respect to the elastic case could be of the order of 2-3, value suggested also by the American Lifelines Alliance [7] and FEMA 450.

Instead of using static method employing seismic force of Tab. 4, a dynamic approach is also possible, using generated floor response spectra, whose shape is based on typical Soil-Structure interaction theory. For industrial piping systems few contributions have been found in literature [2], [3], [4], [17].

For the case study of Fig. 4, floor spectra have been generated by using time-history analysis. Fig. 15 shows the floor spectra for one the three accelerograms used in Time-History analysis (see next section), from which is clear the filtering effect of the pipe-rack. The maximum amplification is now restricted to the range 2-3 Hz, whereas in the ground acceleration spectra was placed in the range 2-6 Hz. The labels Frame 1, 3 and 5 correspond to the labels of the frames indicated in Fig.10. It is also possible to note the variability of the maximum amplification effect within the structure. The maximum acceleration peak is found at frame 3; this because more mass is placed there with respect to the other frames.

Because the natural frequencies of the piping systems are in the range 15-40 Hz the amplification effect due to the inertia is very limited. In fact, the maximum acceleration applied to the pipes corresponds more or less to the maximum acceleration at floor in which the pipes are placed, some peaks a part, at frequency 7 and 10 Hz.

Figure 15 - Case study - Spatial variability of the floor spectra for the El-Centro earthquake

Figure 16 - Case study – Mean floor spectra for several frames and Envelope Floor Spectrum

A possible representation of floor spectra for the case-study is shown in Fig.16 as envelope of the mean spectra at several frames. This allows to account for the spatial variability of the action and its frequency content. This has been used to get the response of the pipes analyzed individually.

Time history analysis

A time history seismic input is rarely used for the design or retrofit of piping systems. Often it is used to generate facility specific response spectra analyses, or as a research tool, to study in detail the behavior of a component or system as a function of time.

Nowadays, the scientific community has widely accepted the use of natural records to reproduce a real input, for several reasons. For many engineering application, the purpose of selection and scaling of real earthquake is to fit the code design spectrum considering the

seismological and geological parameters of the specific site. To comply with the seismic codes set of accelerograms, regardless its type, should basically match the following criteria:

- minimum of 3 accelerograms should be used;
- the mean of the zero period spectral response acceleration values (calculated from the individual time histories) should not be smaller than the value of $a_g \times S$ for the site in question (S is the soil factor, a_g is the Peak Ground Acceleration);
- in the range of periods between $0.2 T_1$ and $2 T_1$, where T_1 is the fundamental period of the structure in the direction where the accelerogram will be applied, no value of the mean 5% damping elastic spectrum, calculated from all time histories, should be $<90\%$ of the corresponding value of the 5% damping elastic response spectrum.

To help engineers in selecting a proper set of records, some tools have been proposed in the literature. The most recent is REXEL proposed by Iervolino et al [18].

More rarely artificial or synthetic accelerograms are used. The first ones are generated to match a target response spectrum, the second ones form from seismological source models and accounting for path and site effects. For artificial signals, even though, it is possible to obtain acceleration time series that are almost completely compatible with the elastic design spectrum, the generated accelerograms often have an excessive number of cycles of strong motion, and consequently have unrealistically high-energy content. For this reason are less used than natural records. Moreover, to generate synthetic accelerograms there is a need for a definition of a specific earthquake scenario in terms of magnitude, rupture mechanism in addition to geological conditions and location of the site. Generally, most of this information is not often available, particularly when using seismic design codes. This representation of a seismic input is rarely used.

According to the above considerations it has been decided, at least for this preliminary analysis, to use natural records and to select only three accelerograms compatible with the spectra of Fig. 13. For the case study the vertical component has been considered as negligible, so only bi-directional motion has been adopted.

The three records were taken from Pacific Earthquake Engineering Research center database (<http://peer.berkeley.edu>), using the following hazard and compatibility conditions (Tab. 5). In Tab. 6 the characteristics of all the selected accelerograms are shown. Fig. 17 and 18 show the elastic spectrum of two records.

Magnitude Mw	Soil conditions	Distance (Km)	PGA (g)	Lower bound	Upper bound
6÷7	D	0÷20	0.24	-10%	+30%

Table 5 – Hazard and compatibility conditions for natural record selection

Event	Data	Mag.	Dist. (Km)	Filter (Hz)	name
Imperial Valley	19/05/1940	7.2	13.0	0.20	El-Centro
Northridge	15/01/1994	6.7	27.6	0.14	Santa Monica
San Fernando	02/09/1971	6.6	24.0	0.50	Old Ridge

Table 6 - List of the three selected natural records

After the identification of the accelerograms, the direct integration of the equation of motion or the integration of the single modal oscillators (time-history modal analysis) can be per-

formed. This latter is used when a limited non-linearity is present in the structure during the seismic event. Most frequently a direct integration scheme is used.

Figure 17 – Elastic spectrum of the El-Centro earthquake

Figure 18 – Elastic spectrum of the San-Fernando earthquake

Differential movement effects

No specific indications are provided by the codes for the differential movement between two supports or between adjacent structures. Only ASCE-07 provides a simplified criterion based on the elastic analysis of the pipe-rack. Chapter 13.3.2.1 suggests evaluating the relative displacements between two connection points within the structure and at the same level using the differential movement for each vibration modes combined using appropriate modal combination procedures.

Unlike the cases of differential movements between adjacent pipe-racks connected by pipes, this effect on pipes within the structure is usually neglected. As observed above, the complete model, pipes + pipe-rack, allows to automatically accounting for this effect.

4.3 Calculation of the seismic response of the case study

The seismic analysis results of the analysed piping system using both static and dynamic methods previously described are illustrated herein.

For each analysis method the results in terms of moments are provided. In particular the maximum local moments M_y and M_z are provided for the straight pipes at each bay (1 to 7) and for the more critical elbows indicated in Fig. 10 with red circles (points A and B)

In Fig. 19 is shown, for the design conditions ($PGA=0.24g$, $q=4$, $\xi=3\%$) the seismic response of the entire structure in terms of moments, shear and axial force for soil condition B and E, obtained using response spectrum analysis.

The maximum moment in the steel columns is about 220 kNm, very far from the ultimate moment of the steel elements. Similar results have been obtained by using T-H analysis. Therefore the support structure can be considered safe against the ultimate limit state. The soil conditions have also a limited effect both in the rack and in the pipes.

For the above observation, in what follows only the soil condition D, relative to the design conditions of the case study, have been considered.

In Tab. 7 the result of the seismic analysis of the case study of Fig. 1, in terms of bending moment in the pipes are shown. They have carried out at the several bays of the steel frame and at top floor and have obtained using all the aforementioned methods. In particular the values of damping (5%), behavior factor ($q=4$) and Importance factor ($I_p=1.5$) provides by the EN13480:3 standard and prEN1998:1 code have been used.

Firstly, a marked underestimation of the bending moment in the pipes using in-structure spectra is noticed. This is probably due to the limited mass of the pipes, which amplifies the relative displacement effects between the different support points of the pipes. In fact, by using the response spectrum method the bending moments have in mean double values.

Figure 19 - Response Spectrum Analysis: Moment distribution for the Eurocode 8-1 Spectra with $\xi=3\%$, $a_g=0.24g$, $q=4$ and Soil D.

The use of dynamic analysis instead of the static one produces slight differences when in-structure spectra are used. This is due probably to the uniform distribution of the seismic force in the first case, whereas, in the second case, the distributions related to the several vibration modes is used. But substantially they provide similar results.

The time-history analysis on the elastic system produced greater values of bending moments. This is due to the absence of non-linear behavior of the structure. Because by applying to the response a reduction factor of 4, the results becomes not far to the results obtained with the response spectrum analysis and $q=4$, they should be considered reasonable. Further analysis will be dedicated to this aspect, modelling the analyzed structure in the non-linear range.

Method	Bay/Moment	1	2	3	4	5	6	7
Static analysis: In-structure spectra method	M_z	2.88	2.40	2.52	2.64	2.76	2.76	2.88
	M_y	1.56	1.56	1.20	1.32	1.44	1.20	1.44
Dynamic analysis: In-structure spectra method	M_z	2.10	2.30	2.30	3.10	3.30	3.00	2.30
	M_y	2.20	2.10	2.10	2.20	1.90	1.90	1.00
Dynamic analysis: Response spectrum method	M_z	5.30	5.50	5.50	3.50	2.90	4.80	5.80
	M_y	2.80	2.60	3.60	3.20	2.20	0.70	3.80
Dynamic method: Time-History analysis (elastic)	M_z	13.50	14.60	14.10	5.05	6.25	14.15	12.32
	M_y	7.30	6.65	4.45	4.65	3.05	1.70	3.85

Table 7 – Results relevant to the seismic analysis of the case study

4.4 Piping stress analysis and checks

One of the fundamental steps for the qualification of a pipe system is the fulfillment of some limits of the pipe stress or strain, for a given working condition. For a seismic action, usually two working conditions are considered:

- Operating condition or design basis earthquake condition: (OBE) is that earthquake which, considering the regional, local geology and seismology, could be reasonably expected to affect the site during the operating life of the plant. It is the earthquake during which the operating conditions of the plant can be still assured.
- Safe shutdown earthquake condition: (SSE) is the maximum ground motion for which some critical components of the plant must be designed to remain functional.

In order to evaluate the safety level stress-based or strain-based approach can be used. The first approach intends to evaluate the maximum stress in the pipes and the calculation is usually based on elastic analysis of the structure.

While stress based approach for pipelines is acceptable for a material with a well defined yield point and with a well defined yield ductility and strength, this design criteria becomes invalid when the stress in pipelines exceeds the limit under some displacement control loads, such as earthquakes and landslides [19]. In this case, strain based approach provides the design rule where the strain in the pipeline is allowed to exceed the specified yield strain provided that the safe operation can be ensured under displacement load. This method allows selected extensions to the stress-based design possibilities to take advantage of steel's well-known ability to deform plastically, but remain a stable structure. Codes and Standards are available for the strain based design approach, see [19] for reference. With the strain-based approach maximum strain in the pipes is calculated and compared with specified strain-limits related to limit states usually identified with buckling or ovalization of the pipes. Unfortunately, this approach needs of the calculation of the seismic response in the non-linear range. This is one of the reasons because the stress approach is more used.

Only EN13480 contains explicit indications for calculating the pipe stresses limits, considering both the above conditions (OBE and SSE), whereas ASME B31.3 indicates only occasional load conditions that can be identified as OBE condition.

For the verification of the pipes against earthquake, the allowable stress approach is usually adopted and will be also adopted in the following.

Load combinations and stress calculation

The response to seismic and other loads (sustained, thermal, pressure, etc..), have to be combined. European and American code prescribe similar combinations. In this respect the seismic load prescribed by the seismic codes (prEN1998:1 and ASCE-07) can be considered as an exceptional seismic action. Under this condition, usually Load and Resistance Factor design (LRFD) approach is adopted. If the allowable stress approach is used, the seismic action has to be reduced, as usual, of a certain safety factor, typically 1.4 (see ASCE-07).

Because the allowable stress approach is widely diffused in piping design in the following section will be used for the calculation of the stresses and the verification of the safety level. In doing this, the ASCE-07 combination formula will be adopted.

ASME B31.3 does not provide an explicit equation for calculating the longitudinal stress, whereas EN13480 provides at point 12.3.3 the formula to evaluate the longitudinal stresses due to sustained, occasional and exceptional loads (e.g. the earthquake). This comes from the beam theory and includes internal pressure P and the resultant moments due to the sustained loads (M_A) and the earthquake (M_B):

$$\sigma = \frac{pD}{4t} + 0.75 \times SFI \frac{M_A + M_B}{Z} \quad (1)$$

where SIF is the stress intensification factor.

Because ASME B31.1 provides a similar expression of the stress, in the following this will be also adopted for ASME B31.3.

ASME B31.3 at point 319.4.4 indicates the way to calculate the resultant moments, similar to that of EN13480:3. In particular:

$$M_R = \sqrt{(SIF_y \times M_y)^2 + (SIF_z \times M_z)^2} \quad (2)$$

This definition has also been adopted for calculating the resultant moments using EN13480.

The resultant moment and the maximum stress in the pipes using the results of spectrum analysis have been calculated for both European and American standards. In particular, the maximum stress obtained is lower than 71 MPa in the straight pipes (bay 7) and 135 MPa in the elbows (B). The stress level here calculated is greater than that determined using in-structure spectra. In any case the stresses are limited and the piping system can be considered as over-designed.

Studies have shown that the present standards for piping system design under seismic loads are over conservative and modifications have been proposed to relax this over conservatism [20],[21]. For example, [21] has applied the present codes to calculate the stress limit on piping systems and experimental results showed significant discrepancy from the real behavior. This aspect will be treated in further studies.

Definition of the allowable stress

EN13480 includes par. 12.3.3., which is dedicated to the definition of the allowable stress calculation. They are defined according to the conditions previously recalled: Operating Basic Earthquake (OBE) and Safe Shutdown Earthquake (SSE). The basic inequality to be respected is:

$$\sigma \leq kf_h \quad (3)$$

where

σ = maximum stress in the pipes due to the sustained and seismic loads.

$k = 1.2$ for design basic earthquake

$k = 1.8$ for safe shutdown earthquake

f_h = is the basic allowable stress given by code

ASME B31.3 does not provide explicit differentiation between OBE and SSE but refers to a Design Earthquake that can be identified with the OBE. It is prescribed that the maximum stress cannot be greater than 1.33 times the basic allowable stress for pipes, indicated in the Appendix A of the same code.

Code	OBE	SSE
EN13480	165.60	248.40
ASME B31.3	183.50	---

Table 8– Pipes allowable stress (MPa) for the analysed case study

Tab. 8 illustrates the capacity of the pipes evaluated using both OBE and SSE seismic condition. The comparison capacity and demand show that the verification is satisfied with a different capacity/demand ratio ρ . In particular, for EN13480 $\rho=1.39$ whereas for ASME B31.3 is equal to 1.36. These values of ρ show, at least in the analyzed case, a slight difference between the two codes in the evaluation of the safety level.

The above calculations confirm that using allowable stress approach and then comparing the capacity with the demand (OBE), the system is highly overdesigned. The attempt of some researchers to modify the equation (1) [21],[22] is not enough to fully exploit the plastic properties of pipes. In this sense the strain-based approach is more promising, especially if the Performance-Based approach would be used to design new pipelines or to assess the seismic behavior of existing ones. This is the reason that has induced to explore the plastic behavior of pipes and pipe-joints using the way of experimental investigation. This activity has been just started and in the following section some details of on-going tests on flanged joints will be provided.

5 EXPERIMENTAL INVESTIGATIONS

5.1 Previous experimental tests

A good number of experimental tests have been performed to characterize piping systems under seismic loading and they are available in literatures, e.g., [20],[21],[22],[23],[24]. It has been found that even strong seismic excitation is not severe enough to significantly damage piping systems unless there is large differential motion of the anchorage [20], and an extremely high level of seismic input is required to introduce damage in the components of a piping system [21]. Additionally, the use of isolation systems reduces seismic demands to the piping systems [22]. Experimental tests, e.g., [20],[23] clearly show that the present design criteria of pipeline under seismic loading are overly conservative and modifications are suggested [20].

Some experimental tests have also been devoted to bolted flange connections in order to assess their behaviour under external loading, e.g., axial and bending loadings [25],[26]. Results show that flanges with lower weights, e.g., a compact VERAX VCF flange joint, have the advantage over the flanges with higher weights, e.g., an ANSI flange joint [25].

5.2 Tests to be performed in the University of Trento

The University of Trento (UniTn) will perform some experimental tests on a number of bolted flanged joints (BFJ) in order to investigate the behaviour of the joints (BFJ) under monotonic and cyclic loadings. These tests are parts of the research works of a European project, INDUSE.

Instead of using conventional thicker joints, two different thinner joints have been designed for the tests due to the fact that thinner joints are expected to exhibit better performance for regular seismic events and for relatively lower working pressure. The two designed flanges have thicknesses 18 mm (Design 01) and 27 mm (Design 02), respectively and have been designed for a pressure of 15 bar. A matlab code has been developed by UniTn to check the joints according to the Eurocode EN 1591-1. One of the joints (Design 02) satisfies the Eurocode EN 1591-1 while the other (Design 01) does not. UniTn aims at performing these experimental tests on these thinner flanges in order to characterise their behaviour in real operating conditions and to check the validity of the design rules of the Eurocode for the flanged joints.

5.3 Test set-ups and programs

Eight experimental tests on BFJs will be performed by UniTn. The test programs and loading protocols are presented in Table 9. On each type of joint four tests will be performed, two of them will be in bending loading and the other two will be in axial loading. In both of the axial and bending tests, there will be monotonic and cyclic loadings. The cyclic loading will be chosen according to ECCS 45 loading protocols [27]. The monotonic and cyclic loading protocols are presented in Fig.21. The load in the BFJs will be applied via 100 ton actuators.

Figure 20: Two plate-flanges designed by UniTn for the experimental tests: a) Design 01 for a flange thickness of 18 mm, and b) Design 02 for a flange thickness of 27 mm.

Design Code	Flange Type	Type of loading		No of Tests	
Non-Standard (Design Code- EN 1591)	Plate (Design 01*)	Axial	Monotonic	2	4
			Cyclic (ECCS 45)		
		Bending	Monotonic	2	
			Cyclic (ECCS 45)

6 CONCLUSIONS

The seismic analysis of piping systems is very different from the analysis of like-building structures for which a long experience has permitted to have enough provisions for obtaining a reliable design against earthquakes. Therefore, the present contribution tried to clarify all the design steps of this type of structures and to identify all the aspect that need to be clarified. This was made through a representative case study analysed according to both European (EN13480:3) and American standards (ASME B31.3) devoted to piping systems. The comparison between EN13480 and ASME B31.3 standards showed that the two codes provide similar indications for the evaluation of the seismic response of pipelines supported by a pipe-rack. From the analysis of the results the following conclusions, considered valid for both the standards, can be drawn.

ASCE-07 provides a simple rule to establish when the dynamic coupling between pipes and supporting structure need to be considered. It is based only on a weight ratio. Actually, other ingredients should be included; for example the vibration periods range of the pipe. In the analysed case the single pipe has a limited weight and therefore short vibration periods. This means that, as already shown, the dynamic coupling between pipes and the pipe-rack is limited; whereas the relative displacements between the pipe supports would represent a more relevant effect. The pipes provide a sort of static coupling between the transverse frames. In fact, the models with and without the pipe stiffness contribution have more or less the same period, whereas the excited mass is differently distributed between the several vibration mod-

es. Therefore, the consequence of considering the structural contribution of the pipes is the introduction of a sort of a rigid floor effect that couples the horizontal movements of the nodes of the same floor. For the above-mentioned reasons an extensive analysis on this particular but important aspect is recommended.

The in-structure spectra suggested by prEN1998:1 and ASCE-07 differs for a term that depends on the pipe-structure frequency ratio, included only in the European code. This aspect is strictly related to the previous observation on the dynamic coupling. The exclusion of the dynamic interaction could introduce a high error in the evaluation of the amplification factor of in-structure spectra. Because usually the frequency of the piping system is relatively high with respect to that of the supporting structure, the amplification effect would be relatively low. In any case, to cover all the possible cases, the use of the European formula for in-structure spectra is highly recommended. The result of this investigation suggested at point 1, should also help to clarify this important aspect toward the direction of simplified but more realistic formulas for in-structure action on pipes.

In the analysis both beam element and shell elements were used to model elbows. The comparison showed the reliability of the more simple elements based on the beam theory, at least for the simple case of elbows. For more complicated situations, the use of finite shell elements should be considered.

The behavior factor q is usually indicated by standards. In particular the values provided for piping systems by ASCE-07 seems to be too high, i.e., $q=6-12$. This is in contrast with the idea of avoiding yielding phenomena in the pipes and to maintain operational conditions also in case of strong seismic events. Certainly, the contribution of the supports in providing dissipation capability should be taken into account; however on the basis of several investigations found in the literature, this exclude the possibility of having so high values of q . For this reason the next step will be an investigation on the reduction factor q also considering the non-linear behaviour of pipes. This could be performed using non-linear beam elements for the straight pipes, and plastic hinges for the simulation of the elbows in the plastic range. In doing so, time-history analysis would be used, even if static non-linear analysis is nowadays very diffused, but difficult to be applied to piping systems for the presence of a uniformly distributed mass of pipes.

The usual way of designing piping systems is based on the allowable stress approach. This means that the structure is considered elastic. Consequently only an operating basis earthquake condition (OBE) can be taken into account for design. Conversely, the modern approach to the seismic design of structures is to differentiate serviceability from ultimate limit states. This latter condition could be represented, for example, by the Safe Shutdown Earthquake (SEE). The problem is that a proper definition of the deformation capability of the pipes and fittings (ovalization, etc..) in the plastic range would be necessary, and on this aspect the research has not reached solid conclusions. But the advantages would be several and first of all the design optimisation. For example in the analysed case, we are very far from the moment capacity of the bolted flanges located in the pipeline. This high level of conservatism seems to be in contrast with the modern performance based-design approach, for which a certain level of yielding in the structure is admitted according to a specific performance. For instance, it would be possible to accept in pipes a certain level of yielding on the condition that leakage would not occur, and the consequence, for example, to accept a reduction of the thickness of the flange. The experimental campaign, briefly described in the paper and that will be performed at the University of Trento in order to evaluate the cyclic behavior of flanged joints, will provide useful information for the design of the flanged joints in the more proper way. Moreover, it should allow one to link the capacity and the demand for several limit states.

Abstract. *In recent years, a number of projects have been funded in China to quantitatively evaluate the tensile and compressive strain limits of pipes and apply these limits to buried pipelines subjected to landslides. This paper covers the technical basis of strain-based design for pipelines subjected to landslides. First, finite element analyses (FEA) were conducted for a total of 594 cases covering a wide range of materials, ratios of pipe diameter to wall thickness, D/t and various internal pressures. By using the calculated data, parametric equations for strain limits of pipelines were developed. FEA analyses were also conducted for 8 cases of buried pipelines subjected to landslides. An approach for design of buried pipelines subjected to landslides using strain-based design was also proposed. It is believed that the above applications may lay the initial base of using the strain-based design method for buried pipeline subjected to landslides for pipelines in China.*

1 INTRODUCTION

With the rapid development of oil and gas pipeline industry, new trend is showing on pipelines for long-distance, large-diameter and high-operating-pressure. This requires the corresponding pipeline design guidelines and criteria to be adapted to these new situations. In the design step, not only the safety and reliability of pipeline but also its economic and efficient operation should be ensured. Most of the existing pipeline design codes are based on limiting stress criteria, which is considered acceptable for steel with a well defined yield point and a well defined ductility and strength. But the stress in pipelines may exceed the limit under some situations, such as earthquakes, landslides, and some displacement-controlled loading, such as that in laying of the submarine pipelines. In these situations, the strength design criteria based on stress is no longer valid.

Stress-based design criteria are based on the minimum yield stress for the pipeline, while strain-based design criteria are based on limit state design in displacement-controlled loading. If the safe operation can be ensured under displacement-controlled loading, the pipeline strain is allowed to exceed the specified yield strain. Although some plastic deformations occur in the pipeline, the pipeline is able to meet the operation requirements with higher operating capacity. Using stress-based design method supplemented with strain-based design method, the deformation capability of pipelines can be fully applied in security and economic design.

Limit state is a state beyond which the structure no longer satisfies the design requirements. Both Det Norske Veritas (DNV, 2000) and Canadian Standards Association (CSA, 2007) use limit state method for pipeline design. There is slightly difference in state limit classification between these codes. In DNV-OSF101 (2000), four kinds of state limits are recognized. They are serviceability limit state, ultimate limit state, fatigue limit state and accidental limit state. When limit state method is applied to the pipeline design, appropriate design criteria are presented in order to make less conservative and more flexibility for the designers.

There are many different classifications on loadings for the pipelines. Displacement-controlled loading can be defined specifically as a loading that can be reduced to zero by a change in the shape of the part of interest. On contrary, a load-control loading cannot be reduced to zero by a simple change in shape. Bigger strain may be allowed to displacement-controlled loading. The loading on a pipeline may generally be a combination of load and displacement controlled. The pressure loading is load controlled, while the soil motion around a pipeline usually causes displacement-controlled moments.

A number of natural gas and petroleum pipelines have been or will be constructed across ancient and currently active landslides in China. The pipelines studied in this paper cross numerous areas of active or potential active landslides that pose a threat to pipeline integrity. The interaction of the moving soil with the pipeline redistributes the axial force along the pipe, increasing tension in some locations and compression in others. It can also increase pipeline curvature, which induces tensile strain in half of the pipe cross-section, and compressive strain in the other half. If unmitigated, excessive tensile strain can lead to pipeline rupture. Large compressive strain may cause buckling, usually accompanied by formation of wrinkles that can rupture due to material fatigue or severe yielding.

The general framework for the application of strain-based design has been the subject of considerable researches during the past twenty years. This work has been achieved through the publication of limit state design rules for submarine pipelines. Det Norske Veritas in 1982 proposed the use of combined stress-based design criteria and strain-based design criteria. In 1996 Det Norske Veritas published a subsea pipelines limit state design criteria with many analytical methods based on a variety of load conditions. In the same year, the Canadian

Standards Association (CSA) published CSA Z662-96 (1996), which comprises strain-based design criteria for submarine pipeline design and the limit state design.

Several codes have provisions that apply of strain-based design to pipelines, including DNV-OS-F101, CSA-Z662, API RP 1111-1999, ASCE, ASME B31.8., API 1104 and ABS 2001. These codes can be placed in three general categories: those that provide a comprehensive overall pipeline standard that includes requirements both for stress-and strain-based design (DNV 2000, CSA Z662-2007), those that specifically allow strain-based design but do not provide extensive provisions related to strain-based design (B31.8, API 1104), and those provide information on strain-based design related to a specific subgroup of pipelines (ABS 2001, API RP 1111). Several organizations have current research projects that will be released to the public domain after their completion in areas that directly or indirectly impact strain-based design of pipelines. The Minerals Management Service (MMS) and the Office of Pipeline Safety (OPS) of USA co-funded EWI (2003) to provide a general guidance on strain-based design for pipelines both for the on- and off-shore environments. DNV and other organizations (Wang, Rudland and Denys, 2002; Wang and Chen, 2004; Dinovitzer and Brian, 1996; Brian and Dinovitzer, 1993; Liu, Liu and Zhang, 2007) also have some research projects about it.

In the present work the control factors of tensile and compressive strain limits of pipelines were examined first. Based on the available experiment data of full scale pipe tests under the axial tensile strain and internal pressure loading, a valid finite element model was found. Finite element analyses were conducted for a total of 711 cases covering a wide range of material, girth weld mismatch and various internal pressures. Some parametric equations were developed based on FEA. The safety factors and appropriate limits for the parametric equations have been determined based on extensive experimental data. FEA was then carried out for 8 cases of buried pipeline subjected to landslides. These examples were used to verify the method used for strain-based design of pipelines. An approach for design of buried pipelines subjected to landslides using strain-based design was also proposed. It is believed that the above applications may lay the initial base of using the strain-based design method for buried pipeline subjected to landslides for pipelines.

2 TENSILE STRAIN LIMIT

The design of pipelines using strain-based approach must count both for resistance to tension and compression along the axial direction of the pipeline. In tension, the issues relate to the failure modes of plastic collapse or fracture. Among those, ductile fracture is often found in pipelines. At its initiation, ductile fracture is not a reasonable limit state to pipeline design within the standard wall thickness regime. The crack initiation in the pipe wall does not cause leaking of product from the pipeline. However, as the fracture expands, it may reach one of these limit states.

The capacity of tensile axial strain of the pipe is affected by a large number of factors: D/t ratio, Y/T ratio, internal pressure, girth weld effect, defect size and location. More details can be found from Liu (2008) and Liu and Zhang (2008).

Wide plate test is widely used as one of the closest representations of pipeline girth weld stress state under construction and service loading conditions. Much of the test development work was done by Denys (1990). Those tests originally focused on achieving plastic collapse of the girth welds, defined as achieving a measured failure strain of 0.5% or above. In recent years, wide plate test is being increasingly used to determine failure strains beyond yield, i.e., greater than 0.5% (Wang, Chen, 2006). The wide plate tests have been designed to obtain the tensile strain limits. The more details can be found from Liu (2008), Liu and Zhang (2008).

2.1 FINITE ELEMENT ANALYSES

Finite element techniques have been widely used for shell analysis. Nowadays FEA is able to provide numerical solutions for issues with many nonlinear effects that some classical techniques cannot deal with effectively. These effects exist in the ductile fracture behavior of pipes.

In the present study, FEA analyses were conducted on quarter length specimens or pipes due to symmetry conditions. Symmetric boundary conditions were imposed on the symmetry planes. Uniform remote axial displacement was applied as the primary loading. All the analyses used a large displacement formulation implemented in ABAQUS version 6.5 (SIMULIA, 2005).

The following assumptions were made to reduce the analysis matrix to a manageable level.

Zero weld cap height was assumed. The weld cap can provide some reinforcing effects to the weld. However, the weld cap height varies around the circumference of a pipe and is process dependent. Assuming zero weld cap height leads to conservative results.

The weld bevel geometry is omitted and the weld joint is assumed to have uniform properties.

The crack-tip opening displacement (CTOD) fracture criterion is one of the fracture criteria applied to fracture of metallic materials with cracks. The failure of the pipe in this paper is defined in CTOD. The crack driving force measured in CTOD is a fundamental parameter representing the magnitude of the driving force imparted on the defect. The failure of a girth weld is assumed when the CTOD driving force reaches material's resistance measured in apparent CTOD toughness (Wang, Horsley and Cheng, 2004).

The defect is located in weld metal, not in HAZ, though it has influence on crack driving force. In this paper the weld joint is assumed to have uniform tensile properties.

Generally speaking, the higher the pipe grade, the lower the strain hardening rate and uniform strain. In this paper using the API 5L minimum yield and tensile requirements as the baseline, generic relations among pipe grade, Y/T ratio, and uniform strain are established. The stress strain curve is assumed to obey the CSA Z662 relation,

$$\varepsilon = \frac{\sigma}{E_s} + \left(0.005 - \frac{F_y}{E_s} \right) \left(\frac{\sigma}{F_y} \right)^n \quad (1)$$

Where σ and ε are the stress and strain respectively. And E_s is elastic modulus, F_y is effective specified minimum yield strength, and n is the strain hardening exponent. This stress strain relation has a continuous yield (no Luders extension).

It is recognized that the actual Y/T ratio of a pipe material can be different from that computed using the API 5L minimum requirements. For each pipe grade, an upper bound and a middle level Y/T ratio are also included in the analysis matrix. The lower bound Y/T ratio is computed from API 5L minimum yield and tensile requirements. The upper bound Y/T ratio is taken as the average of the lower bound Y/T ratio and unity. The middle level Y/T ratio is the averaged value of lower bound and upper bound Y/T ratios. The stress-strain curve of X60 from the API 5L as an example is given in Figure 1.

The stress-strain curves of welds used for finite element analysis are got from standard testing from X60 to X80. The yield strength values are 497MPa, 585MPa, and 662MPa, respectively to X60, X70 and X80.

Three-dimensional FE models simulating the curved wide plate (CWP) and pipe were generated. The C3D20R element of ABAQUS was used. This is a 20-node quadratic brick

element with reduced integration. The outline of a typical FE model and mesh is shown in Figure 2. The crack was meshed by Altair HyperMesh.7.0 (Altair Engineering, Inc, 2001).

Figure 1 Stress-strain curve of X60 from the API 5L.

(a) The CWPs model.

(b) The mesh of Crack tip.

Figure 2 A typical FE model and mesh.

Internal pressure was considered in the FE analysis except that for CWP. For straight pipe, the design pressure for a given design wall thickness or the design wall thickness for a given design pressure was determined by the following design formula in this paper,

$$P_0 = 0.72 \frac{2t}{D} \sigma_s \quad (2)$$

Where P_0 is the design pressure, σ_s is the specified minimum yield strength (SMYS), t is the design wall thickness, D is the outside diameter of pipe.

The finite element analyses for CWPs were corresponded with CWP tests. The matrix of the finite element analysis includes:

Pipe grade

The range of pipe grades analyzed is X60, X70, and X80. Only the middle level Y/T ratios were investigated in the analysis. So the Y/T ratio, $\lambda \in [0.850, 0.917]$.

Pipe diameter and thickness

The pipe diameter ranges from 30 in. (762 mm) to 48 in. (1219 mm). The pipe thickness ranges from 9.5 mm to 17.5 mm.

The internal pressure in pipe

Assuming $\gamma \equiv P_i/P_0$, where P_i is the applied internal pressure in pipe, and $\gamma \in [0,1]$.

The weld strength mismatch

The weld strength mismatch ($M = \sigma_s W / \sigma_s B$) ranges from 0 to 1.2. So The weld strength mismatch, $M \in [0, 1.2]$. When M is equal to zero, the result is corresponding to the plain pipe.

The defect size

The circumferential defect only is considered in this paper. Assuming $\xi \equiv 2c/t$, $\eta \equiv 2a/t$ (for buried defects, and a/t for surface defects), $\psi \equiv d/t$, so $\xi \in [1, 3]$, $\eta \in [0.2, 0.4]$, $\psi \in [0, 0.33]$, d is the depth of the defect.

Apparent CTOD (Crack Tip Open Displace)

Assuming $\mu \equiv \delta a/t$, where δa is the apparent CTOD.

Finite element analyses for a total of 450 cases produced a lot of data for a wide range of material, girth weld mismatch, various defect sizes or locations, buried or surface defects, and various internal pressures. So the tensile strain limits can be developed from finite element analyses.

$$\varepsilon_{ct_FE} = \mu^{0.046+0.1858\xi^{0.061}-0.549\eta^{-0.516}+e^{0.3255(1-\psi)}} \cdot (1+\lambda^{-7.44}) \cdot \text{Exp}[0.142(1-\gamma)-0.879(1-M)] \quad (3)$$

Where when $M = 0$, the equation is for the pipe without weld, and when $M \neq 0$, the equation is for the pipe with weld, and $M = 1$ represents even match. And when $\psi = 0$, the equation is for the pipe with surface defect, and when $\psi \neq 0$, the equation is for the pipe with buried defect.

The equation was validated for $0.8 \leq \lambda \leq 0.95$, $0 \leq \gamma \leq 1$, $0 \leq M \leq 1.2$, $1 \leq \xi \leq 3$, $0.2 \leq \eta \leq 0.4$ and $0 \leq \psi \leq 0.3$. The strain limit is in percentage (%).

The coefficient of correlation of Eq. (3) is 0.921.

The relationship between the tensile strain limits with three defect-size factors predicted by Eq. (3) is shown in Figure 3 (a). From Figure 3 (a), it is seen that for the same type defect, the larger defect has less tensile strain capacity. For the same size defect, the surface defect is more dangerous than the buried defect.

(a) The relationship between the tensile strain limits with three defect-size factors.

(b) The relationship between the tensile strain limits with different Y/T, girth weld mismatch, and internal pressure ratio.

Figure 3 The tensile strain limits predicted by Eq.(3).

As the curved wide plate testing can not develop the relationship between the tensile strain limit and the internal pressure of pipe, the tensile strain limits of pressurized pipes were obtained from FEA. The comparison among the tensile strain limits with the different internal pressure is shown in Figure 3 (b). The figure indicates that the higher internal pressure and the Y/T ratio reduce the ability of deformation resistance of the pipe. However the girth weld over-match does help to the ability of the deformation resistance.

2.2 The Safety Factors for the Parametric Equations

Even though the safety factor is not provided in the parametric equation, it is recommended to decrease the strain limit by 25% for the fracture process. This factor can

decrease the failure probability to the unconditioned safety level in line with normal ULS checks.

3 COMPRESSION STRAIN LIMIT

In compression, the failure modes relate to varieties of buckling. Among those, local buckling is often found in pipelines. Local buckling is not, at its initiation, a reasonable limit state to pipeline design within the standard wall thickness regime. The beginning of a ripple in the pipe wall does not impede the flow of product through the pipeline. But as the buckling extends and expands, it may reach one of these limit states.

The capacity of compressive axial strain of the pipe is affected by a large number of factors: D/t ratio, Y/T ratio, internal pressure and girth weld effect. More details can be found from Liu (2008), and Liu and Zhang (2008).

3.1 FINITE ELEMENT ANALYSES

The following assumptions are made to reduce the analysis matrix to a manageable level.

- (1) The assumption for weld cap height is the same as that for FEA on tension.
- (2) The assumption on weld bevel geometry is the same as that for FEA on tension.
- (3) The failure of the pipe in this study is defined in limit state design, as a condition in which the structure ceases to adequately perform its function. The traditional criteria based upon ultimate strength are no longer relevant. The behaviors of the pipe in terms of the initiation and development of local deformation and wrinkling becomes a rational type of behavior upon which to base such limit state criteria.

Three-dimensional FE models simulating the pipe were generated. To focus the work on the post buckling behavior, the full length model was used. The C3D8R element in ABAQUS was used. This is an 8-node linear brick element with reduced integration in hourglass control. The meshes for CWPs are the same as used in FEA of tension. The outline of a typical FE model and mesh is shown in Figure 4.

Figure 4 A typical FE model and mesh for a pipe

The finite element analysis of curved wide plate test was corresponded with testing. The analysis matrix of the additional finite element analysis as follows.

- (1) Pipe grade

The range of pipe grades analyzed is X60, X70, and X80. All level Y/T ratios, including the lower bound, the middle level and the upper bound Y/T ratios were investigated. So the Y/T ratio, $\lambda \in [0.800, 0.944]$.

(2) Pipe diameter to thickness ratio

The pipe diameter ranged from 30in. (762mm) to 48in. (1219.2mm). The pipe thickness ranged from 9.5mm to 25.4mm. So the diameter to thickness ratio, $\beta \in [43.5, 88.7]$.

(3) The internal pressure in pipe

Assuming $\gamma \equiv P_i/P_0$, where P_i is the applied internal pressure in pipe, and $\gamma \in [0,1]$.

(4) The weld strength mismatch ratio

The weld strength mismatch ratio ($M = \sigma^W / \sigma^B$) ranges from 0.8 to 1.2. So The weld strength mismatch, $M \in [0, 1.2]$.

When M is equal to zero, the result is corresponding to the plain pipe.

A typical pipe post-buckling behavior from FEA is shown in Figs 5 and 6. The criteria of compressive analysis are based on the beginning of a ripple.

Step 1.

(b) Step 2.

(c) Step 3.

(d) Step 4.

Figure 5 The post-buckling process of pressurized plain pipe.

(a) Step 1

(b) Step 2.

(c) Step 3.

(d) Step 4.

Figure 6 The post- buckling process of pressurized weld pipe

Finite element analyses for a total of 144 cases produced data for a wide range of

material, D/t ratios, weld strength mismatch ratio and various internal pressures. By using these data, the following parametric equations were developed:

$$\varepsilon_{\alpha_FE} = \beta \left(7.219 \lambda^{-1.1787} \right) \left(3.305 \gamma^2 - 2.184 \gamma + 14.65 \right) \left(1.63 M^2 - 1.79 M - 0.905 \right) \quad (4)$$

Where when $M=0$, the equation is for the NO weld pipe, and when $M \neq 0$, the equation is for the weld pipe. The equation was validated for $50 \leq D/t \leq 90$, $0 \leq \gamma \leq 1$, and $0.80 \leq Y/T \leq 0.93$. The strain limit is in percentage (%).

The relationship between the compressive strain limits with three factors predicted by Eq. (4) is shown in Figure 7.

Figure 7 The relationship between the compressive strain limits with D/t, M, and the pressure ratio predicted

3.2 The Safety Factors for the Parametric Equations

Even though the safety factor is not provided in the parametric equation, it is recommended to decrease the strain limit by 25% for the post-buckling process. This factor can decrease the failure probability to the unconditioned safety level in line with normal ULS (Ultimate Limit State) checks.

4 THE RESPONSE OF BURIED PIPELINE SUBJECTED TO LANDSLIDES

4.1 The FE Model

In designing pipeline layouts, potentially unstable slope areas are commonly by-passed. In fact, as landslides are sometimes instantaneous and unexpected, enormous costs are incurred by environmental damages caused by conduit or pipeline servicing failures. Nevertheless, either for cost reasons or unclear definition of the boundaries of the unstable areas, it is not always possible to operate this way, unstable areas are not avoidable. The analysis of the problem of the interaction between landslides and pipelines is therefore of some importance. So in this part, the response of buried pipeline subjected to landslides was analyzed for the Lan-cheng-yu pipeline of China National Petroleum Corporation (CNPC).

The Lan-cheng-yu pipeline of CNPC is one of important pipelines of CNPC. It has been designed long ago, and, particularly in Sichuan across the highly unstable region of the Erlang temple (See Figure 8), without much concern for the potential instability of the crossed slopes. As a consequence, failure is likely to occur. In the figure, the landslide is transverse across the pipeline with about 20° bevel.

To introduce the interaction model in a simple way, assume first that the free surface of the slope is planar and that its inclination with respect to the horizontal plane. The soil-pipe interaction model used in the present study is shown in Figure 9.

Figure 8 Er-lang temple landslide of the Lan-cheng-yu pipeline

Figure 9 Simple soil-pipe interaction model used in the present study

Three-dimensional FE models simulating the CWP and pipe were generated. The PSI element was used. After FE analysis, the maximal tensile and compressive strains of the pipe were obtained as: $\varepsilon_t=3.2\%$ and $\varepsilon_c=2.4\%$. They are the same as that calculated from Eqs (3) and (4). Using these two values, the strain based design of buried pipelines subjected to landslides was conducted.

4.2 The FE Analysis Result

In order to find the relationship between the pipe and the soil, 8 finite element analyses were done as shown in Table 1. Four of shape of FE models are set as shown in figure 9, and the others are axial across the pipeline. The width of landslides is shown in Table 1. The soil spring stiffness is shown in Table 2.

No.	Direction	Width/m	Displacement of soil/m
V1	Transverse	50	10
V2	Transverse	100	20
V3	Transverse	150	40
V4	Transverse	200	40
A1	Axial	50	5

A2	Axial	100	5
A3	Axial	150	5
A4	Axial	200	5

Table 1. The analysis matrix of the landslides.

Direction	Stress/MPa	Strain/%
Axial	42000	0.005
	-76705	-0.018
	0	0
Vertical	1252448	0.12
	2000000	0.25
	-370638	-0.124
Horizontal	0	0
	370638	0.124

Table 2. The soil spring stiffness.

As shown in Figure 10, the tensile and compressive strain limits of pipelines decrease with the increase of the transverse landslide width when the landslide width is smaller than 125m, while increase with the transverse landslide width when the landslide width is larger than 125m.

Figure 10 The relationship between the transverse landslide width and the strain of pipeline.

As shown in Figure 11, the tensile and compressive strain limits of pipelines increase with the increase of axial landslide width.

Figure 11 The relationship between the axial landslide width and the strain of pipeline.

4.3 The Strain Based Design Method of Buried Pipeline Subjected to Landslides

When the pipelines cross the area with big ground movement, the strain-based design should be considered. In the present study, the strain based-design method of buried pipeline subjected to landslides was developed. The steps of this method are listed as follows and shown in Figure 12.

Analysis steps for strain based-design of buried pipeline subjected to landslides:

- (1) Estimate the location, range and magnitude of ground displacement.
- (2) Estimate the strain limits.
- (3) Find the material, wall thickness and depth of pipelines.
- (4) Compute the soil-pipe interaction.
- (5) Compute the applied strain of pipelines.
- (6) Compare the strain limits and the applied strain of pipelines.
- (7) Finish

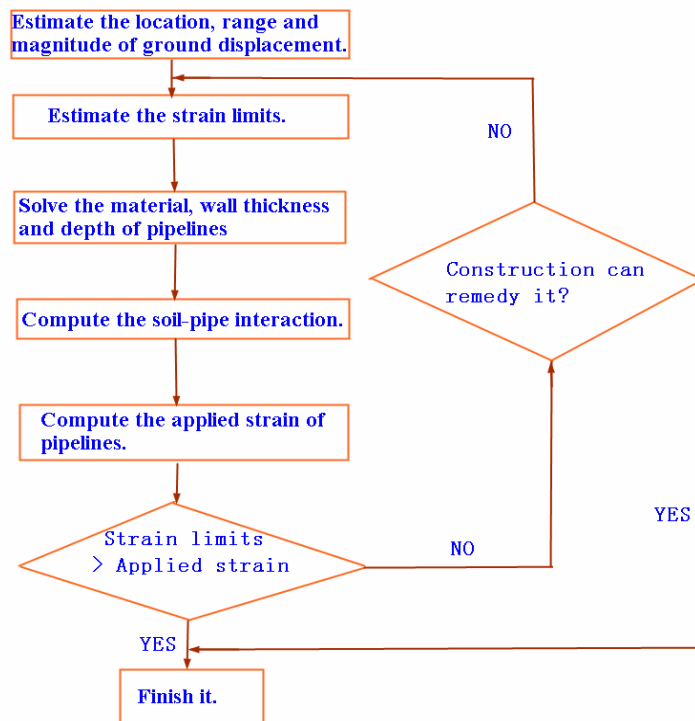

Figure 12 Strain-Based Design Method for Buried Pipeline Subjected to Landslides.

5 CONCLUSIONS

The parametric equations for the quantitative evaluation of tensile and compressive strain capacity of pipelines were proposed based on extensive FEA. The strain-based design method for buried pipeline subjected to landslides was developed. It is believed that the method presented in this paper may lay the initial basis for pipelines integrate assessment using strain-based design for pipelines in China.

6 ACKNOWLEDGEMENTS

This work was supported by China National Petroleum Corporation (CNPC). We would like thank Dr. Yong-Yi Wang, the President of Center for Reliable Energy Systems and all

colleagues from R&D Center of PetroChina Pipeline Company for discussion and advising of this work, especially Dr. Bing Han.

Keywords: irregular industrial buildings, seismic design, seismic response, steel bracing

Abstract. *Seismic behaviour of a heavy industrial building with highly irregular geometry, and mass and stiffness distribution is investigated to assess the effectiveness of current procedures for seismic design of such structures. These procedures were developed essentially for conventional commercial or residential buildings with regular and well-defined seismic force resisting systems, and their use to predict adequately deformations and forces for irregular industrial building may be questionable. The studied building is located near Montreal, Canada, and houses a vertical mechanical process representative of mining and metal refining industry. It is braced by low-ductility concentrically braced steel frames. Three-dimensional elastic dynamic time history analyses were carried out for selected acceleration records compatible with the design spectra at the site. The results are compared to those obtained from the equivalent static force procedure and the response spectrum analysis method. The study shows that the equivalent static method can adequately predict the displacements, but may underestimate column and brace axial forces. In general, response spectrum analysis method, provided appropriate prediction of the seismic response of the highly irregular structure studied.*

1 INTRODUCTION

Current code seismic design provisions for buildings in North America are mostly suited for conventional office or residential buildings framed by regular, continuous and well-defined seismic force resisting systems. Heavy industrial buildings are principally designed to ensure the functioning of an industrial process, and the structural elements are positioned to support heavy equipment and the machinery needed for operation. For these reasons, such buildings usually have complex and irregular geometries and uneven distribution of mass and/or stiffness which results in variety of dynamic characteristics that significantly differ from those found in regular structures. The application of current design provisions to industrial buildings is challenging for practicing engineers, as it requires continuous interpretation and adaptation of design rules and may result in inadequate designs [1, 2].

Structural response of steel-framed industrial buildings in past earthquakes was globally satisfactory, but the interruption of the operation was reported in many cases due to damage of individual components or connections [3]. Downtime periods may lead to loss of income for the industry, unemployment, or shortage of goods, electrical power and communications and have significant social and economical consequences. It is therefore imperative to ensure that seismic design procedures can lead to adequate performance. In view of limited data on the seismic demand imposed on industrial steel buildings by strong ground motions, it is difficult to evaluate if the seismic force and deformation demand on industrial structures can be adequately predicted using methods prescribed in current building design codes.

In this study, the seismic response of an irregular heavy industrial building is examined, and the analysis methods proposed in codes to estimate deformations and forces are critically reviewed in light of the observed response. The study is conducted for an existing building near Montreal, Canada that houses a vertical mechanical process representative of the mining and metal refining industry. Elastic three-dimensional time history analyses are carried out using a suite of ground motion records compatible with the design spectrum and the deformations, as well as axial loads in braces and columns are compared to the predictions from equivalent static force and response spectrum analysis methods. Special attention is given to the appropriate number of modes to use in response spectrum analysis and the possible impact of the direction of seismic loading on member force demand.

2 ANALYTICAL MODEL OF STUDIED BUILDING AND GROUND MOTION RECORDS

2.1 Building geometry and the analytical model

A three-dimensional view and the layout of the columns at the base of the industrial building studied are shown in Figs. 1a and 1b respectively. The main portion of the building has 37 m x 59 m plan dimensions and is 43 m high. An 8 m tall penthouse is located in the south-west part of the structure. The building also includes two extensions, one in the north-west corner (5 m x 6 m, 18 m high) and another one in the south-east corner (24 m x 8 m, 6 m high). In Fig. 1a, a more recent extension located south of column Line 11 can be seen. That addition was not considered in this study and is not shown in the other figures. With the exception of the roof level, the building does not have floors that extend through the whole building but rather a series of platform that are used to provide support and give access to different pieces of equipment. The platforms are mainly concentrated in the south and north portions of the building, leaving a large open space in the centre. Two large capacity silos (750 t and 1200 t) are located between Lines 1 and 4, and other smaller pieces of equipment are placed throughout the structure. Four low-ductility concentrically braced steel frames located

on the perimeter of the building form the primarily lateral load resisting system. Additional braced frames are provided in the vicinity of the heavy equipment and large openings. The building has several irregularities as defined in the 2005 National Building Code of Canada (NBCC) 2005 [4], namely mass irregularity, in-plane discontinuity of vertical lateral load carrying elements, out-of plane offsets and torsional sensitivity.

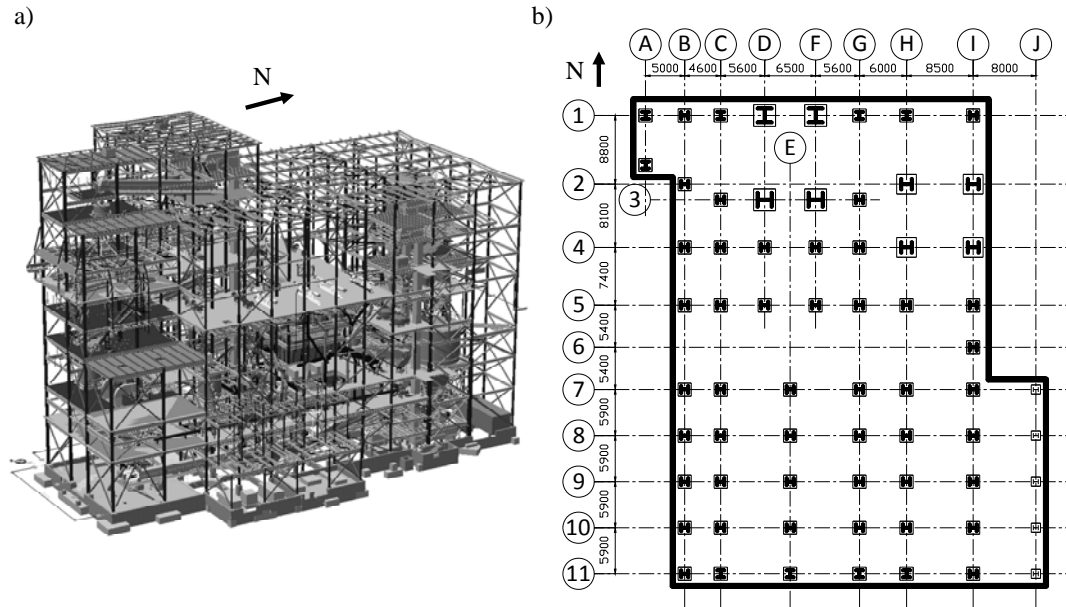

Fig. 1 Irregular building studied: a) Three-dimensional view; b) Column layout at the base.

In order to facilitate the analysis and obtain more general results that could be representative of the behaviour of similar buildings, the geometry and the secondary framing arrangements were simplified. Fig. 2 shows the final three-dimensional numerical model built with the program STAAD.Pro [5]. The model includes the columns, beams, braced frames and horizontal bracing. The members supporting the main equipment were also represented. All the platforms were included in the model, but rigid diaphragm properties were considered only for the floors with a concrete slab.

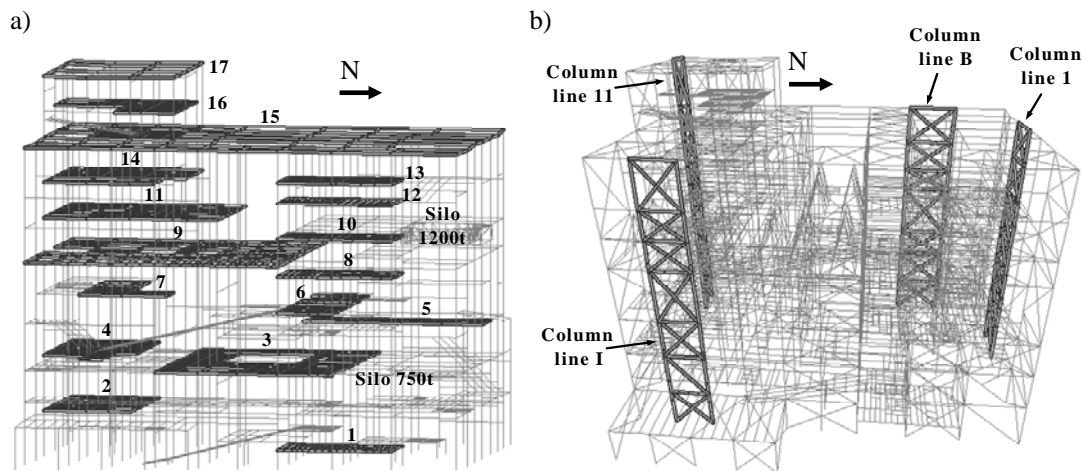

Fig. 2 Analytical model in STAAD.Pro: a) Location of platforms; b) Elevation of the braced frames studied.

The total seismic weight of the structure ($W = 74200$ kN) was determined as specified in NBCC 2005 and consisted of the weight of the structural members, 25% of the roof snow load and the weight of the main equipment in the fully-loaded condition. In order to include the mass of the major equipment at appropriate locations, additional nodes were introduced at the center of the gravity of the pieces of equipment considered, and linked to the rest of the structure by very stiff members. In this way, local overturning moments created by the horizontal inertia forces acting above the platforms that support the equipment could be accounted for in the analyses. The masses of the remaining equipment were assigned to the supporting columns at each floor in proportion to their tributary areas. For simplicity, the effects of accidental torsion, gravity loads and P-Delta effects were not considered in the analysis.

2.2 Selection of ground motion records

Elastic dynamic time history analyses were carried out for an ensemble of ground motions compatible with the NBCC design spectrum for a Class C site in Montreal. Due to the lack of recordings of historical ground motions rich in high frequencies, which are typical at Eastern North-American sites, simulated acceleration records were applied. Fourteen records were selected from the database described in [6] based on magnitude-hypocentral distance scenarios that dominate the seismic hazard. The records were scaled to obtain the match between the intensities of their spectra and the target design spectrum over the range of periods determined on basis of the best visual fit between the two spectra. A detail description of the ground motion selection and scaling can be found in [7]. The resulting median acceleration response spectrum of scaled records is compared to the target design spectrum in Fig. 3.

Fig. 3 Target design response spectrum (NBCC 2005) and median 5% damped elastic acceleration spectra for the ensemble of scaled ground motion

3 VALIDATION OF SEISMIC ANALYSIS METHODS USED IN DESIGN

3.1 Equivalent static force method and response spectrum method

Forces and deformations induced by seismic loads were first determined using the code equivalent static force procedure and response spectrum analysis methods. The seismic loading was not reduced to account for the ductility and the overstrength of the system so that direct comparison with the results of the elastic time history analyses could be made. Although the use of dynamic analysis is required in NBCC 2005 for an irregular building such as the one studied, the equivalent static force method was also considered as it is likely to be used by practitioners in preliminary design due to its simplicity.

The fundamental periods were initially calculated using the NBCC empirical formula for braced frames, $T_a = 0.025h_n$, where h_n is the building height. Taking $h_n = 51$ m for the frame

height at the penthouse location and $h_n = 43\text{m}$ elsewhere in the building, periods equal to 1.28s and 1.08s respectively were obtained. The periods were also calculated using modal analysis. The results are summarized in Table 1. The directions of the building principal modes correspond to the two orthogonal directions of the building, but modes in both directions showed torsional response. Each of the two principal modes were associated with about 54 percent of the total mass, and the contribution of higher modes was relatively small and varied between 0.1 and 7 percent (see Table 1). Thus, a large number of modes had to be considered (70 for the E-W direction and 95 for the N-S direction) to obtain the minimum 90% mass participation required by codes.

Mode	T_i (s)	E-W		N-S	
		M_i (%)	$\Sigma M_i / M$ (%)	M_i (%)	$\Sigma M_i / M$ (%)
1	1.46	0.0	0.0	0.2	0.2
2	1.38	53.2	53.2	2.1	2.1
3	1.32	1.5	54.7	63.4	65.7

126	0.26	0.3	97.1	0.1	96.1

Table 1 Results of the modal analysis: Periods and associated modal masses

Fundamental periods were also computed using the Rayleigh method: 1.29 s and 1.28 s were obtained in the E-W and N-S direction, respectively. Values from all three methods agreed well. The elastic base shear forces from the equivalent static force method, V , were determined using the periods calculated with the Rayleigh method: $V = 8900$ kN along the E-W direction and $V = 9000$ kN along the N-S direction. Two different approaches were examined for the vertical distribution of seismic loads to assess how well they account for higher mode effects, namely (i) linear distribution with a concentrated force at the top of the structure as prescribed in NBCC 2005, and (ii) parabolic distribution, as defined in ASCE 7-05 [8].

In the response spectrum analysis, modal contributions were combined using the CQC rule assuming 5% damping in all modes. As previously mentioned, large number of modes had to be included to obtain the minimum 90% mass participation required by codes: 70 and 95 modes for the E-W and N-S directions, respectively. The base shear forces from response spectrum analysis, V_t , were equal to 5690 kN and 6460 kN representing only 64% and 72% of the seismic base shear forces obtained from the equivalent static method in corresponding directions. When including up to 126 modes, the combined mass participation increases to 97% and 96% in each of the two directions (see Table 1) and the two associated base shear forces increased to 71% V and 79% V , respectively. Further increase in the number of modes in the

response spectrum analyses did not lead to any further augmentation of the base shears. The difference between V_t and V is explained by the inherent inadequacy of the equivalent static force method to represent the dynamic response of complex structures. In this context, the requirement to scale response spectrum analysis results to the values obtained from the equivalent static force method, as currently prescribed in North-American codes, could be questioned when the number of modes used in the spectral analysis is sufficient to reach convergence. However, further investigation is needed on this subject before more general conclusions can be drawn. In this study, the results of the response spectrum analysis conducted for the number of modes engaging 90% participating mass were scaled by the V/V_t ratio, as required in NBCC 2005, and then compared with other methods.

3.2 Dynamic time-history analysis

Three-dimensional dynamic time history analysis was carried out using the modal superposition routine available in the program STAAD.Pro. Damping equal to 5% of the critical value was assigned to all modes. Preliminary analyses were performed to determine the appropriate number of modes required to adequately predict the seismic base shears, storey displacements and maximum brace forces. The number of modes was gradually increased to achieve 90% (70 modes and 95 modes in the E-W and N-S direction, respectively), 97% (126 modes) and nearly 100% (500 modes) participating mass. Increasing the participating mass from 90 to 97%, resulted in peak base shear forces increasing by as much as 25%; however, no further base shear increase was observed beyond 126 modes. Similarly, brace axial loads changed significantly until 126 modes were included but remained fairly constant when additional modes were considered. Storey displacements were the least sensitive to the number of modes selected; however, for specific building levels, it was necessary to engage 97% of the mass to avoid changes in the results. Based on these three observations, 126 modes were selected for the time history analyses performed. Comparison with the other methods was based on median results which can be considered representative in view of number of acceleration records selected. However, 84th percentile values were also tracked to illustrate dispersion. The analyses were conducted for two sets of orthogonal axes: the principal axes of the building and a set of axes oriented at 45 degrees angle with respect to the principal directions. The latter set was chosen to evaluate the impact of the direction of the analysis on the response.

3.3 Comparison of results

Following response parameters were selected for comparison between the three methods: the seismic base shear, storey displacements, and the axial forces in columns and braces of the braced frames. The results are given in Figs. 4, 5 and 6.

Fig. 4 Peak base shear from equivalent static force (STAT), response spectrum (SPEC) non-scaled, and time history (TH-med and TH-84th) analysis methods.

Fig. 4 shows that, regardless of the method, the seismic base shears in the two principal building directions were similar. This was expected because the corresponding building pe-

riods were comparable in the two directions. Elastic base shears calculated using the equivalent static force method exceeded the median time history results by approximately 40%, and were even slightly higher than the maximum peak values. Median results agree well with the values obtained from response spectrum analysis when no scaling of base shear is applied, confirming that the base shear estimates obtained from the equivalent static force method are probably conservative.

Fig. 5 Peak drift from equivalent static force (STAT), response spectrum (SPEC) scaled, and time history (TH-med and TH-84th) analysis methods and for earthquake action along the N-S direction.

Fig. 5 illustrates the calculated peak displacements under loads and ground motions applied in the N-S direction. Displacements are studied instead of inter-storey drifts, because none of the floors extended through the whole building areas. The results shown are normalized by the total storey height measured from the ground. Comparable displacement profiles were predicted from all methods employed. No significant difference was noted when using the NBCC 2005 or the ASCE 7-05 seismic force distributions in the equivalent static force method. Spectrum analysis results were slightly smaller than those obtained from equivalent static load method in all but two locations, and about 40% higher than the mean time history results. The 84th percentile values were also below the predictions of the equivalent static and response spectrum methods. These observations are consistent with those made for base shears.

Column and brace axial load profiles in the selected braced frames, shown in Fig. 6, compare well between the different methods considered. The results are shown for earthquake loads acting along the N-S direction of the building. Similar force profiles were obtained for the E-W direction, and the results are not shown herein. The response spectrum analysis values consistently exceeded the median time history results. They were even higher than the 84th percentile time history values for almost all structural elements studied. This can be explained by the scaling procedure that was applied to the response spectrum analysis results. The results from the equivalent static force method are comparable to response spectrum values for the frames oriented in the direction of the analysis. For the frames in the perpendicular direction, however, the equivalent static force method under-predicted the member forces by a large margin in some cases. This can be attributed to the inadequate treatment of higher modes and in-plane torsional effects when using an equivalent static force method for such irregular structures.

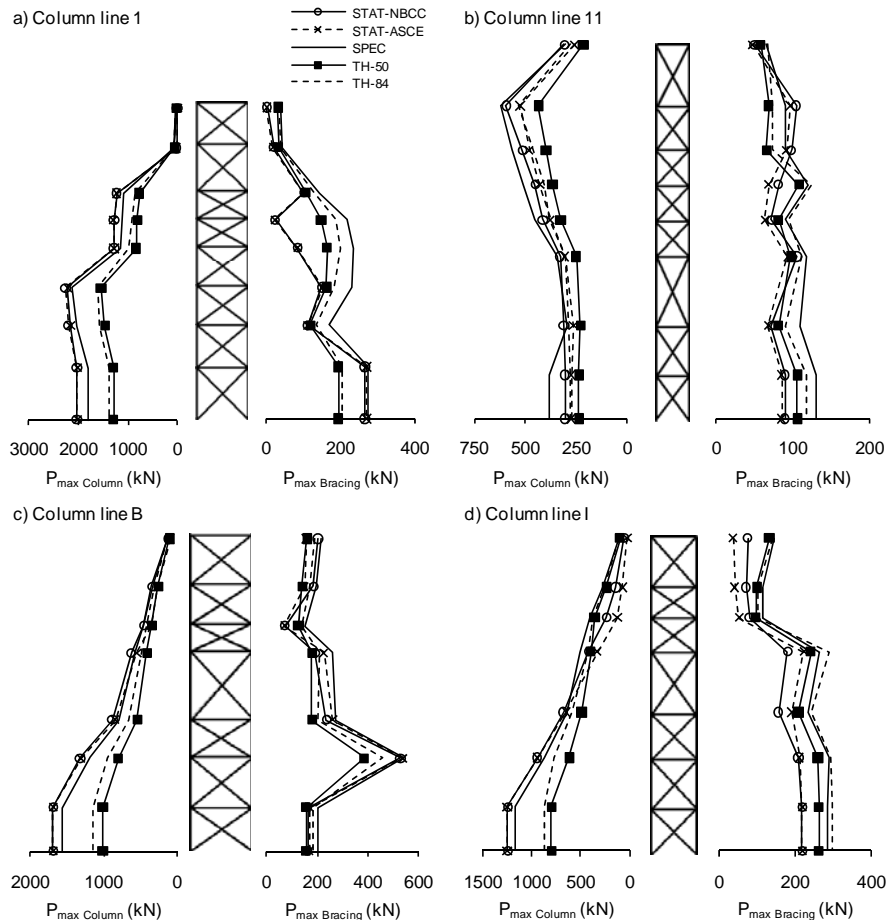

Fig. 6 Comparison of peak axial load in columns and braces induced by seismic loads acting in N-S direction: equivalent static force (STAT), response spectrum (SPEC) scaled, and time history (TH-med and TH-84th) analysis methods

3.4 Impact of the direction of analysis on column and brace forces

According to NBCC 2005, when the components of the seismic force resisting systems are orientated along a set of orthogonal axes, design seismic forces in the members of a building structure can be obtained two independent analyses performed along each of the principal axes of the structure. This condition applies for the structure studied. However, given the presence of irregularities in the structure and the fact that some braced frames shared columns in the upper part of the building, it was of interest to determine if the direction of the application of the loads could have impact on the member forces.

Fig.7 summarizes the results obtained from time history analysis for four directions of load application: two analyses along the principal axes of the building and two analyses along orthogonal axes oriented at 45 degrees angle with respect to the building principal directions. Force envelopes obtained from the response spectrum analysis are also shown for comparison. Note that column lines B and I run in the N-S direction while column Lines 1 and 11 are in the E-W direction. As expected, the highest axial loads in diagonals of the braced frame were developed when seismic action was applied in the direction of the braced frame. The same observation holds true for the columns of braced frames in the N-S direction. On the contrary, in the upper columns of the frames along the E-W direction, up to 30% higher forces were recorded under the ground motions acting in directions other than the direction parallel to the

frames, including loading at 45 degrees. Such a result is explained by the fact that these columns were also part of another braced frame placed in the perpendicular direction to the studied frame. This type of framing arrangements is not uncommon in heavy industrial buildings, and caution should therefore be exercised when selecting the direction of the loading for seismic analysis. In all cases studied, member forces obtained from the response spectrum analysis were the highest and would therefore provide conservative estimates of design forces.

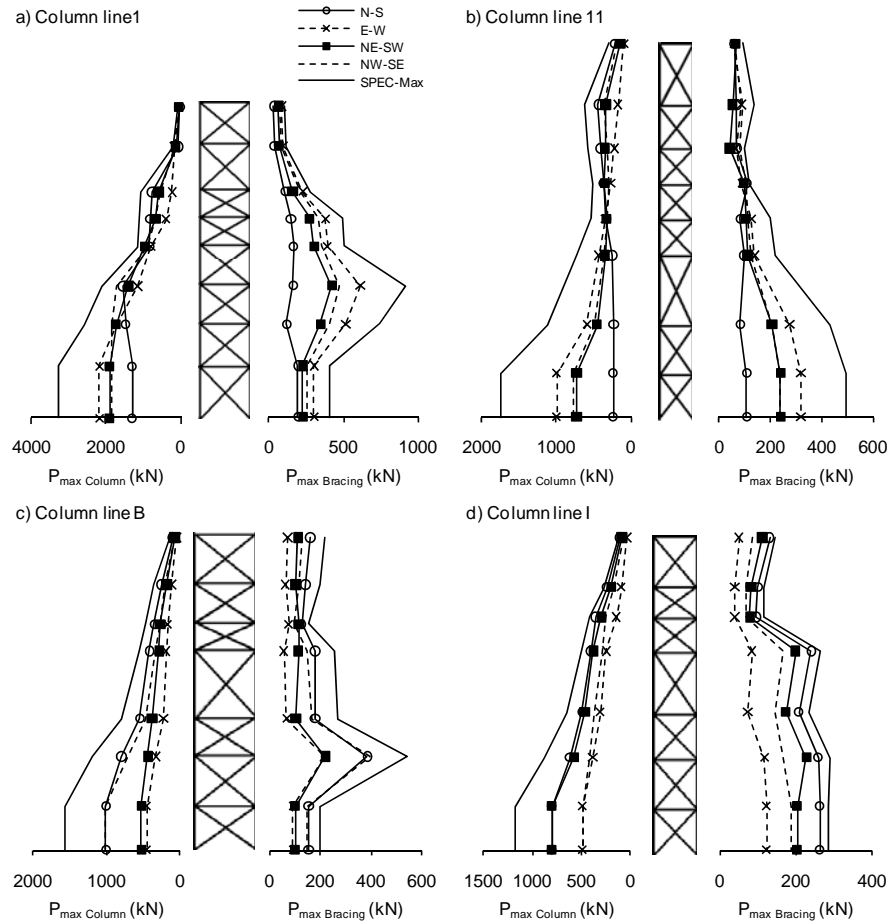

Fig. 7 Impact of direction of the analysis on peak axial load in columns and braces.

4 CONCLUSIONS

- For the building studied, the fundamental periods obtained using the code empirical formulae compared well to values from modal analysis and the Rayleigh method;
- The equivalent static force method gave reasonable estimates of deformations under seismic loads, but under-estimated the axial loads in columns and braces;
- For the response spectrum analysis method, it was necessary to include a large number of modes to engage the minimum 90% mass participation required by building codes: 70 and 95 modes, respectively, for each of the two principal directions of the building studied;

- The response spectrum analysis method provided a fair prediction of both the deformation and force seismic demand, and therefore appeared to be an appropriate method to predict the seismic response of such a highly irregular building;
- In this study, dynamic time history analysis was performed using a modal superposition technique. The results showed that member forces are sensitive to the number of modes considered in the analysis and can be significantly under-estimated if an insufficient number of modes is selected. For the building studied, the number of modes required to obtain 97% global mass participation was needed to adequately predict the base shear forces;
- The study showed that the selection of the direction in time history analysis should be done with care, as the maximum forces in components that are common to two braced frames in orthogonal directions may be induced by seismic loads acting in directions that are not parallel to the braced frame studied.
- The study was limited to a single building with specific dynamic characteristics and the results cannot be generalized before similar study is conducted on additional structures. However, the results provide insight into possible limitations of current seismic design procedures and possible directions for future investigation.

Keywords: liquid storage tank, seismic design, sloshing, finite elements, shell buckling.

Abstract. *The paper examines some special issues on the structural behaviour of upright-cylindrical liquid storage tanks, which are widely used in industrial facilities and for water storage. Two main design standards are considered: EN 1998-4, a relatively new standard, and Appendix E of API 650, which has been through substantial amendments and revisions in its new version (11th edition, 2007). There are significant differences between the two specifications, which are due to the fact that there exist several controversial issues on this subject, open to further research. These issues are (a) the number of modes necessary to estimate accurately the convective seismic force due to the hydrodynamic behaviour of the liquid containment; (b) the appropriate combination of the impulsive and the convective component of seismic force; (c) the uplifting behaviour of unanchored tanks, with emphasis on the base plate behaviour and the increase of meridional compression; (d) the choice of an appropriate reduction (behaviour) factor for calculating both the impulsive and the convective force; (e) the calculation of hydrodynamic hoop stresses due to liquid hydrodynamic motion; (f) the design of tanks against buckling at the top due to liquid sloshing; (g) the importance of nonlinear wave sloshing effects.*

The present paper is aimed at addressing the above issues based mainly on numerical simulations. To simulate the tank shell and its structural behaviour, general-purpose finite element software ABAQUS is employed, whereas to examine hydrodynamic effects, an in-house numerical technique is developed. Existing data from previous investigations are also considered. The results are aimed at better understanding of liquid storage tank seismic behaviour, bridging the gap between the two major design standards (EN 1998-4 and API 650-Appendix E), towards safer seismic design of industrial facilities.

1 INTRODUCTION

The structural response of liquid storage tanks under strong seismic loading constitutes an important issue for safeguarding the structural integrity of industrial facilities, especially in refineries and power plants. Significant damages of tanks have been reported in earthquake events [1][2]. The dominant mode of tank failure is in the form of elephant's foot buckling at the tank base. Other types of earthquake damages include buckling of the top of the tank shell, base plate failure due to uplifting, roof damage due to excessive sloshing, or shell damage at nozzle areas due to non-flexible connections with piping. Current design practice is based on the application of the API 650 provisions [3], as described in Appendix E. This Appendix has been initially incorporated in the standard in the late 70's [4], and has been substantially revised in the 11th edition published in 2007 [3] to be in accordance with the provisions of ASCE 7-05 [5]. In addition, to this standard, the newly published EN 1998-4 standard [6] contains design provisions for the seismic design of liquid storage tanks.

In the following, several issues related to the seismic analysis of liquid storage tanks and the determination of seismic action are addressed and examined, using numerical simulations. It has been recognized that there exist some specific issues that require further investigation and improvement. In particular, the following issues are addressed in the present study:

- The number of sloshing modes to be considered in convective action and their combination with impulsive action.
- The effects of shell deformation on the seismic response.
- Calculations of hoop hydrodynamic stresses
- Uplifting of unanchored tanks
- Buckling at the top of the tank
- Behavior factor of liquid storage tank and elephant's foot buckling
- Nonlinear sloshing effects

The investigation of those issues is aimed at comparing – where possible – the API 650 and the EN 1998-4 provisions for the seismic design of liquid storage tanks, towards proposing possible improvements/amendments of the EN 1998-4 standard. For this purpose, three liquid storage tanks are considered and their seismic response is simulated numerically:

- (a) A moderately-broad tank, referred to as Tank I, is primarily considered. This is a 27.4-meter-diameter tank with a total height of 16.5 meters. The tank is unanchored. The filling height of the tank H is equal to 15.7, which makes an aspect ratio of the tank $\gamma(H/R)$ equal to 1.145. The tank thickness varies from 6.4 mm at its top course to 17.7 mm at its bottom course, the bottom plate is 6 mm thick, and has a 8-mm-thick annular plate.
- (b) The second tank considered, referred to as Tank II, is a tall tank of 18-meter-diameter tank with a total height of 20 meters. The filling height of the tank H is equal to 19, which makes an aspect ratio of the tank H/R equal to 2.1. The tank thickness varies from 6 mm at its top course to 10 mm at its bottom course and it is anchored .
- (c) The third tank, referred to as Tank III, is a very broad tank of 68-meter-diameter with a total height of 20 meters. The filling height of the tank H is equal to 19 resulting to an aspect ratio H/R equal to 0.558. The tank thickness varies from 34 mm at its top course to 38.5 mm at its bottom course.

All three of the above liquid storage tanks are existing tanks, constructed in seismic regions, and have been designed against hydrostatic pressure following the API 650 [3] methodology “Calculation of Thickness by the 1-Foot Method” in section 5.6.3, considering a liquid containment of unit gravity (water). The tanks are depicted in Figure 1.

2 SEISMIC DESIGN CODES FOR LIQUID STORAGE TANKS

Seismic design of liquid storage tanks in petrochemical facilities has been conducted with the relevant provisions of API 650. In particular, Appendix E of API 650 refers exclusively to seismic design, contains provisions for both determining seismic actions on tanks, as well as calculating the strength of the tank. The new edition of Appendix E includes provisions for site-specific seismic input, calculation of hoop hydrodynamic stresses, distinction between ringwall and slab overturning moments, freeboard requirements, and consideration of vertical excitation effects. The latter three issues are new, with respect to the old version of the Appendix [4], whereas the issues of uplifting/anchorage and calculation of shell compression are significantly enhanced. It should be noted that seismic action calculations in the new version of Appendix E are in accordance with ASCE 7 standard [5].

European standard EN 1998-4 [6] is part of the CEN/TC250 standards, often referred to as “Structural Eurocodes”. It includes seismic provisions for silos, tanks and pipelines. In Chapter 2 some general provisions are stated. More specific rules for the seismic design of tanks are stated in Chapter 4 (e.g. behavior factor, limit state description), whereas extensive methodologies for calculating seismic action and verifying shell buckling are presented in Informative Annex A. It has been recognized as a standard that contains state-of-the-art scientific information for determining seismic action, based on the work of Rammerstorfer et al. [7] and Scharf [8] as well as the work of Rotter [9] for shell buckling under internal pressure (elephant’s foot). However, there are some issues that need further investigation and possible improvement; a list of those issues is offered in section 1, and will be discussed extensively in the present paper.

3 SLOSHING MODES AND THEIR COMBINATION WITH IMPUSIVE MOTION

The first issue of interest concerns the number of sloshing (convective) modes to be considered for determining the convective seismic force. The three tanks under consideration have been subjected to base-ground seismic acceleration from 10 artificial earthquakes, generated from the EN 1998-1 design spectrum, as shown in Figure 2. Tables 1 and 2 show some characteristic results from 4 typical accelerograms from those earthquakes (denoted as ACC1, ACC2, ACC3 and ACC4 respectively), in terms of the maximum convective forces for several modes, the corresponding maximum impulsive force, and the maximum total seismic force. For each earthquake event the maximum convective force was calculated as the product of the “convective” accelerations and the corresponding sloshing masses:

$$F_C = \left(\sum_n \mathbf{M}_{nC} \ddot{u}_n \right)_{\max} \quad (1)$$

where the “convective” acceleration is calculated from the following linear oscillator equation:

$$\ddot{u}_n + 2\xi_n \omega_n (\dot{u}_n - \dot{X}) + \omega_n^2 (u_n - X) = 0 \quad (2)$$

In the above equations, the convective (sloshing) mass is computed as follows

$$\frac{\mathbf{M}_{nC}}{\mathbf{M}_L} = \frac{2 \tanh(k_n R \gamma)}{k_n R \gamma (k_n^2 R^2 - 1)} \quad (3)$$

and

$$\frac{\omega_n^2 R}{g} = (k_n R) [\tanh(k_n R \gamma)] \quad (4)$$

is the sloshing (convective) circular frequency of the tank. Similarly, the maximum impulsive force was calculated as the product of the “impulsive” acceleration and the corresponding impulsive mass:

$$F_I = (\mathbf{M}_I \ddot{X})_{\max} \quad (5)$$

where the “impulsive” acceleration is calculated as follows

$$\ddot{u}_I + 2\xi_I \omega_I (\dot{u}_I - \dot{X}) + \omega_I^2 (u_I - X) = 0 \quad (6)$$

In the above equation, the impulsive mass is computed as follows

$$\mathbf{M}_I = \mathbf{M}_L - \sum_{n=1,2,3,\dots} \mathbf{M}_{nC} \quad (7)$$

and

$$\omega_I = \frac{2\pi}{C_i} \sqrt{\frac{Et}{\rho R}} \quad (8)$$

is the impulsive circular frequency of the tank. In the above expression C_i is a nondimensional parameter that depends on the aspect ratio of the tank $\gamma = H/R$ and where t is the average thickness of the tank shell. The integration of linear oscillator equations (2) and (6) is performed through a standard central-difference numerical method. In Tables 1, 2, and in Figure 3a, Figure 3b and Figure 3c, together with the maximum convective and impulsive forces, the maximum total forces are presented, for 4 typical artificial ground acceleration inputs (denoted as ACC1, ACC2, ACC3 and ACC4 respectively), as computed by the following equation

$$F_{\max} = \left(\sum_n \mathbf{M}_{nC} \ddot{u}_n + \mathbf{M}_I \ddot{X} \right)_{\max} \quad (9)$$

		$F_{I,\max}$ [MN]	$F_{C,\max}$ [MN]
Tank1	ACC1	16.757	1.064

	<i>ACC4</i>	78.295	75.471	76.075

Table 2: Combination of maximum impulsive and maximum convective forces.

The values in Tables 1 and 2 indicate the following

- The impulsive force is significantly higher than the convective force. Therefore, in most of the cases, refinements on the value of the convective force are of little importance on the calculation of the total seismic force.
- In the special case, of broad tanks (low values of tank aspect ratio), consideration of more than one sloshing mode (e.g. two sloshing modes) may be necessary for determining of the total seismic force, due to the appropriate determination of impulsive mass M_i in equation (7), rather than the contribution of higher modes on the value of the maximum convective force F_C .
- The combination of impulsive and convective forces should be conducted according to the SRSS rule, rather than the addition of the maximum convective and maximum impulsive forces.

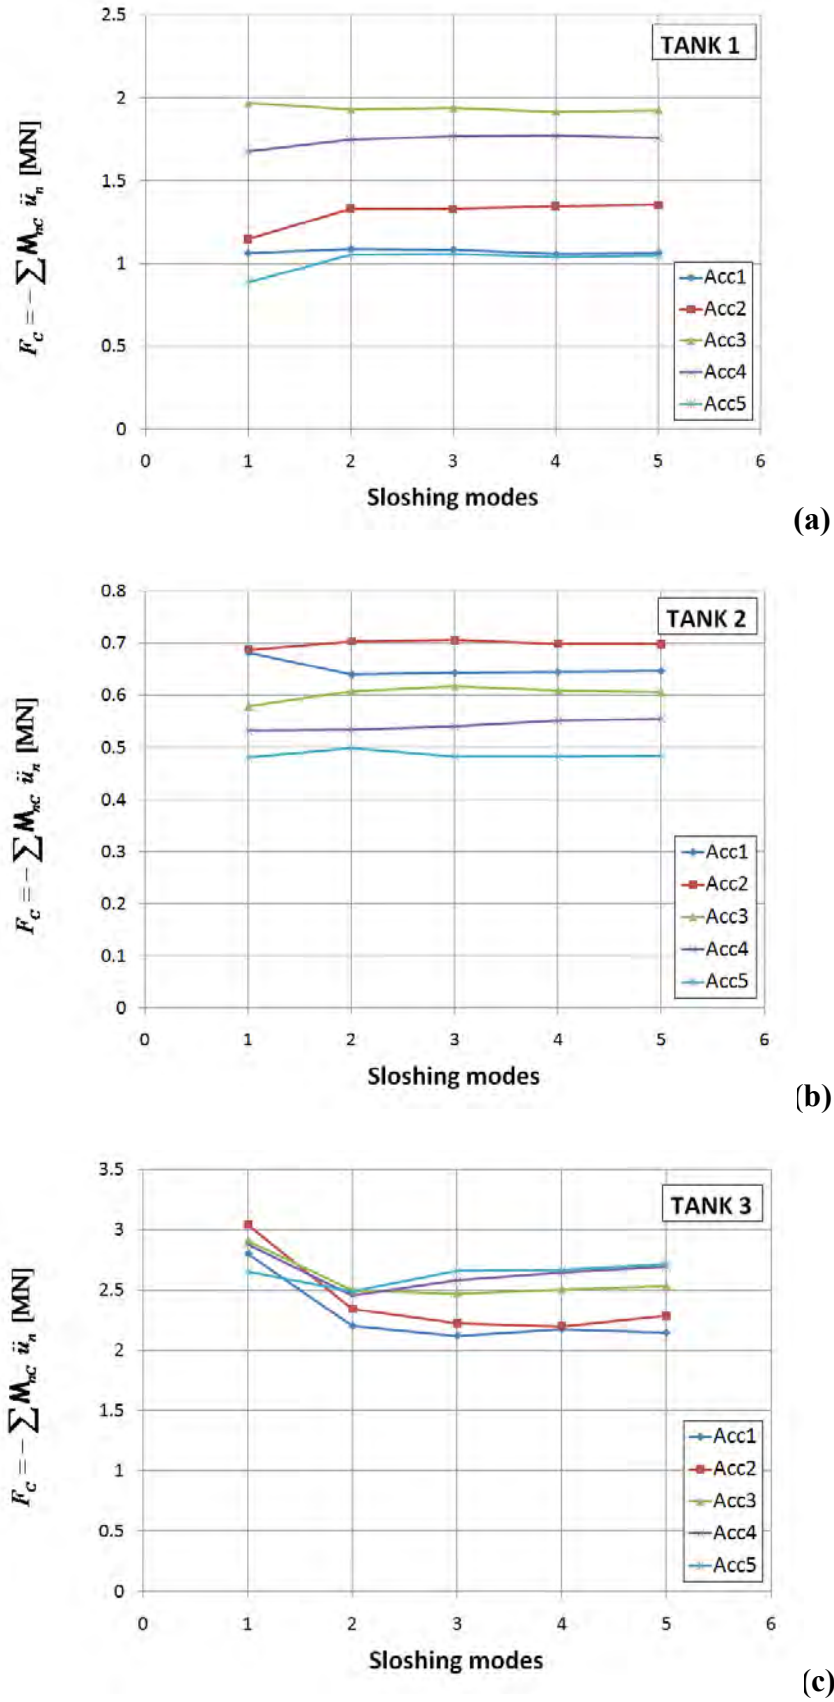

Figure 3: Effect of the number of sloshing (convective) modes on the maximum horizontal convective force for 5 typical ground acceleration excitations (a) Tank I; (b) Tank II and (c) Tank III.

4 EFFECTS OF TANK DEFORMABILITY

In the case of rigid (non-deformable) liquid containers, the impulsive motion is exactly the same as the ground motion, whereas the convective motion is determined by the solution of the hydrodynamic problem within the rigid container. However, steel tanks are not rigid, they deform due to their small thickness with respect to their diameter.

A finite element analysis, which accounted for the dynamic interaction between the liquid and the deformable tank, has been reported by Scharf [8]. Scharf's analysis it is assumed that in flexible tanks the motion of the tank-liquid system is expressed as the sum of three contributions, referred to as: 'rigid impulsive', 'sloshing' and 'flexible'. The third component of liquid motion satisfies the condition that the radial velocity of the fluid along the wall equals the deformation velocity of the tank wall, as well as the conditions of zero vertical velocity at the tank bottom and zero pressure at the free surface of the fluid. The total seismic force is given by the following expression

$$F = \mathbf{M}_l \ddot{u}_l + \sum_n \mathbf{M}_{nC} \ddot{u}_n + \mathbf{M}_f \ddot{a}_f \quad (10)$$

In the above expression, the deformation mass \mathbf{M}_f is multiplied by the generalized coordinate \ddot{a}_f , which expresses the acceleration of the container relative to its base:

$$\ddot{a}_f + 2\xi_f \omega_f \dot{a}_f + \omega_f^2 a_f = -\ddot{X} \quad (11)$$

where ω_f is the natural frequency of the deformation motion. Due to the fact that the dynamic coupling between the sloshing and the flexible components is very weak, due to the large differences between the frequencies of the sloshing motion and of the deformation of the wall, which allows determining the third component of the motion (the deformation component) independently of the others. The rigid impulsive and the sloshing components for non-deformable tanks remains therefore unaffected [10]-[12]. In the work of Scharf [8], closed-form expressions for the impulsive frequency and the deformation mass are reported, and those expressions are included in section A.3.1 of the Informative Annex A of EN 1998-4, stated below:

$$\omega_f = 2\pi \frac{\sqrt{E(t_{1/3})/\rho H}}{2R(0.157\gamma^2 + \gamma + 1.49)} \quad (12)$$

where $t_{1/3}$ is the thickness of the tank shell at height equal to $H/3$, and

$$\frac{\mathbf{M}_f}{\mathbf{M}_L} = \psi \gamma \sum_{n=0}^{\infty} \frac{(-1)^n}{\nu_n} d_n \quad (13)$$

where

$$d_n = 2 \frac{\left[\int_0^1 f(\zeta) \cos(\nu_n \zeta) d\zeta \right]}{\nu_n} \frac{I_1(\nu_n/\lambda)}{I_1'(\nu_n/\lambda)} \quad (14)$$

$\nu_n = (2n+1)\pi/2$, and ψ is a dimensionless parameter that depends on the shape function $f(\zeta)$ and is given by an awkward expression in EN 1998-4, paragraph A.3.1. Scharf [8] de-

scribes a tedious iterative methodology that results in the determination of shape function $f(\zeta)$.

In lieu of such a rigorous and tedious analysis described above, simplified models have also been developed to account for the interaction between the deformable cylindrical tank and the liquid. Such a model has been reported by Veletsos et al. [10], which constitutes the basis of the API 650 provisions [3] in calculating the impulsive seismic force. Similar to Scharf's formulation [8], the Veletsos' model [10] further assumes that the convective motion of the liquid remains unaffected by tank shell deformation. Therefore, the hydrodynamic solution for the rigid container is still applicable, and the tank shell deformation affects only the impulsive motion. This methodology has been adopted by the API 650 provisions, whereas the simplified methodology for deformable containers in section A.3.2.2 of EN 1998-4 is in-line with this approach. In particular, the latter provisions specify an impulsive frequency according to the equation (8), and the maximum seismic force is given by the following equation:

$$F = \mathbf{M}_I \ddot{u}_I + \sum_n \mathbf{M}_{nC} \ddot{u}_n \quad (15)$$

where the impulsive mass, the convective masses and the generalized coordinates u_I and u_n are given by equations (2) and (6) respectively. Assuming the same damping ratio for the impulsive and the deformation motion ($\xi_f = \xi_I$), one readily concludes that the two expressions (10) and (15) for the total seismic force provide identical results provided that (a) the two natural frequencies ω_f and ω_I are equal and (b) the corresponding masses \mathbf{M}_f and \mathbf{M}_I are equal.

Figure 4: Comparison between the impulsive and the deformation natural periods (T_f and T_I).

The comparison between the impulsive and deformation frequencies is offered in Figure 4, in terms of the corresponding natural periods T_f and T_I , where both periods are normalized by the value of $T_n = \sqrt{\rho R H^2 / E t}$, so that $T_f^* = T_f / T_n$ and $T_I^* = T_I / T_n$, and assuming that the average thickness of the tank shell is equal to the value of $t_{1/3}$. The comparison of the two masses \mathbf{M}_f and \mathbf{M}_I is offered in Figure 5. The value of \mathbf{M}_f is directly obtained by a similar

graph in [8]. In the same graph, points (1) and (2) refer to the value of M_f obtained through the application of equations (13) - (14) and assuming a shape function $f(\zeta)$ equal to ζ^2 and ζ respectively.

The above comparison indicates that there exist some differences between the two natural frequencies ω_f and ω_l , and the masses M_f and M_l . However, it is the authors opinion that the simplified methodology proposed by Veletsos et al. [10] can be used for the efficient calculation of seismic action on deformable liquid storage steel tanks.

Figure 5: Comparison between the impulsive and the deformation masses (M_f and M_l).

5 CALCULATION OF HOOP HYDRODYNAMIC STRESSES

Thickness design of liquid storage tanks is based on hydrostatic pressure and the corresponding allowable stress of the tank material, as described in section E.6.1.4 of API 650. This calculation neglects the fact that during an earthquake event, additional hoop stresses will be developed due to hydrodynamic loading, which need to be added to the stresses from the hydrostatic pressure and compared with the allowable stresses. A methodology for calculating hoop stresses has been proposed in the paper of Wozniak & Mitchell [13] based on the work of Veletsos [10], but up to 2007, it was not considered in design. For the first time, consideration of hoop hydrodynamic stresses and their superposition with the hydrostatic stresses is stated in the new Appendix E of API 650, 2007 edition [3]. On the other hand, there is no special provision of such a methodology in EN 1998-4 [6].

Explicit equations for computing hoop hydrodynamic stresses for the convective and impulsive component of liquid motion (denoted as σ_c and σ_l respectively) are stated in section E.6.1.4 of API 650 (not repeated herein for the sake of brevity), and should be superimposed with the hydrostatic pressure σ_h to obtain the total hoop stress σ_T in the course of seismic event as follows:

$$\sigma_T = \sigma_h \pm \sqrt{\sigma_l + \sigma_c} \quad (16)$$

The predictions of the above equation are compared with finite element results in Table 3, for the three tanks (Tanks I, II and III), which were described in section 1. Linear elastic analysis of the tanks is conducted, where the tanks are modeled with 4-node reduced-integration shell finite elements, and the hydrodynamic pressures (impulsive and convective) are applied on their lateral surface according to the following expressions. The impulsive pressure is

$$p_I(\zeta, \theta, t) = C_I(\zeta) \rho H \cos \theta \ddot{X} \quad (17)$$

where ρ is the density of the contained liquid, H is the height from the base to the free surface of the liquid, $\zeta = z/R$ is the nondimensional coordinate along the tank height, θ is the circumferential angle, and $C_I(\zeta)$ is a function that depends on the aspect ratio of the tank. The convective pressure is

$$p_C = \rho \psi_1 \cosh(\lambda_1 \gamma \zeta) J_1(\lambda_1 \gamma \zeta) \cos \theta \ddot{u}_{1C} \quad (18)$$

where:

$$\psi_1 = \frac{2R}{(\lambda_1^2 - 1) J_1(\lambda_1) \cosh(\lambda_1 \gamma)} \quad (19)$$

and $\lambda_1 = 1.841$, $\gamma = H/R$, J_1 is Bessel function of the first order, \ddot{u}_{1C} is the acceleration corresponding to the first sloshing mode. The above impulsive and the convective pressure distributions are imposed in the finite element model through a load-user subroutine. For simplicity, the possibility of uplifting in Tanks I and III is excluded, so that all tanks are considered mechanically anchored. The numerical results indicate a good comparison between the numerical results and the above predictions. Given the fact that EN 1998-4 does not include a methodology for calculating hoop hydrodynamic stresses, the corresponding API 650 equations can be used for an efficient prediction of hydrodynamic effects on the total hoop stress of the tank.

	Type of load	Hoop stress from finite element analysis (MPa)	Hoop stress from API 650 (MPa)
Tank I D=27.4m H=15.7m	hydrostatic pressure	116	119
	hydrostatic pressure +earthquake	140	146.3
Tank II D=18m H=19m	hydrostatic pressure	167	168
	hydrostatic pressure +earthquake	190	200.3
Tank III D=68m H=19m	hydrostatic pressure	155	164
	hydrostatic pressure +earthquake	195	203.6

Table 3: Hoop hydrostatic and hydrodynamic stresses computed from finite element models and predicted by API 650.

6 UPLIFTING EFFECTS ON UNANCHORED TANKS

In most of practical applications, relatively broad liquid storage tanks are constructed unanchored, in the sense that their bottom plate is in simple contact with the ground, without anchor bolts. In such a case, under strong seismic loading, the tank may exhibit uplifting of its bottom plate, which may result in (a) excessive stresses at the connection between the bottom plate and the tank shell, and (b) increase of the maximum compressive stress at the shell bottom. This is shown schematically in Figure 6, referring to locations 1 and 2.

Figure 6: (a) Locations affected by uplifting during seismic action in an unanchored tank; (b) Numerical finite element model for uplifting analysis.

In current design practice, API 650 considers uplifting through the so-called anchorage ratio J defined as follows (neglecting the vertical component of seismic excitation, for the sake of simplicity):

$$J = \frac{M}{D^2 [w_t + w_a]} \quad (20)$$

If the anchorage ratio is between the values of 0.785 and 1.54, the unanchored tank is stable but its base uplifts. The corresponding compressive stress at the tank shell bottom is given by following expressions, written in more convenient terms:

- For tanks without uplifting:

$$N_{anch} = w_t + \frac{1.273M}{D^2} \quad (21)$$

- For unanchored tanks with uplifting

$$N_{unanch} = \frac{w_t + w_a}{0.607 - 0.187(J)^{2.3}} - w_a \quad (22)$$

Paragraph A.9 of Annex A in EN 1998-4 standard describes a methodology for the uplifting effects of unanchored tanks, based on the work of Scharf [8], who conducted a finite element analysis of the tank-liquid system. These effects are presented in graphical form, where the increase of axial compressive stress due to uplifting is plotted against the overturning moment ratio M/WH .

Figure 7: Finite element analysis of unanchored liquid storage tank under lateral loading.

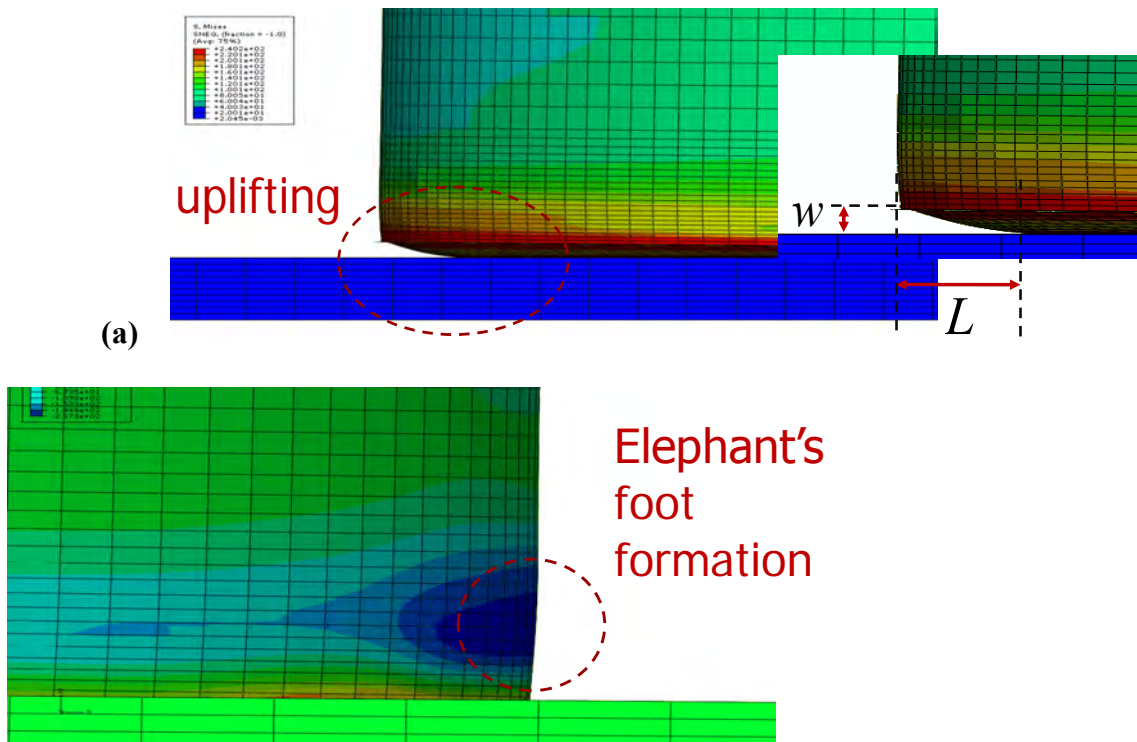

Figure 8: Finite element analysis of unanchored liquid storage tank under lateral loading; (a) uplifting of base plate, (b) development of elephant's foot at the tank bottom.

Figure 9: Overturning moment M versus top horizontal displacement U of tank, subjected to finite element pushover analysis.

Figure 10: Increase of axial compressive stress on tank shell wall due to uplifting with respect to the overturning moment; finite element pushover analysis versus EN 1998-4 provisions.

Figure 11: Uplifting size w in terms of overturning moment for Tank I; finite element pushover analysis.

Figure 12: Uplifting length L in terms of uplifting size w for Tank I; finite element pushover analysis.

Figure 13: Increase of axial compressive stress on tank shell wall due to uplifting with respect to the overturning moment at the tank shell bottom; finite element pushover analysis versus API 650 provisions.

Herein, using more rigorous finite element simulation tools, the above API 650 and EN 1998-4 provisions for tank uplifting are evaluated. Special emphasis is given on effects of uplifting the compressive stress that causes elephant's foot buckling, which constitutes the major failure mode of the tank under strong earthquake loading. For this purpose, Tank I ($H/R = 1.145$) was simulated with shell finite elements, with the model shown in Figure 6b. All parts of the interacting system were modeled: the tank shell, the truss roof, the base plate, the annular plate, and the ground. Four-node reduced-integration shell elements are employed to model the tank shell and the base/annular plates, the truss roof is modeled with beam elements, whereas solid elements are employed for modeling the ground. Contact conditions are considered between the base/annular plate and the ground, with friction coefficient equal to 0.3, allowing for tank uplift. The analysis is nonlinear static, and the hydrodynamic pressure is applied on the tank shell and the base plate for both the impulsive and the convective component. Considering this distribution of pressure, nonlinear "pushover" analysis is conducted controlling the value of the pressure multiplier, through a Riks continuation algorithm, which allows for the detection of possible instability (buckling) phenomena at the tank shell. Figure 7 and Figure 8 show the uplifting response of Tank I, as obtained by the present finite element simulation.

Figure 9 shows the horizontal displacement of the top of the tank in terms of the normalized overturning moment at the tank base M/WH . The value of M is obtained by an appropriate integration of the pressure on the tank shell surface. The increase of axial compressive stress due to uplift is shown in Figure 10 and the numerical results are compared with the graphs in EN 1998-4. The comparison shows that the EN 1998-4 curves are quite conservative in predicting the increase of axial stress due to uplift. In Figure 11 and Figure 12, the uplift magnitude and as the uplift length are plotted. Comparing the numerical results in Figure 9 and in Figure 11, one readily observes nonlinear inelastic behavior of the tank, as soon as some uplifting of the tank starts. This is associated with inelastic deformation at the uplifted

area of the base plate. Furthermore, the comparison between the numerical results and the curves of EN 1998-4 shows that the EN 1998-4 curves represent the general trend but are quite conservative in predicting the effect of uplifting on the axial compressive stress.

Finally, in Figure 13, the finite element results for the axial compressive stress increase due to uplifting are compared with the corresponding provisions of API 650, i.e. expressions (21) and (22). The comparison shows that the API 650 provisions are very conservative. However, this comparison is somewhat unfair, because the overturning moment in API 650 is calculated considering a large value of reduction factor. The value of the reduction factor is discussed in a subsequent section.

7 ELEPHANT'S FOOT BUCKLING

When subjected to earthquake loading, tanks may fail due to excessive compression at the bottom of the tank shell. This is a typical buckling mode of a thin-walled shell under the simultaneous action of meridional compression and hoop tension due to the presence of internal pressure, it is referred to as “elephant’s foot buckling” and is considered as the major source of liquid storage tank failure under seismic action [14]. Figure 14 shows two characteristic cases of the elephant’s foot buckling following strong earthquakes. In the following, elephant’s foot is examined numerically, with emphasis on post-buckling strength.

The possibility of elephant’s foot development in Tank I is examined, through the consideration of an axisymmetric finite element model. From Figure 14, it can be concluded that there is a quasi-uniform state of deformation along a significant part of the tank perimeter. Therefore, it is reasonable to assume axisymmetric conditions, for the simulation of this phenomenon, and a meridian strip of is modeled with axisymmetric shell finite elements, as shown in Figure 15. In particular, the tank area near its bottom is simulated (three bottom courses), and the compressive action is applied as external downward loading at the top of each subjected to compressive stresses. The annular plate and the base plate are modeled and frictionless contact is assumed between the plates and the foundation, allowing for uplifting.

Figure 14: Elephant’s foot buckling caused by strong earthquake action.

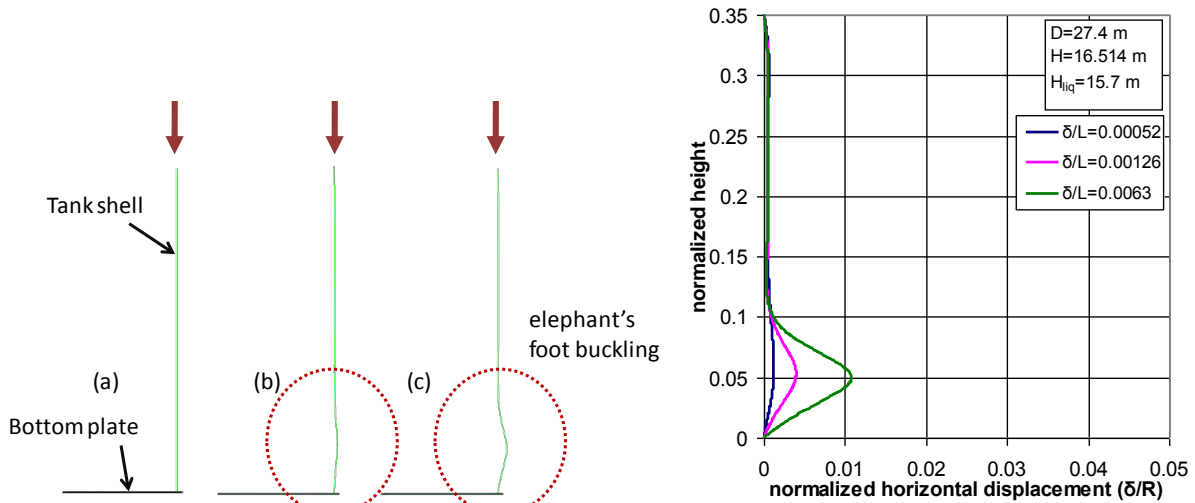

Figure 15: Development of elephant's foot, as predicted by the finite element analysis.

The results from the finite element analysis are shown in Figure 16, in terms of the equilibrium path of the applied axial stress on the tank wall in terms of the vertical and the horizontal outwards displacement of the tank wall. The most important observation refers to the fact that the buckling shape obtained from the finite element analysis is shown in Figure 17 (in a three-dimensional form) and is very similar to observations from real earthquake events, as shown in Figure 14b. The most important observation refers to post-buckling response of the tank, which appears to be unstable; after reaching a maximum stress (load) the capacity drops very rapidly, indicating that the tank has not any ability of absorbing significant amounts of inelastic energy.

8 BUCKLING AT THE TOP OF THE TANK

Apart from elephant's foot buckling at the tank bottom, previous experience has indicated that liquid storage tanks suffer from buckling at their top. This is called "sloshing buckling" and it is shown in Figure 18. The first attempt to explain this phenomenon was report in the paper by Natsiavas and Babcock [15]. In that work, this type of buckling was attributed to the alternating sign of hydrodynamic (sloshing) pressure on the tank wall during the seismic excitation. More specifically, the tank under hydrostatic pressure exhibits tensile stresses on the tank shell that prevent buckling. However, when – in the course of a seismic event – this pressure becomes negative, i.e. directed inwards, it may overtake the internal (outward) hydrostatic pressure, so that the thin-walled tank top is locally under external pressure leading to shell buckling. It is important to note that, at the top of the tank, hydrostatic pressure is small, so that this overtaking is quite likely to occur, depending on the magnitude of the seismic action.

Figure 16: Compressive stress developed at the tank shell wall versus: (a) horizontal outward displacement of the wall, (b) vertical displacement at the top of the model.

Figure 17: Elephant's foot buckling, as obtained by the finite element simulation.

To quantify this effect, Tank I is considered and the impulsive and convective pressures are computed at $\theta = 0$ and $\theta = \pi$ for 7 artificial earthquakes, corresponding to a maximum ground acceleration of 0.25g. Figure 19 shows the distribution of hydrostatic and hydrodynamic (maximum convective and maximum impulsive) pressure on the tank wall, at $\theta = 0$, for a typical earthquake. Considering that the hydrodynamic pressure are of alternating sign, the numerical results in this graph indicate that outward hydrodynamic pressures may become dominant at the top part of the tank, resulting in an external pressurization of the tank at those locations, leading to buckling. This is shown more precisely in Figure 20, where the hydrodynamic pressures are subtracted from the hydrostatic pressure. The graphs indicate that the external pressure of the tank shell extends over a significant part of its height d_c as shown in Table 4 for 10 earthquake inputs, corresponding to 0.25g.

Figure 18: Sloshing buckling at the top of a tank; Kocaeli, Turkey earthquake 1999 [1].

ACC4	0.757	0.05	6.90	76.32
ACC5	0.660	0.05	5.40	46.05
ACC6	0.808	0.05	7.65	97.09
ACC7	0.777	0.05	7.20	84.04
ACC8	0.800	0.05	7.55	93.59
ACC9	0.754	0.05	6.85	75.20
ACC10	0.785	0.05	7.30	87.27

Table 4: Height of the compression zone at the top of the tank and corresponding inward force per unit circumferential length.

An estimate of the compressive hoop stress developed at the tank shell top can be obtained by considering the total inward force per unit circumference length Q distributed along the compression zone d_c (see Figure 20a), so that an equivalent external pressure is computed as follows

$$p_{eq} = f \frac{Q}{d_c} \quad (23)$$

where f is a factor accounting for the non-uniform distribution of pressure on the compression zone, From simple statics of thin-walled cylindrical shells, one can readily calculate the corresponding compressive hoop stress considering axisymmetric conditions around the location of maximum compression $\theta = 0$, one may assume that the top of the tank behaves as a circular under uniform external pressure and the corresponding compressive hoop stress is

$$\sigma_\theta = \frac{p_{eq} D}{2t} \quad (24)$$

Resistance of the thin-walled tank shell against this type of buckling is offered by considering one or more ring stiffeners at the top of the tank. The design of those ring stiffeners can be conducted according to the newly published ECCS European Design Recommendations for Shell Buckling [16]. It is the author's opinion that the stiffener dimensions should be increased to account for the nonlinear effects of liquid sloshing, as well as for the impulsive nature of the sloshing wave. Using the above analysis and considerations, the development of new specific rules for determining the buckling resistance of tank shell at its top is a necessity, but it is outside the scope of the present study.

9 A NOTE ON THE BEHAVIOR FACTOR FOR LIQUID STORAGE TANKS

The behavior factor to be used in the seismic design of liquid storage tanks has created quite some controversy. It is worth noticing that the API 650 provisions adopt totally different values than those of EN 1998-4, as shown in the following Table 5.

	Impulsive	Convective
API 650		
Self-anchored	3.5	2.0
Mechanically-anchored	4.0	2.0
EN 1998-4		
For all anchorage systems	1.5	1.0

Table 5: Values of behavior (reduction) factor for seismic design of liquid storage tanks.

A first observation refers to the smaller values for the convective motion in comparison with the impulsive motion. This is attributed to the fact that the convective response may not be capable at dissipating seismic energy. However, it is quite interesting to note that while EN 1998-4 specifies $q = 1$ for the convective force, the API 650 rules specify $R = 2$, which implies the presence of a dissipating mechanism in the convective (sloshing) motion.

Furthermore, there exist striking differences on the values of q and R for the impulsive component of the seismic force, which need some further investigation. The ductility of the structural system constitutes the main parameter for the reduction of the seismic force. In particular, considering elephant's foot buckling as the dominant mode of buckling, the numerical results presented in a previous section demonstrate the limited capability of the tank shell of absorbing and dissipating seismic energy due to their unstable post-buckling behavior. Communication of the authors with the API 650 drafting committee (see Acknowledgements below) indicated that the relatively high values of reduction factors R adopted by the American standards is based both on previous experience, as well as on other dissipation mechanisms such as radiation damping at the tank foundation (soil-tank interaction), the ductility of the anchor bolts, or the inelastic behavior of the base plate in the case of uplifted unanchored tanks. As far as elephant's foot buckling is concerned, the significant drop of strength following buckling, shown by the numerical results of Figure 16 are not in favor of using a value of behavior (reduction) factor significantly higher than unity. On the other hand, the moment-displacement curve of Figure 9, indicates that such a dissipating mechanism may exist in unanchored tanks exhibiting uplifting. In any case, the identification of appropriate seismic energy dissipation mechanisms that would allow the use of behavior factor larger than unity is an open research issue, which needs significant additional research effort.

10 NONLINEAR SLOSHING EFFECTS

The calculation of hydrodynamic forces described in the above sections was based on linear liquid hydrodynamic theory. The basic assumption for this theory is the small-amplitude of sloshing waves, allowing for the linearization of the liquid free-surface boundary condition. More specifically, assuming ideal fluid conditions, the liquid motion in a undeformed (rigid) container, under horizontal excitation displacement $X(t)$ in the x direction is described by the flow potential $\Phi(x, y, z, t)$, so that the liquid velocity is the gradient of Φ ($\mathbf{u} = \nabla\Phi$), which satisfies the Laplace equation in the liquid domain,

$$\nabla^2\Phi = \frac{\partial^2\Phi}{\partial x^2} + \frac{\partial^2\Phi}{\partial y^2} + \frac{\partial^2\Phi}{\partial z^2} = 0 \quad (25)$$

subjected to the following boundary conditions at the wet surface of the vessel wall

$$\frac{\partial \Phi}{\partial n} = \dot{X}(\mathbf{e}_x \cdot \mathbf{n}) \quad (26)$$

In the free-surface, the liquid should satisfy the kinematic and the dynamic boundary conditions, shown below:

$$\frac{\partial \eta}{\partial t} + \frac{\partial \eta}{\partial x} \frac{\partial \Phi}{\partial x} - \frac{\partial \Phi}{\partial z} = 0 \quad (27)$$

and

$$\frac{\partial \Phi}{\partial t} + \frac{1}{2}(\nabla \Phi)^2 + g\eta = -\ddot{X} \quad (28)$$

If small-amplitude sloshing is assumed, then keeping only the linear terms of η and Φ in the above equations, and eliminating η , one obtained the following combined condition, widely used for linear analysis:

$$\frac{\partial^2 \Phi}{\partial t^2} + g \frac{\partial \Phi}{\partial z} = 0 \quad (29)$$

The question is whether the assumption for small-amplitude sloshing is valid or not in the course of a strong earthquake. This requires an rigorous analysis based on either an asymptotic solution or a nonlinear finite element analysis of the liquid within the container, which is outside the scope of the present study. A preliminary analysis of this type has been conducted by Chen et al. [17], where the containment of rectangular liquid storage tanks have been modeled with finite elements through an in-house moving grid methodology, and subjected to several earthquake inputs. The results indicated that:

- Nonlinear effects may be non-important for the calculation of the total seismic forces
- In strong and distant (low-frequency) earthquakes, the liquid surface elevation (sloshing wave height) can be affected. For the majority of seismic events, this effect is not very important

The above preliminary results demonstrate that the use of linear sloshing theory for determining the seismic action on the tank wall adequate, verifying the expressions proposed in current design standards, whereas the possible nonlinear sloshing effects on the sloshing wave amplitude can be accounted for through an appropriate increase of freeboard height specified by the design specifications.

11 CONCLUSIONS

In this paper several issues on the dynamic behavior of liquid storage tanks have been addressed and investigated. The main conclusions can be stated as follows:

- For the majority of tanks, consideration of only one sloshing (convective) mode is adequate for the calculation of the total seismic force.
- The combination of the convective force with the impulsive force should be conducted according to the SRSS rule, which in accordance with the design provisions of API 650, Annex E.

- Numerical results show that the EN 1998-4 provisions provide a reasonable yet conservative of the increase of axial compression due to uplifting.
- A simple methodology is presented in order to design tanks against buckling at the top, due to liquid sloshing, using the concept of “equivalent” external pressure.
- The behavior (reduction) factor for the seismic design of liquid storage tanks is a controversial issue that has not been examined thoroughly so far. Because of the relatively low post-buckling strength of the shell tank, the authors would be quite cautious in using a behavior factor greater than 1.5 for the impulsive component of motion.
- Nonlinear sloshing effects on the seismic behavior have not been thoroughly investigated so far. Limited numerical investigations, reported elsewhere, indicated that their effects on the total seismic force may not be important, but they can have significant effects on freeboard considerations.

12 ACKNOWLEDGEMENTS

This work was carried out with a financial grant from the Research Fund for Coal and Steel of the European Commission, within **INDUSE** project: “STRUCTURAL SAFETY OF INDUSTRIAL STEEL TANKS, PRESSURE VESSELS AND PIPING SYSTEMS UNDER SEISMIC LOADING”, Grant No. RFSR-CT-2009-00022. The authors also wish to thank Dr. Steven W. Meier, TANK INDUSTRY CONSULTANTS, INC., member of the AWWA D100 and API 650 drafting committees, for his valuable comments on the reduction (behaviour) factor for tank seismic design.

Keywords: Water Depth in Tank, Aqueduct Structure, Seismic Performance.

Abstract. *This paper uses finite element method to study how the change of water depth in tank affects the seismic performance of the aqueduct-water coupled structure. The results shows that sloshing amplitude of the water in U-shape aqueduct is very significant; the vibration frequency of the aqueduct structure is reduced due to the existence of the water body, and then the response wave shape of the aqueduct body is changed relatively. This explains that the effect of the water in the aqueduct structure has great relationship with the spectrum dynamic properties of the input earthquake wave. Water in the aqueduct plays TLD damping when the frequency scale of the input earthquake wave includes the basic frequency of the aqueduct structure and the vibration frequency of the water in the aqueduct is closed to the the basic frequency of the aqueduct structure. Finally an approximate criterion is also put forward to adjudge when the aqueduct water plays TLD damping through judging mass ratio and frequency ratio, and gives the discriminate.*

1 INTRODUCTION

The water weight on the top of the large aqueduct structures is generally heavier than structure self-weight, some reached 1.5 ~ 2.0 times as much^{[1]-[7]}. Under the earthquake, the ground acceleration superpositions of the elastic vibration acceleration on the top of the aqueduct structure, that make fluid vibrate, which causes thus the bigger sloshing amplitude of the fluid and the sloshing of the fluid has impact on the vibration of the aqueduct structure relatively. Many scholars' research shows that^{[8]-[12]}, the role of the aqueduct water sloshing is not allowed to ignore under the earthquake, which has great threats on the security of the aqueduct structure; However in some reference^{[13]-[14]} think the water in the aqueduct plays TLD damping on the bent-support aqueduct structural system, the sloshing of the water is stronger, and the TLD damping effect of the water on the structure is stronger.

Due to the dynamic response of the aqueduct - water coupling structure under the earthquake is complicated, involving many factors, whether the water is benefit or harm to the anti-seismic performance of the whole structure system, still remain to be further studied. In this paper, through changing the water depth in the aqueduct the anti-seismic performance of the aqueduct-water coupling structure is discussed by the analysis of many cases.

2 CALCULATION PARAMETERS AND CALCULATION CASES^[15]

The aqueduct model analyzed in this paper is shown in Fig. 1 and Fig.2. The aqueduct has three spans with the length of 12.0m for each span. The U-type aqueduct body is supported with a bent via a basin-shaped rubber support. The bents of the aqueduct are H-shape with the height of 8.0m and fixed bottoms.

The U-type aqueduct section dimension: width is 8.0m, height is 6.9m, inner radius is 3.5m, out radius is 3.8m. The material parameters used in the calculation are: mass density of reinforced concrete is 2700kg/m³, Poisson's ratio is 0.1667.

Considering the change of the water depth in the aqueduct, the calculation conditions includes that the depth of water in the aqueduct is 0m, 2.50m, 4.41m respectively.

Fig. 1 Section of the aqueduct model

Fig. 2 Section of the bent model

3 DYNAMIC CHARACTERISTICS AND RESPONSE OF HEADINGS OF THE AQUEDUCT-WATER COUPLING STRUCTURE WHEN CHANGING THE DEPTH OF WATER IN AQUEDUCT

Figure 3 shows a three-dimensional calculation model of the bent-type aqueduct - water coupling structure, among which Figure 3 (a) is empty-aqueduct model (water depth $h=0\text{m}$), Figure 3 (b) is half-aqueduct model (water depth $h=3.50\text{m}$), and Figure 3 (c) is full-aqueduct model (water depth $h=4.41\text{m}$).

Fig. 3 Three-dimensional calculation model of the bent-type aqueduct - water coupling structure

3.1 Dynamic characteristics

Table 2 is the first frequency in all direction of the aqueduct structure with different water depth.

Depth of water (m)	Horizontal (X direction)	Longitudinal (Y direction)	Vertical (Z direction)
$h=0$	2.41	1.24	13.58
$h=3.50$	2.07	0.99	10.93
$h=4.41$	1.75	0.86	9.19

Table 1: The first frequency in all direction of the aqueduct structure with different water depth.(Hz)

From the result shown in Table 2, the whole natural frequency of the aqueduct structure is reduced following the depth of water in aqueduct is increased, these indicates that the mass of the structure is larger and the frequency of the structure is lower due to the quality of water body in the aqueduct, which is consistent with experimental results obtained. As the water depth increases from 0m to 3.50m, the whole horizontal base frequency decreases 14.1%, the longitudinal base frequency decreases 20.2%, the vertical base frequency decreases 19.5%. As the water depth increases from 3.50m to 4.41m, the whole horizontal base frequency decreases 18.3%, the longitudinal base frequency decreases 13.1%, the vertical base frequency decreases 15.9%; When the water depth increases from 0m to 4.41m, the whole horizontal base frequency decreases 27.4%, the longitudinal base frequency decreases 30.7%, the vertical base frequency decreases 32.3%.

It indicates that the vibration characteristics of the aqueduct structure in every direction are greatly affected when the depth of water in aqueduct change greatly, especially for the vertical base frequency. Therefore, the effect of the water in aqueduct on the vibration characteristics and anti-seismic performance should be not ignored.

Figure 4 represents the mode schemes of the aqueduct prototype structure in all directions. Figure 4(a)~(b) represent the first order mode schemes of the aqueduct prototype structure without water and full with water in X direction respectively; Figure 4(c)~(d) represent the first order mode schemes of the aqueduct prototype structure without water and full with water in Y direction respectively; Figure 4(e)~(f) represent the first order mode schemes of the aqueduct prototype structure without water and full with water in Z direction respectively. The calculation result indicates that the local modes of water sloshing appears at first when there is water in the aqueduct.

Fig. 4 Mode schemes of the bent-type aqueduct prototype structure in all directions

3.2 Acceleration response characteristics

The top point in the middle of the middle span aqueduct body is selected as research object for better describing the effect of the water in aqueduct on the earthquake response of the aqueduct-water coupling structure. Figure 5 ~ Figure 6 show that the acceleration time-history curves of the measuring point 26 on the top of the aqueduct body under the action of El Centro wave and ANPING wave respectively, when there is different water depth in aqueduct($h=0\text{m}$, 3.50m , 4.41m).

Fig. 5 Earthquake esponse of the aqueduct body with different water depth under El Centro wave

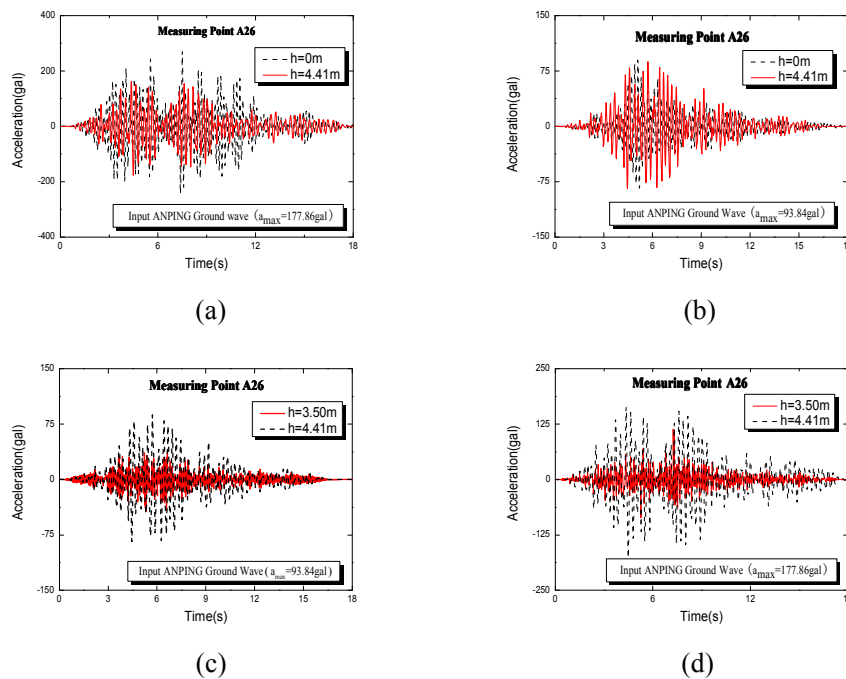

Fig. 5 Earthquake esponse of the aqueduct body with different water depth under ANPING wave

From figure 5~figure 6, it can be observed that the acceleration response of the measuring point A26 increases with the increasement of the peak values of the input earthquake wave. When input El centro wave, the acceleration response of the measuring point A26 with empty-aqueduct is larger than full with water, but its' response is not decrease as the water depth increase. When the water depth is 3.50m, also called half-aqueduct, the acceleration response of the measuring point A26 is smaller than full-aqueduct. When input El Centro wave of the peak accleration 110gal, the ratio of the empty-aqueduct to full-aqueduct is 1.50, the ratio of the full-aqueduct to the empty-aqueduct is 3.43; When input El Centro wave of the peak accleration 300gal, the ratio of the empty-aqueduct to full-aqueduct is 1.34, the ratio of the full-aqueduct to the empty-aqueduct is 2.88; When input El Centro wave of the peak accleration 540gal, the ratio of the empty-aqueduct to full-aqueduct is 1.06, the ratio of the full-aqueduct to the empty-aqueduct is 2.91. When input ANNPING wave of the peak accleration 93.84 gal, the acceleration response of the measuring point A26 without water is little smaller than that full of water except at 3.9~5.5 second. The acceleration response of A26 is larger that the half-aqueduct, and both peak values of the half-aqueduct and the full-aqueduct. The ratio of both peak acceleration is 4.06; When input ANNPING wave of the peak

acceleration 177.86 gal, the acceleration response of the measuring point A26 at full-aqueduct is much larger than that at half-aqueduct. The ratio of the peak value acceleration at the full-aqueduct to half-aqueduct is 3.27. In addition, it can be seen from the figures obviously, that the waveforms of the acceleration response of the measuring point A26 are different when the aqueduct with water and without water.

This shows that the water sloshing in aqueduct changes the dynamic characteristics of the aqueduct structure, and the water plays a TLD damping role to a certain extent, however, TLD effect is not stronger following the more water sloshing more powerful. In this model, inputting El Centro wave horizontally, TLD effect reaches the strongest when the water volume is a half of the whole tank($h=3.50$ m); The acceleration response of the aqueduct-water coupling structure increases when the aqueduct is full with water($h=4.41$ m), but that still smaller than that when the aqueduct is empty. Because the natural frequency of the water is 1.38 Hz when the water depth is 3.50m, the natural frequency of the water is 1.09 Hz when the water depth is 4.41m, the fundamental frequency of the aqueduct structure(2.41 Hz) is closer to the natural frequency of aqueduct when the water depth is 3.50m, and then the main frequency range of El Centro wave across the fundamental frequency of the aqueduct structure. Inputting ANPING ground wave, the water in tank does not play a similar damping effect of TLD, because of the greater difference between the main frequency range of ANPPING wave and the fundamental frequency of the aqueduct structure. In addition, the presence of water makes the vibration frequency of the aqueduct structure reduce, thus changing the aqueduct body's response waveform. This indicates that the effect of the water in tank on the aqueduct structure has great relationship to the spectrum dynamic properties of the input earthquake wave. When the main frequency range of the input earthquake wave across the fundamental frequency of the aqueduct structure, the vibration frequency of the water in tank and the fundamental frequency of the aqueduct structure is similar, the water in tank can play TLD damping on the aqueduct structure, but the effect at the initial stage of time-history is not significant, as the water sloshing needs a process for starting.

4 CONCLUSIONS

Numerical calculations results shows that the water in tank play a TLD damping on the aqueduct-water coupling to some extent. The water in the aqueduct can be seen as deep TLD. Based on the hypothesis of the aqueduct-water coupling structure dynamic interaction, the water in aqueduct is ideal incompressible irrotational fluid, that the space size properties and the damping characteristics of the fluid are determined, therefore the main factors which decide when the water in aqueduct play TLD damping effect is the mass ratio(μ) and frequency ratio(β).

According to the curves of the water damping effect(η) following changes of the mass ratio and frequency under all kinds of cases, drawing the fitting curve, the discriminant of the water TLD damping is obtained as follows:

$$\eta = 296.89\mu^2 + 329.87\mu - 48.17 \quad (0 < \mu < 1) \quad (1)$$

$$\eta = -3085.64\beta^2 + 3491.82\beta - 945.43 \quad (0 < \beta < 1) \quad (2)$$

From the discriminant (1) or (2), it can judge when the water in tank play TLD damping effect on the aqueduct structure.

Keywords: Piping System, Seismic Design, Case Studies, American Standards, European Standards, Static and Dynamic Calculation, Pipeline.

Abstract. *In the framework of the INDUSE project, which aims at innovative design methodologies for the seismic design of industrial equipment and piping systems, case studies have been carried out, performing static and dynamic seismic analyses for two existing steel pipeline systems including steel supporting structures, situated in an area of moderate seismic activity:*

- a) A long aboveground 10" ammonia transmission line situated on sleepers with a vertical expansion loop and ending with a fixed point. The system may be typical for long distance above ground pipelines and for pipelines on jetties.*
- b) A 20" gas transmission pipeline at the interface of a buried pipeline section and an above ground piping section, including a branch connection, a vertical spring support structure and a fixed point, e.g. a tank nozzle. This system is typical for many plant piping systems.*

The calculations were made using commercially available software. Both simplified static equivalent ('uniform load method') calculations as well as dynamic calculations were made in accordance with American (ASCE-7) and European (EN1998 and EN13480) earthquake design standards to identify differences in approach, differences in resulting seismic response spectra and differences in calculated results. The dynamic and static calculations were made with Caesar II software.

The results of the calculations are presented. Conclusions and recommendations are given with respect to:

- The differences between existing earthquake design codes.*
- The validity of the use of the "static equivalent (uniform load) method".*
- The need to include guidelines for design and modeling in the next revisions of existing seismic design standards for (above ground) industrial piping systems.*

1 INTRODUCTION

In the framework of the INDUSE project [1], which aims at innovative design methodologies for the seismic design of industrial equipment and piping systems, a case study was carried out, performing static and dynamic seismic analyses for two existing steel pipeline systems including steel supporting structures, situated in an area of moderate seismic activity:

a) A long aboveground 10" ammonia transmission line situated on sleepers with a vertical expansion loop and ending with a fixed point. The system may be typical for long distance above ground pipelines and for pipelines on jetties.

b) A 20" gas transmission pipeline at the interface of a buried pipeline section and an above ground piping section, including a branch connection, a vertical spring support structure and a fixed point, e.g. a tank nozzle. This system is typical for many plant piping systems.

Both simplified static equivalent ('uniform load method') calculations as well as dynamic calculations were made in accordance with American (ASCE-7 [2]) and European (EN1998-1/4 [3],[4] and EN13480 [5]) earthquake design standards to identify differences in approach, differences in resulting seismic response spectra and differences in calculated results. The dynamic and static calculations were made with commercially available (Caesar II) software.

2 INVESTIGATED PIPE SYSTEMS

2.1 Ammonia transmission line

The 10" pipeline to transport liquid ammonia is located in the Algerian desert. It is roughly 9 km long. For practical reasons the modeled section (Figure 1) is 400 m long. Node 1 is modeled as a fixed point, node 650 allows only for rotation. As is expected with such long pipelines, there are loops to deal with thermal- and pressure expansion. Two vertical expansion loops have been modeled. The spacing between the supports in the straight pipe sections is not uniform to avoid creating any standing waves when the pipe is vibrating at a mode of its natural frequency. Relevant pipe and process data are given in Table 1.

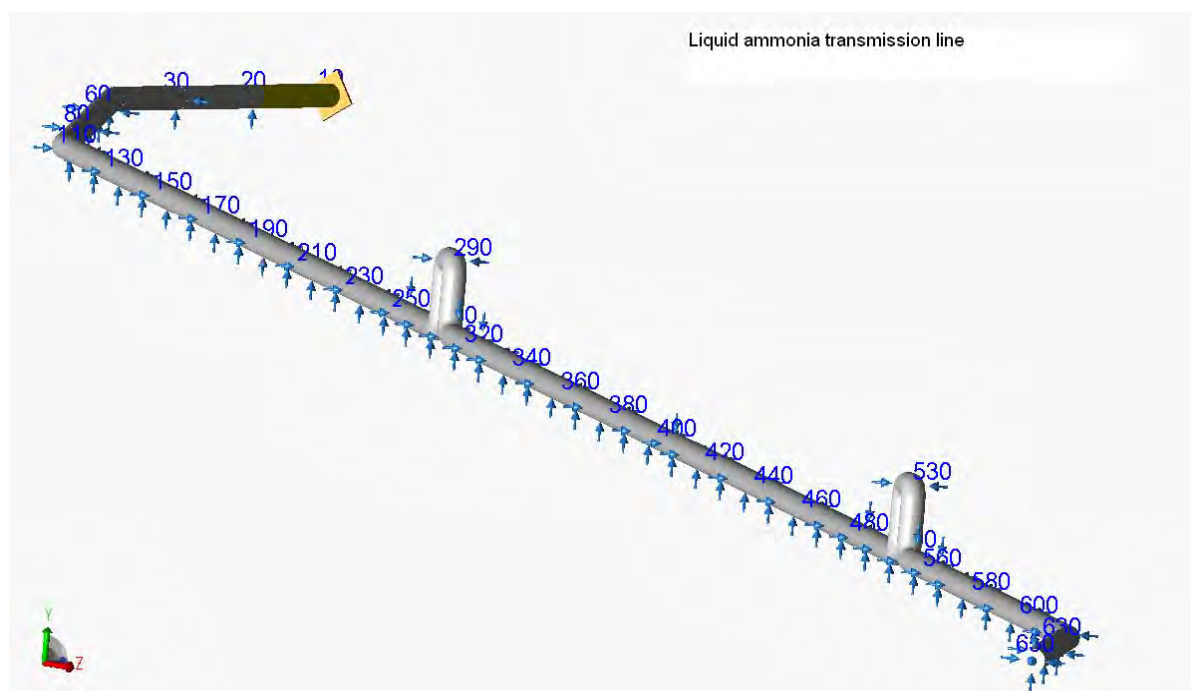

Figure 1: System layout and node numbers Liquid Ammonia line.

Pipe material	Steel A333 Gr.6
Pipe Diameter / wall thickness	10" / Std
Tensile strength, Rm	415 Nmm ⁻²
Yield strength, Re (65°C)	232 Nmm ⁻²
Design pressure	25 bar(g)
Design temperature	65/-35 °C
Installation temperature	40 °C
Corrosion Allowance	3 mm
Medium/ density	Liquid Ammonia, 880 kg/m ³
Thermal Insulation	100 mm, PU Foam, 80 kg/m ³

Table 1: Pipe and process data Ammonia line.

2.2 Gas transmission line

The gas transmission line includes an underground section and is modeled from a point underground to a (nozzle) connection (node 160) and a free end valve (node10) above ground (Figure 2). Relevant pipe and process data are given in Table 2.

Figure 2: System layout and node numbers Gas transmission line.

Pipe material	20" ; branch 16"
Pipe Diameter / wall thickness	Sch. 60 (16.6 & 20.6mm)
Tensile strength, Rm	413 Nmm ⁻²
Yield strength, Re (65°C)	241 Nmm ⁻²
Design pressure	73.5 bar(g)
Design temperature	80 °C
Installation temperature	40 °C
Corrosion Allowance	1.6 mm
Medium/ density	Natural gas, 1 kg/m ³

Table 2: Pipe and process data Gas transmission line.

The pipe is supported by two steel structures, which add a finite amount of stiffness, which have been modeled in Caesar II. The static calculation was made according to ASME B31.8:2007 [8]. For the buried pipe section, the underground pipe modeler in Caesar II calcu-

lates pseudo-supports along the pipe to mimic the behavior of the soil acting on the buried pipe. The buried pipe support distance is pre-calculated by Caesar II, based on pipe stiffness and soil characteristics. Where it is not supported, the buried pipe had six degrees of freedom. However, these are considered negligible due to the pseudo-supports.

3 MODELING THE PIPE SYSTEM BEHAVIOUR UNDER SEISMIC LOAD BY SIMPLIFIED STATIC EQUIVALENT (UNIFORM LOAD) ANALYSIS

3.1 General

Commonly used international standards for seismic design allow for a simplified static equivalent analysis method to deduce a loading value to apply to the pipe system in order to model the seismic behavior. Using this method, the systems own response to different vibrating frequencies and damping rates is ignored and instead the displacements and forces in the piping system are calculated using a single equivalent static accelerating force for each principal direction (X, Y and Z) of the seismic movements. The magnitude of the static loading is directly proportional to the element weight. Earthquake load magnitudes are given in terms of the gravitational acceleration constant, g , i.e. if an earthquake is modeled as having a 0.2 g load in a particular direction, then a factor of 0.2 of the systems weight is turned into a uniform load and applied in that particular direction. Within the framework of this study this method was worked out for the relevant American and European codes.

3.2 Uniform load analysis according to American standard ASCE-7

To determine, in the uniform load case, the overall acceleration described as a fraction of the gravitational constant g , ASCE-7 requires a number of factors to be determined. The following equations are used:

$$S_{DS} = \frac{2}{3} S_{MS} \quad (1)$$

$$S_{MS} = F_a S_s \quad (2)$$

with:

S_{DS} = Design Seismic response acceleration

S_{MS} = Seismic elastic response (spectrum) ground acceleration

S_s = Maximum mapped response acceleration, [ms^{-2}]: Maximum earthquake ground motion at 5% of the critical dampening applied. From ASCE-7 section 11.4.

F_a = Site class coefficient, [-]: This factor, normally varying between 0.8 and 2.5, is determined on the type of soil at the site of interest, The value is dimensionless.

The appropriate seismic acceleration, a_H [ms^{-2}] is found by checking the limits of the following equation, according to ASCE-7 13.3.1:

$$a_H = \frac{0.4 \cdot a_p \cdot S_{DS}}{\left(\frac{R_p}{I_p} \right)} \left(1 + \frac{z}{h} \right) \quad (3)$$

$$0.4 \cdot S_{DS} \leq a_H \leq 1.6 \cdot S_{DS} \cdot I_p \quad (4)$$

with:

I_p = *Importance factor* [-] : This value ranges from 1-1.5 and relates to the occupancy category which itself is dictated by the amount of risk present based on ASCE-7 table 1-1.

z/h = *Component elevation ratio* [-] : The ratio of height of the structure at the point of attachment over the average height of the supporting structure.

a_p = *Component amplification factor* [-] : Constant, based on the relationship between the piping response and the structural response for a piping system, which can be related to the response of a system as affected by the type of seismic attachment. It is determined from table 13.6-1 from ASCE-7. It is an arbitrary constant that varies depending on the mechanical components in question.

R_p = *Component response modification factor*, [-]: Similar to a_p this is an arbitrary constant that varies depending on the mechanical components in question. This value, too, is taken from ASCE-7 table 13.6-1.

Once a_H has been determined, the horizontal force F_p is deduced by introducing the total weight of the system, W_p , to the horizontal acceleration term in the equation:

$$F_p = a_H \cdot W_p \quad (5)$$

The uniform load shall be applied to the static analysis, independently in at least two orthogonal horizontal directions in combination with the service loads associated with the component. An additional vertical component, which is 0.2 of the horizontal loading, is applied in combination with the two separate horizontal cases.

3.3 Uniform load analysis according to the European code EN13480

EN1998-1 and -4 do not specify an equivalent static uniform load method as an alternative to dynamic analysis, however the European piping design code EN13480 calculates the uniform load magnitude in a similar way like ASCE-7. The acceleration component of the equation is based on the maximum value arising from the earthquake. The static equivalent acceleration, a_{cqi} can be found by the following equation from EN13480-3:2002, A.2.1.2:

$$a_{cqi} = k_i \cdot a_i \quad (6)$$

with:

a_i is the acceleration defined for the level in direction i , and k_i is a factor, dependent on the degree of analyses of the natural frequencies of the system Importance factor [-].

$k_i = 1$ when system's natural frequencies of the piping system can be shown not to coincide within 10% of the peak vibration frequencies in the response spectrum of the structure (or the peak ground acceleration if the pipe work is not mounted on a structure or building).

$k_i = 1.5$ where no check on the coincidence of piping and structure vibration characteristics has been undertaken.

For this study the factor $k_i = 1.5$ is used.

3.4 Resulting design acceleration (Uniform load method, Ammonia and Gas pipeline)

To match the original design calculations according the Algerian Earthquake resistance code RPA99:2003, made with the respective software packages AutoPIPE and ROHR2 for the Ammonia transfer line the gas transmission line, a uniform load of 0.2g and 0.14g hori-

zontal and vertical, respectively are calculated, in order to accurately compare results. This gives three separate uniform load cases (Table 3):

Uniform load case	Horizontal acceleration ms^{-2}	Vertical acceleration ms^{-2}
ASCE-7:05	0.14	0.02
EN13480-3:2002	0.37	0.37
AutoPIPE & ROHR2 comparison	0.20	0.20

Table 3: Input seismic forces according equivalent static analyses method (uniform load case).

4 DYNAMIC MODELING OF A PIPING SYTEM UNDER SEISMIC ACTION

4.1 General

For dynamic analyses of a piping system under seismic load it is necessary to get the expected random waveform of acceleration vs. time, caused by the earthquake into a data set, such as a response spectrum. This is followed by a spectrum analyses. A spectrum analysis represents an estimate of the maximum response developed in the piping system during the transient load from the earthquake.

The response of the piping system will depend on the magnitude and the number of its modes of natural frequency (first and higher harmonics). A pipe layout showing a large number of possible natural frequencies will react different compared to piping systems having a higher natural frequency (usually more "rigid" systems).

The steps to be taken are:

- Define the *design seismic response spectra*.
- Define the range of natural frequencies (modes of vibration) of the pipe system under consideration.
- Calculate the response of the pipe system under the design acceleration related to each natural frequency.

4.2 Generation of seismic response spectra

4.2.1 Spectrum generation according to ASCE-7

A horizontal and a vertical design response spectrum are generated. Six parameters, similar to those described under 3.2 for the uniform load method, determine the shape of the (horizontal) design response spectrum according to the ASCE-7 seismic code.

4.2.2 Spectrum generation according to Eurocode 8

Eurocode 8 presents a seismic response spectrum, similar in profile to that produced using ASCE-7. However, the corresponding response amplitudes are extracted based on a different data set, in this case, from the EN1998-1 seismic code.

Once the soil type and the values of the period are selected, two curve types can be formed, Type I and Type II, depending on whether deep geology is accounted for in the calculation. However, if the geology is not known, EN1998-1: 3.2.2.2 recommends using both curve types. This study takes into account both types; this is also relevant to the vertical spectra. Contributing factors to the EN 1998-1 seismic response curve are:

- *Soil Factor S*: Ground types are described in table 3.1 and 3.3 of EN1998-1. These are based on parameters of a geotechnical nature.

- *Damping Factor η* : This is the damping correction factor of which the source is internal friction of the materials, imperfect connections between components, sliding friction, and other features. This is governed by the following expression:

$$\eta = \sqrt{\frac{10}{(5 + \xi)}} \geq 0.55 \quad (7)$$

where ξ is the *damping ratio* of the structure [%]. Throughout this study, the damping ratio was set at 5%, according to EN13480-1 A.2.1.6 where a value of 5% is used for systems with a frequency below 10Hz, thus rendering the damping factor to be unity throughout.

- *Behavior Factor q* : This is the ratio between the peak ground acceleration (PGA) that produces the ultimate displacement or rotation and the PGA that produces the yielding of the first point of the structure under consideration.
- *Ground Acceleration a_g* : The design ground acceleration on type A ground is defined as:

$$a_g = \gamma_1 \cdot a_{gR} \quad (8)$$

Where γ_1 is the topographic amplification factor, which is always greater than 1.

4.2.3 Vertical design spectrum

A major difference between the ASCE-7 and EN1998-1 codes is the magnitude of a vertical component to the calculation. According ASCE-7 the vertical spectrum is set to 20% of the amplitude of the horizontal design response spectrum across the entire period range.

According to EN1998-1 two types of curves can be applied, as seen in the design spectrum for the horizontal component, namely type I & II. However, a behavior factor appears in the equation and two ground acceleration values are mentioned in the code in table 3.4 of EN1998-1, resulting in the vertical spectra, given in fig. 3a and 3b.

4.2.4 Soil type selection

The soil types selected as a basis for the calculations according ASCE 7 and EN1998-1 were best matched to each other, leading to the choice for soil type C (ASCE-7) and soil type B (EN1998-1) respectively.

Soil type C from ASCE-7 is described as "very dense soil and soft rock" with a wave velocity range, as listed in table 20.3-1 ASCE-7, lying between 365-762 ms⁻¹. EN1998-1, which is a little bit more descriptive, describes soil type B as "Deposits of very dense sand, gravel or very stiff clay, at least several tens of meters in thickness, characterized by a gradual increase of mechanical properties with depth." The shear wave velocity range in table 3.1 of EN1998-1 for soil type B is 360-800 ms⁻¹.

For both codes shear wave velocity associated with each soil type is determined in the same way, the difference being constants used to describe the same values. The following equation represents the way that shear wave velocity, $v_{s,30}$ – at 30 meters - is presented in table 3.1 (2) of EN1998-1. ASCE-7-05 presents in equation 20.4-1 an identical manner, with the thickness term h_i presented as d_i .

$$v_{s,30} = \frac{30}{\sum_{i=1,N} \frac{h_i}{v_i}} \quad (9)$$

4.2.5 Input parameters and design seismic spectrum generation

On basis of the foregoing, the input parameters for generating the design seismic response spectra are generated, Table 4 and Table 5). This results in horizontal and vertical design seismic response spectra according to both the ASCE code and the EN1998-1 code. Figure 3 and Figure 4 show the calculated horizontal and vertical design response spectra.

Parameter EN1998-1	CURVE TYPE / VALUE				Reference EN1998-1

For the liquid ammonia pipeline, Caesar II calculated 250 relevant modes of vibration and periods up to 0.866 seconds. Compared to this (cross country) pipeline, most plant piping systems will be smaller and more rigid (more supporting) resulting in fewer relevant modes of vibration.

To be able to see how much influence each spectra has on the piping systems output, one must look at the spectra's period in comparison to the system's modes of natural frequency. As can be seen in fig 3a, the blue shaded region of the curve represents the range in which this particular system's natural frequencies lie; the bold lines are sample modes which have been highlighted. The region outside of the shaded area is above a certain cut-off period, which translates for the ammonia line to 0.866 Seconds, which is 1.154 Hz – the 1st mode of the systems natural frequency. Although the peak of the type II horizontal curve is higher, the maximum acceleration with which Caesar II calculates the system at the 1st mode of vibration

is 0.15 ms^{-2} for the type I horizontal curve. The pipes natural frequency is the determining factor on how much the spectra influence the results.

The higher the mode of vibration the lower the periodicity, thus there will be a particular mode of vibration which matches the peaks of each curve. The vertical lines on the graph below represent the modes of vibration mode 1 can be seen at 0.866 seconds, the 2nd mode is visible at 0.459 seconds, the 25th and 100th modes are also represented on the graph at 0.132 and 0.060 seconds respectively. Similarly the same can be shown when comparing the ASCE-7 curve with the EN1998-1 curves.

Figure 3: Horizontal and vertical seismic design spectra according EN1998-1 and ASCE-7, with natural frequency range (blue shaded) of the ammonia pipeline system.

Figure 4: Horizontal and vertical seismic design spectra according EN1998-1 and ASCE-7, with natural frequency range (blue shaded) of the gas pipeline system.

The number of modes of the natural frequencies present in the gas transmission line, calculated according 4.3, are much fewer compared to the liquid ammonia transmission line. This is expected as the system is more rigid and shorter. Similarly to the curves seen in dynamic analysis of the liquid ammonia pipeline, Figure 4 shows the relevant area of the curve for the natural gas system.

It's quite clear to see from Figure 3 that natural frequency mode 1 ($T \sim 0.3$ S) of the pipe system corresponds to the plateau of the response spectra EN1998, type I and ASCE 7, producing higher acceleration forces (and stress results) compared to EN1998-1 (type 2) spectra, though the latter has a larger plateau compared to EN1998 (type 1).

4.3 Modeling and determination of the range of natural frequencies of the pipe system

Calculation of natural frequencies

The system's modes of vibration will respond to the load in the exact same nature as a single degree of freedom oscillator with the generation of the response spectra, as it obeys Newton's second law for damped harmonic oscillators.

$$F(t) = m \left(\frac{d^2 x}{dt^2} \right) + c \left(\frac{dx}{dt} \right) + k(x) \quad (10)$$

When calculating the modes of vibration and the fundamental frequency of the system, Caesar II, being the software package used for the dynamic calculations, will set the driving force to be zero. Also the damping factor is zero which eliminates the second term of the equation and allows Caesar II to solve the equation harmonically. For simple harmonic motion the displacement can be described as:

$$\begin{aligned} x &= x_0 \cdot \sin \omega \cdot t \\ \frac{dx}{dt} &= x_0 \cdot \omega \cdot \cos \omega \cdot t \\ \frac{d^2 x}{dt^2} &= -x_0 \omega^2 \sin \omega \cdot t \end{aligned} \quad (11)$$

Therefore, substituting in the displacement to the acceleration equation along with the stiffness and mass gives the following equation which Caesar II can use to determine the fundamental frequency:

$$\frac{d^2 x}{dt^2} = -\omega^2 \cdot x \quad \therefore \omega = \sqrt{\frac{k}{m}} \quad (12)$$

The system's overall response can be described in terms of displacement, which is shown in the equation below:

$$x = \frac{v}{\omega} = \frac{a}{\omega^2} \quad (13)$$

Where x is the displacement from response spectrum at frequency f , v is the velocity, ω is the angular frequency at which response spectrum parameters are taken and a is the acceleration from response spectrum at frequency. Caesar II completes the following steps:

1. An Eigen solver algorithm is used to extract the exact modes of vibration from the system. The subsequent modes have a characteristic frequency and mode shape.

2. The maximum response of each mode under the applied load is determined from the spectrum value corresponding to the mode's natural frequency.
3. The total system response is determined by summing the individual modal responses using the square root of the sums of the squares method, where R_i is the total response in direction, i , R_{mi} is the peak response due to mode m and n is the total number of significant modes for the particular system.

$$R_i = \pm \sqrt{\sum_{m=1}^n R_{mi}^2} \quad (14)$$

Figure 5 shows an example of the liquid transmission line vibrating at the fourth mode of its natural frequency. (It is easier to see in this particular piping configuration, compared to the gas transmission line).¹

Figure 5: Caesar II representation of the fourth mode shape driven by the ASCE-7 spectra – Liquid transmission line.

The results are a statistical summation of the maximum displacements, forces, reactions, stresses, etc; the individual responses do not represent an actual physical loading case in that the maxima may all occur at different times. In this particular case, the allowable stresses for occasional loads of ASME B31.3 or ASME B31.8 will be compared to these stress analyses.

Mass point spacing

A system's modes of vibration are an inherent property of the system; however, the calculation method needs a sufficient number of mass points to estimate the system's modes of vibration.

Caesar II converts each element associated with the piping from a continuous beam element between nodes to stiffness between two masses. Supports and anchors are modeled by adding additional stiffness to the mass node. The masses assigned are only half the sum of all element masses framing into the node.

The accuracy of the model can be increased by the addition of just a few mass points to the system. There are a number of rules of thumb to follow when arranging a seismic model. There must be at least one lump mass between two pipe supports, similarly there must be an

¹ An accompanying video of the pipe vibrating at the listed modes is also available.

even mass distribution on bends and where there is concentration of mass, such as a flange, valve or tee. Table 6 gives the ratio to the exact solution of the number of significant nodes Caesar II can calculate depending on the number of nodes between supports.

Nodes (including end nodes)	Ratio (%)
2	69.6
3	88.5
4	93.7
5	95.7
10	97.9

Table 6: Influence of mass point spacing on calculation accuracy.

In the calculation of the liquid ammonia transfer line, having a high number of possible vibration modes, extra nodes had to be added between the supports. The average mass spacing needed is approximately 5 nodes between each supports, which gives approximately 95% ratio to the exact solution of the modes of the natural frequency. The approximate distance at which to split the sections of pipes is given by the following equation:

$$L = 9.2 \cdot \left(\frac{D^3 t}{W} \right)^{\frac{1}{4}} \quad (15)$$

where:

L = distance between two consecutive lumped masses (mm).

D = outside diameter of pipe (mm).

T = wall thickness of the pipe (mm).

W = weight per unit length of the pipe ($\text{kg} \cdot \text{m}^{-1}$).

The results are only a guide, as in some cases it is impossible to split the nodes into the required distance because of the piping geometry. The lumped mass distance for the liquid ammonia transmission line was calculated to be 387 mm and the distance for the natural gas transmission line was calculated to be 480 mm.

Support modeling

Throughout both models, the types of supports which have been modeled are simplistic slide or guide supports. Only the frictional effect has been modeled along with the physical barrier which prevents the pipe moving in the specified direction. This technique is common place in pipe modeling. Where a support is very long, occasionally the stiffness factor will be modeled, however, this does not occur in the two systems studied. The aforementioned system where a steel structure has been modeled Caesar II takes into consideration the stiffness associated with the frame. When modeling the supports as slide or guide supports, the stiffness factor was assumed to be negligible.

Restrictions to modeling

Caesar II does not model any ‘slapping’ – where the pipe lifts up from a support in one time frame and slaps down on the support. The pipe must be restricted or free to move. The restraints which are non-linear in the static cases must be made active or inactive to enable an

accurate dynamic analysis. It is possible to set non-linear restraints to a configuration found in the static results.

Another effect which is non-linear is the force produced from friction. These must also be set to be linear. A default setting for II is to model the supporting as having no frictional effects. If desired, Caesar II can approximate the frictional force in the dynamic case by assuming a +Y restraint the frictional value would instead be added to the X and Z directions and a spring support would be included.

It should be noted that the slapping effect does not arise in a situation where a spring hanger has been modeled in the static stage of the calculation. Therefore, if in one of the load cases a lifting of the pipe occurs at the spring support it will still be modeled as a support at the dynamic stage of the calculation.

5 CALCULATION RESULTS AND DISCUSSION FOR THE AMMONIA TRANSMISSION LINE

The effect of design acceleration on pipe stresses, forces and bending moments was calculated with special focus on the end nozzles.

The pipe stresses for all models were calculated to be within the allowable limits of the applicable design code (The results do not address the flange leak check). Table 7 shows the calculated maximum pipe stresses for both the uniform load method and the dynamic analyses. The location of the maximum stress (node number is shown in Figure 6).

Figure 6: Ammonia transmission line including node numbering.

One can see that applying the uniform load method, the maximum stresses occur at the horizontal bend at node 610 and amount 40% -50% of the allowable code stress. The dynamic analyses however reveal a more severe picture: Maximum stresses occur now at the lower bend of the vertical expansion loop at node 550 and are not only exceeding the allowable code stress but also the yield strength. This might be an indication that for these types of pipe systems, showing high period and low natural frequencies, full dynamic analyses is always required.

Load case / Design seismic spectrum	Type of calculation	Maximum stress in node	Stress [Nmm ⁻²] (<i>vibration mode</i>) ²⁾	Allowable stress [Nmm ⁻²] (ASME B31.3)	Ratio [%]

Table 9: DYNAMIC ANALYSES: Forces and moments on the nozzle at node 10.

It can be seen that – for this particular location, in general the uniform load cases generate higher forces and bending moments, compared to the results of the dynamic analyses, EN13480 giving the most conservative results.

²⁾ An accompanying video of the pipe vibrating at the listed modes is also available.

The maximum values for the dynamic cases occur at different vibration modes. Also differences between results for the different seismic spectra can be observed. In general the calculated forces and moments are rather low.

6 CALCULATION RESULTS FOR THE GAS TRANSMISSION LINE

The effect of design acceleration on pipe stresses, forces and bending moments was calculated with special focus on tees and nozzles and on the influence of a steel support structure, modeled into the dynamic calculations.

6.1 Calculations including modeling of the steel support structure

In this case the steel supporting structure was also modeled in Caesar II, allowing deformations under load. Between the steel structure and the pipe a spring support is modeled. See Figure 7, (also for node numbers).

When removing the steel structure from the calculation, the system's overall mass will be lower. This has an effect on the system's natural frequency. Table 10 shows the calculated differences in the modes of vibration detected with and without the steel structure.

Table 11 presents the calculation pipe stresses for both the uniform load analysis and the dynamic analyses.

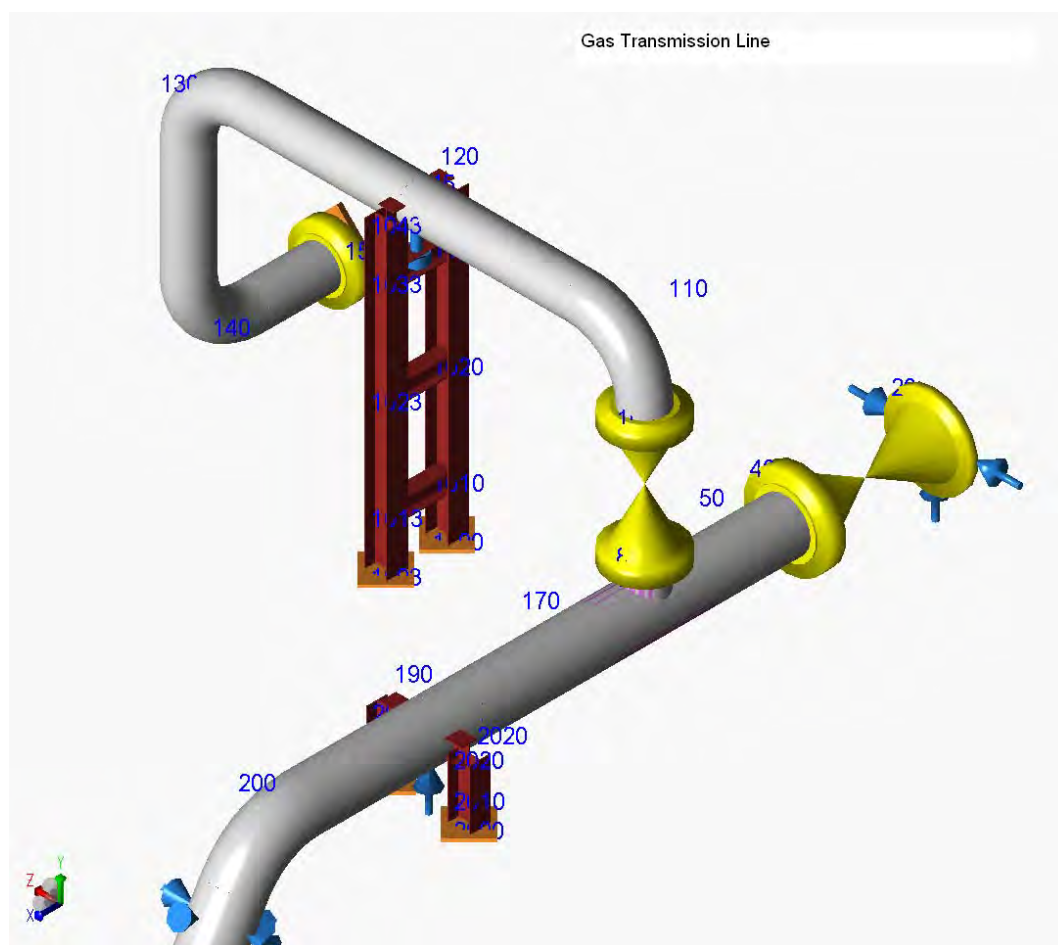

Figure 7: Detail of Gas transmission line, showing steel structure and node numbers.

Vibration Mode #	Freq. (Hz) <i>with steel structure</i>	Freq. (Hz) <i>no steel structure</i>

¹⁾ No steel support structure modeled

Table 11: Gas transmission line: calculation results (Uniform Load & Dynamic).

For this more rigid pipe system, having higher natural frequencies, the uniform load method gives conservative results with stress levels about three times the maximum values of the dynamic analyses, the latter all occurring in the first mode of vibration.

As stated before it's quite clear from Figure 4 that natural frequency mode 1 (T~0.3 S) of the pipe system corresponds to the plateau of the response spectra EN1998, type I and ASCE 7, producing higher acceleration forces (and stress results) compared to EN1998-1 (type 2) spectra. This argument holds true for the forces and moments present on the nozzle and the tee-piece. The forces and moments on the tee-piece have a maximum value at EN1998-1 (type 1) when the system is vibrating at the 1st mode of vibration.

It is also noticed that, applying the uniform load method, the maximum stresses will occur at the T-Piece (node 50), whereas the dynamic analyses shows the maximum stresses occur in the upper bend at node 110.

Comparison of the calculated stresses with and without modeling of the steel support structure shows that the differences are negligible. The (already very low) stresses in the pipe system are hardly influenced by the deformation of the steel structure under the horizontal (friction) load.

Gas transmission line: Tee focus

The 20" x 16" reducing tee piece in the gas transmission line is the subject of special attention. Table 12 and Table 13 present the forces and moments acting on the Tee at node 60 (see Figure 7) calculated with the static (uniform load) method and the dynamic analyses (between brackets the mode of vibration).

¹⁾ No steel support structure modeled

Table 13: Gas pipeline, DYNAMIC ANALYSES: Forces & Moments at T-junction (node60).

The maximum values occur during the uniform load method. Comparing the results of the dynamic analyses for the different codes does not give notable differences. Comparison of the calculated forces and moments with and without modeling of the steel support structure however shows that for F_y and F_z and for the moments marked differences can be seen, not so much with regard to the maximum values but with regard to the direction. *The reason for this phenomenon is not yet quite clear.*

Gas Transmission line: Nozzle focus

The nozzle situated at node 160 (see Figure 7), modeled as a fixed point, is a flange connection and therefore critical with regard to possible leakage. Table 14 and Table 15 represent the results of the forces and moments, calculated for the uniform load cases and for the dynamic analyses (Between brackets the vibration mode).

EN1998-1 (Type II) ¹⁾	4000 (1)	1406 (1)	13248 (1)	18738 (1)	16319 (1)	4358 (1)

¹⁾ No steel support structure modeled

Table 15: Nozzle focus, DYNAMIC ANALYSES: Forces and Moments at the nozzle at node 160.

The result for the nozzle forces are more or less in contradiction with the results of the calculated stresses in the pipes and with the forces and moments for the Tee. Here the maximum forces and moments occur in the dynamic cases. The maximum value for the moment being comparable with the result of the uniform load method (that is for the European code only), the maximum force calculated dynamically is clearly higher. The influence of the modeling of the steel substructure is negligible here.

7 CONCLUSIONS

Spectra comparison

The ASCE and EN seismic codes studied bear similar spectra, be it that that vertical spectrum of ASCE 7-05 is considerably lower than the vertical spectra acc. to EN1998-1. The results show that the EN1998-1 and ASCE-7 spectra in general yield similar stresses, forces and moments. This is due to the fact that the peaks occur roughly in the same periodicity as each other – relevant to a typical piping system with a natural frequency higher than 5Hz.

Dynamic vs. uniform load calculations

A direct comparison between the two methods of seismic calculations shows that in one case studied that the uniform load seismic calculations yielded more conservative results than the dynamic seismic calculations. This supports the already practiced method amongst engineers of rather calculating the uniform load stress then modeling the system dynamically. It is perhaps advantageous to carry out a uniform load seismic stress calculations with all earthquake prone pipelines, provided the natural frequencies are high enough.

However, for loose and long pipe systems, a dynamic analysis is of fundamental importance especially if the natural frequency is lower than 4-5Hz. In such cases the uniform load method might substantially underestimate the stresses and forces

Further investigations are required to determine safe borders for the application of the uniform load method.

Influence of supporting structure

The effect seen when a steel supporting structure is included and modeled dynamically is that the system becomes more flexible, allowing the system to vibrate freely with the supporting structure. In this particular case (the gas pipe system and the steel support structure being rather stiff), the influence on the natural frequencies appeared too little to make much difference.

Influence of design

More important than the differences between codes in seismic design spectra is the design of the piping system. This is the deciding factor in whether the system will be able to withstand a particular seismic event. The philosophy of designing a system to be able to withstand loadings that occur during a static situation are that the right amount of flexibility should be included into the design e.g. to deal with expansion. This is often achieved by adding expansion loops, or by adjusting the geometry of the system. However, when a system is under seismic loading or any other dynamic situation which is likely to vibrate the system close to its natural frequency, it is desirable to design a system which is rigid. Provisions to prevent 'slag' between pipe and support may be necessary. This results in a trade-off between satisfying the needs of the static and dynamic analysis requirements. Often an optimum design can be found by extensive stress analysis. It is recommended to include guidelines for design in the next revision of EN1998-4 and ASCE 7-05.

Influence of computer modeling

When performing dynamic analyses it is very important to apply the correct modeling practice in order to obtain reliable results, however this is not addressed in the present codes.

Non linear modeling of supports during dynamic analyses is not possible yet with commercially available software. For systems with more modes of vibration it is also very important that a sufficient number of nodes between the supports should be applied. It should be checked whether the computer model is able to deal with slag in the supports, etc. It is advised to include recommendations for modeling in the next revision of EN1998-4 and ASCE 7-05

APPENDIX 1: ELASTIC RESPONSE SPECTRUM

In systems where permanent plastic deformation may be taken into account one must calculate the response spectra using the equations for Elastic response. As one can see in the equations below that when the behavior factor of the design response spectra is unity and the critical damping ratio is 5% in the elastic spectra, the plateau and decay of the curves are identical. The curve, like the design response spectra is split into four parts.

$$0 \leq T \leq T_B : S_e(T) = a_g \cdot S \cdot \left(1 + \frac{T}{T_B} \cdot [\eta \cdot 2.5 - 1] \right) \quad (16)$$

$$T_B \leq T \leq T_C : S_e(T) = a_g \cdot S \cdot \eta \cdot 2.5 \quad (17)$$

$$T_C \leq T \leq T_D : S_e(T) = a_g \cdot S \cdot \eta \cdot 2.5 \cdot \left(\frac{T_C}{T} \right) \quad (18)$$

$$T_D \leq T : S_e(T) = a_g \cdot S \cdot \eta \cdot 2.5 \cdot \left(\frac{T_C T_D}{T^2} \right) \quad (19)$$

Damping in elastic response spectra

The determining of a spectrum with a different value of damping other than 5% is taken from the curve mentioned in EN13480 (A5.4.3) as seen in Figure 8 below.

Figure 8: Critical damping.

The critical damping, η directly affects the elastic response spectra curve. The following equation simplifies the damping factor η to 1 when the critical damping ratio is 5%,

$$\eta = \sqrt{\frac{10}{5 + \xi}} \geq 0.55 \quad (20)$$

Where ξ is the damping percentage relative to the critical damping of the system and where the critical damping is given by the following equation:

$$\xi = 2\sqrt{K \cdot M} \quad (21)$$

Where K is the stiffness of the system and M is the mass.

APPENDIX 2: JAPANESE CODE COMPARISON

A brief study between the European codes and the Japanese equivalent (BCJ) code reveals a very different approach to dynamic seismic modeling. An extensive paper already exists [9]. However, this is heavily focused on building structures and does not look at piping systems.

There seems to be a lack of a design response spectrum and an entire vertical component, whereas the European equivalent includes a design response spectrum and an elastic response spectrum, which incorporates the behavior factor, q . Furthermore, the Japanese codes are devoid of any importance factor. However, as can be seen from the spectra, the code is much more conservative than the European code. Assuming the average piping system's natural frequency would not be lower than 5Hz (represented by the shaded area), one can see that the Japanese code would apply a constant load as can see at the plateau in the early stages of the BCJ curve.

Figure 9: Comparison acceleration European and Japanese code.

SEISMIC DESIGN OF SPHERICAL LIQUID STORAGE TANKS (COMPDYN 2011)

Keywords: Spherical Liquid Storage Tanks, Industrial Structures, Behaviour Factor, Sloshing Effect, Seismic Design, Earthquake Engineering.

Abstract: *Spherical storage tanks are widely used for various types of liquids, including hazardous contents; consequently these storage tanks must be adequately designed for seismic actions.*

While very detailed and specific seismic design rules for cylindrical tanks are provided by several codes, such rules are missing for spherical tanks. This paper describes the results of a survey on existing European and American Codes with regard to their applicability to spherical liquid storage tanks and provides comparison of design outcomes according to these codes. The investigations were performed on an example of an existing spherical tank which was selected to be representative for the current practice. The studies comprised numerical FE modelling and calculation as well as simplified models for the estimation of the dynamic properties of the tank structure. The applicability of behaviour factors was discussed based on proposals made by Eurocode 8. Particular attention was paid to the influence of sloshing effects for which no guidance is given in the codes. The sloshing effects were investigated according to the current state of the art based on available publications.

Finally the resistance of the tank was compared to the action effect determined from the European and American codes. The comparison of action effects obtained with and without consideration of sloshing effects showed a rather important influence of these effects on the final results.

1 INTRODUCTION

The contribution describes the results of an investigation of a representative example of a spherical liquid storage tank subjected to seismic actions. The aim of the study was to verify the applicability of existing European and American codes to spherical tanks although no particular design rules for this kind of tanks – neither for the determination of loads nor for the detailing – are provided by the considered codes. Furthermore the influence of sloshing effects was investigated according to the current state of the art [9].

2 OBJECT OF INVESTIGATION

2.1 Dimensions and load cases

The research focused on a spherical pressure vessel (material S 355) with the dimensions given below, see Figure 1. The spherical tank was supported by twelve vertical legs without additional bracings between them.

Figure 1: Spherical pressure vessel with 12 columns (inner diameter of the sphere $D_i = 19.9\text{ m}$)

The numerical investigation considered the following load cases:

- self-weight of the structure (columns and sphere) (total weight $m = 879\text{ t}$);
- operating load (density $\rho = 522\text{ kg/m}^3$, filling height $h_p = 18.1\text{ m}$, weight $m = 2104\text{ t}$);
- seismic load ($a_g = 0.24\text{ g} \approx 2.4\text{ m/s}^2$)

2.2 Seismic actions

In order to compare European and American standards the value of the response acceleration S_d for $T_B \leq T \leq T_C$ according to EN 1998-1:2010 (3.13) [1] was selected to be equal to S_a for $T_0 \leq T \leq T_S$ according to ASCE/SEI 7-05 (11.4-5) [4] (see Figure 2). However, the behaviour factor q is not taken into account at this point ($q = 1$).

$$S_d(T) = a_g \cdot S \cdot \left[\frac{2}{3} + \frac{T}{T_B} \cdot \left(\frac{2.5}{q} - \frac{2}{3} \right) \right] \quad (\text{according to EN 1998-1 (3.13)}) \quad (1)$$

$$S_a = S_{DS} \cdot \left(0.4 + 0.6 \cdot \frac{T}{T_0} \right) \quad (\text{according to ASCE/SEI 7-05 (11.4-5)}) \quad (2)$$

Figure 2: Elastic response spectrum according to EN 1998-1 [1] and ASCE/SEI 7-05 [4]

To consider similar ground conditions for both standards comparable locations were assumed (ground type *C* according to EC 8, part 1 [1] complies with site class *C* according to ASCE 7 [4]).

The model for the determination of the fundamental period T_I was divided into the following sub-systems:

- ground and foundation (soil-structure interaction effects are not considered here);
- spherical pressure vessel structure;
- fluid, sloshing response, etc.

2.3 Fundamental period of the spherical pressure vessel structure

The fundamental period of the tank structure including maximum filling and neglecting sloshing effects was determined as follows (see Figure 3):

- using FEM-calculations, fundamental period was determined to $T_I = 1.54$ s;
- using a strut-and-tie model (single equivalent load in center of gravity) $T_I = 1.56$ s.

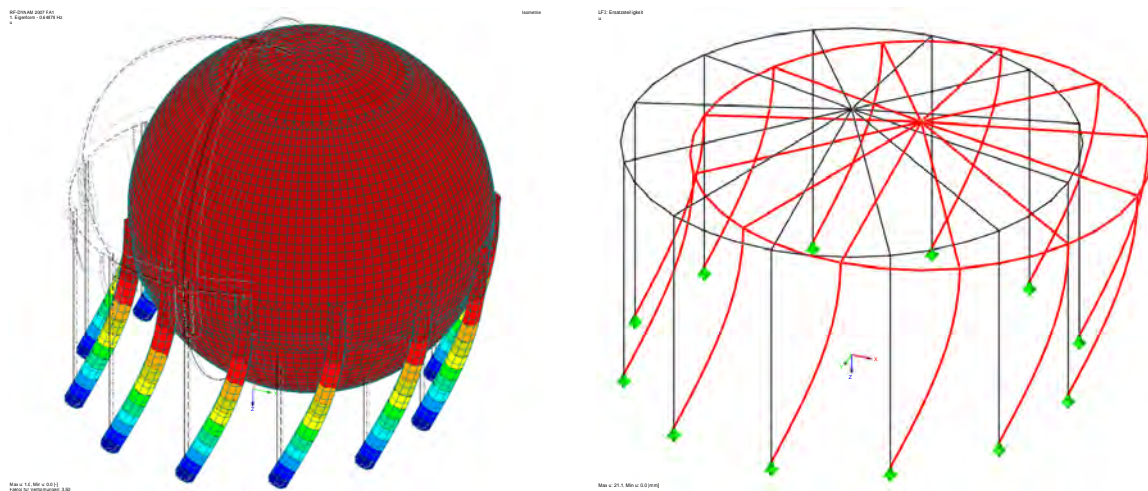

Figure 3: Ascertainment of the fundamental period T_I based on FEM model (left) and strut-and-tie model (right)

3 SELECTION OF A BEHAVIOUR FACTOR

3.1 Basis of the behaviour factor

In the seismic design of structures the behaviour factor q (or response modification factor R) represents the dissipation capability of the structure. This dissipation capability depends on the structural type and the type of the construction (e.g.: concrete, steel, composite ...). The upper limit value of q depends on the ductility class. EC 8, part 1 [1] differentiates between three ductility classes. Structures with small dissipation capability belong to the low ductility class (DCL). Structures belonging to DHM (medium ductility class) or DCH (high ductility class) have to fulfil minimum requirements with regard to plastic deformability (e.g. rotation capacity of the cross-sections) and with regard to detailing (e.g. capacity design of connections). In the following medium ductility class (DCM) was supposed for the steel tanks under investigation.

For structures in Europe basic seismic design rules, including seismic actions, are provided by Eurocode 8 Part 1. In the USA basic rules and seismic actions are provided e.g. by ASCE 7 [4]. With regard to tank structures EN 1998-4 [2] applies in Europe. The American standards API 620 [5] and API 650 [6] are used for the design of ground supported tanks including earthquake. Table 1 shows a compilation of references to the behaviour factor q respectively response modification factor R available the European and American standards.

Behaviour factor q	Response modification factor R
EN 1998-1, chap. 6.3 (steel buildings)	ASCE/SEI 7-05, tab. 12.2 1 (general systems)
EN 1998-4, chap. 2.4 (general)	ASCE/SEI 7-05, tab. 15.4 2 (nonbuilding structures)
EN 1998-4, chap. 3.4 (silos)	API 650, tab. E 4 (ground supported, liquid storage tanks)
EN 1998 -4, chap. 4.4 (tanks)	API 620, tab. L 1Q and L1 R (ground supported, liquid storage tanks) UBC 1997, Volume 2, tab. 16 N (general systems) UBC 1997, Volume 2, tab. 16 P (nonbuilding structures)

Table 1: References of behaviour factor and response modification factor

3.2 Behaviour factor q according to European standards

The provisions given by EC 8 for the application of behaviour factor q to spherical tanks are of limited precision. For elevated tanks EN 1998-4 [2], Chap. 4.4 refers to Chap. 3.4 (silos) where the application of behaviour factor q for an inverted pendulum (see Figure 4) is recommended. Basic definitions of an inverted pendulum system are given in EC8 Part 1. The following definitions given by Eurocode 8 are of interest for assessment of the behaviour factors of spherical elevated tanks:

- EN 1998-1 5.1.2 (1): Inverted pendulum systems – system in which 50% or more of the mass is in the upper third of the height of the structure, or in which the dissipation of energy takes place mainly at the base of a single building element.

NOTE: One-storey frames with column tops connected along both main directions of the building and with the value of the column normalized axial load v_d exceeding 0,3 nowhere, do not belong in this category.

- EN 1998-1 6.3.1 (5): Inverted pendulum structures may be considered as moment resisting frames provided that the earthquake resistant structures possess more than one column in each resisting plane and that the following inequality of the limitation of axial force: $N_{Ed} < 0,3 N_{pl}$, R_d is satisfied in each column.
- EN 1998-4 4.4 (4): behaviour factors specified in 3.4 should be applied also to the part of the response of elevated tanks [...]
- EN 1998-4 3.4 (5): For skirt-supported silos, with the skirt designed and detailed to ensure dissipative behaviour; the upper limit values of the q factor defined in EN 1998-1, Sections 5 to 7 for inverted pendulum structures may be used.

Figure 4: Inverted pendulum (a, b) and MRF (c) according to EN 1998-1, Fig. 6.5 [1]

The modal shapes obtained by the calculations using the FE-model and the strut-and-tie model however, showed that an elevated spherical tank barely behaves like an inverted pendulum as it is intended by EN 1998-1. Rather, the spherical tank supported by a number of columns exposes behaviour comparable to a moment resisting frame with a rigid girder. Moreover, two aspects mentioned in EC 8-1 5.2.1 – potential plastic hinges at the top of columns and more than one single resisting element – indicate a possible classification of such structures as a MRF rather than inverted pendulum. The comparison of elevated tanks to skirt-supported structures as given by EC 8-4, however, suggests the presence of one resisting element only and consequently the maximum q -factor of 2,0 (see Table 2), provided that the structural detailing allows for the development of a plastic mechanism.

STRUCTURAL TYPE	Ductility Class	
	DCM	DCH
a) Moment resisting frames	4	$5\alpha_u/\alpha_1$
b) Frame with concentric bracings Diagonal bracings V-bracings	4	4
	2	2,5
c) Frame with eccentric bracings	4	$5\alpha_u/\alpha_1$
d) Inverted pendulum	2	$2\alpha_u/\alpha_1$
e) Structures with concrete cores or concrete walls	See section 5	
f) Moment resisting frame with concentric bracing	4	$4\alpha_u/\alpha_1$
g) Moment resisting frames with infills Unconnected concrete or masonry infills, in contact with the frame Connected reinforced concrete infills Infills isolated from moment frame (see moment frames)	2	2
	See section 7	
	4	$5\alpha_u/\alpha_1$

Table 2: Table 6.2 from EN 1998-1 [1]

In fact, neither of the possible interpretations – inverted pendulum or MRF – seems to be reasonable in order to estimate the real performance of a spherical tank. The classification as inverted pendulum is probably rather conservative whereas for a classification as a frame detailing rules for the achievement of dissipative behaviour are missing.

3.3 Response modification factor R according to American standards

American standards such as ASCE 7 [4] differentiate between building and non-building structures. Table 15.4-2 in [4] contains declarations for the non-building structure types “tank” respectively “vessels”. The response modification factor for an elevated tank supported by non-braced legs yields the value $R = 2.0$ according to Table 15.4 2 in [4] (see Table 3).

Nonbuilding Structure Type	Detailing Requirements ^c	R
Elevated tanks, vessels, bins, or hoppers:		
On symmetrically braced legs (not similar to buildings)	15.7.10	3
On unbraced legs or asymmetrically braced legs (not similar to buildings)	15.7.10	2
Single pedestal or skirt supported		
- welded steel	15.7.10	2
- welded steel with special detailing	15.7.10 and 15.7.10.5 a and b.	3
- prestressed or reinforced concrete	15.7.10	2
- prestressed or reinforced concrete with special detailing	15.7.10 and 14.2.3.6	3
Horizontal, saddle supported welded steel vessels	15.7.14	3
Tanks or vessels supported on structural towers similar to buildings	15.5.5	Use v categ resi
Flat-bottom ground-supported tanks:	15.7	
Steel or fiber-reinforced plastic:		
Mechanically anchored		3
Self-anchored		2.5
Reinforced or prestressed concrete:		
reinforced nonsliding base		2
anchored flexible base		3.25
unanchored and unconstrained flexible base		1.5
All other		1.5

Table 3: Extract from ASCE/SEI 7-05, Table 15.4 2 [4]

Ostensibly there is a good agreement between the European and the American proposal for the behaviour factor to be applied to elevated tanks ($q = R = 2.0$). In fact however, the American provisions are referring to generally shaped tanks. The detailing requirements of chapter 15.7.10 as given in the table above, are also of general nature and do not provide guidance on how to achieve a ductile behaviour in particular with regard to the connection of the legs to the shell of the tank.

3.4 Selected behaviour factor for further investigations

Considering the uncertainties related to the choice of an adequate behaviour factor and the fact that the selected example has been initially designed using elastic calculation methods the behaviour factor used in the following seismic calculations was assumed to be $q = R = 1.5$. Since the aim of this study was the comparison of design values resulting from the application of the European and American codes, it was important to select comparable design actions and design resistance by using the same behaviour factor for all code-based calculations. On the other hand selecting the lower bound of the available behaviour factors led to safe-sided results with regard to the intended verification of an existing spherical tank.

A more sophisticated, performance based check of the response of the spherical tank to seismic actions would require either nonlinear time-step calculations. In order to determine a realistic behaviour factor these studies would need to be extended to an incremental dynamic analysis and to other dimensions of the tanks. Such a study however was not included in the working programme of the research project.

4 SEISMIC ANALYSIS ACCORDING TO CODES

4.1 Design spectrum

In order to obtain comparable results using European and American standards the following parameters were chosen (see Table 4). The relevant design spectra according to European and American standards are shown in Figure 5. The spectra were selected such that the “plateau”-values for both codes are the same.

EN 1998-1 [1]		ASCE/SEI 7-05 [4]	
• ground type C	(Table 3.1 in [1])	• site class C	(Table 20.3-1 in [4])
$S = 1,0^{1)}$	(Table 3.2 in [1])	• occupancy category III	
$T_B = 0,2 \text{ s}$	(Table 3.2 in [1])	$S_S = 0,85^{2)}$	(Fig. 22-1 to 22-14 in [4])
$T_C = 0,6 \text{ s}$	(Table 3.2 in [1])	$S_I = 0,25^{2)}$	(Fig. 22-1 to 22-14 in [4])
$T_D = 2,0 \text{ s}$	(Table 3.2 in [1])	$T_0 = 0,086 \text{ s}$	(Eq. 11.4-6 in [4])
		$T_S = 0,431 \text{ s}$	(Eq. 11.4-6 in [4])
		$T_L \geq 4,0 \text{ s}$	(Fig. 22-15 to 22-20 in [4])

¹⁾ This value does not agree with table 3.2 in [1] and was only chosen to fit the plateau.

²⁾ This value was selected such that the plateau-values for both codes are the same

Table 4: Values of parameters describing the design spectrum according to EC 8 [1] and ASCE 7 [4]

Figure 5: Comparison of the elastic response spectrum for the spherical pressure vessel according to EC 8 [1] and ASCE 7 [4]

The comparison of the spectra shows, that even with a similar plateau of 0.6g, up to $T = 2.7$ [s] the European spectrum leads to higher values than the American one (see Figure 5). However, the design spectrum of both standards is very dependent on the chosen parameters. Therefore the comparison of the spectra is not discussed further here. In addition for each standard the same importance factor and behaviour factor were chosen:

EN 1998-1 [1]	ASCE/SEI 7-05 [4]
• importance factor $\gamma_I = 1.25$	• importance factor $I = 1.25$
• behaviour factor $q = 1.5$	• response modification factor $R = 1.5$

Table 5: Importance factor and behaviour factor according to EC 8 [1] and ASCE 7 [4]

4.2 Seismic base shear force neglecting sloshing effects

A. According to European standards

The design of tanks, silos and pipeline systems is governed by EC 8, part 4 [2]. In order to obtain the seismic action effects the “lateral force method” based on linear-elastic analysis according to EC 8, part 1 [1] was used. This method is applicable for structures that respond to seismic action approximately as a single-degree-of-freedom system. This requirement is considered to be fulfilled, if the structure meets the “criteria for regularity in elevation” given in EC 8, part 1 [1] and if the fundamental periods T_I for the two main directions are smaller than the following values:

$$T_I \leq \begin{cases} 4 \cdot T_c \\ 2,0 \text{ s} \end{cases} \quad (3)$$

When neglecting the influence of sloshing the fundamental mode may be assumed as clearly governing the response. Also, the structure may be assumed as regular in plan and elevation. Thus the seismic base shear force F_b was determined as follows:

$$F_b = S_d(T_I) \cdot m \cdot \lambda \quad (4)$$

where $T_I = 1.56 \text{ s}$ (see chapter 2.3)

$$S_d(T_I) = a_g \cdot S \cdot \frac{2.5}{q} \cdot \left(\frac{T_c}{T_I} \right) = 1.51 \text{ m/s}^2 \quad (\text{Eq. 13.3 in [1]})$$

$$S_d(T_I) = 0.154 [1/\text{s}] \quad (\text{for } q = 1.5)$$

$$S_d(T_I) = 0.231 [1/\text{s}] \quad (\text{for } q = 1.0)$$

$$m = 879 + 2104 = 2983 \text{ t} \quad (\text{see chapter 2.1})$$

$$\lambda = 1.0 \quad (\text{Ch. 4.3.3.2.2 in [1]})$$

$$F_b = 1.51 \cdot 2983 \cdot 1.0 = 4503.9 \text{ kN}$$

$$F_b = \gamma_I \cdot 4503.9 = 5629.8 \text{ kN} \quad (\text{for } \gamma_I = 1.25)$$

In order to determine the design values for detailed verification of structural elements of the general structure the following application rules must be considered:

- combination of the effects of the components of the seismic action according to EN 1998-1 (4.3.3.5) [1] (here only the horizontal seismic acceleration is considered using

the alternative combination E_{Edx} “+” $0.3E_{Edy}$, because the vertical acceleration should be taken only for horizontal or nearly horizontal structural members);

- if the accidental eccentricity of EN 1998-1(4.3.2) [1] is not taken into account by a more exact method including a 3D-model, the accidental torsional effects are accounted for by multiplying the action effects for the individual load resisting elements:

$$\delta = 1 + 0.6 \cdot \frac{x}{L_e} \quad (5)$$

where x distance of the element under consideration from the centre of mass of the building in plan, measured perpendicularly to the direction of the seismic action considered

L_e distance between the two outermost lateral load resisting elements, measured perpendicularly to the direction of the seismic action considered

- combination of the seismic action with other actions in accordance with EN 1990:2010 (6.4.3.4) [3] and EN 1998-1 (3.2.4) [1], whereas the combination coefficient for the variable action “snow load” and “wind load” is $\psi_{2,I} = 0$

With regard to the first point – combination of earthquake directions – it shall be mentioned that the initial intension of this rule was the consideration of seismic actions acting “diagonally” on structures usually rectangular in plan. Using this simplified attempt it is permitted to calculate a structure for each orthogonal direction separately and to omit the determination of the most unfavourable direction of the seismic action. Contrary to typical buildings the investigated spherical tank does not have “orthogonal” directions as it is practically rotation-symmetric. Thus there is no “unfavourable” load direction and the necessity of the combination of directions needs to be checked.

The consideration of accidental torsional effects by the simplified model was assumed to cover all eccentricities resulting from external installations, connected pipes, inspection ladders etc. and selected due to its applicability to a SDOF-model. The effects of the applied eccentricity however (+30%, see chapter 4.2 C), seem to be very much safe-sided as indicated by the results presented in Table 6.

Further investigations according to EC 8 were carried out using the strut-and-tie model in Figure 3 (right side). The results are shown and discussed in chapter 4.2 C.

B. According to American standards

The Appendix E of API 650 [6] provides only requirements for the seismic design of cylindrical tanks. Therefore the equivalent lateral force procedure of ASCE/SEI 7-05 (12.8) [4] was applied. For the investigated spherical pressure vessel the seismic base shear force V was determined as follows:

$$V = C_s \cdot W \quad (6)$$

where $T = 1.56 s$ (see chapter 2.3)

$$F_a = 1.06 \quad (\text{Tab. 11.4-1 in [4]})$$

$$F_v = 1.55 \quad (\text{Tab. 11.4-2 in [4]})$$

$$S_{MS} = F_a \cdot S_s = 0.901 \quad (\text{Eq. 11.4-1 in [4]})$$

$$S_{M1} = F_v \cdot S_I = 0.388 \quad (\text{Eq. 11.4-2 in [4]})$$

$$S_{DS} = \frac{2}{3} \cdot S_{MS} = 0.601 \quad (\text{Eq. 11.4-3 in [4]})$$

$$S_{D1} = \frac{2}{3} \cdot S_{M1} = 0.258 \quad (\text{Eq. 11.4-4 in [4]})$$

$$S_a(T) = \frac{S_{D1}}{T} = 0.165 [1/s] \quad (\text{Eq. 11.4-6 in [4]})$$

$$C_s = \frac{S_{DS}}{R/I} = 0.5 < \frac{S_{D1}}{T \cdot (R/I)} = 0.138 \quad (\text{Eq. 12.8-3 in [4]})$$

$$W = 879 + 2104 = 2983 \text{ t} \cong 29830 \text{ kN} \quad (\text{see chapter 2.1})$$

$$V = 0.138 \cdot 29830 = 4116.6 \text{ kN}$$

Finally the horizontal seismic load effect E_h shall be determined in accordance with ASCE/SEI 7-05 (12.4.2) [4] as follows:

$$E_h = \rho \cdot Q_E \quad (7)$$

$$\text{where } \rho = 1.3 \quad (\text{Ch. 12.3.4 in [4]})$$

$$\text{for Seismic Design Category D} \quad (\text{Tab. 11.6-2 in [4]})$$

$$Q_E = V = 4116.6 \text{ kN} \quad (\text{Ch. 12.4.2.1 in [4]})$$

$$E_h = 1.3 \cdot 4116.6 = 5351.5 \text{ kN}$$

To determine the design values for detailed verification of structural elements of the general structure the following application rules must be considered:

- according to ASCE/SEI 7-05 (12.5) [4] for structures assigned to Seismic Design Category D, the design seismic forces are permitted to be applied independently in each of two orthogonal directions and orthogonal interaction effects are permitted to be neglected;
- according to ASCE/SEI 7-05 (12.7.2) [4] a minimum of 25% of the filling live load shall be include within the effective seismic weight (here: 100% of the filling live load);
- according to ASCE/SEI 7-05 (12.8.4.2) [4] accidental torsion should be taken into account by assumed displacement of the centre of mass by a distance equal to 5 percent of the dimension of the structure perpendicular to the direction of the applied forces. This approach is exactly the approach according to EN 1998-1(4.3.2) [1] and was not implemented here;
- combination of the seismic action with other actions in accordance with ASCE/SEI 7-05 (12.4.2.3) [4]: $(1.2 + 0.2 S_{DS}) D + \rho Q_E + L + 0.2 S$, whereas the dead load D is equal to the self-weight of the tank, the live load L is equal to the filling and the snow load is zero.

This investigation is carried out using the strut-and-tie model in Figure 3 (right side). The results are shown and discussed in chapter 4.2 C.

C. Comparison of the design value

The static seismic equivalent loads are determined and combined following the rules given above. They are applied as single equivalent loads in centre of gravity of the strut-and-tie model and the action effects are calculated using linear elastic analysis. The results are given in the following Table 6, listing action effects (separated for the individual load cases) and design values (of the load combination) for both column base and column head according to European standards and American Standards respectively. The table also shows results for seismic action in 0° -direction as well as in 15° -direction. Although the static seismic equivalent loads according to European standards are approximately 5% higher than the ones taken from the American standards, the correlation of those results is good. This good correlation is due to the combination of the seismic action with other actions in accordance with ASCE/SEI 7-05 (12.4.2.3) [4].

		column base				column head

¹ (1.2+0.2 S_{DS}) D (combination of the seismic action with other actions according to ASCE/SEI 7-05)

Table 6: Action effects and design values for load directions of $\alpha = 0^\circ$ and $\alpha = 15^\circ$ according to European and American standards

In addition a closer look at the results leads to the following recognitions:

- the methods to calculate the seismic base shear force according to European and American standards are identical, so that the differences in the results only come from the different design spectra;

- the adding of the redundancy factor $\rho = 1.3$ increased the static seismic equivalent load according ASCE 7 [4]; after this step the seismic loads according to Eurocode and ASCE are quite equal
- because of the accidental eccentricity, which was simplified taken into account according to the EC-8 [1], the difference between the results increased again. This becomes apparent by calculating the shear force V_x resulting from the seismic load:

$$V_x = \delta \cdot \frac{F_b}{n} = 609.9 \text{ kN} \quad (\text{Eurocode})$$

$$V_x = \frac{E_h}{n} = 446.0 \text{ kN} \quad (\text{ASCE})$$

where $n = 12$ (number of columns, see chapter 2.1)

$$\delta = 1 + 0.6 \cdot \frac{x}{L_e} = 1.3 \quad (\text{see Eq. 5})$$

with $L_e = 19700 \text{ mm}$ (see chapter 2.1)

$$x = \frac{19700}{2} = 9850 \text{ mm} \quad (\text{see chapter 2.1})$$

To design columns, bases and joints of the columns to the spherical pressure vessel the design values for $\alpha = 0^\circ$ according to EC 8 are relevant. The verification of the individual members as well as the ULS verification of the vessel skin is not discussed here since the focus was only on the comparison of the different action effects.

4.3 Seismic base shear force taking into account sloshing effects

In the European as well as the American standard rules for the consideration of sloshing effect for liquids are provided for cylindrical (EC 8 und ASCE 7) respectively for rectangular (ASCE 7) tanks only. Thereby the maximum height of the sloshing wave is calculated (see equation 8 and 9) which pretend the minimum height of the freeboard. Neither in the European nor in the American standard a calculation of a seismic design shear force due to the sloshing effect is regulated.

$$d_{\max} = 0.84 \cdot R \cdot \frac{S_d(T_{cl})}{g} \quad (\text{EC 8}) \quad (8)$$

$$\delta_s = 0.5 \cdot D_i \cdot I \cdot S_{ac} \quad (\text{ASCE 7}) \quad (9)$$

For this reason the published procedure of KARAMANOS et al. [9] was used to consider the sloshing effect in seismic design of the investigated spherical tank.

Table 7: Variation of Sloshing Masses with respect to Liquid height in a Spherical Container [9]

The calculation of the relevant seismic design shear force due to the sloshing effect was performed assuming a liquid fill height of 90% which was determined to be the most unfavourable condition. The convective and impulsive masses follow from Table 7:

$$M_{nC} = 652.6[t] \quad (10)$$

$$M_I = 1239.4[t] \quad (11)$$

**Figure 6:** Configuration of a spherical container [9]

The relevant acceleration was calculated with the same assumptions regarding to the design spectrum described in Chapter 2.1.

For the convective part of the sloshing effect the periods are shown in Table 8. The angular frequencies were determined according to Table 9.

1.00	100.0				

Table 9: Variation of the first four sloshing frequencies with respect to liquid height in a spherical vessel [9]

The impulsive angular frequency was calculated with the stiffness of the support systems K_{bs} .

$$\omega_{(2)}^2 = \omega_I^2 = \frac{K_{bs}}{M_I} \quad (13)$$

For the evaluation of the impulsive period the support systems stiffness was determined by using the FE-model of the spherical tank. To obtain the same stiffness by hand calculation (see equation 14) the effective column height had to be $h_L = 10.39$ [m].

$$K_{bs} = \sum_{j=1}^N \frac{3 \cdot EI_L}{h_L^3} \quad (14)$$

This resulted in a period for the impulsive part of $T_I = 1.48$ [s]. Table 10 shows the masses and periods neglecting the sloshing effect and with consideration of sloshing. The comparison shows that the impulsive Eigen period T_I is approximately equal to the Eigen period T_I without sloshing. In contrast, the value of the convective Eigen period T_{1C} is more than twice as large.

without sloshing				
	total mass M [t]		period T ₁ [s]	
dynamic analysis	2919.2		1.54

sloshing response	263.96	2644.64	3.18	1.48

Table 10: Comparison of Natural periods

Table 11 shows the ordinates S_d which were evaluated with the periods T_{1C} and T_I as well as the design spectrum according to Chapter 2.1. For the convective part the behaviour factor was set to $q = 1.0$ according to EN 1998-4, Chap. 4.4(4) [2].

$S_d(T_{1C})$	$S_d(T_I)$
0.80	2.74

Table 11: Comparison of the design response spectrum

In the calculation of the seismic design shear force F_D (equation 15) only the first convective period was taken into account. The convective and impulsive parts of the sloshing effect were combined by the “square root of the sum of the squares”-rule (SRSS):

$$F_D = \sqrt{(M_C \cdot S_d(T_{1C}))^2 + (M_I \cdot S_d(T_I))^2} \quad (15)$$

For the investigated spherical pressure vessel the seismic design shear force according equation 15 resulted to $F_D = 7240$ [kN]. The comparison with the seismic base shear force $F_b = 5629.8$ [kN] from Chapter 4.2 A shows that the consideration of the sloshing effect provides significantly higher earthquake loads. Thus the seismic design shear force F_D according equation 15 was used in the following stress analysis.

It needs to be mentioned, that in particular in cases where the convective period is significantly longer than the impulsive period, the application of the SRSS-rule may lead to non-conservative results because of the increased probability of the co-occurrence of the maxima of both modes (see Figure 7).

**Figure 7:** Simplified combination of convective and impulsive modes

4.4 Stress analysis

The stress analysis was performed using a finite element model of the spherical pressure vessel (see Figure 8). Thereto the following load cases from case study 4 were applied.

- dead load (empty weight): 815 [t]
- operating load (90% fill height): 2130 [t]
- internal pressure: 1650.0 [kN/m²]
- external pressure: 101.325 [kN/m²]
- seismic design shear force: 7240 [kN]

Figure 8: FE-model of the spherical pressure vessel

The tank was modelled with shell thicknesses of $t_1 = 71.8$ [mm], $t_2 = 73.1$ [mm], $t_3 = 75.9$ [mm] and $t_4 = 74.6$ [mm] (see Chapter 2.1). The vessel stresses were determined at the upper head, at the lower head as well as a two undisturbed areas of the shell. In addition stresses of the connection column-shell were determined in load direction and transverse to the load direction. The results are shown in Table 12 and Table 13.

load cases	dead load	operating load	internal pressure	external pressure	seismic load

5 OVERALL CONCLUSIONS AND FUTURE PROSPECTS

With regard to the design of spherical liquid storage tanks the seismic provisions of Eurocode as well of the ASCE Code can be described as similar. The main differences in the results obtained by the application of both codes result from different input data for seismic actions. Nevertheless there are some differences within the calculation rules for spherical tanks:

- The ASCE Code provides more detailed data on the choice of a response modification factor, tanks are not classified as simple inverted pendulum systems;
- Distinction is made between braced and unbraced supports;
- Eurocode proposes the assumption of an inverted pendulum system for the behavior factor

Both codes however do not provide methods for the calculation and consideration of sloshing effects in spherical tanks. Furthermore some rules which are used in the practice design of spherical tanks need clarification or enhancement:

- Realistic assessment of the behavior factor – in fact a sphere supported by a number of legs behaves like a frame rather than like a inverted pendulum;
- The assessment of a behavior factor shall be detailing rules allowing for the achievement of a dissipative behavior; this applies in particular to the connection of the legs to the shell as well as to the foundations;
- The application of the simplified eccentricity, which was selected to allow for a simple modelling of the spherical vessel, leads to very conservative results. The application of a severe method to systems, which are obviously symmetric, shall be allowed without the formal requirement of a 3D-investigation;
- The need of application of the 100%-x and 30%-y seismic action with regard to rotation-symmetric structures or components shall be verified;
- Conditions for the consideration of sloshing effects shall be defined together with methods for the calculation of these effects and for the combination of the convective and impulsive modes.

6 ACKNOWLEDGEMENT

The investigations were performed within the European research project INDUSE (Structural Safety of Industrial Steel Tanks, Pressure Vessels and Piping Systems Under Seismic Loading) with the financial support by the Research Fund for Coal and Steel (RFCS) which is gratefully acknowledged.

Keywords: Seismic analysis, lead core rubber bearings, non linear viscous dampers
liquefied natural gas, storage tanks

Abstract. *The time domain seismic response of a representative liquefied natural gas (LNG) tank isolated at its base level with rubber bearings is investigated. The problem is solved numerically by means of a detailed finite element model, taking into account fluid-structure interaction effects. Two types of seismic isolation systems are investigated: lead core rubber bearings and linear rubber bearings combined with non linear viscous dampers. Both these systems are characterized by strong energy dissipation mechanisms. The isolation systems are modeled as non-linear spring-dashpot elements with properties calculated on the basis of experimental data obtained from the literature. The seismic excitation considered is an artificial accelerogram compatible with the Eurocode 8 provisions. Results concerning base shear force, sloshing vertical displacement and deflection of the inner steel container are presented. In order to measure the effectiveness of the isolation systems, percentage reductions of the peak response of all mentioned quantities are calculated using the non-isolated tank as reference.*

1 INTRODUCTION

Natural gas is a fossil fuel (90% or more methane) that is usually transported at its gaseous state through ducts from the production site to the place of its consumption. Alternatively it is possible to cool the product down to -170°C so that it condenses to its liquid state. In that way the density of the product increases by approximately 600 times making it possible to ship it in specially designed vessels and store it in thermally insulated tanks. The stored product can then be re-evaporated in appropriate facilities and piped to the consumption. The facilities related to the unloading, storage and re-vaporisation of the Liquefied Natural Gas (LNG) are located in the same site which is usually called an LNG terminal.

LNG terminals are crucial facilities for a natural gas distribution system because, besides providing a backup in natural gas supply, they balance the difference between the demand, which varies constantly, and the supply from the international ducts, which is essentially constant. Because of the importance of the LNG tanks, very severe requirements are imposed concerning the ability of LNG tanks to withstand several postulated accidental actions such as aircraft impact, explosion, fire, major leak and earthquake. Especially for the earthquake action, LNG tanks are expected to sustain a major seismic event, of a return period of over 5000 years, up to 10000 years, without undergoing catastrophic damage, while being able to remain fully operational during a medium seismic event of a return period of around 500 years. Design issues for LNG tanks can be found in several specialized publications, e.g. Bomhard and Stempiniewski [1] and Tajirian [2].

The modern aseismic design of LNG tanks is based on base isolation and energy dissipation techniques. The seismic protection devices usually implemented in LNG tanks are either rubber-type bearings [4,2], such as lead core rubber bearings and high damping rubber bearings, or sliding-type bearings such as the friction pendulum bearings [5,2]. All the above systems feature main functions: detaching the structure from its foundation, ensuring the necessary restoring force and providing energy dissipation. Alternatively, separate energy dissipation devices can be used in combination with linear rubber bearings. The function of these devices is based either on the hysteretic behaviour of a metal or on the viscous behaviour of a fluid.

In this work, two base isolation systems, i.e., lead core rubber bearings [6] and linear rubber bearings combined with non-linear viscous dampers, are investigated numerically using the finite element method (FEM). Rubber bearings are formed by alternating layers of hot vulcanized elastomer and steel shims. The elastomer layers provide the horizontal flexibility required for the decoupling of the horizontal structural motion from the ground motion, while the steel shims ensure adequate vertical stiffness. In the case of lead core rubber bearings absorption of energy is achieved through yielding of a lead prismatic core placed in the center of the bearing. In the case of non-linear viscous dampers the energy is absorbed during the movement of a piston in a chamber filled with viscous fluid. Selective results concerning base shear force, sloshing and deflection of the inner steel container are presented.

2 DESCRIPTION AND MODELING OF LNG TANKS

A LNG storage tank has several functions related to the safe-keeping of its content: a) keeping the content from escaping to the environment, b) preventing the atmospheric air from entering the tank, c) defending the content against the effects of external events including accidents such as earthquake, fire and explosion d) maintaining the appropriate conditions in the tank particularly in respect of temperature and pressure (slightly above atmospheric). To achieve these conditions LNG tanks are usually configured as a double shell, as shown in Fig.

1. Thus, they are constituted of an outer prestressed concrete cylindrical shell which is capped by a spherical reinforced concrete dome and an inner steel cylindrical shell open at the top and closed at the bottom by a steel plate. In general the capacity of LNG tanks ranges between 50000 m^3 and 250000 m^3 with values around 150000 m^3 being the most preferable nowadays. The height to radius (“slenderness”) ratio ranges from around 0.5 to around 1.5. Ratios higher than 1 allow a better use of the available land but their seismic behavior demonstrates obvious disadvantages. This is, however, what makes them good candidates for the implementation of seismic protection systems. Thus, for the “slender” tank studied in this work, the height to radius ratio is about 1.5. The inner tank height is 36.82m and its radius is 23.60m, while the outer tank height is 39.95m, and its inner radius is 24.48m. The maximum height of the liquid volume is 36.39m. The outer shell is of constant thickness 0.8m along its height, while the thickness of the inner shell increases from top to bottom from 8.0 to 25.5mm. The space between the two shells is filled with perlite to insure proper thermal insulation of the content. The outer shell seats directly on a circular foundation slab, while between the bottom of the inner container and the foundation slab there is a layer of foam glass (0.85m) for thermal insulation purposes

Figure 1: General configuration of an LNG tank with double shell

The seismic analysis of the selected LNG tank is performed by means of the ANSYS finite element program [8]. The outer and the inner shell as well as the dome and the foundation slab are modeled by four-noded, 24 DOF quadrilateral shell elements. The foam glass layer is modeled by eight-noded 24 DOF solid elements. The fluid content is modeled by eight-noded 24 DOF fluid elements. The fluid-structure interaction is approximated by prescribing appropriate coupling equations at the nodal points on the fluid-structure interface.

3 PRELIMINARY DESIGN AND MODELING OF THE ISOLATION SYSTEMS

Both seismic isolation systems under consideration are assumed to comprise a number of similar rubber bearings, or bearings combined with dampers, uniformly distributed under the base slab. The total number of required bearings is derived from the assumption that a single bearing supports approximately $10\text{-}12 \text{ m}^2$ of foundation slab, at maximum. Thus, approximately 190 bearings should be used for the tank under consideration. In general dampers must be placed in two directions. The number of dampers can thus be assumed equal to double the number of bearings, though this is not necessary.

Two major assumptions are inherent in the modeling of the seismic isolation systems analyzed in the present study. The first is that the forces applied from the devices to the base slab are uniformly distributed on the entire area of the slab. The second is that the in-plane stiffness of the slab is infinite. Following these assumptions, the vertical stiffness of the bearings is simulated using Winckler type plate elements [8,9], with an appropriate

foundation coefficient, while the horizontal reaction of the bearings and of the dampers is simulated using a single non-linear spring – dashpot element connected to the centre of the slab (dampers are assumed to act only in the direction of the excitation). This model for the base isolation system is illustrated in Figure 2

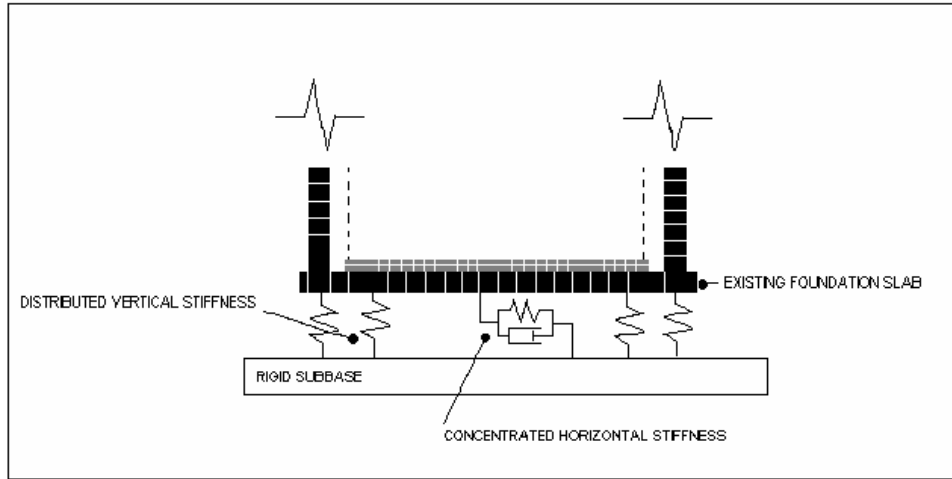

Figure 2: Modeling of the isolation systems

3.1 Vertical stiffness

The Winckler model requires the determination of the elastic foundation stiffness (EFS), which is defined as the pressure required to produce a unit normal deflection of the foundation and is given as

$$EFS = \frac{N * K_v}{A_s} \quad (1)$$

where N is the number of the installed isolators, K_v the vertical stiffness of each isolator and A_s the area of the base slab.

3.2 Horizontal stiffness of lead core rubber bearings

For isolated structures, a fundamental period, i.e. the natural period of the structure moving as an almost rigid body on the isolators, is usually selected in the range of 1.5 to 3 sec. For this study, a fundamental period of 2sec is chosen. Given the total mass M of the structure, the total horizontal stiffness K of an equivalent elastic isolation system, that would lead to a fundamental period of 2 sec, can be approximately evaluated on the assumption of an equivalent single degree of freedom system as

$$K_{eq} = 4 \cdot \pi^2 \cdot M / T^2 \quad (2)$$

The horizontal stiffness of a set of lead core rubber bearings is simulated by a bilinear elastoplastic model, as shown in Figure 4. The assumptions related to the preliminary design of the isolation system are: (a) $\delta_{max}=0.18$ m, (b) $\lambda=K_{el}/K_{pl}=11$, and (c) $\xi=40\%$ which is reasonable for structures isolated with lead core rubber bearings [11].

The assumptions (a) and (b) made for the case of lead core rubber bearings for the determination of the parameters of the applied model, can be also employed in the case of lead core rubber bearings, where the following relationships are also used:

$$K_{eq} \cdot \delta_{\max} = K_{el} \cdot dp + K_{pl} \cdot dl \quad (3a)$$

$$dp + dl = \delta_{\max} \quad (3b)$$

$$4dp K_{el} - K_{pl} \delta_{\max} - dp - 2 \cdot \pi \cdot \xi \cdot K_{eq} \cdot \delta_{\max}^2 = 0 \quad (3c)$$

$$F_y = K_{el} \cdot dp \quad (3d)$$

After computing the various unknown variables appearing in Eqs (3), the bilinear model of Figure (4) is implemented in the finite element model as the force-displacement relationship of a non-linear spring element connected to the centre of the foundation slab.

Figure 3: Energy dissipation loop for the set of lead core rubber bearings used in this work

The parameters corresponding to the model of the particular isolation system used in this work, are $K_{el} = 37.95 \cdot 10^8$ N/m, $K_{pl} = 3.45 \cdot 10^8$ N/m, $f_y = 2.97 \cdot 10^7$ N.

3.3 Horizontal reaction of linear bearings in combination with non linear viscous dampers

In the case of linear bearings the horizontal stiffness of the seismic isolation stiffness that leads to a fundamental period of $T = 2$ sec for a full tank is easily determined from the equation

$$K_{el} = 4\pi^2 (m - m_c) / T^2 \quad (4)$$

where m is the total mass of the structure and m_c is the convective (“sloshing”) mass of the liquid. The convective mass is subtracted from the total mass because it oscillates in a mode with a period much larger than the fundamental period of the isolated structure and, for this reason, is considered uncoupled from the fundamental mode of the isolated structure

In the case of application of non-linear viscous dampers the reaction force of the system is given by

$$F_d = C_{nl} v^{0.15} \quad (5)$$

where v is the velocity of the base and C_{nl} is the constant of the non linear damper system. In this work, the constants of the spring-dashpot element concentrated at the center of the slab are: $K = 5.55 \cdot 10^8$ N/m, $C_{nl} = 5.25 \cdot 10^7$ Nsec/m.

4 NUMERICAL RESULTS AND DISCUSSION

Time domain non-linear dynamic analyses are performed with non-linearities concentrated at the spring simulating the isolation system. The linear acceleration method is used for the integration of the system of equations of motion while the full Newton-Raphson method is

used for the solution of the non-linear systems of equations. An artificial accelerogram compatible with the EC-8 spectrum for soil type C is used as an input excitation.

In the following, selective results of the analyses of both systems investigated in this work are presented (“lrb” stands for lead core rubber bearings and “nlv” stands for non-linear viscous dampers). In Figure 4, the base shear force below the foundation slab versus the corresponding base displacement is plotted for each isolation case. In Figure 5, the total base shear force just above the foundation slab is plotted versus time. For comparison purposes the base shear time history for the non-isolated case (fixed base conditions), is also shown. In Figure 6, time histories of base displacement are plotted for each isolation case. The time history of the horizontal displacement, relative to the base, of the inner shell at the fluid free surface level is plotted versus time in Figure 7. For comparison purposes, the horizontal displacement of the inner shell for non-isolated (fixed base conditions) is also shown. Similarly, in Figure 8 the relative displacement at 2/3 of the height of the inner shell, where the maximum deflection is observed, is illustrated. Finally, in Figure 9 the wave height at the intersection of the fluid free surface and the inner shell is plotted versus time for each isolation case and, for comparison purposes, the fixed base conditions.

From the exhibited results the following conclusions could be made: (a) in terms of base shear force, percentage reduction factors of the order of 70% are calculated for both isolation systems investigated in the present work, (b) maximum stresses in the inner shell are reduced by approximately 60%, in comparison to the non-isolated case where fixed base conditions are considered, and (c) the sloshing height remains practically unchanged in comparison to the non isolated tank.

Abstract. *The present paper focuses on the seismic analysis and design of horizontal-cylindrical and vertical-cylindrical pressure vessels. First, a comparison of the seismic provisions in ASME B&PV code and in EN 13445-3 is conducted for two specific case studies, which constitute typical vessels used in petrochemical facilities. In addition, a numerical investigation is conducted, aimed at proposing a reliable value of the behavior factor for those structures. Those issues are examined numerically, simulating the above pressure vessels with nonlinear finite element models. Finally, a methodology for determining seismic forces due to liquid sloshing horizontal-cylindrical vessels is outlined. The results of the present study can be used towards a safer and more reliable design of industrial pressure vessels under seismic action.*

1 INTRODUCTION

Seismic action constitutes a serious threat for the structural integrity of industrial facilities, such as chemical plants, refineries or power stations. In case of failure of an industrial component, there are severe consequences for the environment, the population, as well as in the economy. In particular, safeguarding the integrity of pressure equipment is of crucial importance for the safety of an industrial facility. The general analysis and design of pressure vessels has been traditionally performed through the application of the European Standard EN 13445-3 [1] or the US code ASME B&PV Code, Section VIII (Div.1 and Div.2) [2], [3]. In those specifications, it is stated that seismic action should be taken into account for structural design, specifying an increase of stress allowables. However, no specific provisions are stated for the seismic analysis of those vessels, especially on how to compute the seismic forces and the corresponding stresses at critical locations.

In the present paper, the seismic design and analysis is conducted for two specific case studies, namely a horizontal-cylindrical and a vertical-cylindrical pressure vessel, which constitute typical vessels used in petrochemical facilities. Following a comparison of the seismic provisions in ASME B&PV code and in EN 13445-3, a numerical investigation is conducted, aimed at proposing a reliable value of the behavior factor for those structures. Those issues are examined numerically, simulating the above pressure vessels with nonlinear finite element models. Finally, a methodology for determining seismic forces due to liquid sloshing for horizontal-cylindrical vessels is outlined.

2 PRESSURE VESSEL DESIGN USING AMERICAN AND EUROPEAN CODES

A comparison of currently used European and American standards for pressure vessels design is being carried out first. The comparison is aimed at:

- outlining the current methodology for pressure vessel design with regard to seismic loading.
- summarizing the provisions of European and American standards for pressure vessel design in terms of earthquake loading.
- pin-pointing important design issues (e.g. missing links, inconsistencies) that require further investigation.

2.1 General

Both the European and the American standard for pressure vessels design, namely EN13445-3 [1], and ASME VIII Div. 1 [2] and Div. 2 [3] respectively, provide only general statements seismic loading design. The same applies for the British and the German national standards, PD5500 [4] and AD Merkblätter [5]. These main points relevant to seismic design included in EN13445-3 [1], and ASME VIII Div. 1 [2] and Div. 2 [3] can be summarized as follows:

1. Earthquake loading shall be considered where required.
2. Earthquake loads may be treated as equivalent static loads.
3. Earthquake and wind loading need not be considered to act simultaneously.
4. The standards refer to regional codes for determining the seismic load actions.
5. Higher values for the allowable stress can be used for exceptional load cases such as an earthquake.

It should be emphasized that those standards are both based on the allowable stress design framework. With respect to the above item No.5, it should be noted that ASME VIII Div. 1 allows for a general 20% increase, while in ASME VIII Div. 2 the compressive stress allowable is increased. However, in general, higher values for the allowable stresses are used in

Div.2. In the European standard an increase in the nominal safety factor for exceptional load cases is allowed but shall not be less than that for the testing load cases, which is 50%. PD5500 states that all allowable tensile stresses and stress intensities (membrane or bending, primary or secondary) may be increased by a factor of 1.2. Limitations on compressive stresses (buckling, attachments, supports and nozzles, and longitudinal compressive general membrane stress) are not hereby relaxed. In AD Merkblätter there exist relevant provisions for higher safety factor when designing for exceptional load cases.

Furthermore, it is important to notice that EN 1998-4 [6], despite its extensive provisions for liquid storage tanks, does not contain any provisions that could be applicable to pressure vessels. The only provisions that might be helpful are the ones in Annex A, section A.7 for determining forces due to liquid sloshing of the container if applicable for the container under consideration, however those provisions are quite incomplete and need significant enhancement to be used for design purposes. In practice EN1998-1 [7] is used for calculating the equivalent static loads similar to the procedure followed for buildings.

Finally, American standard ASCE 7 [8] includes pressure vessels in Chapter 15 for non-building structures. In that Chapter, guidance is given for the selection of seismic factors for calculating the base shear, element design forces. Various types of vessels are addressed, such as elevated vessels on leg or skirt supports, horizontal saddle-supported welded steel vessels and vessels supported on structural towers similar to buildings.

2.2 Description of Case Studies

Two case studies are considered in the present paper; (a) a vertical-cylindrical slender pressure vessel on skirt and (b) a horizontal-cylindrical pressure vessel on saddles. Both pressure vessels are typical vessels for petrochemical facilities.

The vertical-cylindrical pressure vessel is shown in Figure 1 (a). The vessel has an internal diameter of 3.1 m and a total height of 29.2 m. The thickness of the pressure vessel varies from 30 mm at the bottom head and 1st shell course to 28 mm for the rest shell courses and 22 mm for the top head. The skirt has a thickness of 40 mm and a height of 3 m. A corrosion allowance of 3 mm is permitted. The design pressure is 15.7 bar and the operating pressure is 7.3 bar.

The horizontal-cylindrical pressure vessel is shown in Figure 1 (b). The vessel characteristic dimensions are an internal diameter of 1.700 m and thickness of 12 mm (corrosion allowance 6 mm). The height of centerline of the vessel is 1.265 m, the length of the cylindrical part is 6.05 m and the distance between supports 3.63 m. The design and operating pressures are 8.1 and 6.2 bar respectively.

Figure 1 Sketch of (a) vertical pressure vessel on skirt support and (b) horizontal pressure vessel on saddle supports (drawings made by software PV Elite 2010).

2.3 Pressure Vessel Design for Seismic Loads

The design and analysis has been carried out using commercial design software, PV Elite [9]. Initially, in the basic design of the vessel, the thickness of the pressure vessel is determined by the maximum circumferential stress due to internal pressure. For a fair comparison between ASME Section VIII and EN13445 the selection of material, namely P265GH, was based on having similar yield strength.

The seismic input for all the seismic analysis is taken from the provisions of EN 1998-1, paragraph 3.2.2. The basic assumptions are the peak ground acceleration (equal to 0.24g), importance factor equal to 1, damping ratio equal to 5%, and soil type equal to D. Considering type 1 elastic response spectrum and taking the q factor equal to (a) 2 for skirt supported and (b) 3 for horizontal saddle supported welded steel vessel (Table 15.4-2 of ASCE-7-05, page 163), the design response spectrum is shown in the figure below. It is noted that this ASCE-7 standard is the only available source for obtaining a value of q .

Figure 2 Design response spectrum (type 1, soil D) according to EN 1998-1 (5% damping, $S = 1.35$, peak ground acceleration 0.24g), for different values of behavior factor q equal to 1 (elastic design), 2 and 3.

2.3.1. Vertical Pressure Vessel on Skirt Support

Determination of seismic forces

The fundamental period of vibration of vertical pressure vessels on skirts can be calculated using analytical expressions found in [10] for increased level of complexity (with respect to the various courses along the vessel height). The values computed by analytical expressions compare fairly well the numerical solutions calculated by finite element analysis for the vertical pressure vessel. However, it is noted that the fundamental period of the vessel is equal to 0.53 sec, which implies a rather stiff structure, corresponding to the highest part of the design spectrum. Small variations on the value of the fundamental period do not influence the value of the seismic force.

Effects of liquid sloshing

Because of the small diameter of the vessel compared to the height of the vessel as well as because of the presence of equipment inside the vessel, the effects of liquid sloshing can be neglected for this pressure vessel geometry.

Analysis of seismic forces

The general approach for treating seismic loads can be found in many text books [10], [11]. The total base shear V (the total horizontal seismic shear force at the base of the tower) is calculated by multiplying the seismic factor with the total weight of the vessel. An inverse triangular distribution of the seismic loading is assumed across the height of the vessel. A (rather small) portion F_t of the total horizontal seismic force V is applied at the top of the tower, because of the vessel cap. The remainder of the base shear is distributed throughout the length of the tower. The overturning moment is the algebraic sum of the moments of all forces. In the case of a non-uniform pressure vessel varying in diameter, thickness or weight with elevation, the vessel is divided in uniform thickness and diameter sections and the seismic forces are calculated as being proportional to the weight of each section.

The total corroded operating weight of the full vessel is 3130 kN. Considering the spectral value of the seismic factor equal to 0.405 for a fundamental period of vibration of 0.53 sec, for both horizontal directions, the combined seismic factor is : $S_d = \sqrt{S_{dx}^2 + (0.3S_{dy})^2} = 0.423$. Therefore the total base shear force acting V is 1.3 MN. In addition, a horizontal force acting at the top of the vessel F_t is 70.7 kN to account for the vibrating mass of the top spherical cap. The seismic forces are considered for the corroded pressure vessel, which is considered the worst case scenario. The corresponding overturning bending moment is 26.1 MNm.

Calculation of seismic stresses/stress resultants and stress verification

ASME VIII Division 1 only gives general guidelines for the design of vessel supports in Annex G (nonmandatory) and some example calculations in Annex L. Specifically, § G-5 lists the load cases that should be considered for a vertical vessels supported by skirts.

ASME VIII Division 2 recommends two approaches for support design, the first in Part 4 "Design by Rule Requirements" where in §4.15.4 the loads to be considered are listed depending on the position of attachment of the vessel to the skirt. However Part 4 does not provide rules to cover all loading and geometry details. A designer can also select the approach of Part 5 "Design by Analysis Requirements" which refers to numerical analysis.

EN 13445 gives a more detailed description of the loads considered and the stresses developed for vertical pressure vessels on skirt supports in §16.12. As an alternative, "Design by Analysis" Annexes B and C may also be considered. The analysis in EN 13445 (§16.12) deals with the skirt itself and with the critical points where the pressure vessel and skirt join; for three types of skirt geometry. The method described in Annex B deals with various design checks like — Gross Plastic Deformation Design Check (GPD-DC), Progressive Plastic Deformation Design Check (PD-DC) , Instability Design Check (I-DC) , Fatigue Design Check (F-DC) , Static Equilibrium Design Check (SE-DC). The method described in Annex C, referred to as "stress analysis", involves the interpretation of stresses calculated on an elastic basis at any point in a part of a vessel, and then verification of their admissibility by means of appropriate assessment criteria.

2.3.2. Horizontal Pressure Vessel on Saddle Supports

Determination of seismic forces

The calculation of the natural frequency/period based on analytical expressions found in [10], [12] do not compare well with the predictions from finite elements analysis. It should be noted that the value of the natural period is usually rather small and – most likely – falls within the first (linearly increasing) part of the design spectrum. This means that small variations in the calculation of the natural period will result in significant differences in the value of the

seismic coefficient. Because of the uncertainty in calculating the fundamental frequency of the horizontal pressure vessel on saddles supports, in this exercise we consider the maximum acceleration at the plateau of the response spectrum equal to 0.27. Therefore, the seismic force in the longitudinal and the transverse direction of the cylindrical vessel is equal to 48,9 kN for the corroded vessel.

An important note is necessary at this point. The seismic analysis is performed for the corroded state of the vessel. This is the most critical state, however because of the probabilistic nature of earthquake, it is also very conservative that the earthquake would occur at the vessel in the fully corroded state. It is a matter that requires further investigation.

Effects of liquid sloshing

It is important to note that the above calculations are based on the “worst-case scenario” of a full container. If one wishes to consider non-full container, then the accurate determination of seismic forces should account for possible sloshing effects due to liquid free surface. Those effects may be neglected if internal piping or other equipment exist within the vessel, and prevent the development of sloshing motion, as sloshing depressing devices. Otherwise, sloshing effects should be computed.

Sloshing effects can be computed through a methodology similar to the one for vertical cylindrical liquid containers, which consist on determination of sloshing (convective) frequencies and sloshing (convective) masses. Nevertheless, it should be noted that the calculation of sloshing frequencies and masses in horizontal-cylindrical containers is not trivial, due to the lack of closed form analytical solution of the corresponding hydrodynamic problem. A numerical solution of this problem leading to the calculation of sloshing frequencies and masses is offered in [13], [14] and will be outlined in a subsequent section of the paper.

Analysis of seismic forces

The two codes (ASME VIII and EN 13445) do not contain any provisions for the analysis of seismic forces and the calculation of stress resultants in the supports and the seismic stresses in the shell at the vicinity of the supports. The analysis can be conducted in a rather simple way, considering that one saddle is fixed and the other saddle is a sliding support [15], [16]. The seismic action has an overturning effect on the pressure vessel both in longitudinal and transverse direction. This effect, is described by two equivalent static forces which represent the inertia forces due to the seismic action and act at the centerline of the horizontal pressure vessel in the longitudinal and transverse directions.

Calculation of seismic stresses/stress resultants and stress verification

The design of horizontal pressure vessels supported on twin saddles used in BS5500 and ASME Division 2 has been originally developed by Zick [15]. This analysis calculates the developed stresses at critical points based on the reaction force at the saddle. Zick’s methodology was originally proposed for vertical loading of the pressure vessel, but it is straightforward to adjust this methodology to include horizontal (seismic) loading as well. Zick’s analysis is adopted in ASME VIII Div 2. On the other hand, EN13445 adopts a approach, which is based on stress resultants.

2.4 Discussion

The analysis and design of the vertical pressure vessel supported on a skirt and horizontal pressure vessel supported on saddles indicated the following issues:

- Both specifications EN 13445 and ASME VIII do not contain specific provisions for the seismic analysis of pressure vessels and the determination of seismic forces.
- Both specifications EN 13445 and ASME VIII indicate an increase of stress allowables for seismic loading. In EN13445 the safety factor can be increased up to the one used for the testing load cases for both tension and compression. In ASME VIII Div.1 a 20% increase is allowed in tension, while in ASME Div.2 no such increase is specified apart from the compression allowable used in Zick's analysis.
- The main conclusion from the above design and analysis of the two pressure vessels is a lack of guidance for choosing an appropriate value of the behavior factor q . The only source for choosing a value for the behavior factor for pressure vessels is Table 15-4.2 of ASCE 7-05, but these values are not justified. More research work is necessary towards determining appropriate values of the behavior factor q . Such an attempt will be presented in the next section of the present study.
- The calculation of the natural period of the vessel depends on the flexibility of the supports, and may affect significantly the seismic force. This causes some uncertainty in calculating the natural period especially in the horizontal vessel on saddles supports. Therefore, it would be helpful to specify one method to calculate the natural period to be used for design.
- The design procedure in ASME VIII is based on local stresses calculated from Zick's analysis. On the other hand, the design procedure in EN 13445 is based on stress resultants.

3 NUMERICAL MODELING

For analyzing the seismic behavior of the two pressure vessels, discussed above, pushover analysis and incremental dynamic analysis are employed, using a detailed finite element simulation with ABAQUS /Standard 6.10 program.

3.1 Nonlinear Pushover Analysis

A simple and efficient procedure for evaluating the performance of structural systems in strong earthquakes, used extensively for buildings, is the nonlinear static (pushover) analysis [17]. This analysis has been employed to analyze both case studies with an attempt to identify the modes of failure and study the progressive collapse after exceeding the yield limit.

Both vessels have been modeled with general-purpose finite element program ABAQUS /Standard 6.10. The nonlinear modeling accounts for geometric nonlinearities (large displacements and strains), as well as for inelastic material behavior through a von Mises plasticity material model with isotropic hardening, based on the nominal values of P265GH steel. The finite element models of both pressure vessels are given in Figure 3, where general-purpose shell elements S4R were used. An inverted triangular load distribution is applied to the vertical pressure vessel, which is fixed at its base, to represent the seismic inertia forces. For the horizontal pressure vessel a uniform load distribution either in the longitudinal x-direction or the transverse z-direction is applied and a sliding and a fixed support have been used in this model.

Figure 3 Finite element models for the pushover analysis of the (a) vertical pressure vessel with triangular load distribution and (b) horizontal pressure vessel with uniform load distribution in the longitudinal x-direction and (c) transverse z-direction.

The base shear taken from the reaction force at the support, in the direction of the applied loading, is plotted against the displacement at a point on the top of the vessel. A force displacement diagram is produced (pushover curve) showing the capacity of the pressure vessel to withstand a load representative of the seismic action.

For the vertical pressure vessel on skirt the load-displacement pushover curve is given in Figure 4. The seismic load calculated from the response spectra for the equivalent static analysis is equal to 1.3 MN, as stated in the previous section, considering a behavior factor q equal to 2 to account for seismic energy dissipation. The pushover analysis shows that the response of the structure is almost linear up to approximately 2.8 MN and reaches a maximum capacity at 3.8 MN. The corresponding mode of failure is buckling at the first shell course immediately above the skirt, as shown in Figure 5. The effect of internal pressure is insignificant up to the point of maximum capacity of the vessel but is beneficial for post-buckling behavior.

The horizontal pressure vessel is also analyzed using a pushover analysis. The applied load has been calculated from the response spectra approximately equal to 50 kN employing a value of q factor equal to 3. The pushover curves in Figure 6 show a deviation from linearity at approximately 300 kN for the pushover analysis in the longitudinal x-direction and 800 kN in the transverse z-direction. The mode of failure in both directions is buckling at the support plates and the stiffeners, as shown in Figure 7.

The pushover analysis for both pressure vessels shows that for the level of seismic loads used for the design of those vessels (see previous section), the behavior is elastic; in fact, the level of seismic design loads is well below the ultimate capacity level indicated by the pushover curves. For horizontal-cylindrical vessels, the pushover analysis shows a “ductile” behavior, with the vessel capable of sustaining significant deformation in the inelastic range. However, for the case of the vertical-cylindrical vessel, the maximum capacity is reached very

quickly after the first-yield point, whereas the vessel resistance is significantly reduced beyond the maximum loading stage; this indicates that the vessel may not be capable of absorbing significant amount of inelastic energy.

3.2 Incremental Dynamic Analysis

Time history analysis is generally a more complex and computationally expensive method of performing dynamic analysis, but is considered as most realistic for predicting the structural response of a structural system subjected to earthquake loading. In the present study, the vertical-cylindrical vessel is analyzed under incremental dynamic analysis.

The seismic input has been defined in terms of seven artificial accelerograms, corresponding to the design spectrum of EN 1998-1 for 5% damping and peak ground acceleration 0.25g. The nonlinear dynamic analysis was performed considering von Mises plasticity with kinematic hardening to describe inelastic material behavior, and a damping factor of 5%. The seven different artificial accelerograms have been considered at an increasing earthquake level, through a dimensionless “level parameter” λ , and the response of the vessel at critical locations was monitored. An example of input acceleration, and the corresponding top displacement and base shear are given in Figure 8.

Figure 8 Imposed acceleration, predicted top vessel drift displacement and base shear in the direction of the imposed acceleration for one earthquake and level equal to 1.

Based on the previous pushover analysis, presented in the previous section, three regions of the vessel have been identified as critical, namely (a) the skirt, (b) the 1st shell course and (c) the 2nd shell course. The response of the vessel is plotted in terms of the increasing levels

of seismic input is presented in the diagrams of Figure 9, Figure 10 and Figure 11 for the maximum von Mises stress, the maximum equivalent plastic strain and the maximum compressive stress and strain in the longitudinal direction, respectively. Finally, the reaction force (base shear) in terms of increasing level of seismic input is shown in Figure 12.

In order to estimate the q factor, two seismic input levels have to be identified in each of the response curves; (a) the level where transition from linear to non-linear behavior occurs (λ_e) and (b) the level at which a specific failure criterion is satisfied (λ_u). In this study, two different failure criteria, both in terms of strain, are specified as follows:

Failure criterion 1 (Rupture of vessel wall): The equivalent plastic strain reaches a value equal to 0.4%.

Failure criterion 2 (Buckling of vessel wall): The compressive strain in the longitudinal direction reaches a critical value defined by the following formula [18]:

$$\varepsilon_{22,critical} = 0.5 \frac{t}{D} - 0.0025 + 3000 \left(\frac{pD}{Et} \right)^2 \quad (1)$$

Furthermore, the previous pushover analyses have indicated that the critical location of the vessel is at the 1st (bottom) shell course, immediately above the skirt. At this location, the corroded thickness of the pressure vessel is 27 mm, and considering the vessel diameter (3100 mm) and its internal pressure 0.73 MPa, the critical value of compressive strain is equal to 0.24%. Using the above failure criteria, the estimated value of the q factor is given below in Table 1; the values are somewhat lower than the value of 2 suggested by ASCE 7.

	Failure criteria 1	Failure criteria 2
λ_e	1.5	1.5
λ_u	2.5	2.25
q	1.7	1.5

4 HYDRODYNAMIC EFFECTS

Pressure vessels contain liquefied gas, which may interact with the steel container in the course of a strong seismic event and may cause hydrodynamic forces on the vessel wall, which should be taken into account in vessel seismic design.

For full containers, the entire liquid mass follows the motion of the container, and should be added to the container's mass. On the other hand, if one wishes to consider the container not full, then the accurate determination of seismic forces should account for possible sloshing effects due to liquid free surface. Those effects may be neglected if internal piping or other equipment exist within the vessel, which prevent the development of sloshing motion, acting as sloshing depressing devices. Otherwise, sloshing effects should be computed.

Detailed methodologies have been proposed to account for sloshing effects in vertical cylindrical liquid storage containers, which consist on determination of sloshing (convective) frequencies and sloshing (convective) masses. Those methodologies have been adopted by current design standards for liquid storage tanks (e.g. EN 1998-4 and API 650). Those provisions can be applied to vertical pressure vessels (stacks); however, the stacks are very tall, with very high value of aspect ratio H/R , so that sloshing effects are negligible. Consequently, for tall vertical cylindrical vessels, one may neglect sloshing effects and consider the entire liquid mass to vibrate with the flexible container.

On the other hand, in non-full containers of horizontal-cylindrical shape, hydrodynamic effects can be computed through a methodology similar to the one for vertical cylindrical containers. Nevertheless, in liquid containers of horizontal-cylindrical shape, the calculation of sloshing frequencies and masses is not trivial, due to the lack of closed form analytical solution of the corresponding hydrodynamic problem. A numerical solution of this problem leading to the calculation of sloshing frequencies and masses is offered in [13], [14] and is summarized in the following.

Transverse direction

The sloshing frequencies (in dimensionless form $\omega_{nC}^2 R/g$) and the sloshing and impulsive masses M_{nC} , M_I respectively (normalized by the liquid mass M_{nC}/M_L and M_I/M_L) of a horizontal-cylindrical container ($n = 1, 2, 3, \dots$) are shown in Figure 13. It is noticed that only one sloshing mode is necessary for the seismic analysis, and that higher modes can be neglected. The total seismic force can be computed as follows

$$F = M_{nC} S(T_C) + M_I A_g \quad (2)$$

where the impulsive mass contains the mass of the steel, and the impulsive motion is considered as rigid so that the impulsive mass is multiplied by the peak ground acceleration A_g .

Furthermore, $S(T_C)$ is the spectral value corresponding to the sloshing period T_C , which is equal to

$$T_C = \frac{2\pi}{\omega_{1C}} \quad (3)$$

Figure 13 Sloshing frequencies and masses for horizontal cylindrical container under transverse excitation.

Longitudinal direction

The analysis presented in [13], [14] has shown that the dynamic behavior of a horizontal cylindrical container with longitudinal excitation can be approximated with an “equivalent rectangular container”. This equivalent rectangular container has the same free surface dimensions ($2R \times L$) and the same volume as the cylindrical container. This leads to the following expression for the height of the rectangular container:

$$\frac{H_{eq}}{R} = \frac{1}{2} \left[(H/R - 1) + \frac{\sin^{-1}(H/R - 1) + \pi/2}{\sqrt{(H/R)(2 - H/R)}} \right] \quad (4)$$

The seismic force can be computed by equation (2), where only the first mode is considered. Expressions for the sloshing frequencies and masses in the horizontal cylindrical vessels in the longitudinal direction are stated below in a normalized form, based on the corresponding expressions for rectangular containers (e.g. see [19]):

$$\frac{\tilde{\omega}_p^2 R}{g} = \frac{(2p-1)\pi R}{L} \tanh \left[\frac{(2p-1)\pi H_{eq}}{L} \right] \quad p=1,2,3,\dots \quad (5)$$

$$\frac{\tilde{M}_{pc}}{M_L} = \frac{8 \tanh \left[\frac{(2p-1)\pi H_{eq}}{L} \right]}{\left(\frac{H_{eq}}{L} \right) \pi^2 (2p-1)^3}, \quad p=1,2,3,\dots \quad (6)$$

5 CONCLUSIONS

In this paper, the seismic analysis and design of two typical cylindrical steel pressure vessels used in petrochemical facilities is presented (a) a vertical vessel on skirt and (b) a horizontal vessel on saddle supports. First, the provisions of EN 13445-3 and ASME B&PV code, section VIII, for these structures are summarised and important design issues, missing links and inconsistencies are discussed. It is the authors' opinion that more detailed information regarding the estimation of the behavior factor for these structures should be included in the design codes, as well as more detailed guidelines for the determination of the seismic forces. An attempt to estimate the behavior factor for these structures is presented using advanced numerical tools, for pushover analysis and incremental dynamic analysis. The pushover ana-

lysis indicated that the capacity of the pressure vessels is quite higher than the required strength in seismic loading. On the other hand, using incremental dynamic analysis for the vertical-cylindrical pressure vessel, the value of behavior factor calculated is somewhat below the corresponding value suggested by American standard ASCE 7.

Abstract. *Industrial piping can be subjected to severe cyclic loading associated to temporary ground deformations induced by seismic activity. One of the reasons of piping failures under earthquakes can be identified in the accumulation of plastic strains along with biaxial ratcheting of elbows subjected to in-plane cyclic bending. This paper deals with the estimation, using finite element analysis, of the strain evolution in a representative OD 8" X52 grade piping section including an elbow subjected to cyclic in-plane bending and internal pressure. Lemaitre-Chaboche nonlinear kinematic hardening model for plasticity has been employed in FEA to represent the ratcheting phenomenon more efficiently with respect with standard kinematic hardening rule. Numerical results provide an estimation of the plastic strain evolution at critical locations, which may result in crack formation or material damage, and valuable information to address a full future scale testing program that will be undertaken within the INDUSE project*

1 INTRODUCTION

CSM is involved in the European RFCS research program INDUSE [1] which is aimed at developing design guidelines and recommendations, for the seismic analysis and design of industrial equipment steel structures, such as liquid storage tanks, pressure vessels and piping. In this context, CSM is in charge to perform experimental and numerical activities on piping elbows subjected to cyclic in plane bending loading, involving large imposed displacements in the presence of internal pressure.

This paper deals with the estimation, using finite element analysis, of the strain evolution in a representative 8" piping section including an elbow subjected to cyclic in-plane bending and internal pressure. Numerical results provide an estimation of the plastic strain evolution in critical locations, which may result in crack formation or material damage, and valuable information to address the future full-scale testing program.

The behavior of pipelines under large imposed displacements typical of earthquake induced permanent ground deformations (PGD) and other seismic phenomena such as liquefaction and subsidence etc. is recognized to be one of the most important issues in pipeline research. In fact pipelines are frequently required to cross areas where human activity is very intense. Piping components such as bends and elbows connections are recognized to be critical as the deformation tend to concentrate in such locations due to their lower stiffness. It is not surprising that an important experimental and numerical activity has been undertaken in Japan as a consequence of the intense seismic activity. [2] studied the deformation and cracking behavior of induction bends X80 grade subjected to closing bending moment and internal pressure by means of experimental and numerical analysis. Closing and opening bending experiments with internal pressure were conducted by [3] while [4] studied closing bending mode by means of FEA. Ultimate bending capacity of pressurized elbows for the in plane and out of plane bending load has been extensively studied by [5] and [6] by comparing experimental results with analytical formulations and numerical FE predictions.

Several failures have also been recorded for not buried industrial subjected to repetitive alternating loads induced by temporary ground deformations (TGD). In such conditions once again piping connections are subjected to severe deformations as the presence of internal pressure causes biaxial ratcheting. Under such loading conditions trough wall cracking is reported to be one of the main causes of failure as a consequence of the accumulation of plastic strains in the hoop direction at flank position. Recently [7] studied the cyclic behavior of elbows without pressure while [8] investigated also the biaxial ratcheting effect caused internal pressure.

2 FE ANALYSIS

2.1 Geometry overview

The geometry of the piping section analyzed is shown in Figure 1 and its relevant characteristics are reported in Table 1: Relevant characteristics. The elbow element is connected to two straight pipes 1100 mm long and characterized by the same thickness. The length is enough to ensure that no stress interference in the elbow area deriving from the applied loads at the ends occurs. The bending load on pipe elbow has been obtained imposing an alternating displacement along the line connecting the two pipe ends

Figure 1: Overview of the studied geometry.

Outside Diameter (D) (mm)	Wall Thickness (T) (mm)	D/t	R/D	Elbow angle (°)	Straight pipe length (L) (mm)
219.1	8.2	26.7	1.5	90°	1100

Table 1: Relevant characteristics

To investigate the effect of the internal pressure during the cyclic deformation process two levels have been considered: zero pressure and a pressure associated with the 50% of SMYS design factor according to the following relation:

$$p = \frac{k \cdot SMYS \cdot 2t}{D} \quad (1)$$

with:

- D : pipe outer diameter
- t : Pipe wall thickness
- $SMYS$: Specified Minimum Yield Strength
- k : design factor

Internal pressure has been applied first and then maintained constant during the whole cyclic bending. Pressure have also been applied to the pipe ends to account for end cap effect axial induced load. A summary of the load cases analyzed have been is reported in the following Table 2

Load type	Load sequence	Displacement amplitude mm	Internal pressure MPa
Monotonic	opening mode	200mm	0 13.25 (u.f. = 0.5)
	closing mode	200mm	0 13.25 (u.f. = 0.5)
Cyclic	1st cycle opening	+/- 100 mm	0 13.25 (u.f. = 0.5)
	1st cycle closing		0 13.25 (u.f. = 0.5)
	1st cycle closing	+/- 50 mm	0 13.25 (u.f. = 0.5)

Table 2: Summary of analyzed load cases

2.2 Finite element model Description

As shown in Figure 1a representative section of a piping containing an elbow and two sleeve pipes has been modeled by using the commercial software MSC.Marc. To allow for a better estimation of the effect of the accumulated plastic strains on the wall thickness during cycling solid elements have been employed.

Exploiting the planes of symmetry of the geometry and loading conditions the modeling was limited to one fourth of the whole geometry, applying appropriate boundary conditions, thus allowing for more detailed representation of the wall thickness. The mesh adopted and a detail of the welded connection between elbow and pipes are shown Figure 2.

Figure 2: Overview of the mesh employed

The element type used is the three dimensional arbitrary distorted brick which is based in a full integration formulation containing 8 integration points.

To take into account the stresses and strains intensification of, the presence of the welds between the elbow and the straight pipes has been modeled adopting a 1mm increase of thickness in the weld cap. No specific material properties have been assigned to the weld.

In order to reduce calculation resources different element sizes have been used for the mesh the model along length. .

A total amount of 13609 nodes and 9674 elements have been used. More in detail the following subdivision has been implemented:

- 48 elements along elbow axial direction, with thickening close to the weld area;
- 35 elements along straight pipe axial direction, with a refining close to the weld area and a coarsening proceeding towards pipe ends;
- In the circumferential direction a number of 40 elements has been used.
- 4 elements have been used through the wall thickness for the whole elbow length,
- a gradual transition from 4 to 1 element have been adopted trough the wall thickness of straight pipe connected to the elbow;
-

The accuracy of the adopted mesh in describing the elastic plastic behavior of the piping and the concentration of stresses and strains at critical location has been verified trough sensitivity analyses.

To properly account for high deformations that are expected to occur during cyclic process, the following options have been activated for the simulation:

- large displacements;
- large strain additive strain decomposition;
- constant dilatation (incompressible material in plastic range).;

2.3 Material model employed in FEA

The currently available FE software are able to predict with good accuracy the behavior of the material in elastic-plastic regime under monotonic loading, even for a multi-axial stress state. On the other hand, cyclic behavior involves much more complex phenomena which interacts together during loading: ratcheting, hardening or softening, mean stress relaxation etc.

The non linear kinematic hardening, or Lemaitre-Chaboche rule [9] has been adopted to describe of the cyclic material properties.

This model eliminates the typical shortcomings of the standard kinematic hardening rule to describe the cyclic phenomena. Bauschinger effect is better represented as the transition from elastic to plastic regime at strain reversal is smoother, ratcheting, mean strain relaxation, cyclic hardening and softening can also be modeled.

More in detail, this model combines a non linear kinematic rule and an isotropic hardening rule so that Von Mises yield surface undergoes to the following evolution law:

$$F = J_2(\sigma_{ij} - \alpha_{ij}) - R - k = 0, \quad (2)$$

Where:

$$J_2(\sigma_{ij} - \alpha_{ij}) = \sqrt{\frac{3}{2} (\sigma'_{ij} - \alpha'_{ij}) \cdot (\sigma'_{ij} - \alpha'_{ij})} \quad (3)$$

σ_{ij} and α_{ij} are respectively the deviatoric components of the stress tensor and the back-stress tensor, the latter tracking the position of the centre of yield surface. R is a scalar variable which accounts for the isotropic expansion or contraction of the surface during cycling loading and is associated with the accumulated plastic strain ε_e^p and k is the initial elastic limit of the material. The evolution law for α_{ij} is:

$$d\alpha_{ij} = 2/3 \cdot C \cdot d\varepsilon_{ij}^p - \gamma \cdot \alpha_{ij} \cdot d\varepsilon_e^p \quad (4)$$

The previous equation (which was initially proposed by Armstrong-Fredrick) is composed by a linear term which is identical to the Prager rule and expresses a proportionality between σ_{ij} and ε_{ij}^p to which a nonlinear term function of the accumulated plastic strain is superimposed was initially proposed by Armstrong-Fredrick. The evolution law for the R variable is:

$$dR = b \cdot (Q - R) \cdot d\varepsilon_e^p \quad (5)$$

Current version of MSC Marc® only provides the basic Lemaitre-Chaboche rule, while more advanced versions of this model, which adopt a superposition of multiple hardening rules each with a own set of parameters exist. Following values of characteristics parameters, obtained from literature [10] have been adopted.

- $k = 250$ MPa;
- $C = 75000$ MPa;
- $\gamma = 400$.

Within the INDUSE research program base material characterization including true stress true strain monotonic curves as well as cyclic hardening and ratcheting experiments are planned allowing for Lemaitre Chaboche model parameters to be determined.

3 FE ANALYSES RESULTS

3.1 Monotonic behavior

The monotonic behavior of the piping section has been initially analyzed in order to study its basic response to simple bending in opening and closing mode. An imposed displacement of 200 mm has been applied on pipe ends and internal pressure effect have been also considered. The response in terms of applied bending moment at symmetry section of the elbow versus curvature calculated for the whole elbow length is reported in Figure 3, where the elbow curvature is initially shifted to zero for easier reading of results, it is noticeable that the effect of the internal pressure clearly influence the results.

In closing mode after the peak load is reached, there is a slow decrease of the bending moment indicating that buckling takes place. For low D/t values as in the case under study no wrinkling of the compressed side takes place, instead buckling is driven by ovalization which leads to a reduction in the section moment of inertia. Initially the material work hardening counteracts this reduction until a compensation of two competing effect is reached thus resulting in a maximum of the bending moment.

On the contrary in opening mode the moment of inertia is increased due to the orientation along the bending plane of the maximum diameter elbow. Thus work-hardening and ovalization sum their effect. In this case a collapse for high tensile strains is expected.

In closing mode an increase of internal pressure can be considered as beneficial as it increases both the peak moment and the corresponding curvature. In this case the internal pressure counteracts the ovalization of the pipe cross section which is developed along the line connecting the theoretical neutral axis on both flanks of the elbow, and is responsible of the decrease of the moment of inertia of the pipes.

In opening mode the behavior is different: at increasing bending the moment arm reduces so that always more axial tension force is needed to bend the elbow. Such high value of axial force influences the results and decreases the effect of the internal pressure. In fact passing from zero pressure to 13.2 MPa there is only a slight change in peak moment and corresponding curvature. Furthermore the pressure in this case is not beneficial as it contrast the elongation on elbow cross section along the line connecting the extrados and the intrados. In presence of pressure for the opening mode the failure mode is the necking of the intrados pipe wall as shown in Figure 6.

Figure 3: Monotonic bending response in opening and closing mode with and without internal pressure

Opening and closing mode ovalization shape of the elbow cross section are reported in Figure 4 together with tee original un-deformed section. In case of opening the effect of the internal pressure is clearly visible and has the effect to maintain the section more circular. In closing mode, for pressure case, the ovality at peak moment is greater because pressure allows for a larger curvature to be reached.

Errore. L'origine riferimento non è stata trovata. and **Errore. L'origine riferimento non è stata trovata.** show the critical areas, in terms of concentration of strains, of the elbow at peak moment condition with and without pressure, both in closing and opening mode. In case of closing mode the critical position is the flank of the elbow where high strains in circumferential direction are observed. In opening mode if no pressure is applied high tensile strains in axial direction are observed in the intrados of the elbow in the half length section as a result of the combined effect of bending and tensile axial load. With the internal pressure the position of the critical section moves along intrados slightly away from half-length section causing tearing of the pipe wall due to high tensile strains in axial direction.

Figure 4: Cross section shape at half length of the elbow at peak bending moment in closing mode, left and in opening mode right

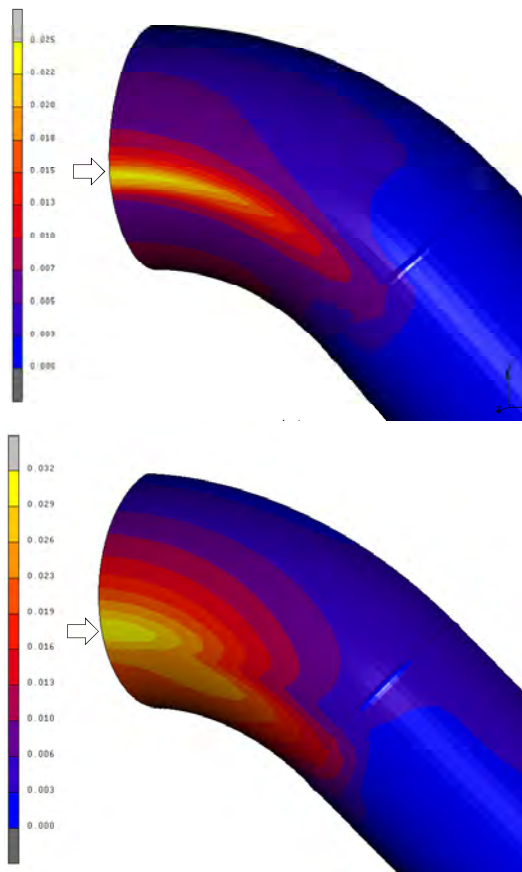

Figure 5: Accumulated equivalent plastic strains at peak closing moment at zero pressure, up and at 13.2MPa down

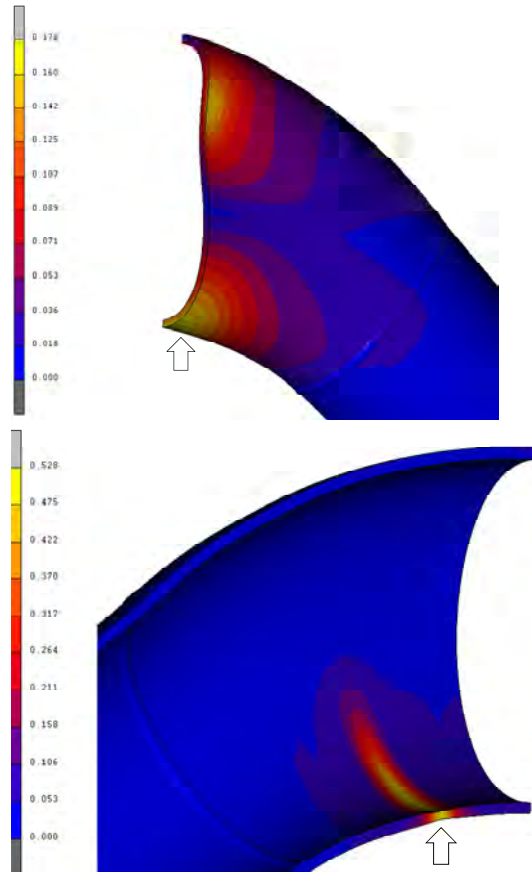

Figure 6: Accumulated equivalent plastic strains at peak opening moment at zero pressure, up and at 13.2MPa down

Figure 9: Cyclic response with zero pressure for cycling starting in closing mode: without pressure, left and for 13.2 MPa right.

3.2 Cyclic behavior

Cyclic behavior has been investigated for different values of internal pressure and imposed displacements of $\pm 100\text{mm}$ at one pipe end, this correspond to impose a curvature of $\pm 0.4\text{m}^{-1}$ a variation of $\pm 12\%$ of the curvature at elbow yielding.

In **Errore. L'origine riferimento non è stata trovata.** the shape of the elbow cross section is reported for the zero pressure case, before cycling and after 20 cycles both for cycling starting in opening or in closing mode. The same result is reported by , for the internal pressure case. In both cases shape differences totally have totally disappeared after 20 cycles.

The shape differs from the basic ones observed in opening and closing modes for monotonic loading, this is particularly true in the case of zero pressure case, where a downward shift of the maximum width amplitude accompanied by a high value of distortion in such locations can be reported. In general greater influence from closing mode is observed, in fact the ovality is always more pronounced along the horizontal DH diameter. This occurrence is present independently of the pressure and can be explained recalling the monotonic behavior for closing and opening bending moment reported in Figure 3: for the particular loading configuration considered, the resistance of the elbow in closing mode is much less if compared with opening mode both in terms of maximum moment than curvature. In other words a 100mm alternating displacement causes the curvature to be far beyond the curvature at peak closing moment but still below the critical curvature for opening moment.

As previously calculated, internal pressure of 13.2 MPa has the effect to introduce a constant hoop stress level of the 50% of SMYS, that in combination with stresses beyond yielding induced in longitudinal direction by bending process results in biaxial ratcheting.

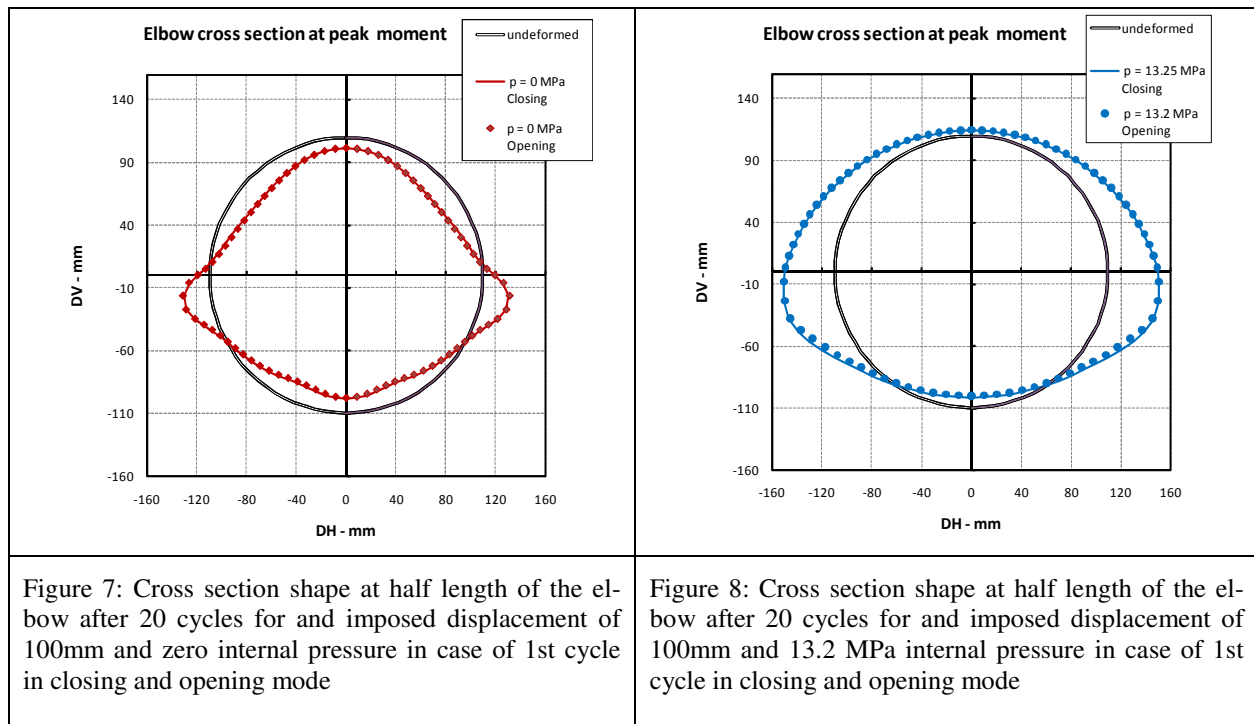

Ratcheting effect is clearly visible in Figure 8 where it is possible to observe that the elbow underwent a marked cycle by cycle increase of perimeter. Furthermore hoop stress reduced the general distortion of the cross section and markedly increase the hoop deformations and consequently the perimeter.

Cyclic moment vs curvature diagrams for bending process starting in closing are reported in , for 1st, 10th and 20th cycle both with zero pressure and for 13MPa of pressure. Very little difference are observed in stress strain distribution and in the moment curvature response if the load cycle starts in opening or closing mode. After a few cycles all differences disappear. and such diagrams are not reported for the opening starting mode.

If no pressure is applied the moment-curvature cycles are stable in position, while with pressure the bending moment is seen to shift in the closing moment part of the diagram. This can be explained by the increase of the moment of inertia of the pipe section caused by ratcheting. From Figure 8 in fact no decrease on DV is observed while DH increase.

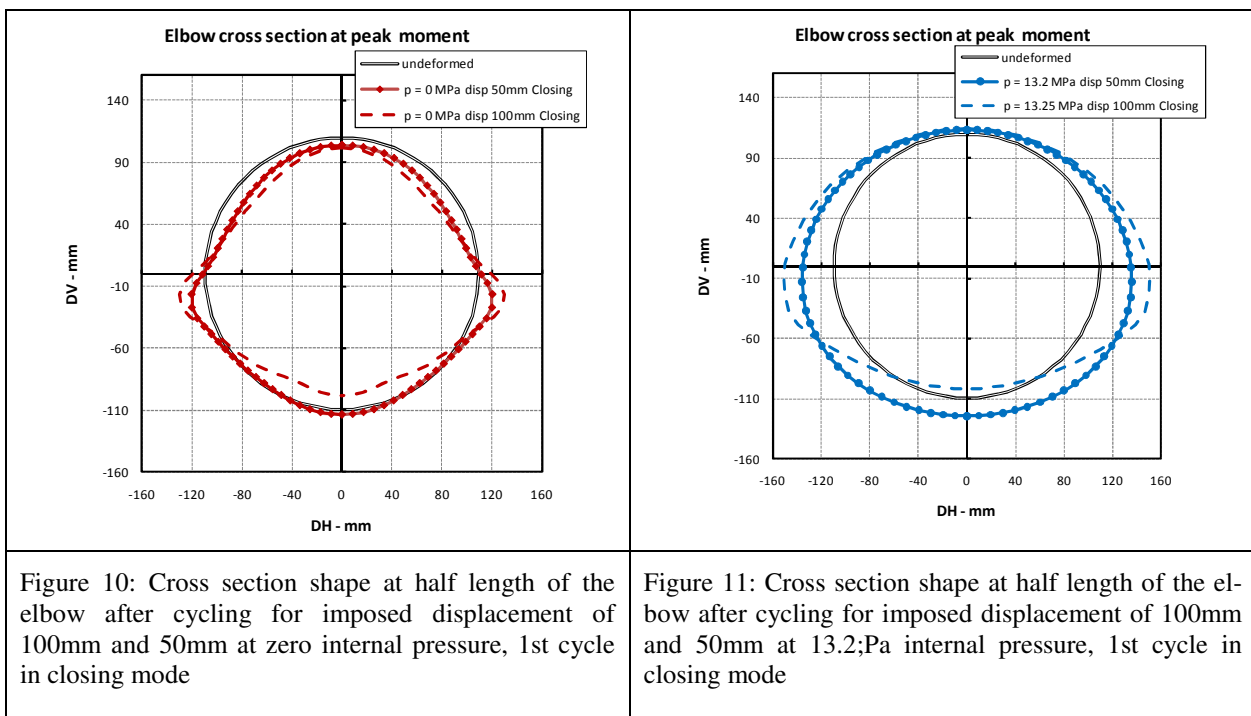

To study the effect of the displacement amplitude on the cyclic bending process, two additional simulations were carried out. For the cyclic loading starting in closing mode, a displacement of $\pm 50\text{mm}$ was imposed at one pipe end, corresponding to a curvature of $\pm 0.2\text{m}^{-1}$ a variation of $\pm 6\%$ of the curvature at elbow yielding.

The simulation was carried out up to 40 cycles twice the number of $\pm 100\text{mm}$ load sequence. Deformed shapes observed at mid length are compared in Figure 10 and Figure 11 with the ones for the larger displacement case. It is possible to notice that independently of the pressure, raising the number of cycles and reducing the amplitude caused an increase of the DV diameter and a reduction on DH with respect to the lower cycles case analyzed. Furthermore in case of pressure DH is larger than un-deformed diameter.

Cyclic moment vs curvature diagrams for bending process starting with closing are reported in , for 1st, 10th and 20th cycles, with zero pressure and in the presence of 13.2MPa of pressure. While in absence of internal pressure the range of bending moment and curvature are stable internal pressure induces a progressive decrease of the average curvature and an increase of the bending moment at peak closing. This last effect can be explained by the increase of moment of inertia associated by DH growth due to pressure. In case of pressure cycles are also seen to translate in the opening part of the diagram indicating that a global straightening has taken place.

Figure 12: Cyclic response for +/50mm displacement amplitude with zero pressure for cycling starting in closing mode: without pressure, left and for 13.2 MPa right.

From Figure 13 and Figure 14 it is possible to observe the deformed shape of the elbow at the end of cycling process starting in closing mode. If no pressure is applied both load sequence lead to similar results; a sharp corner at flank is visible and high tensile hoop plastic strain is present at the external surface, while in the inner surface is compressive. When internal pressure is applied results differ for the two sequences considered: when larger cyclic curvature is imposed local buckling occurs producing an outward bulge. It is interesting to note that such behavior was not observed in monotonic compression even for larger curvatures and is to attribute to the combined effect of the steady internal pressure and accumulation of plastic strain in longitudinal direction.

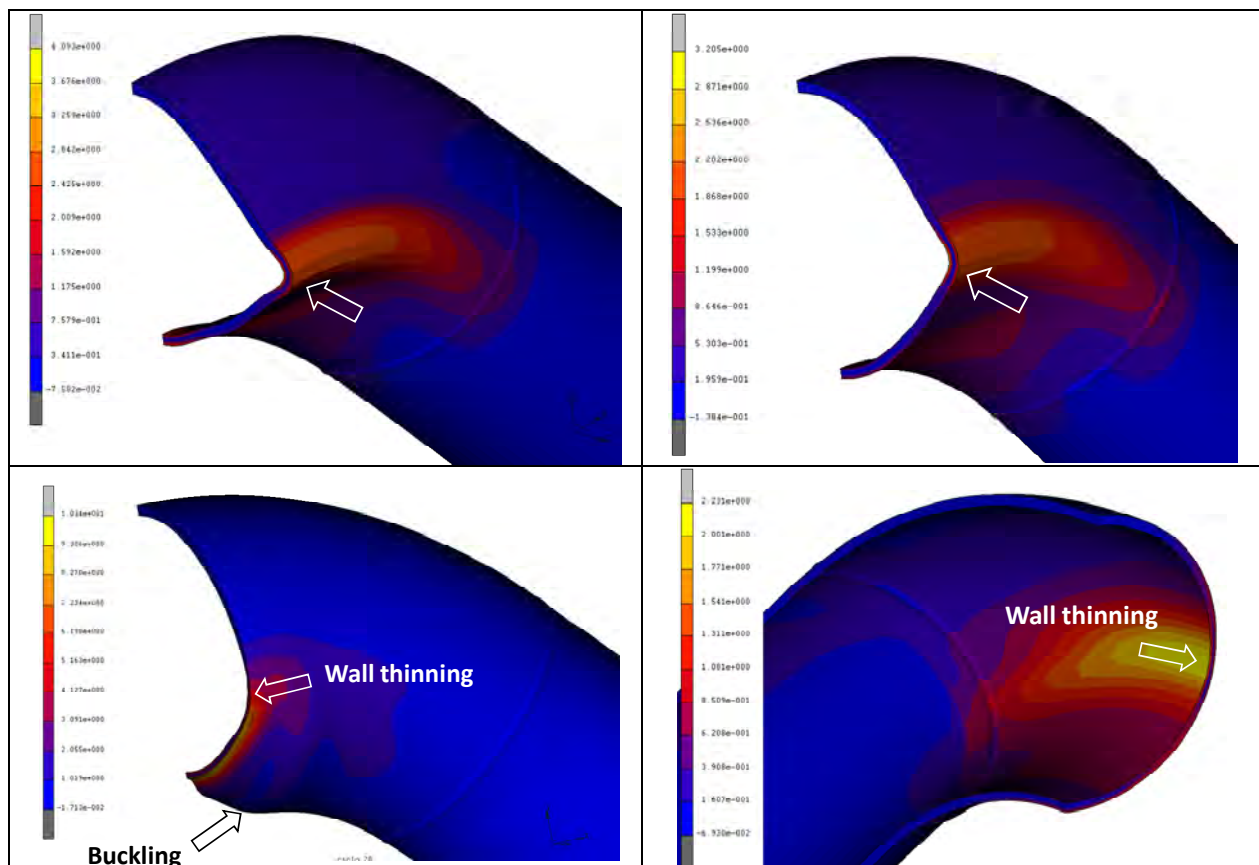

Figure 13: Accumulated equivalent plastic strains after 20 cycles at zero pressure, up and at 13.2MPa down.

Figure 14: Accumulated equivalent plastic strains after 39 cycles at zero pressure, up and at 13.2MPa down

Local strains in such critical locations have been traced along cycles in Figure 15 and Figure 16. Without internal pressure flank position is subjected to tensile hoop strain at the external surface and compressive at internal surface. Alternate tensile strains on pipe surface are to be considered critical because can induce surface cracking that can propagate through the pipe wall. For 20 cycles at larger displacement/curvature sequence tensile and compressive plastic strains have a larger range and tend to stabilize approximately at 15th cycle, while for smaller imposed curvature the range is narrower and an uniform growth is observed. It can be concluded that external surface is critical for the zero pressure case as high tensile plastic strain localize. The reduction of the imposed alternating curvature and the increase in cycle number leads to a slower and continuous increase of the mean values of the hoop strains.

As shown in Figure 16, if pressure is applied in both the internal and external pipe wall sides tensile hoop strains are detectable. For the larger displacements sequence hoop alternating range is very high in the internal surface of the pipe, so that this location has to be considered critical for crack penetration. No stabilization is observed and on both internal and external sides. When alternating displacement amplitude is reduced the rate of hoop strain growth reduces and never reaches the high values of the larger displacements sequence, even for 40 cycles. Hoop strains both in the internal and the external pipe wall are similar in value and trend being internal side slightly more critical.

Figure 15: Hoop plastic strains at most critical locations during cycling without pressure

Figure 16: Hoop plastic strains at most critical locations during cycling with internal pressure

Figure 17 shows a comparison of all cyclic sequences starting in closing mode for pressurized and un-pressurized case based on the wall thickness reduction observed at mid length of the elbow.

If no pressure is applied wall thickness reduction is present in a region between the flank and the intrados. Increase of cycle number and reduction of imposed load amplitude results in a lower accumulation of strains at such locations.

The presence of the internal pressure induces high thickness reduction especially for the area between flank and intrados. Higher thickness reduction accompanied by a more irregular distribution is observed for the larger curvature sequence. In general the extrados does not seem to experience thickness significant variation as in the flank to intrados region. On the other hand, due to production process, wall thickness at the intrados pipe is slightly higher if compared with other parts of the pipe and can be considered less prone to cracking.

Figure 17: Wall thickness distribution along circumference

4 CONCLUSIONS

In this paper in plane bending of a representative 8" OD x 8.2mmWT grade API5L X52 industrial piping section containing a 90° elbow has been studied in this paper by means of finite element analysis, both in monotonic and cyclic conditions. The nonlinear kinematic hardening model (Lemaitre Chaboche) has been employed to take into account for biaxial ratcheting phenomenon.

Monotonic bending simulations show that opening mode show higher resistance capacity in terms of moment and curvature reached before failure, with respect to closing mode.

Cyclical load sequences starting in opening and closing mode have been investigated and after a few cycles the differences between the two load types, totally disappear.

Results show that, for the configuration presented for a symmetric alternating bending load sequence, closing bending deformation mode dominates the cyclic behavior. The most critical position is the elbow flank, both in presence and absence of the internal pressure.

The effect of the internal pressure have been investigated and results show that for monotonic case it can be considered beneficial in closing bending, while slightly negative in opening bending.

If cyclic loading is applied internal pressure induces biaxial ratcheting, causing the growth of large hoop strains that can lead to crack penetration risk. Large wall thinning is also observed.

For the particular range of imposed curvature/displacement considered the effect of reducing the cycles amplitude to one half while increasing up to twice the number of cycles, leads to a lower final accumulation of plastic strains in critical sections.

The performed analysis gave valuable information concerning stress-strain and loads to be addressed to a full scale testing activity that will be conducted within the INDUSE research program.

Abstract. *Within the scope of this study, seismic performance of the St. Mamas Church (Morphy, Cyprus) that dates back to 16th Century was assessed. This structure is one of the finest examples of a three aisled basilica with a central dome that was constructed based on Franco-Byzantine type architectural style. The structure is single-story with a plan area of 19m x 8m and a height of 7.5m that utilizes thick perimeter walls together with a system of cylindrical vaults and a spherical dome. The main construction material used at this structure is local highly sandy calcarenite. With the non-destructive tests carried out, mechanical properties of the material used were identified. Among the non-destructive tests utilized; Rock Hammer, Ultrasonic Pulse Velocity, Infrared Thermography as well as Ground Penetrating Radar Tests can be listed. Based on the detailed information gathered on the structure, its 3D Finite Element model was built. With this model, seismic performance of the church was assessed with the aim of identifying critical parts of this structure. In this paper, our findings are compared with results obtained by other researchers for structures of similar geometry in Europe.*

1 INTRODUCTION

St. Mamas Church of Morphou, Cyprus is a structure that dates back to 16th Century [1]. The era in which St. Mamas Church was constructed corresponds to the latest phase of Lusignan architecture on the island (AC. 1360 to 1581). This phase is characterized by poor building quality, a reflection of impoverished conditions caused by Genoese aggression. Any stimulating contacts with Western Europe appear to have ended and the repertory of construction became almost exclusively insular in this phase [2]. However still, St. Mamas Church is considered to be one of the finest examples of the Franco-Byzantine type architecture on the island [2], which combines features of Byzantine (the dome) and Gothic (the pointed arch) characteristics in it (Figure 1b).

Structurally, St. Mamas Church belongs to the type of three aisled basilica with a dome [2]. It is a single-story structure with a plan area of 19m x 8m and a height of 7.5m that utilizes 1m thick perimeter walls together with a system of cylindrical vaults and a spherical dome (Figure 1). The aisles are separated by two colonnades of five columns. The central aisle is wider than the side aisles and bears a dome on its eastern part. The sanctuary apse is semi-circular and is of the same width as the central aisle. This structure including bearing walls, internal columns as well as the roof system is made up of the local highly sandy, calcarenite stone. In the late 19th Century, a bell tower was added to the structure at the Northeastern corner as well as the porticoes on the north and west sides of the structure [1].

Historical records indicate that St. Mamas Church sustained severe damage from a fire during the Ottoman rule [2]. Some authors suggest that the dome did not exist in the initial construction but was added later by the Byzantine patrons during reconstruction of the collapsed roof after the fire. However the ornamentation of the column capitals at the bays below the dome is different, which is an indication that the position of the dome was decided beforehand during the initial construction of the structure. Today, the roof structure is in a rather deprived state due to high moisture level caused by malfunctioning drainage system. From the search of historical records, no mention of previously sustained earthquake damage could have been found, although [3] indicates that the Morphou region was shook severely by the two rather recent earthquakes of 13 June 1933 and 6 November 1968.

The present St. Mamas Church stands on the ruins of two early Christian basilicas and of a Byzantine church [1]. The non-destructive tests carried out on the structure that will be discussed in detail in the following section as well as the geotechnical and seismic tests carried out at the Church site are supportive of this statement. The geotechnical and seismic tests also indicated that soil condition at the location of interest is of NEHRP D [4] type. Due to the presence of ruins as well as the rather poor soil conditions, cracks are not absent on some of the inside columns supporting the dome structure above.

Within the scope of this study, the material and structural properties of the St. Mamas Church was investigated with the aim of assessing its seismic vulnerability as well as documenting the deterioration of this unique structure. My findings obtained based on non-destructive tests, as well as static and dynamic analyses carried out are discussed in the following sections of this paper.

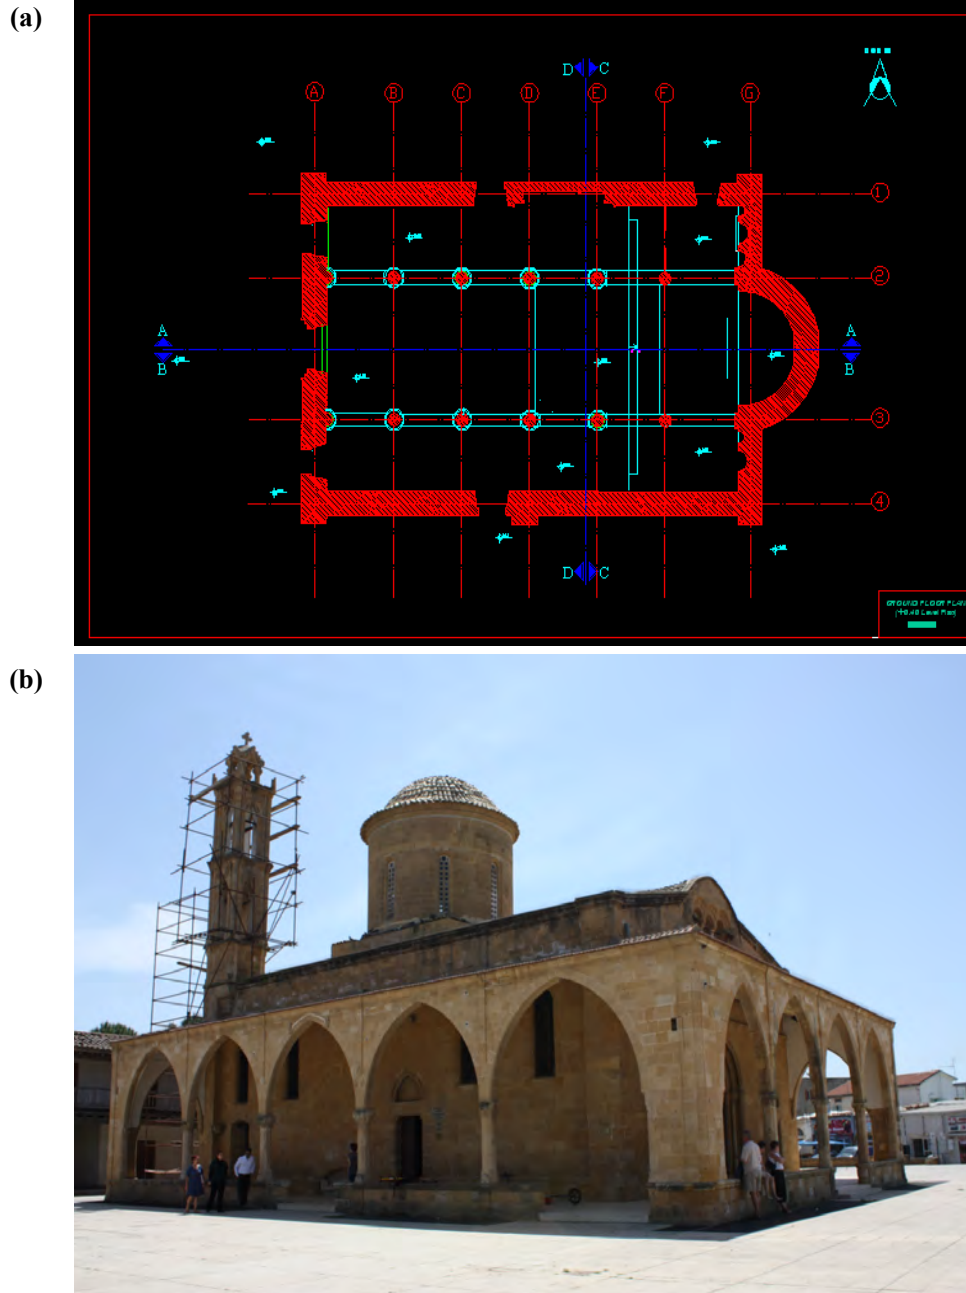

Figure 1: St. Mamas Church (a) plan view (Northern and Western porticoes are not included to the drawing), (b) picture of Northern and Western facades of the structure.

2 NON-DESTRUCTIVE TESTING

In this study, a number of non-destructive tests were employed; including rock hammer, ultrasonic pulse velocity, infrared thermography, ground penetrating radar tests with the aim of assessing the mechanical properties of the calcarenite building material of the structure. Variability of these properties throughout the structure, in addition to the degree of deterioration of the building material in different parts of the structure was studied as well.

Rock hammer test was applied to internal columns and peripheral walls of the structure. The instrument utilized for this purpose was an L-type rebound hammer with an impact energy value of 0.74nm. From each structural element 20 readings were taken, mean and standard deviation values of these readings were later computed to reach conclusions regarding relative strength values of the studied structural elements. Obtained results are summarized in Table 1 for internal columns.

	F2	F3	E2	E3	D2	D3	C2	C3	B2	B3	A2	A3
μ	9.2	13.0	11.2	12.3	10.7	17.6	11.6	14.8	9.2	14.8	8.8	6.8
σ	5.54	7.13	5.74	6.87	5.41	7.68	6.18	6.45	4.23	8.76	4.65	2.57

Table 1: Rock hammer test results (μ : mean, σ : standard deviation) for the interior columns of St. Mamas Church (The reader should refer to Figure 1a for exact locations of these columns).

Results given in Table 1 indicate clearly the considerable variability observed. This was expected as the tested material is natural hence non-uniform. Also due to structure's age, time added additional heterogeneities caused by regional decay of the material under question. The middle columns of axis 3 (F3, E3, D3, C3) have relatively higher mean strength values in comparison to the rest. This can be one reason for observed cracking on columns D2, E2, F2 (supporting the dome above) whereas their mirror image counterparts on axis 3 being crack free. The rock hammer test results obtained for peripheral walls (both interior and exterior readings) have an average value of 11 with a coefficient of variance of 20%, in this respect similar to the results obtained from the interior columns. Regarding peripheral walls, local weaknesses were observed at the sanctuary apse, where axes G and 2 meet as well as G and 3.

Ultrasonic pulse velocity test was applied to internal columns of St. Mamas Church only, at 6 different levels along each element height with an approximate spacing of half a meter. This test was especially applied around observed cracks with the aim of determining whether these cracks are running deep into the element or are just surface cracks. Obtained results are summarized in Table 2. Distribution of mean velocity values (in m/s) are in agreement with above discussed rock hammer test results. With this test, it was also observed that except from cracks of column D2, other reported cracks are probably not running very deep into the column elements. It should be noted that average results obtained for the calcarenite of St. Mamas Church in this study are almost twice as high as the velocity values obtained by [5] for the calcarenite of Saint George of Latins Church at Famagusta, Cyprus.

Table 2: Ultrasonic pulse velocity test results (μ : mean, σ : standard deviation) for the interior columns of St. Mamas Church (The reader should refer to Figure 1a for exact locations of these columns).

The malfunctioning drainage system of St. Mamas Church was already mentioned above. As presence of water accelerates deterioration of masonry and hence weakens it, variations in moisture content were documented by employing the infrared thermography technique. Results obtained indicate positive temperature gradients along the height of internal column elements suggesting moisture intake from the foundation of the structure through capillary action. However the lowest of all temperature measurements taken corresponded to the two side aisle vaults (Figure 2). On these vaults, severe discoloration was observed; the measure-

ments obtained are the proof that these discolorations are not just stains but due to high moisture content of the masonry at these locations.

Figure 2: Pictures depicting two aisle vaults along which the lowest temperatures within the structure were detected.

The main objective of carrying out the ground penetrating radar surveys on the structure floor was to investigate the foundation type of the structure as well as existence of any possible underground structures. For this purpose a ground penetrating radar unit with a 400 MHz antenna was used that is capable of providing moderate resolution up to 5m depth. The structure floor was surveyed regularly in both North-South and West-East directions. Results indicate that the foundation system is pad foundation type with no interconnecting ground beams. Also numerous archeological remains were detected throughout the plan area of the structure. These were found to exist at two main depth levels: (i) 0.75-1.25m and (ii) below 1.5m, probably corresponding to the early Christian and Byzantine church remains mentioned above (Figure 3). Existence of such remains/cavities may give rise to settlement problems; hence the observed difference in behavior of axes 2 and 3 columns can also be attributed to differential settlement caused by these detected remains/cavities. However it should be underlined that remains detected are not localized along axis 2 only but rather distributed throughout the whole floor area.

Above, the variability of properties of structural material utilized at St. Mamas Church was discussed. In order to determine compressive strength and modulus of elasticity parameters corresponding to the structural material under investigation, rock hammer and ultrasonic pulse wave test results had to be calibrated. For this purpose three different sources of information was used: (i) official calibration data of rock hammer employed in this study [6], (ii) mechanical properties measured by [7] for local (not aged though) calcarenite, (iii) mechanical properties measured by [8] for local calcarenite (samples taken from St. Nicholas of Fama-gusta, Cyprus) with lower sand content. Based on this information, a compressive strength value of 10MPa, tensile strength value of 1MPa (assumed to be 1/10 of the compressive strength) and modulus of elasticity value of 2500 MPa was used in the analyses phase of this study. For columns D2, E2, F2, these values were reduced by 20% as a reflection of observed

surface hardness and porosity variations. A density value of 1.7 gr/cm^3 was used throughout the whole structure.

Figure 3: Ground penetrating radar survey result along axis 2. Horizontal axis represents distance along axis 2, vertical axis represents depth. Dotted black lines represent locations of columns B2, C2, D2, E2 from left to right respectively. Black ellipses close identified remains along axis 2.

3 DYNAMIC PROPERTIES

A finite element model of the structure was developed using SAP2000 software. In this model of plan area $19\text{m} \times 8\text{m}$, general height 7.5m that reaches 17m at the dome; all structural elements were represented by shell elements. Thicknesses of these elements vary considerably throughout the structure, i.e. 1m for peripheral walls, 0.55m for internal columns, 0.35m for the vaults and the spherical dome. The dimensions of various structural elements were quite accurately obtained with the help of a laser scanning instrument; except for the vault and dome thicknesses. As accurate dimensioning would require causing damage to the structure, these thicknesses were assumed to be 0.35m in this study. The bell tower and the porticoes were not included into the model of the church explicitly as these parts were added 300 years later to the original church building and hence are structurally independent. The effect of bell tower was taken into account indirectly as additional mass at the Northeastern corner of the structure. All peripheral and internal walls were set fixed at the foundation level in the model.

Figure 4: First three eigen-modes of the structure. First column of figures illustrate the structure as a whole, second column of figures do not include the roof system (hidden from view to illustrate directly the interior elements)

Figures 4a-4f depict the first three eigen-modes of the structure obtained by the linear elastic modal analysis carried out. The translational eigen-mode in the transverse North-South direction (y direction) is the one with the longest eigen-period (Figures 4a-4b, $T=0.21s$). The structural response in this mode displaces the longitudinal walls mainly in an out-of-plane sense, which is achieved by the in-plane deformation of transverse peripheral walls. This first mode mobilizes approximately 59% of the total mass of the structure. This is later followed by a higher translational eigen-mode in the transverse direction that mobilizes only very small portion of the total mass and mainly causes out-of-plane deformation at internal longitudinal walls (Figures 4c-4d, $T=0.20s$). The translational eigen-mode in the longitudinal East-West direction (x direction) is finally reached at the third longest eigen-period (Figures 4e-4f, $T=0.17s$). The structural response in this mode displaces the longitudinal peripheral walls mainly in in-plane manner, with the cylindrical drum at the roof displacing in the East-West direction and the transverse peripheral walls mainly resisting with out-of-plane action. This third mode mobilizes approximately 13% of the total mass of the structure.

4 STATIC ANALYSIS RESULTS

In this part of the study, static behavior of the structure was assessed under three different loading cases. The first of these loading cases is dead load (G) that includes weight of the tile coverings on the roof as well as the weight of the bell tower. From this loading case, live loads were explicitly left out as in the absence of snow loading, which is the case for the structure of interest, the magnitude of live loads were negligible in comparison to dead loads. The second and third loading cases are the earthquake forces E_x and E_y applied in the x and y directions respectively. These earthquake forces include application of an acceleration value of $1g$ ($g=9.81m/s^2$) in the x and y directions. Main objective here was to determine limiting deformations in the two horizontal and vertical directions.

Results are shown in Figures 5a-5f below. Under the effect of dead load only, maximum vertical deformation of 3mm was observed at the spherical dome above the drum; whereas level of vertical deformation at the columns below supporting the drum was 2mm (Figure 5a-5b). The structure is considerably more flexible in the transverse direction than the longitudinal direction. Results also indicate that the internal colonnades are so flexible in both longitudinal and transverse directions that they contribute very little to the resistance in both of these directions. Under E_x , maximum deformation along the longitudinal axis of the structure at the dome level was determined to be 12mm whereas under E_y maximum deformation along the transverse axis of the structure at the dome level was almost twice as much approximately

22mm. Under both E_x and E_y , the deformations at the roof level below the drum were considerably lower than the aforementioned maximums, in the range of 3-4mm for E_x and 8-10mm for E_y . Under E_x , it is mainly the longitudinal peripheral walls resisting with in-plane action. Whereas under E_y , transverse peripheral walls resist with in-plane action and the longitudinal peripheral walls resist with out-of-plane action.

Figure 5: Deformations under (a)-(b) dead load G and (c)-(d) Earthquake load E_x . First column of figures illustrate the structure as a whole, second column of figures do not include the roof system (hidden from view to illustrate directly the deformation of interior elements)

Figure 5 cont.: Deformations under (e)-(f) Earthquake load E_y . Figure on the left illustrate the structure as a whole, figure on the right do not include the roof system (hidden from view to illustrate directly the deformation of interior elements)

5 DYNAMIC ANALYSIS RESULTS

In this final phase of the study, dynamic behavior of the structure was assessed by carrying out a response spectrum analysis. According to the findings of [9], the peak ground acceleration value at the site of interest is in the range of 0.2-0.3g corresponding to a return period of 475 years. As mentioned in the introduction part of this manuscript, detailed seismological and geotechnical tests were carried out at the site of St. Mamas Church within the scope of this study. The geotechnical study included, carrying out a standard penetration test up to a depth of 30m and classification of formations based on samples taken during the test. With the seismological tests, a 2D S- and P-wave velocity profile along an axis of 50 m parallel to the structure was developed. Based on the results of both tests, soil condition at the site of interest was classified as NEHRP D, or class C of Eurocode 8. By utilizing the base response spectrum function of Eurocode 8 together with the peak ground acceleration value and the aforementioned soil type, together with the building importance factor of 1.3, the site specific response spectrum for the St. Mamas Church was developed. In addition to the horizontal loading (E_x when applied in the longitudinal direction, E_y when applied in the transverse direction) described by the response spectrum, dead load was applied to the structure with the following combinations: (1) $G+1.4E_x$, (2) $G+1.4E_y$, (3) $G+0.9E_x+0.3E_y$, (4) $G+0.9E_y+0.3E_x$. Obtained normal and shear stress distributions were investigated in detail and critical structural elements were identified.

In Figure 6, distribution of stresses is shown for peripheral walls, internal colonnades, and the roof structure. Under the average strength values given in section 2 of this manuscript, the structure is not expected to sustain any damage due to seismic loading. However as the non-destructive testing results illustrate, mechanical properties of the masonry vary considerably throughout the structure. If the lower limit strength values are considered rather than the average values obtained, several structural elements appear to be critical throughout the structure. The lower limit strength values that were employed in this study were 3MPa for compressive strength and 0.3 MPa for tensile strength. For columns D2, E2 and F2, 20% lower strength values were used to reflect non-destructive test results. The critical elements identified are the internal columns carrying the drum and the dome of the structure (D2, E2, F2, F3, E3, and F3 of Figure 1a), vicinity of openings (doors, windows, sarcophagus of St. Mamas) on the pe-

ripheral walls, base of peripheral walls and the drum-lower roof intersections of the roof structure. Based on the aforementioned lower limit strength values, masonry over limit factors (ratio of observed stress level to assumed lower bound strength value) were also computed for these critical regions. These masonry over limit factors (R_{up}) are all indicated on Figure 6 as well.

Three aisled basilicas are abundant on the island of Cyprus, as well as neighboring regions such as Balkans. One of the main aims of this study was to compare results of this study with other previously carried out studies on dynamic behavior of basilicas of similar architecture to identify commonalities as a forward attempt towards developing a vulnerability relation for this type of structures that can be utilized in aiding separation of high seismic risk structures from the rest.

In [10], behavior of three different basilicas was studied. Two of these structures had similar plan areas to that of St. Mamas Church, whereas the third structure was considerably larger. The main difference between the structures of [10] and the St. Mamas Church is that St. Mamas Church is considerably taller with a roof structure that is entirely made up of masonry which reaches a height of 17m at the semi-hemispherical dome above the drum. Whereas two basilicas of [10] (with the similar plan area as St. Mamas Church), have wooden roofs at a height of only approximately 7m. This difference between the roof structures appears to be the main reason behind different dynamic behaviors. As a result, St. Mamas Church has longer dynamic periods, as well as eigen-modes dominated by out-of-plane deformation of internal colonnades carrying the drum and the dome of the roof structure. Similarly, internal columns reach critical stress values under seismic loading whereas such behavior was not observed in the study of [10].

In [11-13], the plan area of the structure studied is very similar to that of the St. Mamas Church as well; however it only has a height of 5m with a wooden roof. Expectedly, the eigen-modes are not dominated by the out-of-plane deformation of internal colonnades supporting the roof structure. However results indicate damage incurred by internal columns due to excessive tensile stress once the peak ground acceleration level of 0.25g was surpassed (with tensile strength level corresponding to the lower bound strength level employed in this study).

In [14], structures with similar architecture were investigated both analytically and experimentally. As the plan area of the structure under consideration of [14] is much smaller than that of St. Mamas Church, direct one to one comparisons will not be made here with the findings of [14]. However in [14], it is clearly indicated that structures having a masonry roof system including a central drum and dome will sustain damage first at this critical region, in line with the observations made regarding St. Mamas Church.

Figure 6: Stress distributions under (a)-(c) combination 3 $G+0.9E_x+0.3E_y$ and (d)-(i) combination 4 $G+0.9E_y+0.3E_x$. As the structure is weaker in the transverse direction, the combination 4 yielded more critical results. Most critical regions are marked with the white ellipses, for these regions masonry over limit factors (R_{up} , ratio of observed stress to assumed lower bound strength level) are given as well.

6 CONCLUSIONS

Within the scope of this study, both experimental and analytical work had been carried out on St. Mamas Church of Morphou, Cyprus with the main objective of assessing its dynamic behavior. The following conclusions were reached:

- The non-destructive tests carried out at the structure indicated that mechanical properties of the masonry used vary considerably with coefficient of variation values computed reaching up to 60%. Based on the test results, the average compressive strength value of 10 MPa, modulus of elasticity value of 2500 MPa and tensile strength of 1 MPa were assigned to the structure. However in order to take into account the considerable variability of mechanical properties of masonry, lower bound strength values of 3 MPa for compressive strength and 0.3 MPa for tensile strength were also used.
- Dynamic analysis results indicate that as the internal colonnades of the structure are quite flexible, the structure is weaker in the transverse direction than longitudinal direction. Under the seismic loading with a return period of 475 years, the most critical elements of the structure were identified as the internal columns supporting the drum and dome of the roof system. The stress level at these columns is expected to reach twice the lower limit strength values determined. The second level critical localities are surroundings of openings such as windows, doors, sarcophagus of St. Mamas on the North façade of the church and the drum-lower roof connections of the roof system. Results indicate clearly that presence of the drum and the dome has governing effect on the dynamic behavior of the overall structure.
- Dynamic analysis results indicate the vulnerability of internal columns, hence observed cracking on these columns can not be associated with a differential settlement problem alone.
- Structures with the same architectural form as that of St. Mamas Church are abundant in Europe. Hence several studies assessing dynamic behavior of similar structures can be

found in the literature. Comparison of results indicate that grouping these structures according to floor area (geometry does not vary considerably), roofing structure, material properties and developing vulnerability relations for each group would be a valuable contribution towards preservation of such monuments; as such relations would enable the preliminary categorization of structures according to their seismic risk level. With this statement of course, the intention is not to undervalue the effect of uniqueness of each structure and the effect of considerable variability of building material properties on their dynamic behaviors. However with the aim of approaching the problem of preservation from a more macro perspective, existence of such vulnerability relations would prove to be useful in preliminary categorization of these structures regarding their seismic riskiness.

Keywords: rocking, overturning, analytical dynamics, earthquake engineering, damping

Abstract. *Numerous structures exhibit rocking behavior during earthquakes and there is a continuing need to retrofit these structures to prevent collapse. The behavior of stand-alone rocking structures has been thoroughly investigated, but there are relatively few theoretical studies on the response of retrofitted rocking structures. In practice, despite the benefits of allowing rocking motion, rocking behavior is typically prevented instead of optimized. This paper characterizes the fundamental behavior of damped rocking motion through analytical modeling. A single rocking block analytical model is utilized to determine the optimal viscous damping characteristics which exploit the beneficial aspects of rocking motion while dissipating energy and preventing overturning collapse. To clarify the benefits of damping, overturning envelopes for the damped rocking block are presented and compared with the pertinent envelopes of the free rocking block. Finally, the same principles of controlling rocking behavior with damping are extended to a particular class of rocking problems, the dynamics of masonry arches. A pilot application of the proposed approach to masonry arches is presented.*

1 INTRODUCTION

Numerous heritage structures exhibit rocking behaviour when loaded dynamically, including monuments, towers, bridge piers, sculptures, etc. Recent earthquakes (e.g. Chile and Italy) have increased world-wide incentive to retrofit such structures to avoid collapse during dynamic loading.

The rocking dynamical response is highly nonlinear and extremely complex; the block displays numerous ways to overturn [1, 2] with respect to the number of the preceding impacts, and its response is highly sensitive on the characteristics of the dynamic loading. Most studies assume an idealized ground excitation in the form of a primary impulse [3] or harmonic loading [1]. The significant amount of research assuming harmonic loading originates from the concept that a constant frequency excitation can cause resonance. However, one main advantage of the rocking system is that constant frequency rocking resonance is impossible because the natural frequency changes with rocking amplitude. Further, harmonic ground motions which could cause rocking resonance would have to have a precise time-varying frequency, and are thus extremely unlikely [4]. Rocking behaviour is mostly affected by the distinct time-dependent characteristics of the ground excitation that are less relevant to the response of elastically deformable structures.

In contrast to the significant amount of research on the response of stand-alone rocking structures, there are only a handful of theoretical studies on the response of retrofitted rocking structures [5, 6]. In practice, rocking behaviour is typically prevented instead of limited or confined. Prevention is achieved by tying structures down, reinforcing them internally by drilling through or externally by wrapping with Fibre-Reinforce Polymers (FRP) [7].

While these methods can be effective, they can over-stiffen structures, add stress, and be destructive. More particular, Makris & Zhang [5] showed that the response of the anchored rocking block can be worse of that of the pertinent stand-alone rocking block. In addition, when earthquake loading is rare and relatively minimal, as in the UK, extensive reinforcing of a vast number of structures may be economically infeasible and too invasive for heritage structures. Hence, application of intelligent less invasive intervention methods is sought, through confinement of the rocking response instead of prevention. This research aims to lay the foundation for the development of a new class of retrofit solutions which exploit damping systems.

2 DAMPED ROCKING MOTION

Motivated by the inverse effects of adding strength to the rocking block, this research takes an alternative approach and investigates the benefits of additional damping. Consider first the free standing rocking block of Figure 1 (without dampers) subjected to a pulse-type base excitation with acceleration amplitude a_g and frequency ω_g . Assuming the coefficient of friction is high enough to prevent sliding, the rocking motion initiates when the ground acceleration \ddot{u}_g exceeds the critical value: $\ddot{u}_g \geq a_{g, \min} = g \tan \alpha$ where α is the angle of slenderness and g the gravity acceleration.

The moment equilibrium, during rocking, with respect to the pivot points O (or O' accordingly in Figure 1) gives:

$$I_0 \ddot{\theta} + mgR \sin[\alpha \operatorname{sgn}(\theta) - \theta] = -m\ddot{u}_g R \cos[\alpha \operatorname{sgn}(\theta) - \theta] \quad (1)$$

where θ is the rocking rotation, I_0 the moment of inertia with respect to the pivot point, m the mass of the block, R the half-diagonal and $\operatorname{sgn}()$ the standard sign function. The slenderness angle is defined by $\tan \alpha = b/h$, where $2b$ is the width and $2h$ the height of the block.

To complete the description of the problem, the equation of motion is complemented with a coefficient of restitution η , defined as the ratio of the pre and post impact velocities, which ranges between 0 (for perfectly plastic) and 1 (for perfectly elastic impact):

$$\dot{\theta}^+ = \eta \dot{\theta}^- \quad (2)$$

Figure 1: The rocking block retrofitted with viscous dampers at its edges.

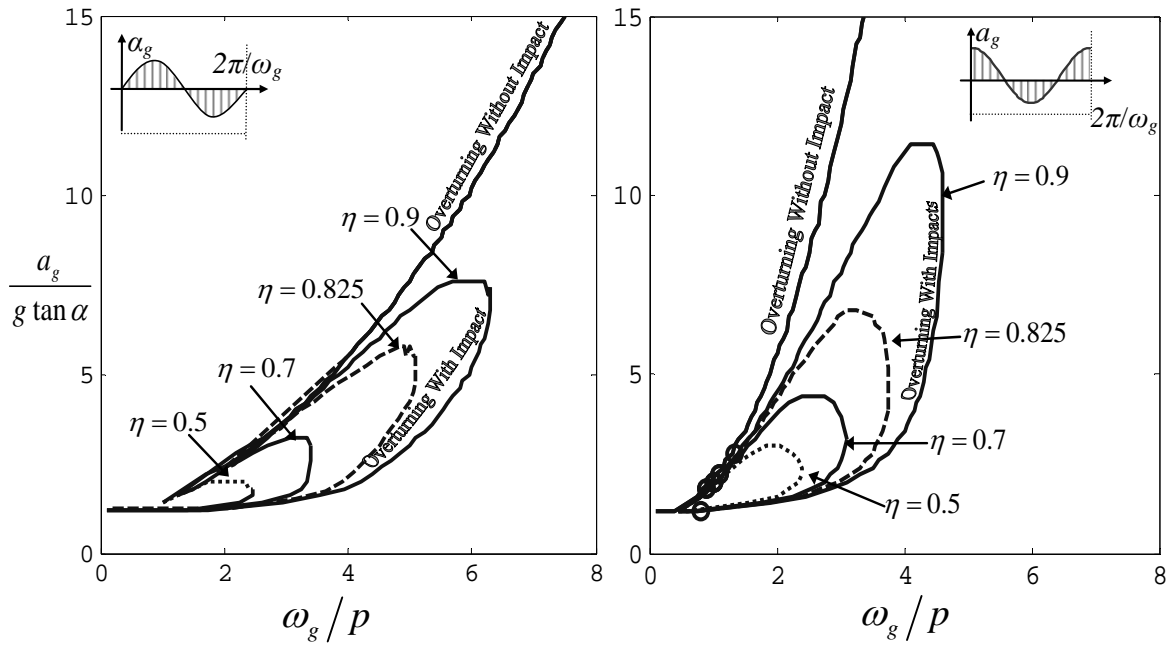

Figure 2: Overturning envelopes of the stand-alone rocking block for different coefficients of restitution η .

The present description of rocking (Equations 1 and 2), is valid under the assumption that the block is slender enough to prevent other impact behaviors to arise such as bouncing.

Figure 2 presents the overturning envelopes of the rocking block, subjected to simple trigonometric pulses, for different coefficients of restitution η . As expected, the coefficient of restitution affects the overturning of the rocking block only when impacts precede overturning. In other words, the energy is damped out of the stand-alone rigid block only during impacts. This poses a theoretical limit to reducing rocking behaviour by increasing energy dissipation at impact, as immediate overturning is unaffected.

2.1 Bilateral Viscous Dampers

As a first approach, consider a rigid block retrofitted with bilateral viscous dampers as in Figure 1. The force P of a viscous linear damper is given by:

$$P = C\dot{v} \quad (3)$$

where \dot{v} is the relative velocity between the ends of the damper and C the damping constant.

Moment equilibrium of the retrofitted block (Figure 1) during rocking gives:

$$I_0\ddot{\theta} + mgR \sin[\alpha \operatorname{sgn}(\theta) - \theta] + P \cdot r = -m\ddot{u}_g R \cos[\alpha \operatorname{sgn}(\theta) - \theta] \quad (4)$$

where r is the lever of the damping force P .

Equation (4) can be written using Eq.(3) and geometric properties:

$$\ddot{\theta} = -p^2 \left\{ \sin[\alpha \operatorname{sgn}(\theta) - \theta] + \frac{\ddot{u}_g}{g} \cos[\alpha \operatorname{sgn}(\theta) - \theta] \right\} - p\gamma(1 + \cos \theta)\dot{\theta} \quad (5)$$

where $p = \sqrt{3g/4R}$ is the frequency parameter of the block, and $\gamma \doteq \frac{3}{2} \frac{C}{mp} \sin^2 \alpha$ is a dimensionless parameter that relates the damping constant C to the mass m , slenderness α and frequency p .

2.2 Unilateral Viscous Dampers

Re-centering, i.e. limiting residual displacements despite large displacement during seismic loading, is an advantage of rocking motion. However, collapse must be prevented. Thus, to limit collapse while encouraging re-centering, unilateral viscous dampers, which are activated only during uplift, are also considered. The behaviour of such unilateral viscous dampers can be described with the help of an ad-hoc function $S(\theta, \dot{\theta})$ defined as follows:

$$S(\theta, \dot{\theta}) = \frac{1}{2} [\operatorname{sgn}(\theta \cdot \dot{\theta}) + 1] = \begin{cases} 1 & \text{when uplifting} \\ 0 & \text{when restoring} \end{cases} \quad (6)$$

The equation of motion for the linear unilateral viscous damper is:

$$\ddot{\theta} = -p^2 \left\{ \sin[\alpha \operatorname{sgn}(\theta) - \theta] + \frac{\ddot{u}_g}{g} \cos[\alpha \operatorname{sgn}(\theta) - \theta] \right\} - p\gamma(1 + \cos \theta) S(\theta, \dot{\theta}) \dot{\theta} \quad (7)$$

2.3 Response of the damped rocking block to pulse-type excitations

Figure 3 presents the overturning envelopes for the bilateral damping, and Figure 4 presents the overturning envelopes for the equivalent unilateral (same γ parameter) dampers. Both figures also contain the undamped (stand-alone) rocking block envelopes. The block is excited with simple trigonometric pulses and the response is calculated by numerically solving the nonlinear differential equations of motion (Eq. 5 and 7 respectively) assuming a constant coefficient of restitution η . The behaviour is described in the dimensionless terms:

$$\frac{a_g}{g \tan \alpha}, \frac{\omega_g}{p}, \eta, \gamma = \frac{3}{2} \frac{C}{mp} \sin^2 \alpha \quad (8)$$

Similarly to the behavior of the stand-alone rocking block [3], the damped rocking block displays two different modes of overturning under a sine and a cosine pulse-excitation (e.g. Figure 3): immediate overturning without impact and overturning with at least one impact (one in the case of a sine pulse excitation and up to 2 in the case of a cosine pulse excitation). In general as expected, the overturning-with-impact mode is more critical since it appears for lower excitation intensities. However, unlike the case of additional strength [5], the higher the additional damping (parameter γ), the more the overturning envelopes shrink, regardless of the excitation type (sine or cosine).

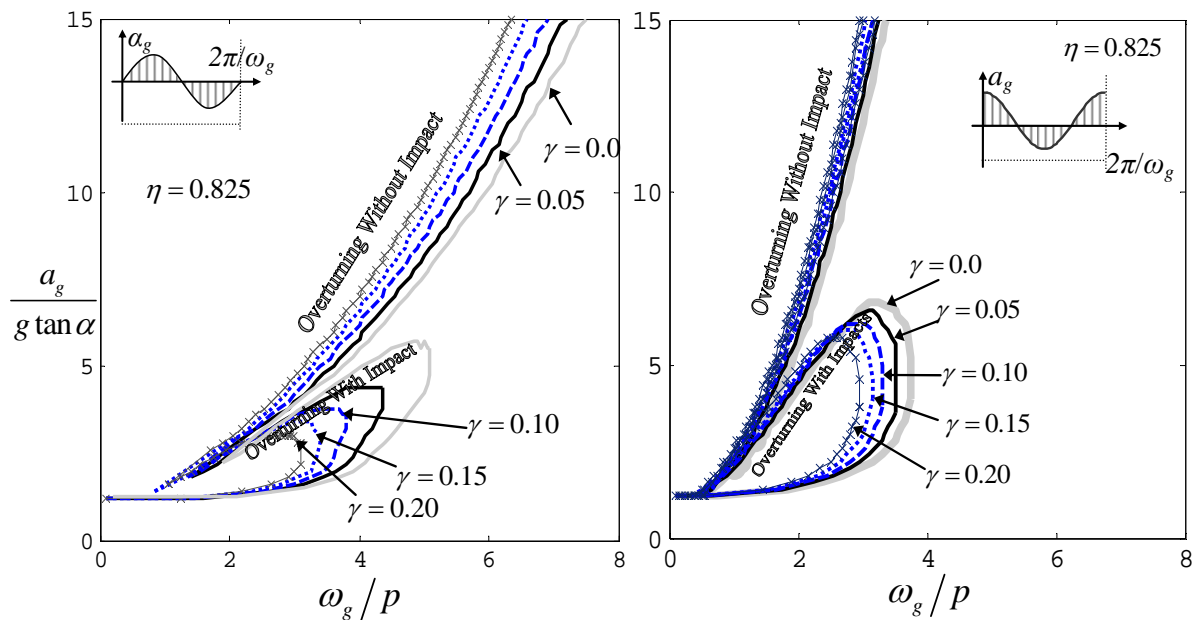

Figure 3: Overturning envelopes for the rocking block with bilateral viscous dampers. Comparison with the stand-alone rocking block (thick grey line).

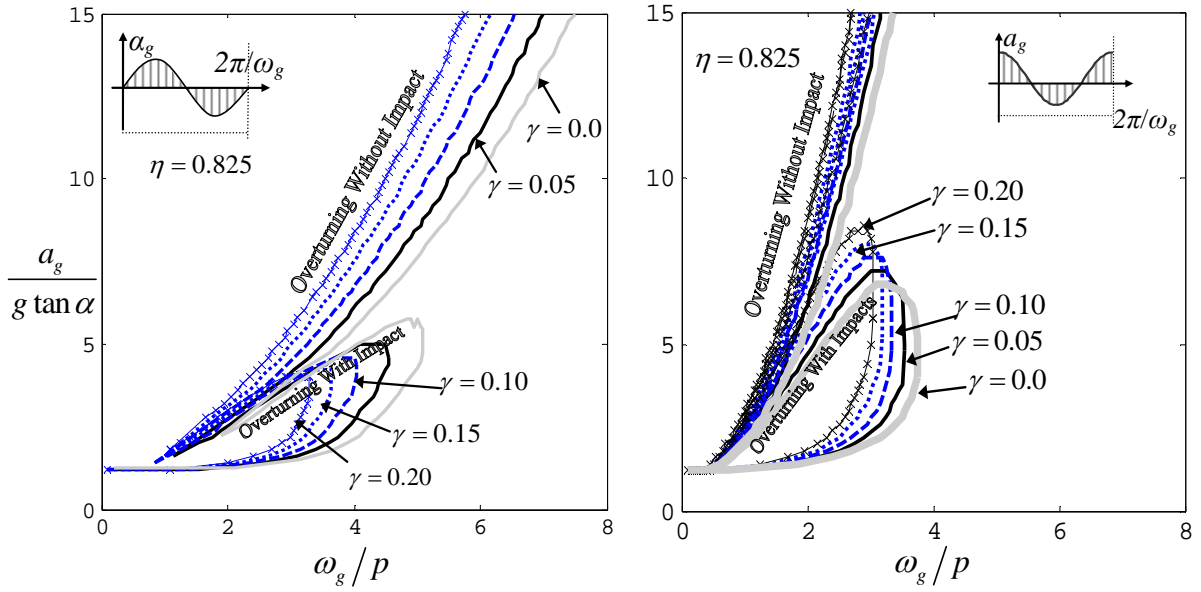

Figure 4: Overturning envelopes for the rocking block with unilateral viscous dampers. Comparison with the stand-alone rocking block (thick grey line).

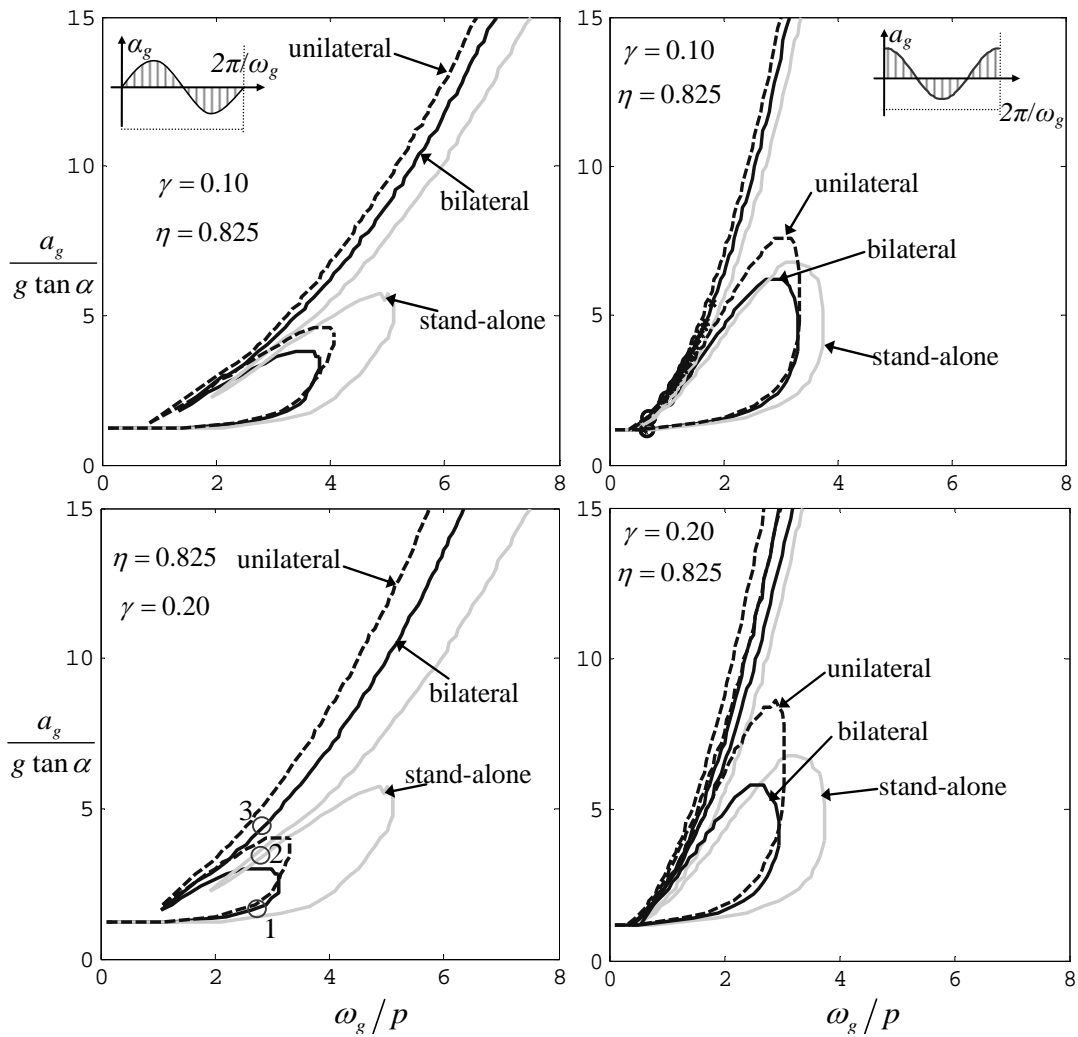

Figure 5: Comparison of overturning envelopes for the rocking block retrofitted with bilateral and unilateral viscous dampers.

In Figure 5, the overturning envelopes for bilateral and unilateral damping are directly compared. Both unilateral and bilateral dampers have a similar beneficial effect for overturning without impact. However, there is a brief change in velocity prior to overturning during which the block tries to recover. Bilateral dampers limit this recovery, while unilateral dampers allow it, making them slightly more effective.

For overturning with impact, both damping options cause a similar beneficial shift in the minimum impulses which cause overturning (the lower limit of the overturning area shifts up and left). However, bilateral dampers provide a larger decrease of the total overturning area through a larger downward shift in the upper limit of the overturning region. While may be beneficial, it should be noted that the intermediate safety area, between the two overturning basins, is a result of the highly nonlinear behavior of the rocking block and is very sensitive to the characteristics of the excitation [1, 2]. Thus, from a design perspective, it is unreliable to depend on this safety region, and the lower limit is more important. Hence, both options have a remarkably similar benefit.

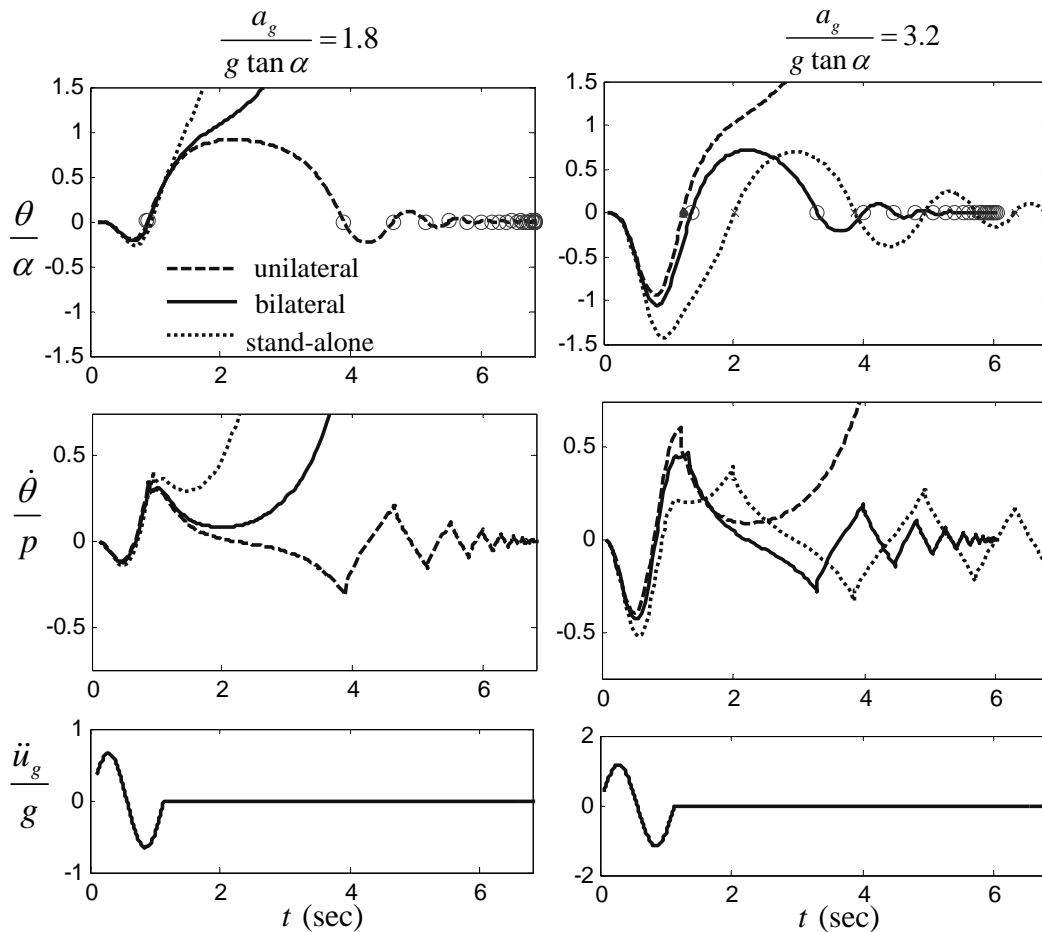

Figure 6: Rocking rotation (top) and angular velocity (middle) time-history of the rocking block ($\omega/p = 2.75$, $\eta = 0.825$) excited with a sine pulse (bottom). Left column point 1 of Figure 5 and right column point 2 of Figure 5.

To further investigate the effects of adding damping and the sensitivity of the rocking response, Figure 6 plots the time-history response (rotation and angular velocity) of the rocking block that corresponds to the points 1 to 3 in the overturning diagram (Figure 5). For $a_g/(g \tan \alpha) = 1.8$ and 4.6 (points 1 and 3) the stand-alone and the bilaterally damped rocking

block overturn, while the unilaterally damped rocking block survives. On the contrary, for $a_g/(g \tan \alpha) = 3.2$ (point 2) the opposite is true: the stand-alone and the bilaterally damped block survive, while the unilaterally damped block overturns. The response is clearly highly nonlinear, and numerous instances where either the bilateral or the unilateral damper performs better can be found. As a general rule, for a given damping parameter γ the performance of the two types of damper are comparable.

Figure 7: Rocking rotation (top) and angular velocity (middle) time-history of the rocking block ($\omega/p = 2.75$, $\eta = 0.825$) excited with a sine pulse (bottom). Point 3 of Figure 5.

3 DAMPING OF MASONRY ARCH ROCKING

The dynamics of masonry arches is a particular class of rocking problems. Under specific conditions outlined in DeJong et al. [8], Oppenheim [9] and Sinopoli [10], the dynamics of the masonry arch can be captured with a single degree of freedom model (SDOF). For single pulse dominated earthquake motions, an SDOF arch model was effective in predicting experimental collapse results for dry-stone masonry arches [8]. Further, arches are prolific in historic structures which stand vulnerable to seismic loading. Retrofit solutions which incorporate damping could potentially provide a viable solution for improving seismic safety.

As a first approach, the damping formulation presented in section 2 is here extended to masonry arches. It is assumed that linear viscous damping is added at hinging locations in the masonry arch, without considering a specific geometrical damper configuration.

The SDOF equation of motion can be derived from Hamilton's principle and Lagrange's equation:

$$\frac{\partial}{\partial t} \left(\frac{\partial T}{\partial \dot{\theta}} \right) - \frac{\partial T}{\partial \theta} + \frac{\partial V}{\partial \theta} = Q \quad (9)$$

The kinetic energy T and the potential energy V can be found in [9]. The generalized force expression is comprised of two parts: the inertial terms due to base excitation Q_g [9] and the additional damping forces Q_d . The total generalized force becomes $Q = Q_g + Q_d$.

Figure 8: The four-link kinematical mechanism of a masonry arch, during rocking under base excitation. Additional linear viscous damping is assumed at hinging locations.

The damping force Q_d can be determined after calculating the work of the non-conservative forces δW_{nc} as:

$$\delta W_{nc} = Q \delta \theta = (Q_g + Q_d) \delta \theta \quad (10)$$

In particular:

$$\begin{aligned} Q_d \delta \theta &= -c \cdot \dot{\theta} \delta \theta - c \cdot \dot{\theta}_{ABC}(\theta) \delta \theta_{ABC} - c \cdot \dot{\theta}_{BCD}(\theta) \delta \theta_{BCD} - c \cdot \dot{\theta}_{CD}(\theta) \delta \theta_{CD} = \\ Q_d \delta \theta &= -c \left[1 + \left(\frac{\partial \theta_{BC}}{\partial \theta}(\theta) - 1 \right)^2 + \left(\frac{\partial \theta_{CD}}{\partial \theta}(\theta) - \frac{\partial \theta_{BC}}{\partial \theta}(\theta) \right)^2 + \left(\frac{\partial \theta_{CD}}{\partial \theta}(\theta) \right)^2 \right] \dot{\theta}(t) \delta \theta \Rightarrow \\ Q_d &= -c \left[1 + \left(\frac{\partial \theta_{BC}}{\partial \theta}(\theta) - 1 \right)^2 + \left(\frac{\partial \theta_{CD}}{\partial \theta}(\theta) - \frac{\partial \theta_{BC}}{\partial \theta}(\theta) \right)^2 + \left(\frac{\partial \theta_{CD}}{\partial \theta}(\theta) \right)^2 \right] \dot{\theta}(t) \end{aligned} \quad (11)$$

where θ_{AB} , θ_{ABC} , θ_{BCD} , θ_{CD} are the angles depicted in Figure 8, and c is the damping constant. After extensive algebra, the equation of motion can be written in the form:

$$M(\theta) R^3 \ddot{\theta} + L(\theta) R^3 \dot{\theta}^2 + F(\theta) R^2 g + D(\theta) R^2 \dot{\theta} = P(\theta) R^2 \ddot{x}_g \quad (12)$$

where $D(\theta)$ is the term introduced due to damping.

Figure 9 plots the time-history response of the masonry arch described in Oppenheim [9], to a simple sine ground motion with acceleration amplitude $a_g = 0.75 g$ and duration $T_g = 1.0$ sec (Figure 9 bottom). The coefficient of restitution is taken as $\eta = 0.93$. The free masonry arch fails during rocking, while the addition of (linear) viscous damping at the hinging locations prevents failure.

Figure 9: Rocking of the masonry arch under a sine pulse excitation (bottom). Rotation (top) and angular velocity (middle) about left hinge. While the free ($c = 0$) arch fails, the addition of damping ($c = 75, 100$ m sec kN).

4 CONCLUSIONS

In this paper the consequences of adding damping to rocking structures are investigated. Interestingly, while additional damping is already implemented in practice, to retrofit rocking structures, there is a lack of theoretical research on the subject.

The overturning envelopes of a rocking block retrofitted with bilateral and unilateral (activated only during uplift) linear viscous dampers, show a substantial enhancement of the behaviour. As a general rule, for a given damping level, the performance of the two types of damper are comparable. However, the unilateral damper delays the first appearance of overturning with impact and the first appearance of overturning without impact mode, but the area of overturning with impact is larger, compared to the pertinent bilateral damped block. Comparing with the alternative of anchoring the rocking system, the additional damping does not lead to counter effects where the behaviour of the retrofitted rocking system is actually worse than that of the stand-alone system.

The masonry arch exemplifies an alternate type of rocking structure for which added damping might be appropriate.

Abstract. *In light of the increasing interest in rehabilitation of heritage neoclassical buildings of the 19th and 20th Century in Greece, often restricted by international treaties for non-invasiveness and reversibility of the intervention and given the practical requirements for the buildings' intended reuse, the present study focuses on the investigation of the parameters that affect the process of their seismic assessment through simulation. This class of load-bearing masonry buildings, which is also present in many European countries, are marked by carefully engineered configuration (layout in plan and elevation, systematic location of openings), that can lead to a specific type of seismic response. In the present paper, also investigated is the effect of horizontal diaphragm stiffness and connection to the walls; their contribution to dynamic response and appropriate methods of modelling are studied. Conclusions are calibrated based on comparative evaluation of the simulation results (obtained from detailed finite element modelling of a representative historic building located in the seismically active region of Thessaloniki) with the extent of actual damage patterns which have been observed due to strong earthquakes that have occurred during the buildings' lifetime. The paper also presents a relatively simple analysis procedure that for this special class of buildings can produce very dependable results compared to those obtained from time-consuming dynamic analyses, in a much easier and fast way.*

1 INTRODUCTION

Rehabilitation and retrofitting of historical and heritage structures of the 19th and 20th Century is an issue of paramount importance in countries with built cultural heritage that also suffer from high seismicity, such as the countries of the eastern Mediterranean basin. In Greece a significant number of neoclassical buildings were constructed starting immediately after the war of independence and continuing over the last two centuries. These are concentrated mainly in significant urban areas and are considered today an inseparable part of the country's inventory of historical buildings. Over the several decades of their service life, many of those buildings have undergone severe shaking during the strong earthquakes that occasionally affect the urban areas of this highly active seismic region. Yet, even today they remain in good condition, being operational in many cases. Due to those buildings' historical importance as examples of an architectural school of thought, an increasing interest for their rehabilitation has recently emerged, often regulated by international treaties for noninvasiveness and reversibility of the intervention combined with the practical requirements for the buildings' modern day intended reuse.

In the effort to assess the residual strength of neoclassical buildings, reduced from a vague undetermined value which represents the initial state and in designing the appropriate retrofit measures for upgrading, sophisticated finite element analysis programs combined with powerful computing means have become a valuable tool for Structural Engineers. Yet, despite the capabilities which can derive from the use of modern technology, the obtained results are not necessarily reliable as they often fail to recognize or reproduce important structural phenomena in the modeling process or due to lack of convergence owing to inherent limitations of the analysis algorithms. As a result, in the process of seismic assessment of historic or heritage buildings of the 19th and 20th Century the residual strength of the corresponding structure can easily be underestimated, which could lead to rather invasive choices of rehabilitation methods that can alter or destroy the unique historical or architectural features of the building in the interest of perceived needs for strength increase of the structure.

The objective of this paper is to highlight the special modeling procedures that are needed in the process of simulation of 19th and 20th century neoclassical buildings. This special class of buildings, which is similar to many historical and heritage buildings across Europe, possess special characteristics due to their design and structural configuration, whose oversight during their modeling procedure could lead to serious misinterpretation of their seismic response. Also presented is a simple and rapid analysis procedure, based on the modal characteristics of this class of buildings, which can lead to as dependable estimates as the results of complicated and time-consuming dynamic analysis.

2 OVERVIEW OF THE SPECIAL CHARACTERISTICS OF THE NEOCLASSICAL BUILDINGS DUE TO THEIR DESIGN AND CONSTRUCTION

Seismic assessment of neoclassical buildings constructed in the 19th and 20th Century is a much more demanding procedure than seismic assessment of reinforced concrete structures in that the structural system in masonry buildings is less clearly defined, whereas a profound knowledge of the design principles and the construction practices of that era is required in modeling the individual structural components to dependably reproduce the mechanics of member behavior.

Knowledge of the designing principles of the 19th and 20th Century is essential for interpretation of the dynamic response of this class of buildings. Architects of the era, being influ-

enced by the shape and form of ancient Greek monuments, were designing neoclassical buildings that were characterized by symmetry in plan and in height, loaded with architectural features and elements inspired from archaic forms (for example colonnades, reliefs in gables, and carefully chosen aspect ratios). In the cases of single-unit buildings, the structure was designed in plan so as to have a simple geometrical shape, rectangular or prismatic, whereas multi-unit buildings were designed to have a system-plan organized in the form of an *H* or a *T*, with courts located in the recesses of these shapes so that the overall plan could be thought to form a concave prism (Fig. 1). In every case, the rooms of the building were symmetrically arranged in both sides of a main corridor that was usually spanning from one end of the building to the other. Side views of the building were designed to have windows and doors symmetrically spaced with respect to a vertical axis that was intersecting the plan symmetry axis. Furthermore, the area occupied by openings (i.e. windows and doors) was gradually increased from the ground level to the top of the building (resulting to the corresponding decrease of the area of walls) to encourage a flexural-type behavior for the building in lateral vibration. Thus, buildings of that era are expected to develop favorable dynamic response during an earthquake, such as the absence of torsional effects in plan and a favorable drift distribution along the building height.

Figure 1: Typical monumental neoclassical buildings built in Greece during the 19th and 20th century.

The construction practice in the 19th and 20th Century was also governed by empirical principles [2 - 6], the consideration of which is essential for proper modeling of the behavioral mechanisms that are developed in neoclassical buildings during an earthquake. Starting from the foundations, different techniques were utilized according to the compressive strength of the foundation soil, in the site where the building was to be constructed. Soft soils were reinforced by driving into the ground in arbitrary manner wooden piles up to 1.30m in length, having diameters that varied from 0.15m to 0.20m, and by filling the space between the piles with gravel. Until the end of the 1860s, grids made by wooden boards of cross sectional dimensions of 80mm x 320mm, closely spaced, were utilized in medium compressed soils in order to uniformly distribute the compressive stresses of the building's walls to a wider area. In stiff soils, wooden beam grids with cross sections of 170mm up to 200mm square were utilized instead of wooden boards. Those beams were spaced at a distance which ranged from 0.45m to 1.00m and the resulting in-between space was filled with compressed gravel. When the soil stability was secured, foundation walls were constructed. Those walls were made of stone and their width was equal or greater than the width of the walls of the first storey of the building. In buildings without a basement, the depth of the foundation walls was equal to 1/7 up to 1/6 of the total building height, whereas in buildings with a basement foundation walls extended to a depth of 1.00m up to 1.20m below the basement floor. During modeling it would be wise to assume that the wooden elements (piles, boards and beams) may have undergone some extent of disintegration after those many decades of contact with the soil or the environment and therefore it would be pertinent to model contacts (structure to soil, timber elements to structure, etc.) through use of proper modeling tools (springs, etc) particularly in representing the stiffness of the foundation of such buildings.

The vertical load-resisting elements of neoclassical buildings were walls comprising stones or bricks. Walls of this type had a significantly larger thickness as compared to the in-fill walls of reinforced concrete buildings (ranging from 0.30m to 1.20m), whereas this thickness was gradually reduced starting from the ground floor to the top of the building. Stone walls were usually three tier walls, having an exterior facade built of large, regularly-shaped rectangular stone blocks, whereas the in-between space was filled with smaller stones of arbitrary geometry, soil and crushed bricks or tiles. To secure the uniform distribution of gravity loads to all of the three vertical layers and to avoid lateral separation of the tiers, horizontal brick lacing layers were constructed for each meter of stone wall height or so and across the entire wall thickness. In the case of brick walls, solid bricks (i.e. without holes) were mostly used. In some cases of buildings with several storeys, the brick walls of the upper storeys were made of bricks with holes (lighter), in order to effect a reduction in the magnitude of the structure's self weight in the upper storeys. Finally, to secure that crossing walls would not separate during an earthquake, timber ties comprising two longitudinal timber beams were placed along the wall's length and anchored at the external face of the crossing walls, forming a passive confining arrangement for the infilled masonry blocks. After the introduction of iron in the construction practice (in the end of the 1860s) timber ties were replaced by iron blades. Keeping in mind the construction practice of the walls of the neoclassical buildings, it is essential to model the different types of strengths of the walls. Also note that analyses procedures referring to combinations of actions in ultimate limit state design of modern buildings which have relatively small weight compared to their total volume (i.e. 1.35g) are inappropriate for neoclassical buildings, as they impose unrealistically large loads and masses to the structure.

Finally, the floor systems of neoclassical buildings built before the 1870s often had timber beams as structural elements, which were spaced at a distance of 0.60m up to 1.00m, serving to transfer the loads from the floor to the surrounding walls. When the wall thickness in two

successive storeys remained constant, the timber beams of the floor between those two storeys were seated in pigeon-holes in the walls. In cases where the wall thickness in the storey above a floor level was reduced by setback of the interior façade of the wall, then the timber beams of the floor were nailed on beams parallel to the walls whose purpose was to uniformly distribute the floor loads along the length of the walls. After the 1860s the timber beams were replaced by iron elements. Two different versions of floors with iron beams were constructed. In the first case, secondary timber beams were placed between successive iron beams, to provide resistance to lateral torsional buckling in order to secure the constant spacing between parallel iron beams and also to allow timber floor planks to be supported by nailing. The second and most usual type of a floor with primary iron beams comprised brick arches spanning between parallel iron beams. Thus, consideration of the mechanisms developed in the structural system of this class of buildings, owing to the different types of floor configuration (friction between the timber beams and the walls, differential movement between the brick arches and the iron beams, etc.), is of paramount importance in the modeling procedure, as they can influence the analyses results to a significant extent.

3 EXAMPLE OF SIMULATING AND ANALYZING A NEOCLASSICAL BUILDING

To investigate the sensitivity of the analysis results obtained from simulation of neoclassical buildings with models comprising the various types of mechanisms that were discussed in the previous paragraph, a series of dynamic analyses have been performed to different types of models of a neoclassical building located in the centre of Thessaloniki. This building was constructed in 1893 in order to house the first Hellenic high school of Thessaloniki, according to the designs of Ernest Chiller, as those modified of the architects Kabanakis and Kokkinakis (Fig. 2); since its construction, the building had been continuously in operation as a school until the summer of 1978, when it suffered damage by a strong earthquake of 6.5 M_w on the Richter scale that struck the city of Thessaloniki. The epicenter of the ground motion was North-East of Thessaloniki, in the Volvi lake region.

3.1 Description of the Structural System

The neoclassical building considered in the analyses is a two-storey building with a basement and a roof, located in the centre of the city of Thessaloniki, Greece. The building has a 20.83m x 16.05m plan, symmetrical with respect to a main corridor that is spanning from the northern side of the building to the southern, whereas the external building height, including the roof, is 14.20m. The first storey comprises six rooms, symmetrically located in both sides of the storey's corridor. The second storey was originally constructed to have four halls, one big hall at each side of the corridor spanning from the front view of the building (north view) to the south and two smaller ones in the southern part of the plan. Over the years, the two big halls were divided, the eastern one with the addition of a 0.15m thick brick wall and the western one with the addition of a wooden panel. The basement comprises five rooms that were used as storage rooms and sanitary facilities, after the addition of miscellaneous infill brick walls. Floors were connected with a wooden stair in the southern part of the main corridor. The walls of the basement are made of stone, having a thickness equal to 0.75m in the perimeter of the building and 0.65m in the inner plan. Walls of the first and the second storey were built of solid brick. Perimetrical walls have 0.50m width, whereas internal walls 0.40m. Floors of the first and the second storey were made of double T iron beams having a 60mm x 180mm cross section, spaced at 0.70m along the small sides of the rooms and the corridors (i.e. having an E-W orientation over the building's corridors and a N-S orientation over the

building's halls), whereas brick-arches spanning in the transverse direction between successive iron beams were encased between the upper and lower flanges of the double T beams. The total thickness of building's floors (including the finishing) is 0.33m at the location of the iron beams and 0.25m at the highest point of the arches. The last storey is covered by a roof made of timber trusses spanning in the east to west direction of the building.

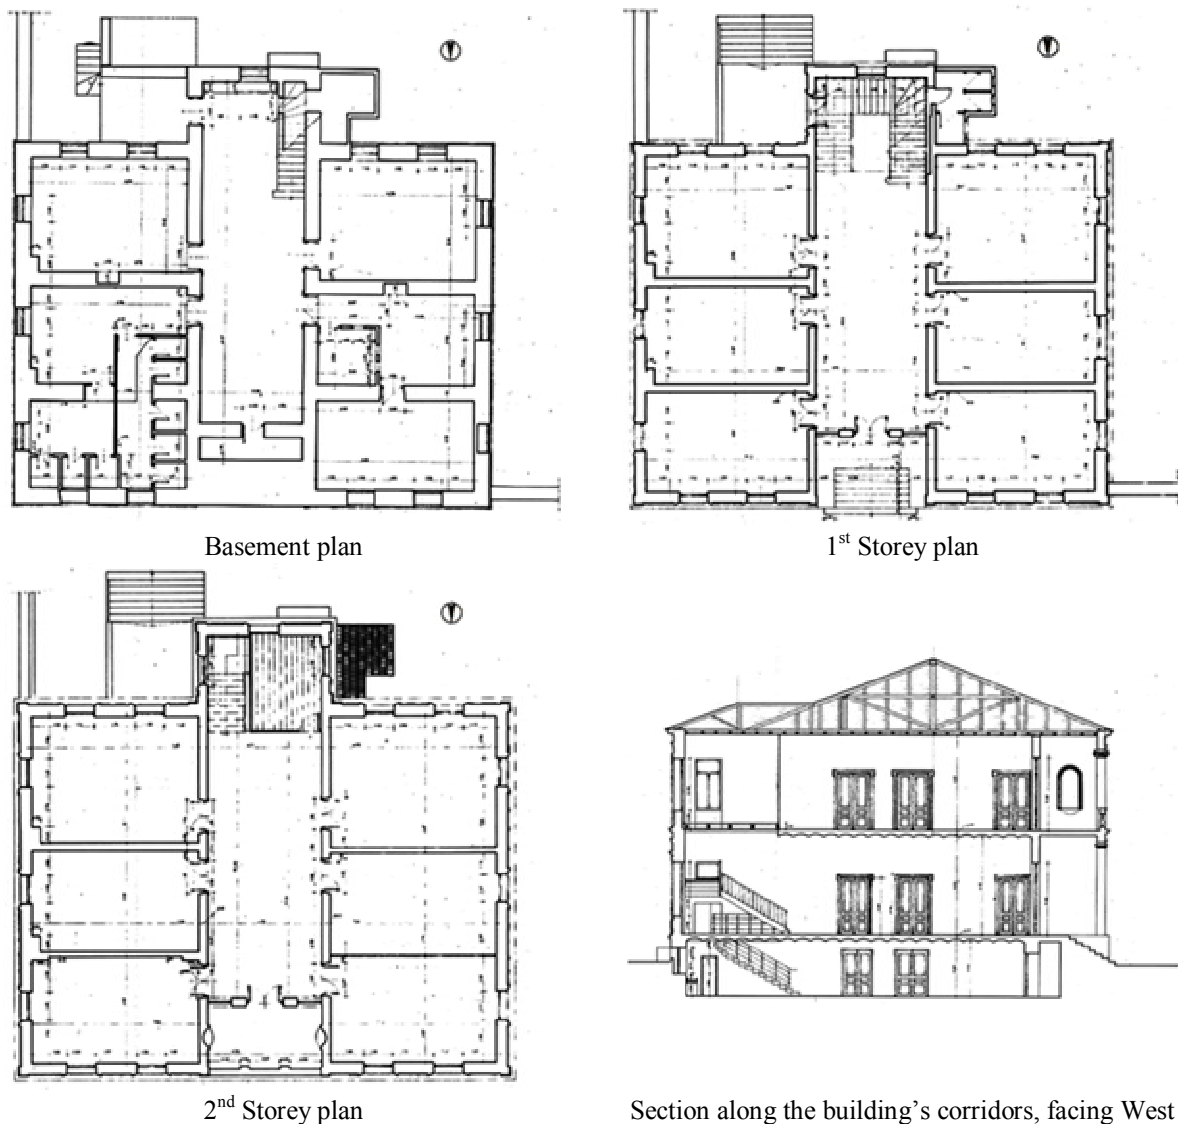

Figure 2: Plan and section views of the building used for the analyses.

3.2 Description of the Structural Modes Used in the F.E. Study

To examine the degree of influence of the different mechanisms that are developed in the structural system of the building on its overall seismic response, parametric dynamic analyses were carried out using the recorded accelerations of the 1978 earthquake; results were compared with the observed damage patterns reported in post-earthquake reconnaissance of the building. Simulation and analyses were carried out using a finite element analysis program [7]. Building walls were modelled using four-node shell elements, capable of supporting forces and moments (6 d.o.f. per node). In the simulation process, the wall thickness was reduced by 50mm from the measured dimensions in order to eliminate the plaster thickness on both sides of the walls. Thus, shell elements simulating the basement walls were assigned a thickness of

0.70m and 0.60m in the cases of exterior and interior walls respectively, whereas upper walls were modelled using a thickness of 0.45m and 0.35m for the exterior and interior brick walls of the first and the second floor. Along the basement walls, above and below the basement windows, two zones of shell elements accounting for brick lacing were used. Infill walls in the location of internal doors between the southern and the central storage rooms of the basement, the northern basement window of the west view of the building and between the northern and the central room at the east side of the corridor at the second storey were simulated using shell elements of 0.15m thickness, accounting for walls made of voided-bricks, since those additions were introduced in 1975. Timber panel divisions were omitted (in the northern and the central room at the west side of the corridor of the second floor). To investigate the degree of alteration of the building's seismic response due to the floors and the roof configuration, two model buildings were produced, *Model A* and *Model B*.

In *Model A*, the 1st and the 2nd storey floors were simulated utilizing linear elements, fixed at their ends to the shell elements of each room's wall, in order to account for the iron beams, whereas the brick arches were modelled as shell elements having a 0.16m thickness (i.e. the average thickness of the structural system of each of the two floors), accounting for voided-bricks, fixed to various points of the surrounding walls and the iron beams. Linear elements were used at the roof level, accounting for the timber beams having a 100mm square cross section over the perimeter walls and the two sides of the corridor, which were considered to be fixed at the nodes of the wall shell elements. Also included were linear elements parallel to the E-S direction of the plan, spaced at 0.60m and fixed at the nodes of the timber beams over the storey walls. These elements had the same cross section as the timber beams over the walls and modelled the horizontal members of the roof trusses.

In *Model B* (Fig. 3), gap elements were added between the nodes of the shell elements that represented the brick arches and the corresponding nodes of the iron beams, replacing the fixity condition for the same contact detail in *Model A*. Thus, gap elements were intended to model the separation between the brick arches and the iron beams when in tension whereas they were considered rigid in compression (perfect contact). Also added in *Model B* were springs between the nodes of the wall elements and the timber beams over the wall, which were meant to account for friction between the wall and the timber beams. Spring-response was described by a multi-linear force-displacement relationship (Fig. 3), that was calculated according with the development capacity over the beams' contact surfaces when accounting for friction with the building walls. In both models, the response of the shell and the linear elements was considered elastic. Modulus of elasticity of stone and bricks was considered 1000 times the value of the corresponding compressive strength, f_k ; for stone $f_k = 5.5$ MPa, for solid bricks $f_k = 4.0$ MPa and for voided bricks $f_k = 1.5$ MPa. In the case of frame (iron and timber) elements, the modulus of elasticity was taken equal to 150 GPa for the iron beams, 10 GPa for timber in the longitudinal direction of the beams and 1GPa in the other two sectional directions. In all cases, the building load was taken equal to the self weight of the building and no variable load was considered, as during the earthquake (8pm of June 20) the school was not operational. Material density was 28.5 kN/m³ for stone, 18 kN/m³ for solid bricks and 14kN/m³ for voided bricks. A roof weight equal to 1.5 kN/m² was assumed, uniformly distributed along the linear elements of the roof trusses according to their tributary area.

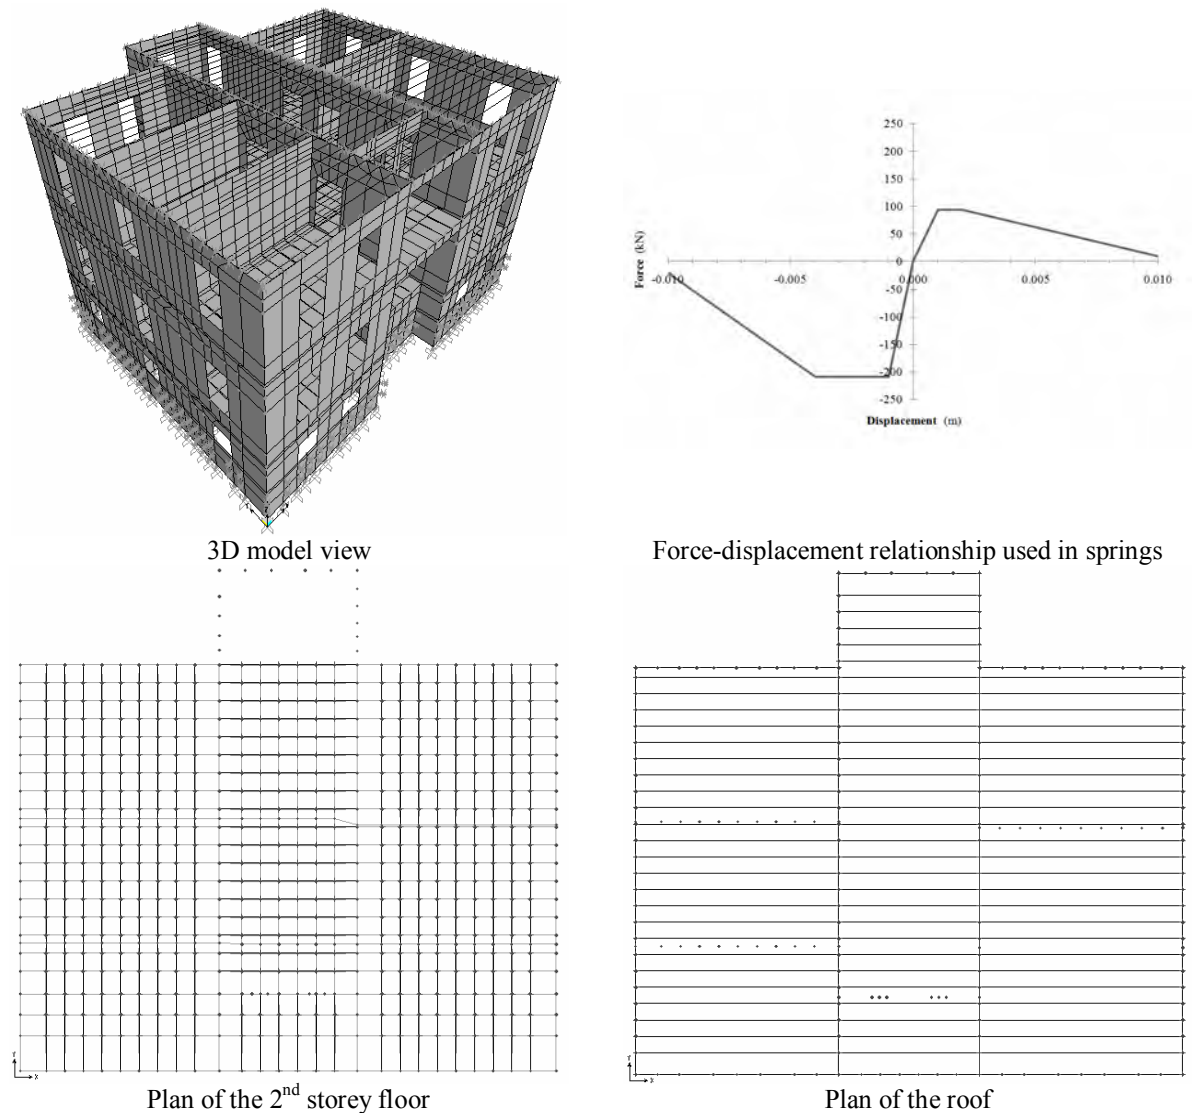

Figure 3: Model B; Three-dimensional view of the model, plan views of the 2nd storey floor, the roof and force-displacement relationship used in the friction springs that connect the timber beams with the walls of the second storey.

Parametric modal and dynamic analyses were carried out on both models. To determine the free vibration mode shapes and the natural periods, T , of the building, both models were subjected to Ritz-vector modal analyses, to account for the spatial distribution of the dynamic loading. Also performed were dynamic time-history analyses according to the earthquake acceleration recordings of the 1978 Thessaloniki earthquake [8]. Response spectra of the accelerations used in the analyses with respect to the building's principal directions in plan, calculated when assuming 5% damping, are presented in Fig. 4. Masses considered in the Modal and Time-History analyses were automatically calculated by the program, by multiplying each element (shell or linear) volume by their material volume mass respectively.

Figure 4: Elastic acceleration response spectra of the two components of the 1978 Thessaloniki earthquake that were used in the model analyses, calculated for 5% damping. The two components resulted from the same earthquake acceleration record, by projecting it to the two primary axes of the building's plan orientation.

From the results of the analyses of *Model A* and *Model B*, the following observations concerning modelling of neoclassical buildings for the purposes of seismic assessment are extracted. The first observation concerns the developed stresses in the shell elements of both models. Figure 5 presents the shear stress distribution across the walls and the floors of the two models as calculated from Time-History analyses in the time interval of the building's maximum seismic response in terms of roof displacement. As observed, the introduction of gap elements in the first and second storey floors as well as the use of friction springs in the connection of the timber beams with the second storey walls resulted in a significant reduction of the developed shear stresses of floors from *Model B* at about 50% in the first and 40% in the second floor as compared to the same shear stresses from *Model A*. Also altered were the stress distributions across the buildings floors, with *Model B* presenting a more uniform shear stress distribution than *Model A*. The same conclusions about the comparison between the magnitude of the developed stresses of *Model A* and *Model B* also apply in the developed shear stresses at the walls of the buildings, with the spread between those values being reduced to about 30%. Figure 6 illustrates the developed shear stresses on the different facades of the two models at the time of the building's maximum seismic response, together with the actual damage patterns of the building after the 1978 earthquake. From this comparison it is concluded that *Model B* correlates better with the actual damage patterns of the building than *Model A*.

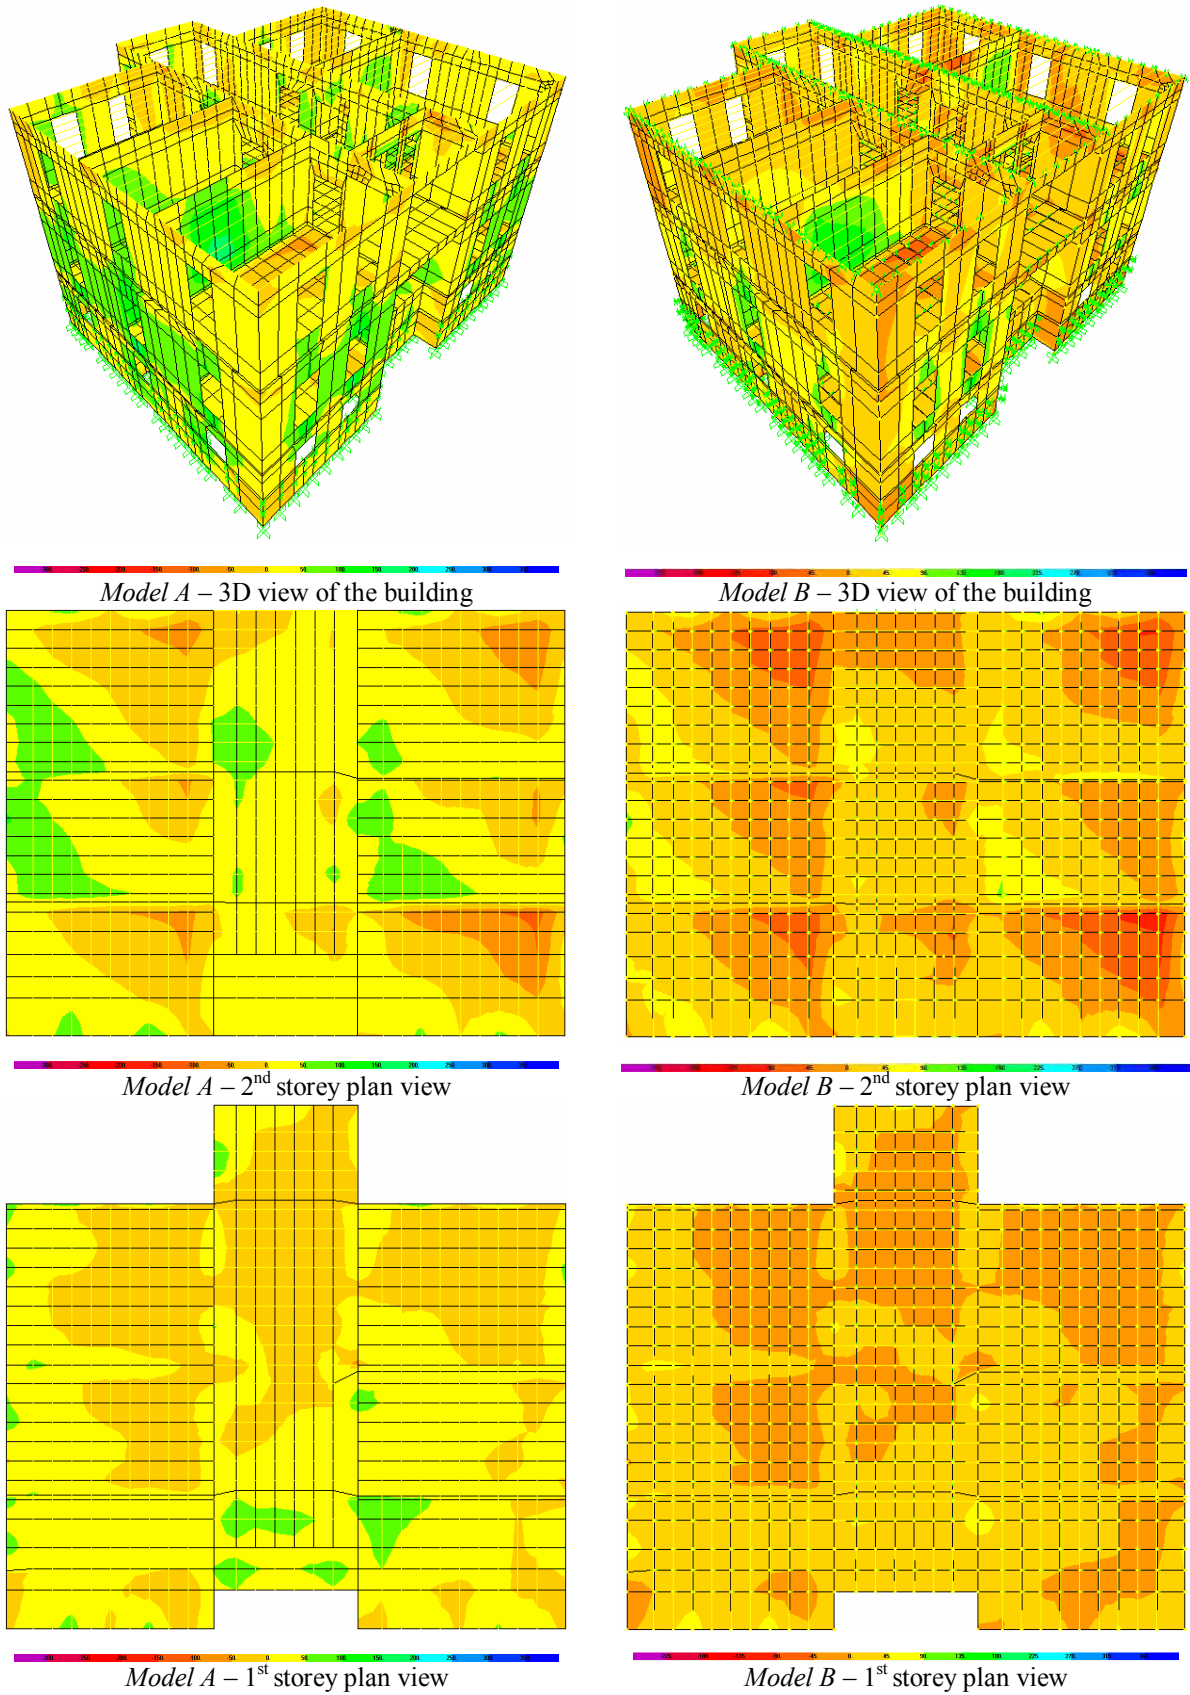

Figure 5: Shear stress distribution over the shell elements of Model A and Model B, as calculated at the time of the building's maximum seismic response from time-history analyses.

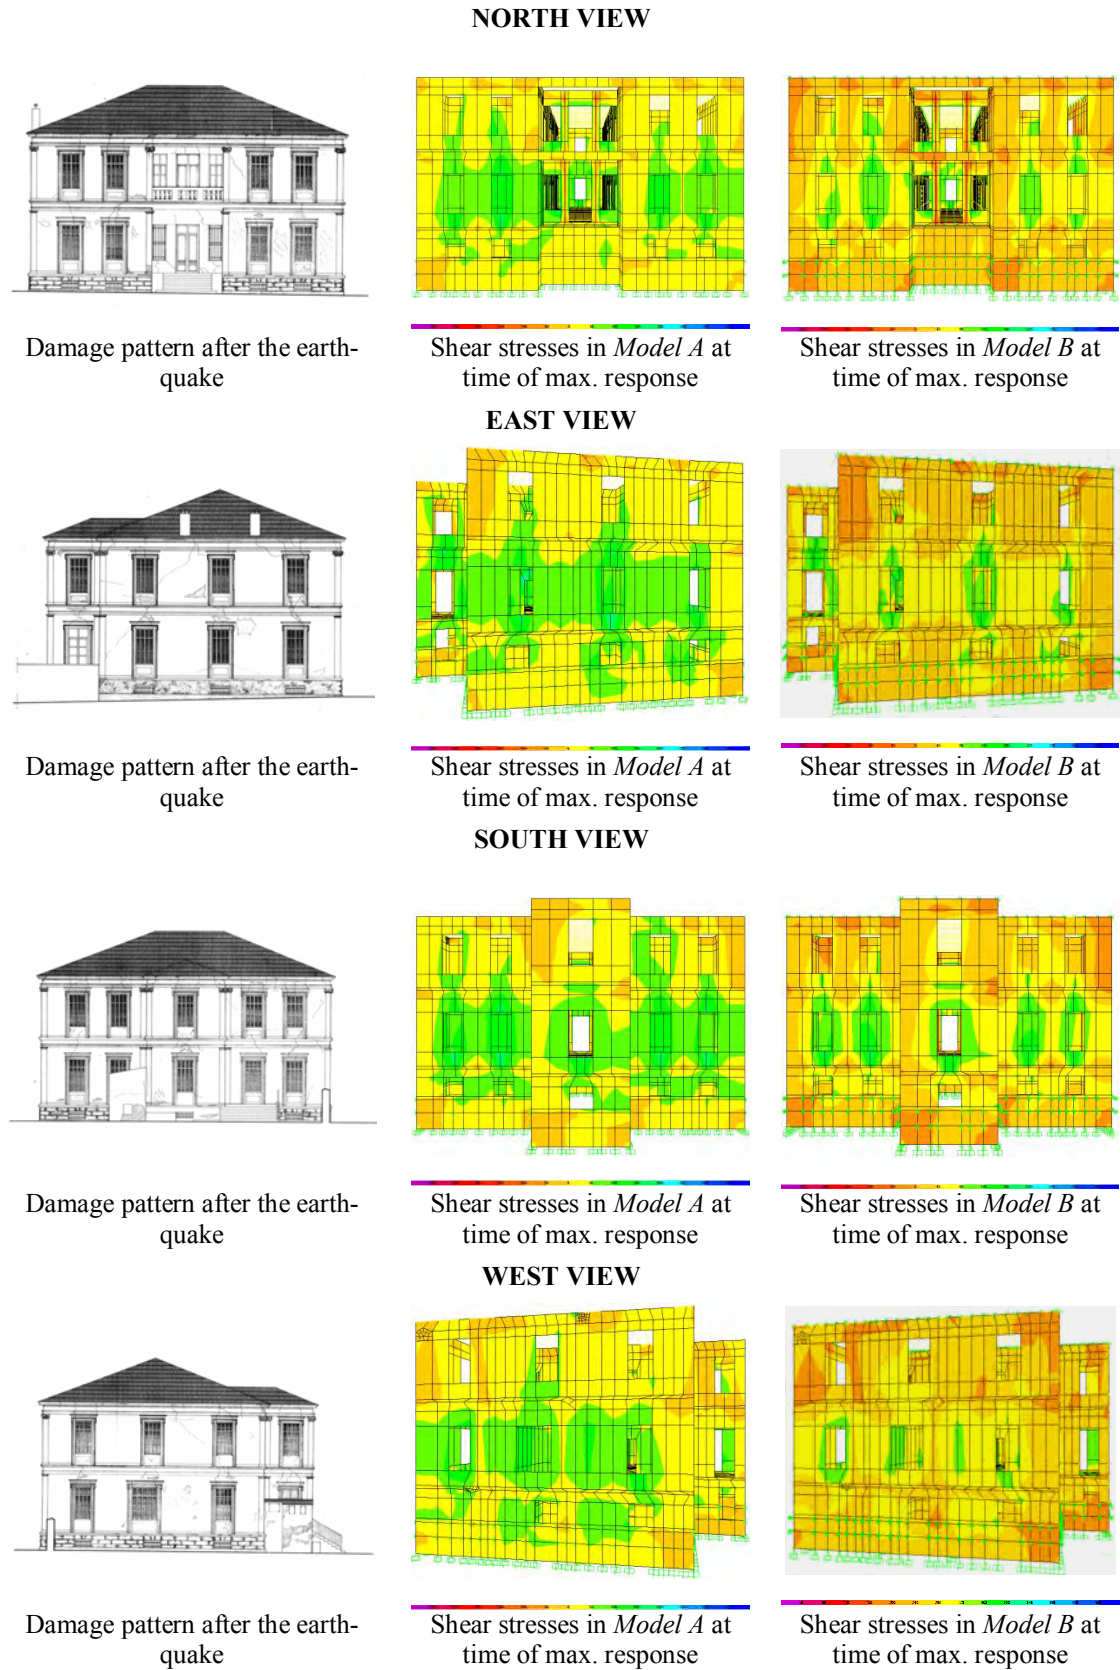

Figure 6: Comparison between the damage patterns of the building after the 1978 Thessaloniki earthquake and the developed shear stresses in *Model A* and *Model B* at the time of the building's maximum seismic response in terms of roof displacement.

Modal analysis conducted on the buildings led to a large number of translational modes with closely spaced periods. This led to a group of very similar modes each having a small participation factor, leading to the requirement of including several modes in the calculation in order to mobilize the structural mass. Here an alternative approach was used to approximate the fundamental mode of vibration of the structure, by subjecting it to a notional gravitational field in the direction of lateral translation (i.e. along the longitudinal and transverse directions of the plan geometry). In light of the fact that gravitational forces are proportional to the mass of the structure, and the restoring forces in this situation are equilibrating these mass-proportional inertia forces, the deflected shape of the structure obtained from this solution is thought to be the closest approximation to the translational mode of vibration since the associated natural frequency would result from the ratio of the work-equivalent inertia force and restoring force [9]. The mass associated with this shape obtained for *Model A* of the building was estimated at 95% of the total mass, a result that suggests a fundamental inconsistency between the modal analysis and the mode approximation method; this inconsistency, which is basically owing to the discretization approach used with the finite element model, is most likely responsible for the apparently false notion that the seismic response of the neo-classical building is governed by many mode shapes with relatively small mass participation factor.

This point is documented in Figure 7 which illustrates the spread of the mass participation factors for the first 100 modes of *Model A* and *Model B* in each of the buildings' principal directions, as calculated from the results of Ritz modal analyses. Also presented are the mass participation factors in each of the corresponding directions, derived from the deformed shape of the two models after lateral loading with their self weight (a horizontally oriented gravitational field). Note that the sum of the mass participation factors of the first 100 modes of *Model A* equals to 61.4% in E-W direction and 68.6% in N-S direction, whereas the corresponding mass participation from lateral loading with the building's weight is 95.0% and 97.1% respectively. Dispersion of the results is greater between the modal analysis mass participation factor, whereas mass participation obtained from lateral loading is even greater in *Model B*; 52.8% vs. 95.2% in E-W direction and 55.9% vs. 96.9% in N-S direction respectively.

Figure 7: Comparison between the mass participation factor for the first 100 modes of *Model A* and *Model B* obtained from Modal Analyses, and Mass participation calculated from the deflected shape when models are subjected to a horizontal gravitational field along the E-W and N-S plan directions.

Based on recent research [10] which indicated that the displacement response distribution of a structure matches very well with the shape of the principal translational mode in the corresponding direction if the mass participation factor exceeds the value of 80%, a rapid ap-

proximate method for determining the maximum seismic response of neoclassical buildings is introduced. According to this procedure, the seismic response of a neoclassical building, in terms of developed stresses or deformed shape, can be determined in a two step procedure:

(a) First a simple static analysis is performed, where the model is loaded laterally with its own self weight acting in each of the two principal directions of the plan.

(b) In each direction of the building's plan, the corresponding quantity which is investigated (nodal displacements and/or developed elements stresses/forces) is multiplied by a factor which equals to the ratio of the spectral relative displacement normalized by the peak displacement throughout the building obtained from the gravitational analysis.

Figure 8 plots the comparison between the displacement profiles obtained from time history analysis and from the proposed spectrum-based procedure for the east corner of the North façade of the building. Note the excellent correlation between the two procedures.

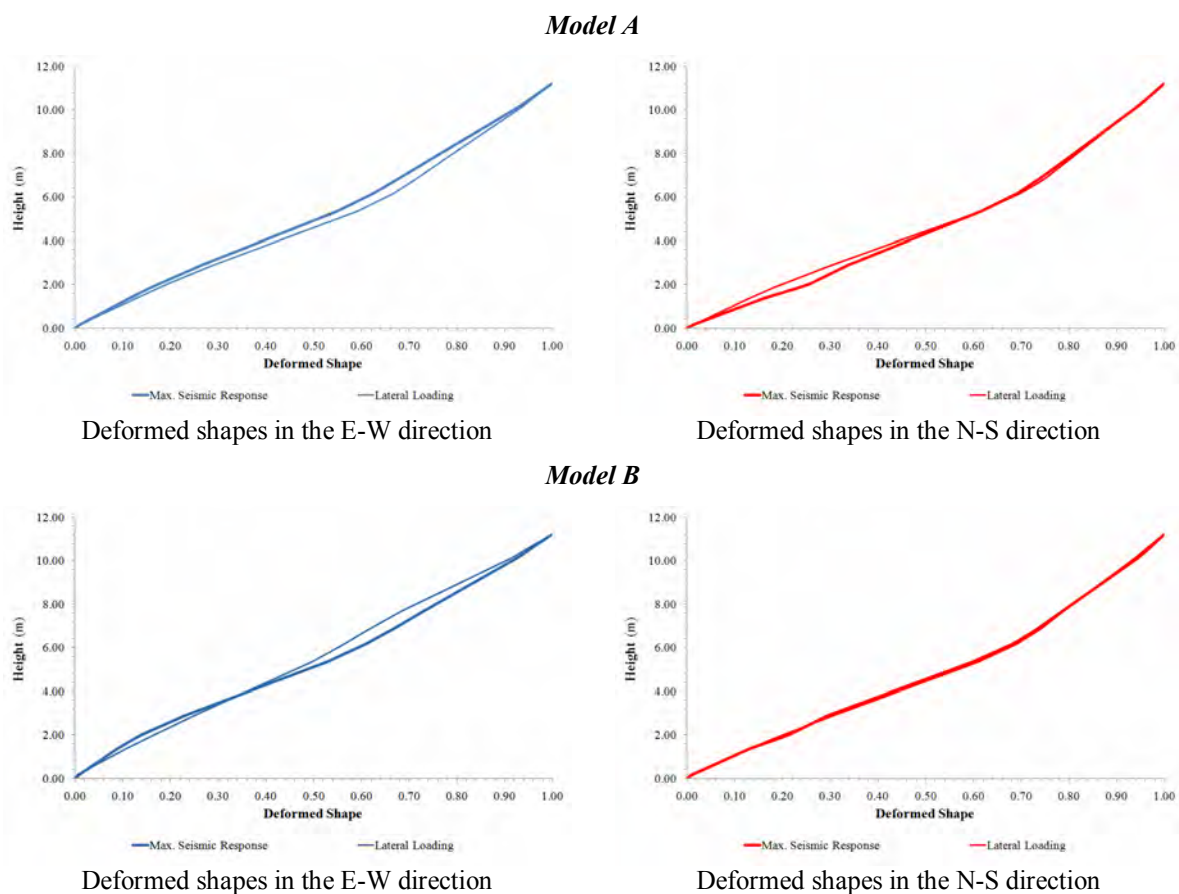

Figure 8: Deformed shapes of the east corner of the building's north face; Comparison between the shapes from the time-history analyses at the time of the building's maximum seismic response and the shapes from the lateral loading of the building with its self weight.

Figure 8 illustrates the displacement profiles of the east corner of the north face of *Model A* and *Model B*, for the cases of the maximum seismic response according to time-history analyses, and the deformed shape as calculated by the lateral loading of the models with their self weight. The correlation of these shapes is very good, especially in the N-S direction of the building.

In Fig. 9, comparison of the shear stress distribution along the shell elements of the building's north view between the cases examined, i.e. the results from time history analysis (at the time

of peak response) against the results from the proposed spectrum-based approach is illustrated for *Model A* and *Model B*. As in the case of the comparison of the models' deformed shapes, the correlation between the shear stresses from the two analysis methods is very good.

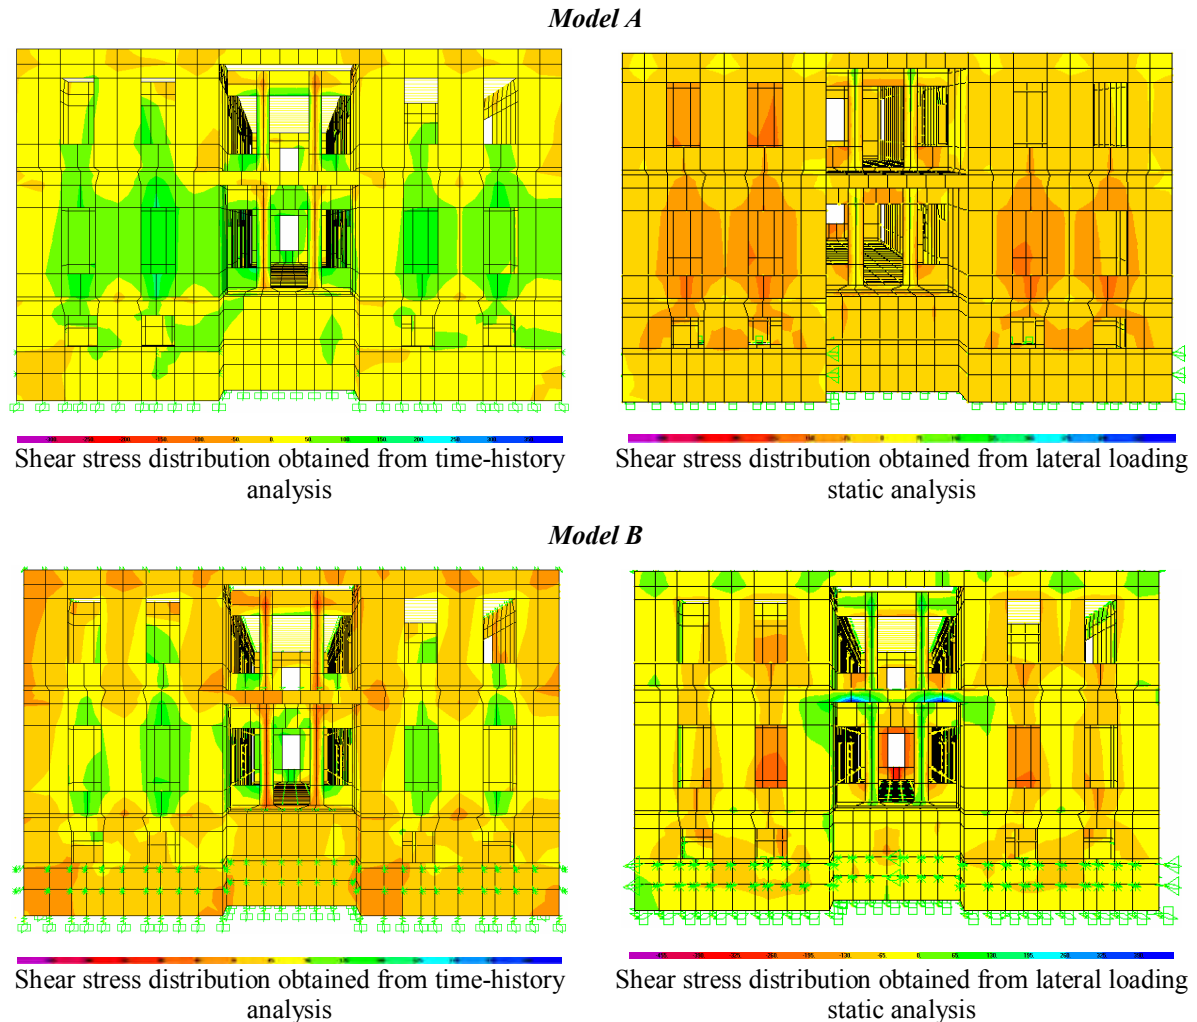

Figure 9: Shear stress distribution at the north face of the building at the time of peak seismic response; Comparison between the results obtained from time-history analyses and static analyses with lateral loading proportional to the building's weight (a horizontal gravitational field).

4 CONCLUSIONS

Seismic assessment of neoclassical buildings of the 19th and 20th century through simulation is a very demanding task. Profound knowledge of the design and construction practices of 19th and 20th Century is essential so that the structural engineer can simulate accordingly the mechanisms that can be developed in this class of structures during an earthquake. By neglecting detailed consideration of the contact effects at the points of interaction between different materials can lead to serious overestimation of demands and a commensurate underestimation of the residual strength of the building, guiding towards severe rehabilitation methods that may alter or destroy the unique historical or architectural characteristics of the building. In the present study an example of modeling of an actual neoclassical building located in the centre of Thessaloniki, Greece, which suffered damages from the 1978 earthquake was presented, were two different types of modeling the horizontal diaphragm stiffness

and the diaphragm connection to the walls were tested. According to the analyses results, the difference in the magnitude of shear stresses developed in the two models was in the range of 45% for the floor elements of the building and about 30% for the walls.

Also presented in this paper is a simple and very reliable analyses procedure, in order to determine the maximum seismic response (displacements and/or forces/stresses) of neoclassical buildings. This procedure is based on the recent research according to which the deformed shape of a building at the time of its maximum response is approximated very well by the shape of its principal translation-twisting mode if the mass participation factor is greater than 80% [10]. According to this procedure, the maximum seismic response of a neoclassical building can easily be determined from the results of a static analysis, where lateral loading of the building model is performed with its self weight, multiplied accordingly so that the horizontal displacements of the target node at the top of the building be equal to the relative displacement of the elastic spectrum used in the assessment procedure.

Keywords: Seismic Isolation, Ancient Statues, Vertical Isolation

Abstract: *This research concerns with the question of how the seismic isolation methods can be applied efficiently to protect the ancient statues under both horizontal and vertical strong earthquake excitations. The results are achieved by carrying out nonlinear dynamical analyses under three dimensional earthquake ground motion data on a generic ancient statue model, considering that it is displayed in a non isolated and a horizontally isolated building. The model is developed with 8-node cubic finite elements, and placed on a rigid platform, which is modelled as an area element of rectangular shape. The isolation devices are modelled as non linear spring elements for the horizontal seismic isolation, and gap elements (compression only) for the vertical seismic isolation.*

1 INTRODUCTION

After the efficiency of seismic isolation technology has been proved for several types of structures such as bridges, buildings, power plants, etc., scientists and researchers in the field started to look for the possible ways to adapt the seismic isolation solutions and furthermore create innovative solutions for the cultural heritage of human history and art objects. The need to protect these objects against earthquakes was found inevitable since they are one of the most precious possessions of the human being on the earth.

Koumoussis et al. [1], in his work for the horizontal seismic isolation of the Statue of Hermes, has designed and proved the adequacy of the FPSTM (Friction pendulum system), after carrying out numerical analyses on the 3D model of the statue. Borri and Grazini [2] have carried out static and dynamic numerical analyses for the statue of Michelangelo's David Statue. They have shown that the horizontal accelerations that could be originated by even moderate earthquakes (0.10-0.15g) can cause very high stress levels on some particular parts of the marble statue. Grazini [3] has done rocking analysis for both the non isolated and horizontally isolated statue models. Borri [2] and Grazini [3] have both pointed out the benefits of seismic isolators for the seismic protection of statues. Tadahiro and Masahiko [4] have developed seismic isolation solutions that are capable of protecting The Gates of Hell statue, which was sculpted by Augustin Rodin and owned by National Museum of Western Art, against very strong earthquakes such as the Great Hanshin Earthquake that occurred, in Kobe in 1995. Yegian et al. [5], has carried out several tests and numerical analysis for the sculptures in Nagoya Museum, with mechanical horizontal seismic isolators. In this project, the effectiveness of the horizontal seismic isolation system is investigated for isolated and non-isolated museum buildings.

Once a rigid block starts rocking, its rotation continues smoothly from point O to O', as shown in the Figure 1. If it does not fail by overturning, its rotation will change direction, and rotate otherwise, and the motion will continue in this manner, and cease some time after the ground motion comes to an end. For the rigid block to sustain this rocking motion, the energy released during the impact should be dissipated. The amount of this energy dissipation increases with the decreasing slenderness of the block [6].

The minimum rocking impulse that causes rocking of an object has been expressed by Calio and Marletta [7]. The minimum rocking impulse I_u , has been derived by equating the overturning moment due to the inertia load caused by the maximum horizontal acceleration, to the resisting moment due to the gravity as;

$$\ddot{u}_{\max}(I_r) = \frac{gb}{h} = \frac{g}{\lambda} \quad (1)$$

Considering zero damping, the maximum acceleration is given by

$$\ddot{u}_{\max} = I\omega \quad (2)$$

Therefore the minimum impulse that starts the rocking motion of a rigid body is represented as;

$$I_u = \frac{g}{\omega\lambda} = \frac{g}{2\pi\lambda}T \quad (3)$$

Where,

g = gravity acceleration

h = height of the center of mass of the object

b = lateral distance between the overturning point and the center of mass

$\lambda = h/b$ (slenderness ratio)

ω = natural frequency of the object

T = natural period

Calio et. al [7] concluded that the object stays in full contact with the ground until the design impulse becomes equal to the minimum rocking impulse. When the minimum rocking impulse is surpassed, the object starts rocking. Calio et al. [7] have shown that the seismic isolation significantly contributes to the stability of the object under horizontal ground motions.

Oliveto, Calio and Greco [8], have evaluated the uplift conditions for the initiation of rocking motion, considering both horizontal and vertical ground motions. They introduced a dimensionless parameter γ , to take into account the vertical accelerations of the ground motion.

$$\gamma = 1 + \frac{\ddot{v}_g}{g} \quad (4)$$

Where

\ddot{v}_g = Vertical ground acceleration (positive, when directed downwards)

g = Gravity acceleration (m/s^2)

They pointed out the significance of the vertical accelerations on the minimum rocking impulse, and expressed it through modifying the minimum rocking impulse expression;

$$I_u = \frac{\mathcal{R}}{\omega\lambda} = \frac{\mathcal{R}}{2\pi\lambda} T \quad (5)$$

As it can be understood from the two expressions above, when the vertical accelerations are directed upwards (against gravity), the minimum rocking impulse decreases, therefore the initiation of rocking becomes easier for the object considered.

Figure 1 Rocking motion of a rigid body

This research concerns with the question of how the seismic isolation methods can be applied efficiently to protect the ancient statues subjected to both horizontal and vertical strong

earthquake excitations. The study seeks to classify the effects of conditions deriving from different building types and earthquake characteristics, to design an efficient isolation system for a particular ancient statue. To achieve the results, computer models under several earthquake ground motion data are developed and compared for a generic ancient statue, considering that it would have been placed either in a non isolated or horizontally isolated building.

2 ANALYSES UNDER HORIZONTAL AND VERTICAL EARTHQUAKE EXCITATIONS

The statues are analyzed under both horizontal and vertical earthquake ground excitations, and the properties of a three dimensional seismic isolation system are decided for the protection of the statues against the three dimensional earthquake excitations.

2.1 The methodology and Ground Motion Data Used for the Analyses

The nonlinear dynamic time history analyses are performed on the 3D finite element solid model of an ancient statue (Figure 2) [9]

Figure 2 Ancient statue used in the numerical analysis

The model is analyzed under the three dimensional acceleration time history data of three different earthquakes which can be seen in Table 1.

Maximum Ground Accelerations (g)	Longitudinal Maximum Acceleration (g)	Translational Maximum Acceleration (g)	Vertical Maximum Acceleration (g)
Athens 1999	0.84	1.01	1.20
El Centro 1940	0.31	0.22	0.21
Aquila 2009	0.41	0.44	0.49

Table 1 Maximum accelerations used in the numerical analysis

The analyses are carried out in three stages. First, the acceleration time-history data of the earthquakes are applied to a 3 storey reinforced concrete frame which represents a generic museum building with a horizontal base isolation system. Then, the acceleration time-history data are obtained at each floor of the building model. Finally, the acceleration time-history data obtained from this model are given as the time history acceleration input to the ancient statue model. The analyses are carried out in two different parts;

1) The acceleration time-history data obtained from the non isolated building is given as the input time history data to the statues, in which case the statues are isolated against both horizontal and vertical excitations,

2) The acceleration time-history data obtained from the base isolated building is given as the input to the statues, in which case the statues are isolated against only vertical excitations.

2.2 Computer Model for the Statues with Three Dimensional Base Isolation System

The model to be analyzed under the earthquake ground motion data is developed with three dimensional 8-node finite elements, and placed on a rigid platform, which is modelled as an area element of rectangular shape (Figure 3).

Figure 3 Three dimensional numerical model

The three dimensional seismic isolation devices are modelled as a combination of two types of elements;

- 1) Non linear spring elements for the horizontal seismic isolation
- 2) Gap elements (compression only) for the vertical seismic isolation

Horizontal seismic isolators are placed between the floor and the rigid platform on which the statues are placed. They are modeled as non-linear spring elements with initial stiffness k_e , post yield stiffness k_y and damping element with the damping coefficient c .

Figure 4 Horizontal isolator element

The hysteresis loop of a horizontal isolator element has a bilinear shape (Figure 4). The force deformation graph is composed of two slopes giving the 'initial' and 'yielded' stiffness respectively. The initial stiffness slope corresponds to the linear deformation; whereas the yielded stiffness slope corresponds to the plastic deformation that takes place in the isolator.

Vertical seismic isolators are placed between the rigid platform and the base of the statues. They are modeled as gap elements, which have positive stiffness values under compression, and zero stiffness under tension loads. Under compression, they show a linear behavior with spring constant k , and damping coefficient c .

2.3 Vertical Isolator Properties used in the Computer Model

The vertical isolation system consists of four springs with linear spring constant k and damping coefficient c . In the computer model, to simulate a vertical base isolation device, a gap (“compression only”) element is used (Figure 5). The force deformation relationship of this element is given by;

$$f(x) = \begin{cases} k(d + open) & \text{if } d + open < 0 \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

Figure 5 Vertical isolator element

As it can be seen in the Figure 6, the gap elements have a linear behavior under compression, and they can not carry any tensile load. In other words, they provide linear stiffness only under compressive loads.

Figure 6 Gap element behaviour

In the model, thanks to the self weight of the statues, these elements are initially compressed. Therefore during the vertical earthquake excitations, they are expected to take action only in the compression range. The vertical isolator elements are constrained at the vertical (z) axis to not to permit differential displacements.

2.4 Behaviour of Three Dimensionally Isolated Statues Displayed in a Building without Horizontal Base Isolation

The analyses are carried out with different horizontal and vertical isolator elements, the properties of which can be seen in Table 2 and Table 3.

Vertical Seismic Isolation Device	Vertical Linear Stiffness(k_v) (N/mm)
Vertical Isolator 1	100
Vertical Isolator 2	50
Vertical Isolator 3	40
Vertical Isolator 4	30
Vertical Isolator 5	20

Table 2 Vertical isolator stiffnesses

Horizontal Seismic Isolation	Initial Stiffness(k_e) (N/mm)	Plastic Stiffness(k_y) (N/mm)	Yield Strength(f_y) (N/mm ²)
Isolator 4	1000	5	350

Table 3 Horizontal isolator properties

The analysis on the seismically isolated model of the statues are carried out under the acceleration time-history data obtained from the ground floor of a non-isolated building. In the Table 4 the reduced vertical accelerations can be seen for three different earthquakes and 5 different vertical isolators.

Maximum Vertical Accelerations on the Statues (Ground Floor)	Athens 1999 (g)	El Centro 1940 (g)	Aquila 2009 (g)
Earthquake Excitation:	<i>1,20g</i>	<i>0,21g</i>	<i>0,49g</i>
Vertical Linear Stiffness (N/mm)			
100	0,79	0,17	0,21
50	0,37	0,13	0,16
40	0,32	0,13	0,16
30	0,26	0,09	0,13
20	0,24	0,05	0,09

Table 4 Maximum vertical accelerations observed on the statues at the ground floor of the museum building

Figure 7 Vertical linear stiffness-maximum vertical acceleration relation

As it can be seen in the Figure 7 and Table 4, the vertical accelerations can be reduced significantly using vertical isolators with low stiffness values. Yet, the stiffness of the isolators must be tuned so that they must be capable of carrying the statue, under its self weight. In Table 5, the initial vertical displacements under the self weight of the statues can be seen.

Maximum Vertical Displacements at the Vertical Isolators	Displacements Under Self Weight (cm)
Vertical Linear Stiffness (N/mm)	
100	3,55
50	7,10
40	8,88
30	11,8
20	17,80

Table 5 Maximum vertical displacements observed at vertical isolators

Using four vertical isolator springs with the stiffness of 20 N/mm under the base of the statue, the initial vertical displacement under the self weight of the statue is 17.8 cm, whereas, it reaches up to 21.65 cm under the strongest vertical excitation (Athens 1999 Earthquake). These results show that under three earthquake excitations, the linear vertical isolator elements perform effectively, satisfying the two necessary requirements:

- They are always under compression
- Their vertical displacement values are within the limits that available products in the market can provide.

Figure 8 Vertical isolator force-deformation graph, Athens 1999 Earthquake

Figure 9 Vertical isolator force-deformation graph, El Centro 1940 Earthquake

From Figure 8 to Figure 10, the link-deformation graphs of the vertical isolator elements, obtained under three different earthquake ground motion can be seen. They represent the behavior of the vertical isolation system placed under each statue and composed of four isolator elements of 20 N/mm linear stiffness.

Figure 10 Vertical isolator force-deformation graph, Aquila 2009 Earthquake

In Figure 11, the displacements at the vertical isolators under the self weight of the statue obtained under three different earthquake ground motion can be seen. All the deformations observed refer to compression condition in the vertical isolation elements.

Figure 11 Stiffness-Displacement relation for the vertical isolation

From the results of the numerical analyses, it can be seen that the accelerations in any direction can be reduced significantly utilizing a three dimensional seismic isolation system. From Table 6, the amount of reduced accelerations and the percentage of reductions can be observed.

The Statues Isolated Three Dimensionally, Placed in a Non- Isolated Building	Longitudinal Maximum Acceleration	Translational Maximum Acceleration	Vertical Maximum Acceleration
	$k_h = 5 \text{ N/mm}$	$k_h = 5 \text{ N/mm}$	$k_v = 20 \text{ N/mm}$
Athens 1999 <i>reduced by:</i>	0,11g 87%	0,10g 90%	0,24g 80%
El Centro 1940 <i>reduced by:</i>	0,06g 81%	0,08g 65%	0,05g 75%
Aquila 2009 <i>reduced by:</i>	0,08g 79%	0,06g 86%	0,09g 82%

Table 6 Reductions in accelerations for the three dimensionally isolated statues placed in the non isolated museum building

The reduction of accelerations can also be seen in the Figure 12, where the peak ground and reduced vertical acceleration history data are drawn.

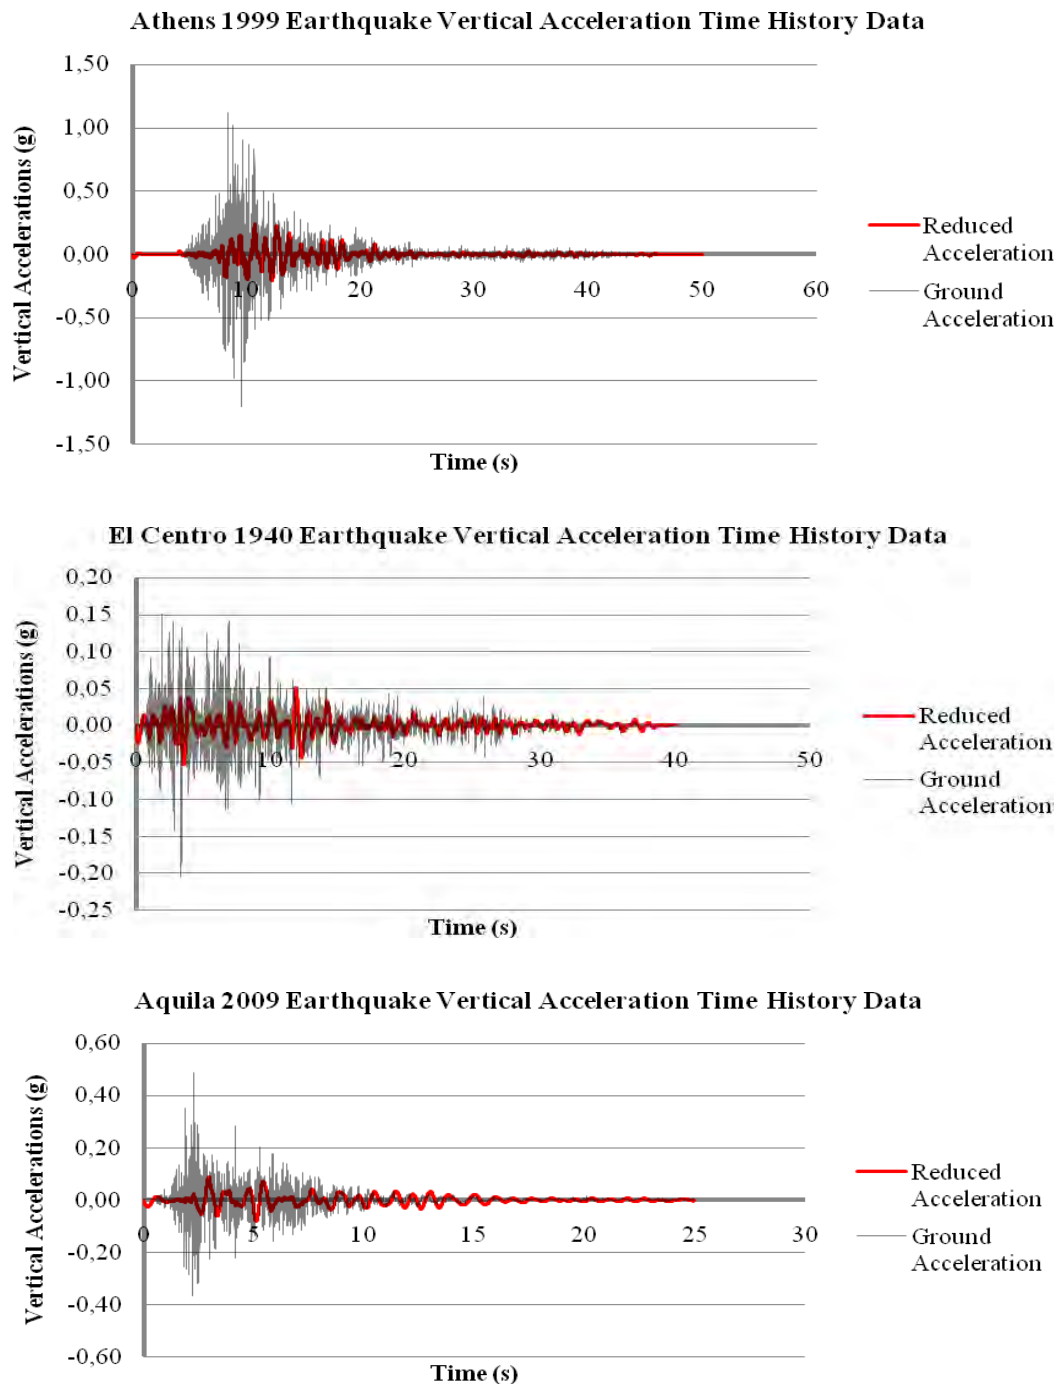

Figure 12 Reductions in Accelerations

2.5 Behaviour of Vertically Isolated Statues Displayed in a Building with Horizontal Base Isolation

In a base isolated museum building, placing the statues upon an additional local horizontal isolation system does not help reducing the accelerations, in contrary, since the frequency contents of the building and the isolated platform of statues become similar to each other, the seismic risk for the statues increase, because of a possible resonance problem. Therefore in order to achieve an effective three dimensional isolation system in a base isolated museum

building, the rigid platform on which the statues are placed is restrained to the ground horizontally, and vertical seismic isolators are mounted between the statue and the rigid platform (Figure 13).

Figure 13 Vertical Isolation Model

For each statue, four vertical seismic isolator elements are used with linear stiffness values of 20 N/mm. From Table 7, the amount of reduced accelerations and the percentage of reductions in each direction can be seen. Note that in this table, the reductions in the horizontal accelerations are obtained thanks to the horizontal base isolation of the building.

Vertically Isolated Statue Placed in a Base Isolated Building	Longitudinal Maximum Acceleration	Translational Maximum Acceleration (g)	Vertical Maximum Acceleration (g)
Athens 1999 <i>reduced by:</i>	0,17g 80%	0,19g 81%	0,24g 80%
El Centro 1940 <i>reduced by:</i>	0,17g 46%	0,13g 41%	0,05g 75%
Aquila 2009 <i>reduced by:</i>	0,08g 81%	0,04g 91%	0,09g 82%

Table 7 Reductions in accelerations for the vertically isolated statues placed in the base isolated museum building

From Figure 14, the reductions of maximum vertical accelerations that the statues experience with decreasing spring stiffness can be seen.

Figure 14 Vertical linear stiffness-maximum vertical acceleration relation

Therefore it can be concluded that in a base isolated museum building, adopting a vertical seismic isolation system, the accelerations that the statues experience in any direction can be lowered significantly.

3 ROCKING ANALYSES

If the vibrations are exceeded above a certain limit, the rigid blocks start “rocking”. Statistically, when the overturning moment caused by earthquake forces reaches the resisting moment due to the self weight, the object starts to rock. This condition can be demonstrated with the following expression for a statue shown in Figure 15 :

$$M_{overturning} = M_{resisting} \quad (7)$$

$$h(ma_h) = b(mg \pm ma_v) \quad (8)$$

where,

h = Height of the center of mass of the object

b = Lateral distance between the overturning point and the center of mass of the object

m = Mass of the object

g = Gravity acceleration

a_h = Horizontal acceleration

a_v = Vertical acceleration

Figure 15 Ancient statue rigid body model

However, since earthquake forces are impulsive, the static approach may not give satisfying results.. Therefore, the accelerations that can start the rocking of a rigid body is estimated using “Impulsive Loading Approach”, in which the minimum impulse that a specific rigid block can tolerate is compared with the impulse caused by the maximum accelerations of the earthquake excitations.

3.1 Initiation of Rocking Motion of a Rigid Block under Impulsive Loads

A rigid block, subjected to the horizontal and vertical accelerations, can either remain in full contact with the ground or it uplifts and starts rocking. During this motion, if the acceleration impulse caused by the earthquake forces becomes larger than the minimum overturning impulse of the system, the object overturns. Otherwise, it continues rocking until the ground motion comes to the end (Figure 16). The object’s full contact to the ground can be kept, if the magnitude of the impulse remains smaller than the minimum impulse required for uplift for the object [8].

While adopting an isolation solution for the protection of ancient statues, attention must be paid to the initiation of uplift because, once the object begins rocking, it starts to have impacts while rotating from one of its corners to the other, and this action may cause serious damage to an ancient statue. In this study, assessment of the horizontal and vertical accelerations that allow the statue to remain in full contact with the ground is carried out in presence of suitable vertical isolation elements.

Figure 16 Rocking and overturning

For the tuning of accelerations through seismic isolation devices, the minimum impulse that can start the rocking motion of the statue is calculated and compared with the impulse caused by maximum earthquake accelerations, which is called as “design impulse”. Finally, interaction diagrams between horizontal and vertical accelerations for the specific ground motions are presented. Examining these diagrams, the allowable horizontal and vertical accelerations that can keep the statue model in full contact with the ground can be decided.

The minimum impulse that initiates the rocking motion of an object is called as the minimum uplift impulse [8]. It depends on the object’s geometric properties (slenderness), natural frequency, (stiffness and mass), and the vertical ground motions. Comparing the minimum impulse of a particular object with the impulse caused by the earthquake excitations, the probability for the initiation of rocking can be foreseen.

In the absence of damping, the minimum uplift impulse of a structure can be found according to the equation (5) in section 1, which shows that, the minimum uplift impulse decreases with the increasing natural frequency and slenderness. Also, the vertical accelerations have a direct effect on the motion. From the equation (5), it can be concluded that,

- More rigid structures (with higher natural frequency) are easier to uplift, than the flexible ones.

- More slender structures (higher h/b ratio) are easier to uplift than the less slender ones
- The upward vertical accelerations reduce the minimum uplift impulse, which results in a lower resistance to the uplift.

Thus, it can be understood that vertical accelerations of the earthquakes are very important for the uplift resistance of the object. The higher values the vertical accelerations have in the upward direction, the easier is the initiation of the uplift.

For instance, if the maximum vertical accelerations of an earthquake equals to $-g$, the vertical excitation parameter, γ (see equation 4) becomes zero, so does the minimum uplift impulse, I_u . This practically means “zero” resistance to uplift, therefore in such a case, even a slight horizontal impulse would be enough to start rocking of the object.

Therefore the effect of the magnitude of maximum vertical accelerations to the uplift resistance of the statue is investigated. To compare with the minimum uplift impulse of the statue, the design impulse caused by the horizontal accelerations of the earthquake excitation must be calculated. After making a comparison between these two values, the probability for the initiation of rocking for the particular object can be estimated.

3.2 Design Impulse

The maximum impulse caused by the horizontal earthquake excitation considered for the analysis is called the design impulse. To estimate the magnitude of the design impulse, the time integral of the earthquake force $p(t)$ should be calculated.

$$\text{Earthquake Force: } p(t) = m \ddot{u}_h(t) \quad (9)$$

$$\text{Magnitude of Design Impulse: } \int_{t_1}^{t_2} p(t) dt \quad (10)$$

This integral can be estimated as the multiplication of the mass of the statue and the area under the acceleration time history graph between two successive time instants, corresponding to the maximum horizontal acceleration. As a reasonable estimation, the triangular area that is drawn in the acceleration time history diagram in Figure 17 gives the magnitude of impulse for unit mass.

Figure 17 Impulse calculation graph

$$I_d = a_{\max} \cdot \frac{1}{2} (t_2 - t_1) \text{ (for unit mass)}$$

In the analyses, the comparison between the design impulse and the minimum rocking impulse of the statue is made by considering three different earthquake data, the properties of which are presented in the previous sections.

The comparison between the magnitude of the design impulse and the minimum uplift impulse shows if the object begins to rock or stays in full contact with the ground.

- If the design impulse is smaller than the minimum uplift impulse, the statue stays in full contact with the ground

$$I_d < I_u \rightarrow \text{Full Contact}$$

- If the design impulse is larger than the minimum uplift impulse, the object starts to rocking

$$I_d > I_u \rightarrow \text{Rocking}$$

To generalize the results for all three of the earthquake data, the same calculation procedure is applied with particular parameters of each analyses, and the results are presented as interaction graphs between the horizontal and vertical accelerations. The interaction graphs are shown in the figures 19,20 and 21. The trend line shows the intersection of the magnitudes of maximum horizontal and vertical accelerations below which the statue stays in full contact with the ground, during the specific earthquake motion. The points above the trend line represent the acceleration values that are sufficient to start the rocking motion.

Figure 18 Interaction diagram of horizontal and vertical accelerations for the initiation of rocking

Figure 19 Interaction diagram of horizontal and vertical accelerations for the initiation of rocking

Figure 20 Interaction diagram of horizontal and vertical accelerations for the initiation of rocking

4 CONCLUSIONS

In this study, the effective ways to protect the ancient statues against three dimensional earthquake ground motions are investigated through seismic isolation methods. Several numerical analyses are carried out to understand which type of isolation system is suitable for each case. It is seen that both the horizontal and vertical accelerations transmitted to the statues can be reduced significantly, with a combination of vertical isolators at the base of the statues and horizontal base isolation system of the building. If the museum building in which the statues are to be displayed is not base isolated, then a three dimensional isolation system must be adopted for the statues.

Rocking analyses are carried out with the results obtained in each case. The results of the rocking calculations for each earthquake data are presented as interaction graphs to show the allowable accelerations under which the statues remain in full contact with the ground, and

suffers no damage due to the impacts during rocking. Principally, it is understood that the vertical earthquake excitations play a very important role on the initiation of uplift of the statues.

It is shown that ancient statues can be protected against three dimensional earthquake excitations effectively, when a seismic isolation system is designed according to their particular material and geometrical properties and the characteristics of the building in which they are to be displayed.

***Abstract.** This paper examines the seismic behavior of three typical traditional houses in the old city of Xanthi using simulation models and the possibilities of restoration and optimization of the Local Historical Structural System used. For this purpose the function of their existing structural system is analyzed and their seismic behavior examined and evaluated using simulation models and time history analysis of the dynamic response to a series of ground motions. Simple, non-invasive structural interventions are selected for restoration and optimization. The seismic behavior of the improved structural system is subsequently re-evaluated using the same modeling procedures. A comparative evaluation of the results obtained from the initial and the post-intervention models is used to assess the global modification of the dynamic characteristics and the anticipated performance effected by the types of interventions examined. The variability of the results owing to parameter changes enables a first assessment of the uncertainties associated with the actual details, geometry and state of materials and the mechanical properties thereof, on the dynamic properties and dependable deformation capacity of the structure at the life-safety performance limit state.*

1 INTRODUCTION

In the framework of a comprehensive strategy for preservation of historical constructions, a decisive step is the thorough identification of the internal force path implicit in their structural system both for assessment of the deficiencies accumulated by deterioration due to ageing and systemic

inadequacies, but also for evaluation of the effectiveness of alternative options for intervention and restoration. In this field of application, detailed simulation through Finite Element modeling, holds promise in promoting understanding of the global building function although at the local level there is great uncertainty with regards the accuracy of modeling a number of behavioral issues, such as interactions between components, individual member connectivity, and constitutive properties of the associated materials.

The present paper explores the use of computer-aided simulation for seismic assessment of a typical historical structural system used in construction of urban residences up to the early 1900's in the area of Xanthi, in Northeastern Greece. Objective of this effort is to identify the potential

Fig. 1: Typical Samples of traditional houses in the historical center of the city of Xanthi.

utility of such methods of analysis in the process of restoration, rehabilitation and reuse of historical or traditional houses, by enabling a better understanding of the structural function of the system of construction, but also in providing guidance for selecting the important behavioral parameters that need to be modified through interventions for improved seismic performance. By definition, when referring to monumental structures that convey a historical value for the community, a certain type of equilibrium must be sought between the need to preserve the structure as a surviving heritage exhibit, and the need to secure the safety of its inhabitants against loss of life or property in the event of a significant earthquake.

In the provinces of Eastern Macedonia and Thrace in the Northeastern part of Greece, and particularly in the region of the city of Xanthi the notion of heritage construction coincides with the traditional buildings in the old city quarters and generally with buildings made with the regional historical building system (RHBS), representing the most significant (from a historical perspective) inventory of the built environment in the region. With regards to the city of Xanthi these buildings comprise a vital portion of its historical fabric, identifying the city (Fig.1). The RHBS uses as primary construction materials the stone (natural blocks or man-made solid clay-bricks) and timber (such as timber structural elements, floor ties, timber lacing elements, etc.) enhances in some situations by the use of iron clamps and ties. The art of construction with these materials, with builder functioning in a complex role of observer, creator and engineer, evolved over the years in an improved system whose performance has stood the test of time in a region of active seismic activity. It is paramount to note here, that although empirical, none of the details of the RHBS was left to chance – the contribution of these techniques therefore, in shaping the art of construction through the history of engineering is most likely their most significant attribute as a human achievement. It is noteworthy that the line of development of timber-laced construction dates back to Minoan times, continues uninterrupted in classical Antiquity and the Roman times (Fig.2), and survived till the previous century when industrialization and the emergence of reinforced concrete displaced tradition in the interest of development ([1] Vitruvius 27-23 b.C. 1997, [2] Touliatos P. 2000, [5] Langenbach R 2002, [9] Müller-Wiener, 1995). Evolution of timber laced construction became prevalent in central Europe but it is also the primary mode of traditional construction in the East (Kashmir, India, [4] Langenbach R 2000) presenting several different versions of the basic structural scheme.

Fig. 2: (A) Early form of timber weaved walls [9], (B) Stone masonry timber laced walls [9], (C) Timber laced walls [1].

The traditional system studied in the present paper combines a stiff load-bearing timber-laced stone-masonry wall system for the lower floor, with the upper floor made of infilled timber frame; these were known from antiquity as “opus craticium”. Today they are referred to as fachwerk, tsatmas, or half-timbered system. Interior dividing walls were made of light timber-woven gages coated with a lime-based mortar (mud-based mortar was used in poorer dwellings), usually reinforced with straw or animal hair; this is also evident in ancient monuments, but its use is found throughout southern Europe and Asia. Therefore, in construction of a traditional house these three structural forms are used selectively, combined in an overall structural system and expanded in space following well-defined rules depending on their weight, load-carrying capacity, and stiffness. The system described represents the historical city quarters of Xanthi in its entirety and is marked for the carefully organized geometry (meant to avoid irregularities and large ratios of slenderness in plan or in height, and to exploit the benefit of symmetry, the optimal distribution of mass, stiffness and ductility).

One important distinguishing characteristic is the relative compliance of connections between members, despite their robustness. This means that all members participate to lateral load resistance as there are no singularly stiff paths for the seismic load to reach the ground. We may say therefore that structures of this class survive the earthquake by practically not “taking”, or “attracting” significant forces; instead, they comply in a controlled fashion, developing wide spread low intensity damage, particularly owing to the frictional interactions between the various components which comprise different materials and types of elements. This creative combination of contact-based resistances, contributes to diffuse the strain energy imparted by the earthquake throughout the building. Thus, through this function, the absorbed energy is consumed by the extensive internal frictions that develop along the interfaces and the connections of the individual elements, materials and structural forms, leading to a large value of *equivalent* or, *effective* damping. Energy dissipation through internal friction is a characteristic mechanism for all three structural forms described (laced masonry, infilled timber frames and timber-woven walls); the process of energy dissipation may continue over a large range of deformation capacity prior to failure. Furthermore, the system is self-adjusting, since failure of the individual building components does not influence to a critical extent the other members of the system. This type of behavior to seismic loads is enhanced by the diaphragm action of the floor system, to a degree that depends on the robustness of its structure and the manner of its connection or attachment to the load bearing walls. In many of these buildings the roof timber truss is elastic and does not contribute by diaphragm action to the structure.

Note that the above observations and interpretations concern systems where the structural function has not been altered or reversed by arbitrary interventions either by the users through additions or removals of building components, inadequate or misguided retrofit of older earthquake-induced damages, or lack of maintenance. All of the above contribute to the notable performance of the traditional building system to seismic action as documented in reconnaissance studies cited in the literature that present comparative evaluations with the parallel performance of lightly reinforced – concrete construction in major seismic events which, upon collapse, have proven lethal to human life. ([8] Gülhan D, Güney I.O 2000, [7] Tobriner S. 2000, [5] Langenbach R., 2002, [3] Vintzileou E., 2007, [4] Langenbach R., 2000, [6] Makarios T., Demosthenous M. 2004).

With regards the objective of seismic upgrading, the need to secure a level of protection to the users of a heritage building under accidental actions that is consistent with contemporary perceptions of acceptable risk, is potentially orthogonal to the spirit of international treaties for preservation and non-invasive restoration of important monuments. These usually encompass both the use, accessibility, appearance of the edifice, but also the structural function of the various components (such as foundations, ability for stress redistribution, compliance of the individual elements and connections thereof, reversibility of the intervention, compatibility (in terms of compliance and physical characteristics) of the new materials with the originals, etc.). A determining factor is the building itself and its condition.

To demonstrate the efficacy of the rehabilitation protocols their performance as a means of modifying the dynamic response and the seismic demands of the structural systems on which they are used, is evaluated through modal analysis of a number of representative traditional houses from the historical center of Xanthi. These are referred to hereon as Buildings A, B and C for convenience. Although built with similar methods of construction, each one of the three structures possesses distinguishing features that are called on here to test or to illustrate the issues of concern in the basic simulation methods employed for the purposes of assessment. Interventions considered in the analytical models are outlined below.

2 PROPOSED REHABILITATION WITH NON INVASIVE METHODS

Usual conditions imposed by international treaties on historical structures restrict the breadth and extent of interventions by the requirement of reversibility and compatibility with the existing substrate. For this reason, materials chosen must be entirely compatible in terms of the rate of strength gain in time, stiffness, porosity, adhesion, while at the same time possessing resistance to biological and chemical corrosion agents. In this work each remedial plan includes a combination of the following measures:

- (a) Deep repointing in the perimeter stone walls (after removal from the joints of any old crumbled mortar and cleaning with water pressure), replacement of decayed timber lacing, repair of all timber connections.
- (b) Fiber reinforced mortar coating on wall surfaces where functionally and aesthetically acceptable by the utility of the rooms and structure.
- (c) Replacement of decayed timber in floor joists, diaphragms and trusses. Where needed add intermediate beams to increase the floor stiffness. Replacement of flooring and roofing interlocking planks and dense nailing on the timber beams in order to secure composite action of the floor beams.
- (d) Removal of roof tiles, replacement or treatment of decayed timber elements, restructuring of the roof with water insulating membranes under the original or properly replicated tiles.

For the needs of computer assisted simulation of the rehabilitated structures, and with reference to the characteristic compressive strength of masonry defined according with EC 6 ($f_{wk} = K f_b^{0.7} f_m^{0.3}$, short term elastic modulus $E = 1000 f_{wk}$, where K a parameter that depends on the type of the stone blocks (sb) and joining mortar (jm), f_b is the compressive strength of the sb's, and f_m the average compressive strength of the jm), the following properties are assumed:

- Stone masonry of lime and granite composition, $f_b = 20$ MPa, $f_m = 2$ MPa, $K = 0.45$. Characteristic strength $f_{wk} = 4.5$ MPa, $E = 4.5$ GPa, and density $\gamma = 2200$ kg/m³.
- Solid clay bricks, $f_{wk} = 2.25$ MPa, $E = 2.25$ GPa, and density $\gamma = 1800$ kg/m³.
- Voided clay bricks, $f_{wk} = 2.25$ MPa, $E = 2.25$ GPa, and density $\gamma = 1800$ kg/m³.
- Timber lacing components, $E = 10$ GPa, density $\gamma = 800$ kg/m³.
- Repair mortar, quality M10 (EN998-2), $f_m = 10$ MPa, composition (lime-cement-sand volume ratios): 0.5:1.0:5.0 which is expected to give rise to an average compressive strength for the joining mortar to 3.55 MPa (based on the preceding strength equation), which is expected to impact the mechanical properties of the finished masonry wall as follows: $f_b = 20$ MPa, $f_m = 3.55$ MPa, $K = 0.45$, $\delta = 1$, and a 19% increase in the characteristic strength to $f_{wk} = 5.358$ MPa, and $E = 5.358$ GPa.
- It is further assumed that the sectional area of the timber diaphragm elements will be doubled from the initial situation by interpolating additional joists, replacement of the flooring planks and addition of roofing layers in each floor (under the joists) and the overall stiffness of the diaphragm will be increased by means of strengthening all connections.

3 DESCRIPTION AND SIMULATION OF BUILDING A:

The building is depicted in Fig. 3. It is located in the Metropolis square, with a total height of 9.05 m from road level (i.e. 9.95 m from basement floor), with plan dimensions of 10.25 by 9.5 m, floor heights 2.4m (basement), 2.8m (first floor), 3.0m (second floor) and 1.75 m (roof). Simulation was based on the idealization of the two facades parallel to the seismic action in each case, using a series of planar frames linked by horizontal nonlinear springs that represented the diaphragm stiffness; nonlinear frame members were located on the centroidal axes of the piers, whereas connectivity was based on rigid links between members to account for the actual

depth of the piers in the direction of seismic action (Fig.4). The earthquake record used to assess the peak dynamic response of the structure is the well known ElCentro (1940) NS component

Fig. 3: Building A: (a) eastern view, (b) plan, (c) cross section

which is often used as a standard design earthquake motion (peak ground acceleration of 0.33g).

4 DESCRIPTION AND SIMULATION OF BUILDING B:

In the same neighborhood as building A, this structure is 12 m high (measured from the basement floor to the top), with a slightly irregular plan, having dimensions of 10.25 m (north side), 11.05 m (south side), 8.80 m (west side), and 8.35 m (east side). The building is depicted in Fig.5. Clear floor height is 2.90 m (basement), 3.4 m (first floor), 3.3 m (second floor), and 1.75 m (roof). Modeling was based on a three-dimensional idealization of the structure using a nonlinear frame-type model for each façade, where the frame elements modeling the masonry piers were located along the axes of the piers with rigid zones securing the connectivity of nodes of adjacent beams and piers (Fig. 6, 7). Diaphragm action was modeled using diagonal braces in the horizontal plane (Fig.8), whereas seismic hazard was represented by the Montenegro earthquake (1979).

Fig. 8: (a), (b) Modelling diaphragm action through diagonal links in the horizontal plane (numbers correspond to frame nodes)

5 DESCRIPTION AND SIMULATION OF BUILDING C:

This building is located on Botsari street in the historical center of Xanthi. Its total height is 12.5 m (measured from the basement to the top), whereas plan dimensions are 12.20 m (north-south direction) by 7.65 m (east-west direction); thus the slenderness ratio for this structure was 1.63 (in the shortest plan direction). Clear storey height is 2.50 m (basement), 3.35 m (first floor), 2.95 m (second floor), 2.5 m (third floor) and 1.20 m (roof). The build-

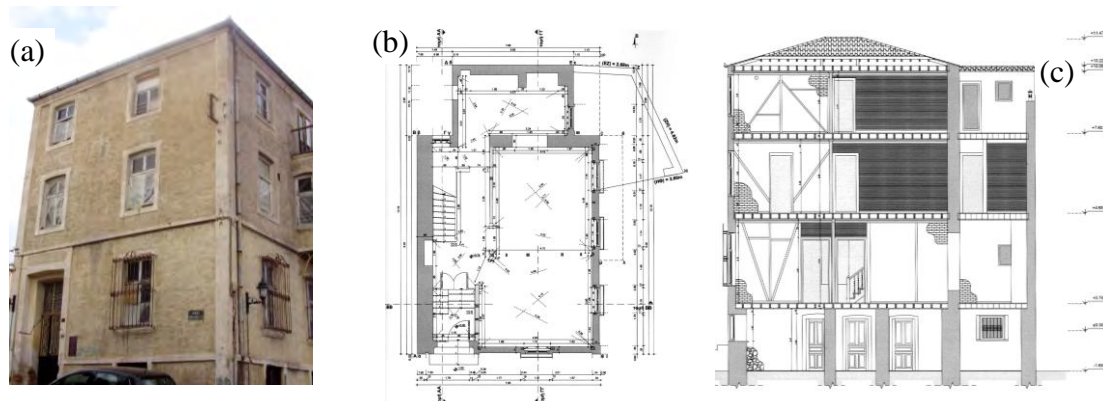

Fig. 9: Building C on M. Botsari Street: (a) South-eastern view, (b) Plan (c) Section

Fig. 10: Discretization of the traditional system, - Views (a) Eastern, (b) Northern, (c) Western, (d) Southern

ing is depicted in Fig. 9. This structure was modeled using 3-dimensional shell elements; finite element dimensions are in the range of 0.3 m to 0.45 m whereas timber lacing is represented by linear beam elements (Fig.10). A grillage analogy is used to model the floor beams at a spacing of 0.7m. Connection of the building along the vertical contact surfaces

(for the embedded depth of the basement) with the ground was modeled through one-sided nonlinear gap elements (mobilized in compression only to model bearing of the wall on soil

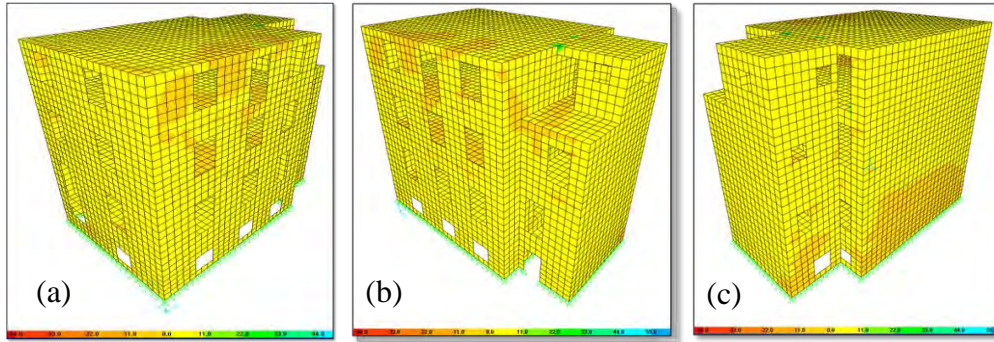

Fig. 11: Distribution of stresses σ_{max} in the original state of the building facades

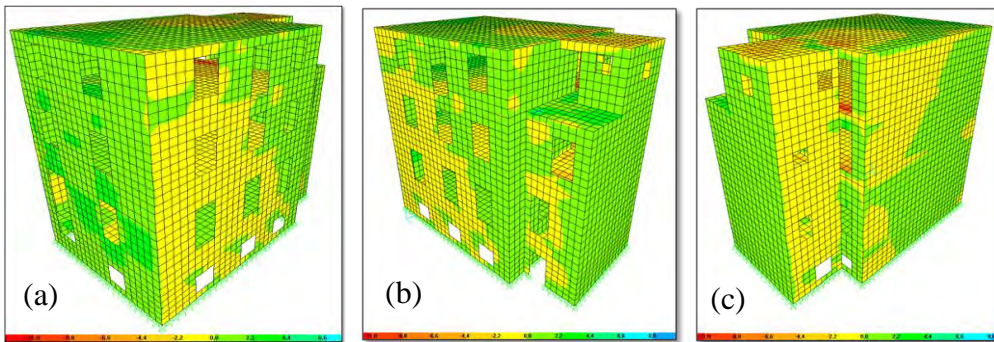

Fig. 12: Distribution of stresses σ_{12} in the original state of the building facades

Fig. 13: (a) Lateral translational pattern U1,

(b) Lateral translational pattern U2

action), whereas at the base fixity conditions were assumed against horizontal sliding. Gap element stiffness in the x and y directions are estimated from

$$\mathbf{K}_x = k_x \cdot \mathbf{A}, \text{ or } \mathbf{K}_y = k_y \cdot \mathbf{A} \text{ where } \mathbf{A} \text{ the tributary area of each node}$$

and k_x or $k_y = 2.4E_s \cdot y/H^2$, where E_s the soil stiffness (estimated in the range of $E_s=40000 \text{ kN/m}^2$), y is the distance of the gap element in consideration from the ground surface, and H the embedded height of the basement.

Flexural stiffness of the shell elements was estimated assuming cracked section (50% reduction from the reference gross value); masses are calculated from the self weight of the building, where masonry walls in the basement are 0.7m thick, reduced to a thickness of 0.25 m in the upper, clay-brick walls (from first wall upwards). The seismic hazard is represented in

Fig. 14: Distribution of σ_{\max} on the building facades, after implementation of intended interventions

Fig. 15: Distribution of σ_{12} on the building facades, after implementation of intended interventions

this investigation by the nominal Greek Seismic design code spectrum (EAK 2000) using a design peak ground acceleration for the region of Thrace in the range of $a_g=0.16g$.

6 REDUCTION OF DISPLACEMENT DEMAND THROUGH INTERVENTION - CONCLUSIONS

The primary results of this analysis are summarized in Table 1. Values of interest is the percent reduction in the average drift for each building estimated in the as-is, as compared with the post-retrofit condition. Note that regardless of the method of modeling and simulation, the proposed interventions effectively reduce the magnitude of the demands, although they appear more effective in buildings with a frame-type tendency where stiffness enhancement was the reason for better control of displacement demand. In the case of building C, which possessed from the beginning a flexural type behavior as marked by the rather low initial period, much lower effectiveness of intervention in controlling the magnitude of the already low displacement is found. This characteristic is more prevalent in building C as compared to B

Building Code ID & slenderness ratio R (Height to smaller plan dim.)	Displ. Demand before Intervention	Displ. Demand after Intervention	Estim. Peak Drift demand before & after Interv.	Initial & Final Rotational Ductility demand
Building A, R=1.0	57 mm	9.5 mm	0.62%; 0.105%	4.3:0.7
Building B, R=1.4	35 mm	14 mm	0.29%; 0.11%	1.93:0.73
Building C, R=1.63	90 mm	60 mm	0.72%; 0.48%	4.8:3.2

Table 1: Summary of the primary results of this analysis

despite the similar overall dimensions, owing to the fact that the latter is stiffened by one more diaphragm level (5 in C as compared to 4 in B) thereby rendering the upper floors at a greater risk due to the tendency for concentration of higher drift demands in the upper floors of flexural-type structures. Here, the objective is better control of demand distribution as evidenced by the deflected shape of the fundamental mode of the structure prior to and after intervention, which effectively suggests great effectiveness in the pattern of anticipated distribution of damage. Note the magnitude of estimated ductilities obtained from the post-repair drift demand assuming a drift at “yield” of the masonry structure elements in the range of 0.15% as recommended by the Greek Code for Seismic Intervention (KANEPE 2010). Note that the ductility demand is much more effectively moderated in buildings A and B, whereas the ductility demand in C is prohibitive even after the proposed rehabilitation. These simulation findings suggest that more effective strengthening measures are required in the case of building C, its primary weakness apparently being the rather low thickness (and commensurate stiffness and strength) of its free standing clay-brick walls which possess a thickness of only 0.25 m above the basement to the top of the structure without other forms of reinforcement.

Abstract. *The Mediterranean basin is characterized by medium up-to high level of seismic hazard but historical masonry structures, as well as a large number of old, still existing buildings, have been designed only for vertical loads; they were erected according to well established rules of common practice. In countries around the Mediterranean basin the main reason for structural failure is the combination of vertical and seismic actions. Strong earthquakes caused damages or collapse of bell towers in Greece. The few survived till today masonry “slender” campaniles are of considerable age (over one hundred years) and many of them are masterpieces of architecture in the past centuries. The aim of this paper is to perform an analysis of this kind of structures. The finite element program SAP 2000 has been used for the study of the dynamic response of bell towers.*

1 INTRODUCTION

Masonry bell-towers are scattered over Greece with various densities and features from North to South. Although characterized by different stylistic decorations, age of construction and original function, their comparable geometric and structural ratios yield to the definition of an autonomous structural type. In a very concise definition, they can be described as monuments in which the total height is the prevalent dimension. Consequently, these monuments are featured by notable slenderness and this also represents one of the main differences from other historic monuments (churches, palaces, etc) or even ordinary buildings.

In Corfu, an island in north-western Greece, there exist many impressive high bell towers, which are a very important part of its main town's history, Figure 1. Bell towers are some of the only tall structures in the town, which allowed them to be invaluable surveying posts during times of war. In the past, these towers have been built as a symbol of strength, ability, and faithfulness to God (in accordance with Venice structural tradition) [1]. Their purpose lay in pointing to heaven and looking forth to survey. In times of peace, the towers were rung for celebration and mourning, to mark the hours, and in correlation with the Christian Orthodox festivals. In the past, bells were rung frequently, to call people to mass, celebrate Christian events and holidays, even just to keep time. There was at least one bell-tower in every neighborhood and typically, the inhabitants look upon their local bell tower with great pride.

Figure 1: The bell tower of St. Spyridon in the town of Corfu and the bell tower St. Mathias in the village of St. Mathias in Corfu.

Nowadays, it has become common that the bells are played automatically, and there is no reason for a bell ringer to inspect them. Since there is no bell ringer visiting the tower daily, there is no one there to observe the towers' condition and the bell-towers can easily fall into a state of disrepair. Also Corfu bell-towers were erected in areas of relatively high seismic activity. So, in addition to that, it has become evident that the bell-towers have suffered from damages

and cracking caused by earthquakes and lack of repair, Figure 2. It is obvious that a seismic strengthening is essential for them, in order to avoid a total collapse and help them to survive.

Figure 2: Corfu bell-towers have suffered from damages and cracking from earthquakes.

2 DYNAMIC ANALYSIS OF A CORFU BELL-TOWER

For the investigation of a bell-tower's dynamic behavior, it is important to have a clear understanding of its structural parts. A bell tower usually consists of a strong base and a high body with the belfry. The foundation and the ground floor of the tower are constructed with heavier and thicker walls than its top parts near the belfry. Thus the most important parts of a bell tower are the base, the shaft, and the belfry. The base is usually the heaviest part and it is constructed with a non-porous stone material which should be strong enough to bear the structural pressure of the tower.

The shaft of a bell tower is by far the largest physical component of the tower. There are staircases and/or ramps that traverse the shaft, often with several landings on the way up. The shaft is usually made of bricks joined by mortar. The form and the strength of the bricks that were used varied according to the year the tower was erected, as brick manufactures improved the quality of their products over the time in order to reach a better brick resistance to higher pressures. On each of the belfry sides there was a double arch supported by a pier on either side and by a stone column in the center of the double arch. Above the belfry was the bell tower roof, a curved dome of bright red color, based on a cubic drum. The belfry is usually constructed using bricks and in many cases elaborated decorations of stone or clay are added. Generally, inside the belfry bells are supported by wooden beams.

To evaluate the dynamic behavior of a typical Corfu bell-tower, an analytical model with 3D shell and frame elements (Finite Element Method) was developed [2], Figure 3. The tower, built in 18th century, was constructed by solid bricks and lime mortar and its height is 30m approximately. The mass of masonry structure is distributed throughout the wall. So, masonry structures should be analyzed by F.E.M. with shell or solid elements.

Figure 3: The analytical model with 3D shell and frame elements (F. E. M.) of the brick masonry bell tower of St. Spyridon church.

Eurocode-6 has been chosen to define the mechanical properties of masonry [3]. So, the characteristic compressive is given by relation: $f_{wc} = k \cdot f_b^{0.65} \cdot f_m^{0.25}$ where k is constant concerned with the characteristic compressive strength of masonry, f_b is the normalized compressive strength of a masonry unit and f_m is the compressive strength of

mortar. The design compressive strength is given by: $f_d = f_k / \gamma_M$ where the γ_M factor for masonry depends on the category of construction control (A \leftrightarrow high, C \leftrightarrow low), and the category of manufacturing control of masonry units (I \leftrightarrow high quality control, II \leftrightarrow normal quality control). So it was belonged in C- II category ($\gamma_M = 3.0$) and group 3 ($k = 0.40$). The modulus of Elasticity is given by: $E_{w0} = 1000 f_{wc}$ (EC-6, part 6-1, 3.8.2), but the existing pattern of cracking in vertical masonry reduces the initial module of Elasticity. We assume that the relationship between module of Elasticity of masonry with cracking and the initial could be: $E_{wcr} = 2/3 E_{w0}$ [2]. So, according to EC-6 [3], are computed:

- $f_{wc} = k \cdot f_b^{0.65} \cdot f_m^{0.25} = 1.977 \text{ MPa}$, $f_b = 10 \text{ MPa}$, $f_m = 1.5 \text{ MPa}$
- $\gamma_M = 3.0$, $f_{wd} = 1.977 / 3.0 = 0.659 \text{ MPa} = 0.66 \text{ MPa}$
- $\gamma_s = 18 \text{ KN/m}^3$, $m_s = 1.83 \text{ t/m}^3$, $v_s = 0.15$
- $E_{w0} = 1000 \cdot f_{wc} \approx 1000 \cdot 1.977 \text{ MPa} = 1977 \text{ MPa}$,

Take into account the cracking on the masonry walls of the bell-tower, the modulus of Elasticity [2] was considered: $E_{wcr} = \frac{2}{3} \cdot E_{w0} = 1318 \text{ MPa}$

As mentioned above, linear elastic analysis was carried out using SAP 2000 software [4], for bell-tower. The direction of ground acceleration corresponded to the X,Y,Z directions within SAP 2000. The elastic spectrum from Eurocode-8 [5] was used anchored to a basic ground acceleration of 0.24g in agreement with the Greek Code which defines that Corfu belongs to seismic zone II, [6]. The seismic effects were then computed according to the current Greek Code, which is in agreement with international recommendations in the field. For the modal-superposition analysis of the campanile subjected to dynamic loads, the Ritz-vector analysis was carried out, Table 1. The reason that Ritz-vectors yield such excellent results is that they take into account the spatial distribution of dynamic loading, whereas the direct use of the natural mode shapes neglects to consider this important piece of information [7]. From the results of analysis it was observed that the maximum tensile stress in the bell-tower wall occurs in and beneath the arched areas of the structure, Figures 3, 4.

3 DESIGN OF THE STRENGTHENING SCHEME

The analysis and design of strengthening scheme is a real challenge. A higher degree of damage in a historical masonry building is expected during an earthquake if the seismic resistance of the building is inadequate. The decision to strengthen it before an earthquake occurs depends on the building's seismic resistance. The structural system of deficient bell tower should be adequately strengthened in order to attain the desired level of seismic resistance. *A "Monument Safety" level corresponds to a situation in which the maximum probable earthquake (during an assigned time of reference, considerably longer than for ordinary buildings) is expected to produce repairable damages only (EC-8, Part 1-4, Annex F, F 4.4), [5].*

The term strengthening comprises technical interventions in the structural system of a building that improves its seismic resistance by increasing the strength, stiffness and/or ductility. New codes and guidelines are founded on the concept of a structural system being designed or rehabilitated to achieve a particular level performance during an anticipated earthquake. These documents on the strengthening of existing masonry buildings, to increase its seismic resistance are:

- FEMA 273: *Guidelines for the Seismic Rehabilitation of Buildings.*
- New Zealand Draft Code [NZDC]: *The Assessment and Improvement of the Structural Performance of Earthquake Risk Buildings.*
- SERC Report: *Formulation of Guidelines for Assessment of Strength and Performance of Existing Buildings and Recommendations on Retrofitting Schemes to Ensure Resistance to Earthquake.*
- UNIDO Vol. 4: *Post-Earthquake Damage Evaluation and Strength Assessment of Buildings under Seismic Conditions.*
- EUROCODE 8: *Design Provisions for Earthquake Resistance of Structures – Part 1-4 General Rules for Strengthening and Repair of Buildings.*

The strengthening scheme of FEMA 273 [8] and EUROCODE-8 [5] consist many strengthening techniques to remedy structural deficiency, as shown in the Table 2. For monumental buildings emphasis is given to strength material type and the adequate technique to success that is the application of a strengthening mortar on the walls of the inside facade.

The simulation method for the strengthen mortar (concrete) that was proposed is based on the principals of Eurocode-6 [3] and Eurocode-2 [9]. The stress-strain diagram for the design masonry [3], Figure 5, is the same as that for the design concrete [9], Figure 6, parabolic up to 0.2%, rectangular up to 0.35%.

So a wall of masonry could be simulated as a wall of a concrete with mechanical properties of masonry, Figure 7. As a consequence of this strengthening scheme, the overall ductility of the structural system was improved. From the results of frequencies, it was observed that reinforced jacket improves the behavior of the bell-tower, Figure 8.

No	FEMA 273	EUROCODE-8
1	Infilled Openings	Reduction of the mass , particularly at high levels, e.g., by removal of heavy roof covering, etc.
2	Enlarged Openings	Reduction of the eccentricity between the mass and the stiffness centers, to avoid large torsional effects, especially in buildings with strong diaphragmatic action on the floor
3	Shotcrete	Strengthening of walls by means of reinforced concrete "jackets" or steel profiles
4	Coatings for (URM) walls	Improvements of the quality of the masonry (e.g. by grouting). Due consideration should be given to the subsequent increase of stiffness and decrease of damping
5	Reinforced Cores for (URM) walls	improvements of the connections between the resisting elements (e.g. anchorage of the horizontal diaphragms in the vertical bearing elements, etc.
6	Prestressed Cores for (URM) walls	Application of vertical and horizontal confining elements to the walls
7	Braced Masonry walls	Addition of new bracing walls
8	Stiffening Elements	Improvement of the diaphragmatic action of the floors by increasing their in-plane shear stiffness and resistance
9	Enlargement of footings by placement of reinforced shotcrete or with additional reinforced concrete section	Repair or strengthening of foundation

4 CONCLUSION

In this paper it has researched the benefits of reinforced concrete strengthening of historical masonry bell towers. This method is proposed as strengthening method from FEMA 273 [8] and EUROCODE-8 [5]. The simulation method for reinforced concrete (gunite) strengthening that it proposed is based on the principals of Eurocode-6 [3] and Eurocode-2 [9]. From the results of frequencies, it was observed an increasing of the total stiffness of a bell tower and generally an improvement of the overall ductility its structural system.

Abstract. *The CEDRAV building in Cerreto di Spoleto, originally a monastery, was built in the 14th century on the top of a rock ridge. The two events occurred on September 26th, 1997, with magnitude $M_s=5.4$ and $M_s=6$, respectively, caused damages to it. Ambient vibration measurements were first performed by using fifteen SS-1 uniaxial velocity sensors (natural frequency 1.0 Hz) connected to five K-2 recorders and deployed in nine different configurations. Then the building was permanently instrumented by using 36 accelerometers. Results from analyses of representative seismic response data acquired from the building specific permanent deployment are also included and classified by means of cumulative normalized energy plots. The building is very complex and rigid. In fact, translational and torsional frequencies are close to one another, coupling occurs and damping ratio is low. Coupling of the frequencies and low damping are two factors that cause beating effect when shaking is strong enough. In the case of this study, the shaking levels are not large but yet the building is affected by beating effect. As stated the CEDRAV is an old buildings and has been altered repeatedly over time. This will cause dynamic interactions with other buildings or substructures during an earthquake.. On the base of recorded data a preliminary analysis in frequency domain, based on the determination of auto and cross power spectral density, has been carried out. Then the modal structure's identification has been performed by means of Ibrahim technique, working in the time domain, and Frequency Domain Decomposition technique, working in the frequency domain.*

1 INTRODUCTION

The dynamic response of the CEDRAV building in Cerreto di Spoleto (Italy), originally a monastery, built in the 14th century on the top of a rock ridge, has been deeply studied by means of experimental measurement campaigns and numerical modeling. Temporary arrays, excited by means of ambient vibration or weak motions, and a permanent array to obtain records of seismic events were deployed. Two events occurred on September 26th, 1997 (epicenter Colfiorito, distance ≈ 30 Km), with magnitude $M_s=5.4$ and $M_s=6$, respectively, and one on October 14th, 1997 (epicenter Sellano distance ≈ 10 Km), $M_s=5.4$. They caused damages to the building but only strong-motion records from the free-field accelerometric array were available to try to correlate the seismic input with the damage. Ambient vibration measurements were first performed by using fifteen SS-1 uniaxial velocity sensors (natural frequency 1.0 Hz) connected to five K-2 recorders and deployed in nine different configurations. Then the building was permanently instrumented by using 36 accelerometers. Transducers were installed in different locations of the structure. In particular, some of these were arranged on the perimeter walls to obtain torsional modes of the structure.

When recording seismic events, use integrated arrays is essential, i.e., to deploy free-field sensors in parallel to those in the building, to assess the ground shaking [1, 2]. It is worth noting that the structure may experience non-linear behavior during strong earthquakes. Thus, if the parameters of linear behavior are known beforehand, it may be easier to extrapolate the non-linear behavior but this process is very difficult for old damaged masonry buildings. For such cases, even for very small excitation, non-linear behavior may be experienced by the structure, which could be approximated with a pseudo-linear approach.

2 ENERGY PLOTS OF RECORDED EVENTS

Results from analyses of representative seismic response data acquired from the building specific permanent deployment are processed and classified by means of cumulative normalized energy plots. Recordings were obtained at 3 different level of the rock basement (CH01, CH02, CH03, CH19, CH20, CH21, CH22, CH23 and CH24 - *Italic evidences sensors in the vertical direction*). Data were compared with those obtained in the station "Cerreto Comune 1 Basement" of the permanent free field array for the event of January 21th, 2000. Figure 1 shows the cumulative Arias intensity for the records at the CEDRAV basement when figure 2 shows the values obtained at the free-field station: for this event the energy in the vertical component seems negligible compared to the horizontals ones. This trend is confirmed in two stations at the CEDRAV basement (CH02, CH20). Figure 3 shows instead the values of cumulative Arias intensity at the array station of "Cerreto Comune 2 Roof" for records obtained during the damaging events (September 26th and October 14th, 1997). First of all we have to outline that accelerograms were recorded by an accelerograph installed in the roof of the building. Of course a larger energy level is observed but the vertical components are still less demanding than the horizontal ones. What it is important to outline is the fact that the after-shock of October 14th was much more damaging for the historical center of Cerreto di Spoleto then the main shock of September 26th. The reason is evident looking at figure 3 where the cumulative Arias intensity evaluated from the acceleration components recorded on October 14th are 4 to 5 times larger than the ones recorded during the main shock (second shock of September 26th). This is shown as well in figure 4 where the cumulative Arias intensity of accelerometric components obtained at Borgo Cerreto Torre station are compared. Values are, of course, smaller because site effect as the hill morphology and the structural amplification are not included, but the global trend is similar.

Figure 1: Cumulative Arias Intensity plots for the acceleration time histories obtained at the basement of the CEDRAV during the seismic event of the January 21st, 2001, MI=4.

Figure 2: Cumulative Arias Intensity plots for the acceleration time histories obtained at "Cerreto Comune 1 Basement" during the seismic event of January 21st, 2001.

3 PERMANENT ARRAY VERSUS TEMPORARY DEPLOYMENT

Information on CEDRAV building may be obtained from two sources: dynamic testing of the structure (ambient and forced vibration) and analyses of data from permanent array. The second is based on strong-motion response data, which depends on a long duration project that is costly to implement and maintain. Therefore, whenever possible, low-amplitude tests are used to verify the results of analytical studies. On the other hand the seismic behavior of structural systems can be better understood if arrays of seismic sensors can be deployed throughout the structures in order to record their responses during strong shaking events. In more details, temporary arrays are generally used for dynamic characterization of structures, which can be excited by means of ambient or forced vibrations [3].

The CEDRAV building was both instrumented with a temporary deployment of velocimetric sensors in 9 configurations and then with a permanent strong-motion array of accelerometric sensors [3]. Recordings of both arrays were analyzed and compared to recover the dynamic characteristics of the building (resonance frequencies, damping, etc.) [3, 6]. Of course, the interest of results is limited by the fact that the building was not instrumented dur-

ing the shocks of September 26th and October 14th, 1997. Nevertheless the following results were obtained:

- The building is very complex and rigid; translational and torsional frequencies are close to one another;
- Coupling occurs. Damping percentage is low. Coupling of the frequencies and the low damping are two factors that cause beating effect when shaking is strong enough. In this study, the shaking levels are not large but the building is affected by beating effect yet.
- The results obtained from the velocimetric recordings are very similar to those obtained by means of the accelerometric recordings. The differences in the resonance frequency values are to be related to the fact that higher energy events were recorded by the temporary arrays.

Figure 3: Cumulative Arias Intensity plots for the acceleration time histories obtained at "Cerreto Comune 2 roof" during the seismic event of September 26st, 1997 (2 shocks magnitude $M_I=6$ and $M_I=5.4$, epicenter in Colfiorito), and of October 14th, 1997 ($M_I=5.4$, epicenter in Sellano).

Figure 4: Cumulative Arias Intensity plots for the acceleration time histories obtained at "Borgo Cerreto Torre" during the seismic event of September 26st, 1997 (2 shocks magnitude $M_I=6$ and $M_I=5.4$, epicenter in Colfiorito), and of October 14th, 1997 ($M_I=5.4$, epicenter in Sellano).

Figure 5 shows velocity time-histories from the temporary array recorded at the three different levels of the building, where an approximate period of 2.5 s for the beatings was computed. In figure 6 the comparison between PSDs of recordings obtained from ambient noise, weak motion and impulse, produced by lifting a caterpillar tractor arm and dropping), in Configuration1 is shown. It is clear that the most severe excitation was the impulse.

Figure 5: Velocity time-histories from the temporary array, Configuration 1. Records were obtained at 3 different level (cdrvch01=basement, cdrvch09=2nd floor, cdrvch11=3rd floor).

Figure 6: PSD (normalized to the peak) of time-histories from the temporary array (CH11), Configuration 1. Records are obtained from weak motion, ambient noise (n) and impulse (s)

As previously stated, the 9 configurations of the temporary array were used for the dynamic characterization of the building, which have been excited by means of ambient or forced vibrations (shock) and sometimes by means of weak seismic events [1, 2, 3, 6]. The knowledge of the influence of the dynamic interactions with adjacent buildings on the modal shapes and frequencies is of fundamental importance to characterize the mechanisms that underlies the damage time history, as will results in the description of behavior of the building. It is worth pointing out that temporary arrays are useful to analyze private buildings, where sensors fixed on the structure are usually not allowed. The reason to select a certain number of configurations depends on the cost/benefit analysis: more configurations you select more accurate your analysis is, but this requires more resources to use for the analysis. So we decided to use eight configurations: four configurations to study the building behavior, and four configurations to investigate the structure-environmental built interaction [6].

The dynamic characterization of the structure, using ambient and forced vibration tests, allowed to have very important information about the health status of the structure and to point out its main dynamic characteristics. Results from Configuration 6 outline a peak at 6.2 Hz associated to a modal shape involving the rectangular building and the church motion, in which the structure rotate with respect to a vertical axis. Results from Configuration 8, in which CEDRAV and a smaller building connected to it by means of a masonry arch were in-

strumented, pointed out that the behavior of the CEDRAV wall with reference to the masonry arch depends on the analyzed event. These observations may be important to evaluate the damage induced mechanism by the October 14th 1997 event ($M_l = 5.4$) on the NW wall of the CEDRAV building.

4 NUMERICAL MODEL AND EXPERIMENTAL DATA

A 3D finite element model has been developed by using the computer code COSMOS with the purpose to compare the numerical results with those obtained by the experimental measures [4]. Based on standard (obtained from literature) material mechanical characteristics, the values of the frequencies for the first twenty modes were evaluated. In particular the elastic modulus was obtained equating the first resonance frequency with the experimental one. Figure 7a shows the selected finite elements representing the CEDRAV building and the environmental built and figure 7b, 7c and 7d show the first three modal shapes. In order to validate this elastic model the acceleration time-histories recorded at the basement during the June 28th 2000 event was used as seismic input for the model, and acceleration time-histories at the measurement points evaluated and compared with the experimental ones.

Subsequently it has been proceeded to the modal structure identification by means of the Ibrahim technique, working in the time domain, and the Frequency Domain Decomposition technique, working in the frequency domain.

The Ibrahim technique was much more performing then the Frequency Domain Decomposition technique due to very close peaks in the PSD of recorded accelerograms [4].

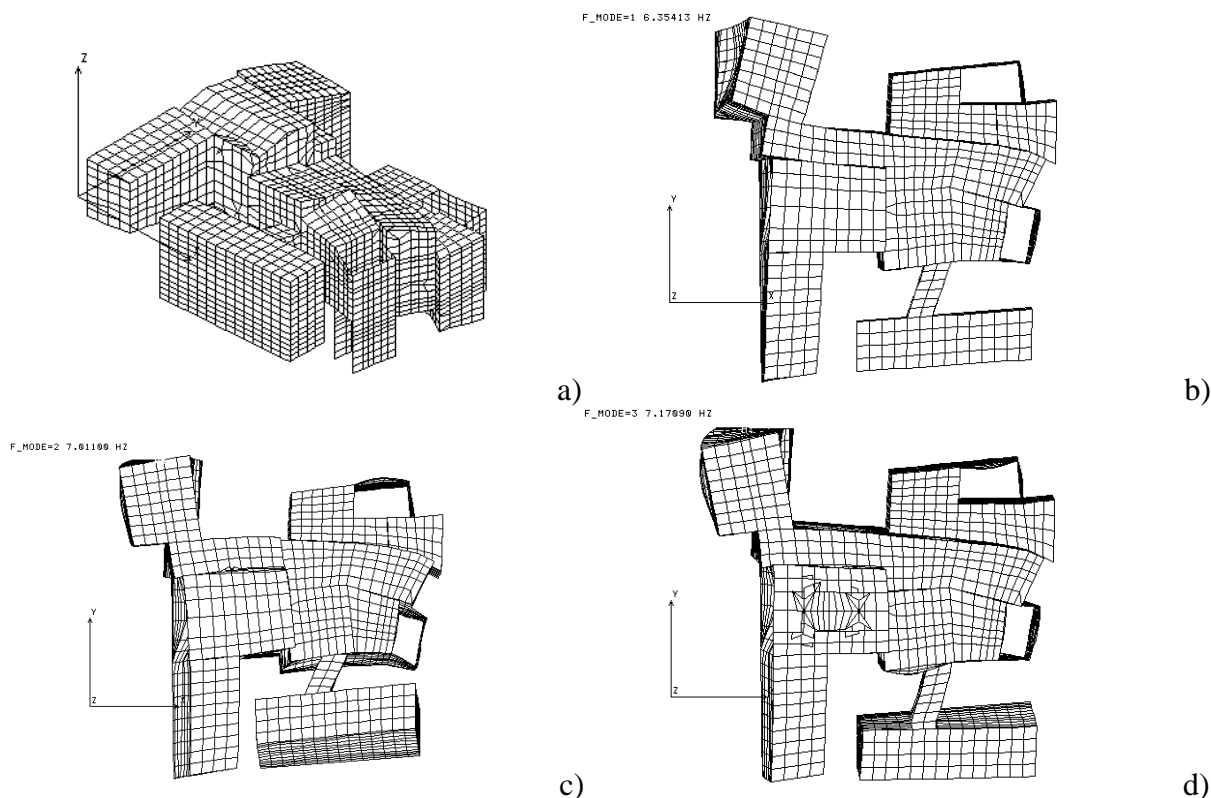

Figure 7: a) Finite elements model; b) first, c) second and d) third modal shapes.

Figure 8: a) Correlation function (Ibrahim technique) and b) singular values of power spectral density matrix function (FDD technique).

5 CONCLUSIONS

The analysis of energy plots from the main shocks of the Umbria-Marche seismic sequence outline the severity of the seismic event. The damage induced to the CEDRAV building was essentially due to the horizontal components of motion. In particular the seismic event of October 24th, 1997, was much more damaging than the main shock of September 26th, 1997, (e.g. the energy in the NS component of the acceleration of the October 14th event was double than the same component in the September 26th event). The dynamic characterization of the structure, using ambient and forced vibration tests, allowed to have very important information about the health status of the structure and to point out its main dynamic characteristics. The knowledge of the influence of building dynamic interaction in modifying the dynamic characteristics is of fundamental importance to characterize the mechanisms that underlie the damage time history. The analysis of temporary array configurations outline how important is the interaction between the building and the environmental built, to the damage mechanism of the NW wall of the building. A deeper investigation of the material mechanical characteristics and the analysis of a model as a sub-assemblies ensemble linked to identification techniques may better correlate the experimental results to the dynamic characteristics.

The health status of the building seems to be quite good. The connections between the walls are effective except for those between the main block and the two adjacent smaller blocks. The structure vulnerability is essentially related to the absence of rigid diaphragms between the walls, necessary to guarantee a suitable distribution of the seismic actions. The floors, in fact, are very flexible to satisfy this requirement. The strengthening of the building will regard essentially this aspect: the existing floors, especially the third and the fourth ones, should be substituted by new rigid floors. The connection between the floors, old and new, and the walls must be realized. The input energy was very low: more evident non-linear effects could be observed in the case of seismic actions.

Abstract. *The paper concerns the seismic vulnerability assessment of masonry bell towers in Italy, which is performed by comparing full non-linear dynamic analysis and non-linear static analysis. An idealized case study is considered, in order to assess some basic and common features of the seismic structural response and to appraise the performance of the proposed approach. The reference model is supposed to be structurally independent, i.e. with no adjacent interacting construction. The geometrical dimensions are chosen in order to represent an average north-Italian masonry bell tower, without the intent to cover all the possible situations.*

The seismic response of these structures involves a coupling between flexural and axial vibration modes, the presence of shear damage patterns, and high vibration modes causing the belfry collapse. The problem is simplified by using a plane 2D scheme. A specific Rigid Body and Spring Model is adopted to describe the in-plane dynamics. Constitutive laws were assigned following a simplified heuristic approach including the main meso-scale damage mechanisms: i) very low tensile strength; ii) significant post-elastic orthotropy plus texture effects; iii) different rules for post-elastic axial and shear damage; iv) different dependence of the shear strength on the vertical and horizontal axial stress component; v) hysteretic energy dissipation due to cyclic loading. Even using a quite coarse mesh, the model is capable to describe the higher vibration modes with a reasonable computational effort and using realistic accelerograms. Non linear static analysis was performed, by using the RBSM model, obtaining the capacity curve and assessing the seismic demand. A comparison between the two approaches is proposed, in order to appraise the difference in the results and to evaluate quality and significance of results in terms of operational drawbacks and reduction of computational times. Particular attention is devoted to the fact that static non-linear analyses tends to neglect the damage effects induced by higher vibration modes, as well as the influence of the shear response on the global damage.

1 INTRODUCTION

In Italy, bell towers are a quite widespread architectural element, with peculiar morpho-typological characters, according to the geographic area.

A main issue in the seismic behaviour of slender masonry towers is the influence of the axial stresses induced by gravity loads, which are often close to the compression strength limit of the masonry material. Considering that historical masonry is typically characterized by complex geometry, irregularities and a high degree of inhomogeneity, stress concentrations can easily occur, which could even trigger a local collapse. Thence, the structural failure can be driven even by a moderate increase in the stress level, which can occur under seismic events or under long term loads. A notable example of the second case is represented by the sudden collapse of the Civic Tower of Pavia, Italy (about 900 years old), on 17 March, 1989 [1]. It is clear, therefore, that masonry towers are vulnerable also to low-intensity earthquakes, since static vertical loads combine with the dynamic loads induced by the ground motion.

The examination of the documentation about the damage caused by the 1976 Friuli earthquake [2] points out that in isolated bell towers damage patterns tend to be distributed all along the height, although it is frequently more severe at the base. This suggests the need of further investigations about the combined effects of flexural and axial actions, as well as the incorporation into the model of the higher vibration modes, which seem to have a relevant role in the damage of the upper part, especially the tower crown and belfry [3].

Moreover, during strong earthquakes shear damages are also often observed, and in this case the reduction of the section stiffness (i.e. the loss of validity of the Eulero–Bernoulli hypothesis of plane cross-section) can significantly affect the overall response of the structure. Specific approaches are needed in order to deal with these aspects, and in particular it is paramount to model the non-symmetry in tension and compression that characterise the masonry material of which these structures are composed [4].

Finally, the investigation of the response to very strong earthquakes requires to describe the effects of the damages that cause a remarkable reduction of the material stiffness, as well as the dissipation of the seismic energy through repeated cycles of plastic deformation [5, 6]. When the tower is not particularly slender, and depending on the frequency content of the forcing actions, a material model which is capable to describe both the axial and the shear response and damage under cyclic loading is also required in order to investigate the global shear damage effects [7, 8, 9].

2 THE RBSM MODEL

The non linear behaviour of the slender medieval towers is studied by means of a specific mechanistic model made by rigid bodies and springs, RBSM which considers only the in-plane dynamics. This model is capable of describing the higher mode of vibration, as well as the combined axial and shear deformation and damage of the material by means of a simplified heuristic approach. The rigid element method (REM) [10] idealises the masonry structure as a mechanism made of rigid elements and springs. The elements are quadrilateral and have the kinematics of rigid bodies with two linear displacements and one rotation, as shown in Figure 1(b). Three springs devices connect the common side between two rigid elements or the restrained sides, as shown in Figure 1(c). These connections are two axial springs k^P and k^R , placed in the point P and R separated by a distance $2b$, and one shear device k^Q placed in the middle of the side. A volume of pertinence V^P , V^Q and V^R is assigned to each connection point. The elastic characteristics of the connecting devices are assigned with the criterion of

approximating the strain energy of the corresponding volumes of pertinence in the cases of simple deformation.

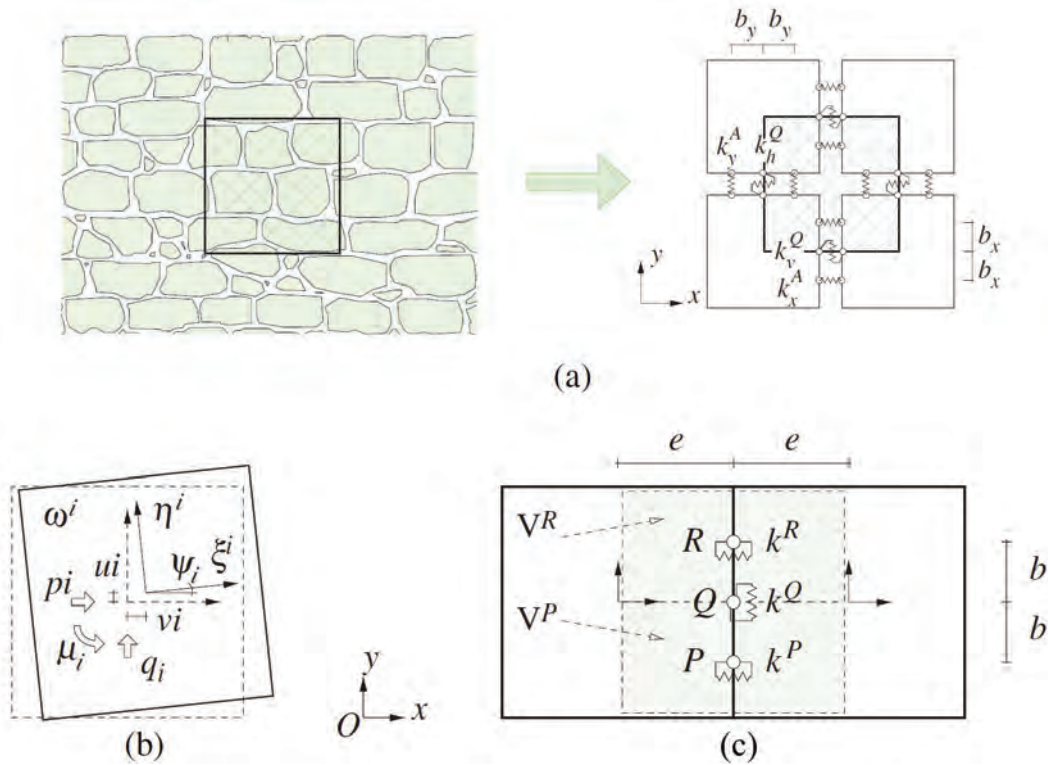

Figure 1: Scheme of a unit cell defined by four rigid elements(a), kinematics (b), disposition of the connecting spring-devices between a couple of rigid elements (c) for macroscale modelling of a representative volume of masonry [10, 11].

The conceptual core of this model is the macroscopic unit cell defined by four quadrilateral rigid elements connected to each other as shown in Figure 1(a). The cell size should be equal or larger than the minimum representative volume (RVE) of the heterogeneous solid material. In particular, the orthotropy of the shear response and the local mean rotation of the blocks, which depend on the different geometric arrangement of the vertical and horizontal material joints as well as the shape and size of the original blocks, are features that can be accounted at the macro-scale [11].

Out-of the linear elastic field, the main macroscopic constitutive aspects are: the very low tensile strength; the significant post-elastic orthotropy combined with the texture effects; the dependence of the shear strength on vertical compression stress; the progressive mechanical degradation during repeated loading; and the energy dissipation capability. To do this, a simplified heuristic approach is proposed, based on the phenomenological consideration of the main in-plane damage mechanisms that can be described at the meso-scale by adopting specific separate hysteretic laws for the axial and shear deformation between the elements. This separation reduces the computational effort, even though a Coulomb-like law is adopted in order to relate the strength of the shear springs to the vertical axial loading.

In the present work, different behaviours have been attributed to the shear connections along the vertical and horizontal directions, somewhat in the spirit of a Cosserat non-linear solid continuum material [11]. Two axial, one shear, and two in-plane flexural loadings are considered for

Figure 2: Schematic representation of the hysteretic rules for the axial (on the left), and the shear connecting springs (on the right).

the parameter identification [10]. The monotonic and hysteretic constitutive laws are assigned to the connecting devices adopting a phenomenological approach and separate phenomenological descriptions of the hysteresis behaviour of the axial and shear connections, as schematically shown in Figure 2. These laws are based on experimental monotonic and cyclic tests available in literature, and should be assigned to rigid elements whose size is approximately comparable to the test specimens in order to limit the problems with size effect. The plastic response of each axial connection is independent from the behaviour of any other connection, while the shear strength is related to the stresses of the axial connections according with Coulomb criterion.

It is worth noting the true discrete character of this model. In fact, during loading, relative motion between two adjacent elements always occurs, with overlapping, separation or sliding between two adjacent rigid elements; numerically, this means compression, tension or shear in the volume of pertinence of the connecting devices. This notwithstanding, the initial contacts do not change during the analysis and the global mechanism maintains the initial connectivity in order to reduce the computational effort.

3 THE REFERENCE TOWER

An idealized case study has been considered, in order to assess some basic and common features of the structural response to seismic actions and to appraise the performance of the approach proposed for the modelling. Such a reference model has been supposed to be structurally independent, i.e. with no adjacent interacting construction, and characterized by geometrical regularity both in plan and in elevation. The dimensions were chosen by looking at a number of significant examples (Fig. 3), in order to represent an average masonry bell tower located in seismic zones of Northern Italy, without the intent, of course, to cover all the possible situations. Of course, the geometry of the model was simplified by disregarding the typical structural details, like – for example – the presence of internal vaults.

On the basis of these observations, it was designed an ideal tower having a $5.30 \times 5.30 \text{ m}$ square base, with a wall thickness varying from 1.00 m at the base to 0.85 m at the top, and having a total height of 28.50 m . In Figures 4 and 5, the 3D drawings and the schematic sections and plans of the tower are shown, and the geometrical characteristics are summarized in Table 1.

Figure 3: Some typical geometry and damage patterns of Italian bell-towers [2].

Figure 4: 3D drawing of the reference tower.

Table 1: Geometrical characteristics of the reference tower.

Total height (H)	28.50 <i>m</i>
Base (LxL)	5.30 <i>m</i> x 5.30 <i>m</i>
Base wall Thickness (t)	1.00 <i>m</i>
Wall mass density (ρ)	1900 <i>kg/m</i> ³
Damping (ξ)	0.05

3.1 Mechanical parameters of the masonry material

According to the constitutive model adopted for the axial and shear springs (Par. 2), a set of parameters are needed in order to define the corresponding skeleton curves and hysteretic rules [7]. The values assigned to the relevant parameters to define the masonry material of the reference tower are: compressive stress at the elastic limit: 1 *MPa*; peak compressive strength: 2 *MPa*; residual compressive strength: 0.2 *MPa*; peak tensile strength: 0.2 *MPa*; residual tensile strength: 0.02 *MPa*; shear value at the elastic limit: 0.088 *MPa*; peak shear strength on the horizontal plane: 0.097 *MPa*; peak shear strength on the vertical plane: 0.165 *MPa*; residual shear strength: 0.02 *MPa* friction coefficient on the horizontal plane: 0.25; friction coefficient on the vertical plane: 0.05.

3.2 Preliminary characterization of the tower

Preliminarily, the analysis of the bell-tower under the only gravity loads was performed (the non structural permanent loads and the service loads were not considered, since they represent a negligible quote of the total loads). The maximum vertical displacement in this loading condition is 2 *mm*. In Figures 12, 13, 14, 15, at the left, are respectively shown the deformed shape, the normal stress map (S_{22}), the shear strain along horizontal direction (E_{12}), the shear strain along vertical direction (E_{21}).

Then the first 3 vibration modes of the tower were determined. The corresponding natural periods are reported in Table 2 and the modes shape are shown in Figure 6.

Table 2: Natural periods of vibration of the first three modes.

Mode #	Period	Type
1	0.517 <i>s</i>	1 st flexural
2	0.128 <i>s</i>	2 nd flexural
3	0.079 <i>s</i>	1 st axial

4 NON LINEAR METHODS: NON LINEAR DYNAMIC VS NONLINEAR STATIC ANALYSIS

Step-by-step nonlinear dynamic analysis is hardly used in the practical application, although it is definitely the most complete and realistic approach for seismic analysis. Indeed, it presents a number of drawbacks, which actually restrict its use to advanced users and very specific case studies: adequate numerical codes, even commercial ones, are not easy available, or introduce too many complications for average end-user; the definition of the model, especially with regard to the constitutive aspects (the post-elastic, hysteretic behaviour of the structure, and the consequent energy dissipation, should be consistently reproduced) is critical; the choice of significant input accelerograms is still a controversial question; the computational cost is very high; the uncertainty about input data strongly influence the reliability of the results. Anyway, in order to predict the nonlinear structural response under strong ground motions, in the last few years simplified procedures have been proposed aimed at performing non linear analysis in a static context (Nonlinear Static Procedures - NSP), where the problem can be more easily managed, and numerical tools with a high circulation are available. These methods, generally known as pushover analyses, have recently assumed a large relevance, especially for the assessment of existing buildings [12]. In these procedures, basically, a computational model of the structure is loaded up with a proper distribution of horizontal static loads, which are gradually increased with the aim of “pushing” the structure into the nonlinear field. The basic idea is that the resulting response conveniently represents the envelope of all the possible structural responses, and can so be used to replace a full nonlinear dynamic analysis. When speaking of historical and monumental buildings, the question is even more critical: nearly all the structural analysis methods suffer from a lot of uncertainties and limitations, mainly derived from the incompleteness of the knowledge level, from the presence of widespread inhomogeneities and nonlinearities, and a complex constructive history.

4.1 Nonlinear Dynamic analyses with design-consistent artificial accelerograms

The full dynamic analyses were performed by using artificial accelerograms to represent the ground motions.

The reference design spectra used are those for the Ultimate Limit State of Life Safety for the zones 1, 2, 3 and 4 in which the Italian territory is classified, assuming an “A”-type soil and no topographic amplification effect (this corresponds to a probability of exceedance $P_{VR} = 10$ in 50 years, i.e. to a return period of the seismic action $T_R = 475$ years).

For each zone, the artificial accelerograms were generated according to the procedure proposed by Sabetta and Pugliese [13]. The resulting accelerograms have been further processed in order to improve the matching with the spectrum.

It will be now presented, as an example, the results of the analyses performed by using 4 accelerograms, one for each of the average hazard level in Italy. In Figures 11, 10, 9, 8 the input accelerograms used respectively for Zone 1, 2, 3 and 4 are shown. In the same figures, some significant outputs of the analyses are also shown: the displacement time-history for two representative points: the control point B, located at the top of the belfry and point A, at the base of the belfry (see Fig. 7); the plot of the base shear against the mean displacement of points A and B; the time history of the dissipated energy. For each zone, the deformed shape at the end of the dynamic analysis have been plotted in Figure 12, and also the vertical normal stress (Fig. 13), the horizontal shear stress (Fig. 14) and the vertical shear stress (Fig. 15).

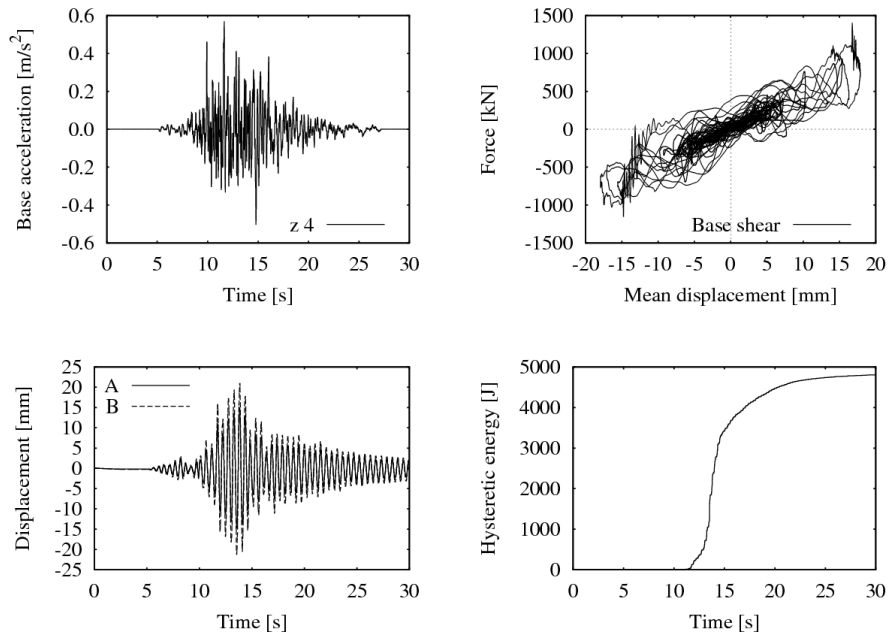

Figure 8: Input artificial accelerogram used for Zone 4; displacement time-history for points A and B (see Fig. 7); Base shear–mean displacement (points A, B) relationship; Hysteretic energy time history.

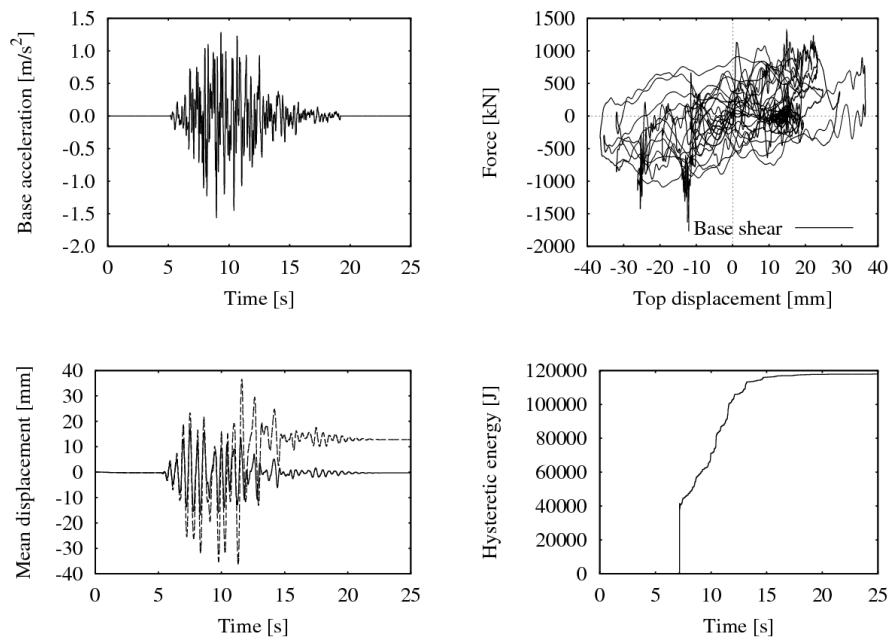

Figure 9: Input artificial accelerogram used for Zone 3; displacement time-history for points A and B (see Fig. 7); Base shear–mean displacement (points A, B) relationship; Hysteretic energy time history.

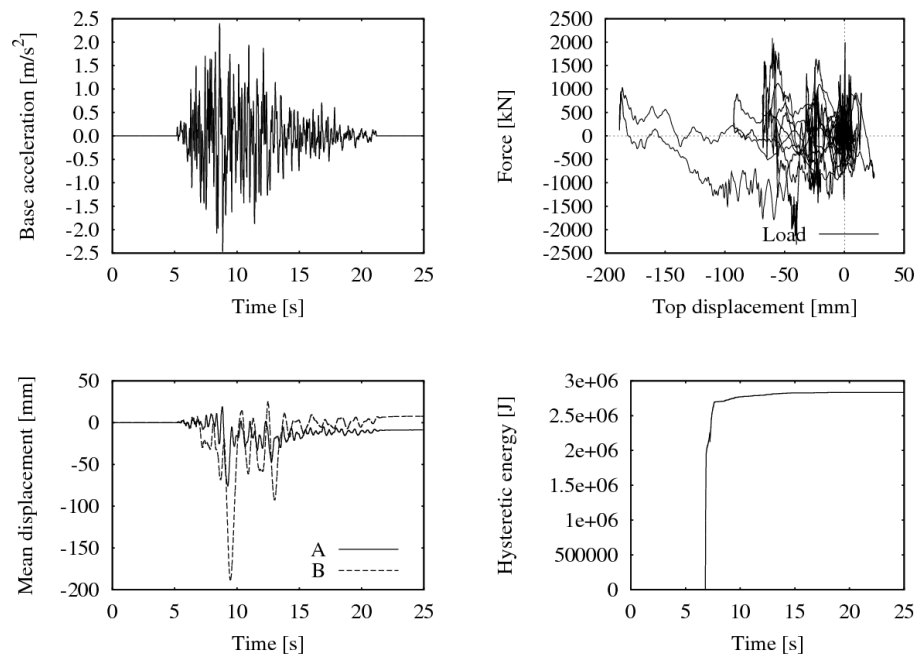

Figure 10: Input artificial accelerogram used for Zone 2; displacement time-history for points A and B (see Fig. 7); Base shear–mean displacement (points A, B) relationship; Hysteretic energy time history.

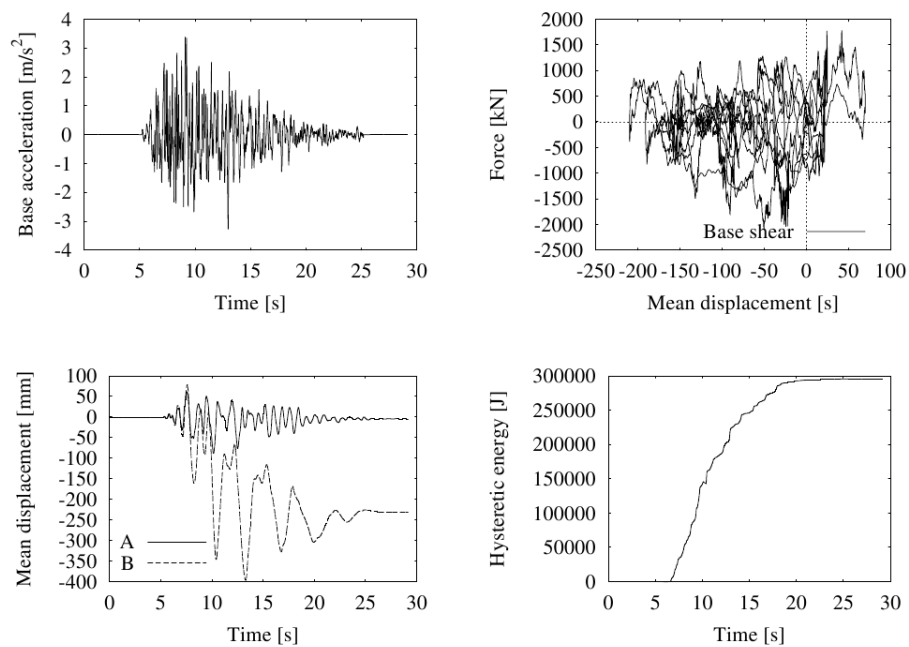

Figure 11: Input artificial accelerogram used for Zone 1; displacement time-history for points A and B (see Fig. 7); Base shear–mean displacement (points A, B) relationship; Hysteretic energy time history.

Figure 12: Deformed shapes for the static loading condition and at the end of full-dynamic analyses (Zone 4, 3, 2, 1).

Figure 13: Normal stress along vertical direction (S_{22}) map: static load condition; ND analyses in Zones 4, 3, 2, 1.

Figure 14: Shear strain along horizontal direction (E_{12}): static load condition; ND analyses in in Zones 4, 3, 2, 1.

Figure 15: Shear strain along vertical direction (E_{21}): static load condition; ND analyses in Zones 4, 3, 2, 1.

The results reported in the figures clearly show the development of a global shear mechanism of damage for the tower. In Zone 4 (low seismic hazard) such a mechanism can already be appraised: by looking at Figure 15, it can be seen that in the lower part of the tower are present significant vertical shear strains in the middle section. The relevance of the global shear collapse mechanism is progressively more evident when considering the accelerogram related to the zones 2 and 1. This is also confirmed by the normal stress map, which shows that the tower is almost split into two separate portions. This is also visible in the deformed shape of Figure 12, where, in the central thin strip, consistent vertical displacements can be observed, which suggest that a failure of the central strip has occurred.

As a consequence of this failure mode, a permanent tilt occurs for all the accelerograms. This can be clearly seen from the displacement time history of point B (Figures 8, 9, 10, 11).

For Zone 4, the permanent tilt is clearly visible in Figure 12, whereas in the other cases it is not evident because of the different metric scale adopted. In fact, for the accelerograms of zones 3, 2 and 1 there is an additional partial collapse mechanism that is activated: the failure of the belfry. The figure 14 shows the development of shear strains on the horizontal plane at the base and top of the belfry, whereas the deformed shape indicates the permanent slidings and rotations suffered by the element: actually it can be said that in these conditions the belfry is collapsed.

4.2 The pushover simulation

The non linear static analysis of the tower is now proposed, following the methods included in the European codes [12], which are based on the well-known “N2 method” [14]. The aim is to perform a critical comparison with the full dynamic analysis, appraising the reliability and relevance of the results. Analyses were performed by applying two different vertical distributions of the lateral loads: a “uniform” pattern (which will be hereafter referred to as “mode 0”), based on lateral forces that are proportional to mass regardless of elevation (uniform response acceleration); a “modal” pattern (which will be hereafter referred to as “mode 1”) corresponding to a distribution of the acceleration proportional to the 1st modal shape.

During the loading process the displacement d_c of the control point B (Fig. 7) was monitored in order to trace the pushover curve in terms of the equivalent lateral force F_b , obtaining the generalized force-displacement relationship: $F_b - d_c$.

The ultimate limit state verification then consists in checking out that the ultimate displacement capacity is larger than the corresponding displacement required by the design seismic action. It is hardly worth observing that in order to perform a nonlinear analysis, even if a static one, a proper numerical code is needed (for instance, a FE code) as well as nonlinear constitutive laws for the materials and the structural elements, able to reproduce the strength and stiffness degradation suffered by the damaged elements. Indeed, the idea of handling a nonlinear static analysis in order to take into account—at least in a simplified way—the inelastic characteristic of the structure was suggested by the availability of codes able to provide these kind of models, whereas the requirements for dynamic analyses are rather oriented to specialist users. It should be anyhow remarked that some operational drawbacks still exist, and even in the most advanced numerical formulations, it is frequent to encounter troubles in the reconstruction of the equilibrium path. In the case study, the pushover analyses were carried out by using the RSBM described in Par. 2.

The methodology includes the following steps: i) transformation of the pushover curve into a simplified bilinear force-displacement relationship for an equivalent SDOF system; ii) definition of the inelastic seismic demand for such SDOF system in the acceleration–displacement

(AD) format; iii) transformation of the displacement demand (i.e. the “target” displacement) for the SDOF system into the corresponding maximum displacement of the original structure; iv) verification of displacement compatibility (according to the current standards, for masonry structures only the global displacement checking is required, and not a specific assessment of single structural elements).

In Figure 16 the results obtained at the end of the pushover analysis performed under the modal pattern are reported: deformed shape; normal stress map; shear deformations along Y -axis; shear deformations along X -axis. The deformed shape at the end of the analysis and the

Figure 16: From left to right: results of the pushover analysis: final deformed shape; vertical axial stress; shear strain along vertical direction; shear strain along horizontal direction.

corresponding maps of the axial stresses and shear deformations reveal that the collapse point is characterized by a global shear mechanism, whereas local damages involving the belfry are negligible.

In Figure 17, the curve expressing the base reactions F_b vs the characteristic displacement d_c of the tower is shown for the loading pattern 1 (distribution of accelerations proportional to the first modal shape), which resulted to be the most demanding condition, together with the force-displacement relationship for the SDOF equivalent system ($F^* - d^*$), obtained by applying the modal participation factor Γ :

$$F^* = \frac{F_b}{\Gamma}; \quad d^* = \frac{d_c}{\Gamma} \quad \Gamma = \frac{\sum m_i \Phi_i}{\sum m_i \Phi_i^2} = 1.79 \quad (1)$$

(Φ is the 1st modal shape of the structure).

The characteristic curve F^*-d^* was then transformed into the bilinear simplified relationship, also plotted in Figure 17, characterized by the yield force $F_y^* = 583.8 \text{ KN}$, by the ultimate displacement $d_u^* = 19.92 \text{ mm}$ and by the displacement at yielding $d_y^* = 15.90 \text{ mm}$ (transformation is based on an equal-energy criterion).

The elastic design spectrum in AD format is a parametric function of the natural period T^* : ($S_{de}(T^*)$, $S_{ae}(T^*)$). Thence, for the idealized bilinear system ($T^* = 0.522 \text{ s}$, $m^* = \sum m_i \Phi_i$), the acceleration demand (strength) in the case of a perfectly elastic behaviour, and the corresponding elastic displacement demand, can be singled out. The inelastic seismic demand is

Figure 17: The pushover curve of the tower (mode 1 load pattern), the capacity curve and the equivalent bilinear curve of the equivalent SDOF system.

henceforth defined by accounting for the system ductility, depending on the range of the spectrum in which the system's period falls. The watershed is represented by the characteristic period of the ground motion T_C , defined as the transition period from the constant acceleration branch of the spectrum to the constant velocity one.

If $T^* \leq T_C$, the displacement response of the inelastic system is larger than the equal period elastic one, and can be evaluated by the following expression:

$$d_{\max}^* = \frac{d_{e\max}^*}{q^*} (1 + (q^* - 1) T^*/T_C) \geq d_{e\max}^* \quad \text{where : } q^* = S_{ae}(T^*) m^*/F_y^* \quad (2)$$

The factor q^* represents the ratio between the force corresponding to a linear elastic response and the yielding force of the equivalent system (it will be always assumed $q^* \geq 1$).

If, instead, $T^* \geq T_C$, like in this case, the equal displacement rule applies: the inelastic displacement demand $S_d(T^*)$ is assumed to be the same as the elastic system having the same period: $d_{\max}^* = d_{e\max}^* = S_{de}(T^*)$, where $S_{de}(T^*) = S_{ae}(T^*) (\frac{T^*}{2\pi})^2$.

Eventually, the displacement demand for the original structure is $d_{\max} = \Gamma d_{\max}^*$, and can be compared with the available ductility provided by the pushover analysis (Fig. 17): $d_u = 35.71 \text{ mm}$.

In Table 3 the results obtained for the four seismic design zones are reported in terms of the elastic spectral acceleration, the factor q^* , the maximum inelastic displacement d_{\max}^* of the equivalent system, and the maximum displacement d_u of the tower.

Table 3: Target displacements and actual available displacements of the structure for the different zones for the modal load distribution.

	<i>Zone 4</i>	<i>Zone 3</i>	<i>Zone 2</i>	<i>Zone 1</i>
$S_{ae}(T^*)$	6.58 m/s^2	4.70 m/s^2	2.82 m/s^2	0.94 m/s^2
$d_{et}^* = d_t^*$	4.55 cm	3.25 cm	1.95 cm	0.65 cm
d_u	3.57 cm			

5 FINAL REMARKS

The use of the RSBM approach [10] is particularly effective for performing in-plane dynamic analyses. In the present work, its application for the seismic assessment of bell-towers has allowed to investigate the structural response under accelerograms corresponding to different levels of hazard, and to perform a nonlinear static analysis, in order to compare two different approaches.

In particular, an interesting result was related to the possible development of different collapse mechanisms. Actually, the main evidence is that while the dynamic analyses provide the presence of a local failure mode involving the belfry, which is a particularly vulnerable element of bell-towers, the pushover analyses only encounter a global shear failure mode. So, even if the results of the assessment performed in displacements terms (seismic demand vs available displacement) supplied by the nonlinear static procedure are quite comparable with the dynamic ones, the information about the damage modes is much poorer. The pushover procedure, indeed, doesn't seem to be able to describe the effect induced by earthquakes on the belfry, which are related to the higher vibration modes.

Abstract. *The paper presents the computational modelling and the seismic damage assessment of a typology of façade that is recurring among the churches built during the colonial period in México, between 16th and 18th century. This typology is symmetric, with two relatively stubby bell towers on either side of the main façade itself, while the openings are usually aligned along the vertical axis of symmetry, including a portal that is much wider than the window underneath the tympanum. Even if these churches were built differently, according to the regional seismicity, this notwithstanding we considered This is an “archetype model” whose characteristics can be considered as a good basis to be representative of this typology in general, even if there is some local variability, mainly related to the regional level of seismicity.*

The main seismic collapse mechanisms of this typology tend to involve both the towers and the central part of the façade with damages that can be related both to in-plane shear actions and to the out-of-plane actions. The central part of the façade often presents damages and cracks along the symmetry axis and along the sides connecting the towers. These towers present very often a localized damage in the belfry due to flexural actions and also can present a damage mechanism related with the torsion in their middle part.

In order to study the complex nature of these damage mechanisms, we adopted two specific Rigid Body and Spring Models (RBSM) to analyse separately the in-plane and the out-of-plane dynamical behaviours. Great attention has been posed into selecting a set realistic constitutive rules to describe the main meso-scale material-damage mechanisms. The main characteristics are: i) orthotropy of the flexural and membranal response; ii) material response is strongly influenced by average vertical axial compression; iii) modelling the hysteretic energy dissipated by repeated cyclic loading.

Given a suitable discretization, these RBSM allowed us to describe realistic damage patterns and also the effects of the higher modes of vibration with a reasonable computational effort and using real accelerograms.

Figure 1: Typical colonial churches built in: a) low seismic risk zone (central Mexico), b) high seismic risk zone (Pacific coast).

1 INTRODUCTION

Ancient masonry structures frequently show extensive damages after being subjected to earthquakes, even in the case of rather moderate seismic intensity. As an example, after the earthquake of magnitude 7.0 that happened in central México on 1999, 1542 colonial churches were detected as damaged, in a radius of more than 100 km from the epicenter. The careful survey and seismic assessment of this architectural heritage affected by such a severe earthquake was a very effective way to understand the structural weaknesses of these construction. These churches, that were mainly built during the colonial period between the 16th to 18th centuries, are quite variable in size and in architectural style, but it is possible to identify a general recurrent typology. Clearly, we should also mention that an important factor which influenced the architectural style was the local experience of the ancient builders due to the regional seismic activity, as shown, for example in Figure 1.

In this context, and for the present study, it seemed appropriate to establish a zone of interest and a typology of church that can be considered as typical. In particular, this typology is inspired by some churches that are present in the the State of Puebla, located around 250 km from the subduction zone. In this area the main earthquakes can be qualitatively considered of “medium” intensity and quite frequent. The survey after the 1999 earthquake showed that even if the number of full collapse was relatively low, this notwithstanding the large part of the hystorical churches suffered heavy damages which had a fairly typical and specific crack pattern. In fact, in these churches the out-of-plane mechanism is rarely preminent, somewhat differently from the experience made after recent Italian earthquakes [1]. On the other hand, it was often observed a complex influence of the presence of two large and relatively stubby bell towers built symmetrically on either side of the main façade.

Figure 2: Typical colonial church of the central Mexico.

2 A TYPICAL COLONIAL CHURCH

Thousands of churches were built in Mexico from 16th to 18th century, and persist to date in rather good conditions; they vary in size and architectural sophistication, but follow some recurrent basic typologies. The simplest among them are rather small parochial churches which are found in every "barrio" of Mexican towns and villages. One important factor that has influenced the evolution of their architectural features has been the experience of damage suffered from earthquake activity. In most areas of the Pacific Coast, where the recurrent destruction of the early colonial constructions produced an evolution towards low rise, heavily buttressed buildings with scarce external ornamentation. In other regions the lower concern for earthquake failures favored taller and more slender constructions, as for example in the area of Puebla, in which we are now focusing our attention.

2.1 Geometric and material description

The typical colonial church in the central Mexico has a Latin-cross floor plan. The Figure 2 shows the isometric projection of the building that we have taken as a representative example of the typology to be studied. In this example, the main nave of the church measures $20 \times 58 \text{ m}^2$, while the height of the vaults is 18 m. Its two bell towers are 28 m high. The roof is constituted by a quadripartite vaulting system. A hemispherical dome is placed over the transept bay and it is supported by the drum. Small buttresses are placed along the main nave. In the first bay there is an intermediate floor for the chorus.

The façade is composed by the "main wall", which is connected with the towers and the frontispiece. A schematic view, in elevation and with a section in plan is shown in Figure 3. The façade has, generally, two openings: the main door and a window for illuminate the chorus. The height of the door is between five to eight meters. The main material of construction is a heterogeneous masonry constituted by stones agglutinated by lime-sand mortar. Frequently, broken clay bricks or lightweight volcanic stones were added to the masonry; this heterogeneous masonry constitutes a kind of concrete whose composition varies according to the structural element; it is lighter than normal stone masonry, and has a tensile strength bigger than brick masonry, due mainly to the absence of weak planes constituted by the mortar layers. On the

Figure 3: Schematical representation of the façade: a) Front view, b) Plan view.

basis of these characteristics, we can consider the material as homogeneous at the macroscopic scale [2]. From the mechanical point of view, the response can be considered almost isotropic, or orthotropic as a function of different factors, such as the type of loading (e.g. in-plane or out-of-plane) and the stress condition (e.g. in the case of prevailing compression load along vertical direction).

The bell tower can be divided in three different parts: the main body of the tower which comprises the base; the belfry which can be made as a combination of superimposed bodies; and the cover, that is often a small hemispheric dome at the top of the bell tower. In plant, the body of the towers can be treated as a square pipe, which is attached to the walls of the façade and to the lateral wall of the nave. Small openings can be found in the main body, which have the function to illuminate and ventilate the stairwell. In general, it is common that the belfry is made by two or three superimposed bodies; being the most top one smaller than the other ones. Sometimes the third body is more similar to a “lantern like” element.

2.2 Typical damages

The observation and evaluation of seismic damage suffered by typical masonry historic churches have allowed to identify their basic modes of failure and the main characteristics of their seismic response: the behaviour is governed by the low tensile and shear strength of constituting materials, which makes it difficult to guarantee the full continuity within and between structural members, in the event of strong ground motions, and leads to specific mechanisms for resisting seismic actions [1, 3].

After the earthquake of 1999, damage surveys of churches from the state of Puebla was made by different institutions, and it was possible to recover reliable data from a total of 30 churches from Puebla. It must be borne in mind that this number is not the total of churches damaged by the 1999 earthquake, especially in the State of Puebla.

The large part of these buildings presented damages on the bell towers, being one of the most damaged elements, both in the belfry and in the main body of the tower, whereas only few cases presented damages in the small dome. The bell towers are rather weak elements, in which the ground motion tends to be amplified in the upper levels. Even if they are relatively low and sturdy, damages are rather common, especially in the vertical elements and in the arches surrounding the belfry. Additionally, their bending and torsion motion tends to separate them from the rest of the church, or to generate shear cracking in the basement of the tower. The façade is typically an heavy wall, poorly connected to the rest of the temple, and the out-of-plane vibrations tend to separate it from the towers. Horizontal cracking in the frontispiece, or in the lower part of the façade weakened by large openings, is rather common, sometimes giving rise to the partial or total overturning of the façade.

3 RIGID BODY AND SPRINGS NUMERICAL MODELS

In order to cover a wide spectrum of possible mechanisms of damage two specific *rigid body spring models* (RBSM) has been considered: one for the *in-plane* [4, 5], and another one for *out-of-plane* numerical analyses [6, 7]. These two numerical models has been implemented with the aim to perform full dynamical analyses by considering non linear behaviour and the mechanical degradation of the masonry material. In the present investigation real recorded ground motions have been adopted as forcing actions.

A procedure of calibration has been performed in order to obtain a good approximation of the fundamental natural modes of vibration of the church, as it resulted from a previous research in which the complete three-dimensional building was investigated in the linear-elastic by a detailed finite element model [8]. In this process, it was also necessary to investigate and consider with some attention the influence of the lateral walls that affects the values of natural periods and modal shapes of the façade. The essential parameters assumed to describe the macroscopic masonry material behaviour are reported in Table 3. Both models were analyzed

Property	Magnitude	Unite
Elasticity modulus	1962	MPa
Shear modulus	817	MPa
Poisson coefficient	0.2	
Mass density	1600	kg/cm ³
Compressive strength	2943	kPa
Tensile strength	147	kPa
Cohesion	200	kPa
Friction angle	15	degree

using as a forcing action the strong ground motion recorded at Ciudad Serdad during the Mexico earthquake on 15 June, 1999. The time history in terms of ground acceleration of the NS and EW components are shown in Figure 4.

3.1 In-plane dynamical analysis

The model implemented for the in-plane dynamic analysis is based on a RBSM approach that was specifically developed for modelling the non-linear behaviour and damage of the ma-

sonry material [11, 4, 12, 13]. This plane model considers the heterogeneous solid material as a mechanism consisting of rigid masses connected by simple elastic-plastic springs, in the spirit of the rigid body spring model (RBSM) [14, 15, 16], and also other discrete element methods [17]. The core of the present model is the *unit cell* defined by four rigid elements connected to each other by two normal springs plus one shear spring at each side, as shown in Figure 5, on the right. Since the model is designed to work at the macro-scale, the size of the unit cell should be equal or larger than the representative volume element of the masonry. Potentially, this model allows to define the elastic characteristics of the springs by a specific procedure of identification with the objective to transfer some characteristics of the internal texture to the macro-scale model [13]. For the present case, as a first approach, and considering the observations written in Section 2.1, the we have hypothesized a masonry texture composed by quite irregular blocks. This implies that this material presents limited effects of microstructure and the description of the global behaviour at the macro-scale can be approximated by assuming a simplified isotropic material based on the parameters reported in Table 3. On the other hand, a simplified phenomenological approach, based on the experimental tests available in the technical literature has been followed in order to model the response under the cyclic loading [18, 19, 20]. Different hysteretic rules are assumed for the axial springs and for the shear springs, as sketched in Figure 6.

A resume of the results obtained by the discrete model made by 237 rigid elements, for a

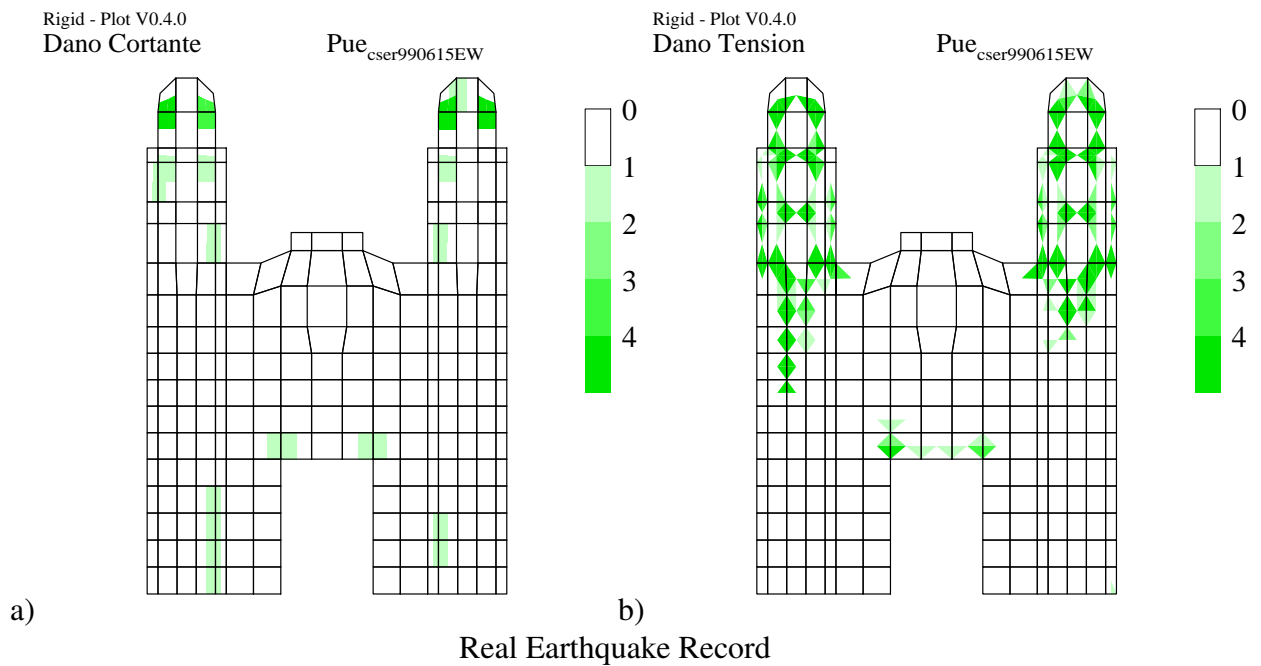

Figure 7: Damages for the in-plane model for real earthquake record: the EW component shown in Figure 4. a) Shear damage, b) Tensile damage

total amount of 711 degrees of freedom, is shown in Figure 7 that reports the damage patterns obtained by a full-dynamic non-linear analysis. A damage index scale $[0 - 4]$ has been created, as a function of the degradation of the mechanical characteristics of the springs of the numerical model. The main damage was related to the tensile stresses due to the belfry flexion. The belfries were the most vulnerable elements in the towers, since they present an appendix-like behaviour. A vertical cracking along the body of the tower is also present, while a slight damage zone due to shear forces is obtained in the main wall of the façade, as well as in the body of the tower. There is no compression damage in any element.

These types of damages are quite similar to the damages observed during the strong ground motions of 1999. The tower tends to separate from the rest of the structure, due to a vertical crack. Thus, this vertical crack is not due to vertical crushing, but it is due to a combination of

shear actions and horizontal tensile forces. As in this particular case, it is rather common that this vertical crack appears along the body of the tower. However in some cases, the vertical crack can appear at the union of the tower with the main wall. Shear cracks are also present in the walls of the central part of the façade as well as in at the base of the tower.

3.2 Out-of-plane dynamical analysis

The out-of-plane behaviour of the masonry façade is modelled at the macro-scale level as an assemblage of quadrilateral rigid elements connected by elastic-plastic joints at which only bending and twisting movements are possible. This model was originally intended to plan out the analysis of relatively slender walls, remaining within the scope of the Kirchhoff plate model [6, 21]. In this sense, as a general rule, the wall should be regarded as a special case of a three-dimensional body $\mathcal{B} \subset \mathbb{R}^3$ with one dimension - the thickness t - small compared to the other characteristic lengths. Hence, the model describes the whole structure in terms of the mid-surface $\mathcal{M} \subset \mathcal{B}$, and only the transverse displacements of this reference mid-surface are considered. For the present research, the model has been enhanced in order to be employed also in the presence of the towers, even if this case cannot be considered, at a first sight, as coherent with the terms of the Kirchhoff model. Nevertheless, we believe that the application of this model is acceptable because it is still able to describe the dynamics of these towers when their response is a mix of flexural and torsional-type. Clearly this analysis should be complemented by the in-plane analysis and moreover it cannot describe the shear damages of the tower out-of the plane the façade.

Thus, a Cartesian reference frame $\{O, x, y, z\}$ is then defined so as the plane $z = 0$ is coincident with the mid-plane mapping that is parametrized by only employing the global coordinates $(x, y) \in \Omega$. The plane domain Ω is then discretized by a partition into m quadrilateral sub-domains ω_i (with $i = 1, m$) such that no vertex of one sub-domain lies on the edge of another one. The mid-point of the sides of these sub-domains is the joint between the elements and is modeled as a spherical hinge from the kinematic point of view. This spherical joint allows small rotations whose axis is in the plane $z = 0$. We distinguish two components of rotation: one in which the axis is parallel to the edge of the abutting elements (flexural deformation), and the

Figure 8: RBSM mesh for the out-of-plane analysis (left), and sketch of an assemblage of 4 rigid elements subjected to flexural and torsional deformation [7].

Figure 9: Heuristics of the mechanical connection between a couple of elements; corresponding layers of non-linear line-springs.

other whose axis is perpendicular to the edge (twisting deformation), as shown in Figure 8 on the right side. The allowed displacements w of the points on the reference xy plane are parallel to z ; they are small when compared to the thickness and are called *deflections*. The mass is lumped into these r connection nodes, as shown in Figure 8 where the mass of the shaded area A_s is given to node S . Then, the mean bending and twisting curvature is measured at each connection joint as a function of the angle between the rigid elements.

The constitutive behavior of joints between the elements is defined on the basis of the one-to-one moment-curvature relations assigned to the bending and twisting springs placed in correspondence of each connection joint S . In the linear-elastic field, the out-of-plane constitutive behavior could be properly described by referring to the homogeneous orthotropic Kirchhoff plate model.¹

Out-of the linear elastic field, the moment-curvature relationship assigned to each connection joint follows a piecewise linear function that is defined following an heuristic procedure in which the behavior of the wall is modelled at a sectional level by a combination of line-springs. In the Figure 9 (top) the cases of flexural damage due to rotation along an horizontal hinge (on the left side) and along a vertical hinge (on the right side) are shown. In the Figure 9 (bottom), we have sketched the different non-linear constitutive laws that are assigned to the line-spring along the vertical direction (for modelling a rotation along an horizontal hinge) and to the line-spring along the horizontal direction (for modelling a rotation along a vertical hinge).

Another aspect that must be considered in the definition of the flexural and torsional out-of-plane behaviour, is the very different effect of the in-plane vertical pressure on the response when considering the horizontal bending or the vertical bending. The geometric texture of the masonry material has also an important role in the definition of the moment-curvature rela-

¹ the orthotropic plate rigidities can be related to the Young moduli and Poisson coefficient according to the following relation, also recommended by M.T. Huber [22]:

$$D_{xx} = \frac{E_x J_{yy}}{1 - \nu^2} \quad , \quad D_{yy} = \frac{E_y J_{xx}}{1 - \nu^2} \quad , \quad D_{xy} = \nu \sqrt{D_{xx} D_{yy}} \quad , \quad D_{ss} = \frac{1 - \nu}{2} \sqrt{D_{xx} D_{yy}} \quad (1)$$

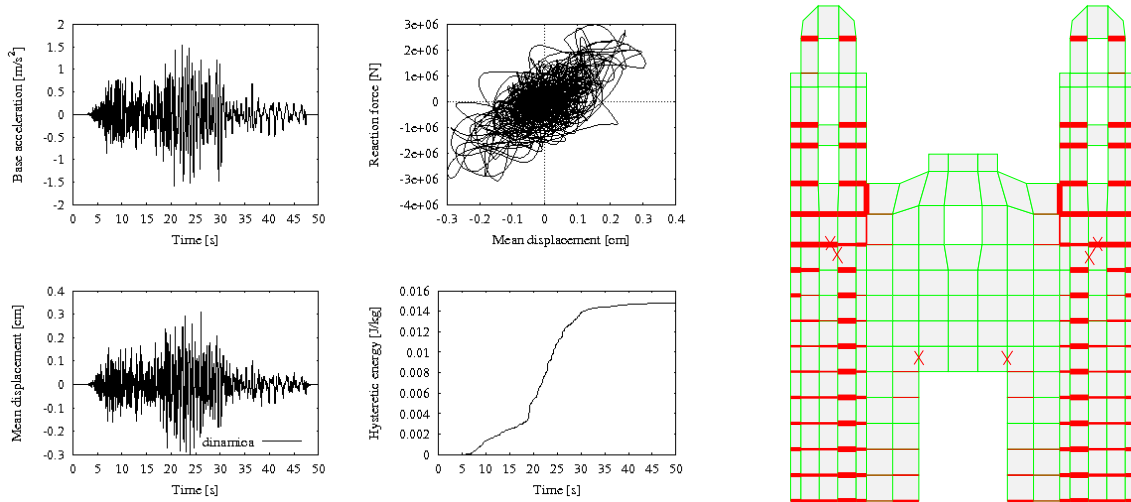

Figure 11: Scheme of damage after PueCSER990615-NS component. Map of energy dissipated.

tionship for the bending along a vertical hinge. As a consequence, the out-of-plane flexural response is strongly orthotropic and variable in the different connection points of the model [23]. In the present model, the simplified out-of-plane homogenization gives skeleton curve that are strongly related to the local vertical compression stress, as shown in Figure 10. As a first approximation, a very simple criterion was adopted here, in which the mean compression stress is assumed as directly proportional to the vertical distance of the connection joint from the upper edge of the specimen.

The non-linear dynamical analysis is performed at the macro-scale by solving the elastic-plastic problem by means of a standard full Newton-Raphson algorithm [24] until the attainment of a prefixed numerical convergence.

The Figure 11 shows a summary of the response to the NS component of the strong ground motion recorded at Ciudad Serdad during the Mexico earthquake on 15 June, 1999. On the left side of the figure, some time histories have been reported, while the drawing on the right side

shows the distribution of the hysteretic energy dissipated during the dynamic analysis, and it can be considered as a reasonable first indication of damage and mechanical degradation. We can observe that the damage pattern is not too much different with respect to the in-plane case already shown in Figure 7. In fact, the most vulnerable parts of the façade are again the belfries (due to out-of-plane flexure) and the joint areas between the towers and central façade. In this particular case we also note that the main body of the façade seems not to suffer from the typical out-of-plane damages that affected in many cases the Italian façades [3, 21].

4 FINAL REMARKS

The first remark of this research is that the behavior of this type of façade, very typical of the colonial churches in México, has some special features that were hardly found in previous studies that were based mainly on the surveys of the masonry churches affected by earthquakes in Italy, for which the out-of-plane collapses were often the main threat. In the present case, the presence of the towers, built in an integrated manner with the façade and not simply constructed in compliance, substantially alter the situation. In fact, on the one hand these towers provide a constraint that reduces the movement off-plan, but also they increase the in-plane actions, and are also committed themselves to a combined bending and torsion stress. We find a framework in which the shear actions have a significant role in the damage patterns, especially in the joints between the facade and towers, and moreover we observed damage due to bending-torsion in the main body of the towers. The complete picture of this behavior must therefore be studied by means of a modelling that should be able to capture all these different aspects. The application of the two models proposed here seems suitable for this purpose and it is considered promising for a subsequent and more detailed investigation of this typology.

Keywords: Earthen Buildings, Adobe masonry, Masonry Modeling, Non-linear Dynamic Analysis.

Abstract. *Despite the fact that earthen construction is a significant feature of the international architectural heritage, the application of sophisticated analysis methods such as Finite Element (FE) modeling in the appraisal and design of adobe masonry structures has received limited attention up to this day. This paper presents some of the outcomes of an ongoing research programme at the University of Cyprus which aims to investigate the structural response of adobe construction. The behaviour of adobe masonry assemblages under the action of compressive loading-unloading cycles is hereby examined both experimentally and numerically. The development of the FE model used in the numerical simulation is based on a macro-modeling strategy while a simple elastic-plastic constitutive law is adopted. All input parameters required are derived from experimental material data. The numerical results are compared with laboratory test outcomes and useful conclusions regarding the applicability of FE modeling are deduced. The use of the formulated FE model is broadened by analyzing a complete adobe structure under various levels of seismic action. The evaluated response of the adobe structure to dynamic excitations is discussed and the constraints imposed by the model used are analyzed. Finally, critical issues that future research should address in order to enable the efficient computational analysis of earthen construction are identified.*

1 INTRODUCTION

Earth masonry composed of unfired clay bricks and earth mortar joints has been traditionally used for thousands of years. Despite its broad and extensive use in the past centuries, its applications in contemporary architecture are nowadays rather limited. However, a large heritage of adobe buildings still survives and constitutes a significant part of the global building stock and an important feature of the international architectural heritage [1]. Experience has shown that unreinforced adobe masonry construction has relatively poor response to dynamic loading and is prone to seismic damage [2-4]. This implies that there is an imminent need for protecting existing earthen buildings from the destructive effects of earthquakes.

The application of detailed/formal engineering procedures in the appraisal of mud-brick structures and the assessment of retrofitting measures is currently hindered, among others, by the absence of accurate computational methods that would account for the specific characteristics of unfired earth. Although over the last few decades the numerical modeling of conventional masonry construction has been studied in depth through academic research (e.g. [5-7]), adobe masonry has generally received limited attention. This is possibly due to its intrinsic complexity that derives from the natural randomness and inhomogeneity of earthen materials. The various constitutive models that have been applied or developed for the numerical analysis of masonry have not yet been studied in the context of earthen construction. In addition, the applicability of the Finite Element (FE) method in the structural evaluation of adobe masonry structural members and buildings has not been adequately investigated and no attempts have been made so far for calibrating and validating numerical models based on the outcomes of laboratory tests and field observations. Furthermore, the formulation of FE models is, up to this date, precluded due to the lack of adequate experimental data describing the properties of earthen materials and the structural behaviour of adobe masonry assemblages.

This paper aims to examine the structural response of earth masonry construction to compressive loading and seismic action through FE analysis. Initially a model of an adobe masonry assemblage is developed and its behaviour under the implementation of compressive loading-unloading cycles is investigated. The formulation of the model is based on the concepts of homogenized material and isotropic elastic-plastic constitutive law, while all the required input parameters are derived from laboratory tests. The numerical results obtained are compared with corresponding experimental data thus enabling the deduction of useful conclusions on the validity of the simulation procedure. In addition, a FE model of a traditional earthen building is developed and used for performing non-linear dynamic analyses. The investigation conducted involves the use of real time accelerograms from a past earthquake. The predicted response of the structure to various levels of seismic acceleration is studied and the outcomes of the FE analyses are presented and discussed. Useful comments regarding the accuracy of the numerical results are made and the technical challenges encountered when dealing with the FE modeling of earthen construction are noted. Furthermore, key issues that future research should address in order to allow for the efficient use of FE modeling in the analysis of adobe structures are identified.

2 FINITE ELEMENT SIMULATION OF ADOBE MASONRY SUBJECTED TO COMPRESSIVE LOADING AND UNLOADING

2.1 Experimental investigation of the response of adobe masonry to compressive loading and unloading

The development and calibration of a reliable FE model that would predict important aspects of the behaviour of masonry construction with adequate accuracy requires the imple-

mentation of laboratory tests [8, 9]. Experimental results can provide information regarding the material properties required for the formulation of the FE model. They can also be used for correcting the inherent deficiencies within the FE model by matching numerical outputs to measured data [9]. Within this framework an adobe masonry assemblage composed of five full-size adobe bricks and earth mortar joints has been subjected to compressive loading-unloading cycles in order to investigate its elastic and post-yield structural response. Prior to this, a number of uniaxial compression tests were also conducted on mud-brick assemblages to assess the capacity of earth masonry to bear static vertical loads [10].

The bricks used for the preparation of the specimen were supplied by a Cypriot manufacturer and belonged to the same production batch. The earth mortar had the same composition as the adobe bricks. It was prepared by mixing soil and straw fibers originating from crushed adobes with water (1155 g of water per 1850 g of solid constituents) to plastic consistency using a mechanical mixer. Stones and gravel with diameter exceeding 4 mm were not included in the mix. The mortar was applied at relatively thin layers (~ 10 mm) between the adobes. The composition of the mortar and the formation of thin joints were intentionally selected in order to replicate the form of adobe masonry that is encountered in local traditional earthen structures. The dimensions of the resulting masonry assemblage were (height x width x length) 28 x 30 x 45 cm³. After being prepared, the assemblage was allowed to cure in the laboratory (22 \pm 2 °C and 42 \pm 5% R.H.) in order to ensure sufficient bonding between the adobe bricks and the mortar.

For the implementation of the compressive loading-unloading test a Lloyd LR300K universal testing machine with 300 kN capacity was used. The machine's platens have a swivel head to accommodate non-parallel bearing surfaces. Four vertical transducers were attached on each corner of the upper loading plate to record vertical displacements during the testing procedure. In addition, two horizontal transducers were placed on each side of the specimen to monitor its deformation in the transverse direction. The test setup is shown in Figure 1. Loads on the specimen were imposed using a displacement-controlled procedure. Displacement was applied at a constant rate of 0.1 mm/sec. Unloading cycles were programmed to take place successively when the load exerted reached a value of 10, 30, 50, 100, 150 and 200 kN. Figure 2 shows the stress-strain curve derived from the experimental data along with the corresponding numerical results obtained from the analysis of the FE model presented in subsection 2.2.

The results of the test indicate that the response of adobe masonry to compressive loading is non-linear and is characterized by intense plasticity and deformability. The parts of the stress-strain diagram that correspond to the application of loading show that the material exhibits progressive hardening. The form of the unloading branches reveals that when the exerted load is released, induced deformation is only partially removed, while considerable inelastic deformations remain present. Plastic deformations start to develop even when the specimen is subjected to low compressive stresses at the region of 0.08 MPa. This behaviour can be attributed to the fact that the sliding and displacement mechanisms, which take place between the soil grains due to the application of pressure, are non-reversible.

During the implementation of the test and after its completion it was noted that the specimen responded monolithically to vertical loading. Compression resulted in the compaction of adobe and mortar in the central axis of the masonry specimen. This led to the formation of a central zone within the body of the masonry assemblage where the visual distinction between the individual adobe bricks and the mortar joints was no longer feasible. No significant cracks or slips occurred at the joints during the loading procedure. Despite the fact that significant cracking and damage was recorded at the lateral sides of the adobe bricks, their central core remained sufficiently integer and did not lose coherence. This particular mode of failure expe-

rienced by adobe masonry under compression has been also noted during the execution of monotonic compression tests [10] and has been reported by other reserachers as well [11].

Figure 1: Pictures of the experimental setup used in the implementation of compressive loading-unloading tests on an adobe masonry assemblage composed of five full-size adobe bricks and earth mortar joints.

Figure 2: Experimental and numerical stress-strain curves referring to the application of compressive loading and unloading cycles on an adobe masonry specimen with dimensions (height x width x length) $28 \times 30 \times 45 \text{ cm}^3$.

2.2 Numerical simulation of compressive loading-unloading experimental test

For undertaking the numerical simulation of the experimental test on the adobe masonry assemblage, the commercial code ABAQUS CAE was employed. Both the adobe masonry specimen and the machine's steel compression plates were modeled. Since the main purpose of the current study is to examine practice-oriented analysis methods that can be applied in the appraisal and design of adobe structural members and full structures, earth masonry was numerically handled in the context of a macro-modeling strategy. The macro-modeling approach treats masonry as a fictitious homogeneous continuum and does not make any distinction between masonry units and mortar joints. Despite this rather oversimplifying assumption, ma-

cro-models have been widely used in the non-linear FE analysis of masonry structures (e.g. [12-14]) and are considered adequate for the characterization of the structural response of large-scale structural elements and full buildings [6, 7]. After all, in practice, the macroscopic structural response (estimation of forces/stresses and elastic/plastic deformations) is primarily of interest as opposed to detailed microscopic information (e.g. cracks initiation and propagation). Treating adobe masonry as a homogeneous medium is further justified by the monolithic behaviour exhibited by the tested specimen during the application of compressive loading.

All components of the FE model were discretized using 8-node 3D linear brick elements (C3D8). Each steel plate was discretized into 70 elements. A more dense FE mesh consisting of 7935 elements was used in the case of the adobe masonry specimen. It was decided to model adobe masonry using a simple isotropic Elastic-Plastic constitutive material model. The isotropic Elastic-Plastic constitutive material model available in ABAQUS CAE is based on classical metal plasticity theory and uses standard Mises yield surface with assorted plastic flow [15]. By default, when cyclic loading scenarios are examined, the aforementioned model assumes that the loading and unloading curves are parallel to the elastic loading curve (with its slope determined through the Young's modulus) [15]. The material characteristics and the elastic and inelastic properties defined in the FE model for simulating adobe masonry were assigned according to the results of laboratory tests. The density of adobe was measured following simple gravimetric methods and the Poisson's ratio was deduced from the recorded values of axial and transversal strains. The Young's modulus was derived from the stress-strain curve of the compressive loading-unloading experimental test. Its value was set to be approximately equal to the slope of the three unloading branches that were recorded after a 5% strain. In order to accommodate for the lack of elasticity that characterizes the behaviour of adobe masonry, a very low value for the yielding stress (0.01 MPa) was assigned. Post-yield behaviour was defined by providing a relation between compressive stresses and plastic strains based on the outcomes of the aforementioned laboratory test. The failure stress was computed from the results of monotonic uniaxial compression tests on mud-brick assemblages [10]. The steel plates are extremely stiff when compared to adobe masonry and were thus modeled using a Linear Elastic material model. The selected values for the properties of the adobe masonry and the steel plates are reported in Table 1. The boundary conditions provided were chosen so as to adequately simulate the test setup. The base nodes of the lower steel plate were considered to be pinned. A uniformly distributed vertical displacement was assigned to the upper steel plate. The amplitude of the displacement over time was formulated according to the mean displacement values that were computed from the data recorded by the vertically placed transducers during the experimental procedure. The contact between the adobe masonry and the steel plates was assumed to be frictionless. The FE model is shown in Figure 3. The simulated stress-strain curve is given in Figure 2.

	Adobe masonry	Steel plates
Weight per unit volume (kg/m^3)	1300	7750
Young's modulus (MPa)	135	220×10^3
Poisson's ratio	0.35	0.30
Yield stress (kPa)	10	-
Failure stress (kPa)	1650	-

Table 1: Parameter values adopted for the formulation of the FE model that was used in the analysis of adobe masonry assemblage subjected to compressive loading and unloading.

Figure 3: Finite element model used for the analysis of adobe masonry assemblage subjected to compressive loading and unloading.

The numerical results show that the FE model, although quite simplistic, reproduces very well the shape of the envelope of the experimental diagram. The difference between the ultimate stress and strain recorded during the experiment and those obtained from the numerical simulation is less than 2%. Taking into consideration the natural randomness and inhomogeneity of earth-based construction material this difference may be considered as negligible. Regarding the loading-unloading branches, these cannot be reproduced in detail by the constitutive model that has been chosen. However, despite the fact that in the FE model the loading-unloading branches coincide, they occur at approximately the same value of strain as the experimental ones. Furthermore, the stress computed by the numerical model after the end of each unloading cycle is equal to zero, as in the case of the actual masonry specimen. Therefore, the simulated response can be deemed adequate when the main aim is the macroscopic investigation of structural behaviour.

3 FINITE ELEMENT MODELING OF TRADITIONAL ADOBE STRUCTURE SUBJECTED TO SEISMIC LOADING

For examining the applicability of the formulated FE model in the assessment of the dynamic response of adobe construction, a model of a traditional earthen building was developed and analyzed under seismic excitation. The model prepared represents a “monochoro” which is the simplest and oldest typology of Cypriot earthen dwelling. A “monochoro” is a longitudinal, rectangular, single-roomed structure whose length is limited by the timber rafters of the roof. The abatements of the roof’s beams are set into the masonry and span the space between the two opposite longitudinal walls. The four load-bearing walls carry the superimposed weight of the roof.

The building that was modeled has external dimensions (height x width x length) $3.50 \times 4 \times 9 \text{ m}^3$ and its walls are 0.45 m thick. A door 2.20 m high and 0.90 m wide is located on its facade while two openings $0.80 \times 0.80 \text{ m}$ are located on the two side walls. The analysis was undertaken using the ABAQUS CAE software. The adobe walls were discretized with 3042 8-noded 3D linear brick elements (C3D8) using the same constitutive material model and input parameters as those reported in subsection 2.2. The timber elements composing the structure’s roof were not modeled because it was assumed that their limited stiffness does not

enable the roof to act as a diaphragm during the application of seismic loading. In addition, no constraints were imposed on the nodes at the upper parts of the walls since it was presumed that these can oscillate freely during a seismic event. The base nodes of the walls were considered to be pinned. The unit area weight of the roof was set as 120 kg/m^2 . The total weight of the roof was assigned to the upper section of the four walls in the form of uniformly distributed pressure. The FE model of the structure is shown in Figure 4. The dynamic action that was chosen for the analysis of the FE model was that of the 1978 June 20th Thessaloniki Earthquake. The duration of the seismic event was 30.59 seconds and the maximum accelerations recorded in the transverse and longitudinal directions were $0.146g$ and $0.139g$ respectively. The amplitudes of the earthquake's transverse and longitudinal components over time are presented in Figure 5. In order to investigate the response of the structure to various levels of dynamic excitation, different analyses were conducted by scaling in each case the two seismic acceleration components. The scaling factors used were: 0.25, 0.50, 1, 2 and 3.

Figure 4: Finite element model used for examining the response of a traditional adobe masonry structure to dynamic loading.

Figure 5: Transverse (a) and longitudinal (b) acceleration components of the 1978 June 20th Thessaloniki Earthquake.

The outcomes of the numerical analysis indicate that the adobe structure examined sustains considerable inelastic deformations when subjected to dynamic loading. The boundary conditions assigned at the corners and at the bottom of the model cause the walls to act as elements fully constrained on their lower part and side edges. Consequently, large displacements and deformations are encountered mainly on the central parts of the upper sections of the façade and the opposite wall (Figure 6). According to the numerical results obtained, the compressive stresses generated by the action of the 1978 Thessaloniki Earthquake do not exceed 50 kPa. However, tensile stresses up to 60 kPa develop at certain parts of the structure. After the dynamic excitation ceases, the compressive stress values encountered are below 15 kPa, but parts of the structure remain in tension (Figure 6). Figure 7 presents the transversal displacement time history of the central node at the upper part of the façade when the 1978 Thessaloniki Earthquake is applied and when the exerted accelerations are amplified by a factor of 3. The maximum transversal displacement of the same node and the out-of-plane deformation of the façade at each amplification level of the seismic action examined are reported in Figure 8. The displacementtime history results show that after the application of the maximum acceleration, the out-of-plane deformation of the façade is non reversible. An examination of the FE model during the time period of seismic loading indicates that the deformation induced does not allow the effective redistribution of loads to all parts of the structure. As a result, the loads are mainly accumulated on the opposite wall and on the two side walls. A comparison of the computed deformations at different levels of dynamic action reveals that when the maximum acceleration of the imposed excitation exceeds 0.07g, severe out-of-plane bulging develops on the façade. Between 0.14g and 0.43g non-reversible transversal displacements can reach values which range from 40 to 150 mm. It is worth noting that, according to the results yielded, the relation between the maximum applied acceleration and the maximum induced transversal deformation is not linear. The results stress out how significantly the response of masonry construction is affected by the existence of sufficient bonding between the load-bearing structural members and the diaphragmatic function at the levels of the roofs and floors.

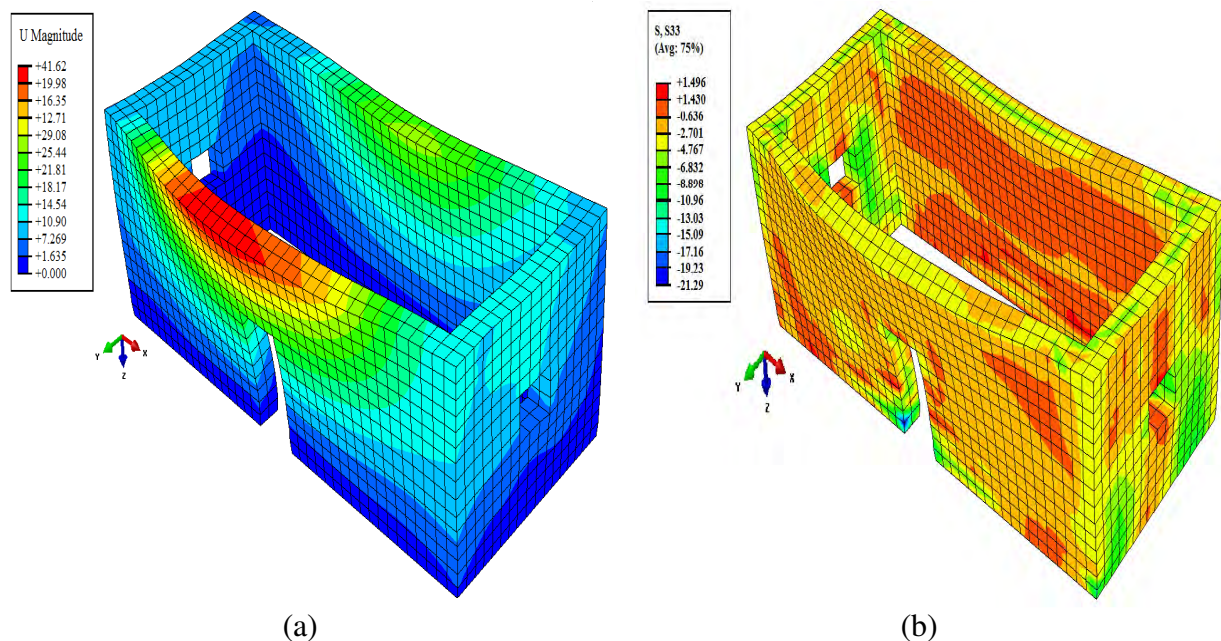

Figure 6: Contour diagrams showing the distribution of transversal displacements (a) and vertical stress (b) on the adobe model structure after the implementation of non-linear dynamic analysis using the acceleration data of the 1978 June 20th Thessaloniki Earthquake.

Figure 7: Transverse displacement time history for the central node at the upper part of the model structure's façade when the analysis is conducted using the acceleration data of the 1978 Thessaloniki Earthquake (a) and when the exerted accelerations are amplified by a factor of 3 (b).

Figure 8: Maximum transversal displacement of the central node at the upper part of the model structure's façade and out-of-plane permanent deformation of the façade at different levels of seismic action. The acceleration data used are those of the 1978 Thessaloniki Earthquake while various factors have been applied in order to scale the amplitude of the dynamic excitation.

4 CONCLUSIONS AND FUTURE RESEARCH AIMS

The numerical results produced by the computational analysis of the adobe masonry assemblage specimen in ABAQUS CAE indicate that the material constitutive model and input parameters hereby suggested may correctly simulate the general behaviour of earthen construction under compressive loading. A comparison among the numerical and experimental data shows that the FE model can provide sufficiently accurate estimates for stress and deformation, especially when applied to monotonic vertical axial loading scenarios. Of particu-

lar importance is the ability of the model to predict the material's actual ultimate strength. The good agreement with experimental results and the low computational cost that results from the use of simple constitutive hypotheses appear to be very encouraging for future applications. However, concerns derive from the inability of the model to predict cyclic behaviour involving cycles of both compression and tension loading. This limitation is a product of the constraints imposed by the selected constitutive model.

Regarding the validity of the numerical results obtained from the analysis of a complete model structure, these cannot be deemed as a sufficiently accurate representation of the actual response of earthen construction, despite the fact that they appear to be in context with the general behaviour of unreinforced masonry. The computed deformations may be considered to be rather excessive with respect to the levels of seismic action examined. In an actual structure the evaluated inelastic displacements would have led to the development of significant cracking at the walls and would have probably caused the out-of-plane collapse of the façade. Although such damage mechanisms have been observed in adobe buildings [2, 3], these have occurred at seismic events where the maximum imposed acceleration was above 0.50g (e.g. Northridge Earthquake, Iran Bam Earthquake). The overestimated displacement values can be attributed to the exclusion of the timber roof structure from the model. The latter, despite its limited stiffness, is anticipated that would have constrained, to some extent, the out-of-plane movement of the walls and would have assisted in a more effective distribution of the loads. Moreover, the boundary conditions assigned to the structure's corners cannot reproduce the actual interaction that takes place at the conjunction of perpendicular walls and force deformations to concentrate at the central part of the walls. Consequently, failure mechanisms such as the formation of detachment cracks at the interconnection of adjacent walls cannot be identified by the model. Uncertainties are also introduced by the fact that the constitutive material model selected for simulating the behaviour of adobe masonry uses a Mises yield surface, thus making no distinction between the response to compression and tension. Although adobe masonry has some considerable resistance to tensile loads, this is much lower than its compressive strength and the constitutive model should be modified in order to account for this behaviour. On the overall, it may be argued that the application of the model hereby presented in the dynamic analysis of complete structures is useful for providing qualitative information regarding the general response of adobe construction rather than accurate quantitative results.

Future work will focus on the modification of existing constitutive models and/or the development of a fully adobe masonry-oriented model that will be able to account for the specific characteristics of earthen construction. Furthermore, the construction and laboratory testing of a scaled model adobe structure in order to study its behaviour under horizontal loading has been scheduled. The experimental results that will be obtained will be used for examining the validity of the numerical data available and will be utilized in the calibration of FE models.

Abstract. *As a common practice, restoration projects of ancient colonnades have to deal with joining together fragments of architectural members using threaded titanium bars (reinforcement) fixed into place with cement mortar. The basic criterion for the design of such connections is that, in case of a seismic event, the reinforcement should absorb the seismic energy and fail before the marble suffers any damage. For the dimensioning of the titanium bars, a methodology based on the capacity design philosophy is usually implemented. The accurate calculation of the forces that will be induced to the reinforcement during an earthquake is not an easy task, since the response of the structure is governed by the rocking and the sliding of the individual stone blocks.*

In this paper, the efficiency of the reinforcement used for the connection of complements, which has been calculated with the above-mentioned capacity design methodology, is investigated for selected severe seismic excitations. The analyses were performed for the case study of the restoration of the colonnades of the Southern part of the Ancient Agora of Kos in Greece. The induced forces were calculated by dynamic analyses, using an accurate numerical description of the restoration's structural scheme and earthquake motions of various characteristics, selected to be compatible with the seismological history and the soil conditions at the site. All the analyses were performed using the code 3DEC, which is based on the distinct element method and has been verified and calibrated by comparison of the numerical results with experimental data. The results show that the simplified design that is applied in practice is adequate, as the stresses induced to the reinforcement bars were always less than the ultimate strength and, in many cases, significantly less than the yield resistance as well.

1 INTRODUCTION

Ancient colonnades consist of stone blocks of different sizes and shapes made of marble, stiff limestone or porous stone, depending on the available material in the nearby region. Typically, the blocks are not connected to each other and the structure behaves as a system of discrete blocks, except of connectors (clamps and dowels) that are provided in certain places only. In current restoration practice, ancient mortises that are preserved in such places are used to connect the stone blocks with new clamps and dowels made of titanium. The basic principle that is followed for the design of the new connectors is that, in case of a seismic event, the connectors should absorb the seismic energy and fail before the surrounding marble suffers any damage.

Apart from the connectors, the use of titanium bars is also common for joining together fragmented ancient blocks or fragments of blocks with new complements so as to restore the unity of each discrete element of the ancient structure. The principle in designing the bars that are used as reinforcement is that those should bear the induced forces in a seismic event and maintain the discrete block as a whole, while the marble does not suffer any damage.

In general, the design of the restoration anticipates the following sequence of response: The joints between independent blocks are the first to be activated. This does not necessarily imply engagement of the connectors (clamps and dowels), because, typically, there is a gap between them and the mortises of the stones. However, forces are induced to the connections between blocks and new complements. When the movements of the blocks exceed certain values, the clamps and dowels are activated, reducing, in general, the forces applied to the restored interfaces of fracture. After the failure of the connectors (clamps and dowels), it is possible that rehabilitated members of the structure lose their integrity; in that event, the titanium bars of the reinforcement should yield prior to any other damage to the marble.

In order to follow the above-mentioned procedure, one should know the forces that will be induced to the connectors and the reinforcement during an earthquake. However, the calculation of these forces is not an easy task, since the response of the structure is governed by rocking and sliding of the individual stone blocks. Previous investigations [1-6] on the dynamic behaviour of single freestanding columns and sub-assemblages of ancient temples have pointed out that the response of these discrete structures is highly nonlinear and very sensitive to even small changes in the parameters. Thus, the imposed excitation and the frequency content of the ground motion, the degree of the accuracy of the numerical model concerning the geometry of the structure and the assumptions adopted in the analysis (joint properties, friction coefficient, etc.) may affect significantly the results of even rigorous nonlinear analyses. For this reason, the dynamic analyses of such structures contain an inherent uncertainty and their outcomes should be used with caution.

In practice, simplified analyses are usually applied for the design of the connections that are implemented during interventions. These analyses are based on the capacity design philosophy, thus they end up with the maximum forces that can be developed theoretically, independently of the earthquake excitation. In this paper, the response of connections of complements, which have been designed by such methodologies, under strong earthquake excitations, is investigated. For this purpose, nonlinear numerical analyses are performed using the discrete element method and the forces induced to the reinforcements are compared with their strength. The analyses are performed for the case study of the restoration of the colonnades of the Southern part of the Ancient Agora of Kos in Greece.

2 PRINCIPLES OF INTERVENTION

2.1 General philosophy

Restoration projects nowadays follow very specific guidelines in order to ascertain the required quality of the intervention. The main scope is the minimum, yet necessary and sufficient, intervention in the monument's inherent characteristics. Of main importance is the respect for the original building techniques, the original structural system and the original materials. Authenticity is a beyond debate concern and goal of the project, in order to maintain the monument at the best possible status and to minimize the alterations. Additional requirements might be reversibility, meaning the ability to revert the monument to its previous - before the restoration- state, maintenance of the structural function and consistency of the individual architectural members.

The use of new material for the complement of missing parts of structural elements is generally restricted to the absolutely necessary and must be kept in a low proportion compared to the original material. Such decisions must not be based only on stability issues, but also take under consideration the forms and volumes, the visitor's perception of the monument and aesthetic issues. It should be kept in mind that the main "recipients" of the monuments are their visitors and that the cultural heritage that they carry is not addressed to scholars and connoisseurs only, but mainly to the public.

2.2 Structural restoration

The term 'structural restoration' signifies the series of interventions that are necessary to ensure the bearing capacity of the structure and of its individual parts. To this end, restoration of the connectors between the structural elements and re-composition of the original geometry of the stone pieces that were retrieved during the excavation by connecting fragments and/or complement of stone elements is deemed necessary in many cases.

In antiquity, the connection elements were made of bronze or iron and were covered with lead, cast in the mortises, which after its congelation offered high insulation to the metallic connectors, protecting them from the oxidization and the corrosion. At the same time, the connectors, being ductile materials, contributed to the overall behaviour of the structure in case of an earthquake. Two types of connectors were used: dowels, which connected elements between consequent layers along the height and resisted the shear forces; and clamps, which connected stones belonging to the same layer and prevented their relative dislocation through their tensile resistance. In the ultimate limit state, the dowels and the clamps were meant to fail before the failure of the stone.

In many restorations realized in the 19th and the 20th century, the structural steel that was used in typical constructions was applied also to monuments for the enhancement of their bearing capacity and for the connection of fragments of architectural members. The steel elements were usually cast in lead, as a follow up of the ancient practice. Cement mortars were widely used for covering mass lacks. This technique caused significant damage to the monuments, because the cast lead failed to reassure the same impermeability as the ancient one and environmental actions, due to their intense corrosive character, led to iron's oxidization and subsequently to fracture of the architectural members.

In modern restoration projects, mostly inorganic materials are adopted, in order not to provoke any additional problems in the long term. Thus, for the connections between restored members of the monument (clamps and dowels), specially formed titanium sheets are commonly used, fixed in place with the use of inorganic mortars. Similarly, for joining together fragments and/or complements, threaded titanium bars are applied.

2.3 Calculation of the reinforcement of the connections

The ancient and the new pieces are typically connected with titanium threaded bars that are inserted in properly drilled holes and fixed into place by mortar. Mortar is also used as the bonding material at the interface of the fraction. As mentioned above, a proper dimensioning of the reinforcement would require difficult nonlinear analyses, which are seldom performed in practice. Usually, analyses based on capacity design effects are performed [7, 8], which lead to the required reinforcement for resisting the maximum forces that can be induced, without restoring completely the strength of the original material. In example, the design of the connection of fractured architraves is based on the assumption that the architrave is subjected mainly to bending under increased gravity loads by a factor around 1.50; for the connection of fragments at column drums and stylobate blocks, the required reinforcement is calculated from equilibrium conditions under capacity actions that include the friction forces, assuming that sliding occurs at the joint, and the ultimate resistance of any existing dowels.

3 CASE STUDY – DESCRIPTION OF THE MONUMENT

The analyses presented herein are based on the part of the southern Arcade (Stoa) of the Ancient Agora in the island of Kos in Greece that has been proposed to be restored. The monument is situated in the center of the modern city of Kos.

An unexpectedly large number of structural members were found in situ. The location where the members were found and the study of the mortises of the connectors confirmed that they derived from specific parts of the building. Thus, the 'erection' of a small part of the Stoa was proposed, using a significant portion of the found ancient members.

The restoration project concerns three columns of the Stoa with the respective parts of the crepis and the entablature (Figure 1). In this restoration, 37 from the 62 ancient members are to be used. In addition, seven new blocks are to be used to ensure the stability of the structure and, also, for aesthetic reasons.

Figure 1: Drawing of the restoration proposal. The ancient members and fragments are shown in gray and the members and complements that will be made of new marble are shown in white.

The original structure rested on a two layered base of height 0.55 m, made of porous blocks that lied under the crepidoma (crepis). The crepis consisted of two steps and the stylobate. The first step had height 0.33 m and was made of gray limestone blocks of varying plan dimensions (their length was varying from 0.60 to 1.40 m and their width from 0.50 to 0.70 m). The second step had height 0.29 m and was made of marble blocks of the same overall dimensions. The stylobate was made of marble blocks of height 0.30 m, width about 1.00 m and varying length.

The marble columns of the Stoa were of doric style without fluting at their lower part, up to a height of 2.07 m. The columns consisted of four drums of uneven height with base diameter 0.78 m. The axial distance between the columns was 2.66 m and their overall height was 5.61 m. The diameter of the capital was 0.635 m and its height was 0.38 m, approximately, while the abacus had plan dimensions 0.85 m \times 0.85 m and height equal to 0.11 m.

The architraves consisted of single blocks, 2.66 m in length, 0.71 m in width and 0.47 m in height. The frieze was made of blocks 1.73 m in length and 0.59 m in height that included two triglyphs and two metopes. Those blocks were either single of full width (~0.47 m) or were supplemented by other blocks of approximately the same dimensions that completed the width of the layer; the latter is the case of the part of the structure that is considered in this analysis. The cornice had height 0.42 m and was projecting 0.325 m. The block that will be used in the restoration is 1.95 m long.

4 NUMERICAL ANALYSIS

4.1 General

The structural and the dynamic analysis of ancient temples or sub-assemblages of ancient temples differ significantly from the analysis carried out for modern structures, mainly because of their articulate construction. During a seismic event, rocking and/or sliding of the stones, independently or in groups, may occur, which results in highly nonlinear behaviour [1-6]. Additionally, the response is very sensitive to the details of the geometry, the characteristics of the ground motion and the joint parameters.

The complexity and the special character of the response of the structure (rocking and sliding) create computational requirements hard to meet with the incorporation of conventional software. For the numerical analyses presented herein, the code 3DEC by Itasca Consulting Group, Inc. [9] was employed, which is based on the discrete element method. The code is designed to allow significant displacements and rotations of the blocks, even total detachment. During the calculation process, the code locates the contacts between the blocks and computes the motion of each block from the forces (normal and shear) that are developed at the joints. The contacts are divided in sub-surfaces, while various types of contact are considered (apex to apex, apex to edge etc.). In this way, rocking and sliding are accurately addressed.

The code 3DEC has been verified and calibrated for the response of ancient colonnades through comparisons of the numerical results with experimental data obtained from shaking table tests performed at the Laboratory for Earthquake Engineering of the National Technical University of Athens [2, 4-6].

4.2 Numerical model

The numerical model used in the analyses was based on the actual restoration proposal. The connections between the ancient fragments and the new complements were assumed from titanium bars and were designed according to the above-mentioned methodology. The exact

geometry and dimensions of the reinforcement were implemented in the numerical model (Figure 2).

The mortar typically used at the interfaces of the connected blocks was not considered, because its actual mechanical properties cannot be precisely defined. In addition, the dowels and the clamps were not included in the numerical model, because sliding can occur before these connectors are activated, since a gap of 1 to 2 cm, not filled with mortar, is commonly left between them and the edge of the mortises. Both assumptions are to the safety side and lead to the upper limit of the forces that can be induced to the reinforcement.

Figure 2: Numerical model used in the analyses with 3DEC. Details of the connections considered in the model are also shown.

The analyses were performed assuming that all the structural elements are rigid blocks. For rigid blocks problems, the 3DEC code gives an accurate contact formulation in which the interaction takes place at a number of contact points [9]. Each contact is assigned a contact area, which is used to calculate the local point stiffness, in terms of the user-defined stiffness of the discontinuity surface. The joint stiffness used in the model was based on former studies [2, 4-6] and was equal to 5×10^9 Pa/m in the normal direction and 1×10^9 Pa/m in the tangential direction. A 10% mass-proportional damping at $\omega = 0.3$ Hz was also considered. The friction coefficient was taken equal to 0.75.

The reinforcement (titanium bars) were simulated as nonlinear springs for which the elastic stiffness, the yield force and the ultimate strain were assigned in both the axial and the shear directions. Since pullout test results were not available, the following theoretical expressions, given in [10] and proposed by 3DEC [9], were used to estimate the axial stiffness, K_a and the shear stiffness, K_s :

$$K_a = \pi \cdot k \cdot d_1 \quad (1)$$

$$K_s = E_b \cdot I \cdot \beta^3 \quad (2)$$

where d_1 is the diameter of the reinforcement; $k = \left[\frac{1}{2} \cdot G_g \cdot E_b / (d_2 / d_1 - 1) \right]^{1/2}$; G_g is the shear modulus of the grout; E_b is the Young's modulus of the reinforcement material; d_2 is the diameter of the hole; I is the second moment of area of the reinforcement element; and $\beta = [K / (4 \cdot E_b \cdot I)]^{1/4}$, with $K = 2 \cdot E_g / (d_2 / d_1 - 1)$.

The ultimate axial strength, P_{ult} , and the shear strength, $F_{s,b}^{max}$, of the titanium bars were calculated using the formulas proposed in [11] and [12], respectively, and adopted by 3DEC [9]:

$$P_{ult} = 0.1 \cdot \sigma_c \cdot \pi \cdot d_2 \cdot L \quad (3)$$

$$F_{s,b}^{max} = 0.67 \cdot d_1^2 \cdot (\sigma_b \cdot \sigma_c)^{1/2} \quad (4)$$

where σ_c is the uniaxial compression strength of the marble (up to a maximum value of 42 MPa); L is the bond length; and σ_b is the yield strength of the reinforcement.

4.3 Selection of base motions

For the selection of the base motions, the geological and seismological data in the area of the monument were taken under consideration. The basic ground formation in the area, where the ancient Agora is situated, is alluvial coastal depositions with significantly low mechanical properties and poor geotechnical behaviour [13-15].

There are many references of large historic earthquakes in the wider area of Kos, with magnitudes up to $M = 6.5$ [13-16]. During these earthquakes, ground raptures, liquefaction and collapse of many structures were reported. It should be pointed out that part of the ancient Agora collapsed in the historic earthquake of 556 A.D. [13]. In Figure 3, the map of the geological hazard of the island of Kos, according to [13], is presented. Note that a normal fault is located in a distance less than 6 kilometers from the area under consideration.

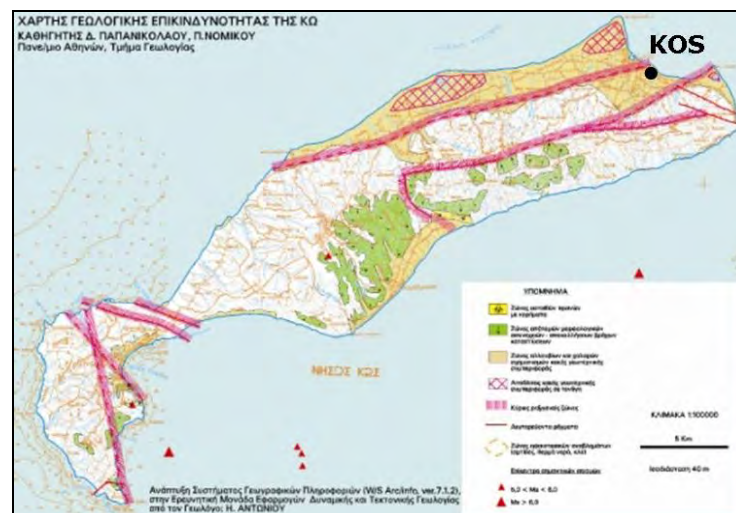

Figure 3: Seismological map of the island of Kos, showing the main faults (reproduced from [13]).

For the selection of the earthquake records to be used in the analyses, the above-mentioned seismotectonic data and the ground profile of the Ancient Agora of Kos were considered. More specifically, the following criteria were posed: adjacency to the seismic fault (near field earthquakes); magnitude around 6.5; and ground motions recorded on soft soil conditions.

Based on these criteria, six earthquake records were selected from the strong motion data bases: Cosmos Virtual Center; Pacific Earthquake Engineering Research Center (PEER); European Strong-Motion Database (ESD); National Observatory of Athens; Institute of Technical Seismology and Earthquake Resistant Structures (ITSAK), which had different characteristics and covered a wide range of spectral accelerations. Both horizontal components of each earthquake were applied as the base excitation. The selected earthquakes and their characteristics are shown in Table 1.

From the analyses performed, it was found that collapse of the structure occurs for the Sylmar, Northridge, USA earthquake. The collapse mechanism is shown in Figure 4. Since the main scope of this research was to determine the behaviour of the reinforcement assuming that collapse does not occur, this record was not further examined. The response spectra of the component that was applied in the transverse direction of the structure of the five remaining records are presented in Figure 5.

5 RESULTS

For all the titanium bars that were used in the connections, the time histories of the axial and the shear forces were obtained from the analyses. Indicative results are shown in Figure 6, where the time histories of the axial force of the four reinforcement bars that were used to connect the two fragmented pieces of the architrave beam are depicted.

From these results, the efficiency factor for each bar was derived as the ratio of the maximum uniaxial stress, $\sigma_{M,max}$, that was developed during each earthquake motion over the yield stress, σ_y . The uniaxial stress was calculated using the Von Mises yield criterion:

$$\sigma_M = \sqrt{\sigma^2 + 3 \cdot \tau^2} \quad (5)$$

where σ is the axial stress of the bar and τ is the shear stress. The yield stress σ_y and ultimate stress σ_u of the threaded titanium bars were taken equal to 330 MPa and 420 MPa, respectively.

Figure 6: Time histories of the axial force of the 4 titanium bars of the architrave connection (Figure 5) for the Imperial Valley earthquake.

Figure 7: Accomplished efficiency factors of the four titanium bars of the architrave connection for the five earthquake excitations used in the analyses.

Figure 7 shows the accomplished efficiency factor of the four reinforcement bars applied at the connection of the architrave. None of the bars reached its yield strength for the earthquakes examined. The two lower reinforcement bars (No 1 and 2), which were in tension under gravity loads, showed an efficiency factor around 0.60, not much affected by the base motion. This value is close to $1/\gamma_G$, where $\gamma_G = 1.5$ is the load factor for the gravity loads that was used for the design of these reinforcements according to the methodology described above. The upper reinforcement bars (No 3 and 4) were stressed significantly less for three of the earthquake excitations (Imperial Valley, Athens and Kalamata), as expected; however, large stresses were induced to these bars for the Lefkada and the Aigion earthquakes, showing that large displacements occurred at the architrave during these ground motions.

Figures 8 to 10 show the efficiency factors of the reinforcement bars used for the connection of the fragments at the drums of the columns. It can be observed that significantly different stresses were induced to the titanium bars for each type of fragmentation. The worst case was observed for the fragment at the first drum of column 2 (Figure 9), in which two out of three bars yielded in most earthquakes. The smallest forces were induced to the connection of the third drum of column 1 (Figure 8), where efficiency factors less than 0.70 were achieved in most cases. Similar was the behaviour of the titanium bars of the connections at the fourth drum of column 2 (Figure 10), which were stressed significantly lower than their yield limit in most cases. It should be noted that the maximum stress was less than the ultimate limit strength of the reinforcements in all cases.

It is evident from these results that both the inclination of the connection and its position along the height of the column affect significantly the forces that are induced to the reinforcement bars. The worst case concerns fragments that form a wedge and are located at the lower part of the column, where the gravity loads are larger. During rocking, large forces are developed at such connections; this was also observed in [17].

Figure 8: Efficiency factors of the four titanium bars used for the complement of the third drum of Column 1, for the five earthquake excitations used in the analyses.

Figure 9: Efficiency factors of the three titanium bars used for the complement of the first drum of Column 2, for the five earthquake excitations used in the analyses.

Figure 10: Efficiency factors of the seven titanium bars used for the complements of the fourth drum of Column 2, for the five earthquake excitations used in the analyses.

The results for the connections at the stylobate are shown in Figures 11 and 12. In case of S3 (Figure 11), in which extended connections were made, the stresses induced to the titanium bars were significant, more than 80% of the yield resistance in most of them (No. 1, 2, 3, 4) for all earthquake motions. In this case, the response of the reinforcement was not affected significantly by the ground motion characteristics. On the contrary, the reinforcement bars of the connection at stylobate S5 showed different behaviour for each earthquake. It is interesting to note that, although the efficiency factors attained at S5 were generally smaller than the ones at S3, probably due to the fact that the new complement was “encased” by the original block, large stresses were induced to some reinforcement bars of S3, which, in one case, surpassed the yield resistance. It should be mentioned that, for the stylobate blocks, reinforcement larger than the required according to the current design methodology was applied, in general, for constructional reasons.

Figure 11: Efficiency factors of the six titanium bars used for the complements of the stylobate S3, for the five earthquake excitations used in the analyses.

Figure 12: Efficiency factors of the five titanium bars used for the complement of the stylobate S5, for the five earthquake excitations used in the analyses.

6 CONCLUSIONS

- The simplified methodology that is used in practice for the dimensioning of the reinforcement of connections between new and old complements, which is based on the capacity design philosophy, was proved to be adequate, since the ultimate strength of the titanium bars was never reached. In most cases, the stresses induced to the reinforcement were significantly less than the corresponding yield stresses.
- The most severe situation was observed for fragments of column drums that form a wedge and are located at the lower part of the column.
- Significant stresses were observed at the connections of the stylobate, which were not expected intuitively, since only sliding can occur at these places. It should be mentioned, however, that failure of the reinforcement at such places does not, in general, puts the structure in danger of collapse.

ACKNOWLEDGEMENTS

Part of the research reported herein was performed in the framework of the structural analysis of the proposed restoration of the southern Arcade of the Ancient Agora of Kos, which was financed by the Hellenic Ministry of Culture on behalf of the Archaeological Institute of Aegean Studies of Rhodes under project EL006 "Designation of the ancient Hellenistic Agora of Kos and the medieval circumferential fortifications of the city of Kos". The Supervisor of the Archaeological Institute of Aegean Studies of Rhodes, archaeologist Ag. Giannikouri has facilitated the realization of the overall project. Sincere thanks are due to the geologist D. Minos-Minopoulos for providing valuable geotechnical and seismological information on the island of Kos.

Key words: Masonry historic structure, Church retrofit, Seismic strengthening, Finite elements analysis, Ambient and laboratory structural and material testing

Abstract. *The Church of St. Constantine & Helen is located in the Municipal Theater square in Piraeus. It was constructed in 1882. A series of recent earthquakes, including the Athens 1999 earthquake, strained the temple and caused serious damages. These damages are mainly attributed to the absence of particular provisions to carry the earthquake loads. In order to evaluate the earthquake vulnerability of the church, a detailed study of the masonry structure was conducted in order to determine the mechanical properties, the building construction details and the current condition of the structure as well as its dynamic behavior through in situ and laboratory testing as well as through finite element analysis. Based on the results, strengthening and repair measures are proposed, using a combination of masonry consolidation techniques, fiber reinforced plastic materials (FRP) and steel tie rods.*

1 INTRODUCTION

Newly introduced materials and technology provide engineers with the ability to repair, reinforce and restore historic buildings with a more scientific, effective and less intrusive approach. The restoration process of a heritage building that has succumbed serious damage, should be based on a reliable assessment of its state of stress and deformation before and after the intervention. Such a process usually employs computer aided methods and arithmetic models; monumental and cultural heritage buildings are often analyzed with the finite element method (FE). The method uses a model that should simulate the actual behavior of the structure for both static and seismic loads. Therefore, it is imperative that the model is developed with data collected from in-situ and laboratory testing (geometry, crack pattern, material properties, etc.) in order to obtain realistic results that can be used for repair and strengthening of the structure. [1]

2 MONUMENT DESCRIPTION

2.1 General information

The Church of St. Constantine & Helen is located in the Municipal Theater square of Piraeus. Its construction begun in 1878 and ended in 1882. It is considered as one of the most majestic temples of Piraeus and was based on the blueprints of the architect John Lazarimos. Moreover, it is characterized by a capacity of 1200 people, its impressive bell-towers and a high dome. After the end of the construction, many prominent hagiographers and marble-sculptors undertook the decoration of the temple interior.

From an architectural perspective, the temple is a “domed basilica”. Its dome is carried on four concave triangular pendentives that serve to the transition from the circular base of the dome to its rectangular base. The weight of the dome passes through the pendentives to four massive piers at the corners. The length of the temple is 29m and the width is 23m. The total height of the temple is 23.4m with the dome and the bell towers being 7.2m and 8.6m high, respectively.

Figure-1: Front view of the temple

Figure-2: Plan view of the temple

2.2 Material and structural data of the church

2.2.1. Stones and mortar

At three characteristic locations of the church, the external cover of the masonry was removed at square surfaces of 50x50cm (Fig.5); two of them on masonry walls and the third on a pier. Subsequently, the stone strength was measured using a rebound hammer that was

calibrated. Based on these measurements, the compressive strength of stone was estimated to be:

$$f_{bc} = 30 \text{ MPa}$$

Mortar samples were analyzed at the laboratories of Chemical Engineering at NTUA. The analysis procedure included three steps: (a) Natural separation of mortar-stone, (b) X-Ray diffraction, see Figure 3 and (c) Thermal analysis TG-DTG, see Figure 4. The analysis showed that mortar is hydraulic lime with a compressive strength:

$$f_{mc} = 1 \text{ MPa}$$

Figure-3: X-Ray analysis results

Figure-4: Thermal analysis results

2.2.2. Masonry wall type

In order to identify the transversal orientation of the materials constituting the masonry walls, drill cuttings were made and with the use of an endoscope the interior layers of the wall were inspected (Fig. 5-6). Results showed that the masonry walls are comprised of three layers. The external layers are stone of 25-30cm thickness. Moreover, the internal layer consists of solid mortar and small diameter stones.

Figure-5: Area without mortar cover

Figure-6: Inside the drill cutting

2.2.3. Masonry wall properties

In order to calculate the compressive strength of the stone masonry, the expression recommended by Tasios et. al. [2] was used:

$$f_{wc} = \frac{2}{3} \sqrt{f_{bc}} - \alpha + \beta f_{mc} \quad (1)$$

where:

f_{bc} and f_{mc} is the compressive strength of stone and mortar, respectively, α is a reduction factor for masonry made of natural stone ($\alpha=1$) and β is a factor that accounts for the contribution of mortar on the masonry wall strength (for stone masonry β is equal to 0.5).

According to bibliography, the tensile strength of masonry and Young's modulus were calculated with the aid of equations (2) and (3). The material properties are presented in Table-1.

$$f_{tc} = f_{wc} / 10 \quad (2)$$

$$E = 1000 f_{wc} \quad (3)$$

Material	Property	Value
Stone	Compressive strength	30 MPa
Mortar	Compressive strength	1 MPa
Stone masonry	Density	2200 kg/m ³
	Young's modulus	3150 MPa
	Poisson's ratio	0.16
	Compressive strength	3.15 MPa
	Tensile strength	0.315 MPa
Marble	Density	2600 kg/m ³
	Young's modulus	64200 MPa

Table-1: Material properties

3 MONUMENT PATHOLOGY

A series of recent earthquakes, including the Athens 1999 earthquake, strained the church and caused serious damage. These damages are mainly attributed to the fact that there are no special provisions in the building to protect it, in case of earthquake. In particular, cracks are located in many parts of the masonry wall, both external and internal and mainly in the intrados of the arcs.

Figure-7: Sample crack at the east ceiling

Figure-8: Sample crack at the south ceiling

Those with the largest width are located on the inner surface of the arcs, along longitudinal and transversal directions. Cracks were also developed at the triangular pendentives, which support the dome.

4 AMBIENT VIBRATIONS TESTS

To measure modes and natural frequencies of the church in its present state, ambient vibrations tests were conducted. In order to fulfill the task of the tests, there were measurements in two distinct positions, ground floor and dome level, along two directions. The results are presented in the following Tables (a) and (b) as they are obtained from the peaks in figures 9 and 10.

Mode	Modal Period (sec)	Damping Ratio (%)
1	0.372	4.5
2	0.273	3.3

(a)

Mode	Modal Period (sec)	Damping Ratio (%)
1	0.240	5.8

(b)

Table-2: Measurements at (a) transverse direction x-x' and (b) longitudinal direction y-y'

Figure-9: Deformation function at transverse direction x-x'

Figure-10: Deformation function at longitudinal direction y-y'

5 NUMERICAL ANALYSIS

5.1 Finite elements model

SAP2000 [3] finite element software was used to create and analyze the structure. The stone masonry and marbles were modeled by eight node solid elements with three degrees-of-freedom per node. Four-node shell elements were used to model the central dome. Two node-frame elements were used for the proper connection and collaboration of solid and shell elements [1]. The final model consists of 31055 solids, 2424 shells, 96 frame elements and 44204 nodes (Fig. 11-12).

Figure-11: General view of the model

Figure-12: Section along the longitudinal direction

5.2 Response spectrum analysis

A response spectrum analysis was conducted. According to Eurocode 8-1 [4], the design spectrum Type-1 was used to calculate the seismic acceleration in both the horizontal and the vertical directions.

For the horizontal components of the seismic action the design spectrum, $S_d(T)$, is defined by the expressions (4)- (7):

$$0 \leq T \leq T_B : S_d(T) = a_g \cdot S \cdot \left[\frac{2}{3} + \frac{T}{T_B} \cdot \left(\frac{2,5}{q} - \frac{2}{3} \right) \right] \quad (4)$$

$$T_B \leq T \leq T_C : S_d(T) = a_g \cdot S \cdot \frac{2,5}{q} \quad (5)$$

$$T_C \leq T \leq T_D : S_d(T) \begin{cases} = a_g \cdot S \cdot \frac{2,5}{q} \cdot \left[\frac{T_C}{T} \right] \\ \geq \beta \cdot a_g \end{cases} \quad (6)$$

$$T_D \leq T : S_d(T) \begin{cases} = a_g \cdot S \cdot \frac{2,5}{q} \cdot \left[\frac{T_C T_D}{T^2} \right] \\ \geq \beta \cdot a_g \end{cases} \quad (7)$$

where T is the vibration period in secs, $a_g = 0.16g$ is the design ground acceleration for type A ground, $T_B = 0.15$ is the lower limit of the period of the constant spectral acceleration branch, $T_C = 0.5$ is the upper limit of the period of the constant spectral acceleration branch, $T_D = 2$ defines the start of the constant displacement response range of the spectrum, $S = 1.2$ is the soil factor, η is the damping correction factor with a reference value of $\eta = 1$ for 5% viscous damping, $q = 1.5$ the behavior factor and $\beta = 0.2$ is the lower bound factor for the

horizontal design spectrum. For the vertical component of the seismic action the design spectrum $S = 1.0$, $T_B = 0.05$, $T_C = 0.15$, $T_D = 1.0$

Figure-13: Design spectra for the horizontal and vertical seismic action

5.3 Analysis results

The results of modal analysis for the first three modes and the corresponding modal participating mass ratios are shown in Table-3. There is a good correlation between the measured and calculated modal periods which validates use of the model of the structure at least for static and small intensity dynamic loads.

Mode	Period (sec)	Ux	Uy	Uz	Rx	Ry	Rz
1 st	0.320	0.728	0.00067	8.746E-07	0.00031	0.29906	0.2789
2 nd	0.296	0.0003	0.776	1.139E-06	0.34906	0.00015	0.35204
3 rd	0.228	0.032	0.00087	3.504E-07	0.00065	0.01385	0.10877

Table-3: Modal periods and participating mass ratios for displacement (U) and rotation (R)

The stresses at the transversal direction x-x' (S11) and at the longitudinal direction y-y' (S22) are shown in Fig. 14. With the deep blue (darkest color) are the areas where developed stresses are greater than the tensile strength of masonry. These areas are extensive and correspond to the areas where damages were observed at the temple.

Figure-14: S11 (a-d) and S22 (e-h) stresses of the temple

It should be noted that this paper presents the first part of the analysis that was conducted for the historic structure. The second part presents a kinematic analysis as well as two displacement based analysis using frame as well as shell elements, respectively. Also, the second part elaborates on the correlation between the experiment and the analytical results and presents a comparison among the results of all three analyses.

6 REINFORCEMENT

According to the results of the analysis and the architectural- intervention restrictions imposed by the authorities that require minimum alteration of the structural configuration of the historic building and its painted walls, rehabilitation and strengthening of the church was based on a combined scheme using grout injections, CFRP and steel tie rods that complied with all limitations [5, 6]. The scheme is described in the following sections.

6.1 Grouting

The technique of grout injection in masonry through small holes drilled in the mortar at the exterior of the church walls will be used to consolidate the three leaf walls. Care will be taken to control the injection application so that the grout will not emerge on the interior surface of

the walls. The compressive strength of the masonry after consolidation, $f_{wc,s}$, is calculated from [7]

$$f_{wc,s} = f_{wc,0} + 0,31(V_{inf} / V) f_{gr}^{1,18} \quad (8)$$

where:

$f_{wc,0}$ the compressive strength before grout injection

V_{inf}/V ratio of grout volume to masonry volume

f_{gr} compressive strength of injected material

According to the international experience for seismic strengthening of three-leaf masonry walls, consolidation of the masonry walls can be accomplished with this technique. A compressive strength of 10 MPa was used in the analysis for the injected material in order to restrain failure in the grout of the consolidated wall.

6.2 Composite materials CFRP and stainless steel tie rods

According to the analysis, undertaking of the tensile stresses can be achieved by applying sheets of fiber carbon impregnated with epoxy resins on the upper exterior surface of the church (roof) as well as at parts of the interior surfaces of certain vaults that are not decorated with historic paintings. Specifically either three or two-ply of carbon fiber reinforced plastics (CFRP), with a carbon sheet thickness of 0.17 mm is selected. The mechanical properties of the carbon fiber are: modulus of elasticity $E_c = 240$ GPa, ultimate strength $f_j = 3500$ MPa.

Also two stainless steel tie-rods F430 with a diameter of 40mm should be placed at the upper part of the arches in the interior of the church. The mechanical properties of the tie-rods are: modulus of elasticity $E_c = 200$ GPa, yield strength $f_y = 379$ MPa, ultimate strength $f_u = 552$ MPa.

7 ANALYSIS OF STRENGTHED STRUCTURE

The results of modal analysis for the first three modes of the strengthened structure and the modal participating mass ratios are shown in Table-4.

Mode	Period (sec)	Ux	Uy	Uz	Rx	Ry	Rz
1 st	0.250	0.74	0.00045	1.639E-06	0.00021	0.30279	0.28297
2 nd	0.230	0.000085	0.77	1.171E-07	0.34847	0.000047	0.3621
3 rd	0.180	0.02743	0.00298	5.506E-07	0.00191	0.01185	0.10544

Table-4: Modal periods and participating mass ratios for displacement (U) and rotation (R)

Figure-15: Placement of CFRP on the intrados of the arced ceiling

Figure-16: Placement of CFRP on the arcs of central dome

Figure-17: Placement of tie rods at arcs

Figure-18: Placement of tie rods at the central arched ceiling

Figure-19: S11 (a-d) and S22 (e-h) stresses of the temple

Comparison between Tables 3 and 4 clearly indicates the anticipating decrease of the model periods of the strengthened structure after the interventions. According to the analysis excess of the compressive strength of the masonry does not appear after the consolidation of the walls with grout injections. Also, tensile stresses are smaller than the tensile strength attributed to the application of CFRP and tie rods. Excess of the tensile strength (10% of the tensile strength of the masonry) is limited at "secondary" places of the masonry walls for the seismic behavior and stability of the structure.

Keywords: Epistemic uncertainty, Aleatory uncertainty, Reinforced concrete frame, Uncertainty analysis, Seismic performance, Incremental dynamic analysis

Abstract. *A simplified methodology for seismic performance assessment of structures with consideration of both aleatory and epistemic uncertainty is briefly presented. The methodology involves pushover analysis for a set of structural models and nonlinear dynamic analysis of corresponding equivalent SDOF models. However, a methodology by itself without any support of sophisticated computational software is not intended to be used for practical applications. Thus, a very efficient software tool, a PBEE toolbox [1] in conjunction with OpenSees, was used in our study in order to perform pushover analyses of required computational simulations, while nonlinear dynamic analysis are approximately computed by using a web application for prediction of IDA curves [2], which was recently developed within ICE4RISK project. Presented methodology and software tools are demonstrated by means of an example of a three-storey reinforced concrete frame building. The results of the presented example have indicated that incorporation of the epistemic uncertainty, in addition to aleatory uncertainty, slightly increases dispersion and can substantially decrease the limit-state intensities. This effect increases with the severity of the limit state. It was also proved that sophisticated software tools are important ingredient of performance-based earthquake engineering and can significantly facilitate transferring knowledge into practice.*

1 INTRODUCTION

Past investigations have shown, e.g. [1, 2], that accuracy of seismic performance assessment of structures can be reasonably improved if different sources of uncertainty are systematically incorporated within evaluation process. Thus, it is important in seismic performance evaluation to consider the effects of aleatory uncertainties, which are usually associated with random nature of earthquakes, and also the effects of epistemic uncertainties arising from incomplete knowledge of physical and modelling characteristics of structure.

Recently, several studies have been performed with a focus on comparisons between the different methods for incorporating the epistemic and aleatory uncertainties in seismic performance assessment, such as that performed by Liel et al. [3], or with the aim of defining simplified nonlinear methods for the evaluation of structural seismic performance, e.g. [4]. Nevertheless, a comprehensive seismic performance assessment with a systematic consideration of aleatory and epistemic uncertainties is from the computational point of view still very time-consuming due to numerous number of the required computational simulations, especially, if seismic response parameters are assessed by means of nonlinear dynamic analysis, such as that in [5, 6, 7]. It is therefore important to develop and use simplified procedures, which are computationally not excessively demanding, and are capable of sufficiently accurate prediction of the seismic response parameters with consideration of both types of the uncertainties.

For these reasons, this paper provides an overview of the procedure for fast seismic performance assessment of structures, which involves approximate IDA by using the web application [8], and allows incorporating the effect of both the aleatory and epistemic uncertainties. The use of the proposed methodology is demonstrated by the example of three-storey reinforced concrete (RC) frame building, which had been designed according to the Eurocode 8 requirements.

2 METHODOLOGY

The methodology for fast seismic performance assessment of buildings, which is explained in this section, involves the pushover analysis of the structure and the dynamic analysis of the equivalent single-degree-of-freedom (SDOF) model. The results of dynamic analysis are obtained by using the web application for prediction of IDA curves [8], which involves response database of SDOF model and n -dimensional linear interpolation. The effects of epistemic uncertainties are considered, by applying the pushover analysis and web application to the set of structural models, determined by utilizing the Latin Hypercube Sampling (LHS) technique [9].

2.1 Determination of set of structural models

In this study a variant of the LHS technique, which was recently proposed by Vorechovsky and Novak [9], was used. In general, two steps are needed to determine the sample of random variables, which are directly applied to the structural model. Firstly, each random variable X_i is sampled by using N_{Sim} values. The j -th sample value of the i -th random variable X_i can be obtained as follows:

$$x_{j,i} = F_i^{-1}(p_{j,i}) = F_i^{-1}\left(\frac{\pi_i(j) - 0.5}{N_{Sim}}\right), \quad i = 1, \dots, N_{Var}, \quad j = 1, \dots, N_{Sim}, \quad (1)$$

where $\pi_i(j)$ is a random permutation of $1, \dots, N_{Sim}$, $p_{i,j}$ is the probability that the random variable X_i is less than or equal to $x_{j,i}$ and $F_i^{-1}(p_{j,i})$ is the inverse of the cumulative distribution function (CDF) of the random variable X_i , evaluated at the probability $p_{j,i}$. The undesired correlation between the different random variables, which is introduced in the described sampling process, can be minimized by the stochastic optimization method called Simulated Annealing (see [9]). For this purpose the norm E , which is a measure for the difference between the generated and the prescribed correlation matrix, is defined by the expression:

$$E = \frac{2}{N_{Var}(N_{Var}-1)} \sqrt{\sum_{i=1}^{N_{Var}-1} \sum_{j=i+1}^{N_{Var}} (S_{i,j} - K_{i,j})^2}, \quad (2)$$

where $S_{i,j}$ and $K_{i,j}$ are, respectively, the generated and prescribed correlation coefficients between the random variables X_i and X_j . The norm E takes into account the deviations between all the correlation coefficients, and is normalized with respect to the total number of all the correlation coefficients. It therefore represents a good measure when examples with a different number of random variables are compared. The norm E is then minimized by the stochastic optimization method known as Simulated Annealing. The result of this optimization is the optimized sample matrix \mathbf{X} with N_{Sim} rows and N_{Var} columns, for which the correlation matrix is close to the target correlation matrix. More details about the LHS technique and its application can be found elsewhere (e.g. in [5, 9]).

The sample of random values is then used to generate a set of N_{Sim} structural models, which reflect the epistemic uncertainties, so that the set represents the probabilistic structural model. In a previous study [5], it was shown that if N_{Sim} slightly exceeds N_{Var} , then the optimized correlation matrix is close to the prescribed correlation matrix, and, usually, the seismic response parameters are in this case predicted with a sufficient accuracy.

2.2 Summary of the web application for prediction of IDA curves

The web application for prediction of approximate IDA curves of reinforced concrete structures, which was recently developed [8], involves response database of the equivalent single-degree-of-freedom (SDOF) model, which was computed for 30 ground motion records used by Vamvatsikos and Cornell [10].

The SDOF model was defined to be representative for reinforced concrete structure. In this case the force-displacement relationship is described by the four parameters (r_v , r_h , μ_u , α) of the pushover curve. The other two parameters of the SDOF model are the period T_1 and the ratio of the critical damping ξ . The four parameters of the force-displacement relationship are dimensionless quantities and are defined as

$$r_v = \frac{F_1}{F_2}, \quad r_h = \frac{u_1}{u_2}, \quad \mu_u = \frac{u_3}{u_2}, \quad \alpha = -\frac{k_{pc}}{k_i}, \quad (3)$$

where points (u_1, F_1) and (u_2, F_2) represent first and the second characteristic point of the idealized force-displacement relationship (Figure 1) and, respectively, roughly represent the cracking of concrete and, in the case of regular structures, yielding of reinforcements at the base of columns. The displacement u_3 is related with the displacement where the strength of the structure starts degrading, while k_{pc} and k_i are, respectively, the post-capping and initial stiffness of the idealized force-displacement relationship. With a suitable variation of the four

parameters the idealized curve can be fitted to almost any pushover curve typical for reinforced concrete structures.

Figure 1: The idealized force-displacement relationship.

The web application was developed on the basis of the classic three-tier client-server architecture [8], which enforces a general separation of three parts: client tier (also named presentation layer or, more specifically, user interface), middle tier (business logic) and data storage tier.

The advantage of the web application for prediction of approximate IDA curves in comparison to other simplified approaches, which are based on limited parametric studies, is that the response database can be expanded by adding results of seismic response of SDOF models for additional ground motion records. Further, web application enables quadrilateral idealization of pushover curve and prediction of global dynamic instability as well as the dispersion measures, which are needed for estimation of seismic risk. These parameters are rarely estimated by simplified methods.

3 EXAMPLE

The use of the presented methodology for seismic performance assessment of structures is demonstrated by means of an example of a three-storey RC frame building, designed for the earthquake resistance according to the Eurocode 8 [11]. The seismic performance of the building is evaluated considering both the aleatory uncertainties due to the random nature of the seismic load, and the epistemic uncertainties, which relate to several sources of the uncertainty in physical characteristics of the structure and its modelling parameters. Based on the approximate IDA curves, the median seismic capacity at the ultimate limit state and the dispersion measures for demand and capacity are estimated and compared to the analysis case, in which the epistemic uncertainties are neglected. In addition, the results are also compared with the results of the N2 method [12], which was for the case of the example building previously applied in the companion study [13].

Two limit states were defined for comparison reasons between the results of the approximate IDA and results of the N2 method. The definition of the limit states differs with respect to the methods involved since the N2 method is not capable to predict global dynamic instability of the structure. In the case of the approximate IDA the limit state was therefore defined with the global stability of the structure (on the following, termed as ultimate limit state), whereas in the case of the N2 method, the limit state under consideration corresponded to the displacement at 80 % of its maximum base shear in relation to the softening part of the pushover curve (termed as near-collapse (NC) limit state). More about both limit states is explained within the related sections, for example, in section 3.4.

3.1 Description of the structure and mathematical model

The example structure is a three-storey RC frame building, which was designed for the earthquake resistance according to the Eurocode 8 [11]. The plan dimensions of the structure are 9.7×10.5 m. All three storeys are 3 m high, with monolithic slabs having a depth of 15 cm. The strength of the concrete and of the steel reinforcement amounted to 33 and 400 MPa, respectively. The masses and corresponding mass moments of inertia amounted to 94.3 t and 1667 tm^2 for the first two storeys, and 94.4 t and 1634 tm^2 for the top storey, respectively. The plan view of the building and the reinforcement of typical cross sections of the columns and beams are shown in Figure 2.

Figure 2: The plan view of the building and typical cross-sections of the columns and beams.

The structure was modelled by one-component lumped plasticity elements, which consist of an elastic beam-column element and two inelastic rotational hinges at the ends. Envelopes, describing a moment-rotation relationships of the hinges, were modelled with equivalent tri-linear relationship using effective initial stiffness of the elements. The three characteristic points of the envelopes are the yield point (Y), the maximum strength (M), and a near-collapse point (NC). The NC point represents a local near-collapse limit state in a column or beam, which is defined by the ultimate rotation θ_u , corresponding to a 20 % reduction in the maximum moment. Near-collapse rotation in the columns was estimated by means of the Conditional Average Estimator (CAE) method [14], whereas in the beams the near-collapse rotation for their hinges was determined by using the formula defined in the Eurocode 8-3 [15].

In the structural model, the rigid diaphragms were assumed at the floor levels due to the monolithic RC slabs. Consequently the masses were lumped at the mass centres. Centreline dimensions of the elements were used with the exception of beams B5 and B6 (Figure 2). These beams are connected eccentrically to column C6.

All analyses were performed with the OpenSees [16] in conjunction with the PBEE toolbox [17].

3.2 Input random variables and the set of structural models

In order to incorporate the epistemic uncertainty into the structural model, the following parameters were treated as random variables: the strength of the concrete and of the reinforcement steel, mass, effective slab width and the parameters describing the characteristic rotations in the plastic hinges, i.e. the yield and the ultimate plastic rotation. These model parameters were defined with the eight random variables, each representing individual model

parameter. Note that the random variables, except for those defining the characteristic rotations in the plastic hinges, were assumed to be uncorrelated. In the study, the correlation factor between the yield and the ultimate rotation in plastic hinges was assumed to be 0.5. The statistical parameters were taken from literature and are presented in Table 1.

Utilizing the Latin Hypercube Sampling (LHS) technique [9], the selected random variables were used to generate the set of 20 structural models (simulations) in addition to the deterministic structural model in order to incorporate the selected sources of the epistemic uncertainties. Note, that the number of simulations generated is slightly higher than two times the number of input random variables. This is about the smallest reasonable number of the simulations, if using the LHS technique. A smaller number of simulations would probably lead to a significant decrease in the accuracy of the results. For more detailed discussion on the effects of number of the simulations on the results of the seismic performance evaluation when using the LHS technique, the reader is referred to the previous study [5].

Variable	COV	Distribution	Reference
Concrete strength	0.20	Normal	Melchers [18]
Steel strength	0.05	Lognormal	JCSS [19]
Mass	0.10	Normal	Ellingwood [20]
Eff. Slab width	0.20	Normal	Haselton [21]
Yield rotation:			
• columns	0.36	Lognormal	Panagiotakos and Fardis [22]
• beams	0.36	Lognormal	
Ultimate rotation:			
• columns	0.40	Lognormal	Peruš et al. [14]
• beams	0.60	Lognormal	Panagiotakos and Fardis [22]

Table 1: The statistical characteristics of the input random variables.

3.3 Results of the pushover analysis

The results of the pushover analysis are, for the simplicity reasons, presented only for the pushover analysis in positive X direction (Figure 3). The horizontal load pattern for pushover analysis was determined by the product of storey masses and the first modal shape in X direction.

The pushover curves for the deterministic structural model are compared with pushover curves of the set of 20 structural models incorporating the epistemic uncertainties (Figure 3). In addition, the 16th, 50th and 84th fractiles of the base shear given the top displacement (“fractile pushover curve”) are also shown in Figure 3. A high scatter in global ductility of the structure is observed. For example, the comparison between the fractile pushover curves and the deterministic pushover curve shows that the epistemic uncertainties mostly affect the displacement ductility of the structure. The epistemic uncertainties have moderate effect on the maximum base shear, while the difference in the initial stiffness between different structural models is almost negligible.

A large difference between the pushover curves presented in Figure 3 can be attributed to the fact that different collapse mechanisms were observed for different structural models, some of them being illustrated in Figure 4, for example at the NC limit state. The most influential parameter, which governs the type of the near-collapse mechanism of the building, is the rotation capacity of the beams. In the case, if rotation capacity of the beams is low in comparison to that of the columns, then the strength degradation of structure is a consequence of the damage in beams of the 1st and 2nd storeys. Thus, the top displacement capacity at NC

limit state is low $D_t = 0.18$ m (Figure 4a). The opposite case, i.e. the damage in plastic hinges of the structural model with high rotation capacities of the beams, is presented in Figure 4b. In this case, the top displacement capacity at NC limit state is equal to 0.59 m.

Figure 3: The pushover curves for the deterministic structural model, for the set of 20 structural models and the fractile pushover curves, representing the 16th, 50th and 84th fractiles of the base shear given the top displacement.

Figure 4: The damage in the plastic hinges of the building for a) the model with the smallest displacement capacity at the NC limit state, and b) for the model with the highest displacement capacity at the NC limit state. The results presented are based on the pushover analysis.

3.4 Prediction of IDA curves and definition of the ultimate limit state

The approximate IDA curves of the structure were determined by using a web application, which involves response database of the equivalent SDOF model. For that reason, the pushover curves were, for the need of the presented case study, idealized with a four-linear force-displacement relationship as presented in Figure 5. The first two points of the idealized force-displacement relationship represent the cracking (Cr) and yielding (Y) of the idealized system, the third point represents the maximum deformation capacity at the end of the plastic plateau (U), and the fourth point represents a complete loss of the base shear capacity. The cracking point was defined in the elastic part of the pushover curve and corresponded to the top displacement of the structure at which the first element (column or beam) starts yielding. The yield force F_y was assumed equal to the maximum base shear obtained by the pushover analysis. The post-cracking stiffness of the idealized system was determined in such a way that the areas under the pushover curve and the idealized force-displacement relationship were equal (termed as an equal energy rule) taking into account the interval between displacement at the cracking of concrete D_{cr} and displacement at the maximum base shear D_m . Similar rule applied also in determining the third point of the force-displacement relationship. The differ-

ence between pushover curve and the idealized force-displacement relationship is small as presented in Figure 5 for the deterministic structural model.

Figure 5: The pushover curve of the deterministic structural model and the corresponding idealization using a four-linear force-displacement relationship.

The modification factor Γ which relate the spectral displacement of an equivalent SDOF model to the roof displacement of the MDOF system is defined as follows:

$$\Gamma = \frac{m_{SDOF}}{\sum m_i \cdot \phi_i^2}, m_{SDOF} = \sum m_i \cdot \phi_i, \quad (4)$$

where m_{SDOF} is equivalent mass of the SDOF model, m_i is the mass of the structure in the i -th storey and ϕ_i is the displacement in the i -th storey, normalized to the displacement at the top storey. The vector ϕ was taken equal to the first modal shape of the structure, which corresponds to translations in X direction. The additional two parameters, which also affect the dynamic response of the SDOF model, are the critical damping factor (ξ), which was in our study assumed equal to 5 %, and the period of the equivalent SDOF model (T_{SDOF}) calculated as:

$$T_{SDOF} = 2 \cdot \pi \cdot \sqrt{\frac{m_{SDOF} \cdot d_{cr}^*}{f_{cr}^*}}, \quad (5)$$

where d_{cr}^* and f_{cr}^* are, respectively, the displacement and the base shear at cracking of the equivalent SDOF model.

Using the procedure described above, the equivalent SDOF models were determined for the deterministic structural model and for 20 structural models incorporating the epistemic uncertainties. Then, by applying the web application, the IDA curves of each structural model have been approximately predicted based on the dynamic analysis of the corresponding equivalent SDOF models. Actually, the output of the approximate IDA, which is presented in the Figure 6, are the IDA points, calculated for different ground motion records and for multiple levels of seismic intensities, and the fractile IDA curves, i.e. the median IDA curve and associated 16th and 84th fractiles for the top displacements.

One of the objectives of this study was estimation of the seismic performance parameters, i.e. the median seismic capacity and the corresponding dispersion measures. These parameters have been in the case of the approximate IDA estimated for the ultimate limit state of the structure, which has been, in our case, defined with the global loss of the structural stability in relation to the approximate IDA curves. These points of the ultimate limit state are marked red in the Figure 6.

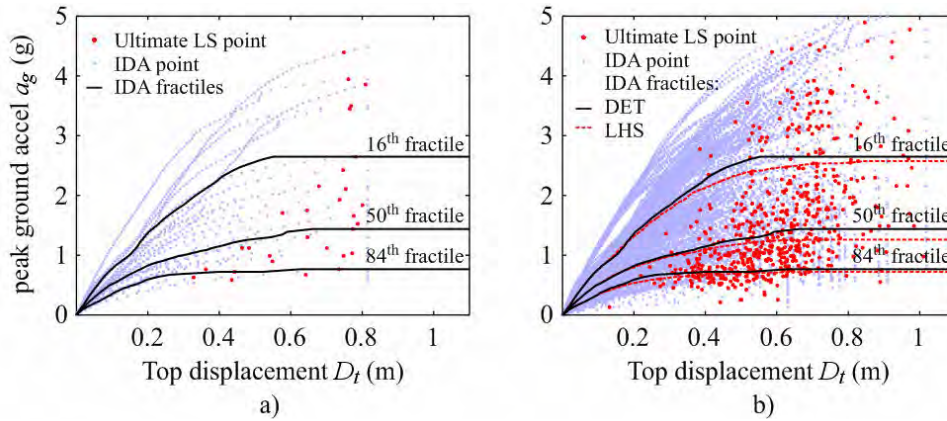

Figure 6: The fractile approximate IDA curves, collapse points and approximate IDA points for a) approximate IDA based on the deterministic structural model and b) for the approximate IDA based on the set of structural models representing the epistemic uncertainties.

Note, that such definition of the ultimate limit state is not completely realistic and probably overestimates the displacement capacity, since in the model the linear post-capping stiffness is assumed all the way to a complete loss of the base shear. Therefore the displacement, which corresponds to the global dynamic instability of structure, is probably smaller than that, which corresponds to the highlighted points in the Figure 6.

In the case if seismic response parameters were determined with the N2 method [12], which was for the same structure used in one of the previous studies [13], the displacement corresponding to the global dynamic stability of structure cannot be obtained. Usually it is conservatively assumed that this displacement corresponds to the NC limit state, as already defined above.

Nevertheless, the difference in the estimated seismic capacity, which was made due to the different definition of the limit states, is small, if expressed with the difference of predicted peak ground acceleration that cause the ultimate limit state or the NC limit-state. This is so, since the gradient of peak ground acceleration in comparison to the top displacement is low in the range of the displacements near global collapse of the structure.

By comparing the results in Figures 6a and 6b it can be concluded that a high scatter in the seismic performance of the structure arises predominantly due to the aleatory uncertainties. For example, the 16th and 84th fractiles of the approximated IDA curves for the deterministic structural model (see Figure 6a), for which only the aleatory uncertainty due to the randomness in the ground motion records were incorporated, and corresponding 16th and 84th fractiles of the approximated IDA curves incorporating both the aleatory and the epistemic uncertainties (see Figure 6b), do not differ significantly. This is observed especially for the 84th fractile and for the first part of the 16th fractile IDA curve. That means that the greatest part of the scatter in seismic performance is due to the random nature of the seismic load, whereas the epistemic uncertainties are relatively minor contributor to overall performance uncertainty. Another fact that can be concluded based on the results presented in Figure 6 is that the median seismic performance at the region of the intensities for the ultimate limit state is reduced if the epistemic uncertainties are included into the analysis. The reduction of the median seismic performance at the ultimate limit state can be visually observed as a vertical shift in the prediction of the median (50th fractile) IDA curve.

3.5 The estimation of seismic response parameters

The maximum top displacement $D_{t,C}$ at the defined ultimate limit state and corresponding peak ground acceleration $a_{g,C}$ were selected for seismic response parameters and assessed with its median value and dispersion measure. In addition, dispersion in top displacement demand was also estimated since it represents an input parameter for the seismic risk assessment if evaluated utilizing the EDP-based formulation. Note that in this case the dispersion depends on the peak ground acceleration and was for the sake of simplicity computed at $a_g = 0.4$ g.

Another distinction between the seismic response parameters was made with respect to the type of the uncertainty, which were considered in the analysis. So, the seismic response parameters were estimated, respectively, for the deterministic structural model, where only the aleatory uncertainties due to the record-to-record variability (R) were considered, and for the stochastic structural model, where both the aleatory and epistemic uncertainties (RU) were simultaneously incorporated. In addition, the results were presented also for the case if seismic response parameters were estimated by using the N2 method. In this case, the results were provided for the deterministic structural model and for the stochastic structural model with consideration of epistemic uncertainties (U).

In all cases the median and the dispersion measure of the seismic response parameters were estimated by using three different methods, all assuming a log-normal distribution of sample values. Thus the dispersion measure was defined as the standard deviation of natural logarithms. The first considered method was a so called counting method (on the following noted as M1), since 16th, 50th and 84th fractiles (y_{16}, y_{50}, y_{84}) of the seismic response parameters were determined according to the counting method and the corresponding dispersion measure was calculated as the average value of $\beta_{16} = \log(y_{50}/y_{16})$ and $\beta_{84} = \log(y_{84}/y_{50})$. The method of moments was the second method (M2) used for assessing median \tilde{m} and dispersion measure β of the seismic response parameters, i.e. the 1st and the 2nd moment of the sample values:

$$\tilde{m} = \bar{m} \cdot e^{-0.5 \cdot \beta^2}, \quad (6)$$

$$\beta = \sqrt{\ln \left(\frac{\sigma^2}{\bar{m}^2} + 1 \right)}, \quad (7)$$

where (\bar{m}) is the average value and (σ) is the corresponding standard deviation of sample values. Lastly, the third method (M3) was the maximum likelihood method, where median and corresponding dispersion were estimated as follows:

$$\tilde{m} = e^{\frac{1}{N} \sum_{i=1}^N \log(y_i)}, \quad \bar{m}_{\log Y} = \log(\tilde{m}), \quad (8)$$

$$\beta = \sqrt{\frac{1}{N} \sum_{i=1}^N (\log(y_i) - \bar{m}_{\log Y})^2}, \quad (9)$$

where y_i is the i -th sample value and N is size of the sample.

The results for estimated median and dispersion of the seismic response parameters with respect to the three adopted methods are presented in Tables 2 and 3. The notations DET and LHS relate, respectively, to the results based on deterministic and the stochastic structural model.

It can be observed (Table 2) that the median peak ground accelerations ($\tilde{a}_{g,C}$) are very similar if estimated with the N2 method and the approximate IDA. The average value of $\tilde{a}_{g,C}$ for deterministic structural model estimated by the approximate IDA equals to 1.43 g, which is

only around 6 % higher to that obtained with the N2 method ($\tilde{a}_{g,C} = 1.35$ g). The estimated $\tilde{a}_{g,C}$ is larger if compared to that, which was obtained in the study conducted by Rozman and Fajfar [23] ($\tilde{a}_{g,NC} = 0.77$ g), since adopted top displacement at the near collapse limit state was significantly smaller than that defined for the case of this study.

A slightly higher difference between the results of the approximate IDA and the N2 method presented in Tale 2 can be observed for the case if epistemic uncertainties are incorporated in the analysis. In that case, the average value of $\tilde{a}_{g,C}$ is reduced and amounts to 1.25 and 1.14 g if estimated by using the approximate IDA and the N2 method, respectively. However, in the contrast to the median peak ground acceleration, the predicted median displacement capacity strongly depends on the way how the limit state is defined. For example, the estimated median displacement capacity for deterministic structural model varies, respectively, from 0.39 m to 0.64 m (by the average), if calculated for the NC limit state as adopted for the N2 method, or for the ultimate limit state as adopted for the approximate IDA. Note that probably none of these values is not correct but represent more or less the boundaries in the prediction of the ultimate displacement capacity of the example structure, suggesting that the displacement at the ultimate limit state as defined in the case of the approximate IDA most probably overestimates the structural displacement capacity due to the adopted structural model, whereas the displacement capacity at NC limit state as defined in the N2 method is rather a conservative estimate for the displacement capacity.

Another phenomenon, which can be observed by comparing the results in the Table 2, is that the median seismic capacity is typically reduced if epistemic uncertainties are considered in the analysis. Thus neglecting the epistemic uncertainties leads to unsafe prediction of median capacity. In the case of the approximated IDA, the median peak ground acceleration at the ultimate limit state is, by the average, around 12 % less than that, which was estimated in the case of the deterministic model. Similar, conclusion can be made based on the results of the N2 method. A relatively high shift in the prediction of median seismic response parameters for the ultimate limit state cannot be simply ignored.

Method		$\tilde{a}_{g,C} (g)$	Δ	$\tilde{D}_{t,C} (m)$	Δ
DET + N2		1.35	-	0.39	-
LHS + N2	M1	1.15	-15 %	0.36	-8 %
	M2	1.08	-20 %	0.31	-21 %
	M3	1.20	-11 %	0.35	-10 %
DET + app. IDA	M1	1.48	-	0.71	-
	M2	1.33		0.59	
	M3	1.49		0.64	
LHS + app. IDA	M1	1.26	-15 %	0.61	-20 %
	M2	1.19	-11 %	0.53	-10 %
	M3	1.32	-11 %	0.58	-9 %

Table 2: The median seismic response parameters ($\tilde{a}_{g,C}$ and $\tilde{D}_{t,C}$) estimated by using the approximate IDA and the N2 method. The relative contribution of the epistemic uncertainties to the reduction of the median capacity is also shown and calculated as $\Delta = (\text{LHS} - \text{DET}) / \text{DET}$.

Important results of this study are the dispersion measures in seismic demand and capacity. Based on the results presented in Table 3, the highest dispersion can be observed for the peak ground accelerations at the ultimate limit state. For example, the average β_{agCR} is 0.57 if only the results based on the second and the third statistical methods (M2 and M3) are considered.

The results of the counting method are excluded, since, it provides overestimated value for β_{agCR} if compared to that determined by the method of moment or maximum likelihood method.

Much smaller dispersion is observed for the displacement corresponding to the ultimate limit state. In this case, by the average, the dispersion in top displacement for the aleatory uncertainties amounts to around 0.24. However, the latter dispersion is slightly increased to the value of 0.26 if the epistemic uncertainties are incorporated into the model. This is true also for the IM-based response parameter. In particular, the dispersion for the peak ground acceleration at the ultimate limit state due to the aleatory and epistemic uncertainties β_{agCRU} increased, by the average, from 0.57 to 0.59. It is a very small increase in the dispersion. For the presented example can be therefore concluded that that epistemic uncertainties have in the contrast to the median estimates of seismic capacity almost negligible influence to the overall dispersion in structural seismic performance.

The dispersion measures in top displacement demand have been calculated for the peak ground acceleration 0.4 g, which approximately corresponds to the seismic intensity at which the 84th fractile IDA curve, if determined with consideration of epistemic uncertainties, becomes horizontal. However, by the average, the dispersion in the displacement demand due to the aleatory uncertainties β_{DR} amounts to 0.44. The dispersion in displacement demand due to aleatory and epistemic uncertainty β_{DRU} cannot be determined by utilizing the method of moments or the maximum likelihood method since, for some cases, the collapse was attained at $a_g=0.4$ g. Therefore, β_{DRU} was estimated by using the counting method and equals to 0.49.

In addition, the Table 3 represents also the dispersion measures due to the epistemic uncertainties, which have been determined in the previous study [13] by applying the N2 method. These values amount to around 0.30 and 0.31, respectively, for the peak ground acceleration and the top displacement at the NC limit state and can be used to calculate the total dispersion in structural seismic performance by using the square root of the sum of the squares of the dispersions for aleatory and epistemic uncertainties.

Method		Peak ground accel. ($a_{g,C}$)	Displ. Capacity (C)	Displ. Demand (D)
LHS + N2	M1	0.27	0.33	0.11
	M2	β_{agCU} 0.30	β_{CU} 0.30	β_{DU} 0.09
	M3	0.31	0.31	0.09
DET + app. IDA	M1	0.72	0.25	0.46
	M2	β_{agCR} 0.56	β_{CR} 0.21	β_{DR} 0.44
	M3	0.58	0.25	0.43
LHS + app. IDA	M1	0.64	0.26	0.49
	M2	β_{agCRU} 0.58	β_{CRU} 0.24	-
	M3	0.60	0.27	-

Table 3: The dispersion measures due to the aleatory uncertainty (randomness) ($\beta_{agCR}, \beta_{CR}, \beta_{DR}$) from approximate IDA, the dispersions due to aleatory and epistemic uncertainty ($\beta_{agCRU}, \beta_{CRU}, \beta_{DRU}$) determined based on the approximate IDA, and the dispersion measures due to epistemic uncertainty ($\beta_{agCU}, \beta_{CU}, \beta_{DU}$) determined by the N2 method.

4 CONCLUSIONS

In the presented study, a methodology for fast seismic performance assessment was presented. The procedure involves approximate IDA by using the web application. The effects of the epistemic uncertainties are considered by the set of structural models, which are deter-

mined by utilizing the Latin Hypercube Sampling (LHS) technique. The outcomes of this process are the seismic response parameters in terms of the median seismic capacity and corresponding dispersion measures, which can be estimated considering both the aleatory and epistemic uncertainties.

The use of the presented methodology was illustrated by applying it to the case of three storey RC frame building. For the example structure it was shown that the aleatory and epistemic uncertainties strongly affect the overall dispersion in seismic performance of structure. It was also shown that neglecting the epistemic uncertainty potentially leads to unsafe design, since median seismic capacity at ultimate limits state can be overestimated if epistemic uncertainties are neglected in the analysis. For example, the median seismic capacity is reduced for about 11 - 15 % if epistemic uncertainties are incorporated into the approximate IDA.

All the analyses have been performed by using the PBEE toolbox in conjunction with the OpenSees. It was proved as a very powerful tool for fast seismic performance assessment of structures, since it allows performing a numerous number of the required computational simulations enables quick post-processing of the results and damage visualization on the structure for different limit state and for different structural models.

Keywords: Seismic risk; Masonry structure; Epistemic uncertainty; Latin hypercube sampling; Pushover analysis; IN2.

ABSTRACT. *The seismic risk assessment of structures is a complex problem, which combines seismic hazard analysis, structural vulnerability analysis and analysis of socio-economic impacts. In addition, seismic risk assessment, especially in the case of old masonry buildings, is subject to many uncertainties, not only due to the random nature of earthquakes but also due to physical and modeling uncertainties related to prediction of structural vulnerability. Recent studies have shown that epistemic (modeling) uncertainties can significantly affect seismic response parameters. However, uncertainty analysis usually involves simulations, and it is therefore computationally extremely demanding, especially if seismic response parameters are computed by using nonlinear dynamic analysis. Therefore, simplified nonlinear seismic performance assessment method is used to estimate seismic response parameters for a set of structural models, which are determined by utilizing the Latin Hypercube Sampling technique. The proposed method is demonstrated by means of an example of two masonry buildings, which are modeled and analyzed by using the computer program Tremuri. Results of the study indicate that the effects of epistemic uncertainties, in addition to aleatoric uncertainties, are significant.*

1 INTRODUCTION

A substantial part of built environment is represented by masonry buildings, which were mainly constructed in the past and are therefore not earthquake resistant structures. Consequently, earthquakes endanger this part of built environment and human lives more than thought. In order to contribute to the mitigation of seismic risk, advanced methods and tools should be developed, which will enable well-informed decision making, this being the key element for the future protection of built environment against earthquakes.

Probably the simplest closed-form solution for seismic risk assessment of structures expressed in terms of the mean annual frequency of exceeding a given limit state was proposed by Cornell et al. [1]. However, the most demanding part of the risk assessment procedure, i.e. the incremental dynamic analysis (IDA) [2], which enables direct evaluation of the record-to-record variability in structural response through a set of ground motion records, can be replaced with the IN2 analysis [3, 4]. These methods were applied in the study presented in the paper. However, several methods for estimating seismic risk of masonry structures exist. For example, a methodology for deriving analytical fragility curves for masonry buildings based on stochastic nonlinear analyses was introduced [5]. The method involves consideration of aleatoric and epistemic uncertainty since the nonlinear static (pushover) analyses are used to define the probability distributions of each damage state with consideration of epistemic uncertainties, while the incremental dynamic analysis for a set of ground motion records is performed to determine the probability density function of the displacement demand.

The effects of epistemic uncertainties are usually not explicitly considered for assessment of seismic risk of structure since this task is computationally demanding and requires sophisticated software tools. Therefore, only approximate methods for seismic performance assessment of structures with consideration of epistemic uncertainties can be adopted for practical purposes. Such a method, which combines the IN2 [3, 4] and a set of structural models determined by utilizing the variant of Latin Hypercube Sampling (LHS) technique [6], is presented in this paper. In its first part the method is briefly summarized, while in the second part its use is demonstrated by means of two examples of three-storey buildings, which were analyzed by structural analysis program - Tremuri [7].

2 SEISMIC RISK ASSESSMENT METHOD

Seismic risk of a building can be, in its most basic formulation, estimated with the mean annual frequency of exceeding a defined limit state (LS), which can be determined as follows:

$$P_{LS} = \int_0^{\infty} P(LS|I_M = i_m) \cdot \left| \frac{dH(i_m)}{di_m} \right| \cdot di_m \quad (1)$$

where $P(LS|I_M = i_m)$ is the probability of exceeding limit state (LS) if the intensity measure I_M is equal to i_m . Hazard function $H(i_m)$ is usually expressed in terms of mean annual frequency that the intensity measure I_M will be larger or equal to i_m and can be approximated as [1]:

$$H(i_m) = k_o (i_m)^{-k} \quad (2)$$

According to this assumption it follows, that the hazard function is linear in log-log coordinates.

The formulation of the seismic risk according to Eq.(1) is the so called IM-based formulation and requires definition of the intensity measure (i_m), which is the peak ground accelera-

tion (a_g) in the case of this study. Cornell had shown that mean annual frequency of exceeding given limit state can be, according to Eqs. (1) and (2) expressed as follows:

$$\lambda_{LS} = H(\tilde{a}_{g,LS}) \cdot e^{\frac{1}{2} \cdot k_{LS}^2 \cdot \beta_{LS}^2} = k_o \cdot (\tilde{a}_{g,LS})^{-k_{LS}} \cdot e^{\frac{1}{2} \cdot k_{LS}^2 \cdot \beta_{LS}^2} \quad (3)$$

where $\tilde{a}_{g,LS}$ is the median value of the IM-based capacity (i.e. the median peak ground acceleration which causes the given limit state), β_{LS} is the corresponding standard deviation of natural logarithms and k_{LS} is the slope of the hazard curve, which has to be estimated for each limit state.

Many different procedures exist, which can be used in order to estimate the fragility parameters $\tilde{a}_{g,LS}$ and β_{LS} . For example, the parametric analysis method IDA, which involves the nonlinear dynamic analysis for a set of ground motion records scaled to different levels of defined intensity measure, is probably the most accurate procedure for determination of fragility parameters. However, it is computationally extremely demanding, especially, if IDA is extended by the set of structural models in order to consider effects of epistemic uncertainties [8]. Two alternative, practice-oriented approaches are the approximate IDA performed by using an equivalent single-degree-of-freedom (SDOF-IDA) model [9] and the N2 method [3,4].

The approximate IDA is more accurate, since both fragility parameters can be evaluated by taking into account the record-to-record variability. The N2 method, which was used in the paper, provides mean estimates for limit-state intensities (e.g. peak ground acceleration corresponding to limit state - $a_{g,LS}$) with respect to record-to-record variability (aleatoric uncertainty), but its dispersion has to be predetermined or assumed. Since λ_{LS} is estimated based on the median $\tilde{a}_{g,LS}$, it was conservatively assumed that $\bar{a}_{g,LS} \approx \tilde{a}_{g,LS}$.

In addition to aleatoric uncertainty, the epistemic uncertainties can also significantly affect the fragility parameters. They are knowledge-based and are most often related to the physical properties of the structure and its modelling parameters. In this study epistemic uncertainties are treated by using the LHS technique [6], which is summarized in the Section 2.1. The result of the LHS technique is N_{sim} structural models and consequently N_{sim} peak ground accelerations corresponding to predetermined limit state are obtained.

The median $\tilde{a}_{g,LS}$ and the dispersion β_{LS} in general depends on the method used for their estimation. In the case of this study the fragility parameters were estimated according to the method of moments, as follows:

$$\tilde{a}_{g,LS} = \bar{a}_{g,LS} \cdot e^{-0.5 \cdot \beta_{LS}^2} \quad (4)$$

$$\beta_{LS} = \sqrt{\ln \left(\frac{\sigma^2}{\bar{a}_{g,LS}^2} + 1 \right)} \quad (5)$$

where $\bar{a}_{g,LS}$ and σ^2 are the sample mean and corresponding variance. In addition to LHS method, which is briefly summarized in next section, a procedure for determining the equivalent SDOF model, which is employed for estimation of the fragility parameters, is also briefly described in the Section 2.2.

2.1 Summary of the Latin Hypercube Sampling technique

The Latin Hypercube Sampling technique [10] uses stratification of the probability distribution function of the random variable X_i , therefore it requires fewer simulations as Monte Carlo method. Within the proposed methodology, the efficient LHS technique, which was re-

cently proposed by Vořechovský and Novák [6], is used and it can be applied for any probability distribution of random variables and the target correlation matrix.

The sample matrix can be calculated in two steps. In the first step, each random variable is sampled using N_{sim} values, which is shown in Figure 1. Firstly, the codomain of the cumulative distribution function is divided into k intervals, each having the length of $1/N_{sim}$. The k -th sample value of the i -th random variable ($x_{i,k}$) is determined based on the mean probability related to each interval as follows:

$$x_{i,k} = \frac{\int_{a_{i,k-1}}^{a_{i,k}} x \cdot f_{X_i}(x) dx}{\int_{a_{i,k-1}}^{a_{i,k}} f_{X_i}(x) dx} = N_{sim} \cdot \int_{a_{i,k-1}}^{a_{i,k}} x \cdot f_{X_i}(x) dx \quad (6)$$

where $f_{X_i}(x)$ is the probability density function of the random variable X_i , while $a_{i,k-1}$ and $a_{i,k}$ are the values of random variable X_i , which correspond, respectively, to the probability at the lower and the upper range of the k -th interval (Figure 1). Boundaries of the interval are estimated as follows:

$$a_{i,k} = F_{X_i}^{-1}\left(\frac{k}{N_{sim}}\right) \quad (7)$$

where $F_{X_i}(x)$ is the inverse of the cumulative distribution function of the random variable X_i .

Figure 1: Sampling of random variable X_i according to the Latin Hypercube Sampling technique.

Such sampling is more accurate with respect to the sampling based on the probabilities in the middle of equidistant intervals since the influence of the data in the tails of probability density function on the variance is smaller [6].

Especially in the case of very small number of samples, undesired correlation can occur between random variables. In this case generated correlation matrix \mathbf{S} significantly deviates from the prescribed (target) correlation matrix \mathbf{K} . The difference between \mathbf{S} and \mathbf{K} is minimized by using the stochastic optimization method called “simulated annealing”. It was first used in metallurgy and has some advantages, since its algorithm is very robust and it makes it possible to search for a global minimum.

In order to formulate the optimization problem, a suitable measure for difference between correlation matrices has to be defined. In the case of discussed problem, the norm E which takes into account deviations of all correlation coefficients simultaneously, is a good fitness function, which can be minimized by permutation of elements in sample matrix \mathbf{X} . It is defined as follows:

$$E = \frac{2}{N_{\text{var}}(N_{\text{var}} - 1)} \sqrt{\sum_{i=1}^{N_{\text{var}}-1} \sum_{k=i+1}^{N_{\text{var}}} (S_{i,k} - K_{i,k})^2} \quad (8)$$

where $S_{i,k}$ and $K_{i,k}$ are the coefficients of the generated and target correlation matrix, respectively, and N_{var} is the number of random variables X_i .

Optimization is an iterative procedure, where each iteration consists of two steps: mutation and selection. Mutation represents the change of the ranks of two randomly selected elements of random variable X_i , while selection makes it possible to decide if the new arrangement of the random variable X_i is acceptable or not. According to the simulated annealing algorithm, the new arrangement is automatically accepted if it results in a decrease of the norm E , otherwise new arrangement is accepted only if the random variable Z , which is defined in Eq. (9), is positive.

$$Z = e^{-\frac{\Delta E}{T}} - R \quad (9)$$

where ΔE is the difference in norms E before and after random change of the ranks, R is uniformly distributed random variable in the interval $[0,1]$ and T is the so-called temperature, which comes from annealing in metallurgy. Note that the initial temperature has to be defined in the algorithm and it is decreased step by step after a certain number of mutations, by using a reduction factor, which has the value 0.95, as recommended in [6].

The result of the optimization is optimized sample matrix \mathbf{X} , which has N_{sim} rows and its i -th row represents i -th structural model.

2.2 The equivalent SDOF model

In this Section the definition of the equivalent SDOF model, which is determined based on the results of the pushover analysis, is briefly described. More details regarding the definition of the equivalent SDOF model can be found elsewhere [4].

It is defined that the lateral loads used in the pushover analysis correspond to the product of mass matrix \mathbf{M} and the vector $\boldsymbol{\phi}$ related to assumed deformation shape, which has the value 1 at the location of the top displacement ($\varphi_n = 1$), and is assumed proportional to the first mode shape. In this case, the pushover curve corresponding to the equivalent SDOF model (F^* and m^*) is determined based on the pushover curve of the structural model by dividing the base shear F and top displacement D with the transformation factor Γ , which is defined as follows:

$$\Gamma = \frac{m^*}{\sum_{i=1}^n m_i \phi_i^2}, \quad m^* = \sum_{i=1}^n m_i \phi_i \quad (10)$$

where m_i and ϕ_i are masses and normalized deformations at the location of the i -th storey, and m^* is the mass of the equivalent SDOF model. The pushover curve of equivalent SDOF model has to be idealized with suitable force-displacement relationship. The corresponding initial stiffness (F_y^* / D_y^*) and the mass of the equivalent SDOF model define its period:

$$T^* = 2\pi \sqrt{\frac{m^* D_y^*}{F_y^*}} \quad (11)$$

where F_y and D_y are, respectively, yield force and yield displacement of the equivalent SDOF model.

3 EXAMPLE

The proposed methodology is demonstrated by means of seismic risk assessment of two three storey masonry buildings. Fragility parameters are estimated with approximate procedure involving N2 method. Results of both buildings are compared and the influence of epistemic uncertainties is discussed.

3.1 Description of the structures and structural models

The first example structure is a three-storey unreinforced masonry building A (Figures 2, 3 - left), which was selected from literature [11]. This building is symmetric around the Y axis and has 5.3 % of shear walls in the Y direction and 5.6 % shear walls in the X direction. Wall thickness is equal to 30 cm and storey height of all floors is equal to 2.8 m.

The second three-storey structure (building B, Figures 2, 3 - right) was derived from the geometry of SPEAR building [12], which was transformed into masonry building by adopting wall thickness equal to 30 cm, which amounted to 7.8 % of shear walls in X direction and 8.1 % walls in Y direction. The height of the first floor of the building B is 2.75 m, while the height of other stories is 3 m.

Both buildings have concrete slabs, which are considered as rigid diaphragms. At each floor level of both buildings, all walls are connected with continuous concrete beams with depth of 30 cm, which are reinforced with four 16 mm rebar (two at the bottom and two at the top) and 2 leg stirrups with 6 mm diameter at 25 cm spacing.

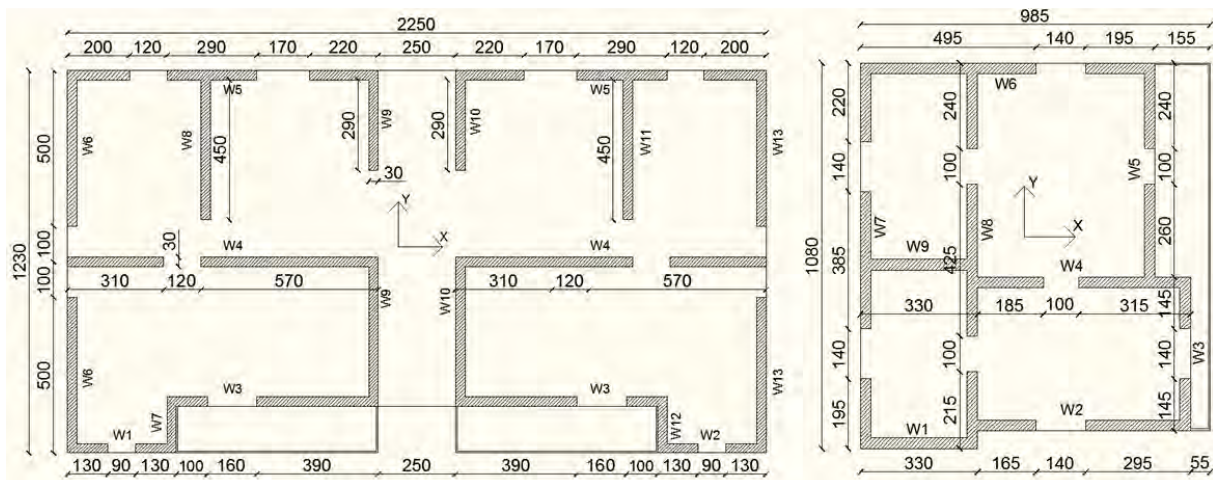

Figure 2: The plan of the building A (left) and building B (right)

Models of both buildings were made by using program 3Muri [13], specialized for seismic analysis and performance assessment of masonry structures, while the analysis was performed by using research version of the same program, Tremuri, which was developed at the University of Genoa [7]. The program is based on effective macro-element approach and enables accurate modelling, nonlinear pushover and time history analysis of masonry

buildings at very small computational burden [14]. Program models nonlinear behaviour of masonry piers and lintels with flexural and shear hinges, defined by a bilinear ideally elasto-plastic moment-rotation or force-displacement relationship, where ultimate drifts are defined for sliding shear mechanism (δ_s) and for flexural collapse mechanism (δ_f).

Figure 3: 3D view of the model A (left) and model B (right)

The vertical loads for both buildings, considered in the pushover analysis, are presented in the Table 1. Note that the live load was combined with the self weight by assuming combination factors 0.3 on the roof and 0.15 elsewhere.

Type of load	Building A	Building B
Self weight of masonry walls	16 kN/m ³	16 kN/m ³
Self weight and dead load of floors	5 kN/m ²	4.3 kN/m ²
Self weight and dead load of balconies	5 kN/m ²	4.3 kN/m ²
Self weight and dead load of staircase	5 kN/m ²	5 kN/m ²
Live load on floors	2 kN/m ²	2 kN/m ²
Live load on the staircase and balconies	4 kN/m ²	2.5 kN/m ²

Table 1: The self weight and the live loads used for definition of vertical load on the structure.

3.2 Uncertain parameters

In the case of this study some material and modelling parameters were considered uncertain. These parameters are: Young's modulus E , shear modulus G , compression strength of masonry wall f_m , initial shear strength f_{v0} , friction coefficient μ , nonlinear deformability parameter G_c , softening parameter β and ultimate drift ratios δ_s and δ_f that correspond to the shear and flexural collapse of masonry element, respectively.

The mean values of the uncertain parameters and corresponding coefficients of variation were adopted from literature [5] due to the lack of our own experimental data and are presented in Table 2. Normal distribution was assumed for all random variables.

Majority of the correlation coefficients between random variables was assumed 0. However, correlation coefficients between E , G , f_m , f_{v0} were determined based on experimental data [15].

The optimized sample matrix \mathbf{X} was determined according to the LHS technique, described in section 2.1, by assuming $N_{sim} = 30$. The norm E has a very low value of 0.0005 and the maximum difference between optimized and prescribed correlation matrix component is only 0.01. Therefore it was assumed, that the sample of uncertain parameters is appropriate for further analysis, although it cannot be claimed that the size of the sample is large enough in order to guarantee prediction of seismic response parameters with sufficient accuracy.

Thirty structural models were generated, since i -th row in optimized sample matrix \mathbf{X} represented a set of input parameters for i -th model in the case of both buildings. Additionally, deterministic models with mean material characteristics were used for comparison with stochastic models.

Name of the variable	Mean	COV	Distribution	Ref
Elastic modulus E [MPa]	1620	0.08	Normal	[5]
Shear modulus G [kN/m ²]	625	0.10	Normal	[5]
Compressive strength f_m [MPa]	1.95	0.19	Normal	[5]
Initial shear strength f_{v0} [MPa]	0.153	0.16	Normal	[5]
Friction coefficient μ [-]	0.065	0.12	Normal	[5]
Deformability parameter G_c [-]	7	0.21	Normal	[5]
Softening parameter β [-]	0.3	0.17	Normal	[5]
Shear drift ratio δ_s [%]	0.4	0.10	Normal	Assumed
Flexural drift ratio δ_f [%]	0.8	0.10	Normal	Assumed

Table 2: The statistical characteristics of the input random variables.

3.3 Definiton of near collapse limit-state

The seismic risk was estimated for the near collapse (NC) limit-state, which was at the top displacement that corresponds to the 80% of the building's shear resistance, which is measured in the range beyond the post-capping point of the pushover curve. Definition of more severe limit-state, i.e. the complete collapse of building, was omitted in this study, since numerical model does not consider all phenomena, which occur in extremely nonlinear behaviour of structure.

Note that the NC limit state depends on the ultimate drift ratio, which differs for shear and flexural collapse mechanism and consequently from model to model.

3.4 Acceleration spectrum and seismic hazard

The seismic action is defined with the elastic acceleration spectrum according to the Eurocode 8 - soil type A, which is shown in Figure 4 (left).

Figure 4: The Eurocode-based acceleration spectrum for soil type A (left) and the hazard curve defined based on the hazard map for return periods of 1000 and 2475 years (right).

The parameters of seismic hazard curve were computed from data, available on the website of the Environment Agency of the Republic of Slovenia [16]. The peak ground accelerations for Ljubljana, soil type A, and return periods of 475 years (10%/50), 1000 years (5%/50) and 2475 years (2%/50), amount to: 0.25 g, 0.30 g and 0.55 g, respectively. Since only two points on the hazard curve are needed in order to calculate parameters k_0 and k (Eq.(2)), it was decided to use the peak ground accelerations corresponding to the return periods of 1000 and 2475 years in order to interpolate the hazard curve in the vicinity of the limit-state intensity $\tilde{a}_{g,LS}$. The resulting curve, which is defined with parameters $k_0 = 1.03 \cdot 10^{-5}$ and $k = 3.8$, is presented in Figure 4 (right).

3.5 Pushover analysis

Pushover analyses for deterministic (mean-valued) model and 30 structural models resulting from LHS technique were performed in Y direction for a building A, and in X direction for a building B, by using the Tremuri [7]. The resulting pushover curves are shown in Figure 5. The force pattern for all pushover analyses was proportional to the product of masses and displacements at first mode shape in the Y direction.

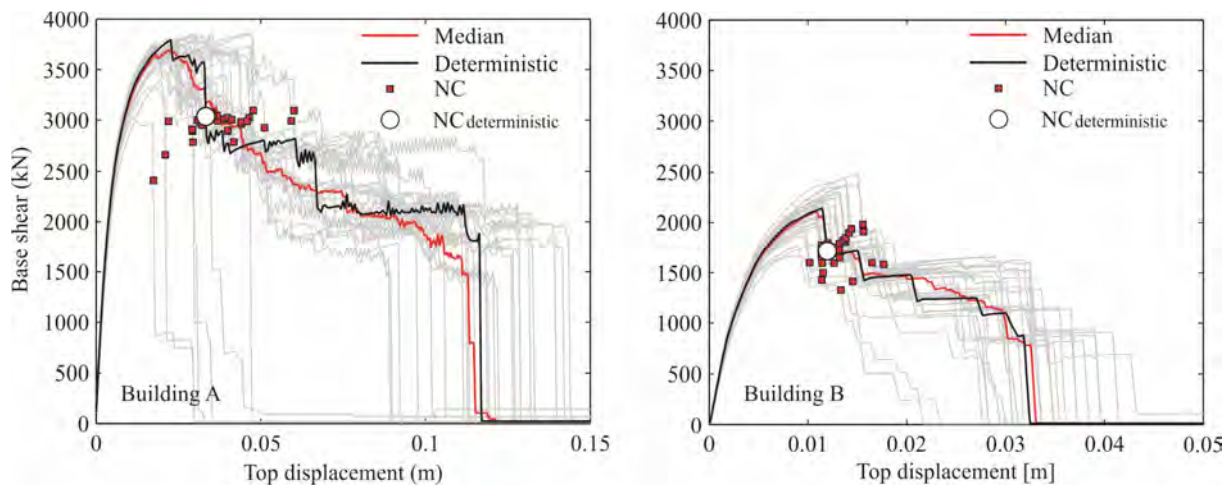

Figure 5: Pushover curves and points indicating the NC limit state for building A (left) and building B (right).

Shear resistance coefficient, which is defined as the ratio between resistance of the building and its weight, has a large value of 0.4 for a building A, and very large value of 0.6 for a building B, due to high percentage of walls in the case of both buildings. In both cases, quite small difference is observed between the median pushover curve, which represents median values of base shear at a given top displacement and the pushover curve of deterministic model.

Red points represent top displacements and corresponding base shears for the NC limit state, which is defined at 80 % of base shear resistance. Similarly, the white circle represents NC limit state of deterministic model. The coefficient of variation of the top displacement at NC limit state for building A is 0.27 and exceeds the coefficient of variation of the corresponding base shear (0.05) for more than five times. The reason for high coefficient of variation of top displacement is not only the high dispersion of the ultimate drift ratios, but also the fact, that uncertainty has the effect on the formation of different plastic mechanisms, which were in this study observed only for building A and are presented in Figures 6, 7 and 8. Different colours in piers represent different failures: red - flexural collapse, yellow - shear collapse and blue - undamaged.

In Figure 6, collapse mechanism of model A8, which occurred at the minimum top displacement ($d_{NC,SDOFA8} = 0.018$ m), is shown. Sudden large drop of base shear observed in the pushover curve is the consequence of simultaneous shear-collapse of several walls in the ground floor (for definition of walls see Figure 2 - left). Such collapse mechanism was expected since the initial shear strength of walls in model A8 is the lowest among these of 30 models and, in addition, the compressive strength and ultimate drift ratios δ_s and δ_f are also low. On the other hand (Figure 7), plastic mechanism of model A27 corresponds to the maximum top displacement ($d_{NC,SDOFA27} = 0.045$ m). At $d_{NC,SDOFA27}$ only a few elements in walls W6 and W13 fail, but at larger displacement, flexural-collapse of all piers in the second storey is observed. In this case, the initial shear strength and ultimate shear-drift ratio are very large, which governs flexural collapse and consequently NC limit-state is attained at larger top displacement. For comparison reasons, plastic mechanism of deterministic model (model A31) is also presented (Figure 8). In this case, structural elements gradually collapse in shear or in flexure at different storeys.

Figure 6: Plastic mechanism corresponding to the NC limit state for Model A8 - minimum top displacement.

Figure 7: Plastic mechanism corresponding to the NC limit state for Model A27 – maximum top displacement.

Figure 8: Plastic mechanism corresponding to the NC limit state for deterministic model A31.

In building B, the coefficient of variation in the maximum force at NC limit state is 0.09 and the coefficient of variation of the top displacement is only 0.13, which is much smaller than that obtained for building A. Namely, only one plastic mechanism forms in the case of building B - the soft storey effect in the ground floor. Firstly, element 46 (Figure 9) fails in shear and later other walls in the ground floor collapse in shear or bending. The strength of the element 46 is approximately 20 % of the strength of first storey, therefore it controls the attainment of NC limit state. In some cases the NC limit state is controlled by more than one wall, since the strength of element 46 is less than 20 % of the strength of the first storey. However, variability in NC displacements is relatively small, from 1 cm to 1.77 cm, where the smallest top displacement corresponds to the smallest δ_s .

Figure 9: Plastic mechanism corresponding to the NC limit state for model B24.

In order to compute peak ground acceleration that causes the structure to violate the defined NC limit state, pushover curves were idealized using bi-linear force-displacement relationship (Figure 10). It was assumed, that initial stiffness of the equivalent SDOF model is defined based on the pushover curve at 70 % of the base shear resistance. Maximum base shear F_y of the idealized force-displacement relationship is calculated by assuming equal area under the pushover curve and idealized force-displacement relationship, if measured in the interval of displacements from 0 to the displacement d_{NC} , when maximum base shear decreases by 20 % (NC limit state (d_{NC} , F_{NC})). The described idealized force-displacement relationship of pushover curves represents input data for definition of equivalent SDOF model and is shown in Figure 10 for building A.

The force-displacement relationship of equivalent SDOF models were determined by dividing forces and displacements with the transformation factor Γ , having a mean value $\Gamma_{mean,A} = 1.33$ and $\Gamma_{mean,B} = 1.37$ for the building A and B, respectively. The masses of the equivalent SDOF models m^* of building A and B amounted to, respectively, 532 t and 230 t.

Figure 10: Idealized bi-linear force-displacement relationship of pushover curve.

3.6 Fragility parameters and seismic risk estimation

The fragility parameters were determined by utilizing the N2 method with consideration of epistemic uncertainty. The IN2 curve, as presented in Figure 11, and peak ground acceleration $a_{g,NC}^{IN2}(I)$ were determined for each model of both buildings.

In Table 3 the fragility parameters, estimated based on the procedure described in Section 2, are presented. Median peak ground acceleration and its dispersion were determined with consideration of epistemic uncertainty (U) according to Eqs. (4) and (5).

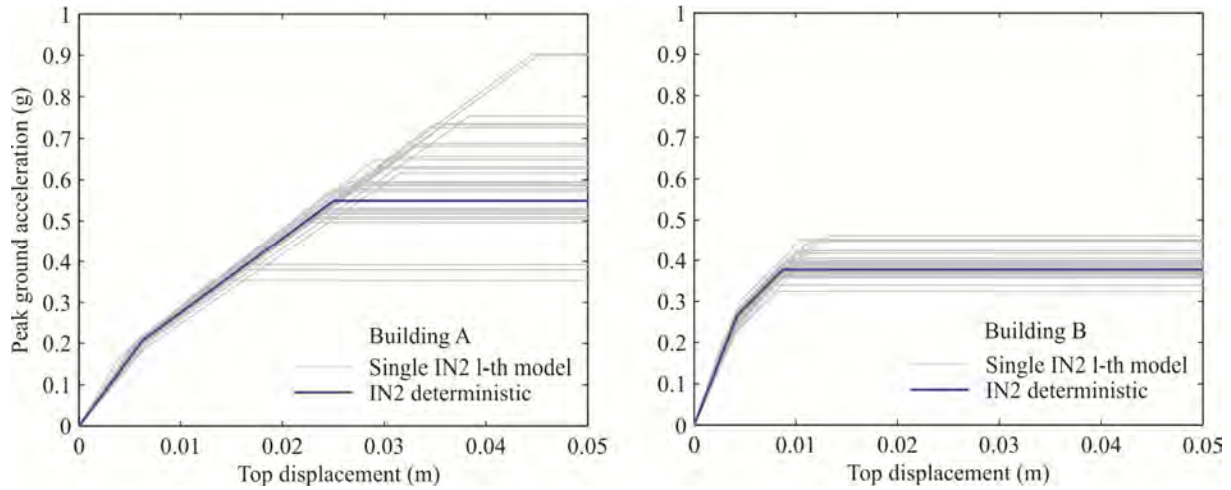

Figure 11: IN2 curves, based on 30 structural models and deterministic model for building A (left) and building B (right).

Method	Building A				Building B			
	$\tilde{a}_g(g)$		β		$\tilde{a}_g(g)$		β	
IN2 ₃₀	$\tilde{a}_{gU,A}^{IN2}$	0.59	$\beta_{U,A}^{IN2}$	0.21	$\tilde{a}_{gU,B}^{IN2}$	0.39	$\beta_{U,B}^{IN2}$	0.08
IN2 _{det}	$a_{g,det,A}^{IN2}$	0.55	-	-	$a_{g,det,B}^{IN2}$	0.38	-	-

Table 3: The fragility parameters for building A and B.

High estimated median peak ground accelerations, at which the NC limit state is attained, are observed in Table 3, mainly due to the high percentage of walls in both buildings. Further, the peak ground acceleration $\tilde{a}_{g,det,A}^{IN2}$, that corresponds to deterministic model, is slightly smaller than the median peak ground acceleration $\tilde{a}_{gU,A}^{IN2}$, which corresponds to stochastic model. An opposite was observed for building A, if fragility parameters were assessed by conducting nonlinear dynamic analysis for the equivalent SDOF model. However, the difference between $\tilde{a}_{g,det,A}^{IN2}$ and $\tilde{a}_{gU,A}^{IN2}$ is very small.

The dispersions for \tilde{a}_{gU}^{IN2} are 0.21 and 0.08, respectively, for building A and B. Quite small dispersion in the case of building B is the consequence of a small number of different plastic mechanisms that formed in this case. Namely, plastic mechanism affects displacement capacity and consequently the peak ground acceleration that causes the NC limit state.

In the Table 3, only epistemic uncertainties are considered, therefore dispersion due to aleatoric uncertainties β_R has to be assumed and in the case of presented examples equals 0.16. This value was adopted from a previous study, where approximate IDA for a single-degree-of-freedom model of the building A was performed for the 30 ground motion records. The total dispersion β_{RU}^{IN2} , which was used for calculation of seismic risk, was obtained by using SRSS rule as follows:

$$\beta_{RU,A}^{IN2} = \sqrt{(\beta_R)^2 + (\beta_{U,A}^{IN2})^2} = \sqrt{0.16^2 + 0.21^2} = 0.26 \quad (12)$$

$$\beta_{RU,B}^{IN2} = \sqrt{(\beta_R)^2 + (\beta_{U,B}^{IN2})^2} = \sqrt{0.16^2 + 0.08^2} = 0.18 \quad (13)$$

Mean annual frequency of exceeding the NC limit state λ_{NC} (MAF_{NC}), the corresponding return period T_{NC} and the frequency of exceeding NC limit state in 50 years λ_{NC}^{50} are presented in Table 4. MAF_{NC} for a building B is four times higher than for building A. This is due to

lower capacity of building B in terms of PGA, which has a much higher influence on result (Eq. 3) than dispersion, which is for building B smaller than that of building A.

Building	λ_{NC}	$T_{NC}(\text{years})$	$\lambda_{NC}^{50} (\%)$
A	$1.28 \cdot 10^{-4}$	7800	0.64
B	$4.67 \cdot 10^{-4}$	2150	2.31

Table 4: Seismic risk in terms of mean annual frequency of exceeding NC limit state λ_{NC} , corresponding return period T_{NC} and frequency of exceeding NC limit state in 50 years λ_{NC}^{50} .

4 CONCLUSIONS

A simplified method for estimating seismic risk in combination with N2 method was used for determination of fragility parameters in the case of two three-storey masonry buildings. It was shown that the formation of plastic mechanisms has a significant effect on the estimation of fragility parameters. If only one plastic mechanism controls the seismic response of the building, the dispersion for \tilde{a}_{gU}^{IN2} and the dispersion in drift capacity of the wall, which is an input parameter, are almost the same. This is not true for building A, where several plastic mechanisms were observed from pushover analyses. Since it is difficult to judge in advance, whether the modeling uncertainties affect plastic mechanism or not, it is also difficult to prescribe the dispersion measures. Therefore the use of simplified methods, which enable fast estimation of effects of epistemic uncertainties on seismic response parameters, may become more often used for risk assessment of masonry buildings.

Abstract. *We propose a new approach for the performance-based seismic design of buildings using a deterministic and a reliability-based structural optimization framework. To overcome the increased computing cost of Incremental Dynamic Analysis (IDA) we adopt an approximate seismic performance estimation tool, known as Static Pushover to IDA (SPO2IDA). The SPO2IDA tool is nested within the framework of a Genetic Algorithm resulting to an efficient seismic design procedure able to consider uncertainty. The Genetic Algorithm steps towards designs of improved performance, locating the most efficient design in terms of the minimum weight of the structure. Reliability-based constraints are considered in terms of the mean annual frequency of preset limit-states not being exceeded. A three-storey steel moment resisting frame is used to demonstrate the design algorithm proposed. The methodology presented leads to efficient real-world building designs within reasonable computing time, directly considering the seismic risk.*

1 INTRODUCTION

The design of a building structure is valued upon the extent to which regional design codes or guidelines are satisfied. This effort comes in hand with the designer's need for reducing the cost in order to obtain a more efficient design solution. Nonlinear, static or dynamic, methods of analysis are expected to lead to less costly designs using high-level performance criteria, since the engineer is allowed to have a better insight on the system's demand and capacity. Among the nonlinear performance estimation methods today available Incremental Dynamic Analysis (IDA) [1] is probably the most powerful and thorough approach.

IDA as well as other nonlinear methods of analysis requires increased computing resources. For practical applications and for designing new structures, approximating methods based on IDA have recently appeared intending to provide a fast alternative to the original method. More specifically, Dolsek & Fajfar [2] proposed the IN2 method, which is a simplified procedure that combines nonlinear static analysis with a design response spectrum. Vamvatsikos & Cornell [3,4] developed the Static Pushover to Incremental Dynamic Analysis (SPO2IDA) tool in an effort to approximate the IDA curve taking advantage information extracted from the static pushover backbone. Han & Chopra [5] proposed the MPA-based IDA method which in essence is a variation of the Modal Pushover Analysis (MPA) method. Azarbakht & Dolsek [6] proposed a method that uses a limited number of ground motions that have been appropriately selected to obtain the mean and the fractiles of the response. All the above procedures are approximate, but their results compare sufficiently to those of IDA while their cost and efficiency varies.

Evolutionary-based optimizers can handle complicated structural problems at the expense of more optimization cycles. Their rapid development made possible the solution of complex and realistic nonlinear structural optimization problems. Evolutionary Algorithms (EA) do not require the calculation of gradients of the constraints, as opposed to mathematical programming algorithms, and thus structural design code checks can be implemented as constraints of the optimization problem in a straightforward manner. Within this concept, different optimization-based seismic design procedures can be developed (Fragiadakis & Lagaros [7]).

This study discusses the use of approximating performance-estimation methods within the framework of an optimization algorithm. The resource-demanding IDA method is replaced by the Static Pushover to Incremental Dynamic Analysis (SPO2IDA) approach. SPO2IDA is employed to provide fast estimates of the mean and the dispersion of the demand at various performance levels. The constraints of the optimization problem are introduced as the exceedance of every performance level calculated either using deterministic or probabilistic design criteria. Deterministic design criteria refer to the exceedance of preset drift values that are set by the codes. Probabilistic criteria refer to the calculation of the mean annual frequency of exceedance of every limit state considering in this way the uncertainties. A Genetic Algorithm is used to handle the resulting optimum design problem. A three-storey, steel moment-resisting frame (SMRF) is used to demonstrate the proposed methodology.

2 STRUCTURAL PERFORMANCE ESTIMATION

2.1 Incremental Dynamic analysis

According to the Incremental Dynamic Analysis (IDA) method [1] the mathematical model of the structure is subjected to a suite of ground motion records incrementally scaled to different levels of seismic intensity. Recent researches show that the scaling practice is legitimate and introduces slight bias on the prediction of the structural response [10]. The building's capacity is visualised with a curve of an Engineering Demand Parameter (EDP),

e.g. maximum interstorey drift ratio, versus an Intensity Measure (IM), e.g. the 5%-damped, first-mode spectral acceleration $S_a(T_1, 5\%)$, representing the seismic intensity. IDA allows calculating the median (50% fractile) and also the dispersion (16%, 84% fractiles) of the building's capacity. Performance limit-states are defined on these curves by appropriate limits which are set, preferably, on the EDPs. The results of IDA can be easily combined with probabilistic seismic hazard analysis in order to estimate the mean annual frequency (MAF) of a limit-state being exceeded.

2.2 Static Pushover To Incremental Dynamic Analysis (SPO2IDA)

The Static Pushover to IDA (SPO2IDA) tool [3, 4] provides an approximate estimation of the IDA curve using the backbone of the static pushover (SPO). SPO2IDA has been verified for numerous SDOF systems and first-mode dominated structures and can be seen as a more elaborate R - μ - T relationship. More specifically, the static pushover is approximated with a trilinear or a quadrilinear envelope in order to extract the parameters that describe the SPO curve (Fig. 1). The extracted parameters are then given as input to the SPO2IDA tool to provide the fractile IDAs in normalized coordinates of the strength reduction factor R versus the ductility μ . The final approximate IDAs are obtained after a series of calculations on the available R - μ data [11].

Figure 1. The SPO curve for the three-storey steel moment resisting frame and its approximation with a trilinear model.

The necessary steps to obtain the approximate IDAs are briefly summarised as follows. The process begins with approximating the static pushover curve with a multilinear envelope. Having approximated the SPO capacity curve with a trilinear model, as can be seen in Figure 1, the parameters that describe the backbone can be easily extracted. These parameters refer to the properties of the backbone curve, which initially allows for elastic behavior up to F_y , then hardens at a non-negative normalized slope of a_h while beyond this point, a negative stiffness segment starts having a normalized slope a_c [11]. These parameters are given as input to SPO2IDA to produce the median capacities. Since the capacities of SPO2IDA are in dimensionless R - μ coordinates, they have to be scaled to another pair of IM-EDP coordinates, such as the 5%-damped, first mode spectral acceleration, $S_a(T_1, 5\%)$, and the maximum interstorey drift ratio, θ_{max} .

The scaling from R - μ to $S_a(T_1, 5\%)$ - θ_{max} is performed with simple algebraic calculations:

$$\begin{aligned} S_a(T_1, 5\%) &= R S_a^{yield}(T_1, 5\%) \\ \theta_{roof} &= \mu \theta_{roof}^{yield} \end{aligned} \quad (1)$$

where θ_{roof} is the roof drift (displacement of the roof divided by the building height) and θ_{roof}^{yield} is the roof drift at yield, respectively. Once θ_{roof}^{yield} is known, θ_{max} can be extracted from the results of the SPO, since for every load increment the correspondence between the two EDPs is always available. To determine $S_a^{yield}(T_1, 5\%)$ and θ_{roof}^{yield} we assume that the yield roof drift is that of the trilinear approximation, while the $S_a^{yield}(T_1, 5\%)$ is related to the approximation of the elastic “stiffnesses” (or slopes) of the median IDA curves plotted with θ_{roof} as the EDP. The stiffness, denoted as k_{roof} , is the median value obtained using elastic response history analysis with a few ground motion records, or alternatively by using standard response spectrum analysis. An approximate relationship for k_{roof} can be found in [11]. Finally, $S_a^{yield}(T_1, 5\%)$ will be:

$$S_a^{yield}(T_1, 5\%) = k_{roof} \theta_{roof}^{yield} \quad (2)$$

In summary, the process of producing an approximate IDA curve from a single static pushover run involves the following steps. Initially perform a static pushover analysis with a first-mode lateral load pattern and then approximate it with a trilinear model. Next SPO2IDA will provide the IDA curves in normalized R - μ coordinates which have to be transformed in terms of $S_a(T_1, 5\%)$ versus θ_{max} . This requires the elastic slope of the actual IDA, k_{roof} when θ_{roof} is the EDP. With the aid of Equations (1) and (2) we obtain the IDAs in $S_a(T_1, 5\%)$ - θ_{roof} coordinates. The final IDAs are obtained using the mapping between θ_{roof} and θ_{max} , available from the results of the static pushover. For a three-storey SMRF building the computing time comes down from 1.5÷2 hours required for a single IDA, to a couple of minutes, approximately two orders of magnitude less.

3 METHODOLOGY-ALGORITHM

The aim of sizing optimization problems is to minimize an objective function which, usually, is proportional to the cost of the structure. The most common objective function for steel structures is the total weight, which is considered to be directly related to the cost. The design variables are chosen to be the cross sections of the members of the structure such that the objective function can be expressed as their linear, or nonlinear, combination. Due to engineering practice demands, the members are divided into groups of design variables, thus providing a trade-off between the use of more material and the need for symmetry and uniformity due to practical considerations. Moreover, due to fabrication limitations, the design variables are not continuous but discrete. A discrete deterministic-based structural optimization (DBO) problem is formulated as follows:

$$\begin{aligned} \min & F(s) \\ \text{s.t.} & \begin{cases} g_i(s) \geq 0, i = 1, \dots, l \\ s_j \in R^d, j = 1, \dots, m \end{cases} \end{aligned} \quad (3)$$

where $F(s)$ is the objective function to be minimized and g_i are the l deterministic constraints. R^d is a given set of discrete values, and s_j is the design variables that can take values from this set. In a similar way, a discrete reliability-based (RBO) structural optimization problem is formulated as:

$$\begin{aligned} \min \quad & F(s) \\ \text{s.t.} \quad & \begin{cases} g_i(s) \geq 0, i = 1, \dots, l \\ s_j \in R^d, j = 1, \dots, m \\ h_k(v_{\text{EDP}}(s) \leq v_{\text{EDP}}^{\text{lim}}(s)), k = 1, \dots, n \end{cases} \end{aligned} \quad (4)$$

where $F(s)$ is the objective function to be minimized, R^d is a given set of discrete values, s_j represents the design variables that can take values from this set, h_k are the n probabilistic constraints, v represents the MAF of exceedance of the k_{th} performance level and finally EDP denotes a chosen engineering demand parameter (EDP) (here is the maximum interstorey drift θ_{max}).

3.1 Solving the optimization problem using Genetic Algorithms

Genetic Algorithm (GA) [12] is the most widely used Evolutionary Algorithm. GA is a machine-learning algorithm that uses a genetic metaphor and imitates the evolution of a population. The resulting numerical tool can be used for general purposes and does not need the calculation of gradients as traditional mathematical optimizers do. Implementations of GA, typically use fixed-length character strings (binary or real-valued) to represent their genetic information. Together with a population of individuals, which undergo mutation and crossover, the GA guides the search process towards the optimum combination of the design variables. The steps of the adopted GA-based algorithm are:

1. *Initialization step*: Random generation of an initial population of the vectors of design variables s^j ($j=1, \dots, n_{\text{pop}}$). The variables are encoded as binary strings.
2. *Analysis step (Fitness evaluation)*: Firstly, perform checks that do not require analysis to ensure that the design complies with the “strong-column-weak-beam” philosophy and that other detailing requirements are met. Subsequently, perform linear elastic analysis to obtain the demand for the non-seismic load combinations and then perform Static Pushover for the seismic actions. Use the SPO2IDA tool to obtain the EDP or its mean annual frequency of exceedance for every limit-state considered. For every constraint that is violated, calculate the penalties and modify the objective function accordingly (section 3.2).
3. *Selection, Generation and Mutation step*: Apply the operators of GA to create the members of the next population t^j ($j=1, \dots, n_{\text{pop}}$).
4. *Final check*: If a prespecified number of generations has been reached stop, otherwise go back to step 2.

3.2 Performance-based earthquake engineering constraints

3.2.1 Design using deterministic criteria

For structural optimization problems under earthquake loading, the constraints adopted follow the performance-based design concept where the performance of the structure is evaluated at distinct levels of seismic intensity. Three performance levels are here considered: Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP). Preliminary checks are performed on every candidate design. These checks include examining whether a soft storey mechanism produced by the hinges formed in the columns rather than the beams. Also, a check whether the sections chosen are of class 1, as EC3 suggests, is carried out. This check is important in order to ensure that the members are able to develop their full plastic moment and rotational ductility. Moreover, geometrical restrictions that ensure the correct

connection of the beams to the columns are performed. Another check ensuring that the bending capacity of the beams is adequate against gravity loads is also carried out. If the checks are not satisfied the design is slightly modified in order to meet the above restrictions. The capacity of the structure against seismic loads is subsequently assessed. For the three limit-states considered the first-mode spectral acceleration is computed with the aid of the EC8 elastic response spectrum. Afterwards, we determine using SPO2IDA the maximum interstorey drift demand. The latter is compared to the drift threshold values of the corresponding limit-state.

When a performance criterion is violated, a penalty, p , is calculated which gives a measure of the deviation of the value obtained with analysis from the acceptable threshold value. In this work the objective function is penalised as follows:

$$\bar{F}(s) = \begin{cases} F(s), & \text{if } s \in R^d \\ F(s) \cdot \max(p), & \text{otherwise} \end{cases} \quad (5)$$

where $\max(p)$ is the maximum value of the violated constraint's penalty parameter and $\bar{F}(s)$ is the value of the penalized objective function. The selection of the penalty parameter is significant, since a large penalty will force the design procedure to work away from the region where the global optimum is located while a small penalty will make the algorithm converge to an infeasible solution. Moreover, the penalty parameter adjusts the weight of the penalty imposed on the objective function during the optimization process.

The penalty adopted for the i -th limit state of the deterministic-based formulation of the optimization algorithm takes the form:

$$p_{\theta_{\max}} = \frac{\theta_{\max}^i - \theta_{\lim}^i}{\theta_{\lim}^i} \quad (6)$$

where θ_{\max}^i and θ_{\lim}^i is the maximum interstorey drift demand and its threshold, respectively.

3.2.2 Design using probabilistic criteria

From another point of view, the use of probabilistic criteria possess the advantage of considering uncertainties through the use of probabilities. In this way, the seismic design checks are applied on the mean annual frequency of every limit-state instead of being applied directly on the EDP. Therefore, every performance objective is realized as the exceedance probability of exceeding a specified performance level. Following this concept, for every performance level we calculate its mean annual frequency (MAF) of exceedance (v_{LS}). The calculation of the MAF can be derived using the total probability theorem:

$$v_{LS}(edp \leq EDP) = \int_0^{+\infty} P(edp \leq EDP / IM = im) \left| \frac{dv(IM)}{dIM} \right| dIM \quad (7)$$

$P(edp \leq EDP / IM = im)$ is the probability of limit-state being exceeded, termed also as fragility or vulnerability function, and $\left| dv(IM)/dIM \right|$ is the slope of the hazard curve. The absolute value is used to prevent from the negative value of the slope of the hazard curve. Equation 7 convolves the ground motion uncertainty, given through the hazard curve of the site, with uncertainties regarding the structural performance represented by the building's fragility curve.

The equation is calculated numerically since the analytical integration is not always possible. There are two ways to calculate the MAF [13]. The first way is calculating the probability that the demand exceeds the capacity of the structure, called the direct or EDP-based method,

or by alternatively using the indirect or IM-based approach. The IM-based approach refers to calculating the probability that the IM will be above the random IM capacity of the structure. In this work the latter method is used, where:

$$P(edp \leq EDP / IM = im) = P(IM_C < IM / IM = im) \quad (8)$$

The mean annual frequency of exceedance of a limit-state is estimated using the statistics of the responses calculated with the aid of SPO2IDA. SPO2IDA gives an estimate of the mean value and the standard deviation of the response and may be used to calculate equation 7, for given EDP value. This is based on the assumption that the IM values are lognormally distributed. The probability of exceeding the IM capacity of the structure is thus calculated and multiplied with the slope of the hazard curve using equation 8. If $\ln(\hat{\theta}_{\max})$ and $\hat{\delta}$ are the logarithmic mean and the standard deviation of $\hat{\theta}_{\max}$ for given intensity $S_a(T_1, 5\%)$, $\hat{\delta}$ is calculated as $\hat{\delta} = 0.5 \cdot (\ln S_a^{84\%} - \ln S_a^{50\%})$ [14].

Figure 2 (a) Hazard curve for $T_1 = 0.93$ sec, and (b) median SPO2IDA curve and its 16th and 84th fractiles.

The seismic hazard at a site can be obtained through probabilistic seismic hazard analysis (PSHA) and is represented by a hazard curve (Figure 2a). The performance levels correspond to exceedance probabilities equal to 50%, 10% and 2% in 50 years (briefly denoted hereafter as 50/50, 10/50 and 2/50). For example, the IO level implies very light damage with minor local yielding and negligible residual drifts within a period of 50 years corresponding to a level of 50% probability of exceedance. Using the first-mode spectral acceleration of the structure and its period it is possible to obtain the mean annual frequency of exceedance of the ground motion $v(IM)$.

The probabilistic constraints are applied on the annual rate of the drift value being exceeded for every limit-state considered. In particular the rates used for the 50/50, 10/50 and 2/50 hazard levels are related to the return period of the limit-state being exceeded with the relationship $\tau_{LS} = 1 / v_{LS}$. The corresponding return periods are 72, 475, 2475 years respectively. This leads to the following probabilistic constraints:

$$\begin{aligned} \tau_{IO} &\geq 72 \text{ yrs} \\ \tau_{LS} &\geq 475 \text{ yrs} \\ \tau_{CP} &\geq 2474 \text{ yrs} \end{aligned} \quad (9)$$

The penalty adopted for the i -th limit state of the reliability-based formulation of the optimization problem is:

$$p_{\tau} = \frac{\tau_{\text{lim}}^i + \tau^i}{\tau_{\text{lim}}^i} \quad (10)$$

where τ_{lim}^i is the return period of the i -th limit state set by the codes and τ^i is the return period of the design given by the optimization algorithm.

4 NUMERICAL RESULTS

The proposed methodology is demonstrated on a three-storey steel moment-resisting frame (SMRF) (Figure 3(a)). The frame has been designed for a Los Angeles site according to the 1997 NEHRP (National Earthquake Hazard Reduction Program) provisions. All analyses were performed on the OpenSees platform [15]. The modulus of elasticity was assumed equal to 200GPa and the yield stress $f_y=235\text{MPa}$. All sections are W-shaped, taken from the tables of the American Institute of Steel and Construction (AISC). The frame is assumed to have rigid connections and fixed supports. The permanent load is taken as $G=5\text{KN/m}^2$ and the live load is considered equal to $Q=2\text{KN/m}^2$. The EDP adopted is the maximum interstorey drift, θ_{max} , and the thresholds were 0.6, 1.5, and 3% for IO, LS and CP levels, respectively. This building is a first-mode dominated structure.

Figure 3 (a) Three-storey, steel moment resisting frame, and (b) optimization history of the three-storey frame using the deterministic-based and the reliability-based procedure.

The optimum designs obtained are shown in Table 1. As can be seen, the MAF of exceedance of the optimum design for the reliability-based optimization case satisfies the probabilistic constraints. The MAF of the optimal design using deterministic-based criteria only is given as well additionally. Figure 3(b) shows the best objective function value as the generations converge to the optimum design. It can be seen that the optimum weight reduces from 58m^3 to 29.64m^3 in the case of deterministic-based design, while for the reliability-based case, the optimum weight reduces from 65m^3 to 37.55m^3 .

Case study	Volume (m^3)	Optimal design	MAF
DBO	29.64	W33×201,	IO 1×10^{-2}
		W27×94, W21×50,	LS 2.8×10^{-2}
		W14×30, W14×38	CP 4.7×10^{-4}
RBO	37.55	W33×263,	IO 1.7×10^{-3}
		W27×94, W21×68,	LS 0.9×10^{-3}

W14×48,W14×26 CP 0.1×10^{-3}

Table 1. Optimal design results for the two buildings used.

Figure 4 compares the capacity curves of IDA and SPO2IDA for the optimal design of the three storey considered using the reliability-based design procedure. For the reliability-based design of the three-storey SMRF (Fig. 4) the two curves seem to be in good agreement in the elastic range. The capacity is overestimated for limit states between the elastic range and until $\hat{\theta}_{\max}=0.054$ while beyond this value as the frame approaches collapse, SPO2IDA underestimates the capacity. These discrepancies introduce a small error in curve calculations, which is sufficient for an automatic design algorithm.

Figure 4 Median IDA curve and its SPO2IDA approximation. The curves refer to the optimal design of the three storey frame obtained by the reliability-based procedure.

5 CONCLUSIONS

A new seismic design procedure for steel moment frames has been developed. The proposed design procedure is expressed with the aid of deterministic and/or probabilistic design criteria. Both types of criteria can be imposed within the performance-based design concept as suggested by the FEMA guidelines with the latter enabling the engineer to define the return periods of preset performance levels. In this way, a common language can be used within the engineers and stakeholders during the building design procedure. The proposed algorithm uses approximate performance-estimation methods and in particular the SPO2IDA method. We have shown that the implementation of structural design code checks is possible and designs that meet the code provisions can be obtained in a straightforward manner. The mean annual frequencies of the limit-states considered are compared to preset values in order to decide whether each candidate design is acceptable. A Genetic Algorithm (GA) was implemented for the solution of the design problem leading to efficient optimal solutions through an iterative procedure. The results obtained reveal the efficiency of the proposed approach for first-mode dominated structures reducing considerably the computing time.

Abstract. *The Targeted Nonlinear Dynamic Procedure is introduced to offer a practical evaluation of the seismic performance of structures. Building upon the SAC/FEMA closed-form probabilistic framework it can incorporate all important sources of variability and can be calibrated for conservatism. The hazard curve is combined with the nonlinear dynamic analysis performed for each limit-state using one or two levels of the intensity measure. This is either the elastic first-mode spectral acceleration or the more sufficient inelastic spectral displacement. From the suite of ground motion records only “targeted” subsets are used that are optimally selected to estimate the median and dispersion of the structural response. The simple factored demand and capacity checking format employed allows for a seamless integration with current engineering practice, while rational safety factors add the required degree of conservatism to account for epistemic uncertainties both for ductile and brittle modes of failure. Using a four-story reinforced concrete frame as an example, the proposed approach is shown to provide a relatively simple means to account for important sources of variability in nonlinear response history analysis. It offers powerful analysis options to a knowledgeable user in a format that can be upgraded incrementally and can provide an excellent introduction to sophisticated analysis techniques with more precisely controlled levels of conservatism.*

1 INTRODUCTION

The assessment of the seismic performance of structures is a fundamental problem in performance-based earthquake engineering (PBEE) that necessitates a compromise between cost and accuracy. Each method that has been proposed achieves a different balance between these two requirements, offering different advantages for the consideration of the engineer-user.

At the lower end of the hierarchy of methods, nonlinear static procedures (NSPs) offer considerable computational simplicity but at a certain cost in fidelity. They have limitations when predicting various engineering demand parameters (EDPs) for most structures. Also, as currently formulated, the nonlinear static procedures cannot treat uncertainty explicitly in estimating EDPs. These limitations are evident from comparisons with results from nonlinear response history analyses (NRHA).

NRHA methods lie at the opposite end of the scale, offering improved accuracy at the cost of requiring results from many ground motions to properly account for record-to-record variability. One example is incremental dynamic analysis (IDA [1]) which offers unparalleled accuracy but necessitates multiple nonlinear dynamic analyses under a suite of ground motion records scaled to several levels of the intensity measure (IM). Simpler NRHA implementations in the guidelines do exist, but they are mostly concerned with finding a single “central” value of response (e.g. a mean or median) for a certain seismic hazard level while completely ignoring the effect of record-to-record variability and epistemic uncertainty. This has led to the familiar prescriptions such as taking the maximum of three records or the mean of seven to determine a representative “central” response level. More recent developments, such as the Scaled NDP [2] also offer dispersion estimates but still do not offer a modern PBEE basis. Thus, practical implementation of complex NRHA methods, such as IDA, is impeded by the computational cost, while the simpler versions often seem to lack proper rigor in the wake of recent PBEE developments. We aim to offer a better alternative that strikes a favorable compromise between these two ends.

From the results of the work on the ATC-76-6 project [3] and its direct predecessors (FEMA 440/440A [4,5]), a Targeted Nonlinear Dynamic Procedure (Targeted NDP) is formulated conceptually as outlined herein. Although experience with this procedure is limited, it is expected to be more broadly applicable than predecessor nonlinear static procedures with regard to structural irregularities, component hysteretic behavior, and site-dependent ground motion characteristics (e.g. type of source mechanism and proximity to fault). At the same time, it is simpler and considerably less costly than IDA while obviously paying for it with lower accuracy. The mitigating factor though is that it is formulated to take into account epistemic uncertainties, including its inherent errors, and wherever possible shift them in such a way as to incur higher conservatism throughout its range of application. Furthermore, this implied conservatism is, to a certain degree, user-defined and can be tuned to properly cover a variety of safety requirements.

2 PROPOSED METHODOLOGY AND APPLICATION

In brief, the Targeted NDP the method is composed of 6 basic steps. At its basis lie the formation of a multi-degree-of-freedom model and its equivalent single-degree-of-freedom model, the use of subsets of records and the determination of response via NRHA:

1. Inelastic MDOF and equivalent SDOF models
2. Seismic shaking hazard and intensity measure selection
3. Stability assessment
4. Record set and subset selection
5. Nonlinear response history analyses and statistics of EDPs.

6. Safety checking

The procedure utilizes a multiple-degree-of-freedom model of the structure capable of capturing inelastic behavior and degradation at a component and system level. First mode pushover analysis of the model produces a capacity boundary for an equivalent-single-degree-freedom representation of the structure that is used to assess the potential for dynamic instability. Based on the characteristics of the structural mode, the seismic shaking hazard at the site of the structure is evaluated. This offers the fundamental consideration of uncertainty and naturally conveys the expected seismic threat level.

In the procedure described herein, two options for an intensity measure are available for scaling the ground motion records for use in nonlinear response history analyses of the MDOF model. The traditional approach, best suited when site specific ground motion records are available, is to scale records to match the spectral acceleration associated with a specific hazard level at the fundamental period of vibration of the model. This approach is sometimes referred to as $S_a(T_1)$ scaling. The alternative option is to use the peak displacement of the ESDOF model at the hazard level as the basis for scaling the ground motion records. This option allows use of a larger range of ground motion records and is sometimes referred to as S_{di} scaling.

At present we will focus on the application of the more familiar basis of $S_a(T_1)$ scaling: Two subsets of scaled ground motions are selected and median EDP's and related dispersions are estimated based on the results of nonlinear response history analyses of the MDOF model. Finally, this data is used to develop statistical representations of EDP demand and related capacities and perform safety checking in the Demand and Capacity Factored Design format introduced by FEMA-350/351 [6,7].

In the following pages the methodology will be presented in detail using the assessment of a 4-story reinforced concrete moment-resisting frame designed for California as an illustrative example.

2.1 Inelastic MDOF and equivalent SDOF models

First, a model representing the mechanical behavior of the structure to be assessed is created. The model must be capable of representing important potential inelastic mechanisms and degradation of strength and stiffness as well as P-Delta effects. The building under consideration is a 4-story reinforced concrete moment-resisting frame (RCMRF) building designed according to the 2003 IBC [8] that was developed as an archetype in FEMA-P695 [9] (see Haselton [10]).

The structural model was formed using the OpenSees platform and it is shown in Figure 1. It has accurate representation of the nonlinear behavior of beams and columns while it also incorporates nonlinear modeling of the beam-column joints. A leaning column has been included to supply any additional P-Delta forces. This is a first-mode dominated structure with a fundamental period of $T_1 = 0.86$ sec.

Conventional static pushover analysis was performed using a first-mode load pattern to develop the capacity curve of the structure shown in Figure 2. The structure was pushed well into the nonlinear range, beyond its maximum base shear capacity, to allow observation of the negative stiffness region. The resulting pushover curve is in turn fitted via a trilinear elastic-hardening-softening backbone that will serve as the capacity boundary of the equivalent SDOF (ESDOF) model that will be used for stability assessment.

Figure 1: The four-story RC moment resisting frame building (reproduced from [8]). The bay width is 9.1m (30ft) and the story heights are 4.6m (15ft) for the first story and 4.0m (13ft) for the higher ones.

Figure 2: Capacity boundary (pushover curve) of the equivalent single-degree-of-freedom system fitted to the results of a first-mode pushover of the 4-story reinforced concrete moment frame building model.

2.2 Seismic hazard and intensity measure selection

As the next step, the seismic shaking hazard at the site of the structure is defined, allowing for the analysis results to be expressed probabilistically. Hazard may be determined from a site-specific probabilistic seismic hazard analysis. For sites within the United States, $S_a(T_1, 5\%)$ hazard data are available on the USGS website (www.usgs.gov).

Figure 3 presents an example of such data for the 4-story reinforced concrete frame structure at $T_1 = 0.86$ sec, which corresponds to the first-mode period. Mean hazard information is preferred over median data because the higher mean hazard curve also incorporates the important effect of epistemic uncertainty in the seismic hazard, as described in Cornell et al. [11]. Use of the mean hazard curve effectively allows the considerable uncertainty in seismic hazard to be addressed at this stage in a transparent way that simplifies the assessment process and avoids the need to explicitly account for seismic hazard uncertainty in subsequent steps.

Determining the seismic hazard goes hand-in-hand with selecting the intensity measure that will be used to scale the ground motion records for NRHA. Two possible choices have been considered for application with the Targeted NDP, namely the elastic spectral acceleration S_a and the inelastic spectral displacement S_{di} .

Scaling ground motions to $S_a(T_1, 5\%)$ is most appropriate where site-specific hazard data, including ground motion records, are available. Since seismic hazard data are readily available in terms of S_a , it naturally offers a very simple assessment path. Still, it is plagued by issues of sufficiency, in so far that it cannot describe adequately important seismological parameters. This may introduce a bias in the estimation of performance that is generally conservative. On the other hand, as stated by Tothong and Cornell [12], S_{di} offers advantages over $S_a(T_1, 5\%)$ in that S_{di} removes the so-called peak-valley effects associated with period elongation during nonlinear response. It can reduce the potential bias in scaling the amplitude of ground motions, thus simplifying record selection by avoiding strong emphasis on other ground-motion record properties such as epsilon [13], M_w , and distance. It is thus less restrictive than $S_a(T_1, 5\%)$ scaling as far as the selection of acceptable ground motion records. The disadvantage of the use of S_{di} as an intensity measure is the need to compute a custom-made S_{di} hazard curve that depends upon the characteristics of the ESDOF system. This may be achieved, e.g., by a probabilistic seismic hazard analysis performed using attenuation relationships for S_{di} (e.g., Tothong and Cornell [14]), or by using the ESDOF itself to determine the S_{di} from the $S_a(T_1, 5\%)$ hazard [3].

We will presently not expand further into this process which can cut down on the conservative bias induced by $S_a(T_1)$ to provide a closer estimation that is more suitable for accurate assessment. Thus we will proceed with S_a as the intensity measure, which is also the simpler version of the Targeted NDP.

Figure 3: Seismic hazard curve for the intensity measure $S_a(T_1, 5\%)$ for $T_1=0.86s$.

2.3 Stability assessment

Lateral instability occurs when lateral resistance degrades due to damage caused by seismic shaking. NRHA of the MDOF system is considered the most accurate approach for assessing the likelihood of lateral instability. However, several simpler approaches based on pushover analysis may be used for this purpose—it seems that evaluation of lateral instability

by pushover analysis may be more robust than evaluation of nonlinear response via NSP more generally, possibly due to the response at collapse being dominated moreso by a single mode than at lower levels of nonlinear response. Each of these pushover-based approaches makes use of the capacity boundary determined from nonlinear static pushover analysis.

One approach uses the percentile IDA curves obtained from either explicit NRHA of the ESDOF oscillator or SPO2IDA [15] relationships (the rightmost panels of Figures 4 and 5) to assess the median and distribution of collapse capacity—collapse due to lateral instability is considered to occur when the 16/50/84% IDA curves have zero slope, which indicates the corresponding percentile value of pseudo-spectral acceleration at which lateral displacements increase without limit. In case of the NRHA analyses, the record suite that will be selected for the formation of subsets for NRHA in the following section may be used for this purpose. In case of SPO2IDA though, no records are needed, as the software tool [16] is capable of instant delivery of the needed collapse capacity values in the form of the 16/50/84% percentile values of the allowable strength reduction factor.

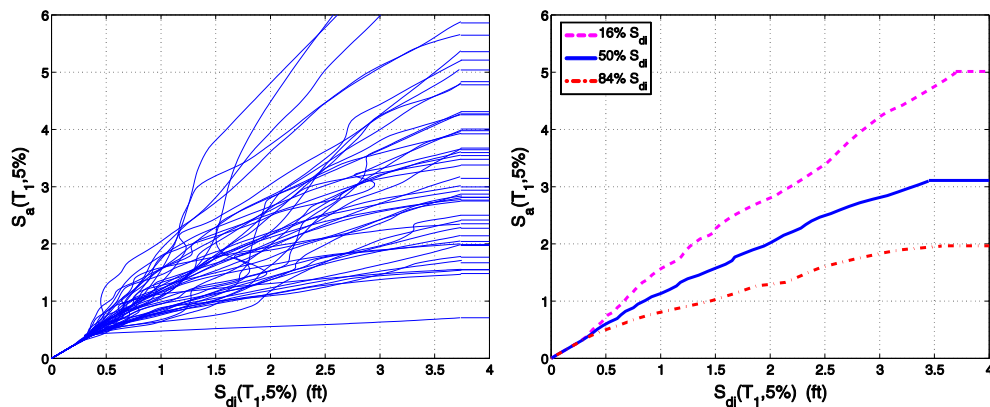

Figure 4: Complete set of 44 IDA curves and the summary 16th, 50th, 84th percentile IDA curves in S_a - S_d coordinates as produced by nonlinear response history analysis for the equivalent single-degree-of-freedom fitted to a 4-story reinforced concrete moment frame building model.

Figure 5: Percentile IDA curves in R - μ and S_a - S_d coordinates as produced by SPO2IDA [14] for the equivalent single-degree-of-freedom fitted to a 4-story reinforced concrete moment frame building model.

A second approach to assess the median collapse capacity does so by means of a maximum limit on strength reduction factor R_{di} , developed through a large number of SDOF simulations in FEMA P440A [5]. In this approach, $R_{di} = S_a / S_{ay}$, where S_a = the median spectral acceleration causing instability and S_{ay} = the strength of the oscillator, expressed as a spectral acceleration. Terms used in Equation 1 are defined in Figure 6.

$$\begin{aligned}
 R_{di} &= \left(\frac{\Delta_c}{\Delta_y} \right)^a + b \frac{T_e}{3|\gamma|} + \frac{F_y}{F_r} (\Delta_u - \Delta_r) \sqrt[3]{T_e} \\
 a &= 1 - \exp(-dT_e) \\
 b &= 1 - \left(\frac{F_y}{F_c} \right)^2
 \end{aligned} \tag{1}$$

Figure 6: The backbone characteristics used in the FEMA 440A equation for maximum strength factor, R_{di} , to avoid dynamic instability.

2.4 Record Set and Subset selection

Nonlinear response history analyses of the MDOF model of the structure can be implemented at a given hazard level either by using a moderately large pool (greater than 30) of ground motion records or, more economically, by selecting subset(s) of ground motion records to estimate index values of the demand parameter distributions. The use of record subsets here follows the initial ideas presented by Azarbakht and Dolsek [17,18]. The ground motion records used in the nonlinear response history analyses are individually scaled to the target S_a or target S_{di} level, according to our choice of intensity measure. The target pseudo-spectral acceleration level $S_a(T_1)$, symbolized as S_a^{des} , is determined from the S_a hazard curve at the desired mean annual frequency of exceedance.

When using S_a as the intensity measure of choice, sufficiency (Luco and Cornell [19]) becomes an important issue. Thus, ground motion records for this approach ideally should be epsilon-consistent (Baker and Cornell, [13]) to obtain unbiased response quantity estimates. Nevertheless, ignoring this issue generally will lead to conservative estimates. A simple alternative to better control the level of conservatism is to select ground motions for which the scale factor applied to each natural (corrected) record is between 0.4 and 2.5. In our case, the far-field set of 44 records selected for FEMA-P695 [9] will be used. These motions are generally consistent with the smoothed elastic response spectrum for this site, needing scale factors within the suggested limits for reaching the design value of spectral acceleration, S_a^{des} , given by $S_a(T_1, 5\%)$ at the designated hazard level of 10% in 50yrs.

Figure 7: The 5%-damped 16,50,84% S_a spectra of the 44 records scaled to match the set median at $T_1=0.86\text{sec}$.

Figure 8: The 1,3,5 and 7 best record subsets A as selected to optimally match the 50% scaled-spectrum of Figure 7 in the regions of interest.

Figure 9: The 1,3,5 and 7 best record subsets B as selected to optimally match the 84% scaled-spectrum of Figure 7 in the regions of interest.

Median values of demand parameters are estimated using a subset of records whose spectra individually and collectively best approximate the median (50th percentile) spectrum; these records comprise record subset A. Where estimates of dispersion are sought, records are selected whose spectra individually and collectively best approximate a desired higher level of response spectrum (taken as the 84th percentile in this discussion); these records comprise subset B.

Subsets are selected using the elastic response spectra determined for the entire suite of ground motion records, scaled either to the target S_a value or to the target S_{di} value. The scaled elastic response spectra determined for the entire pool are used to generate 50th percentile (median) and 84th percentile spectra of S_a as a function of T . Subsets of ground motion records are selected based on how well the corresponding elastic spectra match the median or 84th percentile spectral amplitudes over a relevant period range. For records scaled to the target S_a , investigations in ATC-76-6 [3] suggest that spectral matching should be done over a period range defined by the two intervals, designed to capture both the higher mode effects and the expected lengthening of the “first-mode” after yielding. In the case of S_{di} scaling, the period range need not extend up to and past the first-mode period as the use of S_{di} is expected to directly take into account the lengthening of the “first-mode period” of the structure that occurs as inelastic response develops. Thus, the period range of interest becomes:

$$R_T = \begin{cases} [0.8T_i, 1.2T_2] \cup [0.8T_1, 1.5T_1], & \text{if } S_a \text{ - scaling} \\ [0.8T_i, 1.2T_2], & \text{if } S_{di} \text{ - scaling} \end{cases} \quad (2)$$

The lower period is T_i determined as a function of the number of stories $N_{st} > 1$, where $i = \text{ceil}(\sqrt{N_{st}})$, “ceil” being the ceiling function that rounds up to the nearest higher integer.

To properly describe the subset selection method, the following symbols are introduced: The operator $[.]_{D,x\%}$ denotes the x percentile of dataset D , while the designations “sub” and “all” are used to distinguish the subset and the full set. Then, the selection method for S_a -scaling may be formally defined as follows: Minimize the sum of the absolute *relative* differences from the median of the elastic spectrum of the ground motion suite within the period range R_T . Formally:

$$\text{minimize} \int_{R_T} \left| \frac{[S_a(T)]_{\text{sub},x\%} - [S_a(T)]_{\text{all},x\%}}{[S_a(T)]_{\text{all},x\%}} \right| dT \quad (3)$$

A proper optimization to select the true optimal subsets would be cumbersome, involving a difficult combinatorial optimization problem. In its place, a simplified selection procedure is introduced that can be easily implemented, e.g. in a spreadsheet:

1. For a given $x\%$ (50/84%) fractile to be estimated, calculate the “signed” and “unsigned” objective values $S_{x\%}^i$ and $U_{x\%}^i$ for each i -th record by adapting Equation (3) with and without the absolute value, respectively:

$$S_{x\%}^i = \int_{R_T} \frac{S_a^i(T) - [S_a(T)]_{\text{all},x\%}}{[S_a(T)]_{\text{all},x\%}} dT \quad (4)$$

$$U_{x\%}^i = \int_{R_T} \left| \frac{S_a^i(T) - [S_a(T)]_{\text{all},x\%}}{[S_a(T)]_{\text{all},x\%}} \right| dT \quad (5)$$

2. Separate the records into two lists: A “negative” and a “positive” list according to the sign of the “signed” objective value. Sort each in ascending “unsigned” value.

3. Merge the two lists by selecting records alternatively from each: Start from the “positive” list and pick the record with the lowest “unsigned” value, then similarly proceed with the “negative” list to pick the second record. Remove them from the lists.
4. Continue with step 3 until the desired subset size is reached.

The above algorithm should be applied twice, first for $x = 50\%$ to determine subset A to estimate the median response and then for $x = 84\%$ to determine subset B and allow determination of the response dispersion. The use of 7 to 11 records in each subset appears to be adequate for many cases. There is no restriction to the maximum size of subset A or B, apart from a logical limitation of about one third the total number of records employed. The reason is that the subsets should always be small enough so that no single record appears in both A and B. Thus, for a minimum pool size of 30 records, the maximum suggested corresponding subset size is 10 for each subset. Due to the approximate nature of the results obtained with record subsets, wherever greater accuracy is required, larger subsets may be selected from an even larger pool size, or the entire pool of records may be used, disregarding subsets entirely.

The results of applying the selection algorithm for the 4-story RC building appear in Figures 8 and 9, showing the progressive selection of the 1/3/5/7 best records for subsets A and B, respectively. Obviously, the proposed method adopts a structure-dependent fitting range and a simple selection algorithm exploiting the relative robustness of the percentile estimators to run more efficiently. It also employs an integral over relative differences rather than plain differences. Since higher differences generally appear at the lower end of the spectrum, this distinction means that plain differences will tend to weigh lower periods more heavily than relative differences. Thus, the presented algorithm strives for more equal weighting across periods. Of course, it is conceivable that the degree of nonlinearity in the structure itself should influence the relative weighting of different areas in the spectrum, favoring, for example, the periods above T_1 when deep in the post-yield range of response versus periods around, e.g., T_2 when close to linear elastic behavior. This points to the expectation that, for the sake of simplicity, the proposed selection method may not be equally efficient at all intensity levels.

2.5 Nonlinear response history analyses and EDP statistics

Having selected the two subsets A and B, the corresponding two groups of nonlinear response history analyses are performed. Estimates of median values of each engineering demand parameter (EDP) are given as the median of the demand parameter values obtained using record subset A as follows:

$$EDP_{50} \cong [EDP_i]_{A,50\%} \quad (6)$$

However, the estimation of the 84% needs more care, as the errors can be much higher than with estimates of the median. Consider that for a given scale factor (or intensity level) record subsets A and B have sizes N_A and N_B , respectively. Then, a relatively conservative estimate of the 84% can be made by taking the maximum of three distinct values:

1. $[EDP_i]_{B,50\%}$, the median of EDP values obtained using subset B
2. $[EDP_i]_{\max(A,B),50\%}$, the median of the N_B largest EDP values from both subsets A and B
3. $[EDP_i]_{A+B,84\%}$, the 84% of the EDP values from subsets A and B pooled together.

Care should be exercised though: the 3rd estimate is intended to be useful only for large samples, as it can become too conservative for small subset sizes, smaller than 20% of the total (e.g. N_B less than about 9 relative to a full set size of 44). On the other hand, it has to be used for larger subsets as the use of medians in the first two estimates will tend to underestimate the 84th percentile. Therefore, the combined, multi-part estimate of the 84% EDP is:

$$EDP_{84} \cong \begin{cases} \max([EDP_i]_{B,50\%}, [EDP_i]_{\max(A,B),50\%}), & \text{if } N_B < 0.2 N_T \\ \max([EDP_i]_{B,50\%}, [EDP_i]_{\max(A,B),50\%}, [EDP_i]_{A+B,84\%}), & \text{if } N_B \geq 0.2 N_T \end{cases} \quad (7)$$

Median and 84th percentile values are “counted” values, typically obtained by linear interpolation between the two closest values of the sample. Any collapses, assuming they are less than 10% of N_T , are still considered in the calculations as having an infinite EDP. The dispersion (aleatory randomness) in the demand parameter is thus estimated as

$$\beta_{DR} = \beta_{EDP|IM} \cong \ln(EDP_{84}) - \ln(EDP_{50}) \quad (8)$$

If the entire set of ground motion records is used to determine the MDOF response, then, allowing for modeling limitations, the evaluation procedure would be expected to introduce negligible additional uncertainty (error) in the EDP statistics. On the other hand, if the more efficient subsets are used, there is additional (non-negligible) error to consider that depends on the number of records employed in each subset and the EDP type itself. To represent this error, it is suggested that additional epistemic uncertainty dispersion is introduced in the safety checking given by

$$\beta_{SubU} = \begin{cases} 0.60 / \sqrt{\min(N_A, N_B)}, & \text{for global EDPs} \\ 0.75 / \sqrt{\min(N_A, N_B)}, & \text{for story - level EDPs} \\ 1.00 / \sqrt{\min(N_A, N_B)}, & \text{for component - level EDPs} \end{cases} \quad (9)$$

Examples of global EDPs are maxima over the entire building such as the maximum story drift or the peak roof drift over all stories; examples of story-level EDPs are story drifts and floor accelerations, and examples of component-level EDPs are member forces and section rotations.

In addition, to the two groups of NRHA corresponding to subsets A and B, in order to approximate the general shape of the IM to EDP relationship, one more group of analyses is needed. The determination of the mean annual frequency of exceedance of a demand parameter, or the required strength to ensure the capacity meets or exceeds the demand within limits implied by the mean annual frequency of exceedance at a given confidence level, necessitates the estimation of response for at least one additional seismic intensity level. When multiple intensity levels are being evaluated simultaneously (e.g., at the 50%, 10% and 2% in 50 year hazard levels) then the results at the next highest (if available) intensity level (lower probability, P_o) can be used for this purpose.

Alternatively, if the performance assessment is being made at only a single performance level (i.e., only one value of probability P_o), median response at a higher intensity level must also be determined, using a third subset of records comprising subset A scaled by a factor of 1.10 or larger. If the median capacity EDP-value for which we are testing is EDP_C then if IM^{des} (e.g. S_a^{des} for S_a -scaling) is the level of IM where we previously run subsets A and B, we can now rerun subset A at $IM' = IM^{des} \cdot EDP_C / EDP_{50}$. By virtue of Equation (6), the new set of results yields its median, EDP'_{50} , to be used in the following section.

Figure 10: The mean S_a -hazard curve and the power-law approximation in the region of the 475 year intensity level.

2.6 Safety checking

Design decisions ultimately require ascertaining that a design satisfies performance expectations, and this often requires comparison of seismically induced demands with the capacities associated with the materials and components that form the structure. Although structural engineers are accustomed to treating uncertainty in demands and capacities in ultimate strength design for non-seismic loads, seismic design practice generally has neglected uncertainty, particularly on the demand side.

The Demand and Capacity Factored Design (DCFD) format developed by Cornell et al [11] is meant to be used as a check of whether a certain performance level has been violated. It cannot provide an estimate of the mean annual frequency of exceeding a given performance level. Instead, it was designed to be a checking format that conforms to the familiar Load and Resistance Factor Design (LRFD) format used in all modern design codes to check, e.g., member or section compliance. It can be represented by the following inequality:

$$FC_R \geq FD_{RP_o} \cdot \exp(K_x \beta_{TU}) \Leftrightarrow \phi_R \cdot EDP_{C,50} \geq \gamma_R \cdot EDP_{50} \cdot \exp(K_x \beta_{TU}), \quad (10)$$

where FC_R is the factored capacity and FD_{RP_o} is the factored demand evaluated at the probability P_o associated to the selected performance objective. The subscript R denotes that they only include aleatory uncertainties. Correspondingly, EDP_C is the median EDP capacity defining the performance level (for example, 2% maximum interstory drift for a Life Safety limit-state) and EDP_{50} is the median demand evaluated via subset A at the IM intensity level that has a probability of exceedance equal to P_o . For example, $P_o = 0.0021 \approx 1/475$ for a typical 10% in 50 years Life Safety performance level. The capacity and demand factors ϕ_R and γ_R are similar to the safety factors of LRFD formats and they are defined as:

$$\phi_R = \exp \left[-\frac{1}{2} \frac{k}{b_{EDP}} \beta_{CR}^2 \right] \quad (11)$$

$$\gamma_R = \exp \left[\frac{1}{2} \frac{k}{b_{EDP}} \beta_{DR}^2 \right], \quad (12)$$

β_{DR} is the demand record-to-record (aleatory) variability, determined according to Equation 8 from the results of NRHAs of subsets A and B. β_{CR} is the aleatory variability in the EDP-value of limit-state capacity that can be determined, e.g., from experimental tests. The parameter k is the slope of the hazard curve when plotted in log-log coordinates and depends on local seismicity and site characteristics. The slope may be derived by taking a straight-line approximation to the hazard curve in log-log coordinates, as shown in Figure 10. The approximation should closely fit the hazard curve in the region $[0.25S_a^{des}, 1.5S_a^{des}]$, as suggested by Dolsek and Fajfar [20]. On the other hand, following Jalayer and Cornell [21], b is estimated by taking advantage of the additional group of NRHAs performed with subset A at increased intensity IM' . Specifically, let EDP'_{50} denote the median demand parameter at the higher IM' level, then the log-slope, b , of the median demand parameter curve is estimated as follows:

$$b_{EDP} = \frac{\ln(EDP'_{50}) - \ln(EDP_{50})}{\ln(IM' / IM^{des})} \quad (13)$$

The epistemic uncertainty in demand and capacity is introduced by the total uncertainty dispersion

$$\beta_{TU} = \sqrt{\beta_{DU}^2 + \beta_{CU}^2}. \quad (14)$$

The two components of β_{TU} are β_{DU} and β_{CU} to address epistemic uncertainty in the demand, e.g., due to modeling parameters, and also on the EDP capacity. Any value determined or provided for β_{DU} should be inflated by β_{SubU} , which represents epistemic uncertainty associated with using record subsets to estimate demand, as given by Equation (9). The final β_{DU} value should be estimated by taking the square root of the sum of the squares of the individual components. Figure 11 provides an illustrative breakdown of the sources of variability included in the assessment and how they influence the parameters of Equation (10).

Finally, to ensure the factored capacity, FC_R , exceeds the factored demand, FD_{RPO} , with the designated MAF at a confidence level of α , we include K_x . This is the standard normal variate corresponding to the desired level α . Values of K_x are widely tabulated, and can also be easily calculated by the NORMINV function in Excel. For example NORMINV(0.9,0,1) yields $K_x = 1.28$ for $\alpha = 90\%$, while NORMINV(0.5,0,1) produces $K_x = 0$ for $\alpha = 50\%$ confidence.

Equation (10) allows a user-defined level of confidence to be incorporated in the assessment. This is a quality that may prove to be very useful since different required levels of confidence can be associated with ductile versus brittle modes of failure or local versus global collapse mechanisms. The significant consequences of a brittle or a global failure often necessitate a higher level of safety and can be accommodated with an appropriate higher value of K_x . This is fundamental in the practical application of the FEMA-350/351 [6,7] guidelines where different suggested values of the confidence level are tabulated for a variety of checking situations.

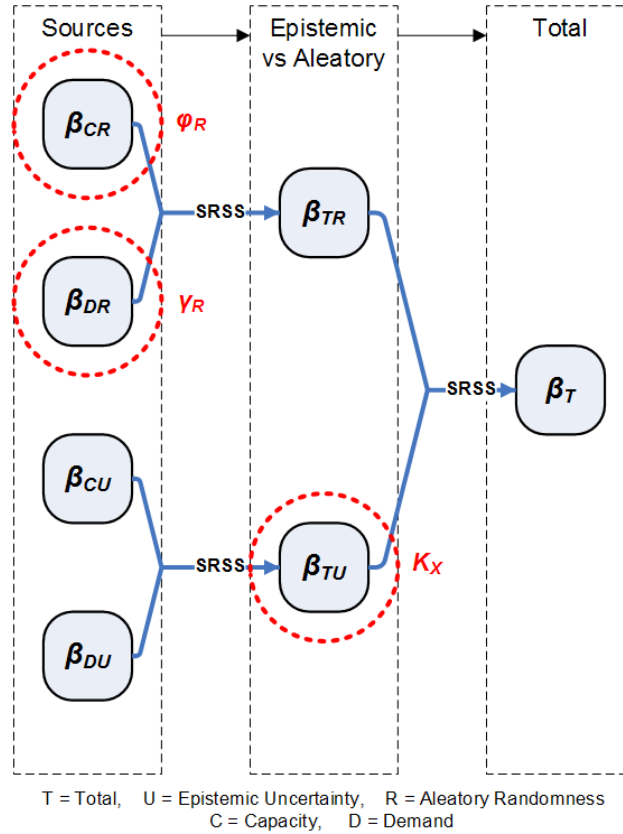

Figure 11: Breakdown of the total dispersion β_T to its four contributing sources. The circled items are the components used for the targeted NDP format.

3 ILLUSTRATIVE ASSESSMENT

The interstory drift capacity limit of 2% is subject to both aleatory randomness and epistemic uncertainty. The aleatory randomness is associated with natural variability of earthquake occurrence while epistemic uncertainty is associated with our incomplete knowledge of the seismotectonic setting (i.e. the hazard), the building and its properties. Uncertainty in the hazard is addressed by using mean rather than median hazard information (Cornell et al. [10]). The latter two sources cause the true capacity limit to be lognormally distributed with dispersions (standard deviation of the natural log of the data) that are assumed here to be $\beta_{CU} = 30\%$ and $\beta_{CR} = 20\%$. Furthermore, based on relevant results (e.g., Liel et al [22], Dolsek [23] and Vamvatsikos & Fragiadakis [24]), we set the base value of β_{DU} at 20% as a possible estimate of dispersion due to epistemic uncertainty, associated mainly with the modeling parameters. Since we are using subsets A and B with 7 records each and assessment is performed via a global EDP (interstory drift) this base value is inflated by $\beta_{SubU} = 0.6 / \sqrt{7} = 23\%$. Other sources of uncertainty that have not been accounted for may increase such estimates considerably.

Assessment based on $S_a(T_1)$ follows the basic steps discussed in the previous section. The first step is to determine the $S_a(T_1, 5\%)$ design point corresponding to the 10% in 50 years design level. This corresponds to a mean annual frequency (MAF) of $\lambda = -\ln(1 - 0.10)/50 = 0.00211$ or 1/475 years, resulting in $S_a^{des} = 0.62g$. The stability assessment performed via SPO2IDA (Figure 5b) clearly shows that there is insignificant chance of global collapse at this intensity level, as the 16% value of collapse capacity is approximately $1.7g \gg 0.62g$.

Now, a straight line is fitted to the hazard curve in log-log coordinates within the “region of interest”, defined by $\lambda_{Sa} = k_0 \cdot S_a^{-k}$. This region, according to the suggestions in Dolsek &

Fajfar [20], should be defined over the interval $[0.25S_a^{\text{des}}, 1.5S_a^{\text{des}}]$. The region is extended further into the lower intensities since these are the ones that have the higher probabilities of exceedance. The resulting fit appears as a red dashed line in Figure 10, corresponding to a slope of $k = 2.14$. From its relationship with the hazard curve we can tell directly that we will be overestimating the hazard more or less for any value of S_a . This observation implies that the S_a -based approach will result in a conservative evaluation.

Ground motion records are individually scaled to the S_a^{des} level in the first set of nonlinear dynamic analyses. The maximum interstory drift response θ_{max} , determined in each nonlinear dynamic analysis is the only engineering demand parameter (EDP) of interest in this example. Out of the total 14 nonlinear response history analyses, only one did not converge, signifying the occurrence of global dynamic instability. Such results are not to be excluded from the analyses. They may be considered to correspond to infinite EDP response and thus contribute to the estimation of the percentile values of the sample; use of percentiles is robust to infrequent infinite values. The median of the maximum interstory drift values obtained with subset A is $\theta_{\text{max},50} = 0.0115$. Subset A together with B provide $\theta_{\text{max},84} = 0.0153$ via Equation (7). Thus, dispersion can be estimated as

$$\beta_{DR} = \beta_{\theta_{\text{max}}|S_a} = \ln \theta_{\text{max},84} - \ln \theta_{\text{max},50} = \ln(0.0153) - \ln(0.0115) = 29\%$$

If, on the other hand, collapse has been observed for more than 10% of the records, the probability of collapse should be considered explicitly with an alternative format (see Jalayer, [25]).

To estimate the slope of the median θ_{max} versus S_a diagram, a second set of nonlinear dynamic analyses were done using ground motion records scaled to $1.10 \cdot S_a^{\text{des}}$ to determine the median value $\theta_{\text{max},50(1.10)}$. Using the full set of 44 records resulted in a median value of $\theta'_{\text{max},50} = 0.0124$. These median values allow the slope of the median EDP curve to be estimated as

$$b = \frac{\ln(\theta'_{\text{max},50}) - \ln(\theta_{\text{max},50})}{\ln(1.10)} = \frac{\ln(0.0124) - \ln(0.0115)}{\ln(1.10)} = 0.83.$$

In this case, an assumption of $b = 1$, as originally suggested by FEMA-350/351 [6,7], would be slightly unconservative.

Finally, factored demand and factored capacity are estimated as:

$$FD_{RP0} = \theta_{\text{max},50} \exp(0.5 \cdot k \cdot \beta_{\theta_{\text{max}}|S_a}^2 / b) = 0.0115 \exp(0.5 \cdot 2.14 \cdot 0.29^2 / 0.83) = 0.0128$$

$$FC_R = \theta_{\text{max},C} \exp(-0.5 \cdot k \cdot \beta_{CR}^2 / b) = 0.02 \exp(-0.5 \cdot 2.14 \cdot 0.2^2 / 0.83) = 0.0190$$

If exceedance of the 2% maximum interstory drift is assumed to involve a ductile mechanism for this building that may only produce some local problems, the probability of exceedance can be evaluated (for the purposes of this example) at a 50% confidence level. This corresponds to a lognormal standard variate of $K_x = 0$, effectively discounting in its entirety the detrimental effect of epistemic uncertainty. Thus, the evaluation inequality becomes:

$$FC_R > FD_{RP0} \cdot 1,$$

or equivalently, $0.0190 > 0.0128$, which is satisfied. A result of $FC_R = FD_{RP0}$, would have indicated that the capacity is equal to the demand induced in the building, on average, at least once every 475 years, at a 50% level of confidence. The actual result indicates that the capacity exceeds the demand induced in the building at a longer mean recurrence interval.

In some circumstances a higher level of confidence for a given recurrence interval may be desired in evaluating factored capacities, especially if involving a brittle or a global collapse mechanism that will have severe consequences on the building occupants. For illustration

purposes, let us assume that this is indeed the case in this situation. For a confidence level of 90%, the lognormal standard variate is $K_x = 1.28$ and the evaluation inequality becomes:

$$FC_R > FD_{RPO} \exp(K_x \cdot \beta_{TU}) = 0.0128 \cdot \exp(1.28 \cdot \sqrt{0.3^2 + 0.2^2 + 0.23^2}) = 0.0221$$

Since the factored capacity of 0.0190 is lower than the factored demand of 0.0221 the result is not satisfactory at the 90% confidence level. This clearly indicates that while the structure may be adequate at the 10% in 50yrs level if it presents a ductile low-consequence failure, like plastic beam hinging, it should not be considered safe if the failure mode examined is, e.g., a shear failure with important consequences.

4 CONCLUSIONS

The Targeted Nonlinear Dynamic Procedure has been introduced as an alternative to the nonlinear static procedure, offering a higher level of accuracy in seismic performance assessments within a practical format. It uses both a realistic MDOF model and its equivalent SDOF to achieve inexpensive calculations. Lateral stability assessment is performed on the equivalent SDOF, while the expensive MDOF is selectively used for nonlinear response history analysis. This is achieved by employing small subsets of ground motion records appropriately selected to match the 50/84% elastic spectra to efficiently estimate the median and the dispersion of seismic demand. The final results are integrated with seismic hazard information using the practical SAC/FEMA format to check for limit-state violations.

It is a powerful alternative to typical pushover-based methods that properly incorporates both epistemic and aleatory sources of variability while it offers a user-controlled level of confidence in safety checking. Thus, it allows proper consideration of different modes of failure (e.g., brittle versus ductile) according to their expected consequences. While not as accurate as modern PBEE approaches, it is nevertheless designed to err on the conservative side and offer an inexpensive and user-friendly method that can serve as an introduction to more sophisticated analysis techniques.

Keywords: equivalent SDOF, bilinearization, static pushover, incremental dynamic analysis.

Abstract. *The bilinear approximation of force-deformation capacity curves is investigated for structural systems with non-negative-stiffness. This piecewise linear approximation process factually links capacity and demand; it lies at the core of the nonlinear static assessment procedures, and it has become part of seismic guidelines and codes, such as ASCE-41 and Eurocode 8. Despite codification, the various fitting rules, used to derive the bilinear representation, can produce highly heterogeneous results for the same capacity curve. This is especially valid for highly-curved backbones resulting from structural models with accurate representation of the initial, uncracked, stiffness or buildings characterized by a global collapse mechanism that leads to a gradual plasticization of the elements.*

The error introduced by the bilinearization of the force-deformation relationship is quantified by studying it at the single-degree-of-freedom (SDOF) level, away from any interference from multi-degree-of-freedom (MDOF) effects, thus avoiding the issue related to MDOF - SDOF approximation. Incremental Dynamic Analysis (IDA) is employed to enable a direct comparison of the actual backbones versus their bilinear approximations in terms of the spectral acceleration capacity for a continuum of limit-states, allowing a direct comparison of the results in terms of seismic performance.

Code-based procedures are found to be less than ideal wherever there are significant stiffness changes, while in general remaining relatively conservative. The practical fitting rules determined allow, instead, a near-optimal fit regardless of the details of the capacity curve shape.

1 INTRODUCTION

In the last decades, improvements in the computational capabilities of personal computers have allowed the employment of nonlinear analysis methods in many earthquake engineering problems. In this framework, nonlinear static analysis is becoming the routine approach for the assessment of the seismic capacity of existing buildings. Consequently, nonlinear static procedures (NSPs) for the evaluation of seismic performance, based on static pushover analysis (SPO), have been codified for use in practice. All such approaches consist of the same five basic steps: (a) perform static pushover analysis of the multi-degree-of-freedom (MDOF) system to determine the base shear versus (e.g., roof) displacement response curve; (b) fit a piecewise linear function (typically bilinear) to define the period and backbone of an equivalent single degree of freedom system (SDOF); (c) use a pre-calibrated R - μ - T (reduction factor – ductility – period) relationship for the extracted piecewise linear backbone to obtain SDOF seismic demand for a given spectrum; (d) use the static pushover curve to extract MDOF response demands; (e) compare demands to capacities; see [1] for example.

In fact, NSP is a conventional method without a rigorous theoretical foundation for application on MDOF structures [2], as several approximations are involved in each of the above steps. On the other hand, its main strength is to provide nonlinear structural capacity in a simple and straightforward way. Although several improvements and enhancements have been proposed since its introduction, any increase in the accuracy of the method is worth only if the corresponding computational effort does not increase disproportionately. Extensively investigated issues are the choice of the pattern considered to progressively load the structure and the implication of switching from the nonlinear dynamic analysis of a multiple degree of freedom (MDOF) system to the analysis of the equivalent SDOF sharing the same (or similar) capacity curve. Regarding the shape of the force distributions, it was observed that an adaptive load pattern could account for the differences between the initial elastic modal shape and the shape at the collapse mechanism [3, 4, 5]. Contemporarily, other enhanced analysis methodologies were proposed to account for higher mode effects and to improve the original MDOF-to-SDOF approximation [e.g., 6]. Regarding the demand side, efforts have been put to provide improved relationships between strength reduction factor, ductility, and period (R - μ - T relationships), to better evaluate the inelastic seismic performance at the SDOF level [7, 8].

One of the issues that have not yet been systemically investigated is the approximation introduced by the imperfect piecewise linear fit of the capacity curve for the equivalent SDOF. The necessity to employ a *multilinear* fit (an inexact, yet common, expression to describe a piecewise linear function) arises due to the use of pre-determined R - μ - T relationships that have been obtained for idealized systems with piecewise linear backbones. This has become even more important recently since nonlinear modeling practice has progressed towards realistic multi-member models, which often accurately capture the initial stiffness using uncracked section properties. The gradual plasticization of such realistic elements and models introduces a high curvature into the SPO curve that cannot be easily represented by one or two linear segments. It is an important issue whose true effect is often blurred, being lumped within the wider implications of using an equivalent SDOF approximation.

The investigation presented deals only with the bilinear approximation of the capacity curves and it is limited to non-softening force-deformation relationships. Although R - μ - T relationships that can capture far more complex backbones have recently appeared [9], the bilinear approach is by far the most widely employed in guidelines and literature [10 – 15]. The approach presented herein will be based on the accurate assessment of the effect of the equivalent SDOF fit on the nonlinear static procedure results. The latter can be achieved by proper

quantification of the bias introduced into the estimate of the seismic response at the level of the SDOF itself.

Incremental dynamic analysis (IDA) [16] will be used as benchmark method to quantify the error introduced by a bilinear fit with respect to the exact capacity curve of the SDOF. Figure 1a shows a typical example, where an elastoplastic backbone fit is used according to FEMA-440 [13]. While this fit approach is meant to result to an unbiased approximation in terms of seismic performance, the median IDA results of Figure 1b show the actual error that is introduced by such code-mandated fitting rules. In most cases, they lead to an unintended and hidden bias that is generally conservative. On the other hand, this bias can become unreasonably high in many situations.

Therefore three issues come out: First, develop a methodology aimed at quantifying the bias introduced by the fitting of a capacity curve; second, assess the error introduced by the fitting rules already employed in codes and literature; third, perform a systematical investigation aimed at providing alternative fits that can reduce this discrepancy to almost a minimum. The comparison with existing approaches will function as the benchmark to evaluate the improvement introduced by the alternative fitting rules proposed.

Figure 1. (a) Example of exact capacity curve versus its elastoplastic bilinear fit according to FEMA-440 and (b) the corresponding median IDA curves showing the negative (conservative) bias due to fitting for $T=0.5$ sec.

2 METHODOLOGY

The first main target is the quantification of the error introduced in the NSP-based seismic performance assessment by the replacement of the original capacity curve of the system, termed the “exact” or “curved” backbone, with a piecewise linear approximation, i.e., the “fitted” or “approximate” curve (e.g., Figure 1a). This will enable a reliable comparison between different fitting schemes in an attempt to minimize the observed discrepancy between actual and estimated performance. In all cases, to achieve an accurate and focused comparison of the effect of fitting only, it is necessary to disaggregate the error generated by the fit from the effect of approximating an MDOF structure via an SDOF system. Thus, all the investigations are carried out entirely at the SDOF level, using a variety of capacity curve shapes, different periods and hysteresis rules and using IDA as the method of choice for assessing the actual performance of the different alternatives.

2.1 Exact versus approximate SDOF systems

An ensemble of SDOF oscillators is considered with varying curved shapes of force-deformation backbones. They all display a monotonically decreasing stiffness that starts from elasticity and ends at a final zero or positive stiffness that remains constant for all higher deformations (e.g., Figure 1a). According to their final stiffness, these will be termed “generalized elastoplastic” and “generalized elastic-hardening” systems, respectively. They are all fitted accordingly with bilinear elastoplastic or elastic-hardening shapes.

For each considered curved backbone shape, 5% viscous damping was used and appropriate masses were employed to obtain a range of matching “reference” periods of 0.2, 0.5, 1 and 2 sec. The concept of the “reference” period, instead of the actual initial (tangent at zero displacement) period, is introduced because of the highly curved shape of some backbones. In some cases they show a strictly localized significant change in the initial stiffness, resulting in periods lower than 0.01 sec. Since this initial stiffness disappears almost immediately for any kind of loading history, a more representative reference period is required for each exact capacity curve. The reference period (T herein) was defined as the secant period at 2% of the displacement corresponding to the peak force capacity. Actually, in the vast majority of the cases there was insignificant difference between the initial tangent period and the reference secant period. In all cases, both the exact and the approximate system share the same mass, but, due to the lower initial stiffness of the latter, the “equivalent” period is equal to, or higher than, the “reference” one, thus replicating the approach followed in the conventional NSP methodology [2].

In order to draw general conclusions, independent of the hysteretic behavior assumed, two distinct hysteretic rules were considered for the each curved backbone and its bilinear fits. The first is a standard kinematic strain hardening model without any cyclic degradation characteristics. The second is a pinching hysteresis featuring cyclic stiffness degradation (see Ibarra et al [17]). When comparing an original system with its approximate having a piecewise linear backbone, the same hysteretic rules are always employed, so that both systems display the same characteristics when unloading and reloading in time-history analyses. In other words, all differences observed in the comparison can be attributed to the fitted shape of the approximate backbone; obviously also capturing any differences in the oscillator period.

For each exact shape of the SDOF’s capacity curve and for each period value, several piecewise linear fit approximations have been considered according to different fitting rules. These include typical code-suggested fits, e.g., as laid out in FEMA-440 [13], ASCE/SEI 41-06 [14] and Eurocode 8 (EC8, [10]). In addition a multitude of different bilinear fits, with varying initial stiffness and yield point definition, have been employed in an attempt to pinpoint the consistent characteristics that can define an optimal or near-optimal fit. To enable a precise comparison that will allow distinguishing among relatively similar backbones in consistent performance terms, as it was previously stated, incremental dynamic analysis (IDA, [16]) will be employed.

2.2 Performance-based comparison via IDA

IDA is arguably the most comprehensive analysis method available for determining the seismic performance of structures. It involves performing a series of nonlinear dynamic analyses by scaling a suite of ground motion records to several levels of intensity, characterized by a scalar Intensity Measure (IM), and recording the structural response via one or more Engineering Demand Parameters (EDPs). The results typically appear in terms of multiple IDA curves, one for each record, plotted in the IM – EDP plane. These can be in turn summarized into the 16, 50, 84% fractile curves of EDP given IM (EDP|IM) or, equivalently (Vamvatsikos

and Cornell [18]), as the practically identical 84, 50, 16% fractile curves of IM given EDP (IM|EDP). The summarized curves thus provide the (central value and the dispersion of the) distribution of EDP seismic demand given the IM intensity of the earthquake or, vice-versa, the distribution of a structure's IM-capacity that a ground motion should exceed to achieve the given value of EDP response.

To perform IDA for each exact and approximate oscillator considered, a suite of sixty ground motion records was used, comprised of both horizontal components from thirty recordings [19] from the PEER NGA database. They are all characterized by relatively large magnitudes of 6.5 – 6.9 and moderate distances of 15 – 35km, all recorded on firm soil and bearing no marks of directivity. Using the hunt & fill algorithm [18], 34 runs were performed per record to capture each IDA curve with excellent accuracy. The IM of choice was the 5%-damped spectral acceleration at the period T of the oscillator, $S_a(T)$, while the oscillator displacement δ was used as the corresponding EDP, being the only SDOF response of interest when applying the NSP method. To avoid the appearance of arbitrary displacement scales and units, using a normalized displacement δ_n is also attractive. Unfortunately, the concise definition of a single yield point on a curved backbone is impractical, unless tied to some preselected bilinear fitting rule; therefore using some yield displacement to normalize δ to a ductility equivalent is not possible without bias. It was chosen, instead, to normalize by the value of 0.1m that signals the onset of constant stiffness in the oscillator backbone (Figure 1a).

Once the IM and EDP are decided, interpolation techniques allow the generation of a continuous IDA curve from the discrete points obtained by the 34 dynamic analyses for each ground motion record. The resulting sixty IDA curves can then be employed to estimate the summarized IDA curves for each exact and approximate pair of systems considered. Still, in order to be able to compare an exact system with reference period T with its approximation having an equivalent period T_{eq} it was necessary to have their summarized IDA curves expressed in the same IM. In this case it is chosen to be $S_a(T)$, i.e. the spectral ordinate at the period of the curved backbone oscillator. Thus, while the approximate system IDA curves are first estimated as curves in the $S_a(T_{eq}) - \delta$ (or δ_n) plane, they are now transformed to appear on $S_a(T) - \delta$ axes. This is achieved on a record-by-record basis by multiplying all 34 $S_a(T_{eq})$ values comprising the i -th IDA curve by the constant spectral ratio $[S_a(T) / S_a(T_{eq})]_i$ that characterizes the i -th record [20].

The error is evaluated for every value of displacement in terms of the relative difference between the two system median S_a -capacities, both evaluated at the reference period T of the exact system:

$$e_{50}(\delta_n) = \frac{S_{a,50}^{fit}(\delta_n) - S_{a,50}^{exact}(\delta_n)}{S_{a,50}^{exact}(\delta_n)} \quad (1)$$

Alternatively, one could use the relative error in the median displacement response given the level of spectral acceleration:

$$e_{50}(S_a) = \frac{\delta_{n,50}^{fit}(S_a) - \delta_{n,50}^{exact}(S_a)}{\delta_{n,50}^{exact}(S_a)} \quad (2)$$

Similarly, the same definitions can be used to estimate the errors for different response or capacity fractile values, e.g., 16% or 84%, or even for the dispersion in response or capacity, which, assuming lognormality, can be defined as one half the difference between the corresponding 84% and 16% values. Thus, two different ways of measuring the discrepancy between IDA curves are available, e.g., the two median IDA curves shown in Figure 1b. In one case “horizontal statistics” are employed, working with the median EDP given IM, and in the

other case “vertical statistics” of IM given EDP. As Vamvatsikos and Cornell [18] have shown, the median IDA curve is the same, regardless of how it is calculated, while, as discussed earlier, the 16, 84% fractiles are simply flipped. In addition, while there might be differences in the error estimates using these two different methods, these are only an issue of scale. Figures 2a, 2b compare the two error quantification methods for the median IDAs shown in Figure 1b. The observed trends are actually the same, but simply inverted: obviously, an overestimation in response becomes an underestimation in capacity and vice-versa.

Why then should one method be preferred over the other? There are three important reasons that make the IM-based method (IM|EDP) a more attractive solution. First, parameterizing the error in terms of the displacement response simplifies its visualization as displacement is directly mapped to specific regions of the oscillator force-deformation backbone. Thus, it is possible to see directly in Figure 2b whether the elastic or the post-elastic part is causing the accumulation of error, when it is compared vis-à-vis Figure 1a. Figure 2a is much more difficult to understand, especially if more complex backbones, than the ones used here, are considered. Second, comparing on the basis of S_a -capacity is actually directly linked to comparing in terms of the seismic performance, as expressed by the mean annual frequency (MAF) of violating limit-states defined by the oscillator displacement (Vamvatsikos [21]). An over/under-estimation of S_a -capacity maps to a consistent (although not commensurable) under/over-estimation of the MAF of limit-state exceedance. Finally, when collapse enters the problem it is obvious that the error in displacement may easily become infinite when at a given intensity level one system has collapsed, showing infinite response, while the other has not. In fact, on the contrary, this is never a problem for the S_a -based error. Although only non-collapsing systems, whose backbones never drop to zero strength, are used herein, this is another compelling reason to recommend the S_a -based comparison for general use.

Figure 2. The relative error in the median (black line) shown versus the overall average (grey line) as introduced by the bilinear fit in Figure 1. It is expressed on the basis of (a) response given intensity (EDP|IM) and (b) intensity given response (IM|EDP).

3 INVESTIGATION OF BILINEAR FITS

Bilinear elastic-plastic or elastic-hardening fits are the fundamental force-deformation approximations employed in all NSP guidelines. The simplicity of the bilinear shape means that the only need is to estimate the position of the nominal “yield point” and select a value for the constant post-elastic stiffness. Eurocode 8 [10] suggests a piecewise bilinear fit based on the equivalence of the area discrepancy above and below the fit, assuming an elastic-plastic idealized backbone for the equivalent SDOF. This approach is similar to the original N2 method

[2]. As a consequence, EC8 prescribes an $R-\mu-T$ relationship [7] based on the elastic-perfectly-plastic fit. FEMA documents [11, 12, 13] gradually upgraded the proposed piecewise linear fit by integrating rules to account for softening behavior. According to FEMA 356 [12], the idealized relationship is bilinear with an initial slope and a post yield slope evaluated by balancing the area above and below the capacity curve up to the target displacement and calculating the initial effective slope at a base shear force equal to 60% of the nominal yield strength. The proposed graphical procedure is iterative. FEMA 440 [13] and ASCE/SEI 41-06 [14] assume the basic approach of FEMA 356 with additional rules regarding the softening behavior. In the following pages only non-softening capacity curves (generalized elastic-plastic or elastic-hardening) are investigated, thus in essence it is the original FEMA 356 and the EC8 fit rules that are tested.

In order to develop an improved bilinear fit, we choose to investigate separately the fitting of the initial “elastic” segment and then focus on the post-elastic non-negative stiffness part. Thus, we will first study generalized elastic-plastic systems, where the stiffness becomes zero beyond a displacement of 0.10 m and the target displacement is assumed to be well into the fully plastic region. Thus the post-elastic segment is fixed to have zero stiffness while the initial “elastic” part can be fitted at will. In both the FEMA and EC8 fitting rules, the fitted “elastic” stiffness can be a function of the target displacement due to the area balancing used. This can make the bilinear fitting yield different results depending on the limit-state of interest and may initially put the code-mandated fits (as implemented herein) at a slight disadvantage. It will be remedied in the second part of the study where generalized elastic-hardening systems will be tackled. They have varying post-yield stiffness and lower target displacements, allowing more fitting flexibility and providing a more rigorous comparison of code fits against any proposal for a near-optimal fit. Generally, the target, herein, is the development of a simple fitting rule that performs well for a continuum of limit states. Therefore, the performance of all rules will be carefully examined even outside the immediate region of interest defined by a target displacement.

3.1 Bilinear fits of generalized elastic-plastic systems

First a family of generalized elastic-plastic capacity curves is considered that exhibit a stiffness gradually decreasing with deformation, starting from the initial elastic and reaching zero slope. The shapes are characterized by the magnitude of the changes in stiffness. Figure 3a and 3b give an example of the shapes employed in the investigation of this family of backbones and emphasize two opposing cases. The first (Figure 3a) is not characterized by significant curvature, while the second (Figure 3b) shows a significant change in slope that can be representative of the behavior of a model that accounts for uncracked stiffness. Both the kinematic strain hardening and the pinching hysteresis are considered.

Three basic fitting rules are compared: (a) the FEMA fit (60% rule) assuming a target displacement high enough so that the slope of the second branch of the bilinear can be assumed to be zero; (b) the EC8 fit using a simple equal area criterion; (c) the “10% fit”, defined so that the intersection between the capacity curve and the fitted elastic segment is at 10% of the maximum base shear. The latter is the proposal for a simple rule that can better capture the initial stiffness. Figure 3a shows that in the case in which the capacity curves are not characterized by significant stiffness changes at the beginning of the backbone, the three fits are very similar to each other. They differ significantly though when the initial backbone stiffness diminishes rapidly, as in Figure 3b. In all cases the fitted post-elastic stiffness is set to zero.

As described in the previous section, IDA is performed for each of the SDOF systems presented in Figure 3 and their fitted approximations for a range of periods. Figures 4 and 5 show

the comparison in the median Sa-capacity for T equal to 0.2 and 0.5 sec, respectively. Obviously, the shapes of the backbones have a significant impact. In all cases, the error becomes significant for the shape with non-trivial curved segments. In both cases though, the maximum error appears at the earlier backbone segments. Curiously, the 10% fit leads to a remarkable decrease in the error for any deformation level, even for the highly curved shape of Figure 3b where it clearly violates any notion of equal area (or equal energy) that seems to be prevalent in current guidelines. The new fit introduced leads to a slightly non-conservative estimation of the capacity for displacements before the full plasticization (for δ_n up to 1) and only for short-period systems, $T = 0.2$ sec (Figure 4). On the other hand, even in case of highly-curved backbones (Figure 4b) only a 10% underestimation appears at most. On the contrary, it has to be noted that code approaches are always conservative for all the displacement levels and all the shapes considered, but at a cost of almost 20 – 40% underestimation of capacity. The trends identified are generally confirmed for all other periods considered (T equal to 1.0 and 2.0 seconds).

Figure 3. Comparison of generalized elastic-plastic capacity curves and their corresponding fits having (a) insignificant versus (b) significant changes in initial stiffness.

Figure 4. Median relative error comparison between the 10%, FEMA and equal area fits for $T = 0.2$ sec, when applied to the capacity curves of Figure 3: (a) insignificant versus (b) significant changes in initial stiffness.

Figure 5. Median relative error comparison between the 10%, FEMA and equal area fits for $T = 0.5$ sec, when applied to the capacity curves of Figure 3: (a) insignificant versus (b) significant changes in initial stiffness.

Figure 6. (a) Backbones and (b) hysteretic behavior according to standard kinematic strain hardening rule of the generalized elastic-plastic systems considered.

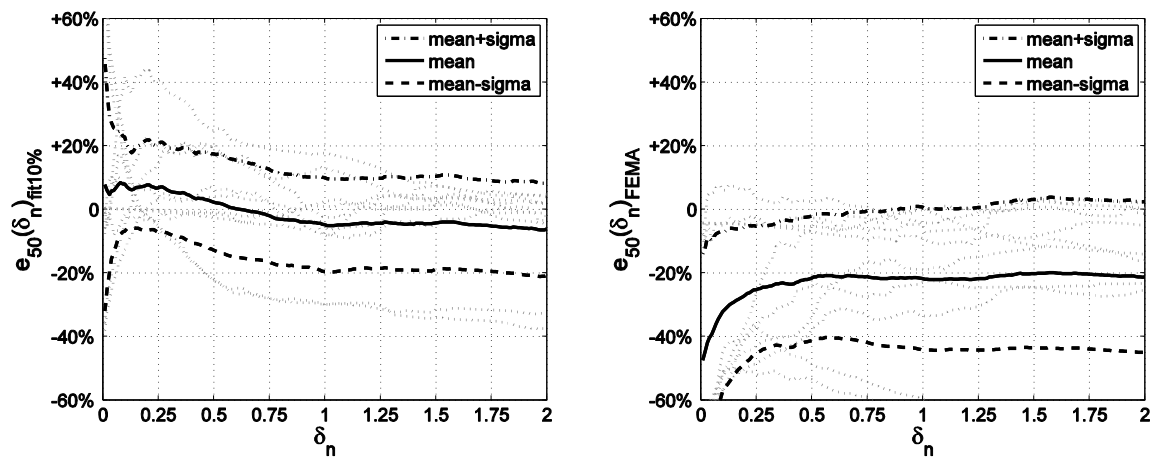

Figure 7. The median relative error for (a) the 10% fit and (b) the 60% FEMA fit, $T = 0.2$ sec, in case of elastic-plastic SDOF system family (grey dotted lines).

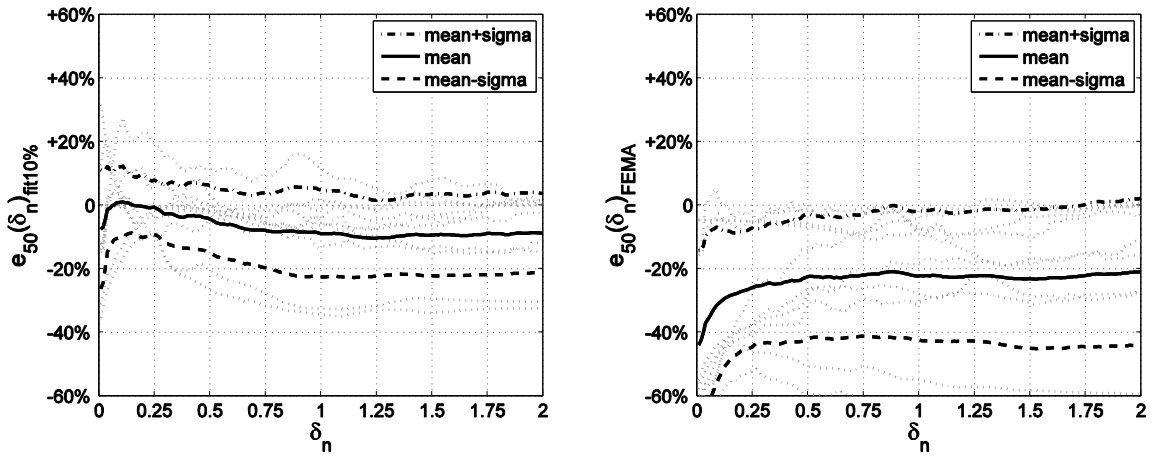

Figure 8. The median relative error for (a) the 10% fit and (b) the 60% FEMA fit, $T = 0.5$ sec, in case of elastic-plastic SDOF systems family (grey dotted lines).

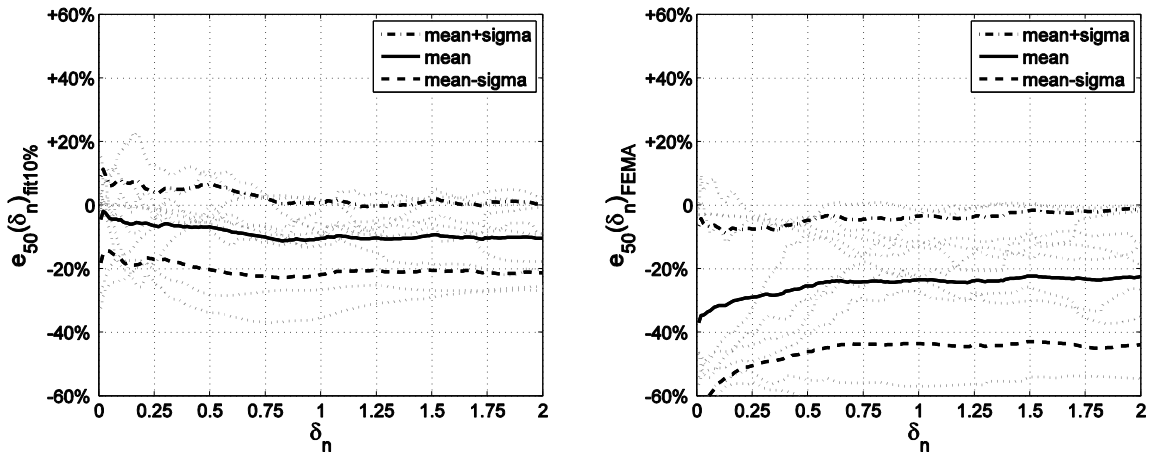

Figure 9. The median relative error for (a) the 10% fit and (b) the 60% FEMA fit, $T = 1.0$ sec, in case of elastic-plastic SDOF systems family (grey dotted lines).

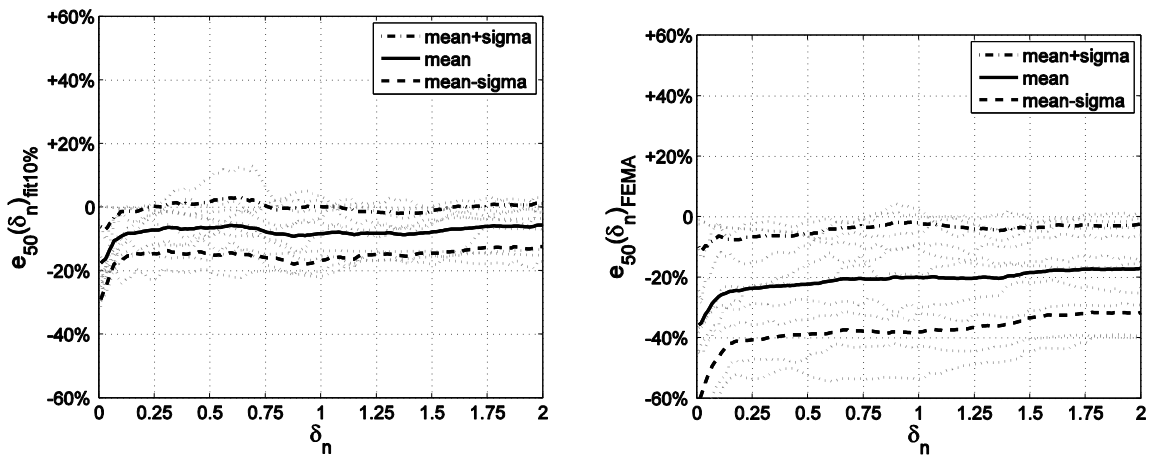

Figure 10. The median relative error for (a) the 10% fit and (b) the 60% FEMA fit, $T = 2.0$ sec, in case of elastic-plastic SDOF systems family (grey dotted lines).

Beyond the two curved shapes shown in Figures 3a, b, a number of different generalized elastic-plastic shapes were also investigated. A sample of ten backbones is considered aimed at drawing out general conclusions regarding the proposal fit investigated. The sample consists of five different shapes (see Figure 6a) times the two hysteretic rules described in section 2. In Figure 6b the standard kinematic strain hardening rule is shown for the five shapes considered.

Figure 7 to Figure 10 show the relative error on the median S_a -capacity evaluated at each period for the 10% fit proposed and the conventional FEMA fit. The bias is evaluated up to δ_n equal to 2, where most of the significant differences appear. This is evident for the two shapes in Figure 3a and 3b where it was evaluated up to δ_n equal to 10. Figure 7 to Figure 10 show grey dotted lines representing the error related to a specific shape of the backbone and to a specific hysteretic rule. The hysteretic rule chosen was found to be insignificant, as the error depends primarily on the shape of the fit; thus the two different hysteretic behaviors have been considered together to build up a heterogeneous family of generalized elastic-plastic behavior.

The 10% fit enjoys an insignificant bias on average for all the periods considered and the error introduced by the fit never exceeds 20%. FEMA fits shows a strictly negative, i.e., conservative, bias of 20% or even 60%, depending on the shape of the original backbone. Most of the bias is concentrated at the beginning of the backbone as it was already emphasized by the examples in Figure 3. Error comparisons for the S_a -capacity dispersion (record to record) are not shown as all fits roughly achieve similar performance. Some differences may appear in the region preceding the nominal yield point of the approximation. Therein the fitted system will predict no dispersion whereas the actual one shows some small variability. Still, this is to be expected and it is not important enough to make us favor one fit over another.

Summing up, it can be stated that the fit should capture as close as possible the initial stiffness of the backbone while the generally low secant stiffness assumed in most of the guidelines and codes tends to be overly-conservative. The only possible exception to this rule appears only for initially ultra-stiff systems that very quickly lose their initial properties. This is the reason why fitting the “elastic” secant at 5% or 10% of the maximum base shear, as opposed to 0.5% or 1% is considered a more robust strategy.

3.2 Bilinear fits of generalized elastic-hardening systems

The second family of shapes investigated is characterized by a generalized elastic-hardening behavior. Only the pinching hysteretic rule was considered for this family of backbones, given the insignificant differences observed earlier when compared to the kinematic hardening. Each backbone considered was characterized by different curvatures and final hardening stiffness, allowing a wide coverage of the typical shapes that can be obtained considering different structural behaviors and modeling options.

In analogy with the two examples showed in the previous subsection, two different backbones will be presented in detail from the family considered. The first (Figure 11a) is not characterized by significant changes in the stiffness, in contrast to the second (Figure 11b). The target displacement is assumed to be equal to 0.2 m. The EC8 fit is not applied as it is restricted to elastic-plastic approximations which are clearly inferior for the shapes shown in Figure 11. On the other hand, the FEMA fit rule can be applied without problems, although it might call for different approximations depending on the value of the target displacement. Still, the results and the corresponding conclusions remain the same in all cases. The alternative fit proposed, termed the “H-10%” rule, determines the initial stiffness at 10% (instead of 60%) of the nominal yield shear defined in accordance with FEMA, while the post-elastic

stiffness is determined by minimizing the absolute area discrepancy between the capacity curve and the fitted line. The area minimization leads to similar results as the balancing of areas above and below the fitted line. While easy to apply graphically, the latter is an ill-defined problem that can yield mixed results: Imagine two coincident equal-size linear segments where one, the “approximation”, is rotated by an arbitrary angle around the common center. Obviously, the rotated segment always satisfies the area balancing rule as a valid approximation to the original. Only when it becomes coincident does it satisfy the minimum area criterion. Thus, area minimization is algorithmically superior. The proposed H-10% procedure came out as the simplest rule with a near-minimum error for this family of backbones. While many alternatives were considered, they are not showed herein for the sake of brevity.

It has to be noted that elastic-plastic fits according to the proposal of the previous subsection have been also considered in the investigation of this family of backbones, assuming the plateau of the fit at the force corresponding to the target displacement (e.g. at 0.2m here); even if less performing than the H-10% rule, considered in the following, the still low bias of those trials compared to the FEMA-356 fitting rule, enforced the general conclusion that capturing the initial stiffness is the dominant criterion that leads to a significant bias reduction with respect to actual code fit prescriptions.

The results of the two fitting procedures (H-10% and FEMA-356) applied to the example shapes appear in Figure 11. Obviously, when the stiffness of the backbone is not characterized by abrupt changes in the curvature (Figure 11a) both fits tend to be practically the same. Figure 12 and Figure 13 show the error introduced by each fit, for both backbone shapes considered in Figure 11, in the cases of $T = 0.2$ and 0.5 sec, respectively. In analogy with the results presented for the elastic-plastic case, most of the error is concentrated at the beginning of the backbone. In the case of the backbone with low changes in the stiffness (low curvature), it can be observed that the error is very small and very similar for both fits. A higher curvature of the backbone increases the error introduced by the fit and emphasizes that although at the target displacement the backbones and their fits in both cases are coincident, this is not enough to guarantee the same error. The earlier fitted segments and especially the defined equivalent period can make a large difference. As the H-10% rule manages to capture the initial stiffness better, it provides better predictive capability for higher displacements.

The evidence, again, confirms the general trend already shown in the previous section, that it is important to capture the initial stiffness of the capacity curve to have an unbiased fit. In this case, as well, the code approach results in a conservative error that can be over 50% in the case of non-trivial shapes and at the lower displacement values (see Figure 11b). In the same range, the H-10% fit leads to a slightly non-conservative solution only for the short periods ($T = 0.2$ sec), an effect that was also observed in the elastic-plastic backbone family. Otherwise the fit remains conservative and overall it can be considered to be relatively unbiased.

In this case a sample of only four shapes is considered, the different shapes shown in Figure 14a and the pinching hysteretic rule assumed for this backbones appearing in Figure 14b. In Figure 15 to Figure 18 the relative errors in the median S_d -capacity, are compared for the four different periods and the different SDOF backbones. The importance of capturing the initial stiffness is highlighted by the results at each period, and the H-10% fit leads to a small and relatively unbiased error, which seldom exceeds 10%. In this case the sample of backbones considered for the elastic-hardening case was smaller than the elastic-plastic case but the robustness of the general results, showing the same trends in both cases, supports our remarks. It should be noted that the results of the FEMA approximation will improve somewhat at low displacements if we refit for a lower target displacement, but not enough to alter the above conclusions.

4 CONCLUSIONS

Structural seismic assessment based on the nonlinear static procedure is a method that, in its different versions, has become common in the last decades among researchers and practitioners. It is based on the fundamental approximation that the behavior of an MDOF system can be interpreted by the response of an equivalent SDOF. This necessitates a number of approximations at various stages of the procedure. Herein, the problem of the optimal bilinear fit to be chosen as the idealized base shear–displacement curve is systematically investigated by means of an IDA-based procedure applied to the case of non-softening capacity curves.

Assessment of different fits is achieved on an intensity-measure capacity basis that allows a straightforward comparison of the performance of structural systems characterized by different periods, in this case the period of the capacity curve and its bilinear approximation. Therefore the approach followed allows the investigation of a continuum of limit states at the SDOF level, excluding other sources of error that have already been investigated by other detailed studies.

The investigation led to the general rule and recommendation that it is fundamental to capture the initial stiffness of the capacity curve rather than aiming at balancing or minimizing

the area above or below the elastic segment of the fit. A 10% of a reference value of yield base shear, i.e., the maximum attained for elastic-plastic and the nominal yield value for elastic-hardening systems, is suggested as a robust point for the intersection between the capacity curve and the fit of the elastic secant segment. The subsequent non-negative stiffness segment should be chosen to minimize the area discrepancy between the fitted and the exact model in the region of interest.

The low bias introduced by this enhanced fit is found to be an improvement with respect to existing code approaches. Essentially it can be assumed to be a near-optimal solution especially in the case of capacity curves with significant changes in stiffness, representative of modern modeling approaches that account for the uncracked section properties. The error introduced by the near optimal bilinear fit does not exceed 20% for elastic-plastic fits and it seldom exceeds 10% for systems with hardening, while codified approaches were found to be generally conservative, sometimes more than 50% for highly curved shapes.

Keywords: Incremental Dynamic Analysis, Fragility Curves, Probability of Collapse, Redundancy, Stiffness Distribution, Strong Column-Weak Beam ratio

Abstract. *The inelastic behavior of reinforced concrete structures subjected to a number of strong motion excitations of escalated Intensity Measure (IM) and monitoring of characteristic Engineering Demand Parameters (EDPs) of the structure for all these different instances is presented. This provides the necessary data to estimate the overall response of a structure at a particular site of specified seismic hazard and constitutes the framework of Incremental Dynamic Analysis (IDA). In this, generation of data regarding capacity and demand evolves following a lognormal distribution while the corresponding cumulative distribution function is used to define the corresponding fragility curves. This analysis facilitates further the deduction of statistically sound estimates of the measured parameters. The hysteretic inelastic response of reinforced concrete members, i.e. beams and columns designed on the basis of Eurocodes is of primal importance. The Bouc-Wen model, as implemented in “Plastique” code is considered following the IDA procedure, the parameters of which are established based on existing experimental data. Through this modelling, a series of plane frames of different number of spans and storeys designed in a similar manner is investigated. Also, the effect of some general design code provisions on collapse capacity of these frames, such as stiffness distribution along height and strong column- weak beam ratio, are examined. Numerical results are presented and their corresponding fragility curves are derived. Interesting features are revealed, regarding the effect of each alternative design on collapse capacity, which often deviate from collapse predictions made using the static pushover analysis.*

1 INTRODUCTION

One of the main objectives of current earthquake-resistant design codes is to ensure increased levels of safety commencing with protection of human life during strong earthquakes, while reducing damage - repair cost for small and medium excitations for new and existing structures. This constitutes the framework of Performance Based Earthquake Engineering (PBEE) by defining performance levels which correspond to different damage situations. The level of collapse prevention for example, demands certain probability of collapse that does not exceed the acceptable limits set for this purpose. However, at the moment, code provisions are deterministic in nature, as they are based on return periods relating seismic excitation with specific levels of damage.

Hence, it is important to establish these probabilities and follow design methods that statistically ensure the non exceedance of the specified damage state. The Incremental Dynamic Analysis (IDA) [1, 2] addresses this issue by calculating statistical data in terms of Intensity Measure (IM) and Engineering Demand Parameters (EDPs). This is followed by a statistical analysis of the outcome and the evaluation of fragility curves [3, 4]. This procedure is capable of revealing significant probabilistic evidence of structural behaviour by defining relation between probability of collapse and ground motion IM. If fragility curves are combined with seismic hazard data from a certain region of interest, that combine the same IM with the seismic hazard, the Mean Annual Frequency (MAF) of exceeding a performance state is derived for the particular seismic hazard site.

In this paper the aforementioned methodology is used to assess collapse capacity of Reinforced Concrete plane frames designed following different considerations. It should be noted that these frames are centreline models of 3D symmetrical structures with equal inertia characteristics and fixed supports. More specifically, this study concentrates on the performance state of dynamic collapse by examining the effect of geometrical and structural frame parameters on the probability that a collapse event occurs.

2 ANALYTICAL PROCEDURE

2.1 Implementing IDA

In order to perform nonlinear elastoplastic dynamic analysis following the IDA method, the "Plastique" [5] program was used which employs the phenomenological Bouc-Wen hysteretic model, the parameters of which were defined as described in [6]. To establish more realistic results as the structure approaches collapse where large displacements, i.e. P- Δ effects, become significant and they were introduced according to [7]. This is a simple, approximate, non-iterative technique, where lateral forces are introduced to each storey level due to the overturning moments caused by the movement of diaphragm masses.

As far as IDA is concerned, as the scalar, escalated intensity measure (IM) the 1st eigenmode spectral acceleration with 5% viscous damping $S_a(T_1, 5\%)$ was selected. Respectively, the engineering demand parameter (EDP) that measures demand on different levels of structural deterioration is the maximum interstorey drift ratio. To save computational time the haunt & fill algorithm as the method to trace IDA curves, after repeated runs, was selected [2]. This was parameterized properly to achieve as much accuracy as possible in the region of dynamic instability. Twenty accelerograms were selected for the analysis, corresponding to major earthquakes in California and they are listed in [2, 8]. They consist of relatively large magnitude excitations, moderate distances from fault, so as to avoid pulse excitations and near field effects [9]. In Figure 1, the median and the 84% percentile response spectra for all twenty excitations are presented. The only source of uncertainty used in this

study is the record to record variability (aleatory uncertainty) which is sensitive to the dispersion of spectra in the region of structure's 1st eigenperiod. For the selected ground motions this dispersion in their spectral accelerations is computed in terms of logarithmic standard deviation through equation (1) and the final graph is presented in Figure 2.

$$\sigma_{\ln,y} = \ln \left(\frac{y_{84}}{y_{50}} \right) \quad (1)$$

where, y_{50} are the median spectral values while y_{84} are the 84% percentile spectral values for a given eigenperiod.

Figure 1: Median and 84% percentile response spectra for all twenty earthquakes

Figure 2: Dispersion of twenty acceleration spectra for the eigenperiods of interest.

2.2 Statistical evaluation

After performing the computationally demanding IDA, some very important features usually emerge with the proper statistical evaluation of the outcome. The statistical sample in this work consists of twenty spectral accelerations (Sa_c) where dynamic collapse occurred. Collapse is considered to happen, when a global or local collapse mechanism is formed, or when maximum interstorey drift ratio exceeds the value of 12%. In order to pursue analytical calculations, a lognormal distribution is fitted to the data and by calculating its cumulative

distribution function (CDF) a collapse fragility curve, based on the IM approach [3, 4], is derived as follows:

$$P[Sa_c \leq Sa] = \Phi \left[\frac{1}{\beta_{Sa,c}} \ln \left(\frac{Sa}{n_{Sa,c}} \right) \right] \quad (2)$$

where, $\beta_{Sa,c}$ is the standard deviation of the natural logarithm, while $n_{Sa,c}$ is the lognormal median of the data.

Figure 3: a) All 20 IDA curves, b) Corresponding empirical and analytical fragility curves

The above described steps are presented in Figure 3, for the case of a 6-storey, 2-bay plane RC frame with first eigenfrequency, $T_1 = 0.639$ sec. In the figure, the lognormal distribution, fitted to the data, is presented and consists the fragility curve for this frame.

Furthermore, in the literature several indices are defined that can be used to quantify the stochastic nature of fragility. To determine the most representative ones, a Probabilistic Seismic Hazard Analysis (PSHA) for the seismic site of interest is required, that provides the necessary hazard spectra and hazard curves. This data, when combined with fragility curves, can reveal the very important feature of how rarely a structure collapses when it is subjected to spectral accelerations that are possible to occur in the specific geographical region. This measure is the mean annual frequency (MAF) of collapse and its inverse is the collapse return period of the structure. In this study, the hazard curves that were implemented in the procedure are referred to the IM and are given in [10]. The indices used [11] are the median collapse spectral acceleration ($Median(Sa_c)$), the probability of collapse for the earthquake with probability of occurrence 10%/50 years ($P_{C|10\%/50y}$), the Margin Against Collapse (MAC) for the 10%/50 years earthquake (eq. 3) and the MAF of collapse (eq. 4). Also, the dispersion of structural behaviour according to different seismic excitations can be described through the standard deviation of the natural logarithm of the data (σ_{\ln}).

$$MAC_{10\%/50\text{ years}} = \frac{Median(Sa_c)}{Sa_{10\%/50\text{ years}}} \quad (3)$$

where $Sa_{10\%/50\text{ years}}$ is given in the hazard spectrum and defines the spectral acceleration that is expected to occur when the earthquake with probability of occurrence 10% in 50 years strikes.

$$MAF = \lambda_c = \int_0^{\infty} F_{C,Sa,c}(x) \left| d\lambda_{Sa}(x) \right| \quad (4)$$

where $F_{C,Sa,c}(x)$ is the collapse fragility curve and $\lambda_{Sa}(x)$ is the ground motion hazard curve.

3 EFFECT OF DESIGN CRITERIA IN THE COLLAPSE CAPACITY OF RC FRAMES

3.1 Effect of the number of bays and storeys

In Figure 4, eight plane RC frames of 3 and 6 storeys have been designed according to Greek codes, with number of bays ranging from 1 to 4. In order to facilitate comparison they retain the same reinforcement in the interior and exterior columns respectively.

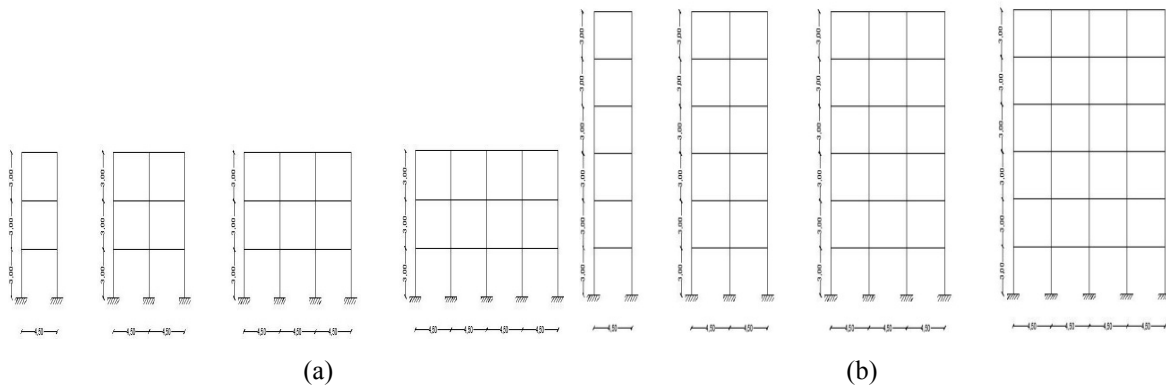

Figure 4: a) 3 storey frames, b) 6 storey frames

Column sections (m)	Beam sections (m)	Bay length (m)	Storey height (m)
0.25x 0.25	0.30x0.20	4.50	3.00

Table 1: Plane frames geometrical features

Figure 5: a) Pushover curves for 3 story frames, b) Pushover curves for 6 story frames

Next, the static pushover results with triangular lateral force distribution are displayed in Figure 5. The general trend is that, as the number of bays increases, redundancy also increases and the greater possibility for force redistribution exists, resulting into higher capacity [13].

Figure 6: a) Collapse fragility curves for 3 storey frames, b) Collapse fragility curves for 6 storey frames

The same frames are analysed following the IDA method. Collapse fragility curves are produced and they are presented in Figure 6. In Table 2 the probabilistic indices for collapse estimation have been calculated, together with measures of deformation such as the median interstorey drift ratio (IDR) and the median roof drift ratio (RDR). It is important to notice that the results are meant only for comparison between the different frames of the analysis as they appear inadequate to withstand the strong earthquakes of California, as they are poorly designed with the minimum code reinforcement.

Storeys	Bays	T1(sec)	Median(Sa_c)	σ_{ln}	$P_{C 10\%/50y}$	MAC	λ_c	Median (IDR)	Median (RDR)
3	1	0.324	0.87	0.63	74%	0.67	0.0121	0.031	0.023
	2	0.349	1.06	0.70	61%	0.82	0.0098	0.079	0.053
	3	0.357	1.02	0.67	64%	0.78	0.0103	0.054	0.041
	4	0.362	1.12	0.71	59%	0.86	0.0093	0.089	0.054
6	1	0.650	0.70	0.68	75%	0.63	0.0100	0.045	0.022
	2	0.693	0.86	0.76	65%	0.75	0.0086	0.080	0.035
	3	0.708	0.93	0.82	60%	0.81	0.0076	0.080	0.038
	4	0.717	1.00	0.77	57%	0.87	0.0068	0.076	0.040

Table 2: Collapse capacity quantification for all RC frames

A basic difference between pushover and IDA is that in the case of 3-storey frames collapse capacity does not increase with the increase of the number of bays. More specifically, the 2-bay frame exhibits smaller probability of collapse for the 10%/50 years earthquake and smaller MAF of collapse than the 3-bay frame. Comparing the two different groups of frames, the 6-storey frames result into larger dispersion of the results due to the fact that their eigenperiods represent larger spectral dispersion according to Figure 2. Also, median collapse spectral acceleration (Sa_c) takes smaller values for the 6-storey frames. Although it results

that with the increase of frame height collapse capacity decreases, which is logical as P- Δ effects becomes important and also higher axial load in columns causes their ductility to diminish, this statement can't be generalised due to the limited sample of the current study. In contrast, the MAF of collapse for the 6-storey frames seems to be smaller, meaning larger collapse return periods, since smaller spectral accelerations are expected to appear in larger eigenperiods. The context of table 2 is displayed graphically in Figure 7.

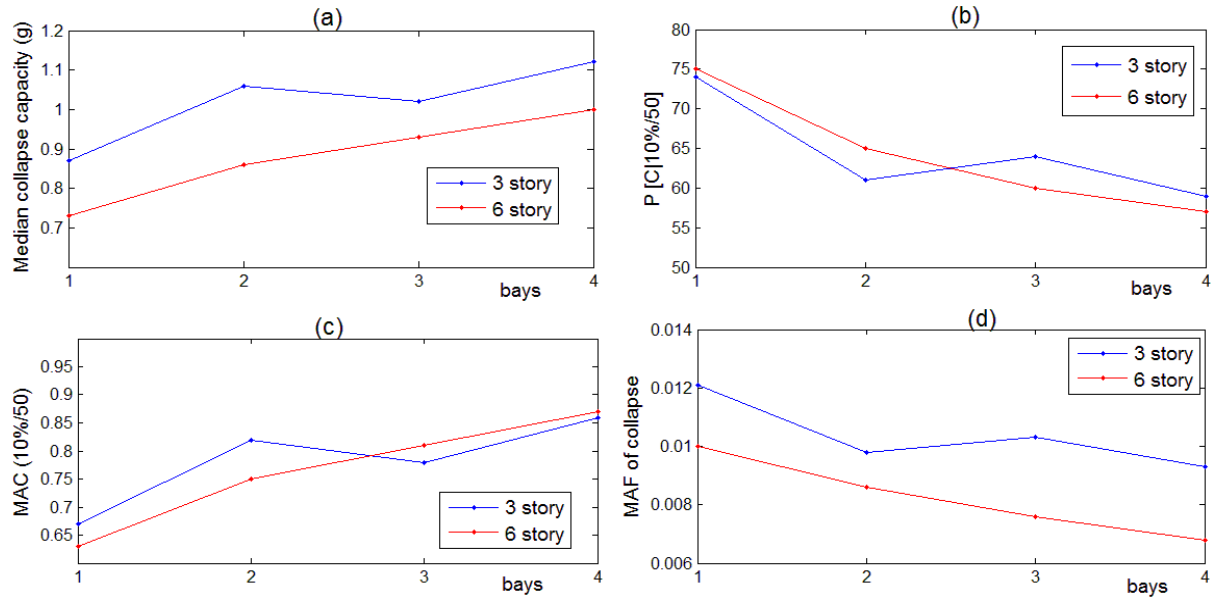

Figure 7: Effect of the number of bays and storeys in frames collapse capacity. a) Median collapse capacity, b) Probability of collapse for the 10%/50 years earthquake, c) MAC for the 10%/50 years earthquake, d) MAF of collapse

The results of the last 2 columns in table 2 that refer to deformations are presented in Figure 8.

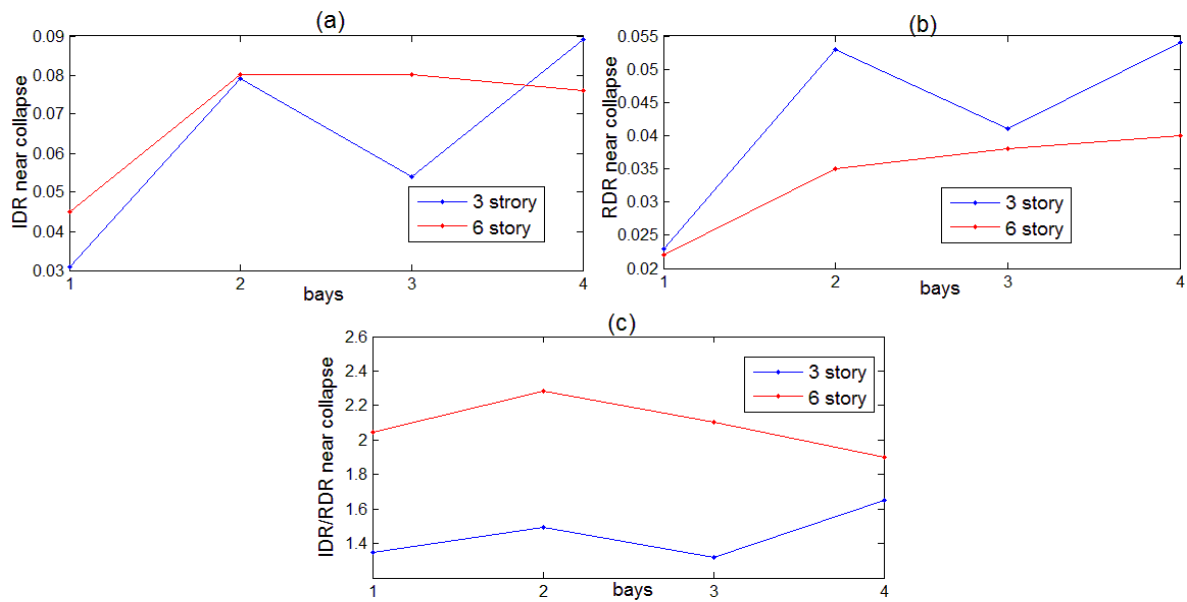

Figure 8: Effect of the number of bays and storeys in frames displacements near collapse. a) Interstorey drift ratio (IDR), b) Roof drift ratio (RDR), c) IDR/RDR

In Figure 8c, IDR/RDR ratio depicts the degree of damage accumulation in a few storeys. As the ratio becomes bigger, like in 6-storey frames, it is portrayed that damage is localized in a few storeys of the building, while in 3-storey frames damage is almost equally distributed along the height. Generally, 1-bay frames develop smaller displacements and for 6-storey frames they seem to stabilize when more bays are added. Also, 6-storey frames don't exhibit as large demands in displacements as the 3-storey frames, for the same reasons that collapse capacity in terms of spectral accelerations decreases, as it was mentioned.

Figure 9: Number of plastic hinges involved in collapse for 2-bays and 3-bays frames

In Figures 7 and 8 it is evident that for 3-storey frames, although it was expected to develop higher strength against collapse than the 2-bay frames, the opposite happens. It is probable that this feature is caused by local collapse mechanisms that don't allow the structure to take advantage of its full redundancy. To elaborate more on this fact, the measure of structural redundancy that was given by Bertero and Bertero [14] was investigated. This measure is the number of plastic hinges n that yield or fail at structural members ends until total collapse. So, in each single record IDA run where collapse is detected, the number of formed plastic hinges is recorded. This number is divided by the number of static indeterminacy of the structure to determine the redundancy ratio. Thus, a statistical set with 20 values is formed and the results are presented in the form of a cumulative distribution function in Figure 9. It is clear that the 3-bay frame stays behind in consuming its full redundancy for a specific probability of collapse. Therefore, for a given probability of collapse, in the 3-bay frame the redundancy ratio, that expresses the cross sections that have yielded or failed, is smaller than the redundancy ratio in the 2-bay frame respectively, a fact that reveals the probabilistic nature of structural redundancy as related to seismic loading.

The nonlinear modelling of structures with the notion of plastic hinge formation reveals the estimated form of collapse. For every collapse mechanism identified in each single record IDA, the number of storeys involved in the mechanism is recorded and the results are shown in Table 3. A particular storey is assumed to participate in the collapse mechanism when at least one plastic hinge appears on its columns or on its beams.

Geometrical features		Percentages of observed plastic hinges						Percentages of storeys involved in collapse (%)
Storeys	Bays	Storeys 1-1 (%)	Storeys 1-2 (%)	Storeys 1-3(%)	Storeys 1-4(%)	Storeys 1-5(%)	Storeys 1-6(%)	
3	1	0	40	60	0	0	0	87
	2	0	25	75	0	0	0	92
	3	0	25	75	0	0	0	92
	4	0	30	70	0	0	0	90
6	1	0	0	15	15	45	25	80
	2	0	0	15	15	35	35	82
	3	0	0	10	30	35	25	79
	4	0	0	5	30	40	25	81

Table 3: Storeys involved in collapse mechanism for each frame

For example in 6-storey, 2-bay frame, plastic hinges are formed in the first 3 storeys in 15% of all the occasions, in the first 4 storeys in 15%, in the first 5 storeys in 35% and all storeys are involved in collapse mechanism in 35% of all the occasions. Also, the total percentage of storeys where plastic hinges are formed in their beams or columns is 82%. Generally, from Table 3 it is observed that the distribution of plastic hinges along height is not influenced by the number of bays and that there is a tendency for concentration of damage in higher floors. There is no case of first storey mechanism for the 3-storey frames, not first or second storey mechanism for 6-storey frames. The involvement of fifth and sixth storey is significant, since flexural strength of columns is about 3 times bigger than flexural strength of beams causing the beams in upper floors to yield faster. Finally, percentages of storeys involved in collapse for 6-storey frames are clearly smaller, a fact that comes in agreement with Figure 8(c). Hence, it is evident from a different perceptive that damage concentrates in few storeys in the case of the 6-storey frames.

3.2 Effect of stiffness distribution along height

To examine the effect of stiffness distribution along the height in RC frames collapse capacity, 2 different designs of the 6-storey 2-bay frames have been analysed. The study refers to normal, moment resisting frames, mass is considered equal in all storeys and distribution of stiffness between 2 consecutive storeys doesn't exceed 60%. Also, the same moment of inertia is attributed to the same floor's members, as all beams and columns have the same geometrical properties. In order to quantify stiffness variation for every alternative design, the indices in equations (5) to (7) are used as in [15]. These indices provide information about the form of building lateral displacements, whether they are shear-type or flexural-type dominated. Index ρ_i is defined as the ratio of the sum of stiffness ratio of all beams at floor i to the sum of the stiffness ratio of all columns at the same floor. When ρ_i equals to zero, then pure flexural-type deformation occurs and if ρ_i becomes infinite then pure shear-type deformation occurs, while intermediate values stand for a combination of the 2 types where both beams and columns deform in flexure. Index ρ_b quantifies the variation of beams stiffness and is defined as the ratio of the sum of stiffness ratio of all beams at each floor to the sum of the stiffness ratio of all beams at the first floor. Similarly, index ρ_c is defined for columns.

$$\rho_i = \frac{\sum_{\text{story } i \text{ beams}} \frac{EI_b}{L_b}}{\sum_{\text{story } i \text{ columns}} \frac{EI_c}{L_c}} \quad (5)$$

$$\rho_b = \frac{\sum_{\text{story } i} \frac{I_b}{L_b}}{\sum_{1st \text{ story}} \frac{I_b}{L_b}} \quad (6)$$

$$\rho_c = \frac{\sum_{\text{story } i} \frac{I_c}{L_c}}{\sum_{1st \text{ story}} \frac{I_c}{L_c}} \quad (7)$$

In Figure 10, all the above indices are presented for the 3 frames designed to have different stiffness variation along height. Frame (a) is the 6-storey, 2-bay frame presented in §(3.1). This frame is designed according to Greek codes with variation in columns reinforcement along height. External columns maintain the same amount of reinforcement, while the interior ones reduce steel bars diameters in the 5th and 6th floor. Frame's (b) reinforcement remains constant along height in each column so as in all storeys its index ρ_i to take approximately the same mean value with frame (a). Frame (c) is based on frame (b), but with beam cross sections varying as number of floor increases. This variation is applied only in cross sections and not in the reinforcement so as yield moment strength to remain practically constant.

Figure 10: Variation of stiffness along height for the 3 alternative designs. a) Storey stiffness index ρ_i , b) Beam stiffness index ρ_b , c) Column stiffness index ρ_c

In the first two frames, that present constant beam stiffness in all storeys, ρ_i index attains

bigger values in upper floors as reinforcement in columns decreases. On the other hand with beam cross section reduction in size in the 3rd design, index ρ_b becomes smaller as presented in Figure 10b. In the same figure, plots for frames (a), (b) are identical as their beams are the same everywhere, while in Figure 10c, plots for frames (b), (c) are identical as they have the same column properties. In general, variation of beam moments of inertia affects the frames in which beams rotations influence their deformation more than columns lateral displacements.

After performing IDA for the three frames, fragility curves are determined which are presented in Figure 11. Intuitively, one would expect that equal stiffness in each storey would have forced damage to concentrate on lower floors, dictating the collapse capacity to decrease. However, as it is portrayed in Figure 11, using the same amount of reinforcement in columns results into slight augmentation of collapse spectral acceleration. Nevertheless, there is no more collapse capacity increase when beam cross sections vary while keeping the reinforcement and the cross section of columns constant.

Figure 11: Fragility curves of the 3 RC frames with different stiffness variation along height

Fragility behaviour is quantified through the calculation of probabilistic indices described in §(2.2). The new outcomes are presented in table 4 below.

Frame	T1(sec)	Median(Sa_c)	σ_{ln}	$P_{C 10\%/50y}$	MAC	λ_c	Median (IDR)	Median (RDR)
a	0.693	0.86	0.76	65%	0.75	0.0078	0.080	0.035
b	0.694	0.94	0.74	61%	0.82	0.0072	0.080	0.046
c	0.705	0.93	0.75	62%	0.81	0.0072	0.076	0.035

Table 4: Collapse capacity quantification for the 3 different design alternatives

From Table 4 a significant feature based on IDR/RDR ratio is displayed, which describes damage localization in specific storeys. The smaller value for frame (b), meaning more similar damage distribution along height, is a main reason for the higher collapse capacity exhibited. This ratio is smaller because displacements in terms of roof drift ratio appears to be greater for frame (b) since it has less stiffness in its lower columns, facilitating in this way plastic hinge formation in these critical regions. Therefore, plastic hinges at the bottom of first

floor columns helps seismic energy dissipation and is a positive feature for capacity design. More specifically, plastic hinge distribution at collapse can be found in Table 5. Generally, no significant differences are observed in the way that stiffness distribution affects plastic hinge distribution. For the case of frame (b) with uniform column reinforcement, in 50% of all the occasions plastic hinges are formed up to 5th storey. Hence, it isn't the fact that more storeys are involved in collapse mechanism which increases collapse capacity, but the fact that more columns participate in the mechanism, as they aren't as stiffened as in frame (a) where lower storey columns were designed with increased reinforcement.

Frames	Percentages of observed plastic hinges						Percentages of storeys involved in collapse (%)
	Storeys 1-1 (%)	Storeys 1-2 (%)	Storeys 1-3(%)	Storeys 1-4(%)	Storeys 1-5(%)	Storeys 1-6(%)	
a	0	0	15	15	35	35	82
b	0	0	15	10	50	25	81
c	0	0	15	10	45	30	82

Table 5: Storeys involved in collapse mechanism for each frame

3.3 Effect of the strong column-weak beam ratio

The aim of the strong column-weak beam (SCWB) design provision is to avoid localized story mechanisms and thus attain more distributed failure mechanisms. In order to study the effect of this concept, only yield moments of beams and columns are taken into account through index α [15], which is defined as the ratio of the sum of columns yield moments to the sum of beams yield moments that exist in a given joint.

$$\alpha = \frac{\sum M_{c,y}}{\sum M_{b,y}} \quad (8)$$

In this work, the alternative designs are based in the 3-storey, 3-bay frame, where beams reinforcement remains constant and only columns reinforcement varies from one design to another resulting in different α values. Lastly, index α is referred to the middle joint of the 1st floor.

Figure 12: Static pushover curves for the different SCWB ratios

First, a static pushover analysis is performed for the five resulting RC frames and the outcome is presented in Figure 12 in order to depict the primal behaviour which will be compared with IDA. Generally, the dominant tendency is an increase of ultimate strength with the increase of column reinforcement. In addition, ductility is getting bigger and bigger up to $\alpha = 2.30$, where reinforcement area is the 2% of cross sectional area.

After performing IDA for all five frames, the fragility curves are determined which are displayed in Figure 13. Also, the accompanying probabilistic indices are included in Table 6.

Figure 13: Fragility curves for the different SCWB ratios

α	T1(sec)	Median(Sa_C)	σ_{ln}	$P_{C 10\%/50y}$	MAC	λ_C	Median (IDR)	Median (RDR)
1.30	0.386	0.80	0.65	77%	0.62	0.0133	0.052	0.032
1.60	0.375	0.96	0.66	68%	0.74	0.0109	0.069	0.048
1.90	0.368	1.07	0.63	62%	0.82	0.0098	0.066	0.049
2.30	0.365	1.07	0.67	62%	0.82	0.0097	0.076	0.056
2.80	0.363	1.06	0.68	62%	0.82	0.0097	0.077	0.056

Table 6: Collapse capacity quantification for the 5 different SCWB ratios

The results in Figure 13 and Table 6 present increased collapse strength until $\alpha = 1.90$ and after that, further increase in α does not result into bigger collapse capacity, as fragility curves for $\alpha = 2.30$ and $\alpha = 2.80$ slightly differ from the fragility curve for $\alpha = 1.90$. Actually, due to larger dispersion in the last two cases, these curves present smaller collapse spectral accelerations at low collapse probabilities. Therefore, a difference in results is observed in comparison with pushover, since collapse capacity doesn't increase repeatedly when more reinforcement is added in columns. However, IDA defines a strength limit that can be assessed, meaning that the addition of more reinforcement in columns has no effect except the increase in cost. For the case of the frame studied here, this limit is accessed for $\alpha = 2$, when yield moment of columns is twice the yield moment of beams.

The results of Table 6 are displayed graphically in Figure 14. Both from Table 6 and figure 14 it is evident that there is an improvement by 15% in collapse capacity from the worst to the best design. Also an improvement of 33% at median collapse spectral acceleration and at the margin against collapse occurs, while the return period of collapse increases by 28 years. In terms of displacements, frame exhibits repeatedly larger interstorey

and roof drifts up to $\alpha = 2.30$, while for $\alpha = 2.80$ no further increase occurs, which is in agreement with the static pushover results. In order to elaborate on the fact that improvement of collapse capacity is bounded up to a certain level, the results of plastic hinge formation during formation of collapse mechanisms are listed in Table 7.

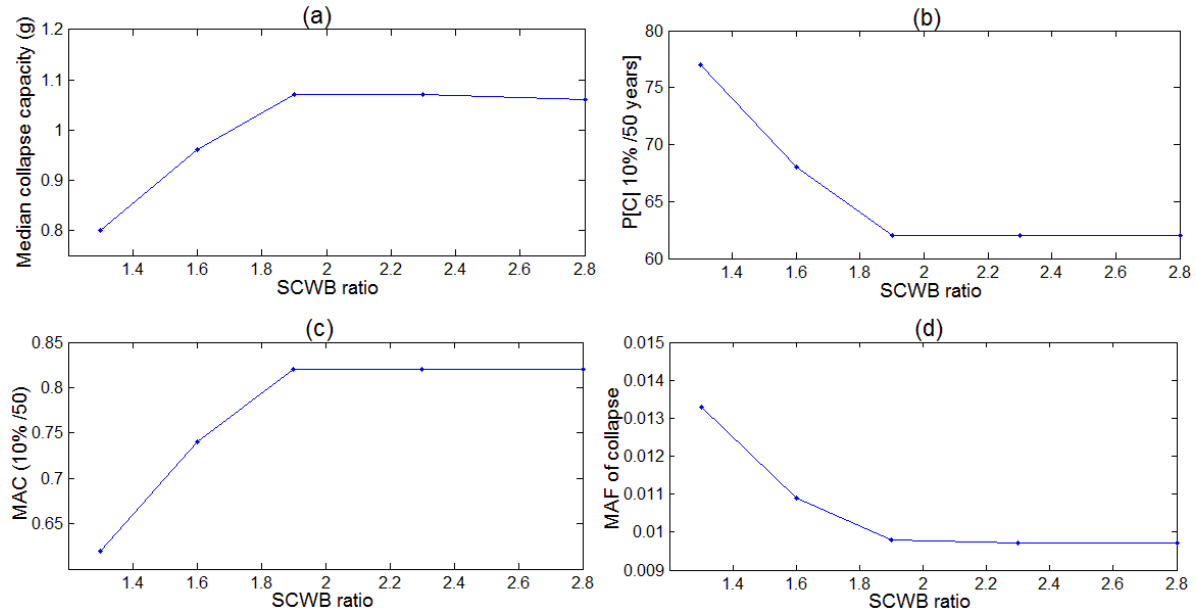

Figure 14: Effect of SCWB ratio on collapse capacity for a 3 storey, 2 bay RC frame

α	Average number of plastic hinges formed (%)	Plastic hinges percentages at columns (%)	Plastic hinges percentages at beams (%)	Capacity design violation percentages (%)
1.30	19.5	57	43	55
1.60	21	45	55	45
1.90	21	33	66	15
2.30	19.5	20	80	15
2.80	18	12	88	5

Table 7: Plastic hinge percentages at collapse

In the last column of Table 7, capacity design violation is considered to occur when a column fails prior to a beam at a given joint in the structure. Such violation can happen even if the formation of a plastic hinge at a beam isn't adequate to prevent final failure at column in the joint. As expected, more plastic hinges are formed in beams as column flexural strength increases, while the average number of total plastic hinges formed remains unaffected with SCWB ratio, meaning that only distribution of plastic hinges changes. Also, violation of capacity design regulation percentages are reduced while this ratio gets bigger. However, for values larger than 1.90 this percentage doesn't appear to differ a lot, a fact that is also portrayed by the similarity of fragility curves presented in Figure 13. Thus, it is clear that when capacity design provisions are robust, then an optimum design with respect to the probability of collapse can be achieved.

It must also be stated that an even better design can be assessed combining both beam and column flexural strength in the process and not just the SCWB ratio. Indicatively, in Figure 15 two fragility curves are presented which represent the same frame with $\alpha = 2.30$ and an alternative design where beams yield moment improved with the ratio α becoming 1.75. It is

clear that this transformation increases slightly collapse capacity by increasing beam rotational capacity, justifying the claim that total structural strength is not affected only by the SCWB ratio but also by the member's strength.

Figure 15: Fragility curves for the same frame after reducing α through beam yield moment increase

4 CONCLUSIONS

In this work fragility curves following IDA have been determined for a series of 2D RC frames to estimate the effect on their collapse capacity when some of their properties are changed. The main remarks drawn can be summarized as follows:

- For the set of frames studied in this work IDA offers similar results with pushover analysis. However, pushover analysis predicts larger differences between results in collapse capacities.
- By calculating mean values for the two groups of frames concerning 6 and 3-storey frames, 17% reduction in collapse probability assuming the 10% in 50 years earthquake occurs and 28% reduction in terms of MAF of collapse achieved when number of bays increased from 1 to 4.
- When stiffness distribution along height varies, probability of collapse reduced only 3% and MAF of collapse improved by 8%.
- With regard to the SCWB ratio, probability of collapse becomes 15% lower, while MAF of collapse is reduced by 27%. Also, it was found that there is an upper limit beyond which collapse capacity is not improving.
- By quantifying the sensitivity in collapse capacity with respect to the investigated factors, it can be concluded that the major factor is redundancy of the structure which is affected by adding more bays. Of equal importance is the SCWB ratio that affects the form of collapse mechanism throughout the structure. Stiffness distribution along the height of the structure appears to be insignificant, suggesting constant reinforcement along the height.
- More elaborate analysis should be performed to establish more general results which should be based on more representative samples and further variation of parameters.

Abstract. *In an effort to reduce seismic risks, the Geological Survey of Canada has recently taken important steps by initiating a project on quantitative assessment of earthquake related risks. One of the objectives of this project is to study the seismic vulnerability of historic stone masonry buildings generally known for their poor performance during strong ground motion. This paper focuses on the development of analytical displacement-based fragility curves reflecting the characteristics of existing stone masonry buildings in Canada. The fragility analysis provides the necessary link between the building damage and earthquake intensity in a probabilistic setting, where the extent of building damage is best correlated to the amount of induced building displacement. The old historic center of Quebec City was selected as a typical study area due to the concentration of stone masonry buildings, which combined to the high heritage value increases the potential consequences of failure. Comparison was made with similar fragility curves implicit in Hazus-MH and ELER seismic risk assessment tools. Differences have been observed between the three sets of fragility curves which may lead to significantly disparate damage estimates. This comparison shows the importance of the development of fragility curves specific to the generic construction characteristics in the study area and emphasizes the need of critical use of existing risk assessment tools and generated results.*

1 INTRODUCTION

Majority of existing historic buildings in old urban centers in Eastern Canada are stone masonry structures and represent un-measurable architectural and cultural heritage. Historic stone masonry buildings were built to resist gravity loads only and generally offer poor resistance to lateral seismic loads. Damage occurred to stone masonry buildings from past earthquakes is attributed to inadequate structural integrity due to the lack of connection between stone masonry structural walls and wooden floors and roofs; and to ensuing inadequate structural resistance, which results into typical shear cracking and disintegration of stone walls and partial or total collapse of buildings [1].

The high seismic risks related to stone masonry buildings are even more increased due to their location in densely populated urban centers in a way that the consequences of failure of these structures tend to be severe with regards to human casualties, heritage damage and economic losses [2]. Seismic risk assessment of historic stone masonry buildings is therefore the first necessary step in providing mitigation plans for seismic retrofit and preservation.

In an effort to reduce seismic risks, the Geological Survey of Canada has recently taken important steps by initiating a project on quantitative assessment of earthquake related risks. One of the objectives of this project is to study the seismic vulnerability of historic stone masonry buildings. The old historic center of Quebec City was selected as a typical study area.

Seismic risk is often considered as the convolution of seismic hazard (expected ground motion at given location), exposure (demographics, buildings, essential facilities, utilities, etc.), and vulnerability (response of structures to earthquake impacts, generally defined by expected degree of damage under different levels of seismic loading). These three components are integrated to determine direct and indirect physical damage and losses. Fragility analysis is the key component in performance based seismic risk assessment. It provides the link between the two other components of the seismic risk assessment process, inventory and seismic hazard.

The most widely used risk assessment tool in North America, Hazus-MH [3], seems to not adequately represent the response of stone masonry structures to earthquake loading. It considers only one structural class for unreinforced masonry buildings, URM, mainly covering brittle brick masonry structures. The European ELER tool [4] recognizes explicitly the stone masonry as a specific structural type among the unreinforced masonry typology. URM building typologies in ELER tool cover a wide range of masonry construction encountered in Europe, such as rubble stone, adobe, simple stone, massive stone, brick masonry with wooden floors and brick masonry with reinforced concrete floors.

The objective of this paper is to introduce a procedure for the development of displacement based fragility curves for typical stone masonry buildings in Old Quebec City and to present the generated results. It was first necessary to make an inventory of the existing masonry buildings and to include their special structural and material characteristics. At the end, a comparison is made with fragility curves implicit in Hazus and ELER seismic risk assessment tools in order to assess differences and the potential disparities they may exert on damage probability estimates.

2 ANALYTICAL FRAGILITY ANALYSIS FRAMEWORK

Fragility refers to the probability of reaching or exceeding a given damage state defined as a function of earthquake loading. The output of the fragility analysis is a set of fragility curves describing different damage or limit states. Fragility curves can be obtained from empirical, judgmental, analytical, and hybrid approaches [5]. All these methods contain epistemic and aleatory uncertainties in the assessment procedures and use data including: measurement un-

certainty related to observations of damage, inconsistency in the quality of available databases and related analyses, variability in the ground motions, uncertainty in experts judgment, statistical uncertainty inherent in the parameter estimates, uncertainty due to simplification of strength and stiffness models of structural materials and components, uncertainties in seismic demand and capacity of structures due to variations of their geometry and material properties, uncertainty in the definition of the damage limit states, etc.

Because of the scarcity of observational damage data in regions of moderate seismicity such as Quebec City and the subjectivity of judgmental damage data, modern risk assessment methodologies adopt analytical development of fragility curves. Analytical methods rely on structural modeling and analytical evaluation of the likelihood for a given building to experience damage by earthquakes of a given intensity and distance, as well as on consideration of related uncertainties.

The derivation process of analytical fragility curves for a particular building or building typology comprises several components: (1) buildings Inventory, (2) damage/limit state model, (3) building capacity model, (4) seismic hazard, (5) seismic demand model, and (6) fragility generation (Figure 1).

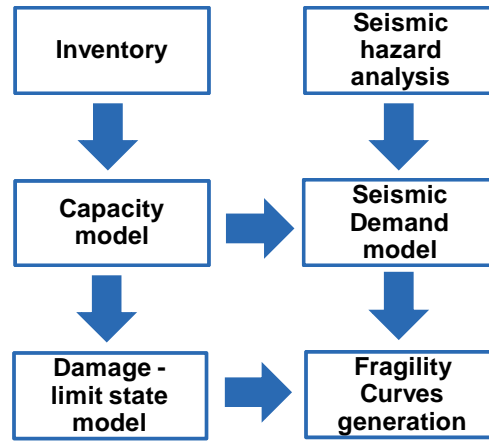

Figure 1: Derivation process of analytical fragility curves.

Fragility curves are given in the form of lognormal fragility distribution that relates the probability of being in or exceeding a given damage state for a given intensity measure (e.g., spectral inelastic displacement demand). The conditional probability of being in or exceeding a particular damage state, DS given the spectral displacement S_d is defined by the function:

$$P[DS | S_d] = \Phi \left[\frac{1}{\beta_{DS}} \ln \left(\frac{S_d}{\bar{S}_{d,DS}} \right) \right] \quad (1)$$

$$\beta_{DS} = \sqrt{CONV(\beta_C, \beta_D)^2 + \beta_r^2}$$

where: $\bar{S}_{d,DS}$ is median value of the spectral displacement at which the building reaches the threshold of damage state DS , β_{DS} is standard deviation of the natural logarithm of spectral displacement for damage state DS , and Φ is standard normal cumulative distribution

function. β_{DS} describes the total variability of a fragility curve damage state. Three primary sources contribute to the total variability of any given damage state, namely, the variability in the capacity model β_C , the variability in the demand model β_D , and the variability in the threshold of a damage state from the damage model β_T . Since the seismic demand is dependent on the building capacity, a convolution process is required to combine their respective variability [6]. In the case the variability in the seismic demand, β_D , is already modeled in the Probabilistic Seismic Hazard Analysis (PSHA) process, it should be removed from β_{DS} as follows [5],

$$\beta_{DS} = \sqrt{\beta_C^2 + \beta_T^2} \quad (2)$$

3 INVENTORY OF STONE MASONRY BUILDINGS IN OLD QUEBEC CITY

A detailed inventory has been carried out to characterize the historic stone masonry buildings in Old Quebec City. Besides the field survey, the inventory consisted of review of architectural reports and dissertations, historic documents [7], and archives of the Bibliothèque et Archives Nationales du Québec (www.banq.qc.ca).

Figure 2 shows the three most frequent types of stone masonry buildings, selected among the typologies reported by Vallières [7] and retained as representative structural types for the study area. These building types were constructed during the 18th and mid-19th century. The massive façade walls are relatively thick, ranging from 40 to 60 cm, and have regular window and door openings on both sides of the building. The typical story height ranges from 2.75m to 3.35m. Lateral fire walls are of the same thickness as the façade walls. The typical floor is made of wood resting on the façade walls. The massive façade and fire walls provide the buildings' lateral resistance in both directions.

Figure 2: Main stone masonry building typologies in Old Quebec City [7].

4 DISPLACEMENT-BASED DAMAGE MODEL AND FRAGILITY CURVES

The good correlation between the earthquake induced displacement and the extent of structural damage lead to the development of modern performance-based seismic assessment procedures which are based on the evaluation of the structure-specific deformation capacity and earthquake-induced displacement demand.

Recently, simplified displacement-based procedures were proposed for the risk assessment of masonry structures [8] and [9]. The procedure proposed in [9] is adopted in this study. It assumes modeling of the masonry structures by an equivalent single degree of freedom system with effective global parameters (ESDOF). The structural damage state threshold at the effective height of the ESDOF is obtained according to the assumed deformed shape of the structure. A linear shape is assumed for elastic behavior and a soft story deformed shape is assumed for inelastic behavior which is the most common failure mechanism of masonry structures under earthquake loading (Figure 3.a). Damage state drift thresholds for masonry walls are identified from experiments on masonry wall elements.

The displacement at the threshold of each damage state at the effective height of the ESDOF Δ_{DSi} , equivalent to the spectral displacement, and can be evaluated as:

$$\Delta_{DSi} = \theta_{DS1} \cdot k_1 \cdot H + (\theta_{DSi} - \theta_{DS1}) \cdot k_2 \cdot h_s \quad (3)$$

where: H is total height of the building, h_s is height of the first story walls, θ_{DS1} is drift threshold for the first story walls at the elastic limit, θ_{DSi} is the drift threshold for the first story walls at higher damage states, k_1 is the effective height coefficient to convert the multi degree of freedom system into ESDOF, k_2 is the effective height of the first story walls going into the inelastic range when openings are present, $k_2=1.0$ when there are no openings.

For a regular distribution of masses and a uniform story height, k_1 is equal to 0.667. When the mass distribution is not regular, what is common in the case of unreinforced stone masonry, the buildings are better represented by a distributed mass corresponding to the mass of the masonry walls plus lumped masses corresponding to the mass at each floor. In this case, k_1 and k_2 have to consider the different mass distributions. The computation of these two factors is explained in details by [9] and the proposed values are given in Table 1.

Damage states drift thresholds are identified on the envelope curve of stone masonry walls as shown in Figure 3.b [10] and [11]. The lateral response of stone masonry walls is strongly nonlinear. As the displacement due to cracking increases, the walls experience both strength and stiffness degradation. The thresholds on the horizontal axis correspond to flexural cracking (θ_{DS1}), shear cracking (θ_{DS2}), maximum shear strength (θ_{DS3}), and ultimate deformation at 20% loss of strength (θ_{DS4}). They are considered as respective thresholds for the slight damage state, moderate damage state, extensive damage state, and complete damage state.

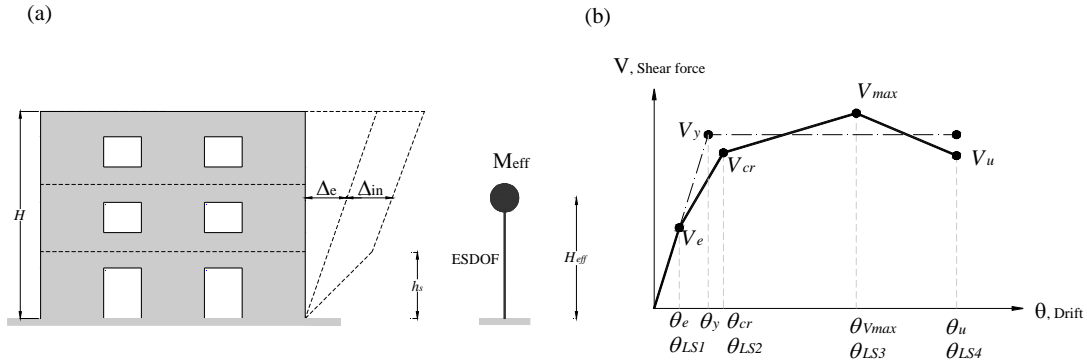

Figure 3: Simplified model for damage limit states (a), and identification of drift limits for masonry walls (b).

Number of stories	k_1	k_2
1	0.79	0.96
2	0.72	0.95
3	0.69	0.92

Table 1: Values of effective height coefficients of the ESDOF for different number of stories [9].

In the context of this study there are no laboratory test results on stone masonry walls representative for URM in the Old Quebec City, therefore damage states drift thresholds were derived from typical literature data on stone masonry wall elements [11];[12];[13]. A Matlab code [14] was used to obtain an empirical cumulative distribution (CDF) of each damage state drift threshold from collected data. The lognormal cumulative distribution was employed to fit the empirical distribution. This parametric probability distribution has the advantage of being fully defined by two statistical parameters that incorporate the central tendency (median) and dispersion (lognormal standard deviation) of the data (Figure 4.a). These values were implemented in Equation 3 as lognormal distributed random variables. The story height value was assumed deterministic as the median height from the inventory ($h_s = 3.0\text{m}$). The respective displacement threshold resulting data were then fitted with lognormal distributions which represent the displacement threshold fragility curves of the ESDOF (Figure 4.b).

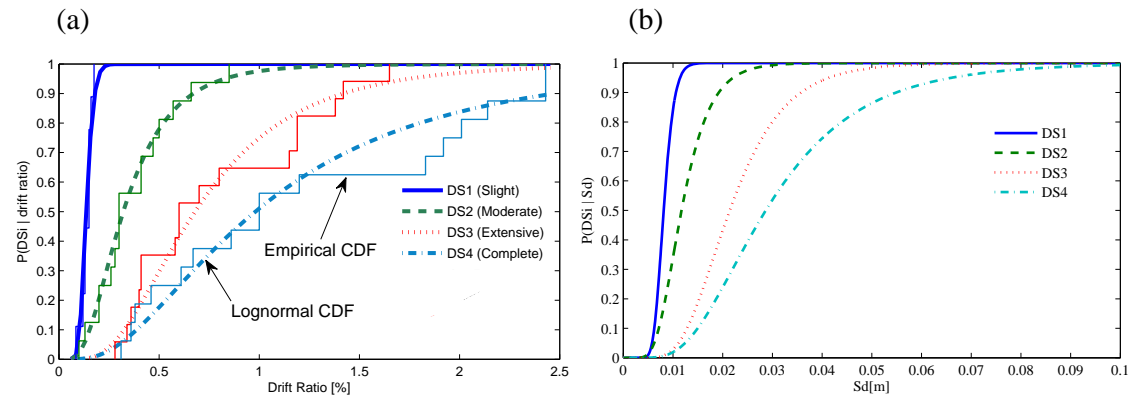

Figure 4: Drift threshold variability (a), and Displacement-based damage threshold fragility curves for two-story stone masonry buildings (b).

Figure 5 illustrates the developed fragility curves for two-story stone masonry buildings. For comparative purposes, the fragility curves for the Hazus pre-code unreinforced masonry buildings (URM) and ELER simple stone low-rise buildings are also presented. For the moderate damage state (DS2), the median displacement threshold $\bar{S}_{d,DS2}$ developed in this study is 0.7 and 3.3 fold of those implicit in Hazus and ELER, respectively. For the complete damage state (DS4), $\bar{S}_{d,DS4}$ developed in this study is 0.3 and 2.4 fold of those implicit in Hazus and ELER, respectively. The lognormal standard deviation of the moderate and complete damage state threshold are $\beta_{T,DS2} = 0.38$ and $\beta_{T,DS4} = 0.50$, respectively. This is in fair agreement with the assumed standard deviation in both Hazus and ELER for all damage states, $\beta_{T,DSi} = 0.4$. This variability can be reduced by conducting laboratory tests on typical stone masonry walls found in Old Quebec City.

One can argue that these curves can not be directly compared because of the different assumptions, information and tools used in the development process. The objective of Figure 5 is rather to show the importance for the development of specific fragility curves that reflect the generic construction characteristics for the considered study area.

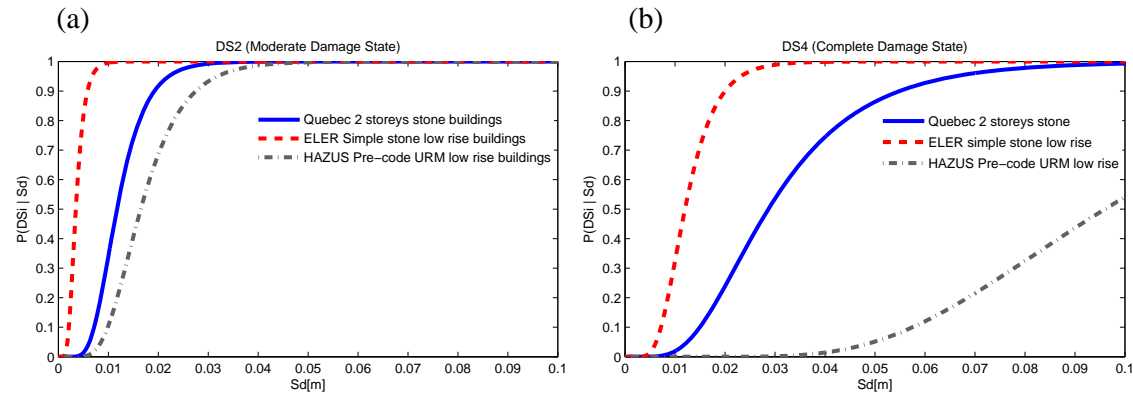

Figure 5: Comparison of fragility curves of Quebec, Hazus and ELER for (a) moderate damage state and (b) complete damage state.

5 CAPACITY MODEL

The three main typologies of existing stone masonry buildings typologies (Figure 2) were used to develop the capacity model. The variation in capacity of stone masonry buildings is relatively high since small modification in geometry or in material properties may result in different seismic resistance. Quebec City stone masonry buildings are mainly constructed from limestone and sometimes sandstone with lime mortar. However, no specific information on material mechanical properties was available. These properties were therefore obtained from the literature data [15], and may introduce significant variability in the developed capacity models.

In order to develop a representative capacity model for a building typology, a simplified mechanical model was used with some modifications [16]. The elastic deformation of the building is approximated by a linear shape up to the point where the shear capacity of the wall is reached, whereas the inelastic deformation is assumed perfectly plastic and concentrated at the first story, which is the typical damage observed in past earthquakes. The effective stiffness of the linear elastic part can be determined using secant stiffness at the capacity, V_y , and is selected such that the bilinear curve is equivalent to the experimental curve using the Ener-

gy equivalence criteria [17]. The base shear strength of the building in one direction is assumed to equal the sum of the shear strengths of the first story walls in that direction (Figure 6). Two simple criteria were used to evaluate the strength of the first story walls based on the expected failure mechanism: flexural rocking failure and diagonal cracking failure [17]. Example of the variability in capacity curves due to material uncertainty is shown in Figure 7 which presents five capacity curves corresponding to different masonry strength. More details about the development of capacity curves for the selected typologies can be found in [18].

Figure 6: Simplified mechanical model for capacity curve evaluation of stone masonry buildings.

Figure 7: Variability in capacity curves for a Quebec City stone masonry typology and comparison with Hazus and ELER tools respective median capacity curves.

The fitted lognormal distributions for the capacity model parameters, the fundamental period of vibration and the yield acceleration, are shown in Figure 8. The median fundamental period of vibration for 1 to 2 story buildings considered in this study is 0.18sec, with a lognormal standard deviation of 0.34. This value is in agreement with the ELER value (0.19sec), however, it is stiffer than the respective median value implicit in Hazus (0.35sec). The median yield acceleration is 0.30g with 0.26 lognormal standard deviation, which is slightly higher than the corresponding median values implicit in ELER (0.24g) and in Hazus (0.2g) both characterized with lognormal standard deviations of 0.3.

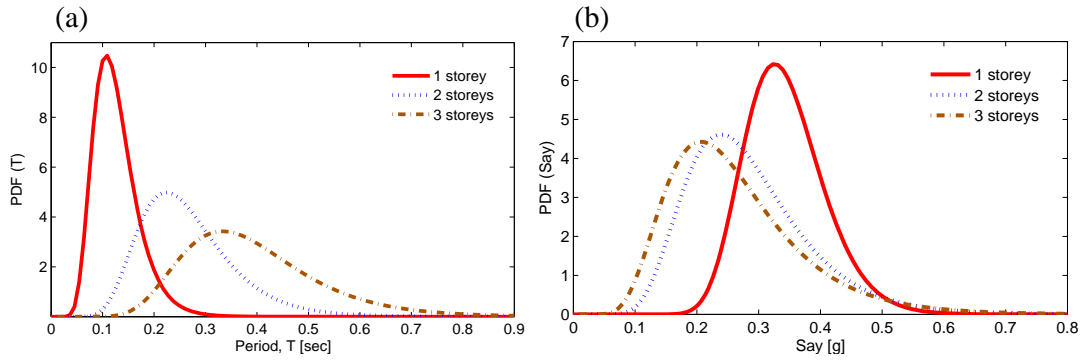

Figure 8: Statistics of the capacity model: fundamental period variation (a) and yield acceleration variation (b).

6 FRAGILITY BASED SEISMIC DAMAGE ASSESSMENT

The displacement based fragility curves with combined variability in capacity and damage state threshold, equation 2, were used for determining the damage state probabilities of two-story stone masonry buildings in Old Quebec City at a specific earthquake median uniform hazard levels with 2% probability of exceedance in 50 years obtained from PSHA [19].

The improved displacement coefficient method (DCM) presented in [20] was used to evaluate the spectral displacement demand which is the input to the displacement based fragility curves. The DCM essentially modifies the linear elastic response of the ESDOF system with 5% damping by multiplication with a series of coefficients to generate an estimate of the inelastic displacement demand S_d .

$$\begin{aligned}
 S_d &= C_1 \cdot C_2 \cdot S_a(T_e) \cdot \frac{T_e^2}{4 \cdot \pi^2} \cdot g \\
 C_1 &= 1 + \frac{R-1}{a \cdot T_e^2} \\
 C_2 &= 1 + \frac{1}{800} \left[\frac{R-1}{T_e} \right]^2 \\
 R &= \frac{S_a(T_e)}{S_{ay}}
 \end{aligned} \tag{4}$$

where, C_1 is modification parameter which relates the expected maximum displacement of an inelastic ESDOF system with elastic-plastic hysteresis properties to the displacement calculated from the linear elastic spectral response, a is related to the type of local NEHRP soil classification ($a=130$ for soil class B - rock), C_2 accounts for the effects of pinched hysteresis shape, stiffness degradation, and strength deterioration on the maximum displacement response, $S_a(T_e)$ is the spectral acceleration at the effective fundamental period of the system coming from the capacity curve, and S_{ay} is the yield acceleration of the system. The median T_e and S_{ay} of the two-story stone masonry buildings were obtained from the capacity model as 0.25sec and 0.24g, respectively. The corresponding spectral acceleration $S_a(T_e)$ with 2% probability of exceedance in 50 years is 0.49g, and spectral displacement S_d is 0.01m.

The final damage state probabilities are shown in Figure 9 together with respective damage probabilities obtained from fragility curves defined in Hazus and ELER. For the given spectral displacement demand, discrete damage state probabilities are evaluated as the difference of the cumulative probabilities of reaching or exceeding successive damage states. The damage estimation obtained using Hazus shows highest probability of occurring to no damage and to slight damage, ELER yields highest probabilities to extensive and complete damage, whereas damage estimates generated by this study and for the same intensity measure ($S_d=0.01m$) indicate that slight to moderate damage will be the most probable damage experienced by the stone masonry buildings.

This comparative example shows the importance of the development of specific fragility curves that reflect the generic construction characteristics for the considered study area for seismic risk assessment and emphasizes the need of critical use of existing risk assessment tools and the obtained results.

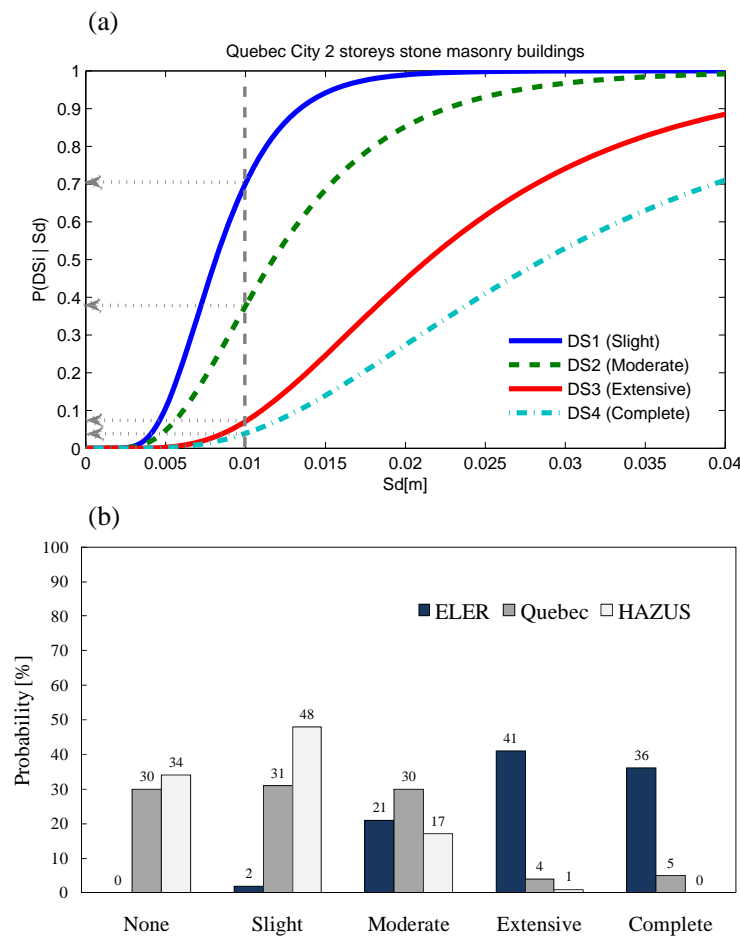

Figure 9: Damage state probabilities for Old Quebec City two-story stone masonry buildings (a), compared with respective damage states computed with fragility curves implicit in Hazus and ELER (b).

7 CONCLUSIONS

The procedure for analytical displacement based fragility analysis of stone masonry buildings in Old Quebec City is presented. The first step consisted of an inventory of existing buildings in the study area and characterization of representative typologies of stone masonry buildings. These typologies were utilized to develop a building capacity model using a simplified mechanical model with linear elastic and perfectly plastic domains which proved particularly effective for carrying out analyses of uncertainties with significantly reduced computational time.

A simplified displacement based procedure was used to develop damage state fragility curves based on drift limits of stone masonry walls which were assigned based on literature data. It is expected that using drift limits obtained from laboratory testing of stone masonry walls representative of those existing in Old Quebec City would help to reduce the uncertainties in the damage prediction. A comparison of the developed fragility curves is made with their corresponding curves in existing regional seismic risk assessment tools Hazus and ELER. Significant differences have been observed between fragility curves defined by the three methodologies. These differences were replicated in comparatively significant disparities among the estimates of the probabilities of different damages states to be experienced by stone masonry buildings in the Old Quebec City for the same seismic hazard with probability of 2% exceedance in 50 years.

Keywords: Solar Power Plant Chimneys, Cooling Towers, Free Vibration, Earthquake, Finite Element Modeling, Ring Elements.

Abstract. *In this paper, the basic mechanical principles for structural modeling of shells of revolution using ring elements are briefly summarized. For the representation of mechanical variables in hoop direction, Fourier series are used within this numerical model. Further, solution properties for free vibration and for transient dynamic problems are presented with special regard to ring element models. The presented algorithms are implemented in computer code ROSHE [7] which has been successfully applied to the analysis and design of a large number of cooling towers world wide. In this contribution, the challenging step from natural draft cooling towers which are currently built with standard heights up to 200 m towards large solar upwind power plant chimneys with heights of approximately 1000 m is dared. Hereby, the pre-design of a 1000 m solar chimney by Krätzig is taken as reference geometry. With this design, the dynamic behavior of this large 1000 m solar chimney subjected to horizontal earthquake acceleration is studied. The behavior of this tower is compared to dynamic behavior of cooling towers subjected to horizontal earthquake acceleration. While significant non-linear effects such as uplift from ground, cracking of columns and shell arise in cooling towers, the behavior of solar chimneys is totally different. Due to very high period of the first relevant eigenmotion, these structures behave similar to base isolated structures. The structure will not follow the ground motion in upper parts. Despite of the large height, uplift or loss of stability due to tilting will not become a problem. Tensile meridian membrane forces occur only in upper parts of the shell between 600 m and 1000 m. In this paper, the transient response of the 1000 m solar chimney is studied in comparison to a standard natural draft cooling tower of height 180 m. They are both subjected to NS component of Kern County earthquake acceleration with peak ground acceleration 0.35 g. Simplified response spectrum analysis with presentation of modal contributions is further conducted for a simplified beam model of the solar power plant chimney which confirms the obtained results. Powerful post processing tools have been developed and will be utilized within the presentation to visualize the structural response of both systems.*

1 INTRODUCTION / SUMMARY

Natural draft cooling towers up to heights 200 m are commonly found at every power plant where process water has to be cooled down. Due to their height and their slender wall thickness, they represent one of the most challenging and fascination civil engineering structure. The highest natural draft cooling tower world wide has been built at the Niederaussem power plant site close to Cologne in Germany. Cooling towers have to resist mainly dead weight, wind and earthquake action.

Recently, the discussion about solar power plant chimneys has come up again. Solar power plant chimneys use a huge circular glass roof collector to heat up the air. The air is flowing under this glass roof towards a high chimney in the middle. Due to the natural updraft effect through the chimney, the air flow is used to run several turbines which are installed at the bottom of the chimney. With such a solar chimney of height 1000 m and a collector roof of diameter 3 km, an electrical power output of 200 MWe can be generated.

For such a high structure, it must be questioned how it will behave when subjected to horizontal earthquake acceleration. Will earthquake be the dominating action? Will tilting become a problem? Which non-linear effects will occur?

For this clarification, a first step will be done within this paper. Therefore, a comparison of the structural behavior between natural draft cooling towers and solar power plant chimneys will be conducted which are both very slender shells of revolution with negative curvature.

A very simple but effective ring element model is used for this aim. Both structures are subjected to a representing earthquake acceleration (Kern County NS component) with maximum peak ground acceleration 3.50 m/s². The results for the solar power plant chimney are further confirmed by simple beam response spectrum analysis. It can be stated that tilting will not occur for the solar power plant chimney and significant tensile meridional stresses arise only in upper regions of the structure due to higher mode contribution.

2 MECHANICAL BACKGROUND AND FINITE ELEMENT CONCEPT

In Figure 1, a cut-out of a shell of revolution with its body forces and stress resultants is depicted. Internal stress resultants are described by membrane forces $n^{\alpha\beta}$ and bending moments $m^{\alpha\beta}$ which are obtained by numerical stress integration through section depth in general. They are obtained using Eq. (1) and Eq. (2) for arbitrary constitutive behavior [2].

$$n^{\alpha\beta} = \int_{-h/2}^{+h/2} \mu(\theta^3) \cdot [\delta_{\lambda}^{\beta} - \theta^3 \cdot b_{\lambda}^{\beta}] \cdot \sigma^{\alpha\lambda}(\theta^3) d\theta^3 \quad (1)$$

$$m^{\alpha\beta} = \int_{-h/2}^{+h/2} \mu(\theta^3) \cdot \theta^3 \cdot \sigma^{\alpha\beta}(\theta^3) d\theta^3 \quad (2)$$

Equations of motion are formulated using dynamic equilibrium by application of principle of virtual work with additional consideration of damping and inertia forces.

$$\begin{aligned} & \iint_A p^{\alpha} \delta u_{\alpha} + p^3 \delta u_3 dA + \oint_C n^{\alpha} \delta u_{\alpha} + n^3 \delta u_3 dC - \iint_A \tilde{n}^{\alpha\beta} \delta \alpha_{\alpha\beta} + m^{\alpha\beta} \delta \beta_{\alpha\beta} dA \\ & - \iint_A \rho h \cdot [a^{\alpha\beta} \ddot{u}_{\alpha} \delta u_{\beta} + \ddot{u}_3 \delta u_3] dA - \iint_A [c_t a^{\alpha\beta} \dot{u}_{\alpha} \delta u_{\beta} + c_n \dot{u}_3 \delta u_3] dA = 0 \end{aligned} \quad (3)$$

The principle of virtual work implies dynamic equilibrium in weak formulation. The equations of motion are solved by structural discretisation using finite ring elements. Further, the equations of motion are linearized to apply an implicit time integration scheme with corrective iteration steps [7], [8].

Figure 1: Numerical model for structural analysis of shells of revolution acc. to [7], [8], [9].

For structural analysis of shells of revolution, ring elements according to Figure 1 can be advantageously deployed since the computational effort is significantly decreased. The shell is described by its meridian curve. Each element possesses two nodes. Displacements are interpolated using cubic polynomials in meridian direction and a Fourier series in hoop direction. For linear elastic behavior, the structural problem is decoupled in Fourier terms: Body forces result in structural response in the same Fourier term, solely. This property is of special interest in linear earthquake analysis of shells of revolution which is conducted within this paper.

3 NUMERICAL MODELS FOR NDCT AND SPCC

In Figure 2, structural models of a modern natural draft cooling tower which has been recently built and of the pre-design of a 1000 m solar chimney by Krätzig [5], [6] are depicted.

The natural draft cooling tower consists of one upper ring beam which is modeled by a ring beam element. The double curved shell consists of 43 ring elements with a minimum wall thickness 20 cm in major parts of the shell. At its bottom, the shell is supported by V-truss columns (46 column pairs with diameter 90 cm). These truss columns are modeled by a special column macro ring element where 3D beams are coupled along the upper and lower nodal circles. The ring foundation is modeled by a ring beam element which is supported by a ring spring element to account for the elastic soil support. The geometry of the double curved middle surface of the shell is described by two hyperbolic functions below and above the throat of the shell which follows Eq. (4).

$$R(Z) = R_0 + a \cdot \sqrt{1 + \left(\frac{Z - Z_0}{b} \right)^2} \quad (4)$$

with $R_0 = -15.3644$	$Z_0 = 115.83$	$a = 51.9644$	$b = 113.9896$	below throat
$R_0 = +36.3422$	$Z_0 = 115.83$	$a = 0.25780$	$b = 8.0293$	above throat

Figure 2: Structural models for earthquake analysis of NDCT and SPPC.

Further, the structural model of the 1000 m solar chimney can be found in Figure 2. This model consists of 50 shell ring elements while each element is representing a vertical section of 20 m. The base of the solar chimney is fixed. Modeling of air openings in the lower part is neglected for this study of global earthquake response behavior. The wall thickness of this 1000 m solar tower is starting at 65 cm at its bottom and reaches a minimum thickness of 26 cm in upper parts according to buckling safety requirements. At distances of 100 m, stiffening rings are attached to the shell. On top of the shell, a ring beam is attached with 5 times stiffness of standard stiffeners. A high performance concrete C 70/85 is used. All geometric and material properties are chosen according to pre-design by Krätzig, see [5], [6].

The structure is described by a double curved shell middle surface comparable to the presented natural draft cooling tower. The throat position is located at height 400 m. The geometry follows Eq. (4) with following parameters:

$R_0 = -8209.2709$	$Z_0 = 400.00$	$a = 8275.9709$	$b = 3227.9274$	below throat
$R_0 = +66.577380$	$Z_0 = 400.00$	$a = 0.1226204$	$b = 12.424908$	above throat

Although both structures are described in a similar way by a double curved shell surface (hyperbolic shape, negative curvature) with two geometric functions (below and above the throat) as can be seen in Figure 2, the earthquake behavior and structural response will be totally different due to significant discrepancies in mass and stiffness. The solar chimney will behave more or less like a very flexible cantilever beam similar to base isolated structures which can be already guessed.

4 DESCRIPTION OF EARTHQUAKE ACTION AND EQUIVALENT BODY FORCES

As reference earthquake for earthquake studies, Kern County earthquake NS component is used (21.07.1952, Taft Lincoln School, USGS Station 1095) [10]. This acceleration time history is depicted in Figure 3 with normalization to unit acceleration value 1 m/s^2 .

Figure 3: Acceleration time history of Kern County earthquake NS component.

Earthquake accelerations acting on a shell of revolution are described by the following body forces in tangential and horizontal direction with a_{gr} maximum ground acceleration, $f(t)$ time history function (scaled to unit value), h shell thickness, θ^1 angle of circumference.

$$\begin{aligned}
 p^{<1>} &= +a_{gr} \cdot f(t) \cdot h \cdot \sin(\theta^1) && \text{tangential direction} \\
 p^{<2>} &= +a_{gr} \cdot f(t) \cdot h \cdot \cos(\theta^1) \cdot \sin(\alpha) && \text{meridional direction} \\
 p^{<3>} &= -a_{gr} \cdot f(t) \cdot h \cdot \cos(\theta^1) \cdot \cos(\alpha) && \text{normal direction} \\
 &&& \alpha \text{ inclination angle of meridian curve} \\
 &&& \tan \alpha = -dR / dZ
 \end{aligned}$$

Earthquake acceleration generates equivalent body forces in Fourier term $n = 1$, which implies circumferential distribution $\cos(n \cdot \theta^1)$ or $\sin(n \cdot \theta^1)$. Thus, for computation of linear structural earthquake response only Fourier term $n = 1$ is of interest so that the equations of motion can be simplified significantly.

5 EARTHQUAKE RESPONSE OF NDCT AND SPPC

5.1 Natural Eigenperiods

In Figure 4, the corresponding response spectrum for Kern County time history is presented scaled to unit ground acceleration (rigid body value at $T = 0 \text{ s}$). Further, the response spectra according to DIN 4149 [4] for soil class A-R and C-S are presented for comparison purpose. By solving the linear eigenvalue problem of free vibration for Fourier term $n = 1$

$$({}^{11}\mathbf{K} - \omega^2 \cdot {}^{11}\mathbf{M}) \cdot \boldsymbol{\psi} = \mathbf{0} \quad (5)$$

the governing eigenperiods and eigenmodes of both systems are obtained. The following eigenmodes can be identified:

NDCT	1st mode $n = 1$	motion on elastic soil support	$T = 0.73 \text{ s}$
NDCT	2nd mode $n = 1$	motion on elastic column support	$T = 0.40 \text{ s}$
NDCT	3rd mode $n = 1$	shell bending mode	$T = 0.18 \text{ s}$
SPPC	1st mode $n = 1$	cantilever bending mode #1	$T = 5.66 \text{ s}$
SPPC	2nd mode $n = 1$	cantilever bending mode #2	$T = 1.36 \text{ s}$
SPPC	3rd mode $n = 1$	cantilever bending mode #3	$T = 0.66 \text{ s}$

Figure 4: Eigenperiods of NDCT and SPPC with corresponding response spectra.

From natural periods, it becomes obvious that the SPPC in comparison to the NDCT is a very soft structure. The 1st period of SPPC is almost 10 times higher than the 1st period of NDCT. The SPPC is too flexible to follow the ground motion. In contrast, the NDCT is strongly affected by earthquake acceleration since the governing eigenperiods coincide with maximum response accelerations. This fact results in very high column stresses (in case of V-columns: compressive and tensile forces, in case of I-beams: bending moments).

5.2 Transient Response to Kern County Earthquake

Linear transient time history analyses have been carried out for the two presented systems NDCT and SPPC. Hereby, Kern County NS acceleration according to Figure 3 with maximum peak acceleration 0.35 g has been used as reference.

In general, the following effects can be observed for NDCT subjected to earthquake acceleration:

- uplift from ground (in case of raft foundation)
- cracking of concrete of supporting columns (exceedance of concrete tensile strength)
- cracking of shell (exceedance of concrete tensile strength)

From conducted analyses for SPPC subjected to horizontal earthquake acceleration, the following effects can be observed:

- Uplift from ground does not occur. Tilting will not become a problem since 1st period is so high that the upper structure cannot follow the ground acceleration.
- Tensile meridional forces arise only in upper parts of the structure between 600 m – 1000 m.
- Higher modes which describe higher bending modes of the cantilever system will become relevant for the structural response which can be seen from Figure 5.

In Figure 5, the structural response in terms of maximum meridional forces is depicted for both systems. For the NDCT, it can be observed that under dead weight, the complete shell is under meridional compression. Horizontal earthquake acceleration generates tensile meridional forces throughout most parts of the shell. Cracking will occur at meridional forces $0.20 \text{ m} \times 2.56 \text{ MN/m}^2 = 510 \text{ kN/m}$. The prestressing effect due to dead weight is totally used up. For the SPPC system, it can be observed that dead weight still represents the dominating part. Tilting will not occur since the base is in compression. Assuming a tensile strength of HPC C 70/85 $f_{ctm} = 4.60 \text{ MN/m}^2$, the cracking meridional force $0.26 \text{ m} \times 4.60 \text{ MN/m}^2 = 1200 \text{ kN/m}$ is not exceeded. Since the first period of the SPPC is such high, the structure cannot follow the base acceleration. Therefore, higher modes have to be considered to correctly assess the structural response in upper parts. The contribution of different vibration modes to the dynamic response can be found in Figure 5.

Figure 5: Meridional tensile forces due to earthquake acceleration Kern County NS component (0.35 g).

5.3 Simplified Analysis of SPPC Using Response Spectrum Method for Cantilever

The total mass of the solar power plant chimney yields approximately 501.000 t. The equation of motion for a structure subjected to earthquake motion is given in Eq. (6). By modal

transformation, Eq. (7) is obtained. Hereby, the physical degrees of freedom \mathbf{V} are transformed to modal coordinates q so that the system of coupled equations of motion is decoupled into independent equivalent single degree of freedom systems.

$$\mathbf{K} \cdot \mathbf{V} + \mathbf{C} \cdot \dot{\mathbf{V}} + \mathbf{M} \cdot \ddot{\mathbf{V}} = -\mathbf{M} \cdot \mathbf{I} \cdot a_{gr} \cdot f(t) \quad (6)$$

$$\boldsymbol{\psi}^T \cdot \mathbf{K} \cdot \boldsymbol{\psi} \cdot q + \boldsymbol{\psi}^T \cdot \mathbf{C} \cdot \boldsymbol{\psi} \cdot \dot{q} + \boldsymbol{\psi}^T \cdot \mathbf{M} \cdot \boldsymbol{\psi} \cdot \ddot{q} = -\boldsymbol{\psi}^T \cdot \mathbf{M} \cdot \mathbf{I} \cdot a_{gr} \cdot f(t) \quad (7)$$

By using the response spectrum diagram, the maximum response acceleration is obtained in dependence of the natural eigenperiod T of the considered eigenmode and in dependence of damping ratio according to Eq. (8). With this maximum response acceleration, equivalent static loads $\mathbf{H}_{E,i}$ for each eigenform i can be computed using Eq. (10).

$$\max \ddot{q}_i = \frac{\boldsymbol{\psi}_i^T \cdot \mathbf{M} \cdot \mathbf{I}}{\boldsymbol{\psi}_i^T \cdot \mathbf{M} \cdot \boldsymbol{\psi}_i} \cdot a_{gr} \cdot \beta(T, \xi_i) \quad (8)$$

$$\mathbf{H}_{E,i} = \mathbf{M} \cdot \boldsymbol{\psi}_i \cdot \max \ddot{q}_i = \mathbf{M} \cdot \boldsymbol{\psi}_i \cdot \frac{\boldsymbol{\psi}_i^T \cdot \mathbf{M} \cdot \mathbf{I}}{\boldsymbol{\psi}_i^T \cdot \mathbf{M} \cdot \boldsymbol{\psi}_i} \cdot a_{gr} \cdot \beta(T, \xi_i) \quad (9)$$

The results from equivalent static loads for each eigenform now have to be combined again for the total solution. Results for two different methods are presented in the following: square root of sum of squares (SRSS) and sum of absolute sum.

The results of section 5.2 can be confirmed by using simplified cantilever beam analysis in conjunction with response spectrum analysis. Tilting and uplift from ground will not become a problem while tensile meridional forces arise only in the upper part of shell for the solar power plant chimney. Meridional forces using method SRSS and ABSSUM are depicted in Figure 6. ABSSUM rule provides more unfavorable results since single mode contributions are directly added assuming that maximum response for all contributing modes occurs at the same time.

Figure 6: Simplified analysis using response spectrum analysis (SRSS and ABSSUM).

6 CONCLUSION

This contribution shall be only regarded as a first step into dynamic earthquake behavior of solar chimneys subjected to earthquake acceleration. Existing algorithms which have been developed for general shells of revolution and successfully applied to the design of a large number of natural draft cooling towers by the author world wide are deployed to this end. Although the structures SPPC and NDCT are described in a similar way by double curved hyperbolic shapes, the response to earthquake accelerations is totally different. Due to absolute values of eigenperiod, NDCTs behave more critical under earthquake acceleration than SPPCs. Non-linear effects such as uplift, cracking of shell and columns become significant for NDCT while for the analyzed 1000 m SPPC not even tilting will become a problem.

The results presented in this contribution have been obtained using transient time integration analysis for a representative earthquake acceleration time history for a full shell model (ring elements). Simplified response spectrum analysis method (hand calculation) using a cantilever beam model has been used for checking purpose which confirms the obtained results.

However, this study can be only seen as a first approach. Only a base acceleration by a rigid body ground motion has been considered (base of structure remains in original shape). Further effort has to be spent into design studies and into research in this new and demanding field of SPPC structures.

Keywords: Retrofitting, Pushover Analysis, Moment Resisting Frames, Damage Index.

Abstract. *The present study is focused on the comparison of non-linear static analysis (Pushover) which is used by two major guidance documents, the New Zealand guideline and the US FEMA 440, on the assessment of existing buildings currently available for moment resisting concrete frames. The main purpose of the study is to trace the differences in the results produced by these two guidelines. For this, three different moment resisting concrete frames are assessed under these two guidelines to determine the PGA value that causes their collapse. In the next step, these are compared by their similar values that are determined from the non-linear dynamic analysis in which Park and Ang damage index is used as acceptance criteria for components. As is found, the result of force based approach which is proposed by New Zealand guideline is more compatible with the nonlinear dynamic analysis.*

1 INTRODUCTION

The disastrous effects observed in recent seismic events, in terms of loss of lives as well as immediate and long-term economic damage has prompted the need to produce documents in the area of assessment and improvement of the structural performance of existing buildings in times of an earthquake. One of the earliest guidelines which has been published for the evaluation and retrofit of concrete buildings is ATC-40 [1]. After it, FEMA 273 and FEMA 356 have been published respectively as a guideline and pre-standard for the seismic rehabilitation of buildings [2,3]. In 2005, FEMA 440 has been published. The purpose of the FEMA440 has been to evaluate current non-linear static procedures (NSPs), as described in FEMA 273/FEMA 356 and ATC-40, and to develop improvements where feasible. The primary objectives were, to develop guidelines for practicing engineers on how to apply the procedures to new and existing buildings.

The first step of the assessment process in FEMA440 is definition of “Rehabilitation Objectives”; where each goal shall consist of a “Target Building Performance Level” and an “Earthquake Hazard Level”. Building performance is a combination of the performance of both structural and nonstructural components. Three performance levels are considered such as: Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP) for structural components and the nonstructural performance level of a building shall be selected from five discrete performance level consisting of Operational (N-A), Immediate Occupancy (N-B), Life Safety (N-C), Hazard Reduced (N-D), and Not Considered (N-E) [4]. The seismic hazard can be represented either by an acceleration response spectrum or by acceleration time history.

Four different analysis procedures are allowed for the evaluation of the response of the buildings: the linear static (LSP), the linear dynamic (LDP), the non-linear static (NSP) and the non-linear dynamic (NDP). The two linear procedures are permitted only for buildings with “regular” structural configuration. As the non-linear dynamic procedure is the most complex, using non-linear static analysis is more common for its simplicity and ability to estimate components and system deformation demands with an acceptable accuracy.

In nonlinear static procedure the demand of the buildings is calculated by means of a pushover analysis. For this, the target displacement, which is intended to represent the maximum displacement likely to be experienced during the designed earthquake, shall be determined at first. According to this standard, the control node shall be located at the center of the roof of a building and its target displacement can be calculated by the Coefficient Method as below:

$$\delta_t = C_0 C_1 C_2 S_a \frac{T_e^2}{4\pi^2} g \quad (1)$$

Where C_0 is a modification factor to relate spectral displacement of an equivalent single degree of freedom (SDOF) system to the roof displacement of the building, C_1 is a modification factor to relate expected maximum displacements to displacements calculated for linear elastic response, C_2 is a modification factor to represent the effect of pinched hysteresis shape, cyclic stiffness degradation, and strength deterioration on maximum displacement response, S_a is the response spectrum acceleration at the effective fundamental period and damping ratio, and T_e is the effective fundamental period of the building.

Acceptance criteria for nonlinear procedures are presented by the plastic rotation angle for the concrete components. One of the conditions which can affect the acceptance criteria of components is the conditions of transverse reinforcement. A component is conforming if, within the flexural plastic hinge region, hoops are spaced at $\leq d/3$, and if, for component of moderate and high ductility demand, the strength provided by the hoops is at least three-

fourths of the design shear. Otherwise, the component is considered nonconforming. Where d is effective depth of the cross section.

In 1996, a draft was published for the assessment and improvement of the structural performance of earthquake risk building in New Zealand titled NZSEE 1996 [5]. This draft has been reviewed twice till now and is now available as NZSEE 2002 and NZSEE 2006 [6, 7]. The New Zealand documents concentrate only on matters relating to life safety, i.e. collapse which leads to loss of life.

Three possible approaches for performing the assessment are indicated in the document: time history analysis, force analysis and displacement analysis. The first one is the most accurate but the most complex as well, so the others are considered as the main approaches for assessments.

In the document it is stated that “the displacement based approach is generally considered to produce more rational and less conservative assessment outcome, the force based one is more familiar to designers” [7].

Five analysis methods are proposed for the evaluation of the structural response: equivalent static analysis, modal response spectrum analysis, simple lateral mechanism analysis, lateral pushover analysis and inelastic time history analysis. In this study, the proposed lateral pushover analysis is compared with the similar procedure of FEMA440.

The demands of the buildings are dependent upon the analysis method applied. In the force based approach, the acceleration response spectra are used to model the earthquake action and the demand is stated by the structural ductility factor which can be found as below:

$$k_{\mu} = \frac{C(T_1)S_P W_t (\%NBS)_t}{V_{prob}} \quad (2)$$

Where $C(T_1)$ is the ordinate of the elastic site hazard spectrum for T_1 and for the site, W_t is total seismic weight of the structure, S_P is structural performance factor and $(\%NBS)_t$ is target percentage of new building standard which is considered equal to one in this study.

In the displacement based approach, the displacement response spectra are used to model the earthquake action and the demand is stated by the displacement at the effective height of building which is found from the spectra using the effective period and the equivalent viscous damping.

The ultimate curvature is considered as the acceptance criteria of concrete components. To calculate the ultimate curvature, having the ultimate concrete strain is inevitable. It is stated in the document that for unconfined concrete the ultimate concrete strain, $\epsilon_{cu} = 0.004$ and for the confined concrete, Mander model can be assumed as below [8]:

$$\epsilon_{cu} = 0.004 + \frac{1.4\rho_s f_{yh} \epsilon_{su}}{f_{cc}} \quad (3)$$

Where ϵ_{cu} is ultimate concrete strain; ρ_s is the volumetric ratio of transverse reinforcement and can be approximated by:

$$\rho_s = 1.5A_v/b_c s \quad (4)$$

Where A_v is total area of transverse reinforcement in a layer, s is spacing of layers of transverse reinforcement, b_c is the width of concrete core, f_{yh} is the yield strength of the transverse reinforcement, ϵ_{su} is the steel strain at maximum stress, and f_{cc} is the compressive strength of the confined concrete.

The document presents conditions corresponding to confined and unconfined sections. One of these conditions which are dealt with in this study is spacing of hoops. According to NZSEE guideline, when the spacing of hoops or stirrups sets in potential plastic hinge greater than or equal to $d/2$ or $16d_b$, the section shall be assumed as “unconfined”, where d is the effective depth of section and d_b is the diameter of longitudinal reinforcement. However the sections are assumed as confined in this study.

Lupoi et al. presented a comparison of the practical applicability, the relative ease of use and the degree of agreement on the results of the methods proposed by FEMA 356, NZSEE 2002 and Japanese Standards. The PGA_f value that causes the collapse of three structures is determined based on the above mentioned documents and in comparison with each other. As it is mentioned in the paper, from the small number of cases examined, all studied structures have three stories, thus it is not possible to systematically trace the differences in the results produced by the different approaches [9]

In this study, 5, 10 and 15 story moment resisting concrete frames are assessed by the NZSEE 2006 and FEMA440 to determine the PGA_f values that cause the collapse. Then the frames are analyzed against twenty two earthquakes with the use of nonlinear dynamic analysis to determine the PGA_f value. To find, the performance of frames in the latest analysis, Park and Ang Damage Index has been used as is explained in the following paragraphs [10].

2 COMPARATIVE STUDY

This section presents the choices and assumptions made by using the above mentioned documents in order to compare results.

2.1 The studied frames

Three moment resisting concrete frames with 5, 10 and 15 stories are considered in this study. Figure 1 illustrates five-story moment resisting frame. As is shown, the frame has four bays with the width and the height of 6 and 3.2m, respectively. The design details of other frames are revealed on Table 1, 2 and 3. The gravity load containing both dead and live load is assumed 28.86 kN/m for all the levels.

Table 2. Element Properties of 10-srory Reinforced Concrete special Moment Frame

2.2 Term of Comparison

The comparison of selected procedures is made in terms of the PGA_f value that causes the collapse of the structures. The PGA_f has been arbitrarily related to the spectrum of Standard No. 2800-05 (Iranian code of practice for seismic resisting design of building) for the soil type 2; it is believed that the results of the comparisons would not change to any significant extent if a different reference spectrum were selected.

The PGA_f values for different approaches are determined as follow:

Element	Story	b(mm)	h(mm)	ρ	ρ_n	ρ_{sh}	S(mm)
Beams	st-1	500	700	0.007	0.005	0.0010	125
	st-2	500	700	0.009	0.006	0.0010	125
	st-3	500	650	0.011	0.008	0.0011	120
	st-4	500	650	0.011	0.008	0.0011	120
	st-5	500	650	0.012	0.008	0.0011	120
	st-6	500	600	0.013	0.009	0.0009	100
	st-7	500	600	0.013	0.009	0.0008	100
	st-8	500	600	0.013	0.009	0.0008	100

Table 3. Element Properties of 15-story Reinforced Concrete special Moment Frame

Figure 2: Standard No. 2800-05 acceleration spectrum for soil Type 2

1. The nonlinear static approach of FEMA440 (Displacement Modification):

$$(PGA_f)_{FEMA440} = \frac{(V_{prob}/W_t) \cdot (\delta_u/\delta_t)}{C(T_1)} \quad (5)$$

2. The force-based NZ procedure:

$$(PGA_f)_{NZ,force} = \frac{(V_{prob}/W_t) \cdot \mu_{sc}}{C(T_1)} \quad (6)$$

3. The displacement-based NZ procedure:

$$(PGA_f)_{NZ,displacement} = \frac{U_{el}}{C(T_{eff}) \cdot (T_{eff}^2 / 4\pi^2) \cdot g \cdot k(\xi_{eff})} \quad (7)$$

Where :

$$T_{eff} = 2\pi \sqrt{\frac{M_e}{K_{eff}}} \quad (8)$$

$$K_{\xi} = \sqrt{\frac{7}{2 + \xi}} \quad (9)$$

3 NON-LINEAR DYNAMIC

To estimate the response of the frames under earthquake, nonlinear dynamic analysis is done using twenty-two acceleration time histories as described in Table 4. Records are selected from the PEER-NGA strong motion database which recommended by FEMAP695 [11].

Park and Ang damage index is used as acceptance criteria for components as below [10]:

$$DamageIndex = \frac{\delta_{max}}{\delta_u} + \frac{\beta}{F_u \cdot \delta_u} \int dE \quad (10)$$

Where δ_{max} is the peak deformation, δ_u is the ultimate deformation capacity under monotonic loading, F_u is the calculated yield strength, β is the calibration parameter for cyclic damage and is considered to equal 0.2 in this study, and E is the dissipated energy. Maximum rotation and yield moment under monotonic loading are selected as ultimate deformation and yield strength, respectively. DI is considered equal to one for the severe damage regards to CP levels based on the classification suggested by Park et al. [12].

After doing nonlinear dynamic analysis for all above mentioned records and finding PGA_f 's for each one, Minitab [13] as a software was used to fit best probabilistic distribution on 22 data's. The variability in the PGA_f is best described by a lognormal distribution so present study uses average of natural log dates instead of simply average.

Table 4. Selected records for the nonlinear dynamic analysis

4 NON-LINEAR NUMERICAL ANALYSIS

Available element models generally do not accurately represent the full range of behavior (low level, frequent ground motions which contribute most to damage and financial loss as well as high level, rare ground motions which contribute most to collapse risk). Therefore, plastic hinge model to capture strength and stiffness deterioration and collapse, are used. The plastic hinge model also includes the beam-column element lumps the bond-slip and beam column yielding response into one concentrated hinge. Due to modern capacity design provisions for RC SMRF buildings, shear failure is not expected for the elements of RC SMRF buildings, so only flexural damage is modeled.

OpenSees was used for the structural analyses. P-Delta effects are accounted for using a combination of gravity loads on the lateral-resisting frame and gravity loads on a leaning column element. The model includes 5% Rayleigh damping anchored to the first and third modal periods [14]. As shown in Figure 3, plastic hinge models for beam columns have a trilinear backbone curve described by five parameters (M_y , θ_y , K_s , $\theta_{cap,pl}$, and K_c). The model captures the four important modes of cyclic strength and stiffness degradation; this is based on an

energy dissipation capacity and a term that describes how the deterioration rate changes as damage accumulates. Model parameters (for initial stiffness and deformation capacity) of RC beam columns are based on recommendations from Fardis et al. [15] and Haselton calibrations to test data using the PEER structural performance database [16].

Figure 3: Monotonic backbone curve

5 DISCUSSION AND CONCLUSION

The PGA_f values that cause the collapse in the first element of the frames are reported in Table 5 and shown in Figure 4 for all the approaches. Figure 5 illustrates percent of error among each nonlinear static procedures and nonlinear time history analyses. As shown, the result of nonlinear dynamic analysis is more compatible with the New Zealand force approach and also has lower error.

No. Story	Collapse Peak Ground Acceleration (PGA_f) in Units of g				
	New Zealand		FEMA440		Time History
	Force Based	Displacement	Displacement Modification	Equivalent Linearization	
5	0.55	0.77	0.75	0.72	0.48
10	0.59	0.72	0.76	0.71	0.51
15	0.62	0.68	0.68	0.77	0.54

Table 5: The PGA_f values that cause the collapse

Figure 4: The PGA values cause the collapse from different approaches

Figure 5: Error Percentage

From the figure 5, it can be concluded that the New Zealand force approach is most compatible with the nonlinear dynamic analyses in all cases. The New Zealand displacement approach gives appropriate results for all frames but its results are not conservative.

DEVELOPING FRAGILITY SURFACES FOR MORE ACCURATE SEISMIC VULNERABILITY ASSESSMENT OF MASONRY BUILDINGS

Keywords: vulnerability, unreinforced masonry, fragility surfaces, ground-motion parameters

Abstract. *Usual methods for the vulnerability assessment of buildings often result in fragility curves, with respect to one intensity-measure parameter like PGA or spectral displacement. However, the seismic loading is very complex and describing it with one parameter may result in neglecting other significant characteristics of the ground motion [1]. Thus, this study proposes a methodology to develop fragility surfaces, which express the probability of damage with respect to more than one parameter, in order to better account for uncertainties related to the hazard description. The proposed methodology is applied to a model of a two-story unreinforced masonry building (real structure tested on a shaking table by [2]) and the following steps are carried out:*

- *modeling the structure with TREMURI code [3] and static pushover analysis;*
- *developing a set of models with an aleatory distribution of mechanical properties;*
- *based on Latin hypercube sampling, performing hundreds of dynamic analyses (using real and synthetic accelerograms) and assessing the damage level from each analysis;*
- *studying the ground-motion parameters: clustering methods and correlation analyses help to select the appropriate couple of variables to use in the fragility surfaces;*
- *applying the kernel estimation of density in order to get a non-parametrical distribution of damage probability and interpolation into fragility surfaces;*
