

COMPDYN 2011

*3rd International Conference on
Computational Methods in Structural Dynamics
and Earthquake Engineering*

PROCEEDINGS

An IACM Special Interest Conference

M. Papadrakakis, M. Fragiadakis and V. Plevris (Eds)

Computational Methods in Structural Dynamics and Earthquake Engineering

Proceedings of the 3rd International Conference on Computational
Methods in Structural Dynamics and Earthquake Engineering
Held in Corfu, Greece
25-28 May 2011

Edited by:

M. Papadrakakis

National Technical University of Athens, Greece

M. Fragiadakis

National Technical University of Athens, Greece

V. Plevris

School of Pedagogical and Technological Education, Greece

A publication of:

Institute of Structural Analysis and Antiseismic Research
School of Civil Engineering
National Technical University of Athens (NTUA)

Computational Methods in Structural Dynamics and Earthquake Engineering

M. Papadrakakis, M. Fragiadakis, V. Plevris (Eds.)

First Edition, February 2012

PREFACE

This volume contains the full-length papers presented in the 3rd International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering (COMPDYN 2011) that was held on May 25-28, 2011 on the Corfu island, Greece.

COMPDYN 2011 is one of the thematic Conferences of the European Community on Computational Methods in Applied Sciences (ECCOMAS) and a Special Interest Conference of the International Association for Computational Mechanics (IACM). COMPDYN 2011 has been also promoted by the European Committee on Computational Solid and Structural Mechanics (ECCSM) of ECCOMAS. The purpose of the Conference was to bring together the scientific communities of Computational Mechanics, Structural Dynamics and Earthquake Engineering in an effort to facilitate the exchange of ideas in topics of mutual interests and to serve as a platform for establishing links between research groups with complementary activities.

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the colleagues who contributed to the organization of the Minisymposia and to the reviewers who, with their work, contributed to the scientific quality of this e-book.

M. Papadrakakis

National Technical University of Athens, Greece

M. Fragiadakis

National Technical University of Athens, Greece

V. Plevris

School of Pedagogical and Technological Education, Greece

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the Computational Methods in Structural Dynamics and Earthquake Engineering to the following organizations:

- European Community on Computational Methods in Applied Sciences, ECCOMAS
- International Association for Computational Mechanics (IACM)
- School of Civil Engineering, National University of Athens
- Greek Association for Computational Mechanics (GRACM)
- European Association for Earthquake Engineering (EAEE)
- John Argyris Foundation
- Attiko Metro S.A., Greece
- Information Technologies & Digital Engineering, Ioannina, Greece
- TWT Science & Innovation, Stuttgart, Germany
- STRUDL Europe
- Earthquake Planning and Protection Organization (OASP), Greece

Plenary Speakers and Invited Session Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers : A. Elnashai, C. Felippa, Th. Hughes, A. Shabana

Semi-Plenary Speakers: O. Allix, T. Burczynski, A. Combescure, F. Filippou, G. Hulbert, J. Ingham, R. Ohayon, K. C. Park, P. Steinmann, K. Tamma, W. A. Wall, Sh. Yoshimura

MS Organizers: Guglielmo S. Aglietti, Antonio Arede, Domenico Asprone, Ivan Au, Ferdinando Auricchio, Alessandro Baratta, Michele Barbato, Rui Carneiro Barros, Svetlana M. Bauer, Michael Beer, Rui Calcada, Adriano Calvi, Alain Combescure, Gian Paolo Cimellaro, Joel P. Conte, Panos Dakoulas, Raimundo Delgado, Pedro Delgado, John Dolbow, Anders Eriksson, Dan Givoli, Isaac Harari, Muneo Hori, Hector Jensen, Boris Jeremic, Andreas Kappos, Spyros Karamanos, Nikos D. Lagaros, Adrian Lew, Dimitrios Lignos, David Littlefield, Giuseppe Carlo Marano, Mikayel Melkumyan, Andrei Metrikine, Chara Ch. Mitropoulou, Michalis Fragiadakis, Makoto Ohsaki, Stavroula Pantazopoulou, Manolis Papadrakakis, Costas Papadimitriou, Vagelis Plevris, Alessandro Reali, Guido De Roeck, Evangelos Sapountzakis, Gerhart Schueller, Geza Seriani, Anastasios Sextos, Stefano Sibilla, Andrei L. Smirnov, Lena Smyrou, Christian Soize, Sergey V. Sorokin, Aram Soroushian, Costas Spyrakos, George Stefanou, Mahdi Taiebat, Yiannis Tsompanakis, Dimitrios Vamvatsikos, Ioannis Vayas, Shinobu Yoshimura, Farzin Zareian

SUMMARY

Preface.....	iv
Acknowledgements.....	vi
Contents.....	viii
Minisymposia	
MS 01 Accuracy and Computational Efficiency in Seismic Structural Analysis.....	1
<i>Organized by Aram Soroushian</i>	
MS 02 Advances in Computational Mechanics for Security Applications.....	114
<i>Organized by David Littlefield</i>	
MS 03 Advances in Computational Structural Vibrations.....	144
<i>Organized by Evangelos Sapountzakis</i>	
MS 04 Advances in Numerical Methods for Linear and Nonlinear Dynamics.....	248
<i>Organized by Alexander Idesman and Greg Hulbert</i>	
MS 06 Balloon Mechanics in Biology and Medicine.....	365
<i>Organized by Svetlana M. Bauer, Andrei L. Smirnov and Anders Eriksson</i>	
MS 07 Computational Methods for Interface Problems.....	408
<i>Organized by Isaac Harari and John Dolbow</i>	
MS 08 Control of Vibrations in Civil Engineering by Passive Active and Semi-Active Devices.....	420
<i>Organized by Rui Carneiro Barros and Alessandro Baratta</i>	
MS 09 Dynamic Effects On High-Speed Railway Tracks.....	640
<i>Organized by Raimundo Delgado and Rui Calcada</i>	
MS 10 Dynamic Soil-Structure Interaction.....	783
<i>Organized by Boris Jeremic and Mahdi Taiebat</i>	
MS 11 Fuzzy Methods in Computational Dynamics.....	851
<i>Organized by Giuseppe Carlo Marano, Michael Beer and Yiannis Tsompanakis</i>	
MS 12 Identification Methods in Structural Dynamics	950
<i>Organized by Costas Papadimitriou and Ivan Au</i>	
MS 13 Innovative Algorithms for Transient Computations.....	1101
<i>Organized by Alain Combescure and Adrian Lew</i>	
MS 14 Innovative vs. Conventional Retrofitting of Existing Buildings.....	1187
<i>Organized by Mikayel Melkumyan</i>	
MS 15 Linear Wave Propagation in Advanced Elastic Wave Guides.....	1335
<i>Organized by Sergey V. Sorokin</i>	

MS 16 Meshless Methods.....	1461
<i>Organized by Ferdinando Auricchio, Domenico Asprone, Alessandro Reali and Stefano Sibilla</i>	
MS 17 Optimization Methods and Applications in Structural Dynamics and Earthquake Engineering.....	1511
<i>Organized by Vagelis Plevris, Chara Ch. Mitropoulou and Nikos D. Lagaros</i>	
MS 18 Performance - Based Engineering.....	1577
<i>Organized by Joel P. Conte and Michele Barbato</i>	
MS 19 Progress and Challenges in Spacecraft Structural Dynamics.....	1645
<i>Organized by Adriano Calvi, Guglielmo and S. Aglietti</i>	
MS 20 Recent Developments in Assessment and Design of Masonry Structures.....	1782
<i>Organized by Costas Spyrakos and Lena Smyrou</i>	
MS 21 Reliability of Structural and Mechanical Systems for Uncertain Operating Conditions.....	1883
<i>Organized by Hector Jensen, Gerhart Schueller and Michael Beer</i>	
MS 22 Resilience Assessment of Communities and Infrastructures.....	1949
<i>Organized by Gian Paolo Cimellaro</i>	
MS 23 Seismic Analysis and Design of Industrial Facilities and Pipelines.....	2024
<i>Organized by Spyros Karamanos and Panos Dakoulas</i>	
MS 24 Seismic Assessment of Heritage Structures and Monuments Through Simulation.....	2255
<i>Organized by Stavroula Pantazopoulou</i>	
MS 25 Seismic Performance Evaluation Under Uncertainty.....	2414
<i>Organized by Dimitrios Vamvatsikos and Michalis Fragiadakis</i>	
MS 26 Seismic Safety Assessment of Structures.....	2515
<i>Organized by Raimundo Delgado, Antonio Arede and Pedro Delgado</i>	
MS 27 Steel Structures Under Dynamic and Seismic Loading.....	2753
<i>Organized by Ioannis Vayas</i>	
MS 29 The Stochastic Finite Element Method: Applications To Structural Dynamics.....	2874
<i>Organized by George Stefanou and Manolis Papadrakakis</i>	
MS 30 The Synchronization Phenomenon in Modern Structural Dynamics: Wind, Flow, Ice and Pedestrian - Induced Vibrations of Structures.....	2916
<i>Organized by Andrei Metrikine and Guido De Roeck</i>	
MS 31 Uncertainty and Reliability in Computational Structural Dynamics.....	2983
<i>Organized by Christian Soize and Gerhart Schueller</i>	
MS 32 Waves and Computation.....	3130
<i>Organized by Dan Givoli and Geza Seriani</i>	

MS 33 High-Performance Computing for Structural Mechanics and Earthquake Engineering.....	3236
<i>Organized by Shinobu Yoshimura, Muneo Hori and Makoto Ohsaki</i>	
MS 34 Information & Communication Technologies in Earthquake Engineering and Structural Dynamics.....	3272
<i>Organized by Anastasios Sextos</i>	
MS 35 Practical Analytical Methods in Estimation of Engineering Demands of Structural Systems Subjected To Natural and Man-Made Hazards.....	3332
<i>Organized by Farzin Zareian and Dimitrios Lignos</i>	
MS 05 Analysis Methods for the Seismic Design and Assessment of Bridges.....	3414
<i>Organized by Andreas Kappos</i>	
Plenary Lecture.....	3607
RS 01 Numerical Simulation for Structural Dynamics.....	3623
RS 02 RC Structures.....	3760
RS 05 FEM: Modelling and Simulation.....	3834
RS 07 Masonry Structures.....	3972
RS 08 Soil-Structure Interaction.....	4036
RS 10 Active - Passive Control.....	4045
RS 12 Computational Methods in Geotechnical Earthquake Engineering.....	4123
RS 15 Design Methods Under Dynamic and Seismic Action.....	4188
RS 18 Repair and Retrofit of Structures.....	4326
RS 19 Solution Algorithms and Reduced Order Methods.....	4414
RS 20 Steel Structures.....	4462
Semi - Plenary Lecture I.....	4537
Semi - Plenary Lecture II.....	4551

CONTENTS

MS 01 Accuracy and Computational Efficiency in Seismic Structural Analysis

An Efficient Quadrature Beam Model to Simulate Inelastic Seismic Behavior of Steel Frames.....	1
R. He, R. Zhang, H. Zhong	
On the Performance of a Technique for More Efficient Time Integration When Applied to Bridge Structures Seismic Analysis.....	12
A. Soroushian, M. Hosseini, A. Vasseghi	
Co-Rotational Dynamic Formulation for 2D Beams.....	22
T. N. Le, J. M. Battini, M. Hjiiaj	
On Less Computational Costs for Analysis of Silos Seismic Behavior by Time Integration.....	37
F. Nateghi, M. Yakhchalian	
Error Estimation and Improvement of Convergence for a Time Stepping Algorithm Based on a Finite Element Approach in Time.....	46
D. Ostermann	
Physically Simplified Model of Multi-Story Buildings for Their Quick Dynamic Analysis.....	56
M. Hosseini, A. Ashtari Larki	
Dynamics of Marine Stationary Platform Under Action of Horizontal Seismic Loading.....	68
V. A. Shekhovtsov, P. E. Tovstik, T. M. Tovstik	
Simplified Dynamic Analysis of Sloshing Phenomenon in Tanks with Multiple Baffles Subjected to Earthquake.....	77
M. Hosseini, P. Farshadmanesh	
On the Role of Computational Methods in Earthquake Engineering.....	93
A. Soroushian, A. Ganji, M. Hassanzadeh, A. Sarvghad Moghadam, H. Sarmadi	
On Essentiality of Further Research on Computational Issues of Earthquake Engineering in Different Countries.....	99
A. Soroushian, A. Ganji, M. Hassanzadeh, A. Sarvghad Moghadam	
Faster Time Integration Analysis for Buildings Structural Systems Subjected to Three-Component Earthquakes.....	105
O. Bahar, S. Ramezani	

MS 02 Advances in Computational Mechanics for Security Applications

- The Effect of Initial Geometric Imperfection on the Load Bearing Capacity of Double Layer Barrel Vault Space Structures..... 114
M. Mohabbi Yadollahi, R. Gül, R. Polat, B. Mohebbi Yadollahi, M. S. Gül
- Multiscale Rkpm Formulation for Modeling Penetration of An Ultra High-Strength Concrete Material..... 125
M. Roth, J.S. Chen, Th. Slawson, N. Boone, X. Ren, Sh. W. Chi, C.H. Lee, P.C. Guan
- On the Calibration of High Explosive Thermodynamic Equations of State for Broad Application..... 135
E. Baker, G. Stunzenas, L. Stiel, D. Murphy

MS 03 Advances in Computational Structural Vibrations

- Dynamic Load Allowance for Reinforced Concrete Bridges..... 144
J. Wekezer, E. Taft
- Nonlinear Effects in Elastic Flexural - Torsional Vibrations of Beams of Arbitrary Cross Section..... 157
E. Sapountzakis, I. Dikaros
- Modal Analysis of the Fgm Beams with Spatial Variation of Material Properties Under Longitudinal Variable Elastic Winkler Foundation..... 181
J. Murin, M. Aminbaghai, V. Kutis
- Piezoelectric Torsional Sensors and Actuators - a Computational Study..... 204
Ch. Zehetner, M. Zellhofer, M. Krommer
- Theoretical Analysis and Numerical Modeling of Elastic Wave Propagation in Honeycomb-Type Thin Layer..... 215
B. Tian, B. Tie, D. Aubry
- Bi-Hierarchical Finite Element for the Analysis of the Non Axisymmetric Free Vibration of Shells of Revolution..... 224
M. N. Ouissi, A. Houmat
- Discrete Equivalence Principle for Model Order Reduction of Dynamic Structures..... 237
F. K. Corbaci

MS 04 Advances in Numerical Methods for Linear and Nonlinear Dynamics

- A Fast Method for Computing Convolutions with Structural Green's Function : Application to Tire/Road Contact Problems..... 248
R. Meftah, D. Duhamel
- Dispersion Errors of B-Spline Based Finite Element Method in One-Dimensional Elastic Wave Propagation..... 263
R. Kolman, J. Plesek, M. Okrouhlik, D. Gabriel
- Studies in Numerical Stability and Critical Time Step Estimation Bu Wave Dispersion Analysis Versus Eigenvalue Computation..... 275
J. Plesek, R. Kolman, D. Gabriel
- Accurate Numerical Solutions of Structural Dynamics and Wave Propagation Problems Based on New Dispersion-Reduction Technique and New Two-Stage Time-Integration Technique..... 287
A. Idesman

Impact Modeling by Manifold Approach in Explicit Transient Dynamics.....	301
T. Saksala, J. Mäkinen	
Nonlinear Modeling and Analysis of R.C. Spatial Frames to Study the Effects of the Vertical Component of Near-Fault Ground Motions.....	314
F. Mazza, M. Mazza	
Searching for Local Contact Constraints by the Quasi-Newton Methods in the Finite Element Procedures for Contact-Impact Problems.....	328
D. Gabriel, J. Kopacka, J. Plešek, M. Ulbin	
Effect of Higher Order Shear Deformation on the Nonlinear Dynamic Analysis of Laminated Composite Plate Under In-Plane Loads.....	340
H. Ammash	
An Efficient H-Adaptive Scaled Boundary Element Method for Transient Elastodynamics.....	357
Z. Zhang, Z. Yang, G. Liu, Y. Hu	
MS 06 Balloon Mechanics in Biology and Medicine	
Nonclassical Models in the Shell Theory with Applications to Multilayered Nanotubes.....	365
S. Bauer, A. Ermakov, S. Kashtanova, N. Morozov	
Nonlinear Deformation of An Inflatable Anisotropic Toroidal Membrane.....	375
S. Filippov	
Nonlinear Viscoelastic Analysis of a Pneumatic 2D Structure Interposed Between a Couple of Rigid Moving Planes.....	384
A. De Simone, A. Luongo	
Quasi-Static Simulations of Thin Space Membranes, Aiming At Stability Analyses of Balloon-Like Structures.....	395
A. Eriksson	
MS 07 Computational Methods for Interface Problems	
Interface Treatment in Computational Fluid-Structure Interaction.....	408
Th. Kloppe, A. Popp, W. A. Wall	
MS 08 Control of Vibrations in Civil Engineering by Passive Active and Semi-Active Devices	
Dynamic Characteristics of Structures with Viscoelastic Dampers Modeled by Means of Generalized Rheological Models.....	420
R. Lewandowski, A. Bartkowiak	
The Rocking Response of Seismically Isolated, Free-Standing Rigid Blocks.....	438
M. Vassiliou, N. Makris	
Seismic Design Methodology for Control of 3D Buildings by Means of Multiple Tuned-Mass- Dampers.....	462
Y. Daniel, O. Lavan	
Non-Linear Dynamic Behaviour of a Ball Vibration Absorber.....	486
J. Naprstek, C. Fischer, M. Pirner, O. Fischer	

Maxwell Nonlinear Slider Model for Seismic Response Prediction of Semi-Active Controlled Magneto-Rheological Dampers.....	500
Y. Chae, J. Ricles, R. Sause	
A Two Stage Approach for the Seismic Analysis of Base-Isolated Structures.....	512
G. Muscolino, A. Palmeri, C. Versaci	
Collapse Resistance of Buildings with Large-Scale Magneto-Rheological (Mr) Dampers.....	528
Y. Chae, J. M. Ricles, R. Sause	
Model Uncertainties in Smart Structures.....	540
A. J. Moutsopoulou, G. E. Stavroulakis, A. T. Pouliezios	
Vibration Control of Structures with a Novel Semi-Active Tuned Mass Damper Using Wavelet Transform.....	559
S.S. Feizabadi-Sani, A.K. Ghorbani-Tanha	
Semi-Active Control of An Experimental Frame Using Mr Dampers: Numerical Results and Experimental Validation.....	569
M. Cesar, R. Barros	
The Use of Tmd's with Heavy Mass to Mitigate the Seismic Response of Structures.....	580
J. Barros, C. Moutinho, R. Barros	
Comparisons of a Tall Building Wind Response with and Without a Tmd.....	592
N. Ferreira, R. Barros, R. Delgado	
Neural Network Based Semi-Active Control Strategy for Structural Vibration Mitigation with Magnetorheological Damper.....	627
S. Bhowmik	
MS 09 Dynamic Effects On High-Speed Railway Tracks	
Dynamic Performance of Existing High-Speed Railway Bridges Under Resonant Conditions, Retrofitted with Fluid-Viscous Dampers Supported on Clamped Auxiliary Beams.....	640
J. Lavado, M.D. Martinez-Rodrigo, P. Museros	
Verification of An Empirical Prediction Method for Ground Borne Vibrations in Buildings Due to High Speed Railway Traffic.....	662
H. Verbraken, S. Francois, G. Degrande, G. Lombaert	
High-Speed Railway Tracks of a Surface, Bridge and Tunnel Line and Some Effects on the Train-Induced Bridge and Ground Vibrations.....	677
L. Auersch	
Dynamic Effects of Railway Traffic Due to Lateral Motion in Long Viaducts with High Piers.....	694
J. M. Goicolea, P. Antolin	
Dynamics of a Precast System for High-Speed Railway Tracks.....	710
C. Vale, N. Ribeiro, R. Calçada, R. Delgado	
Analysis of the Vehicle-Track-Structure-Soil Dynamic Interaction of Railway Bridges for Hst.....	731
A. Romero, J. Domínguez, P. Galvín	
Experimental Validation of a 2.5D FEM-BEM Model for the Assessment of Vibrations Induced by Traffic.....	746
P. Alves Costa, R. Calçada, A. Silva Cardoso	

Effect of the Type of Track on the Dynamic Behaviour of High Speed Railway Bridges.....	765
J. M. Proença, H. Casal, M. Neves	

MS 10 Dynamic Soil-Structure Interaction

On Analysis of Liquefaction-Induced Displacement in a Caisson Quay Wall.....	783
M. Manzari, K. Yonten, M. El Ghoraiby, Ch. Beyzaei	

The Decoupling of Linear Dynamical Systems.....	791
M. Morzfeld, F. Ma	

Hybrid Laplace-Time Domain Approach for Nonlinear Dynamic Soil-Structure Interaction Problems.....	803
A. Nieto Ferro, D. Clouteau, N. Greffet, G. Devésa	

Influence of Type of Wave and Angle of Incidence on the Seismic Response of Pile Foundations and Pile Supported Structures.....	811
J. M. Zarzalejos, J. J. Aznárez, L. A. Padrón, O. Maeso	

On Intensity Measure Selection for Nonlinear Dynamic Analysis of Soil-Mdof Structure Interacting Systems.....	830
F. Abedi Nik, F. Khoshnoudian	

Seismic Evaluation of Existing Basement Walls.....	839
A. Ahmadnia, M. Taiebat, L. Finn, C. Ventura	

MS 11 Fuzzy Methods in Computational Dynamics

Fuzzy and Fuzzy Stochastic Methods for the Numerical Analysis of Reinforced Concrete Structures Under Dynamical Loading.....	851
F. Steinigen, J. U. Sickert, W. Graf, M. Kaliske	

Periodic Shear Beam As a Model of High Building Under Fuzzy Non-Stationary Excitation.....	868
K. Mazur-Sniady, R. Sieniawska, P. Sniady, S. Zukowski	

Robust Design of Tuned Liquid Column Dampers Under Stochastic Ground Motion Considering Fuzzy Uncertainties.....	886
G. Quaranta, S. Chakraborty, G. C. Marano	

Application of Interval Fields for Uncertainty Modeling in a Geohydrological Case.....	905
W. Verhaeghe, W. Desmet, D. Vandepitte, I. Joris, P. Seuntjens, D. Moens	

Seismic Structural Analysis Using Interval Response Spectrum.....	921
M. Modares, A. Venezia	

Classification of Seismic Damages in Buildings Using Fuzzy Logic Procedures.....	932
A. Elenas, E. Vrochidou, P. Alvanitopoulos, I. Andreadis	

A Probabilistic Approach to Fuzzy Methods.....	942
M. Kuková	

MS 12 Identification Methods in Structural Dynamics

A Modified Truncation Method for Pressure Reconstruction in Case of Non Ponctual Impact on An Elastic Plate.....	950
F. El Khannoussi, A. Hajraoui, A. Khamlichi, A. Limam, E. Jacquelin	
Fatigue Assessment of Panaro Bridge: Preliminary Results.....	958
F. V. Lippi, W. Salvatore	
Joint Estimation of States and Input in Linear Structural Dynamics.....	982

Design Optimization of Foundation for Rotating Machinery Against Standing-Wave Vibration in a Building.....	1434
B. Niu, N. Olhoff	
Identification and Sizing of Defects in Pipelines by the Wave Finite Element Method Using Torsional Guided Waves.....	1451
M. Kharrat, W. Zhou, O. Bareille, M. Ichchou	
MS 16 Meshless Methods	
Seismic Wave Propagation and Perfectly Matched Layers Using Gfdm.....	1461
F. Ureña, J. J. Benito, E. Salete, L. Gavete	
Dynamic Analysis of Plates and Beams by Gfdm.....	1478
F. Ureña, L. Gavete, J. J. Benito, E. Salete	
Sph Modeling of Rapid Multiphase Flows and Shock Wave Propagation.....	1497
S. Manenti, S. Sibilla, M. Gallati, G. Agate, R. Guandalini	
MS 17 Optimization Methods and Applications in Structural Dynamics and Earthquake Engineering	
Numerical and Experimental Assessment of Various Non-Classical Methods for Parametric Identification of Nonlinear Viscous Dampers.....	1511
J. Avakian, G. C. Marano, G. Monti, G. Quaranta, F. Trentadue	
Optimal Whole-Life-Cycle Seismic Design of Concrete Frames.....	1530
B. Gencturk, A. Elnashai	
Optimization of Structures Equipped with Viscoelastic Dampers Modeled Using the Fractional Order Derivatives.....	1541
Z. Pawlak, R. Lewandowski	
Normalized Domination Selection Criteria for Differential Evolution Algorithms in Constrained Optimization for Seismic Engineering.....	1554
J. Avakian, A. Fiore, D. Serio, R. Greco, G. C. Marano	

MS 18 Performance - Based Engineering

An Analytical Approach for the Vulnerability Assessment of RC Buildings Subjected to Earthquake Induced Ground Displacements.....	1577
S. Fotopoulou, K. Pitilakis	
Introducing a New Scaling Method for Near-Fault Ground Motions Based on the Root-Mean-Square of Spectral Responses.....	1595
A. Yahyaabadi, M. Tehranizadeh	
Modeling Energy Dissipation: a Paradigm for Performance-Based Engineering of RC Moment-Resisting Frame in Seismic Loading.....	1605
P. Jehel, P. Leger, A. Ibrahimbegovic	
A Single Mode Energy-Based Pushover Procedure.....	1616
G. Manoukas, A. Athanatopoulou, I. Avramidis	
Reliability-Based Assessment of Seismic Pounding Risk Between Adjacent Buildings.....	1629
E. Tubaldi, M. Barbato	

MS 19 Progress and Challenges in Spacecraft Structural Dynamics

An Overview of the E.C.S.S. Handbook for Spacecraft Loads Analysis.....	1645
A. Calvi	
Nonlinear Modal Analysis of Aerospace Structures.....	1653
M. Peeters, G. Kerschen, J. C. Golinval, C. Stephan, P. Lubrina	
Filter Failure Analysis for the Swap Instrument on Board of Proba2.....	1676
S. Jonckheere, B. Bergen, B. Pluymers, J. P. Halain, P. Rochus, W. Desmet, D. Vandepitte	
Disturbance Sources Modeling for Analysis of Structure-Borne Micro-Vibrations.....	1695
G. S. Aglietti, Z. Zhang, G. Richardson, B. Le Page, A. Haslehurst	
Dimensional Stability Loss in Structures Subject to Random Vibration.....	1705
R. Edeson, G. Aglietti, A. Tatnall	
Dynamic Shape Reconstruction of Three-Dimensional Frame Structures Using the Inverse Finite Element Method.....	1717
M. Gherlone, P. Cerracchio, M. Mattone, M. Di Sciuva, A. Tessler	
Efficient Model Updating of the Goce Satellite Based on Experimental Modal Data.....	1738
B. Goller, M. Broggi, A. Calvi, G. Schueller	
Non-Linear Experimental Modal Analysis and Application to Satellite Vibration Test Data.....	1758
M. Link, M. Böswald, S. Laborde, M. Weiland, A. Calvi	

MS 20 Recent Developments in Assessment and Design of Masonry Structures

In-Plane Design Loads for Seismic Assessment and Retrofit of Walls in Unreinforced Masonry Buildings.....	1782
J. Ingham, Ch. Knox, A. Wilson, K. Elwood	
Seismic Rehabilitation of Traditional Un-Reinforced Masonry Buildings in Iran.....	1797
A. Azarbakht	

High Continuity Second-Order Homogenization of In-Plane Loaded Periodic Masonry.....	1808
A. Bacigalupo, L. Gambarotta	
Masonry Infilled Reinforced Concrete Frames with Openings.....	1823
P. Asteris, Ch. Chrysostomou, I. Giannopoulos, E. Smyrou	
Risk Assessment of Historic Residential Brick-Masonry Buildings in Vienna by Rapid-Visual-Screening.....	1838
G. Achs, Ch. Adam	
A Study on the Effect of Tie Elements' Properties on the Seismic Behavior of Confined Masonry Walls by Using Nonlinear Finite Element Analyses.....	1852
F. Ranjbaran, M. Hosseini	
Composite Materials Technologies in Constructions Structural Retrofitting: New Developments and Applications in Historical Buildings and Applications in Seismic Zone.....	1866
L. Credali, G. Ussia	
MS 21 Reliability of Structural and Mechanical Systems for Uncertain Operating Conditions	
Reliability Sensitivity of Linear Dynamical Systems Subject to Gaussian Excitation.....	1883
M. Valdebenito, H. Jensen, G. Schuëller, F. Caro	
Optimal Design of Base-Isolated Systems Under Stochastic Earthquake Excitation.....	1902
H. Jensen, M. Valdebenito, J. Sepulveda	
Computational Stochastic Dynamics Based on Orthogonal Expansion of Random Excitations.....	1920
X. F. Xu, G. Stefanou	
Enhanced Monte Carlo for Reliability-Based Design and Calibration.....	1928
A. Naess, M. Maes, M. R. Dann	
The Effect of Non-Synchronous Sensing in Wireless Sensors on Structural Modal Identification.....	1939
Z. Feng, L. Katafygiotis	
MS 22 Resilience Assessment of Communities and Infrastructures	
A New Method for Probabilistic Aftershock Risk Evaluation of Damaged Bridge.....	1949
S. Alessandri, R. Giannini, F. Paolacci	
Software for Measuring Disaster Community Resilience According to the Peoples Methodology.....	1969
V. Arcidiacono, G. P. Cimellaro, A. M. Reinhorn	
Resilience-Driven Disaster Management of Civil Infrastructure.....	1987
P. Bocchini, D. Frangopol	
Risk-Based Decision Making for Resilient Systems.....	1998
Y. Xenidis, A. Skiadopoulou, D. Angelides	
The P.E.O.P.L.E.S. Resilience Framework: a Conceptual Approach to Quantify Community Resilience.....	2014
Ch. S. Renschler, A. M. Reinhorn, L. A. Arendt, G. P. Cimellaro	

MS 23 Seismic Analysis and Design of Industrial Facilities and Pipelines

Finite Element Analysis of Buried Steel Pipelines Under Strike-Slip Fault Displacements.....	2024
P. Vazouras, S. Karamanos, P. Dakoulas	
Simulation of Industrial Elbow Response Under Strong Cyclic Loading.....	2042
G. E. Varelis, P. Pappa, S. Karamanos	
Analytical Model Versus Numerical Model in Stress-Strain Analysis of Buried Steel Pipelines Subjected to Fault Displacements.....	2068
O. Trifonov, V. Cherniy	
Experimental Study on the Seismic Behavior of Shell-Base Connections in Large Storage Tanks.....	2084
G. Cortes, A. Nussbaumer	
Seismic Analysis and Component Design of Refinery Piping Systems.....	2092
F. Paolacci, S. Reza, O. S. Bursi	
The Strain-Based Design of Buried Pipeline Subjected to Landslides.....	2116
B. Liu, Z. Wu, X.J. Liu, H. Zhang	
Seismic Design and Response of Heavy Industrial Steel Buildings.....	2132
J. Richard, S. Koboevic, R. Tremblay	
On the Seismic Behaviour and Design of Liquid Storage Tanks.....	2142
P. Pappa, D. Vasilakis, P. Vazouras, S. Karamanos	
Study on Effects of Water Depth on Seismic Performance of the Aqueduct-Water Coupling Structure.....	2167
Q. Duan, L. Yang, M. Lou	
Industrial Steel Pipe Systems Under Seismic Loading: a Comparison of European and American Design Codes.....	2174
G. J. Dijkstra, B. Francis, H. Van Der Heden, A. M. Gresnigt	
Seismic Design of Spherical Liquid Storage Tanks.....	2196
M. Wieschollek, M. Kopp, B. Hoffmeister, M. Feldmann	
Dynamic Analysis of Liquefied Natural Gas Tanks Seismically Protected with Energy Dissipating Base Isolation Systems.....	2214
V. Gregoriou, S. Tsinopoulos, D. Karabalis	
Seismic Analysis and Design of Industrial Pressure Vessels.....	2223
K. Diamanti, I. Doukas, S. Karamanos	
Bending Cyclic Loading on Pressurized Elbows - Finite Element Analyses.....	2239
J. Ferino, E. Mecozzi, A. Lucci, G. Demofonti	

MS 24 Seismic Assessment of Heritage Structures and Monuments Through Simulation

Computer Modelling and Seismic Performance Assessment of a Byzantine Basilica.....	2255
Z. Cagnan	
Seismic Overturning of Damped Rocking Structures.....	2269
E. Dimitrakopoulos, M. DeJong	

Seismic Assessment of 19th Century Heritage Building Through Simulation.....	2280
S. Pardalopoulos, S. Pantazopoulou	
Three Dimensional Nonlinear Dynamic Modeling of a Vertically Isolated Ancient Statue Displayed in a Base Isolated Museum Building.....	2295
C. A. Castiglioni, A. Kanyilmaz	
Simulation for Seismic Assessment of Traditional Houses in the Historical Core of the City of Xanthi Before and After Non-Invasive Structural Interventions.....	2314
M. Papadopoulos, S. Pantazopoulou	
Structural Analysis and Diagnosis of Masonry Towers.....	2326
S. Kouris, M. Karaveziroglou-Weber	
Interpretation of Records From Temporary and Permanent Instrumentation to Identify the Dynamic Response of a Historical Building to Seismic Actions.....	2337
D. Rinaldis, P. Clemente, G. Buffarini	
Seismic Vulnerability Assessment of Masonry Towers: Full Non-Linear Dynamics Vs Pushover Analyses.....	2345
S. Casolo, G. Uva	
Numerical Analysis of the Two Basic Collapse Mechanism of a Typical Colonial Façade.....	2363
S. Casolo, F. Peña	
Dynamic Finite Element Analysis of Earth Masonry Structures Based on Experimental Material Data.....	2376
R. Illampas, D. C. Charmpis, I. Ioannou	
Numerical Investigation of the Seismic Behaviour of Connections of Ancient Colonnades.....	2387
M. E. Dasiou, I. Psycharis, A. Vrouva	
Seismic Strengthening of the Historic Church of St Heleni and Constantine in Piraeus.....	2401
C. Spyrakos, P. Kiriakopoulos, E. Smyrou	
MS 25 Seismic Performance Evaluation Under Uncertainty	
Fast Seismic Performance Assessment of RC Frame Structures with Consideration of Aleatory and Epistemic Uncertainties by Utilizing Pbee Toolbox and Web Application for Prediction of IDA Curves.....	2414
D. Celarec, M. Dolšek	
Prediction of Seismic Response Parameters of Typical Masonry Building with Consideration of Epistemic Uncertainties.....	2428
J. Snoj, M. Dolsek	
Optimal Performance-Based Seismic Design of Steel Structures Using Approximate Performance Estimation Methods.....	2442
Ath. Zacharenaki, M. Fragiadakis, M. Papadrakakis	
A Targeted Nonlinear Dynamic Procedure to Evaluate the Seismic Performance of Structures.....	2452
D. Vamvatsikos, M. Aschheim, C. Comartin	
Near-Optimal Bilinear Fit of Capacity Curves for Equivalent Sdof Analysis.....	2470
F. De Luca, D. Vamvatsikos, I. Iervolino	

Fragility Assessment of RC Frames Collapse Capacity.....	2487
I. Gkimousis, V.I. Koumousis	
Analytical Displacement-Based Seismic Fragility Analysis of Stone Masonry Buildings.....	2503
A. Abo-El-Ezz, M. J. Nollet, M. Nastev	
MS 26 Seismic Safety Assessment of Structures	
Free Vibration and Earthquake Behavior of Solar Power Plant Chimneys.....	2515
Ch. Lang	
Comparison of Different Nonlinear Static Analysis Used for Seismic Assessment of Existing Buildings.....	2524
A. Moshref, S. M. Moghaddasi, M. Tehranizadeh	
Developing Fragility Surfaces for More Accurate Seismic Vulnerability Assessment of Masonry Buildings.....	2536
P. Gehl, S. Sy, D. Seyedi	
Development and Application of Damage Spectra to Evaluate the Seismic Performance of Reinforced Concrete Buildings in Greece.....	2552
A. Karbassi, B. Mohebi, P. Lestuzzi, G. Ghodrati Amiri	
Structural Dynamic Instability Due to Earthquake Loads.....	2562
N. Gluck, R. Farhat, U. Tzadka	
Developing Fragility Curves for a Typical Pile-Supported Wharf Structure.....	2572
A. Shafieezadeh, R. DesRoches, K. Ramanathan	
Implementation of a Bio-Inspired Two-Mode Structural Health Monitoring System.....	2582
T. K. Lin, L. Ch. Yu, Ch. H. Ku, K. C. Chang, A. Kiremidjian	
Combination Coefficients for Yielding Structures Under Tri-Directional Earthquake Excitations.....	2603
H. Sesigür, O. C. Celik, F. Cili	
Seismic Assessment of Concrete Tanks Considering Fluid Structure Interaction and Nonlinear Time History Analysis.....	2617
H. Friedl, M. Kwapisz, A. Lechner, R. Flesch	
Modelling Issues on Seismic Assessment of Irregular RC Structures.....	2626
R. Sousa, F. Bianchi, R. Pinho, R. Nascimbene, D. Kazantzidou	
Definition of a Prioritisation Procedure for Structural Retrofitting of Italian School Buildings.....	2642
B. Borzi, P. Ceresa, M. Faravelli, E. Fiorini, M. Onida	
Seismic Damage Analysis of Reinforced Concrete Structures with Substandard Detailing.....	2657
P. Mergos, A. Kappos	
Seismic Shear Demand on RC Structural Walls: Review and Bibliography.....	2681
A. Rutenberg	
Rapid Preliminary Seismic Assessment Methodology for Non-Conforming Reinforced Concrete Buildings.....	2705
S. Pardalopoulos, G. Thermou, S. Pantazopoulou	

Computational Damage Measure for RC Frame Structures Under Seismic Loading.....	2721
N. Celik, Y. Petryna	

Seismic Safety Assessment of Curved Bridges Using Pushover Analysis.....	2730
M. Araújo, R. Delgado	

MS 27 Steel Structures Under Dynamic and Seismic Loading

Nonlinear Seismic Analysis and Fatigue-Accumulated Damage of Steel Frames with End-Plate Bolted Connections.....	2753
M. Saranik, D. Lenoir, L. Jézéquel	

New Method for Providing Favorable Seismic Performance in Panel Zone Regions of Moment Resisting Connections of Beams to Flanged Cruciform Column Section.....	2768
R. Mirghaderi, M. Motallebi	

Evaluation of Energy Dissipation Capacity of Steel Frames with Steel Shear Walls.....	2782
F. Dinu, C. Neagu, D. Dubina	

Behavior of Concentrically Braced Frames with Friction Dampers.....	2793
F. V. Norin, S. Aurel, D. Dubina	

Experimental and Numerical Investigation of Non-Seismic Reinforced Concrete Frames Strengthened with Concentric Steel Braces.....	2808
D. Dubina, S. Bordea, F. Dinu	

Nonlinear Dynamic Response of Dissipative Devices for Seismic Resistant Steel Frames: Experimental Behaviour and Numerical Simulation.....	2819
A. Kanyilmaz, C. A. Castiglioni, A. Drei, I. Vayas, L. Calado, T. Rauert	

An Analytical Study on Low Cycle Fatigue Effects in Buckling Restrained Braces.....	2832
M. E. Shemshadian, S. A. Razavi, A. Hosseini, S. R. Mirghaderi, M. Khan Mohammadi	

A Detailed 2D Finite Element Model for the Seismic Assessment of Steel Frames with Top-And-Seat Angle with Double Web-Angle Connections.....	2847
H. Mahmoud, A. Elnashai	

Seismic Retrofit of Existing Steel Moment Resisting Frames with Innovative Materials: Large Scale Hybrid Simulation Tests.....	2856
D. Lignos, D. Moreno-Luna, S. Billington	

MS 29 The Stochastic Finite Element Method: Applications To Structural Dynamics

Mean and Variability Response Functions for Stochastic Systems Under Dynamic Excitation.....	2874
V. Papadopoulos, O. Kokkinos	

A Novel Galerkin Projection Approach for Damped Stochastic Dynamic Systems.....	2895
A. Kundu, S. Adhikari	

MS 30 The Synchronization Phenomenon in Modern Structural Dynamics: Wind, Flow, Ice and Pedestrian - Induced Vibrations of Structures

Dynamic Loads Due to Synchronous Rhythmic Activities of Groups and Crowds.....	2916
V. Racic, J. M. W. Brownjohn, A. Pavic	

Footbridge Lateral Vibrations Induced by Synchronised Pedestrians: An Overview on Modelling Strategies.....	2929
F. Venuti, L. Bruno	

The Challenges Associated with the Introduction of a Frequency Dependent Coupling Into a Phenomenological Model for Vortex-Induced Vibration.....	2966
R. Ogink, A. Metrikine	

MS 31 Uncertainty and Reliability in Computational Structural Dynamics

Numerical Solution of the Fokker-Planck Equation by Finite Difference and Finite Element Methods - a Comparative Study.....	2983
L. Pichler, A. Masud, L. A. Bergman	

Random Dynamical Response of a Multibody System with Uncertain Rigid Bodies.....	3000
A. Batou, Ch. Soize	

Hermite Polynomial Chaos Expansion Method for Stochastic Frequency Response Estimation Considering Modal Intermixing.....	3013
H. Yu, F. Gillot, M. Ichchou	

Damage Identification for a Reduced Scale Spatial Steel Frame.....	3029
M. Betti, P. Biagini, L. Facchini	

Thermal-Bridge Shunt Elements Modelling for Seismic Vulnerability of Buildings Evaluation.....	3049
T.T. H. Nguyen, F. Ragueneau, D. Bahon, N. Ruaux	

A New Method of Generation of Nonlinear Normal Modes for Nonlinear Dynamics of Disordered Structures.....	3058
L. Facchini, M. Rizzo	

A Comparative Study of Uncertainty Propagation Methods in Structural Problems.....	3069
M. Corradi, M. Gherlone, M. Mattone, M. Di Sciuva	

Intra-Event Spatial Correlation of Ground Motion Using L'aquila Earthquake Ground Motion Data..	3091
G. P. Cimellaro, A. De Stefano, A. Reinhorn	

An Efficient Meta-Modeling Approach for Natural Frequency Approximation: the Q-Method.....	3109
A. Gallina, L. Pichler, T. Uhl, L. A. Bergman	

Damage Identification of Monumental Masonry Structures: the Case of Fossanova Gothic Church..	3120
F. Campitiello, M. G. Masciotta, G. De Matteis, M. Vasta	

MS 32 Waves and Computation

High Order Absorbing Boundary Conditions for Elastodynamics.....	3130
D. Rabinovich, D. Givoli, Th. Hagstrom, J. Bielak	

Non-Periodic Homogenization of the Elastic Wave Equation for Wave Propagations in Complex Media.....	3137
Y. Capdeville, L. Guillot, J. J. Marigo	

Reflection of Plane Harmonic Waves At a Plane Interface of a Semi-Infinite Lattice and a Semi-Infinite Continuum.....	3148
A. Kudarova, A. Metrikine	

Extension of the Pufem to Elastic Wave Propagation in Layered Media.....	3161
O. Laghrouche, A. El-Kacimi, J. Trevelyan	
Non-Conforming Spectral Approximations for the Elastic Wave Equation in Heterogeneous Media.	3173
I. Mazzieri, Ch. Smerzini, P. Antonietti, F. Rapetti, M. Stupazzini, R. Paolucci, A. Quarteroni	
Sh Surface Waves in a Half Space with Random Inhomogeneities.....	3190
Ch. Du, X. Su	
Dynamic Rupture Modelling on Unstructured Meshes Using a Discontinuous Galerkin Method.....	3201
Ch. Pelties, M. Käser	
Stabilized Hybrid and Mixed Finite Element Methods for Helmholtz Problems.....	3210
A. F. D. Loula	
Full-Waveform-Based Inversion for Site Characterization: Theory, Numerical Simulations, and Physical Experiments.....	3223
S. Kucukcoban, L. Kallivokas	
MS 33 High-Performance Computing for Structural Mechanics and Earthquake Engineering	
High-Precision Fe-Analysis for Seismic Collapse Simulation of Steel Building Frames.....	3236
T. Yamashita, T. Miyamura, M. Ohsaki, M. Kohiyama, D. Isobe, K. Onda, M. Hori, J.Y. Zhang, H. Akiba, K. Kajiwara	
Application of PDS-FEM to Seismic Failure Analysis of Reinforced Concrete Bridge Pier.....	3246
M. Hori, K. Oguni, Y. Takahashi, T. Maki, Sh. Okazawa, T. Yamashita	
Seismic Response Estimation of a Nuclear Power Plant Structure Considering Nearby Fault Based on a Multiscale Approach.....	3254
P. E. Quinay, T. Ichimura, M. Hori	
Seismic Performance Analysis of Underground Ramp Tunnel Structure Using 3-D Massive Numerical Computation.....	3262
H. Dobashi, Y. Terashima, M. Hori, T. Ichimura, N. Ohbo, T. Yamada, T. Obara	
MS 34 Information & Communication Technologies in Earthquake Engineering and Structural Dynamics	
Integrated System for Earthquake Impact Assessment.....	3272
S. L. Lin, A. Elnashai, J. Li, B. Spencer	
Issars: An Integrated System for Structural Analysis and Earthquake Records Selection.....	3285
E. Katsanos, A. Sextos, Th. Notopoulos	
Using the New Sap2000 Open Application Programming Interface for Developing An Interactive Front-End of the Modal Pushover Analysis of Bridges.....	3302
A. Sextos, G. Balafas	
A Computational Framework for the Assessment of Earthquake-Induced Rocking in CIDH Pile Supported Bridges.....	3316
A. Sextos, E. K. Mylona, G. Mylonakis	

**MS 35 Practical Analytical Methods in Estimation of Engineering Demands of Structural Systems
Subjected To Natural and Man-Made Hazards**

A Rough Collapse Assessment of Earthquake Excited Structural Systems Vulnerable to the P-Delta Effect.....	3332
Ch. Adam, C. Jäger	
Usability of Pushover Analysis for Asymmetric Base-Isolated Buildings.....	3349
V. Kilar, D. Koren	
Evaluation of a Modified-Ssap in Estimating Seismic Demands of a Torsionally Flexible Building.....	3358
M. Ebrahimi K., A. S. Moghadam	
Comparative Assessment on Modeling Approaches for the Seismic Response of RC Shear Walls.....	3368
Ch. Stathi, M. Fragiadakis, A. Papachristidis, M. Papadrakakis	
Seismic Assessment of Steel Moment Frames Using Simplified Nonlinear Models.....	3384
D. Lignos, Ch. Putman, H. Krawinkler	
Simplified Method for Seismic Performance Assessment of Skewed Bridges.....	3402
P. Kaviani, F. Zareian, E. Taciroglu, M. Sarraf	

MS 05 Analysis Methods for the Seismic Design and Assessment of Bridges

Direct Displacement-Based Seismic Assessment of Multi-Span Simply Supported Deck Bridges.....	3414
D. Cardone, G. Perrone, L. Petrini	
Fragility Curves for Typical Multispan Simply Supported Bridge Classes in Moderate Seismic Zones: Pre- and Post-Seismic Design Considerations.....	3434
K. Ramanathan, J. Padgett, R. DesRoches	
An Improved Displacement-Based Seismic Design Methodology for Bridges Accounting for Higher Mode Effects.....	3453
A. Kappos, K. Gkatzogias, I. Gidaris	
Blind Prediction of a Full-Scale RC Bridge Column Tested Under Dynamic Conditions.....	3477
F. Bianchi, R. Sousa, R. Pinho	
Generalized Fragility Curves for Bearing-Supported Skew Bridges, for Arbitrary Angle of Incidence of the Seismic Action.....	3486
I. Moschonas, A. Kappos	
Preliminary Design of Seismically Isolated R/C Highway Overpasses - Features of Relevant Software and Experimental Testing of Elastomeric Bearings.....	3509
G. Manos, S. Mitoulis, A. Sextos	
Investigation of the Dynamic Response of the Evripos, Cable-Stayed Bridge in Greece, Under Asynchronous Ground Motion Record.....	3529
Ch. Karakostas, A. Sextos, V. Lekidis, S. Papadopoulos	
A Numerical Study on the Behavior of High-Performance Buckling-Restrained Braces.....	3548
T. Usami, C. Wang, J. Funayama	
Numerical Simulations of the Warth Bridge Seismic Response.....	3562
P. Delgado, N. Vila Pouca, A. Arêde, R. Faria, R. Delgado	

Simplified Seismic Performance Assessment Over the Lifetime of a Highway Bridge Subject to Pier Reinforcement Corrosion.....	3573
Ch. Giannelos, D. Vamvatsikos	
Seismic Bridge Response to Differential Ground Motion and Comparison with Algerian Seismic Design Rule.....	3585
N. Benmansour, M. Djafour, A. Bekkouche, D. Zendagui	
Numerical Simulation of Bridge Piers' Seismic Behavior: a Blind Prediction Methodology.....	3593
N. Vila Pouca, A. Monteiro, A. Arede, P. Delgado, R. Delgado	
 Plenary Lecture	
Integration of Geometry and Finite Elements in the Analysis of Nonlinear Systems.....	3607
A. Shabana, A. M. Hamed, P. Jayakumar, M. D. Letherwood	
 RS 01 Numerical Simulation for Structural Dynamics	
Investigation of Coupling Between External and Parametric Resonances in Small Sagged Inclined Cables.....	3623
C. Douthe, Ch. Gantes	
An Efficient Use of the Symbolic Spline-Based Differential Quadrature Method in Vibration Analysis of Shells.....	3641
A. Krowiak	
Implementation of Fracture Mechanics Concepts in Dynamic Progressive Collapse Prediction Using An Optimization Based Algorithm.....	3653
D. Tubul, O. Lavan	
Stabilization Effect of Shock Non-Linearity on the Dynamics of a Steam Generator Tube.....	3671
Th. Thénint, E. Balmes, M. Corus	
Impact and Explosive Loads on Concrete Buildings Using Shell and Beam Type Elements.....	3685
M. Bermejo, J. M. Goicolea, F. Gabaldon, A. Santos	
Influence of the Fluid-Structure Interaction on the Modal Analysis, and on the Dynamics of Composite Monofin: Optimization of Propulsion.....	3699
B. Mahiou, F. Razafimahery, L. R. Rakotomanana	
Coupled Damage-Plasticity Based Constitutive Modeling of Metallic Membrane Element Under Cyclic Loading.....	3712
B. Ayhan Tezer, P. Jehel, A. Ibrahimbegovic, H. Engin	
Experimental and Numerical Simulation of Drop Tests of Corrugated Cardboard Packaging Using An Analytical Homogenized Model.....	3719
A. D. Hammou, B. Abbes, Y. Q. Guo, M. Makhoulouf	
Arlequin Framework for Structural Transient Dynamics.....	3730
A. Ghanem, T. Baranger, N. Mahjoubi, M. Torkhani	
Vibrations in Neighborhood Buildings Due to Rock Concert in Stadiums.....	3743
R. D. Bertero, A. Lehmann, J. Mussat, S. Vaquero	

RS 02 RC Structures

- Nonlinear Analysis of R/C Panels by a Two Parameter Concrete Damage Model..... 3760
L. Tesser, F. Filippou, D. Talledo, R. Scotta, R. Vitaliani
- Inelastic Seismic Shear in Multi-Storey Cantilever Columns..... 3780
M. Fischinger, M. Ercolino, M. Kramar, C. Petrone, T. Isakovic
- Modeling the Bond-Slip Behavior of Confined Large-Diameter Reinforcing Bars..... 3790
J. Murcia-Delso, A. Stavridis, B. Shing
- Seismic Strength Evaluation of Reinforced Concrete Shear Walls with Cracks, Using the Notion of Fractal Geometry.....3804
O. Panagouli, E. Mistakidis, K. Iordanidou
- Gravity Load-Designed Concealed Wide Beam-Narrow Column Connections: Experimental Assessment of Seismic Response..... 3822
A. Elsouiri, M. Harajli

RS 05 FEM: Modelling and Simulation

- Cutoff Wave Numbers for Energy-Orthogonal Twenty-Node Hexahedral Elements..... 3834
F. Brito
- Detection of Interlaminar Cracks in Composite Structures with the Use of Piezoelectric Sensors and Thermography..... 3858
P. Kędziora
- An Efficient Beam-Column Element for Nonlinear 3D Frame Analysis..... 3870
S. Kostic, F. C. Filippou, Ch. L. Lee
- Finite Element Modelling of Yielding Shear Panel Device for Passive Energy Dissipation..... 3884
Md R. Hossain, M. Ashraf, F. Albermani
- Damage Assessment of Hyperbolic Paraboloidal Shells Using Finite Element Updating..... 3903
R. Castro, D. Talaslidis, R. Gallego, G. Rus
- Enhanced 3D Fiber Beam-Column Element with Warping Displacements..... 3923
V. Le Corvec, F. C. Filippou
- Adaptive Force-Based Frame Element for Regularized Response..... 3934
J. Almeida, S. Das, R. Pinho
- Detailed FEM Modelling of Stone Masonry Arch Bridges Under Road Traffic Moving Loads..... 3950
C. Costa, A. Arêde, A. Costa
- Damage Detection in Plate Using Gradient Search Sensitivity Method of Fe Model Updating..... 3965
R. Soman, J. Sinha

RS 07 Masonry Structures

- An Investigation on the Value-Based Evaluation: Optimum Rehabilitation Process of the Unreinforced Masonry Buildings.....3972
B. Mahzoun Azmoodeh, A. Sarvghad Moghadam
- Seismic Response of a Stone Masonry Spire..... 3993
M. DeJong, Ch. Vibert

Earthquake Resistant Design of Masonry Structural Systems.....4004
I. Giannopoulos, P. Asteris

Numerical Simulation of Unreinforced Masonry Walls Subject to Dynamic Out-Of-Plane Loading... 4016
L. Reindl, Ch. Butenweg, Th. Kubalski

In-Plane Behavior of Reinforced Masonry Walls: Experimentally Based Modelling..... 4026
F. Mosele, G. Guidi, L. Nicolini, F. Da Porto

RS 08 Soil-Structure Interaction

Numerical Simulation of Adjacent Bridge Structures with Nonlinear Sfsi..... 4036
N. Chouw, E. M. Behrens

RS 10 Active - Passive Control

Theoretical Evaluation of Yielding Shear Panel Device for Passive Energy Dissipation..... 4045
Md R. Hossain, M. Ashraf, F. Albermani

Evaluation of Response of An Isolated System Based on Double Curved Surface Sliders.....4064
A. Pavese, Ch. Casarotti, M. Furinghetti

A Parametric Study for the Investigation of the Effectiveness of Rubber Shock-Absorbers As a Mitigation Measure for Earthquake-Induced Structural Poundings..... 4079
P. Polycarpou, P. Komodromos

Negative Stiffness Device for Seismic Protection of Structures - An Analytical and Experimental Study.....4091
A. Sarlis, D. Pasala, M. Constantinou, A. Reinhorn, S. Nagarajaiah, D. Taylor

Seismic Vibration Control of Izad-Khast Bridge Using Viscous Dampers.....4114
H. Anajafi, M. Rahimian, A. Ghorbanitanha

RS 12 Computational Methods in Geotechnical Earthquake Engineering

Mathematical Modelling of Irreversible Deforming, Micro- and Macrofracture of Rock in the Vicinity of a Borehole in Its Dynamical Unloading..... 4123
A. Kiselev, P. Zacharov

Numerical Modelling of a Geosynthetic Reinforced Steep Slope Subjected to Seismic Loading..... 4131
C. Vieira, M. L. Lopes, L. Caldeira

Free Vibration Problem of Prsi Bridges: Analytical Solution and Parametric Analysis..... 4146
E. Tubaldi, A. Dall'Asta

A Proposal for An Alternative to Seismic Isolation Practice: Implementation in a Seismic Isolated Railway Bridge..... 4166
S. Tegou, I. Tegos

The Impact of Underground Tunnelling on the Acceleration At Ground Surface During Earthquake. 4178
C. Spyrakos, D. Vasileiou

RS 15 Design Methods Under Dynamic and Seismic Action

Computational Efficiency of Progressive Incremental Dynamic Analysis.....	4188
M. Brozovič, M. Dolsek	
Comparison of Seismic Screening Methods for Schools in a Moderate Seismic Zone.....	4200
H. Tischer, D. Mitchell, G. McClure	
Intensity Parameters As Damage Potential Descriptors of Earthquakes.....	4215
A. Elenas	
Bracing Configuration in Earthquake Resistant Structure.....	4222
A. Sophocleous, M. Phocas	
Incremental Dynamic Analysis and Pushover Analysis. a Probabilistic Comparison.....	4236
Y. F. Vargas, L.G. Pujades, A. H. Barbat, J. E. Hurtado	
Kernel Density Estimation Techniques for Seismic Hazard Analysis of South India.....	4247
Ch. Ramanna, G. Dodagoudar	
Nonlinear Dynamic Behaviour of a Saddle Form Cable Net Modeled by An Equivalent Sdof Cable Net.....	4264
I. Vassilopoulou, Ch. Gantes	
Influential Parameters for the Design of Nonstructural Components in Multi-Story Buildings.....	4287
M. Sadeghzadeh-Nazari, M. Ghafory-Ashtiany	
Seismic Response Amplification Due to Near-Field Ground Motions.....	4301
V. Dimakopoulou, M. Fragiadakis, C. Spyrakos	
Estimation of the Seismic Reliability of Buildings Using Incremental Dynamic Analysis Method of the Secant Stiffness Degradation Index (Idam-Ssdi). Part Ii.....	4314
M. A. Montiel Ortega, G. A. Díaz de León Piña	

RS 18 Repair and Retrofit of Structures

Constitutive Model for Frp and Tie-Confined Concrete.....	4326
K. Megalooikonomou, G. Monti, S. Santini	
Analytical Model for Predicting the Response of Old-Type Columns Rehabilitated with Concrete Jacketing Under Reversed Cyclic Loading.....	4347
G. Thermou, V. Papanikolaou, A. Kappos	
A Comparative Study of Force-Deformation Relationship of Frp-Confined Concrete Columns.....	4369
B. Erdil, U. Akyuz, I. O. Yaman, A. Irfanoglu	
Experimental and Numerical Study of the Behavior of High Dissipation Metallic Devices for the Strengthening of Existing Structures.....	4378
A. Karalis, K. Georgiadi-Stefanidi, Th. Salonikios, K. Ath. Stylianidis, E. Mistakidis	
Damage Detection of Frame Structures Subjected to Earthquake Loading.....	4398
N. Pnevmatikos	

RS 19 Solution Algorithms and Reduced Order Methods

Development of a Family of Unconditionally Stable Explicit Direct Integration Algorithms with Controllable Numerical Damping Using Discrete Control Theory.....	4414
Ch. Chen, J. Ricles	
Structural-Acoustic Vibration Reduction Using Piezoelectric Shunt Techniques: Fe Formulation and Reduced Order Model.....	4426
J. F. Deü, W. Larbi, R. Ohayon	
Controlling the Critical Time Step with the Bi-Penalty Method.....	4439
J. Hetherington, A. Rodriguez-Ferran, H. Askes	
Experimental and Numerical Investigation on the Performance of Shear Deficient RC Beams Strengthened with Nsm Gfrp Reinforcement Under Cyclic Loading.....	4445
R. Hawileh, M. Tanarslan, M. Naser, J. Abdalla	
Explicit Calibration and Simulation of Stochastic Fields by Low-Order Arma Processes.....	4452

Keywords: Distributed Plasticity, Consistent Mass Matrix, Seismic Time History Analysis, Quadrature Beam Model, Force-based Beam Model.

Abstract. *Developing nonlinear structural models with high accuracy and affordable computing cost is a challenging issue and one of the pressing needs in earthquake engineering. The paper presents a quadrature beam model for distributed plasticity seismic analysis of steel frames. It is based on the newly developed weak-form quadrature element method, in which the variation principle and the differential quadrature analog are combined. One quadrature beam element can simulate a beam-column member with varying cross-section and non-uniformly distributed loads. The formulations of tangent stiffness matrix and consistent mass matrix are derived. The section constitutive relation of a beam-column member is directly derived using fiber model and material properties. Inelastic time history analysis of the LA 3-story moment-resisting steel frame is conducted to demonstrate the accuracy and efficiency of the quadrature beam model. For verification and comparison, the frame is also analyzed using ANSYS with its BEAM188 element and OpenSEES with the force-based beam element. It is shown that: a) by increasing the number of integration points in one element, results of the quadrature beam model are in excellent agreement with those computed by the displacement-based model in ANSYS; b) degrees of the freedom and the CPU time consumption of the quadrature beam model are much lower than those of the displacement-based model; c) the convergence rate of the quadrature beam model is comparable to that of the force-based model, and the time consumption of the quadrature beam model is slightly higher. In contrast to the only available lumped mass matrix of the force-based model, it is easy to acquire consistent mass matrix in the quadrature beam model for inelastic dynamic analysis, highlighting its great potentials in seismic analysis of frames.*

1 INTRODUCTION

Developing nonlinear structural models with high accuracy and affordable computing cost is a challenging issue and one of the pressing needs in earthquake engineering [1]. For inelastic seismic analysis of frame structures, the lumped plasticity model [2] enjoys simplicity and computational efficiency but it cannot simulate the spread of plasticity and its empirical designation of hinge positions and spring properties sometimes leads to unreliable results. The distributed plasticity model is usually regarded to be more accurate.

One way to construct a distributed plasticity model is using displacement-based (DB) finite beam elements. Elements based on cubic [3] and quartic [4] shape functions were previously studied. These elements with only a few internal nodes are insufficient to carry out seismic analysis of frames with one element per member. When using a higher-order nodal element, the whole set of shape functions has to be reformulated when increasing the order and the simple choice of nodal points may yield ill-condition stiffness matrices [5]. The research work extending the p-version element to inelastic analysis of frames has been rather sparse yet.

Another way is using a force-based (FB) beam element, which adopts exact interpolation functions for internal forces and avoids discretization errors accordingly [6-8]. It realizes simulation of a nonlinear frame member with one beam element, leading to lower DOFs. The FB element prevails in earthquake engineering platform OpenSEES [6] for seismic analysis of frames. However, implementation of FB elements in a finite element program suffers some inconvenient procedures when dealing with non-uniformly distributed loads, state determination [7-8], geometrical nonlinearity [9] and consistent mass matrices [10], etc.

In this paper, a new distributed plasticity model, named as quadrature beam (QB) model, is presented for seismic analysis of structures. It is based on the newly developed weak-form quadrature element method, in which the variation principle and the differential quadrature analog are combined. The weak-form quadrature element method has been validated to be accurate and efficient in elastic problems of varying cross sections [11-12]. In this paper, a distributed plasticity QB beam model is formulated. Its consistent mass matrix is given for dynamic analysis. Inelastic time history analysis of the LA 3-story steel frame [13] is conducted as an example. The accuracy, convergence and CPU time consumption of the QB model are evaluated, and compared with those of the DB and FB models. Results indicate that the quadrature beam model is accurate and efficient.

2 DIFFERENTIAL QUADRATURE ANALOGS

The essence of the conventional differential quadrature analog is that the derivative of a function at a grid point is expressed by weighted linear summation of function values at all grid points in the domain of problem [14]. For instance, the first order derivative of a function f with respect to a variable ξ at a grid point $\xi = \xi_i$ is approximated by

$$\left. \frac{df}{d\xi} \right|_{\xi=\xi_i} = \sum_{j=1}^M C_{ij}^{(1)} f(\xi_j), \quad i = 1, 2, \dots, M \quad (1)$$

where $C_{ij}^{(1)}$ are the weighting coefficients for first order derivatives, which are only dependent upon the number of grid points M and their explicit expressions are given by [12]

$$C_{ij}^{(1)} = \begin{cases} \frac{g'(\xi_i)}{(\xi_i - \xi_j)g'(\xi_j)}, & i \neq j; \\ -\sum_{k=1, k \neq i}^M C_{ik}^{(1)}, & i = j; \end{cases} \quad g(\xi) = \prod_{j=1}^M (\xi - \xi_j) \quad (2)$$

For Bernoulli-Euler beam analysis, the C1 continuity at ends of the element requires generalized differential quadrature analogs where the first order derivative of the function at each end is included in approximation. Thus, the n th order derivatives is approximated by

$$\left. \frac{d^n f}{d\xi^n} \right|_{\xi=\xi_i} = G_{i1}^{(n)} \left. \frac{df}{d\xi} \right|_{\xi=\xi_1} + \sum_{j=1}^M G_{i(j+1)}^{(n)} f(\xi_j) + G_{i(M+2)}^{(n)} \left. \frac{df}{d\xi} \right|_{\xi=\xi_M} \quad (3)$$

where $G_{ij}^{(n)}$ are the weighting coefficients which can be determined by Hermitian interpolation functions, i.e.

$$G_{i1}^{(n)} = h_{11}^{(n)}(\xi_i), \quad G_{i(M+2)}^{(n)} = h_{M1}^{(n)}(\xi_i), \quad G_{i(j+1)}^{(n)} = h_{j0}^{(n)}(\xi_i), \quad j = 1, 2, \dots, M \quad (4)$$

where Hermitian interpolation functions are given by

$$\begin{aligned} h_{11}(\xi) &= \frac{(\xi - \xi_1)(\xi - \xi_M)}{\xi_1 - \xi_M} l_1(\xi), \\ h_{M1}(\xi) &= \frac{(\xi - \xi_1)(\xi - \xi_M)}{\xi_1 - \xi_M} l_M(\xi), \\ h_{10}(\xi) &= \frac{\xi - \xi_M}{\xi_1 - \xi_M} \left[1 - (\xi - \xi_1) \left(l_1'(\xi_1) + \frac{1}{\xi_1 - \xi_M} \right) \right] l_1(\xi), \\ h_{M0}(\xi) &= \frac{\xi - \xi_1}{\xi_M - \xi_1} \left[1 - (\xi - \xi_M) \left(l_M'(\xi_M) + \frac{1}{\xi_M - \xi_1} \right) \right] l_M(\xi), \\ h_{j0}(\xi) &= \frac{(\xi - \xi_1)(\xi - \xi_M)}{(\xi_j - \xi_1)(\xi_j - \xi_M)} l_j(\xi), \quad j = 2, 3, \dots, M-1 \end{aligned} \quad (5)$$

with

$$l_j(\xi) = \frac{g(\xi)}{(\xi - \xi_j)g'(\xi_j)} \quad (6)$$

Differential quadrature analogs are characterized by that only the function values and derivatives at grid points are concerned, so approximation of derivatives is direct and efficient.

3 FORMULATION OF THE QUADRATURE BEAM MODEL

3.1 Model and assumptions

Figure 1: A planar beam model with varying cross-section

A planar beam model with varying cross section is shown in Figure 1. The Bernoulli-Euler beam theory and the hypothesis of plane section hold true. Small deflections and moderate rotation are assumed. The transverse shear deformations are not considered here. In Figure 1, (x, y) is the local coordinate system attached to the beam where x is in the axial direction. L is the beam length. N and Q are axial and shear forces at beam ends, and M is concentrated moments. p and q are non-uniform distributed loads in the x and y directions, respectively. u and v are the translational displacement components along x and y directions, respectively.

For a Bernoulli-Euler beam, the deformations at a certain section x are usually represented by the axial strain at the reference axis ε_x and curvatures κ . And the corresponding section forces are the axial load N and the bending moment M . Generally the section deformation is given in terms of the displacements as

$$\boldsymbol{\varepsilon}(x) = \begin{Bmatrix} \varepsilon_x \\ \kappa \end{Bmatrix} = \begin{Bmatrix} \frac{du}{dx} \\ \frac{d^2v}{dx^2} \end{Bmatrix} \quad (7)$$

For nonlinear problems, an incremental section constitutive relation is usually written, i.e.

$$\delta \mathbf{R}(x) = \mathbf{k}(x) \delta \boldsymbol{\varepsilon}(x) \quad (8)$$

where $\mathbf{R}(x) = [N \ M]^T$ is the vector of internal forces at section x . $\mathbf{k}(x)$ is the section stiffness matrix given by

$$\mathbf{k}(x) = \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} \quad (9)$$

Once the section deformation $\boldsymbol{\varepsilon}(x)$ is known, the internal forces $\mathbf{R}(x)$ and section stiffness matrix $\mathbf{k}(x)$ can be obtained using either fiber section models or load-deformation relations of sections. Details of inelastic section models can be found in [4] and [8]. Different models at sections in one member can be used to deal with problems of varying cross sections and even varying material properties.

3.2 Variation principles and static equilibrium equations

Inducing a dimensionless coordinate $\zeta = 2x/L - 1$, the governing equations of the above problem are established from virtual work principle, i.e.

$$\delta U_{\text{int}}^{(e)} + \delta U_{\text{ext}}^{(e)} = 0 \quad (10)$$

where the internal virtual work and the external virtual work are given by

$$\begin{aligned} \delta U_{\text{int}}^{(e)} &= S \int_{-1}^1 \delta \bar{\boldsymbol{\epsilon}}^T \mathbf{R} d\xi \\ \delta U_{\text{ext}}^{(e)} &= -S \int_{-1}^1 (p\delta u + q\delta v) d\xi - (N\delta u + Q\delta v + \frac{M}{S} \frac{dv}{d\xi}) \bigg|_{\xi=-1} - (N\delta u + Q\delta v + \frac{M}{S} \frac{dv}{d\xi}) \bigg|_{\xi=+1} \end{aligned} \quad (11)$$

and $S = L/2$. Lobatto integration rule with M sampling points (see Fig. 2) is used to evaluate the integrals, resulting in

$$S \sum_{i=1}^M W_i \delta \bar{\boldsymbol{\epsilon}}_i^T \mathbf{R}_i = \delta \mathbf{d}^{(e)T} \mathbf{F}^{(e)} \quad (12)$$

where $\boldsymbol{\epsilon}_i = \boldsymbol{\epsilon}(\xi_i)$, $\mathbf{R}_i = \mathbf{R}(\xi_i)$, ξ_i and W_i are the Lobatto sampling points and weighting coefficients [15]. The element nodal displacement vector in Eq. (12) is written as

$$\mathbf{d}^{(e)} = [\mathbf{d}_1^T \quad \mathbf{d}_M^T \quad \mathbf{d}_2^T \quad \cdots \quad \mathbf{d}_{M-1}^T]^T \quad (13)$$

where

$$\mathbf{d}_i^T = \begin{cases} \begin{bmatrix} u_i & v_i & \left(\frac{dv}{d\xi} \right)_i \end{bmatrix}, & i = 1, M; \\ \begin{bmatrix} u_i & v_i \end{bmatrix}, & i = 2, \dots, M-1. \end{cases} \quad (14)$$

Correspondingly, the element nodal force vector in Eq. (12) is expressed by

$$\mathbf{F}^{(e)} = [\mathbf{F}_1^T \quad \mathbf{F}_M^T \quad \mathbf{F}_2^T \quad \cdots \quad \mathbf{F}_{M-1}^T]^T \quad (15)$$

where

$$\mathbf{F}_i^T = \begin{cases} [N(\xi_i) + SW_i p(\xi_i) & Q(\xi_i) + SW_i q(\xi_i) & M(\xi_i)/S], & i = 1, M; \\ [SW_i p(\xi_i) & SW_i q(\xi_i)], & i = 2, \dots, M-1. \end{cases} \quad (16)$$

Figure 2: Lobatto points of a QB element

Based on differential quadrature analogs, the derivatives in section deformation vectors at the Lobatto points $\boldsymbol{\epsilon}_i$ are directly approximated using the nodal displacement vector $\mathbf{d}^{(e)}$. The section deformation vector at Lobatto points i is expressed in terms of ξ coordinate as

$$\boldsymbol{\epsilon}_i = \mathbf{D} \boldsymbol{\epsilon}_{0i} \quad (17)$$

where $\mathbf{D} = \text{diag}[1/S \quad 1/S^2 \quad 1/S^2]$ and

$$\begin{aligned} \boldsymbol{\varepsilon}_{0i} &= \left[\left(\frac{du}{d\xi} \right)_i \quad \left(\frac{d^2v}{d\xi^2} \right)_i \right]^T = \mathbf{B}_{0i} \mathbf{d}^{(e)}, \quad (i = 1, \dots, M); \\ \mathbf{B}_{0i} &= \begin{bmatrix} \mathbf{B}_{0i,2} & \tilde{\mathbf{B}}_{0i,1} & \mathbf{B}_{0i,M+1} & \tilde{\mathbf{B}}_{0i,M+2} & \mathbf{B}_{0i,3} & \dots & \mathbf{B}_{0i,M} \end{bmatrix} \\ \mathbf{B}_{0i,j} &= \begin{bmatrix} C_{i(j-1)}^{(1)} & 0 \\ 0 & G_{ij}^{(2)} \end{bmatrix}, \tilde{\mathbf{B}}_{0i,j} = \begin{bmatrix} 0 & 0 \\ 0 & G_{ij}^{(2)} \end{bmatrix} \end{aligned} \quad (18)$$

After substitution of the section deformation approximation in Eqs. (17-18) into Eq. (12), the incremental-form equilibrium equations are obtained as

$$\delta \mathbf{F}^{(e)} = \mathbf{K}^{(e)} \delta \mathbf{d}^{(e)} \quad (19)$$

where the element tangent stiffness matrix is given by

$$\mathbf{K}^{(e)} = S \sum_{i=1}^M W_i \mathbf{B}_{0i}^T \mathbf{D} \mathbf{k}_i \mathbf{D} \mathbf{B}_{0i}, \quad (20)$$

3.3 Consistent mass matrix

The kinematic energy of the beam element is given by

$$\begin{aligned} T^{(e)} &= \frac{1}{2} \int_0^L \rho A(x) (\dot{u}^2 + \dot{v}^2) dx + \frac{1}{2} \int_0^L \rho I(x) \left(\frac{\partial \dot{v}}{\partial x} \right)^2 dx \\ &= \frac{S}{2} \sum_{i=1}^M W_i \rho A_i (\dot{u}_i^2 + \dot{v}_i^2) + \frac{1}{2S} \sum_{i=1}^M W_i \rho I_i \left(\frac{\partial \dot{v}}{\partial \xi} \Big|_{\xi=\xi_i} \right)^2 \end{aligned} \quad (21)$$

where $\rho A(x) = \iint \rho(y, z) dy dz$ and $\rho I(x) = \iint \rho(y, z) y^2 dy dz$, respectively. The derivatives in the integral are also approximated using differential quadrature analogs. Therefore, the kinematic energy can be written as

$$T^{(e)} = \frac{1}{2} \dot{\mathbf{d}}^{(e)T} \mathbf{M}^{(e)} \dot{\mathbf{d}}^{(e)} = \frac{1}{2} \dot{\mathbf{d}}^{(e)T} (\mathbf{M}_0^{(e)} + \mathbf{M}_R^{(e)}) \dot{\mathbf{d}}^{(e)} \quad (22)$$

$\mathbf{M}_0^{(e)}$ is the translational component of mass matrix and $\mathbf{M}_R^{(e)}$ is the rotational component of mass matrix, given by

$$\mathbf{M}_0^{(e)} = S \begin{bmatrix} W_1 \rho A_1 \mathbf{I} & & & & \\ & \mathbf{0} & & & \\ & & W_M \rho A_M \mathbf{I} & & \\ & & & \mathbf{0} & \\ & & & & W_2 \rho A_2 \mathbf{I} \\ & \mathbf{0} & & & & \ddots \\ & & & & & & W_{M-1} \rho A_{M-1} \mathbf{I} \end{bmatrix} \quad (23)$$

$$\mathbf{M}_R^{(e)} = \frac{1}{S} \sum_{i=1}^M w_i \rho \mathbf{I}_i \mathbf{B}_{Gi}^T \mathbf{B}_{Gi}$$

in which \mathbf{I} is a 2×2 unity matrix, and \mathbf{B}_{Gi} is a vector given by

$$\begin{aligned} \mathbf{B}_{Gi} &= [\mathbf{b}_{Gi,2} \quad \mathbf{b}_{Gi,1} \quad \mathbf{b}_{Gi,M+1} \quad \mathbf{b}_{Gi,M+2} \quad \mathbf{b}_{Gi,3} \quad \cdots \quad \mathbf{b}_{Gi,M}] \\ \mathbf{b}_{Gi,j} &= [0 \quad G_{ij}^{(1)}] \end{aligned} \quad (24)$$

Since the numerical integration scheme and differential quadrature analog in the mass matrix formulation are consistent with those in stiffness matrix, the mass matrix in this section is still called “consistent mass matrix”.

4 ANALYSIS OF LA 3-STORY MOMENT-RESISTING FRAME

Time history analysis of a 3-story moment-resisting steel frame (Figure 3) is presented to verify the QB model. The frame is in the North-South (NS) direction, as a piece of the Los Angeles 3-story model building in the SAC steel project [13]. The material is bilinear kinematic hardening, with the elastic modulus 210,000MPa, and the hardening modulus 6,300MPa. The yielding stress of the steel is 248MPa for all beams, and 345MPa for all columns. The distributed load on the first and second story beams is 13.90KN/m, while on the third story beams 4.57KN/m. The additional floor mass on the first and second story beams is 1,372Kg/m, while on the third story beams 915Kg/m. The mass of walls is added on the columns, which on the side columns is 1,098Kg/m and on the inner columns is 1,555Kg/m.

Figure 3: Elevation and member sizes of the LA 3-story Frame.

An acceleration time history of the TAFT earthquake is chosen (Figure 4) and scaled to generate ground motions with the Peak Ground Accelerations (PGAs) 0.10, 0.20, 0.30, 0.40, 0.45, 0.50 and 0.55g respectively. Time interval of the ground motions is 0.005s. Dynamic analysis of the frame is undertaken using the QB model with consistent mass matrix, coded in Fortran. To reduce the computational cost, a Guyan condensation procedure is included to condense the internal DOFs of each QB element. The characteristics of convergence and computational efficiency are studied. Dynamic analysis using the BEAM188 element with consistent mass matrix is conducted in ANSYS [16] for verification. Meantime, comparison is made with the FB beam model in OpenSEES (v2.2.0), in which only lumped mass matrix is available for inelastic dynamic analysis of frames. All computations were performed on a laptop computer with a 5-core processor @2.65GHz and 4.00G memory. The convergence criterion of Newton-Raphson iteration process is set as that the Euclid norm of residual forces is controlled to be less than 10^{-6} .

Figure 4: An acceleration time history of the TAFT earthquake.

Figures 5 and 6 show the displacement responses and acceleration responses at the roof for the three models. In QB and FB models, the number of integration points in one element is chosen as $M = 10$. In ANSYS, 10 four-node BEAM188 elements are used to simulate one frame member, and shear deformation is adjusted to be negligible. The QB results agree with ANSYS results, and are slightly different from the FB results in OpenSEES.

Figure 5: Time histories of the roof displacement responses for the three models, PGA=0.50g.

Figure 6: Time histories of the roof acceleration responses for the three models, PGA=0.50g.

The peak values of the responses are illustrated in Figures 7 and 8. Referring to the ANSYS results, the QB model is accurate in the inelastic dynamic analysis. The FB results have relative errors about 5% to 10%. It is believed that the lumped mass matrix of the FB model reduces the accuracy.

Figure 7: Peak values of the roof displacement responses for different PGAs.

Figure 8: Peak values of the roof acceleration responses for different PGAs.

Figure 9 gives the convergence of the peak response $|u|_{\max}$ of the QB and FB models under $\text{PGA}=0.50\text{g}$ for different number of integration points M . In OpenSEES, M is restricted to be not greater than 10. Results of both models can converge by increasing M , and their convergence rates are similar.

Figure 9: Peak values of the roof displacement responses for different M , $\text{PGA} = 0.50\text{g}$.

The CPU time consumptions of the three models are listed in the Tables 1 and 2. The commercial code ANSYS is versatile and accurate, but its computational cost is much greater for seismic analysis of an entire structure. The computational cost of the QB model is close to that of the FB model in OpenSEES. When increasing the number of integration points M , the CPU time consumption of the QB model increases almost linearly. The quadrature beam model is efficient and suitable for seismic analysis of frames.

PGA/(g)	$t_{\text{QB}}/(\text{s})$	$t_{\text{OpenSEES}}/(\text{s})$	$t_{\text{ANSYS}}/(\text{h})$

5 CONCLUSIONS

- A distributed-plasticity quadrature beam (QB) model with consistent mass matrix is formulated in this paper. For inelastic dynamic seismic analysis of frames, one member is simulated by one QB element.
- The accuracy and the convergence of the QB model are verified. Results of the QB model are in excellent agreement with those of the DB model in ANSYS, but the CPU time consumption is much lower. The convergence rates of the QB and the FB models are comparable, and the time consumption of the QB model is slightly higher. In contrast to the only available lumped mass matrix of the FB model, however, the consistent mass matrix of the QB model makes it advantageous for inelastic dynamic analysis.
- The quadrature beam model is accurate and efficient, highlighting its great potentials in seismic analysis of frames.

Abstract. *The true behavior of structural systems is dynamic, that in many cases can not be simplified to static. The most versatile tool for structural dynamic analyses, is time integration, and, hence, under special attention in the seismic analyses of structural systems, becoming more complicated everyday. Nevertheless, the responses of time integration are inexact and generally being obtained after considerable computational cost. Considering these, besides the digitized nature of ground strong motion records, a technique for considerably reducing the computational cost with small loss of accuracy is recently proposed. With attention to the notion of convergence and its role in numerical analyses, the technique replaces seismic records, with records, digitized at larger steps. The good performance of the technique is displayed in implementation in simple and complicated structural systems analyses. In continuation of the studies, the objective, in this paper, is to examine whether we can successfully implement the technique in time integration of bridges structural systems. The technique is briefly reviewed, and after introducing a bridge structural system, designed according to the Iranian practice, the finite element model of the system is time integrated, once ordinarily, and then again, after implementing the technique. The numerical results evidence the good performance of the technique, and the essentiality of further investigations.*

1 INTRODUCTION

The true behavior of structural systems is dynamic, that, when subjected to severe seismic excitations, cannot be simplified to static. In order to study the dynamic behaviors, the broadly accepted approach is to discretize the structural and mathematical models in space and arriving at the semi-discretized model below:

$$\begin{aligned} \mathbf{M} \ddot{\mathbf{u}} + \mathbf{f}_{\text{int}} &= \mathbf{f}(t) \\ \text{Initial Conditions : } &\begin{cases} \mathbf{u}(t=0) = \mathbf{u}_0 \\ \dot{\mathbf{u}}(t=0) = \dot{\mathbf{u}}_0 \\ \mathbf{f}_{\text{int}}(t=0) = \mathbf{f}_{\text{int}_0} \end{cases} \\ \text{Additional Constraints : } &\mathbf{Q} \end{aligned} \quad (1)$$

$$0 \leq t < t_{\text{end}}$$

analyze equations (1) with an appropriate method [1-4]. In equations (1), t and t_{end} imply the time and the duration of the dynamic behavior, \mathbf{M} is the mass matrix, \mathbf{f}_{int} and $\mathbf{f}(t)$ stand for the vectors of internal force and excitation, \mathbf{u} , $\dot{\mathbf{u}}$, and $\ddot{\mathbf{u}}$ denote the unknown vectors of displacement, velocity, and acceleration, \mathbf{u}_0 , $\dot{\mathbf{u}}_0$, and $\mathbf{f}_{\text{int}_0}$, representing the vectors of displacements, velocities, and internal forces at $t = 0$, together, define the initial status of the model (regarding the essentiality of considering $\mathbf{f}_{\text{int}_0}$ in equations (1), also, see [4]), and \mathbf{Q} indicates some restricting conditions, e.g. additional constraints in problems involved in impact or elastic-plastic behavior [5,6]. The most versatile method to analyze equations (1) is direct time integration [7,8]. However, especially, for nonlinear multi-degree-of-freedom problems, the formulations of time integration methods are inexact and hence the obtained responses are approximations [9,10]. This inexactness, when considered together with the step-by-step nature of time integration methods, summarized in marching throughout the integration interval, computing the responses at distinct time stations from the responses at previous stations, consecutively, (see Figure 1), implies the importance of integration step sizes, in time integration

Figure 1: Typical arrangement of time steps and time stations in time integration analyses.

analyses (specially, regarding the accuracy and computational cost of the analysis). Considering Δt , as a positive definite parameter, scaling (linearly controlling) the size of integration steps, throughout $t \in [0, t_{\text{end}}]$ [11], one of the broadly accepted comments, for the selection of Δt , is as noted below [11-13]:

$$\Delta t = \text{Min} \left(h_s, \frac{T}{10}, f \Delta t \right) \quad (2)$$

In equation (2), T is the smallest dominant period in the response, in general, approximated with the smallest natural period of the system at $t = 0$, likely effectual in the response, h_s is the largest value of the integration step, providing numerically stable responses ($h_s = \infty$ for unconditionally stable methods), and ${}_f\Delta t$ is the digitization step size for excitations available as digitized records (for other excitations ${}_f\Delta t = \infty$). When, ${}_f\Delta t$ dominates equation (2), i.e.

$$\Delta t = {}_f\Delta t < \text{Min}\left(h_s, \frac{T}{10}\right) \quad (3)$$

Δt is to be set smaller than required for accuracy (see the inequality in equation (3), merely because of the size of digitization steps, ${}_f\Delta t$. This leads to additional computational cost. With the aim of decreasing this computational cost, a technique is recently proposed [11].

The technique changes ${}_f\Delta t$ to the larger value ${}_f\Delta t'$,

$${}_f\Delta t' = n {}_f\Delta t \cong \text{Min}\left(h_s, \frac{T}{10}\right) \quad , \quad n = 1, 2, 3, \dots \quad (4)$$

($n = 1$ implies the limiting case, when the inequality in equation (3) is being replaced with equality), and replaces the excitation with a new excitation, digitized at steps equal to ${}_f\Delta t'$, such that in time integration analysis of the system subjected to the new excitation,

$$\Delta t = {}_f\Delta t' \cong \text{Min}\left(h_s, \frac{T}{10}\right) \quad (5)$$

and meanwhile the replacement of the excitation preserves responses convergence and the rate of convergence. (Convergence is the most important essentiality for all approximate analyses [14,15].) The technique is already successfully implemented in the analysis of some simple structural systems [11], i.e. a tall building [16], a fuel storage tank [17], and a silo [18], and also subjected to further theoretical investigation [19]. In continuation of the carried out investigations, this paper presents a study on the performance of the technique, when applied to the analysis of a traditionally designed bridge against a ground strong motion.

A brief review of the recent technique is presented in Section 2, after which, a bridge structural system is introduced and examined for the performance of the technique in Section 3, and finally, with a set of conclusions and guidelines for future research, the paper is ended in Section 4.

2 THE RECENT TECHNIQUE IN BRIEF

In order to replace the digitized excitation with a new excitation digitized at larger steps, such that the responses rate of convergence (generally two) [9,10,20] is preserved, a theory is set [11,21,22] and formulated in view of four assumptions. In brief, provided the assumptions below (implied in Figure 2):

1- The excitation steps, ${}_f\Delta t_i$ $i = 1, 2, \dots$, are equally sized,

$$\forall i, j \quad {}_f\Delta t_i = {}_f\Delta t_j = {}_f\Delta t > 0 \quad (6)$$

2- The integration steps, Δt_i $i = 1, 2, \dots$, are equally sized,

$$\forall i, j \quad \Delta t_i = \Delta t_j = \Delta t > 0 \quad (7)$$

$$\Delta t = n_f \Delta t \leq \text{Min} \left(h_s, \frac{T}{10} \right) \leq t_{end} \quad (12)$$

with generally small loss of accuracy in time integration. Since, the new excitation, $\tilde{\mathbf{f}}$, is digitized at steps equal to $n_f \Delta t$, when considered instead of the original excitation, can lead to a reduction in computational cost (including the time spent and memory essential for the analysis), A_C , about and not more than

$$A_C = 100 \left(\frac{n-1}{n} \right) \% \quad (13)$$

3 NUMERICAL STUDY

Consider the structural system introduced in Figure 3. The structure is a three span precast concrete girder bridge with equal spans of 30 meters. The superstructure is 12 meters wide and carries two traffic lanes. The superstructure consists of a 25 centimeters thick concrete slab and five reinforced concrete girders. The girders are connected by transverse diaphragm and at each end simply supported on 400×400 millimeters steel reinforced elastomeric bearings. Each bearing consists of two exterior layers with 6 millimeters thickness, four interior layers with 12 millimeters thickness, and five 2 millimeters steel reinforcement. The stiffness properties of the bearings are as noted below:

$$\begin{aligned} \text{Vertical Stiffness: } & 3227000 \text{ KN/m} \\ \text{Shear Stiffness: } & 5220 \text{ KN/m} \\ \text{Rotational Stiffness: } & 1420 \text{ KNm/Rad} \\ \text{Torsional Stiffness: } & 118 \text{ KNm/Rad} \end{aligned} \quad (14)$$

Figure 3: The bridge structural model considered in the numerical study in this paper.

The substructure consists of two closed end seat type abutments and two interior bents. Each bent consists of three concrete columns, each with 7.75 meters height and 1.2 meters diameter. The abutments are assumed to be rigid. The finite elements model, in Figure 3, is consisted of frame elements for the girders and shell elements for the superstructure slab. The shell elements are vertically offset to locate them at their actual position, and the columns are modeled using frame elements, and are assumed fixed at pile cap interface. The elastomeric bearings are modeled by spring elements with appropriate stiffness properties for all six degrees of freedoms (see equations (14)). The model is subjected to the excitation in Figure 4, once ap

Figure 4: The digitized ground strong motion applied to the structural model in Figure 3 once in the x and then in the y direction.

plied in the x direction and then again in the y direction (see Figure 1, where, \ddot{u}_g and g respectively stand for the ground acceleration and the constant of gravity, i.e. 9.81 m/sec^2). The excitation step size, $_f \Delta t$, equals 0.01 sec. The geometry and structural design of the bridge model is according to the practice, conventional in Iran [24-26].

In view of the approximate response partially reported in Figure 5, a good selection for T is as noted below:

$$T \cong 0.25 \quad (15)$$

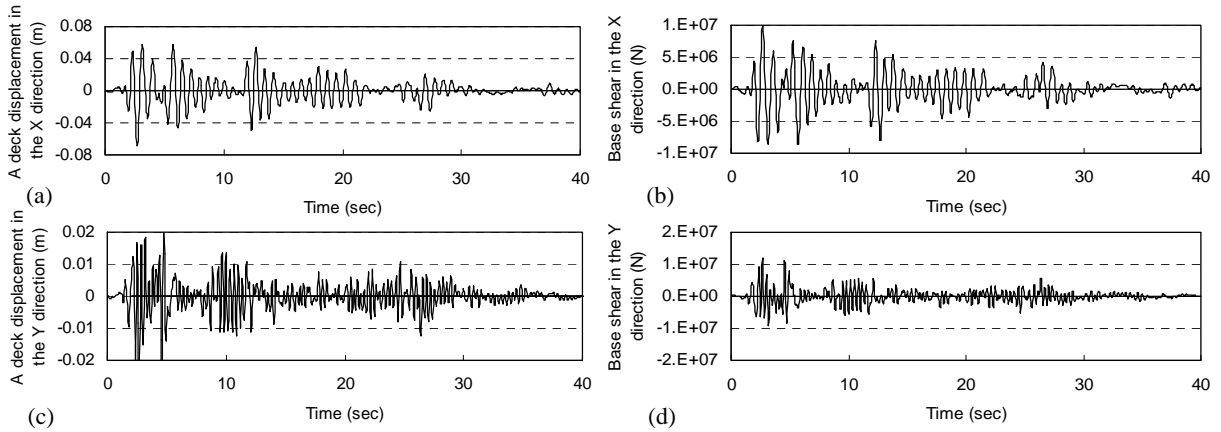

Figure 5: The approximate responses when applying the excitation to the structural model in Figure 3: (a) x direction, a deck displacement, (b) x direction, base shear, (c) y direction, a deck displacement, (d) y direction, base shear.

and hence, with attention to equations (4) and (12),

$$n = 2 \quad (16)$$

is an appropriate selection for the n in equations (11) and (12). Nevertheless, for a broader study, the cases:

$$n = 2, 4, 8, 20 \quad (17)$$

are also considered in time integration analyses with the Newmark average acceleration method [27]. The accuracies are compared in Figures 6 and 7. Considering the time spent and CPU memory essential for the computation, the computational costs are reported in Table 1, and, for the sake of completion, the original and new excitation records are reported in Figure 8. Figures 6 and 7 and Table 1 clearly display the good performance of the recent technique and imply that the technique has a good chance to reduce the computational costs in analyses of bridges seismic behaviors by time integration.

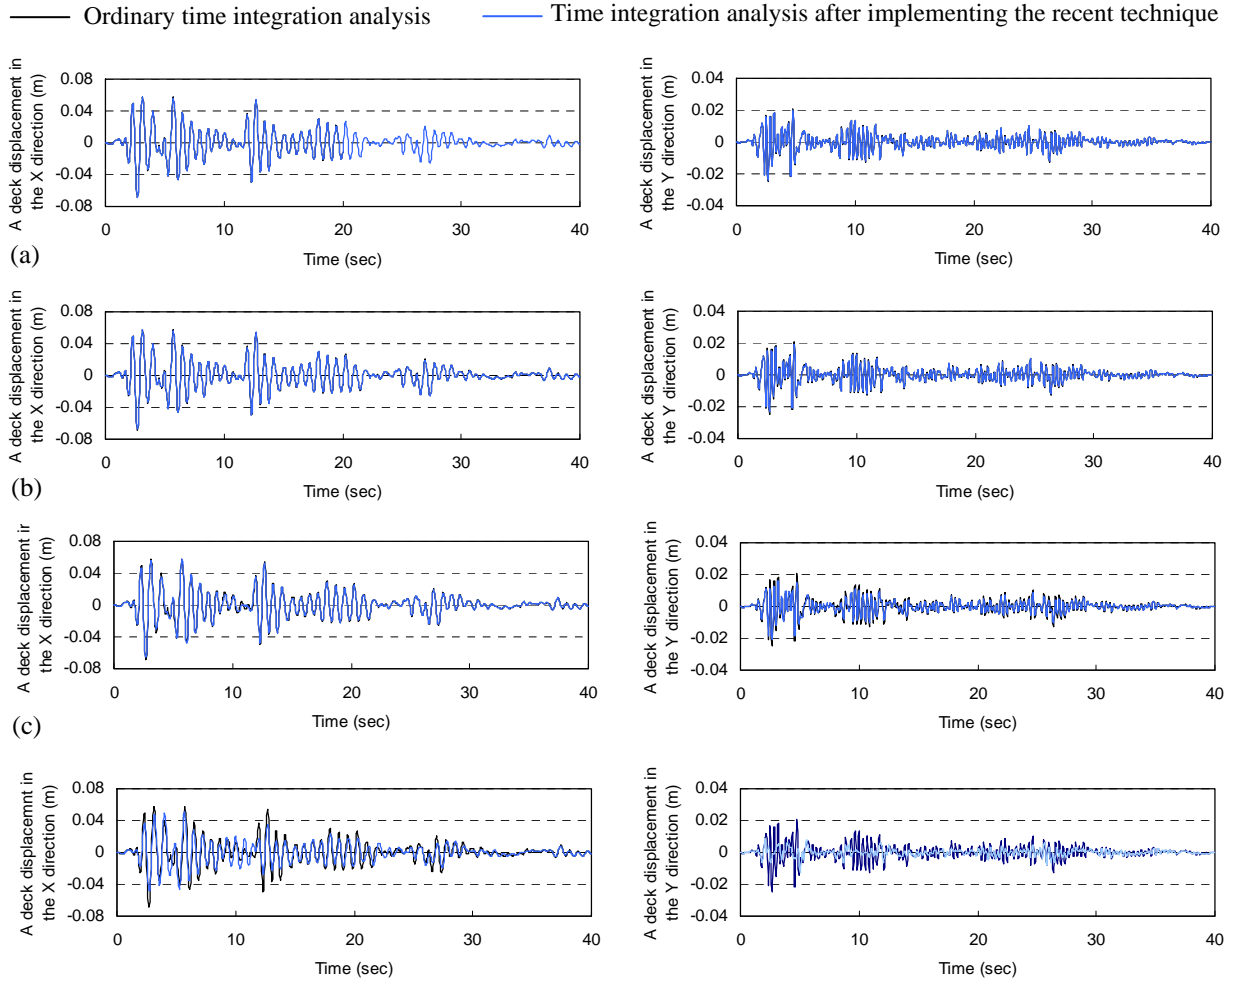

Figure 6: The performance of the recent technique when implemented in direct time integration analysis of the structural system introduced in Figures 3 and 4 and equations (14), by the average acceleration Newmark method [27], for a deck displacement: (a) $n = 2$, (b) $n = 4$, (c) $n = 8$, (d) $n = 20$.

The bridge structural system and excitation, considered in the numerical study, presented above, are common in Iran. Nevertheless, since, in view of the explanations in Section 2 and specifically equations (10)-(13), the performance of the technique might be different for different values of n , and n depends on both the structural system and the excitation, further study regarding the sensitivities is essential. Meanwhile, from the point of view of the analysis method, specifically, when considering behaviors against severe earthquakes, it is essential to study the performance of the technique, in presence of nonlinearities, considering a variety of integration methods, and different iterative nonlinearity solution methods.

Ordinary	$n = 2$	$n = 4$	$n = 8$	$n = 20$
100	50	25	12.5	5

Table 1: An approximate study on the computational costs, $100 - A_C$, when implementing the recent technique [11], compared to the ordinary analysis, with computational cost 100.

4 CONCLUSIONS

The performance of a new technique proposed for reducing the computational cost of seismic analysis by time integration is examined considering a bridge structural system common in Iranian practice. The numerical results display that, for the bridge structural system studied here, considerable reduction of computational cost is attained and the loss of accuracy is even less than expected. Further study in this regard, considering different bridge structural systems, different ground strong motions, different integration methods, and different nonlinearity solution methods is suggested for further research.

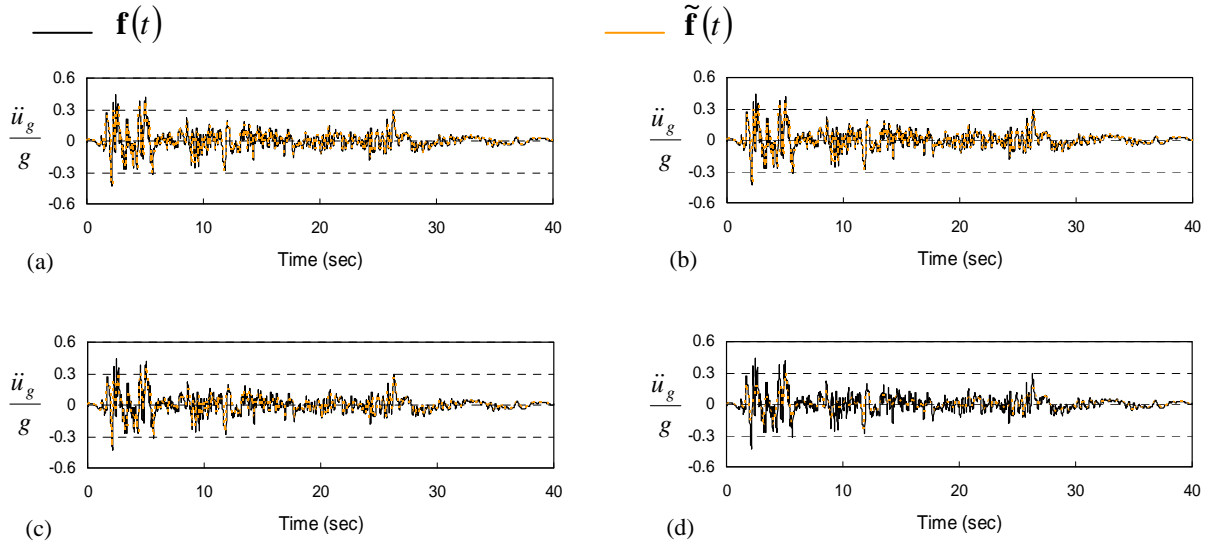

Figure 8: The excitations, $\tilde{\mathbf{f}}(t)$, when implementing the recent technique in the numerical study considering: (a) $n = 2$, (b) $n = 4$, (c) $n = 8$, (d) $n = 20$.

Abstract. *The corotational method is an attractive approach to derive non-linear finite beam elements. In a number of papers, this method was employed to investigate the non-linear dynamic analysis of 2D beams. However, most of the approaches found in the literature adopted either a lumped mass matrix or linear local interpolations to derive the inertia terms (which gives the classical linear and constant Timoshenko mass matrix), although local cubic interpolations were used to derive the elastic force vector and the tangent stiffness matrix. In this paper, a new corotational formulation for dynamic nonlinear analysis is presented. Cubic interpolations are used to derive both the inertia and elastic terms. Numerical examples show that the proposed approach is more efficient than using lumped or Timoshenko mass matrices.*

1 Introduction

The corotational approach is an attractive method to derive efficient nonlinear finite beam elements [1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11]. The main idea of the method can be summarized as follow: the motion of the beam element is decomposed into rigid body and pure deformational parts. A local coordinates system, which moves and rotates with the element's overall rigid body motion, is defined. The deformational part is measured in this local system.

Many different assumptions to represent the local deformations, giving different possibilities for the local element formulation, can be found in the literature. If linear interpolations are used for the local formulation, inertia corotational terms are easily derived and the classical linear and constant Timoshenko mass matrix is obtained. However, this assumption has the drawback that the local vertical displacements are zero along the element, which is not accurate, especially for flexible beams. If cubic interpolations are used for the local formulation, then the derivation of the inertia terms becomes very complicated. To avoid this complexity, Crisfield and al.[2] used the constant Timoshenko mass matrix, although they used local cubic interpolations to derive the elastic force vector and tangent stiffness matrix. The same approach was adopted in [6]. In [7, 8, 9], the authors used a constant lumped mass matrix without any attempt to check its accuracy. In [10], Behdinan and al. proposed a corotational dynamic formulation. However, the cubic shape functions were used to describe the global displacements, which is not consistent with the idea of the corotational method.

In this paper, a new corotational formulation is presented where cubic shape functions are adopted. In order to consider the bending shear deformations, the cubic shape functions of the Interpolation Interdependent Element (IIE) [12] are used to derive the local elastic force vector and local tangent stiffness matrix. It is shown that with some simplifications, the inertia terms can be derived. The new formulation provide accurate results with a minimum number of elements.

The paper is organized as follows: in Section 2 and 3 the corotational kinematic of a 2D beam element and the derivation of the elastic force vector and tangent stiffness matrix are presented. More details about that can be found in [13]. Section 4 and 5 are devoted to the derivation of the inertia terms. In Section 6, two examples are presented in order to assess the accuracy of the present dynamic formulation. Finally conclusions are given in Section 7.

2 Beam kinematics

The notations used are defined in Fig. 1. The coordinates for the nodes 1 and 2 in the global coordinate system (x,z) are (x_1, z_1) and (x_2, z_2) . The vector of global displacements is defined by

$$\mathbf{q} = \begin{bmatrix} u_1 & w_1 & \theta_1 & u_2 & w_2 & \theta_2 \end{bmatrix}^T \quad (1)$$

The vector of local displacements is defined by

$$\bar{\mathbf{q}} = \begin{bmatrix} \bar{u} & \bar{\theta}_1 & \bar{\theta}_2 \end{bmatrix}^T \quad (2)$$

Figure 1: Beam kinematics 1.

The components of $\bar{\mathbf{q}}$ can be computed according to

$$\bar{u} = l_n - l_o \quad (3)$$

$$\bar{\theta}_1 = \theta_1 - \alpha = \theta_1 - \beta - \beta_o \quad (4)$$

$$\bar{\theta}_2 = \theta_2 - \alpha = \theta_2 - \beta - \beta_o \quad (5)$$

In (3), l_o and l_n denote the initial and current lengths of the element, respectively. The current angle of the local system with respect to the global system is denoted as β and is given by

$$c = \cos \beta = \frac{1}{l_n}(x_2 + u_2 - x_1 - u_1) \quad (6)$$

$$s = \sin \beta = \frac{1}{l_n}(z_2 + w_2 - z_1 - w_1) \quad (7)$$

The differentiation of equation (7) gives

$$\delta\beta = \frac{1}{l_n} \begin{bmatrix} s & -c & 0 & -s & c & 0 \end{bmatrix} \delta\mathbf{q} \quad (8)$$

The differentiation of equations (3) to (5) gives

$$\delta\bar{\mathbf{q}} = \mathbf{B} \delta\mathbf{q} \quad (9)$$

with

$$\mathbf{B} = \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \\ \mathbf{b}_3 \end{bmatrix} = \begin{bmatrix} -c & -s & 0 & c & s & 0 \\ -s/l_n & c/l_n & 1 & s/l_n & -c/l_n & 0 \\ -s/l_n & c/l_n & 0 & s/l_n & -c/l_n & 1 \end{bmatrix} \quad (10)$$

3 Elastic force vector and tangent stiffness matrix

By equating the virtual work in the local and global systems, the relation between the local elastic force vector \mathbf{f}_l and the global one \mathbf{f}_g is obtained as

$$V = \delta \mathbf{q}^T \mathbf{f}_g = \delta \bar{\mathbf{q}}^T \mathbf{f}_l = \delta \mathbf{q}^T \mathbf{B}^T \mathbf{f}_l \quad (11)$$

The equation (11) must apply for any arbitrary $\delta \mathbf{q}$. Hence the global elastic force vector \mathbf{f}_g is given by

$$\mathbf{f}_g = \mathbf{B}^T \mathbf{f}_l \quad \mathbf{f}_l = \begin{bmatrix} N & M_1 & M_2 \end{bmatrix}^T \quad (12)$$

The global tangent stiffness matrix is defined by

$$\delta \mathbf{f}_g = \mathbf{K}_g \delta \mathbf{q} \quad (13)$$

By taking the differentiation of (12), it is obtained

$$\mathbf{K}_g = \mathbf{B}^T \mathbf{K}_l \mathbf{B} + \frac{\mathbf{z} \mathbf{z}^T}{l_n} N + \frac{1}{l_n^2} (\mathbf{r} \mathbf{z}^T + \mathbf{z} \mathbf{r}^T) (M_1 + M_2) \quad (14)$$

where

$$\mathbf{r} = \begin{bmatrix} -c & -s & 0 & c & s & 0 \end{bmatrix}^T \quad (15)$$

$$\mathbf{z} = \begin{bmatrix} s & -c & 0 & -s & c & 0 \end{bmatrix}^T \quad (16)$$

The local elastic force vector \mathbf{f}_l and local tangent stiffness matrix \mathbf{K}_l , which is defined by $\delta \mathbf{f}_l = \mathbf{K}_l \delta \bar{\mathbf{q}}$, depend on the definition of the local formulation. In this work, the shape functions of the IIE (Interdependent Interpolation Element) are used together with a shallow arch beam theory. The shallow arch longitudinal and shear strains are given by

$$\epsilon = \frac{1}{l_o} \int_{l_o} \left[\frac{\partial u}{\partial x} + \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 \right] dx - \frac{\partial^2 w}{\partial x^2} z \quad (17)$$

$$\gamma = \frac{\partial w}{\partial x} - \vartheta \quad (18)$$

Using IIE's shape functions taken from [12], the axial displacement u , the vertical displacement w and the local rotation ϑ are given by

$$u = \frac{x}{l_o} \bar{u} \quad (19)$$

$$w = \varphi_1 \bar{\theta}_1 + \varphi_2 \bar{\theta}_2 \quad (20)$$

$$\vartheta = \varphi_3 \bar{\theta}_1 + \varphi_4 \bar{\theta}_2 \quad (21)$$

where

$$\varphi_1 = \mu x \left[6 \Omega \left(1 - \frac{x}{l_o} \right) + \left(1 - \frac{x}{l_o} \right)^2 \right] \quad (22)$$

$$\varphi_2 = \mu x \left[6 \Omega \left(\frac{x}{l_o} - 1 \right) - \frac{x}{l_o} + \frac{x^2}{l_o^2} \right] \quad (23)$$

$$\varphi_3 = \mu \left(1 + 12 \Omega - \frac{12 \Omega x}{l_o} - \frac{4 x}{l_o} + \frac{3 x^2}{l_o^2} \right) \quad (24)$$

$$\varphi_4 = \mu \left(\frac{12 \Omega x}{l_o} - \frac{2 x}{l_o} + \frac{3 x^2}{l_o^2} \right) \quad (25)$$

$$\Omega = \frac{E I}{G A K_s l_o} \quad (26)$$

$$\mu = \frac{1}{1 + 12 \Omega} \quad (27)$$

A, I : Section's area and inertia moment

K_s : Shear correction coefficient.

For a rectangular cross-section, $K_s = \frac{5}{6}$

With $\Omega = 0$, the hermitian shape functions of the classical Bernoulli elements are obtained. The interest of IIE formulation is to keep the accuracy inherent to the cubic interpolation and with Ω to add the bending shear deformation.

4 Inertia force vector and mass matrix

The inertia force vector is calculated from the kinetic energy by using the Lagrange's equation of motion:

$$\mathbf{f}_K = \frac{d}{dt} \left[\frac{\partial K}{\partial \dot{\mathbf{q}}} \right] - \left[\frac{\partial K}{\partial \mathbf{q}} \right] \quad (28)$$

The kinetic energy K of an element is given as

$$K = \frac{1}{2} \rho \left\{ \int_{l_o} A (\dot{u}_G^2 + \dot{w}_G^2) dl + \int_{l_o} I \dot{\theta}^2 dl \right\} \quad (29)$$

where

ρ : Mass density

u_G, w_G : Global displacements of the centroid of the cross-section

θ : Global rotation of the cross-section

The global position of the centroid of the cross-section is given by (see Fig. 2)

$$\mathbf{OG} = (x_1 + u_1) \mathbf{i} + (z_1 + w_1) \mathbf{j} + \frac{l_n}{l_o} x \mathbf{a} + w \mathbf{b} \quad (30)$$

Figure 2: Beam kinematics 2.

with

$$\mathbf{a} = \cos \beta \mathbf{i} + \sin \beta \mathbf{j} \quad (31)$$

$$\mathbf{b} = -\sin \beta \mathbf{i} + \cos \beta \mathbf{j} \quad (32)$$

After some algebraic manipulations, the velocities components can be derived

$$\dot{u}_G = \dot{u}_1 + \frac{x}{l_o}(\dot{u}_2 - \dot{u}_1) - \dot{w} \sin \beta - w \dot{\beta} \cos \beta \quad (33)$$

$$\dot{w}_G = \dot{w}_1 + \frac{x}{l_o}(\dot{w}_2 - \dot{w}_1) + \dot{w} \cos \beta - w \dot{\beta} \sin \beta \quad (34)$$

The global rotation of the cross section is given by

$$\dot{\theta} = \dot{\vartheta} + \dot{\alpha} = \dot{\vartheta} + \dot{\beta} \quad (35)$$

For the dynamic formulation, Ω is taken to 0. It is worth mentioning that assumption simplify the computations. Furthermore, extensive numerical studies performed by the authors have shown that this simplification does not modify the numerical results. The exact expression of the kinetic energy K can be obtained by substituting (33),(34) and (35) into (29), and by using (8) to calculate β . K can be written as

$$K = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M} \dot{\mathbf{q}} \quad (36)$$

The local mass matrix \mathbf{M}_l is defined by

$$\mathbf{M} = \mathbf{T}^T \mathbf{M}_l \mathbf{T} \quad (37)$$

where \mathbf{T} is rotation matrix.

Consequently, one obtains

$$K = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{T}^T \mathbf{M}_l \mathbf{T} \dot{\mathbf{q}} \quad (38)$$

At this point, two simplifications are introduced in the expression of the local mass matrix: the local displacement w is assumed small and therefore the terms containing w^2 are neglected; due to the assumption of the small deformation, the approximation $l_n = l_o$ is taken. With these simplifications, the local mass matrix is only function of $\bar{\theta}_1$ and $\bar{\theta}_2$ and is given by

$$\mathbf{M}_l = \mathbf{M}_{l1} + \mathbf{M}_{l2} \quad (39)$$

where \mathbf{M}_{l1} is the mass matrix for local axial and vertical displacements, defined as

$$\mathbf{M}_{l1} = \frac{\rho A l_o}{420} \begin{bmatrix} 140 & m_1 & 0 & 70 & -m_1 & 0 \\ m_1 & 156 & 22l_o & m_2 & 54 & -13l_o \\ 0 & 22l_o & 4l_o^2 & 0 & 13l_o & -3l_o^2 \\ 70 & m_2 & 0 & 140 & -m_2 & 0 \\ -m_1 & 54 & 13l_o & m_2 & 156 & -22l_o \\ 0 & -13l_o & -3l_o^2 & 0 & 22l_o & 4l_o^2 \end{bmatrix}$$

with

$$m_1 = (21\bar{\theta}_1 - 14\bar{\theta}_2)$$

$$m_2 = (14\bar{\theta}_1 - 21\bar{\theta}_2)$$

\mathbf{M}_{l2} is the mass matrix for rotation, defined as

$$\mathbf{M}_{l2} = \frac{\rho I}{30 l_o} \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 36 & 3l_o & 0 & -36 & 3l_o \\ 0 & 3l_o & 4l_o^2 & 0 & -3l_o & -l_o^2 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -36 & -3l_o & 0 & 36 & -3l_o \\ 0 & 3l_o & -l_o^2 & 0 & -3l_o & 4l_o^2 \end{bmatrix}$$

The differentiations of the kinetic energy can be computed as

$$\frac{\partial K}{\partial \dot{\mathbf{q}}} = \mathbf{M} \dot{\mathbf{q}} \quad (40)$$

$$\frac{d}{dt} \left[\frac{\partial K}{\partial \dot{\mathbf{q}}} \right] = \mathbf{M} \ddot{\mathbf{q}} + \dot{\mathbf{M}} \dot{\mathbf{q}} \quad (41)$$

\mathbf{M} is function of $\beta, \bar{\theta}_1, \bar{\theta}_2$ which are dependent on the time:

$$\dot{\mathbf{M}} = \frac{\partial \mathbf{M}}{\partial \beta} \dot{\beta} + \frac{\partial \mathbf{M}}{\partial \bar{\theta}_1} \dot{\bar{\theta}}_1 + \frac{\partial \mathbf{M}}{\partial \bar{\theta}_2} \dot{\bar{\theta}}_2 \quad (42)$$

Using the notation $\frac{\partial \mathbf{M}}{\partial \beta} = \mathbf{M}_\beta$; $\frac{\partial \mathbf{M}}{\partial \bar{\theta}_1} = \mathbf{M}_{\bar{\theta}_1}$; $\frac{\partial \mathbf{M}}{\partial \bar{\theta}_2} = \mathbf{M}_{\bar{\theta}_2}$, the above equation can be rewritten in a more compact form

$$\dot{\mathbf{M}} = \mathbf{M}_\beta \left(\frac{\mathbf{z}^T}{l_n} \dot{\mathbf{q}} \right) + \mathbf{M}_{\bar{\theta}_1} (\mathbf{b}_2^T \dot{\mathbf{q}}) + \mathbf{M}_{\bar{\theta}_2} (\mathbf{b}_3^T \dot{\mathbf{q}}) \quad (43)$$

The differentiation of K with respect to \mathbf{q} is given by

$$\begin{aligned} \left[\frac{\partial K}{\partial \mathbf{q}} \right] &= \frac{\partial K}{\partial \beta} \frac{\partial \beta}{\partial \mathbf{q}} + \frac{\partial K}{\partial \bar{\theta}_1} \frac{\partial \bar{\theta}_1}{\partial \mathbf{q}} + \frac{\partial K}{\partial \bar{\theta}_2} \frac{\partial \bar{\theta}_2}{\partial \mathbf{q}} \\ &= \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_\beta \dot{\mathbf{q}} \right) \frac{\mathbf{z}}{l_n} + \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_{\bar{\theta}_1} \dot{\mathbf{q}} \right) \mathbf{b}_2 + \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_{\bar{\theta}_2} \dot{\mathbf{q}} \right) \mathbf{b}_3 \end{aligned} \quad (44)$$

Substituting (43), (44) into (28), one obtains the expression of \mathbf{f}_K as

$$\begin{aligned} \mathbf{f}_K &= \mathbf{M} \ddot{\mathbf{q}} + \left\{ \mathbf{M}_\beta \left(\frac{\mathbf{z}^T}{l_n} \dot{\mathbf{q}} \right) + \mathbf{M}_{\bar{\theta}_1} (\mathbf{b}_2^T \dot{\mathbf{q}}) + \mathbf{M}_{\bar{\theta}_2} (\mathbf{b}_3^T \dot{\mathbf{q}}) \right\} \dot{\mathbf{q}} \\ &\quad - \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_\beta \dot{\mathbf{q}} \right) \frac{\mathbf{z}}{l_n} - \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_{\bar{\theta}_1} \dot{\mathbf{q}} \right) \mathbf{b}_2 - \left(\frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M}_{\bar{\theta}_2} \dot{\mathbf{q}} \right) \mathbf{b}_3 \end{aligned} \quad (45)$$

The expression of \mathbf{M}_β is given by

$$\mathbf{M}_\beta = \frac{d\mathbf{T}^T}{d\beta} \mathbf{M}_l \mathbf{T} + \mathbf{T}^T \mathbf{M}_l \frac{d\mathbf{T}}{d\beta} \quad (46)$$

where

$$\frac{d\mathbf{T}}{d\beta} = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \mathbf{T} = \mathbf{I}_1 \mathbf{T} \quad (47)$$

Hence,

$$\mathbf{M}_\beta = \mathbf{T}^T (\mathbf{I}_1^T \mathbf{M}_l + \mathbf{M}_l \mathbf{I}_1) \mathbf{T} = \mathbf{T}^T \mathbf{M}_l^\beta \mathbf{T} \quad (48)$$

$\mathbf{M}_{\bar{\theta}_1}, \mathbf{M}_{\bar{\theta}_2}$ are calculated by

$$\mathbf{M}_{\bar{\theta}_1} = \mathbf{T}^T \frac{\partial \mathbf{M}_l}{\partial \bar{\theta}_1} \mathbf{T} = \mathbf{T}^T \mathbf{M}_{l, \bar{\theta}_1} \mathbf{T} \quad (49)$$

$$\mathbf{M}_{\bar{\theta}_2} = \mathbf{T}^T \frac{\partial \mathbf{M}_l}{\partial \bar{\theta}_2} \mathbf{T} = \mathbf{T}^T \mathbf{M}_{l, \bar{\theta}_2} \mathbf{T} \quad (50)$$

where

$$\begin{aligned} \mathbf{M}_{l, \bar{\theta}_1} &= \frac{\rho A l_o}{60} \begin{bmatrix} 0 & 3 & 0 & 0 & -3 & 0 \\ 3 & 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & -2 & 0 \\ -3 & 0 & 0 & -2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \\ \mathbf{M}_{l, \bar{\theta}_2} &= \frac{\rho A l_o}{60} \begin{bmatrix} 0 & -2 & 0 & 0 & 2 & 0 \\ -2 & 0 & 0 & -3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -3 & 0 & 0 & 3 & 0 \\ 2 & 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \end{aligned}$$

5 Non-linear equation of the motion

The non-linear equation of motion is

$$\mathbf{f}_K(\mathbf{q}, \dot{\mathbf{q}}, \ddot{\mathbf{q}}) + \mathbf{f}_g(\mathbf{q}) = \mathbf{p} \quad (51)$$

where

\mathbf{f}_K : Inertia force vector

\mathbf{f}_g : Elastic force vector

\mathbf{p} : Applied external loads

To solve (51), the differentiation of each terms must be calculated. The following notations are used

$$\mathbf{K}_g = \frac{\partial \mathbf{f}_g}{\partial \mathbf{q}} \quad (52)$$

$$\mathbf{M} = \frac{\partial \mathbf{f}_K}{\partial \ddot{\mathbf{q}}} \quad (53)$$

$$\mathbf{C}_K = \frac{\partial \mathbf{f}_K}{\partial \dot{\mathbf{q}}} \quad (54)$$

$$\mathbf{K}_K = \frac{\partial \mathbf{f}_K}{\partial \mathbf{q}} \quad (55)$$

The stiffness matrix \mathbf{K}_g and the mass matrix \mathbf{M} are defined in previous sections. Using (45), \mathbf{C}_K can be computed as

$$\mathbf{C}_K = \dot{\mathbf{M}} + \mathbf{C}_1 - \mathbf{C}_1^T \quad (56)$$

with

$$\mathbf{C}_1 = \mathbf{M}_\beta \left(\dot{\mathbf{q}} \frac{\mathbf{z}^T}{l_n} \right) + \mathbf{M}_{\bar{\theta}_1} \left(\dot{\mathbf{q}} \mathbf{b}_2^T \right) + \mathbf{M}_{\bar{\theta}_2} \left(\dot{\mathbf{q}} \mathbf{b}_3^T \right) \quad (57)$$

The matrix \mathbf{K}_K can be written as follow

$$\mathbf{K}_K = \mathbf{K}_1 + \mathbf{K}_2 - \mathbf{K}_3 \quad (58)$$

where

$$\mathbf{K}_1 = \mathbf{M}_\beta \ddot{\mathbf{q}} \frac{\mathbf{z}^T}{l_n} + \mathbf{M}_{\bar{\theta}_1} \ddot{\mathbf{q}} \mathbf{b}_2^T + \mathbf{M}_{\bar{\theta}_2} \ddot{\mathbf{q}} \mathbf{b}_3^T \quad (59)$$

$$\begin{aligned} \mathbf{K}_2 = & \left(\frac{\mathbf{z}^T}{l_n} \dot{\mathbf{q}} \right) \left(\frac{\partial \mathbf{M}_\beta}{\partial \beta} \dot{\mathbf{q}} \frac{\mathbf{z}^T}{l_n} + \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_1} \dot{\mathbf{q}} \mathbf{b}_2^T + \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_2} \dot{\mathbf{q}} \mathbf{b}_3^T \right) + (\mathbf{b}_2^T \dot{\mathbf{q}}) \frac{\partial \mathbf{M}_{\bar{\theta}_1}}{\partial \beta} \dot{\mathbf{q}} \frac{\mathbf{z}^T}{l_n} \\ & + (\mathbf{b}_3^T \dot{\mathbf{q}}) \frac{\partial \mathbf{M}_{\bar{\theta}_2}}{\partial \beta} \dot{\mathbf{q}} \frac{\mathbf{z}^T}{l_n} - \left(\mathbf{M}_\beta - \mathbf{M}_{\bar{\theta}_1} - \mathbf{M}_{\bar{\theta}_2} \right) \dot{\mathbf{q}} \dot{\mathbf{q}}^T \left(\frac{\mathbf{r} \mathbf{z}^T + \mathbf{r} \mathbf{z}^T}{l_n^2} \right) \end{aligned} \quad (60)$$

$$\begin{aligned} \mathbf{K}_3 = & \frac{1}{2} \left[\left(\dot{\mathbf{q}}^T \frac{\partial \mathbf{M}_\beta}{\partial \beta} \dot{\mathbf{q}} \right) \frac{\mathbf{z} \mathbf{z}^T}{l_n^2} + \left(\dot{\mathbf{q}}^T \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_1} \dot{\mathbf{q}} \right) \frac{\mathbf{z}}{l_n} \mathbf{b}_2^T + \left(\dot{\mathbf{q}}^T \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_2} \dot{\mathbf{q}} \right) \frac{\mathbf{z}}{l_n} \mathbf{b}_3^T \right. \\ & + \left(\dot{\mathbf{q}}^T \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_1} \dot{\mathbf{q}} \right) \mathbf{b}_2 \frac{\mathbf{z}^T}{l_n} + \left(\dot{\mathbf{q}}^T \frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_2} \dot{\mathbf{q}} \right) \mathbf{b}_3 \frac{\mathbf{z}^T}{l_n} \\ & \left. - \dot{\mathbf{q}}^T \left(\mathbf{M}_\beta - \mathbf{M}_{\bar{\theta}_1} - \mathbf{M}_{\bar{\theta}_2} \right) \dot{\mathbf{q}} \left(\frac{\mathbf{r} \mathbf{z}^T + \mathbf{r} \mathbf{z}^T}{l_n^2} \right) \right] \end{aligned} \quad (61)$$

The expressions of $\frac{\partial \mathbf{M}_\beta}{\partial \beta}$, $\frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_1}$ and $\frac{\partial \mathbf{M}_\beta}{\partial \bar{\theta}_2}$ can be easily derived from (48), (49) and (50).

6 Numerical examples

Two numerical applications are presented in this section in order to assess the performance of the dynamic corotational formulation proposed in Sections 4 and 5. In particular, the accuracy of the new formulation is compared to the one of two formulations usually found in the literature, i.e. the lumped mass matrix and the Timoshenko mass matrix. These two constant mass matrices are given by

$$\mathbf{M}_{\text{Lumped}} = \frac{\rho A l_o}{2} \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & l_o^2/12 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & l_o^2/12 \end{bmatrix}$$

$$\mathbf{M}_{\text{Timoshenko}} = \rho l_o \begin{bmatrix} A/3 & 0 & 0 & A/6 & 0 & 0 \\ 0 & A/3 & 0 & 0 & A/6 & 0 \\ 0 & 0 & I l_o/3 & 0 & 0 & I l_o/3 \\ A/6 & 0 & 0 & A/3 & 0 & 0 \\ 0 & A/6 & 0 & 0 & A/3 & 0 \\ 0 & 0 & I l_o/3 & 0 & 0 & I l_o/3 \end{bmatrix}$$

For all dynamic formulations, the elastic force vector and tangent stiffness matrix have been derived using the IIE shape functions in order to account for shear deformability. For each example, the three dynamic formulations are compared with a reference solution. This solution is obtained with a large number of elements and is identical for the three considered dynamic formulations. The reference solution has also been checked with Abaqus (Total Lagrangian formulation) and the same results have been obtained.

To solve the equation of motion, the Alpha method, which is presented in [14], is employed, with $\alpha = -0.01$. This moderate value of α gives a small numerical damping, which limits the influence of higher frequencies on the response. Damping is not considered.

For the presentation of the results, the following colors are used in all figures:

6.1 Shallow arch

Consider a shallow, circular, elastic arch (see Fig. 3) of span $L = 10m$ with clamped ends. The radius R of the arch is equal to $10m$ with $\phi = 30^\circ$. The shallow arch has a uniform rectangular cross-section and is subjected to a sinusoidal concentrated vertical force $P = P_o \sin(wt)$ at mid-span. The amplitude of the load P_o is taken equal to -80 MN and its frequency w is 1000 rad/s . The arch has cross-sectional area $A = 0.087 \text{ m}^2$, modulus of elasticity $E = 210 \text{ GPa}$, second moment of area $I = 3.562 \cdot 10^{-3} \text{ m}^4$ and mass per unit volume $\rho = 7850 \text{ kg/m}^3$. The time step size is chosen to be $\Delta t = 5 \cdot 10^{-5} \text{ s}$. In Fig. 4, the mid-span vertical displacement $v(t)$ history is depicted for the 3 different dynamic formulations as well as the reference solution, which has been obtained with 48 elements. Only 6 elements have been used for the

Figure 3: Shallow arch: geometrical data

Figure 4: Shallow arc - Vertical displacement history

computations with the 3 formulations. It can be observed that the results obtained with the new

approach are nearly identical to the reference solution. However, large discrepancies between the results obtained with the lumped and Timoshenko approaches and the reference solution can be observed. This indicates that the present formulation is able to capture the nonlinear dynamical behaviour of structures with minimal number of elements.

6.2 Lee's frame

A Lee's frame with uniform rectangular cross-section subjected to a suddenly applied constant load $P_o = 4.1$ MN is considered, (see Fig. 5). The frame and cross-section data (see Fig. 5) are : $L = 2.4$ m, $a = 0.2$ m and $e = 0.3$ m. The members of the frame have modulus of elasticity $E = 210$ GPa and mass per unit volume $\rho = 7850$ kg/m³. The loading is defined as follows:

$$P = \begin{cases} 0 & \text{if } t \leq 0 \\ P_o & \text{if } t > 0 \end{cases}$$

The reference solution, obtained with 60 elements, and the results obtained with 10 elements

Figure 5: Lee's frame: geometrical data

are presented in Fig. 6. The time step size is $\Delta t = 2.5 \cdot 10^{-3}$ s. It can be noted that, with 10 elements, the results obtained with the new approach are in good agreement with the reference solution. However, the discrepancy between the results obtained with the lumped or Timoshenko approaches and the reference solution is not negligible.

Figure 6: Lee's frame - Vertical displacement history

7 Conclusion

In this paper, a new dynamic formulation for corotational 2D beam has been presented. The new feature is that cubic interpolations are used to derive both inertia and elastic terms. The inertia terms are analytically derived by introducing some simplifications. Two numerical examples were implemented to compare this new formulation with linear Timoshenko and lumped mass matrices, which are often used in literature. The results show that the new formulation requires more computational time but allows to reduce significantly the number of elements. This advantage is due to a better representation of the local displacements in the inertia terms.

Keywords: Time Integration, Steel Silo, Computational Cost, Earthquake Excitation.

Abstract. *Time integration is the most versatile tool for analyzing semi-discretized equations of motion. Nevertheless, the associated computational costs are generally high and the computed responses are approximate. Integration step size is the main parameter affecting the computational cost and accuracy, in different ways; and hence, should be set equal to the largest value, acceptable from the point of view of accuracy. For practical cases, subjected to digitized excitations, an additional restriction, potentially increasing the computational costs, is the digitization size of the recorded excitations. Recently, a technique uses a convergence-based replacement of the digitized excitations with excitations digitized at larger steps, to arrive at time integration analyses in need of less computational cost. The good performance of the proposed technique regarding simple linear and nonlinear structural dynamic systems and shear frame structures has been displayed. Considering these, the importance of time history analysis in seismic analyses, the fact that the sizes and complicatedness of structural systems are in increase and the earthquakes are likely being recorded in smaller steps everyday, and meanwhile, the strategical role of silos in most of countries, the objective in this paper is to study the effectiveness of the new technique, when applied to analysis of silos seismic behaviors. After brief theoretical discussion, a steel silo designed based on existing codes, is once analyzed without implementing the technique, and then again, when implementing it, considering 80 percent of the mass of granular material inside silo as the effective mass. The numerical results clearly evidence the good performance of the technique.*

1 INTRODUCTION

Time integration is the most versatile tool to analyze the semi-discretized equation of motion, below:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{f}_{\text{int}}(t) = \mathbf{f}(t) \quad (1)$$

Initial conditions: $\left\{ \begin{array}{l} \mathbf{u}(t=0) = \mathbf{u}_0 \\ \dot{\mathbf{u}}(t=0) = \dot{\mathbf{u}}_0 \\ \mathbf{f}_{\text{int}}(t=0) = \mathbf{f}_{\text{int}_0} \end{array} \right.$

Additional constraints: \mathbf{Q}

$$0 \leq t < t_{\text{end}}$$

In equations (1) t and t_{end} imply the time and duration of dynamic behavior; \mathbf{M} is the mass matrix; $\mathbf{f}_{\text{int}}(t)$ and $\mathbf{f}(t)$ represent the vectors of internal force and excitation; $\mathbf{u}(t)$, $\dot{\mathbf{u}}(t)$ and $\ddot{\mathbf{u}}(t)$ are the unknown vectors of displacement, velocity, and acceleration, \mathbf{u}_0 , $\dot{\mathbf{u}}_0$, and $\mathbf{f}_{\text{int}_0}$ define the initial status of the model, and \mathbf{Q} represents some restricting conditions, e.g. additional constraints in problems involved in impact or elastic-plastic behavior. In spite of the versatility, time integration analyses suffer from considerable computational cost and computational errors [1], both mainly depending on integration step size, Δt . Time integration initiates with selection of time step size or a criterion for adaptive time stepping, then considering the initial conditions, the analysis is being continued with marching along the time axis and computing the responses for distinct time stations. Typical arrangement of time steps and time stations in time integration analyses is shown in Figure 1.

Figure 1. Typical arrangement of time steps and time stations in time integration analyses [2].

Due to the fact that smaller integration steps result in more precision and also more computational cost, it is mandatory to select time step sizes as small as acceptable from precision point of view. The existing proposed values for Δt in technical literature are presented below [3,4,5].

$$\Delta t = \text{Min}\left(h, \frac{T}{10}, {}_f\Delta t\right) \quad \text{for linear systems} \quad (2)$$

$$\Delta t = \text{Min}\left(h, \frac{T}{100}, {}_f\Delta t\right) \quad \text{for nonlinear systems}$$

In equations (2) h represents the requirements regarding response numerical stability and consistency, T is the dominating period of oscillations, not precisely known in advance, and ${}_f\Delta t$, representing an additional restriction for practical cases where the excitation $\mathbf{f}(t)$ is available as digitized record, implies the size by which the excitation is recorded. Reducing the effect of ${}_f\Delta t$ in equations (2) can decrease the computation cost considerably. Recently a technique is proposed [2], which replaces the digitized excitations with the step size equal to ${}_f\Delta t$ with excitations digitized at steps equal to $n {}_f\Delta t$, $n \in \mathbb{Z}^+$, such that to preserve responses rate of convergence. The technique is implemented in simple linear and nonlinear systems analysis and also in a shear frame model analysis and led to considerable computational cost reduction with tolerable loss of accuracy [2,6]. In this paper the performance of this technique is investigated in the case of a steel silo.

2 THE RECENTLY PROPOSED TECHNIQUE [2]

In view of equations (2), considering the case when ${}_f\Delta t < \text{Min}(h, T/(10 \text{ or } 100))$ and taking into account the four assumptions mentioned below:

- 1- The excitation steps are equally sized, (see Figure 2)

$$\forall i, j \quad {}_f\Delta t_i = {}_f\Delta t_j = {}_f\Delta t > 0 \quad (3)$$

- 2- The integration steps are equally sized,

$$\forall i, j \quad \Delta t_i = \Delta t_j = \Delta t > 0 \quad (4)$$

- 3- The excitation steps are embedded by the integration steps (the first time station is a station for both excitation and integration),

$$\exists \quad n \in \mathbb{Z}^+ \quad \frac{\Delta t}{{}_f\Delta t} = n < \infty \quad (5)$$

- 4- The $\mathbf{f}(t)$ in equations (1) is a digitized representation of an actual excitation $\mathbf{g}(t)$ which is smooth with respect to time,

$$\delta(t-\alpha_i)=\begin{cases} 1 & t=\alpha_i \\ 0 & t\neq\alpha_i \end{cases}$$

Integration steps:	1	2
--------------------	---	---

Figure 2. Typical distribution of excitation and integration stations in [2].

we can replace the original excitation with a new excitation defined by:

$$t_i = t_{end} : \quad \tilde{\mathbf{f}}_i = \mathbf{f}(t_i),$$

where,

$$t = t_{end} - \Delta t \quad : \quad n' = n - 1$$

and Δt and n ($n \in \mathbb{Z}^+$) are the largest values satisfying

$$\begin{aligned}
\Delta t = n_f \Delta t &\leq \text{Min}\left(h, \frac{T}{10}\right) && \text{for linear systems} \\

\Delta t &\leq t_{end}
\end{aligned} \tag{9}$$

and obtain responses from time integration with much less computational cost. Following the numerical examples already successfully examined in the literature [2,6], the technique is in the next section implemented in the analysis of a steel silo by time integration.

3 SEISMIC ANALYSIS OF A STEEL SILO

In this paper a steel silo subjected to an earthquake excitation is taken into account. The mass density of granular material inside silo is considered equal to 1500 kg/m³. Dimensions of the silo model are presented in Table 1 [7]. ABAQUS finite element package [8] is used for finite element modeling. 4-noded shell element S4R is used for modeling the wall of silo. The modulus of elasticity of the wall of silo is considered equal to 2×10⁵ MPa. For decreasing the computation time only half of silo is modeled and symmetric boundary conditions are used at the center of silo. Eurocode 8 Part 4 [9] has proposed that if more accurate evaluations are not undertaken, the global seismic response and the seismic action effects in the supporting structure may be calculated assuming that the particulate contents of the silo move together with the silo shell and modeling them with their effective mass, the contents of the silo may be taken to have an effective mass equal to 80 percent of their total mass, In common silo design in ACI 313 [10], 80 percent of granular material mass is proposed to be considered as effective mass for calculation of seismic loads. For modeling the silo, 80 percent of granular material mass is uniformly applied to the wall of the silo. The computed fundamental period, T , equals 0.2038 sec. The finite element mesh of the model is shown in Figure 3.

Silo height H (m)	Diameter D (m)	Silo wall thickness t (m)
20	10	0.03

Table 1. Dimensions of the silo model.

Figure 3. The finite element mesh of silo model (half of silo is considered).

The excitation which is a strong motion record, digitized at steps equal to $f \Delta t = 0.005$ is shown in Figure 4. Generally in conventional time integration analyses using integration steps as small as $f \Delta t$ is essential, but by using the technique described in Section 2, we can consider $n=2,3,4$ to perform time integration analyses by replacing the digitized excitation shown in Figure 4 with the step size of $f \Delta t = 0.005$ with excitations digitized at steps equal to $n f \Delta t = 0.01, 0.015, 0.02$ in consistence with equations (2), Hilber-Hughes-Taylor method [11] is implemented as the integration method, with a parameter, α , equal to -0.05. The base shear and top displacement histories of the silo structural system subjected to the original excitation and when considering the technique with $n=2,3,4$ are reported in Figures 5 and 6. As shown, the results obtained considering new excitations with $n=2,3,4$ have a good correlation with the results obtained from the conventional time integration by applying the earthquake excitation depicted in Figure 4 to the silo model. The computation time and the computation cost saved for each analysis are presented in Table 2. As shown in Table 2, the computation cost saved when integration steps are equal to $4 f \Delta t$ is 77.65 percent with a negligible loss of accuracy (see Figures 5-6). The obtained results clearly display that the recently proposed technique can be successful in time integration of silos structural system.

Figure 4. The earthquake excitation.

Type of analysis	Computation time (sec)	Computation cost saved (%)
Integration steps equal to $f \Delta t$ (conventional)	1383	-----
Integration steps equal to $2 f \Delta t$	716	48.22
Integration steps equal to $3 f \Delta t$	468	66.16
Integration steps equal to $4 f \Delta t$	309	77.65

Figure 6. Comparison between top displacement time histories for different values of n .

4 CONCLUSIONS

In this paper, the performance of a new technique recently proposed for decreasing the computational cost of time integration analysis is investigated in the case of seismic analysis of a steel silo. The results show that using the new technique leads to significant computational cost reduction with negligible loss of accuracy. Further study in this regard, especially with different silos, different strong motion records and different integration methods is recommended.

ACKNOWLEDGMENTS

We happily acknowledge Dr Aram Soroushian for his useful guides and generating the digitized excitations for us.

ERROR ESTIMATION AND IMPROVEMENT OF CONVERGENCE OF A TIME STEPPING ALGORITHM BASED ON A FINITE ELEMENT APPROACH IN TIME

Keywords: Finite Element Method, Betsch-Method, Time Stepping Algorithm, Convergence.

Abstract. *In seismic engineering either a modal analysis (based on the response spectra method) or a time history analysis may be performed. The response spectra method usually over-estimates the dynamic reactions of the structure. Therefore, the time history analysis is more appropriate if realistic results shall be obtained. In time history analysis the convergence of the times stepping algorithm that is used is of key importance.*

In the current paper an error estimation is performed for a time stepping algorithm based on a Finite Element approach in time (the so-called Betsch method, see [1] and [2]). The convergence rate of the time stepping algorithm is derived analytically and proofed numerically for different polynomial degrees of the shape functions. In order to increase the convergence rate a 3-step algorithm according to Tarnow [6] is implemented into the Betsch method. This allows high accurate results even when large time steps and only linear shape functions are used.

1 INTRODUCTION

The Finite Element Method is an approximation method. Hereby the accuracy of the results depends on the discretization (i.e. the number of elements used) and the quality of the elements (i.e. the polynomial degree of the shape functions). When the accuracy of the results is insufficient, the user has two methods to improve the accuracy: He can either increase the number of elements (h-method) or he can use elements with shape functions of higher polynomial degree (p-method).

The Finite Element method is not limited to a spacial discretization. It is also possible to derive a time stepping algorithm that is based on a Finite Element Approach in time, see [2]. Then the h-method means smaller time steps. The p-method is often not possible, because in most commercial Finite Element programs only very few time stepping algorithms are implemented and time stepping algorithms based on approaches of high polynomial degree are rarely available.

In the current contribution a third possibility to increase the accuracy of the solution is introduced: A 3-step algorithm according to Tarnow [6] is described. Hereby the step size is chosen in a way, that the errors of first and second order are eliminated and the method has the same order of convergence as if elements with quadratic shape functions were used.

2 ABBREVIATIONS AND NOMENCLATURE

e	Error
h_n	Time step size
p	Generalized momentum
q	Generalized displacement
t	Time
F	Force
H	Hamiltonian function of total energy
M_I	Shape function
M	Mass matrix
α	Local coordinate $0 \leq \alpha \leq 1$

3 TIME STEPPING ALGORITHM

The time stepping algorithm that is presented in this section goes back to an idea of Betsch and is described in detail in [1] and [2]. In this section a brief summary of the Betsch method is given.

The basis for the time stepping algorithm is formed by Hamilton's equations of motion:

$$\begin{aligned}\frac{\partial H}{\partial \mathbf{p}} - \dot{\mathbf{q}} &= \mathbf{0} \\ \frac{\partial H}{\partial \mathbf{q}} + \dot{\mathbf{p}} &= \mathbf{0}\end{aligned}\tag{1}$$

These equations can be transferred into the variational form either by multiplication with test functions and integration over the time domain or by formal variation of the Lagrangian function. Both methods lead to

$$\int_0^T \left(\frac{\partial H}{\partial \mathbf{p}} - \dot{\mathbf{q}} \right) \cdot \delta \mathbf{p} - \left(\frac{\partial H}{\partial \mathbf{q}} + \dot{\mathbf{p}} \right) \cdot \delta \mathbf{q} \, dt = 0 \quad (2)$$

Now the time domain is subdivided into time steps of size $h_n = t_{n+1} - t_n$ and the abbreviation $\alpha = (t - t_n)/h_n$ is introduced. The local coordinate α is 0 at the beginning of each time step and 1 at the end of each time step. The generalized coordinate \mathbf{q} and the momentum \mathbf{p} are interpolated with the functions M_I of polynomial degree k , which are continuous at the element borders:

$$\begin{aligned} \mathbf{q}^h(\alpha) &= \sum_{I=1}^{k+1} M_I(\alpha) \mathbf{q}_I \\ \mathbf{p}^h(\alpha) &= \sum_{I=1}^{k+1} M_I(\alpha) \mathbf{p}_I \end{aligned} \quad (3)$$

The same is done for the virtual generalized coordinate $\delta \mathbf{q}$ and the virtual generalized momentum $\delta \mathbf{p}$. Hereby shape functions of polynomial degree $(k-1)$ are used, which are discontinuous at the element borders:

$$\begin{aligned} \delta \mathbf{q}^h(\alpha) &= \sum_{I=1}^k \tilde{M}_I(\alpha) \delta \mathbf{q}_I \\ \delta \mathbf{p}^h(\alpha) &= \sum_{I=1}^k \tilde{M}_I(\alpha) \delta \mathbf{p}_I \end{aligned} \quad (4)$$

The time derivatives of \mathbf{q} and \mathbf{p} can be expressed by the derivatives of the shape functions M_I :

$$\begin{aligned} \dot{\mathbf{q}}(\alpha) &= \frac{1}{h_n} \sum_{I=1}^k \frac{dM_I(\alpha)}{d\alpha} \mathbf{q}_I = \sum_{I=1}^k \tilde{M}_I(\alpha) \cdot \tilde{\mathbf{q}}_I \\ \dot{\mathbf{p}}(\alpha) &= \frac{1}{h_n} \sum_{I=1}^k \frac{dM_I(\alpha)}{d\alpha} \mathbf{p}_I = \sum_{I=1}^k \tilde{M}_I(\alpha) \cdot \tilde{\mathbf{p}}_I \end{aligned} \quad (5)$$

As the polynomial degree decreases by derivation for the time derivatives of \mathbf{q} and \mathbf{p} the virtual functions \tilde{M} of polynomial degree $(k-1)$ can be used. Inserting this into the variational form of Hamilton's equations leads to

$$\begin{aligned} \sum_{l=1}^k \delta \mathbf{p}_l^T \left(\sum_{J=1}^k \int_0^1 \tilde{M}_J \tilde{M}_l d\alpha \tilde{\mathbf{q}}_J - h_n \sum_{J=1}^{k+1} \mathbf{M}^{-1} \int_0^1 M_J \tilde{M}_l d\alpha \mathbf{p}_J \right) &= 0 \\ \sum_{l=1}^k \delta \mathbf{q}_l^T \left(\sum_{J=1}^k \int_0^1 \tilde{M}_J \tilde{M}_l d\alpha \tilde{\mathbf{p}}_J + h_n \int_0^1 (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) \tilde{M}_l d\alpha \right) &= 0 \end{aligned} \quad (6)$$

For linear shape functions \mathbf{M}_I one obtains a residual equation that can be solved for the unknown vector \mathbf{q}_{n+1} :

$$\mathbf{R} = \frac{2}{h_n} \mathbf{M} (\mathbf{q}_{n+1} - \mathbf{q}_n) - 2\mathbf{p}_n + h_n \int_0^1 (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha = \mathbf{0} \quad (7)$$

For quadratic shape functions \mathbf{M}_I one obtains

$$\mathbf{R} = \begin{bmatrix} \frac{1}{h_n} \mathbf{M} (-\mathbf{q}_n + \mathbf{q}_{n+1}) - \mathbf{p}_n + h_n \int_0^1 (1-\alpha) (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha \\ \frac{1}{h_n} \mathbf{M} (5\mathbf{q}_n - 8\mathbf{q}_{n+\frac{1}{2}} + 3\mathbf{q}_{n+1}) + \mathbf{p}_n + h_n \int_0^1 \alpha (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha \end{bmatrix} = \mathbf{0} \quad (8)$$

And for cubic shape functions one obtains

$$\mathbf{R} = \begin{bmatrix} \frac{1}{h_n} \mathbf{M} \left(-\frac{5}{2} \mathbf{q}_n + \frac{3}{2} \mathbf{q}_{n+\frac{1}{3}} + \frac{3}{2} \mathbf{q}_{n+\frac{2}{3}} - \frac{1}{2} \mathbf{q}_{n+1} \right) - \mathbf{p}_n + h_n \int_0^1 (2\alpha^2 - 3\alpha + 1) (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha \\ \frac{1}{h_n} \mathbf{M} (3\mathbf{q}_n - 3\mathbf{q}_{n+\frac{1}{3}} - 3\mathbf{q}_{n+\frac{2}{3}} + 3\mathbf{q}_{n+1}) + h_n \int_0^1 (-4\alpha^2 + 4\alpha) (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha \\ \frac{1}{h_n} \mathbf{M} (-7\mathbf{q}_n + 15\mathbf{q}_{n+\frac{1}{3}} - 12\mathbf{q}_{n+\frac{2}{3}} + 4\mathbf{q}_{n+1}) - \mathbf{p}_n + h_n \int_0^1 (2\alpha^2 - \alpha) (\mathbf{F}_{\text{int}} - \mathbf{F}_{\text{ext}}) d\alpha \end{bmatrix} = \mathbf{0} \quad (9)$$

The procedure for shape functions of higher polynomial degree is described in [5].

4 THEORETICAL DERIVATION OF THE CONVERGENCY RATE

The Betsch algorithm described in section 3 can only be an approximation of an exact solution $\mathbf{q}^*(t)$. The exact solution $\mathbf{q}^*(t)$ can be developed into a Fourier series:

$$\begin{aligned}\mathbf{q}^*(t) &= \mathbf{q}^*(t_n) + \frac{\mathbf{q}^{*'}(t_n)}{1!}(t-t_n) + \frac{\mathbf{q}^{*''}(t_n)}{2!}(t-t_n)^2 + \dots \\ &= \sum_{i=0}^{\infty} \mathbf{a}_i (t-t_n)^i\end{aligned}\tag{10}$$

$$\text{with } \mathbf{a}_i = \frac{\mathbf{q}^{*(i)}(t_n)}{i!}$$

The solution $\mathbf{q}^h(t)$ is approximated by the shape functions M_I of polynomial degree k as described in section 3.

$$\mathbf{q}^h(t) = \sum_{I=1}^{k+1} M_I \mathbf{q}_I\tag{11}$$

When both expressions are compared it is found that the exact solution $\mathbf{q}^*(t)$ contains all terms with polynomial degree $i \geq 0$. However, the approximation $\mathbf{q}^h(t)$ does only contain terms with polynomial degree $0 \leq I \leq k$.

Therefore the difference between the exact solution $\mathbf{q}^*(t)$ and the approximation $\mathbf{q}^h(t)$ is of order $(t-t_n)^{k+1}$:

$$\|\mathbf{q}^*(t) - \mathbf{q}^h(t)\| \sim (t-t_0)^{k+1}\tag{12}$$

Hereby the term $(t-t_0)$ is limited by the time step size h_n .

The error e can also be written as a product of an (unknown) coefficient C and the time step size h_n with exponent $(k+1)$:

$$e = \|\mathbf{q}^*(t) - \mathbf{q}^h(t)\| = C \cdot h_n^{k+1}\tag{13}$$

Normally the error is displayed in a diagram with double-logarithmic axes. Then the equation describes a straight line with slope $(k+1)$:

$$\log e = \log C + (k+1) \cdot \log h_n\tag{14}$$

However, when the error is evaluated only in the nodes (i.e. at the end of each time step and not within each time step), the slope of the convergence line is $(2k)$ instead of $(k+1)$. A detailed proof can be found in [4].

5 NUMERICAL DERIVATION OF THE CONVERGENCY RATE

The convergence rate can also be calculated numerically. Therefore the “accurate” solution is calculated with the algorithm explained in section 3 with a very small size of time steps. Then the error is negligibly small, so that this displacement-time process may be used as a reference solution $\mathbf{q}^*(t)$.

The diagram in Figure 1 shows the displacement-time process for the reference solution \mathbf{q}^* (continuous line) and for an approximation \mathbf{q}^h with time step size $h_n=0.5s$ (dashed line).

Figure 1: Displacement time process for reference solution \mathbf{q}^* (continuous line) and for the approximation \mathbf{q}^h (dashed line)

During the first seconds both solutions are almost identical. But with the time both solutions are drifting apart. After about 24s the reference solution \mathbf{q}^* and the approximation \mathbf{q}^h are out of phase.

The error can be calculated as the sum of the differences between the reference solution \mathbf{q}^* and the approximation \mathbf{q}^h over the investigated time domain:

$$\|e\|_{L_2} = \left(\sum_i (q_i^h - q_i^*)^2 \cdot \Delta t_i \right)^{\frac{1}{2}} \quad (15)$$

Hereby the time interval Δt can either be equal to the time step size h_n (when the error is evaluated only in the nodes, i.e. at the end of each time step) or the time interval Δt can be less than the time step size h_n (when the error is evaluated also within each time step).

The couple of time step size h_n and error e gives one particular point of the convergence line in Figure 2. When the displacement-time process is calculated with other time step sizes and the error is evaluated for each of these calculations more points of the convergence line

are obtained and a trend of the convergence line can be found. This has already been proofed in [1].

Figure 2: Convergence line

For very small time step sizes (in this particular case $h_n < 0.01s$) the convergence line tends to the horizontal. Here the accuracy of the computer is reached because the calculations are performed only with a fixed number of digits. A further reduction of the time step size does not result in a more accurate solution.

5.1 Linear Shape Functions

For linear shape functions one obtains the convergence lines displayed in Figure 3. The left diagram is obtained when the error is evaluated only in the nodes (i.e. at the end of each time step). The slope of the convergence line is $(2k)=2$.

The right diagram is obtained when the error is evaluated also within the time steps. Hereby the displacement within the time steps is approximated with the shape functions M_I . Then the slope of the convergence line is $(k+1)=2$. This has already been proofed in [1]. Both findings confirm the theoretical considerations from section 4.

Figure 3: Convergence for linear shape functions
(left diagram: error evaluation only in the nodes, right diagram: error evaluation also between the nodes)

5.2 Quadratic Shape Functions

For quadratic shape functions one obtains the convergence lines displayed in Figure 4. Again, the left diagram shows the convergence line when the error is evaluated only in the nodes. This gives a slope of the convergence line of $(2k)=4$.

The right diagram shows the convergence line when the error is evaluated also between the nodes. In this case, the slope of the convergence line is $(k+1)=3$. The lower slope of the convergence line (3 instead of 4) is only due to a different definition of the error evaluation. Of course, the results in the nodes are of the same accuracy in both cases.

Figure 4: Convergence for quadratic shape functions
(left diagram: error evaluation only in the nodes, right diagram: error evaluation also between the nodes)

5.3 Cubic Shape Functions

The convergence lines for cubic shape functions are displayed in Figure 5. In the left diagram (evaluation of the error only in the nodes) the slope of the convergence line is $(2k)=6$ while the slope of the convergence line in the right diagram (evaluation of the error also between the nodes) is $(k+1)=4$.

Figure 5: Convergence for cubic shape functions
(left diagram: error evaluation only in the nodes, right diagram: error evaluation also between the nodes)

6 3-STEP-METHOD FOR IMPROVEMENT OF THE CONVERGENCY RATE

As seen in the last section, it is high effort to obtain relatively accurate results. Either the time step size has to be reduced significantly (leading to high computational costs) or the polynomial degree of the shape functions has to be increased (often these high sophisticated algorithms are not available). Therefore a method would be desirable that gives high accurate results with relatively large time steps, although using linear shape functions. This goal can be reached by implementing the Tarnow method (see [6] and [7]) into the above described time stepping algorithm of Betsch. The procedure of the 3-step algorithm according to Tarnow is as follows:

- The values at time t_n are known from the previous time step. The values at time t_{n+1} shall be calculated. The Tarnow method does not calculate these values directly. Instead, the values at time $t_{n+\alpha}$ are calculated in a first step. The values are not accurate, they include an error of second order, third order and higher order because linear shape functions are used.
- In a second step, the values at time $t_{n+1-\alpha}$ are calculated based on the results at time $t_{n+\alpha}$. Again, the results include an error of second order, third order and higher order.
- In a third step, the values at time t_{n+1} are calculated based on the results at time $t_{n+1-\alpha}$. In this step the errors are again of second order, third order and higher order.

The parameter α can now be chosen in a way that the errors of second order and third order are compensated in the intermediate steps and only an error of forth and higher order remains. This is the case when the parameter α is chosen to 1.3512. A detailed proof of this method can be found in [6].

Figure 6: 3-step algorithm according to Tarnow

The above described Tarnow method has now been implemented into the time stepping algorithm of Betsch. Figure 7 shows the results when the Betsch algorithm is used with linear shape functions and the 3-step algorithm. The results are of 4th order accurate, therefore the slope of the convergence line is 4. So the same accuracy is reached as for a 1-step algorithm with quadratic shape functions.

Figure 7: Convergence for linear shape functions with 3-step algorithm

7 SUMMARY

The convergence rate of the Betsch method depends on the polynomial degree of the shape functions. For linear shape functions a convergence rate of 2 was found. When the 3 step algorithm according to Tarnow is implemented into the Betsch method, the convergence rate is increased from 2 to 4. This allows high quality results, even when only linear shape functions and large time steps are used.

Key words: Time History Analysis, Base shear, Base moment, Required calculation time

Abstract. *To increase the tendency of practicing engineers, engaged in the seismic design and evaluation of structural systems, to performing dynamic or Time History Analyses (THA) one way is reducing the volume of data, engaged in THA, and therefore, the volume of dynamic calculations. This would increase the computational efficiency in seismic structural analyses. One way for reducing the volume of input data and the corresponding output and information is the physical simplification of Multi-Degree-Of-Freedom (MDOF) systems, so that instead of working with $n \times n$ matrices, resulted from the n -Degree-Of-Freedom system, the engineer works with $n_r \times n_r$ matrices ($n_r \ll n$), belonging to a physically simplified system which has n_r degrees of freedom. For multi-story shear beam type buildings finding the equivalent simplified system is not very difficult. In fact, it is possible to introduce for a multi-story building an equivalent building with the same overall height, but having fewer number of stories with the same story mass while the stories' heights are more so that their stiffness values are less and the proportion of stiffness and mass of the original building is kept in the simplified model. In this way the modal frequencies of the reduced model will be correspondingly equal to the first few modal frequencies of the original building. However, the amount of base shear force and base moment of the reduced model will be less than that of the original building, and will be related to them by some specific factors which are functions of the ratio of number of stories of the original building and the reduced model. Several examples of response time histories calculated for a series of multi-story buildings and their simplified reduced models, obtained by using the proposed method, show that by using the proposed simplification technique the volume of elaborations needed for THA of building systems are reduced drastically. The amount of reduction in the 'required calculation time', and also the achieved level of precision in response values both depend on the number of stories of the original building and the ratio of number of stories of the original building and the reduced model.*

1 INTRODUCTION

The tendency of practicing engineers, engaged in seismic design and evaluation of structural systems, to performing dynamic or Time History Analysis (THA) of structures is very little. The main reason behind this fact is the very large volume of elaborations and computational materials required in THA of structures. These include the several time steps in which the response values should be calculated on the one hand, which make the calculations very time consuming, and the input, and particularly output data required for evaluation, on the other hand, which requires a large storage volume in the computer for saving and handling the data. On this basis, if the volume of data, engaged in THA, is reduced by some way it would be very useful for increasing the computational efficiency in seismic structural analyses.

Since mid 80s some researchers have tried to present simple dynamic or pseudo-dynamic analysis methods for this purpose. Cruz and Chopra (1986) have presented some simplified procedures for earthquake analysis of buildings [1]. Lai and his colleagues (1992) have also proposed a simplified analysis method for evaluation of earthquake actions and their distribution on regular high-rise buildings [2]. They have considered shear type, shear-bending type and bending type regular high-rise buildings and have used the modal analysis through response spectrum procedure and lumped mass story models. Wilkinson and Thambiratnam (2001) have also proposed a simplified procedure for seismic analysis of asymmetric buildings [3]. Their method is based on modification of the shear beam model, and has been applied to treat the seismic analysis of asymmetric buildings, as well. Their three dimensional procedure accounts for torsional coupling and the bending rotations at beam-column junctions and it can be used with a personal computer to give fast and reasonably accurate results, which compare well with those from comprehensive finite element analysis. They have claimed that their procedure is useful for preliminary seismic analysis and design of buildings.

In 2005 Miranda has proposed a simplified building response analysis for rapid seismic performance evaluation of existing buildings [4]. His simplified seismic analysis tool uses a continuum model consisting of a flexural beam coupled with a shear beam. Expressing that the earthquake response of many buildings can be estimated by considering only the first two vibration modes in the response spectrum analysis (RSA) procedure, Miranda has presented a simplified response spectrum analysis (SRSA) procedure, which provides very similar estimates of design forces for many buildings. With the development of the SRSA, a hierarchy of four analysis procedures to determine the earthquake forces are available to the building designer: code-type procedure, SRSA, RSA, and RHA (response history analysis). Miranda claims that the criteria presented to evaluate the results from each procedure and to decide whether it is necessary to improve results by proceeding to the next procedure in the hierarchy use all the preceding computations and are, therefore, convenient

An alternative way for reducing the volume of input data and output and information is the physical simplification of Multi-Degree-Of-Freedom (MDOF) systems, so that instead of working with $n \times n$ matrices, resulted from the n -Degree-Of-Freedom system, the engineer works with $n_r \times n_r$ matrices ($n_r < n$), belonging to a physically simplified system which has n_r degrees of freedom. Details of this method are presented in the next section of the paper for shear beam type buildings.

2 PHYSICAL SIMPLIFICATION OF SHEAR BUILDINGS

The main idea for this physical simplification is finding an appropriate reduced n_r -Degree-Of-Freedom system for the original n -Degree-Of-Freedom system in such a way that the modal frequencies of the simplified system are correspondingly equal to the first n_r frequencies (the lower modes) of the original system. Obviously, this can be achieved by adjusting

the amount of stiffness and mass in various parts of the simplified system. In this way the modal frequencies of the reduced model will be correspondingly equal to the first n_r modal frequencies of the original building. However, the amounts of base shear force and also base moment of the reduced model will be less than that of the original building, and related to them by some specific factors which are functions of n/n_r ratio and story mass and height in both original and simplified models of building.

For multi-story shear beam type buildings finding the equivalent simplified system is not very difficult. In fact, it is possible to introduce an n_r -story building with the same height and story mass as the original n -story building, in which the stiffness values of the stories have been decreased in a specific way to keep the existing proportionality of stiffness and mass of the original n -story building. For this purpose, it is enough to consider the stories with the same story mass m of the original building just in every other story level, or every other two, three, four story level, and so on, while keeping the rotation restraints imposed to columns at story levels.

a) The original 12-story bldg b) Simplified 6-story bldg c) Simplified 4-story bldg d) Simplified 3-story bldg

Figure 1: Physical simplification of a 12-story building (a) with total mass of $12m$ to: b) a 6-story building with total mass of $6m$, c) a 4-story building with total mass of $4m$, and d) a 3-story building with total mass of $3m$

In this way the stiffness of each column in the simplified model of the building, which the height of $2h$ (h being the story height), $3h$, $4h$ and so on, depending on the number of deleted stories, will be obtained based on the formula of springs in series, that is:

$$\frac{1}{k_{eq}} = \frac{1}{k_1} + \frac{1}{k_2} + \frac{1}{k_3} + \dots \quad (1)$$

where k_{eq} is the stiffness of the equivalent column in the simplified model of the building, and k_1, k_2, k_3 and so on are the stiffness values of the successive columns in one vertical line. Considering the same stiffness value of k for the successive columns, Equation (1) leads to a value of $k/2, k/3, k/4$ and so on, corresponding to deletion of, respectively, every other one story, every other two, three, four stories, and so on, as shown in Figure 1.

As shown in Figure 1, the original building (a) has a total mass of $12m$, while in case (b) the simplified model has a mass of $6m$, which is as half of the original building, and proportionally the stiffness of stories is $k/2$. In cases (c) and (d) the total mass of the simplified model is, respectively, $1/3^{rd}$ and $1/4^{th}$ of the original building, and accordingly the stiffness of stories in these two cases is, respectively, $1/3^{rd}$ and $1/4^{th}$ of the original building as well.

Based on this logic, the modal frequencies of the reduced model of an n -story building will be correspondingly equal to the first n_r modal frequencies of the original building. However, the amounts of base shear force and base moment of the simplified model, subjected to any accelerogram of a horizontal component of an earthquake ground motion, will be obviously less than that of the original building, due to the lower mass of the simplified model. Paying attention to the ratios between the masses and story heights of the simplified model and the original building, in case of buildings with the same story masses and equal story heights, the modification factors for the base shear force and the base moment, by which the values obtained for the simplified model should be multiplied, to give the values of base force and base moment of the original building, are respectively:

$$\text{Base Shear Modification Factor} = \frac{n}{n_r} \quad (2)$$

and

$$\text{Base Moment Modification Factor} = \frac{\sum_i^n H_i}{\sum_j^{n_r} H_j} \quad (3)$$

where H_i and H_j are height of, respectively, the i^{th} floor of the original building, and the j^{th} floor of the simplified model above foundation level. For buildings with unequal story masses and heights the given modification factors will have some errors. However, the amount of error will not be remarkable for most of actual cases, as shown in the next section, in which some numerical examples are presented.

3 NUMERICAL EXAMPLES

Several examples of response time histories calculated for a series of multi-story buildings and their simplified (reduced) models, obtained by using the proposed method have been worked out, of which some are presented in this section of the paper to show the efficiency of the proposed simplification technique. These examples include a 10-story building simplified as a 3-story model, a 21-story building, simplified once as a 3-story and once again as a 5-story model, a 40-story building, simplified as a 10-story model, and finally a 60-story building, simplified as a 15-story model. The original buildings have been assumed to be regular in both plan and elevation to avoid the torsion effects. The buildings have been designed by considering the drift limitation of the seismic design code, and therefore, their fundamental period values are close to the code value. Results of the 40-story and 60-story buildings are shown in this section. These results include the time histories of roof displacement, roof acceleration, base shear, and base moment of the original and the simplified buildings. Table 1

shows the modal periods of the original 40-story building and the simplified 10-story model for their first ten modes.

Table 1: Modal periods (in seconds) of the original 40-story building and its simplified 10-story model

Mode No.	40-Story Original Building	10-Story Simplified Building	Accuracy (%)
1	3.06	2.91	95
2	2.81	2.78	99
3	2.49	2.41	97
4	1.01	1.09	92
5	0.93	1.05	88
6	0.83	0.93	89
7	0.57	0.63	91
8	0.55	0.61	88
9	0.50	0.54	91
10	0.41	0.43	95

As it is seen in Table 1 the modal periods of the simplified model match very well with those of the original building. This shows that the proposed simplification technique has a very good precision. For the THA the accelerograms of two well-know earthquakes of Kobe (1996 - FUK090_AT2 Component) and El Centro (1940 - Imperial Valley Station, I-ELC180_AT2 Component) have been used, which have different frequency contents. Figures 2 to 5 respectively show the time histories of roof displacement, roof acceleration, base shear, and base moment of the original and the simplified buildings for the case of 40-story building subjected to Kobe accelerogram.

Figure 2: Roof displacement time histories of the original and simplified models for the case of 40-story building subjected to Kobe earthquake accelerogram

Figure 3: Roof acceleration time histories of the original and simplified models for the case of 40-story building subjected to Kobe earthquake accelerogram

Figure 4: Base shear force time histories of the original and simplified models for the case of 40-story building subjected to Kobe earthquake accelerogram

Figure 5: Base moment time histories of the original and simplified models for the case of 40-story building subjected to Kobe earthquake accelerogram

Figures 6 to 9 show the same four set of results of the 40-story building and its 10-story simplified model subjected to El Centro earthquake.

Figure 6: Roof displacement time histories of the original and simplified models for the case of 40-story building subjected to El Centro earthquake accelerogram

Figure 7: Roof acceleration time histories of the original and simplified models for the case of 40-story building subjected to El Centro earthquake accelerogram

Figure 8: Base shear time histories of original and simplified models for the case of 40-story building subjected to El Centro earthquake accelerogram

Figure 9: Base moment time histories of original and simplified models for the case of 40-story building subjected to El Centro earthquake accelerogram

Comparing Figure 2 with Figure 3 and also Figure 6 with Figure 7, it can be seen that the agreement between displacement time histories is better than that between acceleration time histories. The reason behind this fact is that the acceleration response is more sensitive than displacement response to high frequency excitations. Better agreement of results in case of El Centro earthquake than Kobe earthquake can be also due to the lower frequency content of El Centro earthquake. Table 2 compares the modal periods of the original 60-story building and its simplified 15-story model, which are again in good agreement .

Table 2: Modal periods (in seconds) of the original 60-story building and its simplified 15-story model

Mode No.	60-Story Original Building	15-Story Simplified Building	Accuracy (%)
1	4.30	4.17	97
2	3.98	3.95	99
3	3.22	2.78	86
4	1.42	1.47	97
5	1.33	1.40	94
6	1.12	1.11	98
7	0.81	0.83	97
8	0.77	0.80	95
9	0.66	0.65	98
10	0.56	0.55	100
11	0.53	0.54	99
12	0.46	0.45	96
13	0.41	0.40	96
14	0.40	0.39	98
15	0.35	0.33	94

Figures 10 to 13 show the four set of results of the 60-story building and its 15-story simplified model subjected to El Centro earthquake.

Figure 10: Roof displacement time histories of the original and simplified models for the case of 60-story building subjected to El Centro earthquake accelerogram

Figure 11: Roof acceleration time histories of the original and simplified models for the case of 60-story building subjected to El Centro earthquake accelerogram

Figure 12: Base shear time histories of original and simplified models for the case of 60-story building subjected to El Centro earthquake accelerogram

Figure 13: Base moment time histories of original and simplified models for the case of 60-story building subjected to El Centro earthquake accelerogram

Figures 10 to 13 show again that the proposed simplification technique leads to very satisfactory results, and therefore, it can be considered as a high efficiency method for THA of multi-story buildings.

4 CONCLUSIONS

Several examples of response time histories calculated for a series of multi-story buildings and their simplified reduced models, obtained by using the proposed method, show that:

- by using the proposed simplification technique the volume of elaborations needed for THA of building systems are reduced drastically.
- The amount of reduction in the ‘required calculation time’, and also the achieved level of precision in response values both depend on n and also the n/n_r ratio.
- By using a value of 4 or 5 for n/n_r ratio, the response values can be calculated with negligible error, while the required calculation time for THA is significantly reduced, particularly for buildings with larger number of stories.

Keywords: Earthquake, Oilindustrial Engineering, Marine Stationary Platform, Horizontal Seismic Loading, Beam Model, Tube-like Ferroconcrete Rod.

Abstract. *Dynamics of a marine stationary platform under action of the seismic loading is investigated. The structure consists of a tube-like ferroconcrete rod of variable cross-section. To describe the rod vibrations the beam-like model is used. The system of partial differential equation is reduced to the system with 6 degrees of freedom. Some numerical examples are studied. It is established that at design it is necessary to pay the main attention to the concrete strength when the extension deformations appear.*

INTRODUCTION

One of the possible structures of a marine stationary platform for the oil industrial engineering is studied. The platform consists of a tube-like ferroconcrete rod with the upper operating floor. This structure may be used for the depth of sea near 250 m. At the design of structure some external forces are to be taken into account. Among them there are the influence of a surface gravity waves, of a wind acting on the operating floor, of a water stream, and at last of an earthquake. For this structure the influence of surface waves is investigated in [1]. Here we study only the action of a horizontal seismic excitation and find the rod bending deformations. Peculiarity of this system is that its lowest natural frequency is much smaller than the typical frequency of the seismic excitation. That is why we seek the solution as a sum of 6 natural modes. For calculation we take not real, but model seismic impulse which allows us to find the dependence of rod vibrations on its frequency. The main result of this investigation is that at design it is necessary to pay the main attention to the concrete strength when the extension deformations appear.

1 MATHEMATICAL MODEL OF PLATFORM

The structure consists of a tube-like ferroconcrete rod of variable cross-section. Below the rod is attached to the foundation which can move in the horizontal direction and rotate around the horizontal axis. The operating floor is attached above the rod. Vibrations in one plane are studied. The attached mass of water and the resistant force of water proportional to the square of the cross-section velocity are taken into account. It is assumed that the water is stationary, influence of the surface waves and of the stream is ignored. The seismic load is horizontal, and the ground acceleration $a(t)$ is given as a function of time and in the limits of foundation it is not depend on the spatial co-ordinates. The mathematical model used here is described in [1], the difference is that instead the surface waves here the action of the seismic load is studied.

Figure 1: The structure diagram.

The foundation and the basic platform are supposed to be rigid bodies 0 and 1 (see Fig. 1), which are attached to the rod S . For the rod the beam model is accepted. Equation of the rod

bending in the movable co-ordinate system is

$$\frac{\partial^2 M}{\partial x^2} + \frac{\partial}{\partial x} \left(P(x) \frac{\partial u}{\partial x} \right) + \rho(x) \frac{\partial^2 u}{\partial t^2} = f(u, x, t), \quad (1.1)$$

where

$$M = J(x) \left(\kappa \psi(\kappa, x) + \frac{\beta_0}{\omega} \frac{\partial \kappa}{\partial t} \right), \quad \kappa = \frac{\partial^2 u}{\partial x^2}, \quad f = -\rho(x)a(t) - f_v. \quad (1.2)$$

Here $u(x, t)$ is the horizontal deflection of the rod cross-section x , $0 \leq x \leq H$, H is the rod height, M is the bending moment, κ is the curvature, J is the rod bending stiffness in linear approximation, f is the external load per unit length. The moment M is given with the account of the nonlinear visco-elastic properties of the cross-section materials. The function ψ is described in Section 2, in linear approximation $\psi = 1$. In (1.2) β_0 is the dimensionless resistant coefficient, ω is the typical frequency.

The water resistance force per unit length is denoted as f_v and it is equal to

$$f_v = C_v \gamma_w R(x) v |v|, \quad v = \frac{\partial u}{\partial t} + v_0, \quad v_0(t) = \int_0^t a(t) dt, \quad (1.3)$$

where C_v is the dimensionless coefficient, γ_w is the water density, $R(x)$ is the cross-section diameter.

In (1.1) $P(x)$ is the axial compressing force

$$P(x) = \left(m_1 + m_s - \int_0^x \rho_s(x) dx \right) g, \quad m_s = \int_0^H \rho_s(x) dx, \quad (1.4)$$

where m_1 and m_s are the masses of the body I and of the rod, $\rho_s(x)$ is the rod density per unit length, $g = 9.81 \text{ (m c}^{-2}\text{)}$ is the gravity acceleration

$$\rho(x) = \rho_s(x) + \xi(x) \rho_w(x), \quad \rho_w(x) = \pi R^2(x) \gamma_w, \quad (1.5)$$

$\rho_w(x)$ is the density of the additional mass of water, and $\xi(x) = 1$ at $x < H_1$, $\xi(x) = 0$ at $x > H_1$, $H_1 < H$ is the depth of water.

The boundary conditions at the bottom $x = 0$ and at the upper end $x = H$ are the motion equations of the bodies O and I

$$\begin{aligned} m_0 \left(\frac{d^2 u_0}{dt^2} + a \right) &= - \frac{dM}{dx} \Big|_{x=0} - P(0) \varphi(0) + F_0, \quad u_0 = u(0) - h_0 \varphi(0), \\ J_0 \frac{d^2 \varphi(0)}{dt^2} &= M(0, t) - h_0 \frac{dM}{dx} \Big|_{x=0} + L_0 + (h_0 - h_*) F_0, \\ m_1 \left(\frac{d^2 u_1}{dt^2} + a \right) &= \frac{dM}{dx} \Big|_{x=H} + P(H) \varphi(H), \quad u_1 = u(H) + h_1 \varphi(H), \\ J_1 \frac{d^2 \varphi(H)}{dt^2} &= -M(H) + h_1 \frac{dM}{dx} \Big|_{x=H}, \quad \varphi = \frac{\partial u}{\partial x}, \end{aligned} \quad (1.6)$$

where m_0 , m_1 are the bodies masses, J_0 , J_1 are the central inertia moments, h_0 , h_1 are the distances to the mass centers (see Fig. 1) of the bodies O and I respectively.

The non-linear force F_0 and moment L_0 of the ground and the foundation interaction are accepted as [2]

$$\begin{aligned} F_0 &= -c_u u_* \phi_u(u_*) - \frac{\beta_u c_u}{\omega} \dot{u}_*, \quad u_* = u(0) - h_* \varphi(0), \\ L_0 &= -c_\varphi \varphi_0 \phi_\varphi(\varphi(0)) - \frac{\beta_\varphi c_\varphi}{\omega} \dot{\varphi}(0), \\ \phi_u &= \left(1 + \left|\frac{u}{u_{cr}}\right|^{m_u}\right)^{-1/m_u}, \quad \phi_\varphi = \left(1 + \left|\frac{\varphi}{\varphi_{cr}}\right|^{m_\varphi}\right)^{-1/m_\varphi}, \end{aligned} \quad (1.7)$$

where h_* is the distance to the force horizontal center of the ground and the foundation interaction, parameters $c_u, c_\varphi, \beta_u, \beta_\varphi, m_u, m_\varphi, u_{cr}, \varphi_{cr}$ are to be given. In linear approximation $\phi_u = \phi_\varphi = 1$. The second summands in relations (1.7) take into account the visco-elastic ground properties.

2 THE BENDING ROD STIFFNESS

The rod is the three layered ferroconcrete tube with the variable cross-section (see Fig. 2). The outer layers $r_1 \leq r \leq r_2$ $r_3 \leq r \leq r_4 = R$ are steel, and the middle layer $r_2 \leq r \leq r_3$ is concrete.

$$r_k(x) = r_{k0} - bx, \quad k = 1, 2, 3, 4, \quad b = \frac{R_0 - R_1}{H}, \quad (2.1)$$

where r_{k0} are the layers radii at $x = 0$, R_0 and R_1 are the radii of lower and upper tube cross-sections.

Figure 2: The three layered tube cross-section.

We accept the following dependences between stresses σ and strains ε (in the vertical direction neglecting the other stresses and strains):
for the steel

$$\sigma = E_s \begin{cases} -\varepsilon_s & \text{at } \varepsilon < -\varepsilon_s, \\ \varepsilon & \text{at } |\varepsilon| \leq \varepsilon_s, \\ \varepsilon_s & \text{at } \varepsilon > \varepsilon_s, \end{cases} \quad \sigma_s = E_s \varepsilon_s \quad (2.2)$$

and for the concrete

$$\sigma = E_c \begin{cases} -\varepsilon_c & \text{at } \varepsilon < -\varepsilon_c, \\ \varepsilon & \text{at } -\varepsilon_c \leq \varepsilon \leq 0, \\ 0 & \text{at } \varepsilon > 0, \end{cases} \quad \sigma_c = E_c \varepsilon_c. \quad (2.3)$$

Here E_s , E_c are the Young modules for steel and for concrete, ε_s is the yield limit of steel which is accepted identical at extension and at compression, ε_c is the flowing limit for concrete at compression. Relations (2.2) and (2.3) correspond to the Prandtl model, and relation (2.3) fixes the assumption that the concrete does not resist the extension. In the linear approximation the both materials are linearly elastic ones, and for the steel $\sigma = E_s \varepsilon$ and for the concrete $\sigma = E_c \varepsilon$.

The rod cross-section x is compressed by the axial force P and let the curvature $\kappa(x)$ is given. Our aim is to find the dependence between the bending moment M and the curvature κ . It is supposed that the hypothesis about the plane cross-sections is fulfilled. According to this hypothesis the deformation ε of the fibre lying at the distance z from the cross-section diameter is equal

$$\varepsilon(r, \varphi) = \varepsilon_0 + \kappa z, \quad z = r \cos \varphi. \quad (2.4)$$

In the linear approximation

$$\begin{aligned} P &= -K\varepsilon_0, & K &= \pi (E_s(r_2^2 - r_1^2) + E_c(r_3^2 - r_2^2) + E_s(r_4^2 - r_3^2)), \\ M &= J\kappa, & J &= \frac{\pi}{4} (E_s(r_2^4 - r_1^4) + E_c(r_3^4 - r_2^4) + E_s(r_4^4 - r_3^4)). \end{aligned} \quad (2.5)$$

Due to the compression $P > 0$ we get $\varepsilon_0 < 0$, therefore for the small enough curvature κ the linear relations (2.5) are valid. At

$$|\kappa| > \kappa_* = \min \left\{ \frac{\varepsilon_0 + \varepsilon_s}{r_4}, \frac{\varepsilon_0 + \varepsilon_c}{r_3}, \frac{-\varepsilon_0}{r_3} \right\} \quad (2.6)$$

one or the both materials become as the nonlinear ones and the relations (2.5) are to be corrected.

$$P = \int \sigma(r, \varphi, \varepsilon_0) r dr d\varphi, \quad M = \int \sigma(r, \varphi, \varepsilon_0) r^2 \cos \varphi dr d\varphi, \quad (2.7)$$

where the integration is fulfilled on the circular area occupied by materials, and the stress $\sigma(r, \varphi, \varepsilon_0)$ is calculated by the relation (2.2) or (2.3). If the curvature κ and the compressing force P are given then by the first relation (2.7) we find the deformation ε_0 , and then by the second relation (2.7) we calculate the moment M . Therefore the function $\psi(\kappa) = M/(J\kappa)$ is build.

3 THE MODEL OF THE GROUND ACCELERATION AT THE EARTHQUAKE

For the analytical description of the acceleration $a(t)$ we use the relation

$$a(t) = At^2 e^{-\alpha t} \sin(\nu t + \theta). \quad (3.1)$$

It is necessary to put the following restriction on the function $a(t)$

$$\int_0^\infty a(t) dt = 0, \quad (3.2)$$

because in the opposite case the ground will move after the seismic impulse is finished. For the function (3.1) the relation (3.2) is fulfilled if

$$\alpha(3\nu^2 - \alpha^2) \sin \theta + \nu(\nu^2 - 3\alpha^2) \cos \theta = 0. \quad (3.3)$$

In Fig. 3 the impulse with the parameters $A = 0.295$, $\alpha = 0.4$, $\nu = 10$ is shown (the value θ is to be found from the equation (3.3)).

Figure 3: The seismic impulse.

4 THE APPROXIMATE SOLUTION OF THE EQUATION (1.1)

In Sections 1–3 the problem is formulated. We seek its solution satisfying to the initial condition $u(x, 0) = 0$ as a partial sum of the Fourier series of eigen functions $U_k(x)$ of the linear boundary value problem

$$u(x, t) = \sum_{k=1}^K U_k(x) q_k(t). \quad (4.1)$$

The boundary value problem for natural modes $U_k(x)$ and for the corresponding natural frequencies ω_k is to be obtained from equation (1.1) and boundary conditions (1.6) after replacements

$$\frac{\partial^2}{\partial t^2} = -\omega^2, \quad f = a = \beta_0 = \beta_u = \beta_\varphi = 0, \quad \psi = \phi_u = \phi_\varphi = 1. \quad (4.2)$$

For $\omega_k \neq \omega_n$ the natural modes satisfy to the orthogonality condition

$$\int_0^H \rho U_k U_n dx + m_0 U_{k0} U_{n0} + J_0 U'_k(0) U'_n(0) + m_1 U_{k1} U_{n1} + J_1 U'_k(H) U'_n(H) = 0, \quad (4.3)$$

Where by the trait the derivative with respect to x is denoted.

At $n = k$ the left side of the equality (4.3) gives the equivalent mass M_k corresponding to the k^{th} natural mode

$$M_k = \int_0^H \rho U_k^2 dx + m_0 U_{k0}^2 + J_0 (U'_k(0))^2 + m_1 U_{k1}^2 + J_1 (U'_k(H))^2. \quad (4.4)$$

To construct the equations for unknowns $q_k(t)$ in (4.1) we use the Bubnov–Galerkin method according which the work of active forces and of inertia forces on the displacement $U_k(x)$ is equal to zero. As a result we get

$$M_k (\ddot{q}_k + \beta_k \omega_k \dot{q}_k + \omega_k^2 q_k) + M_k^a a = Q_v + Q_s + Q_F, \quad k = 1, \dots, K. \quad (4.5)$$

whis

$$M_k^a = \int_0^H \rho U_k dx + m_0 U_{k0} + J_0 U'_k(0) + m_1 U_{k1} + J_1 U'_k(H). \quad (4.6)$$

By dots the derivatives with respect to time t are denoted. The summand $\beta_k \omega_k \dot{q}_k$ in (4.5) (β_k are the dimensionless resistant coefficients) takes into account the resistance of the k^{th} natural mode. Here we make the additional assumption that the decreases of various natural modes are not connected to each other. As Q_k^v , Q_k^s , Q_k^F we denote the nonlinear generalized forces which are connected with the resistance of water, with the plastic properties of the rod, and with the interaction forces between the foundation and the ground respectively

$$\begin{aligned} Q_k^v &= -\int_0^H C_v \gamma R(x) v |v| U_k(x) dx, \quad v = \int_0^t a(t) dt + \sum_{i=1}^K U_i(x) \dot{q}_i(t), \\ Q_k^s &= -\int_0^H J(x) (1 - \psi(\kappa)) U_k''(x) dx, \quad \kappa = \sum_{i=1}^K U_i''(x) \dot{q}_i(t), \\ Q_k^F &= c_u u_* (1 - \phi_u(u_*)) U_{k*} + c_\varphi u'(0) (1 - \phi_\varphi(u'(0))) U_k'(0), \\ u_* &= \sum_{i=1}^K (U_i(0) - h_* U_i'(0)) q_i(t), \quad U_{k*} = U_k(0) - h_* U_k'(0), \\ u'(0) &= \sum_{i=1}^K U_i(0) q_i(t). \end{aligned} \tag{4.7}$$

At $Q_v = Q_s = Q_F = 0$ the system (4.5) divides to K independent equations.

5 NUMERICAL RESULTS.

We fix the values of structure parameters and study the series of values of parameters of the seismic acceleration in (3.1).

We take the following parameters given in SI. The dimensions of structure and radii of the rod layers: $H_1 = 235$, $H = 250$, $r_{10} = 4.9$, $r_{20} = 4.95$, $r_{30} = 5.95$, $r_{40} = R_0 = 6$, $R_1 = 5$. The densities of water, steel, and concrete: $\gamma_w = 10^3$, $\gamma_s = 7.85 \cdot 10^3$, $\gamma_c = 2.2 \cdot 10^3$. The Young modules and the yield limits of steel and concrete: $E_s = 2.06 \cdot 10^{11}$, $E_c = 0.131 E_s$, $\varepsilon_s = 0.00134$, $\varepsilon_c = 1.16 \varepsilon_s$. The mass parameters and the distances to the mass centers of bodies 0 and 1: $m_s = 2.32 \cdot 10^7$, $m_0 = 10^7$, $m_1 = 10^7$, $J_0 = 15 m_0$, $J_1 = 10 m_1$, $h_0 = 3$, $h_1 = 3$. The foundation parameters: $c_u = 10^7$, $c_\varphi = 10^{12}$, $u_{cr} = 10$, $\varphi_{cr} = 0.1$, $m_u = 2$, $m_\varphi = 2$. The visco-elastic resistant parameters: $\beta_k = 0.1$, $k = 1, 2, 3, 4$. The resistant coefficient of motion in water $C_v = 2.2$.

We take $K = 6$. In Table 1 there are the first six natural frequencies ω_k , the corresponding periods, and the mass parameters M_k , M_k^a .

k	1	2	3	4	5	6
ω_k	0.256	0.688	3.117	8.158	15.89	26.39
T_k	24.56	9.15	2.02	0.77	0.40	0.24
$M_k \cdot 10^{-7}$	2.58	7.20	7.19	19.30	66.13	931.00
$M_k^a \cdot 10^{-7}$	1.32	-0.22	2.52	1.42	4.91	46.28
M_k^a / M_k	0.514	-0.031	0.351	0.074	0.071	0.050

Table 1: The natural frequencies and the mass parameters.

In the last line of Table 1 there is parameter M_k^a / M_k , which characterizes the level of the k^{th}

eigen mode excitation. We see that the modes with $k = 1$ and $k = 3$ are excited larger than the other ones.

We bound with the analysis of the seismic impulses of the form shown in Fig. 3 and change the maximal amplitude $A_{max} = \max_t |a(t)|$ and frequency ν . Then the parameters in (3.1) are $A = 0.295A_{max}$, $\alpha = 0.4$, and the parameter θ is to be found from (3.3).

We change the frequency ν of seismic impulse in the limits $0.5 \leq \nu \leq 30$ (1/c), and will increase A_{max} and fix the value, for which the rod material turns in the nonlinear area according the condition (2.6). Calculations show (see also Table 2) that in all studied cases the condition when the concrete is extended is critical. Such deformations are inadmissible from the point of view of the concrete strength.

Figure 4: The boundary of the parameters $(\nu$ (1/c), A_{max} (m/c²)) area, below which the concrete is compressed only.

In Fig. 4 the boundary of parameters area in the plane (ν, A_{max}) , upper which the concrete may be stretched. The more dangerous are impulses with the lower values of the frequency ν , which are not typical for the seismic ones. For seismic impulses the values $10 \leq \nu \leq 300$ [3]. Here the impulses with $\nu \leq 30$ are studied because for $\nu > 30$ the used beam model is doubtful.

k	ν	A_{max}^{k0}	$u^{k0}(H_1)$	A_{max}^{ks}	$u^{ks}(H_1)$	A_{max}^{kc}	$u^{kc}(H_1)$
1	10	6.7	0.06	18.1	0.24	24.4	0.28
2	15	1.3	0.01	14.4	0.07	14.9	0.08
3	20	8.6	0.02	23.7	0.07	33.3	0.10

Table 2: The amplitudes of transition in the nonlinear area of the rod deformations.

In Table 2 three values of ν are studied, and the values ν_1 and ν_3 correspond to the points of the relative maximum of the curve $A_{max}(\nu)$ (Fig. 3), and ν_2 corresponds to the minimal point. As A_{max}^k and $u^k(H_1)$ the maximal amplitude of the seismic impulse (in m/c²) and the maximal deflection of the upper body I (in m). Indexes 0, s, c correspond to appear extended deformations in concrete, to appear the yield of steel and to appear the yield of concrete at compression. It is clear that the values A_{max}^{ks} and A_{max}^{kc} are too large for seismic impulses. Therefore at design it is necessary to pay the main attention to the concrete strength.

6 CONCLUSIONS

In book [1] there is the investigation of the platform dynamics under action of surface gravity waves. In this problem the typical frequency of waves in some cases is close to the first natural frequency of structure. That is why it is possible in [1] to reduce the system to the single equation of the first order (with $K = 1$). At the seismic excitation the typical frequencies are much larger than the first natural frequency of structure. We take $K = 6$ but for $\nu > 30$ the exactness of the system (1.1) is not enough (see the values ω_k in Table 1) and it is desirable to use the more complex mathematical models of this structure.

Plans of the following investigation of this structure may consist in the complication of model by introducing the shear rod deformations. It is important in one side if we want to study the seismic excitations with the more high frequencies, and in the other side to take an attention that the concrete badly hold the shear stresses. Also it is necessary to study the vertical seismic excitation and the corresponding vertical vibrations of the rod. At last it is desirable to study the simultaneous action of the horizontal and the vertical seismic excitation and the interaction of the bending and the longitudinal rod vibrations.

Here we take the model seismic impulse. It seems that the real random seismic impulse with the same maximal amplitude leads to the smaller amplitude of the rod vibrations. Nevertheless it is desirable to study the structure reaction under action of the random seismic impulse with the given spectral density.

Key words: Multiple vertical baffles, Time history analysis, Neural network, Required calculation time

Abstract. *Sloshing is a well-known phenomenon in liquid storage tanks subjected to base or body motions. In recent years the use of baffles for reducing the sloshing effects in tanks subjected to earthquake has been studied by some researchers. However, the use of multiple baffles has not been taken into consideration so much. On the other hand, although some of the existing computer programs are capable to model sloshing phenomenon by acceptable accuracy, the full dynamic analysis subjected to random excitations such as earthquake induced motions is very time consuming, particularly when there are vertical and horizontal baffles inside the tank, which postpone the convergence of response calculations. Therefore, a simplified method for evaluation of sloshing effects in baffled tanks is desired. In this paper a method is presented for this purpose based on conducting several dynamic analysis cases, by using a powerful Finite Element (FE) method for rectangular tanks with various dimensions, subjected to both harmonic and seismic excitations, and then using neural network to create simple relationships between the dominant frequency and amplitude of the base excitations and the maximum level of liquid in the tank during the sloshing and also the maximum dynamic pressure on the tank wall. At first, the FE numerical modeling has been verified by using some existing experimental data. Then, dynamic analyses have been conducted to obtain the required numerical results for teaching the neural network. In the next stage, the neural network model has been developed. Finally, the predicted results of the neural network have been compared with those obtained by some other cases of analyses as control values, to make sure on the accuracy of the neural network model. The proposed simplified neural network model can be used also for finding the proper number and features of baffles for minimizing the sloshing effect on the tank for a group of given earthquakes, or other cases of base excitations.*

1 INTRODUCTION

One of the most important phenomena in fluid storage tanks, either buried, semi-buried, aboveground or elevated, is the oscillation of fluid due to the movements of the tank body, because of its base motions during an earthquake. Past earthquakes have shown that this phenomenon can result in sever damages to water storage tanks. To prevent tanks against sloshing induced damages, the use of baffles have been suggested and studied by some researchers since mid 60s [1], however, just few studies have been conducted on using baffles for reducing the earthquake induced sloshing effects.

As one of the first works in this regard Shaaban and Nash (1977) studied on response of partially filled liquid-storage circular cylindrical tank with or without an interior cylindrical baffle under seismic actions using Finite Element (FE) technique [2]. They worked on an elastic cylindrical liquid storage tank attached to a rigid base slab. Their studied tank was either empty or filled to an arbitrary depth with an in-viscid, incompressible liquid. They presented a FE analysis for both tank and liquid, to investigate the free vibration of the coupled system permitting determination of natural frequencies and associated mode shapes. They employed Sanders shell theory to express the strain-displacements relationship in the derivation of the shell FE. They determined the response of the tank to artificial earthquake excitation, and performed similar investigations with the addition of an elastic cylindrical perforated baffle to control the system natural frequencies.

In 1999 Gedikli and Ergüven worked on the seismic analysis of a liquid storage cylindrical tank with a rigid baffle [3]. In that study the fluid was assumed to be incompressible and in-viscid, and its motion was assumed to be ir-rotational. They implemented method of superposition of modes to compute the seismic response, and used the boundary element method to evaluate the natural modes of liquid in the tank. In that study the linearized free surface conditions was taken into consideration.

Yasuki and his colleagues (2000) conducted a study on suppression of seismic sloshing in cylindrical tanks with baffle plates [4]. The purpose of that study was proposing the evaluation model of damping characteristics of cylindrical tank with ring baffle plates. They carried out shaking table tests, in which the location and geometry of the baffle plates were varied, with sinusoidal excitation. Their experimental results showed that the damping characteristic is dependent on the location and geometry of baffle plates. Their model for solid baffle plates was extended to be applicable to both solid and perforated baffle plates, and the validity of their evaluation model was confirmed with the experimental results.

Maleki and Ziyaeifar (2007) conducted a study on damping enhancement of seismic isolated cylindrical liquid storage tanks using baffles [5]. Mentioning that in moving liquid containers, baffles play an important role in damping the liquid motion, to study the effects of using baffles in seismically isolated tanks, in the first instance they have analyzed the velocity contours in a cylindrical tank to determine the most effective shape of baffle. Then they have determined the damping coefficients analytically for horizontal ring shape and vertical blade shape baffles. To estimate the sloshing height level and the damping ratio, Maleki and Ziyaeifar have developed a methodology, based on Tank Body Spectra, in which the higher sloshing amplitude and the relative fluid velocity with respect to baffles in base isolated tanks are taken into consideration. They have also developed a computer program to put all these together and investigate the effect of baffles for different tank dimensions under the effect of earthquakes. Their results show that the average damping ratio of sloshing mode due to ring baffle increases with a decrease in liquid height and highest damping may be achieved for height to radius ratios of 1.0 to 1.5. In addition, for reasonable ring baffle dimensions, an average reduction of 6% in base displacement of base isolated tanks and an average reduction

of more than 30% in the sloshing height of base isolated and fixed base tanks may be achieved. To study the effect of baffles on the distribution of hydrodynamic and tank body forces with height, Maleki and Ziyaeifar have proposed a simple dynamic model. The results of analyses using this model indicate a constant reduction in sloshing forces and different reductions in moment and shear forces for different heights. This happens because contribution of the sloshing force to the total hydrodynamic force varies with height.

Wu (2010) has conducted a thorough study the nonlinear liquid sloshing in a 3D tank with baffles, in which the mechanism of liquid sloshing and the interaction between the fluid and internal structures have been investigated [6]. He has applied a developed 3D time-independent finite difference method to solve liquid sloshing in tanks with or without the influence of baffles under the ground motion of six-degrees of freedom. He has solved the 3D Navier-Stokes equations and has transformed to a tank-fixed coordinate system, and has considered the fully nonlinear kinematic and dynamic free surface boundary conditions for fluid sloshing in a rectangular tank with a square base. In that study the fluid was assumed incompressible. The complicated interaction in the vicinity of the fluid-structure interface was solved by implementing one dimensional ghost cell approach and the stretching grid technique near the fluid-structure boundaries were used to catch the detailed evolution of local flow field. A PC-cluster was established by linking several single computers to reduce the computational times due to the implementation of the 3D numerical model. The Message Passing Interface (MPI) parallel language and MPICH2 software were utilized to code the computer codes and to carry out the circumstance of parallel computation, respectively.

Wu has verified his developed numerical scheme by rigorous benchmark tests, and has also performed some further experimental investigations [6]. In that study for a tank without internal structures, the coupled motions of surge and sway were simulated with various excitation angles, excitation frequencies and water depths. The characteristics of sloshing waves were dissected in terms of the classification of sloshing wave types, sloshing amplitude, beating phenomenon, sloshing-induced forces and energy transfer of sloshing waves. Six types of sloshing waves, named single-directional, diagonal, square-like, swirling-like, swirling and irregular waves, were found and classified in Wu's study and he found that the occurrence of these waves are tightly in connection with the excitation frequency of the tank. The effect of excitation angle on the characteristics of sloshing waves was explored and discussed, especially for swirling waves. In that study the spectral analyses of sloshing displacement of various sloshing waves were examined and a clear evidence of the correlation between sloshing wave patterns and resonant modes of sloshing waves were demonstrated. The mechanism of switching direction of swirling waves was also discussed by investigating the situation of circulatory flow, the instantaneous free surface, the gravitational effect and the instantaneous direction of external forcing.

Wu also considered a 2D tank with vertically tank bottom-mounted baffles and has discussed the influence of baffle height on the natural mode of the tank, the evolution of vortices and vortex shedding phenomenon, the relationship between the vortex shedding frequency and the excitation frequency of the tank, the vortex size generated in the vicinity of the baffle tip, and the interaction of vortices inside the tank [6]. Based on the results the baffle height shows a significant influence on the shift of the first natural frequency of the baffled tank and the liquid depth also plays an important part in determining this influence. In other words, the shift of the first natural mode due to various baffle heights varies with water depths. Wu has claimed that the design of two baffles separated by 0.2 times the tank breadth is an efficient tool to not only reduce the sloshing amplitude, but also switch the first natural frequency of the tank. The results also show that sloshing displacement is affected distinctly by different numbers of baffles mounted vertically on the tank bottom. The more baffles

mounted onto the tank bottom, the smaller the sloshing displacement is presented in both the transient and steady-state periods. Wu has categorized the processes of the evolution of vortices near the baffle tip into four phases: the formation of separated shear layer and generation of vortices, the formation of a vertical jet and shedding of vortices, the interaction between shedding vortices and sloshing flow (the generation of snaky flow) and the interaction between snaky flow and sloshing waves. Results show that vortex shedding phenomenon due to stronger vertical jets occurs when the excitation frequency is close to the first natural mode of the baffled tank, and that is discussed and the size of vortex, generated near the baffle tip, is closely correlated with the baffle height. In that study two types of 3D tuned liquid dampers, a vertically tank bottom-mounted baffle and a vertical plate, were discussed for a tank under coupled surge-sway motions. Results show that the wave types of diagonal and single-directional waves switch to the swirling type due to the influence of the baffle. The phenomenon of square-like waves or irregular waves coexisting with swirling waves is found in the baffled tank under diagonal excitation. The shift of the first natural mode of the baffled tank due to various baffle heights is remarkable. The length of the plate can cause a significant influence on not only the variation of the natural frequencies but the type of the sloshing waves. The influence of the vertical plate on the irregular waves is insignificant and several peaks appear in the spectral analysis of the sloshing displacement for the irregular waves and the numbers of peaks are more than that of the baffled tank.

It is seen in the review of the literature that the analysis of baffled tanks in general is very complicated and time consuming, even with just one or two baffle(s). It is then clear that multiple baffles make the behavior of the liquid inside the tank more complicated, and accordingly makes the analysis much more difficult and time consuming. In this study a simplified method for evaluation of sloshing effects in rectangular tanks with multiple baffles is presented. The method is based on conducting several dynamic analysis cases, by using a powerful FE method for tanks with various dimensions, subjected to both harmonic and seismic excitations, and the use of neural network to create simple relationships between the dominant frequency and amplitude of the base excitations and the maximum level of liquid in the tank during the sloshing and also the maximum dynamic pressure on the tank wall. The details of the study are discussed in the following section of the paper.

2 FINITE ELEMENT MODELING AND ITS VERIFICATION

In order to verify the numerical modeling of the tanks by FE analysis at first the numerical FE model of a tank, previously tested at the Hydraulic Institute of Stuttgart University on shake table (Figure 1) by some other colleagues (Goudarzi et al. 2010) [7], were developed by the employed computer program.

Figure 1: The scaled-down tank model on the shake-table [7]

The length, height, and width of the liquid volume inside the tank have been respectively 1.00, 0.64, and 0.40 meters. Figures 2 and 4 show experimental, analytical, and numerical results of sloshing in the considered scaled tank model all together, studied by Goudarzi and his colleagues subjected to sinusoidal base excitations ($u_b(t) = u_0 \sin \omega t, u_0 = 5 \text{ mm}$) in two cases of, respectively, resonant ($\omega = \omega_N$) and with a lower frequency ($\omega < \omega_N$), and Figures 3 and 5 show the results obtained by the FE model developed in this study.

Figure 2: Experimental, analytical and numerical results of sloshing in the tank scaled model subjected to sinusoidal base excitations at resonance [7]

Figure 3: Numerical results obtained by FE analysis of sloshing in the tank scaled model whose experimental and analytical results for sinusoidal base excitations at resonance are shown in Figure 2

Figure 4: Experimental, analytical, and numerical results of sloshing in the tank scaled model subjected to sinusoidal base motion with $\omega < \omega_N$, [7]

Figure 5: Numerical results obtained by FE analysis of sloshing in the tank scaled model whose experimental and analytical results for sinusoidal base excitations with $\omega < \omega_N$ are shown in Figure 4

Comparing Figure 3 with Figure 2 and also Figure 5 with Figure 4, the very good agreement between the numerical result obtained by the FE model, developed in this study, and the experimental and analytical results can be seen. Based on this verification, the employed FE modeling process could be used for more detailed analysis of sloshing in tanks as explained in next sections.

3 CONSIDERED TANKS FOR THE FINITE ELEMENT ANALYSES

In this study the typical double-compartment aboveground water tanks, used in water supply system in Iran, were used. The general geometric features of the tanks, considered for the study, are shown in Figure 6.

Figure 6: General geometric plan features of the double-containment tanks considered for the study

To have the minimum length of the tank's wall (to minimize the amount of required construction materials) for a given tank's area, in the case of double-compartment tanks shown in Figure 6, it can be shown easily that b should be around $1.5a$. Also usually the water depth in the tank, h , is considered not to be less than 0.1 of the width, a , and not more than 6 meters. The common specifications of tanks with different water volumes or capacities, based on the above conditions, are as shown in Table 1.

Table 1: Common specifications of tanks with different water volumes, and their fundamental sloshing period

The tank water capacity (m^3)	Tank water height, h , in the tank (m)	a (m)	$b=1.5a$	h/a	h/b	T (sec)
125	3.0	5.270	7.905	0.758	0.569	2.619
250	3.0	7.453	11.180	0.536	0.402	3.197
500	3.0	10.540	15.811	0.379	0.284	4.029
1000	3.0	14.907	22.360	0.268	0.201	5.270
5000	4.0	28.867	43.301	0.184	0.138	8.408
10000	5.0	36.514	54.772	0.182	0.136	9.502
15000	5.5	42.640	63.960	0.171	0.128	10.523
20000	5.5	49.236	73.854	0.148	0.111	12.019
30000	6.0	57.735	86.602	0.138	0.103	13.434

The values of the first or fundamental sloshing modes of tanks in Table 1 have been calculated based on the following formula which gives the natural angular frequencies of sloshing modes in tanks [8]:

$$\omega_n^2 = \pi(2n - 1) \left(\frac{g}{a} \right) \tanh \left[\left(\pi(2n - 1) \left(\frac{h}{a} \right) \right) \right] \quad (1)$$

where n is the sloshing mode number and g in the acceleration of gravity. Based on the above explanations, and considering the exponentially growth of the required computational time with number of elements in the FE analysis, on the one hand, and the time step size in the time history analysis, on the other, explained in the next section of the paper, in this study the following values were considered as the basic case of the tank for analyses:

$$a = 1.00 \text{ m}$$

$$b = 1.50 \text{ m}$$

$$h = 0.15 \text{ m}$$

By using some appropriate scaling factors these dimensions can be used for tanks of real size, such as those given in Table 1. The scaling requirements are explained in the following section, along with the presentation of numerical results.

4 SCALING EFFECTS AND SLOSHING RESPONSE TO HARMONIC BASE EXCITATIONS

Regarding that in this study the effects of using multiple vertical baffles is the main concern; the base excitation and accordingly the induced sloshing have been assumed to occur in just one main direction of the tank length. On this basis, it was important to know if the tank's width, which is the dimension in direction perpendicular to the excitation direction, does have any effect on the analyses results. For this purpose various values were considered for the parameter b and by using a specific excitation the analysis was repeated, of which the results are shown in Figure 7.

Figure 7: The effect of the tank's width on the water level variation when excitation is along the tank's length

Figure 7 indicate that, as long as the excitation is just in one main direction of the tank plan, the tank dimension perpendicular to the excitation direction does not have any major effect on the response values. On this basis, in all analyses cases, a constant value of 0.1 m (instead of 1.5 m) was used for the tank's width to reduce the required time for the analysis.

Another important factor, which affects the required time for the response analysis, is the size of the tank. In fact, the experience gained in this study showed that the required analysis time for a scaled-down model of a tank is several times less than that of the real tank. The main reason behind this fact is in the size of the time step, which should be used for a scaled-down tank. Actually, considering that based on Equation (1) the sloshing frequencies vary inversely with variation of the square root of the tank's length, shown in the equation by 'a', it can be easily seen that the sloshing period in a scaled model, T_m , is related to the sloshing period in the prototype tank, T_p , by:

$$\frac{T_m}{T_p} = \sqrt{\frac{L_m}{L_p}} \quad (2)$$

where L_m and L_p are respectively the length of the scaled model tank and that of the prototype tank. On this basis, it is clear that the sloshing period in a scaled-down model with the length of 1/36 (for example) of the real size tank will be 6 times shorter than the sloshing period in the prototype tank. This means that the size of the time step of the earthquake digitized record, considered for analyzing the scaled-down model, should be also scaled down by the same factor of 6 to keep the proportions of the excitation periods with respect to the sloshing period in the prototype tank. Accordingly, the duration of the record, used for the scaled-down model, will be 6 time shorter than the real record, although the number of time steps is the same as the original record. It is clear that using a much shorter time step in time history analysis leads to much higher convergence rate, which in turn, reduces the required analysis time to a great extent. On this basis, it was decided in this study to use a scaled-down model tank with the length of 1.0 meter, which is almost 1/36 of a tank with 10000 m³ capacity, as shown in Table 1. This capacity relates to a very common set of tank features, as shown in table 1, with 5.0 m water height, and plan dimensions of 36.5 m by 54.8 m. In the 1/36 scaled-down model with 1.00 meter length and of 0.15 meter water height, the periods of the first three modes can be calculated based on the corresponding natural frequencies given by Equation (1) in previous section. Their values are respectively 1.708, 0.693, and 0.511 seconds. The first set of dynamic response analyses of the modeled tank is related to the base harmonic excitation of the form of $u_b(t) = u_0 \sin \omega t$, $u_0 = 5 \text{ mm}$ with the frequency of each of the first 3 sloshing modes. Figure 8 shows a sample of the water surface profile in the case of excitation with the 1st sloshing mode frequency, when various number of baffles are used.

Figure 8: The water surface profile in the time instance of 5.1 seconds in the case of excitation with the 1st sloshing mode frequency when using no, 1, 2, 3, or 4 vertical baffle(s)

In case of using just one baffle it has been considered to be at the middle of the tank's length, and in cases of using 2, 3, or 4 baffles they have been considered equally spaced, so that the tank's length have been divided accordingly into 3, 4, or 5 parts of equal lengths. As in can be seen in Figure 8, there is an abrupt change of water surface elevation at the location of each baffle. Looking at Figure 8 it seems that using more baffles leads to more decrease of the water level rising, however, since Figure 8 is showing only one instant of the time history, to make sure the using more baffles has a decreasing effect on the water level rising at all points along the reservoir's length, the maximum water level beside either the tank's wall or the baffle(s) should be studied. For this purpose the water level variation beside the tank wall was studied first. Figures 9 to 11 show these variations in cases of harmonic excitation with the frequency of respectively the 1st, the 2nd, and the 3rd sloshing mode in the tank, when using no, 1, 2, 3, or 4 baffle(s).

Figure 9: Water level variation beside the tank wall in the first sloshing mode with various number of baffles

Figure 10: Water level variation beside the tank wall in the second sloshing mode with various number of baffles

Figure 11: Water level variation beside the tank wall in the third sloshing mode with various number of baffles

It can be seen in Figure 9 that using more vertical baffles results in more reduction in the maximum water level variation, when the excitation frequency is equal to the frequency of the first sloshing mode. Figure 10 shows that when the excitation frequency is equal to that of the second sloshing mode, using two baffles leads to increase, rather than decrease, of the maximum water level variation comparing with the case of using no baffle, however, the maximum water level variation is less than its values in the case of excitation with the first sloshing mode frequency. Also, Figure 10 shows that when the excitation frequency is equal to that of the third sloshing mode, using more baffles again results in more increase in the maximum water level variation comparing with the case of using no baffle, however, the maximum water level variation is less than its value in the case of excitations with the first and second sloshing mode frequencies. Furthermore, comparing Figures 9, 10, and 11 it can be observed that the rate of increase in the maximum amplitude of water level variations, and reaching its steady state response increases with increasing the excitation frequency. This implies that the water body shows larger values of damping when it is subjected to higher frequency excitations. After realizing the effects of using multiple vertical baffles in sloshing response to harmonic excitations, by considering some appropriate earthquake records the sloshing response to seismic excitations, and the effect of using multiple vertical baffles in that case was studied, as explained in the next section of the paper.

5 SLOSHING RESPONSE TO SEISMIC EXCITATIONS AND THE EFFECT OF USING MULTIPLE VERTICAL BAFFLES

To investigate the effect of using multiple vertical baffles in the sloshing response in tanks, when subjected to seismic excitations, and establishing a reasonable relationship between the baffles' number and their features as well as the seismic excitation's characteristics as the input and the maximum water level variation as well as maximum hydrodynamic pressure on the tank wall, as the output, some earthquake records were considered based on their frequency content, and were applied with various scales. The earthquake records were selected by considering the sloshing frequencies of tanks with real size, which are generally low, for tanks with common sizes, which as shown in Table 1, have sloshing periods in range of 2.5 to 13.5 seconds. Among the available earthquakes, Chi-Chi (CHY024 component),

Taiwan earthquake of 1999, San Fernando earthquake of 1971, and Northridge earthquake of 1994, were selected, whose spectral pseudo velocity curves are shown in Figure 12.

Figure 12: Pseudo-velocity response spectra of the three selected earthquakes for time history analyses

As it is seen in Figure 12, the selected earthquakes have relatively high energy in the range of long periods, and can excite well the sloshing modes in relatively large tanks with sloshing periods of larger than 2.5 seconds. All of these earthquakes have long period oscillations in their displacement history in the period range of 2.5 to 10 seconds. For example, the long period motions of Chi-Chi earthquake, as a sample, can be seen in Figure 13, which shows the displacement time history of this earthquake component.

Figure 13: Displacement time history of Chi-Chi earthquake (CHY024 component)

The displacement histories of these earthquakes, when scaled-down by a factor of 1/6, as explained in the previous section, have displacement oscillations in the period range of around 0.5 to 1.5 seconds. To reduce the required analysis time, only the 6 seconds of the strong ground motion parts of the scaled records, containing about 4 to 12 major oscillations, were used in time history analyses. As mentioned before, the variation of water level beside either the tank wall or the baffle(s) is a good response value for studying the sloshing phenomenon and the effect of using baffles on it. Therefore, these variations, corresponding to the aforementioned earthquakes, are shown in Figures 14 to 16, which show respectively response to Northridge earthquake in cases of using no baffle comparing to the cases of using 1, 2, or 3 baffles, response to Chi-Chi earthquake in case of using no baffle comparing to the cases of using 2 or 3 baffles, and finally response to San Fernando earthquake in case of using no baffle comparing to the cases of 1 or 3 baffles.

Figure 14: Water level variations beside the tank wall with different number of baffles, when subjected to the scaled Northridge record

Figure 15: Water level variations beside the tank wall with different number of baffles, when subjected to the scaled Chi-Chi (Chy024) record

Figure 16: Water level variations beside the tank wall with different number of baffles, when subjected to the scaled San Fernando record

It is seen in Figures 14 to 16 that using baffles in general leads to decrease in the water level variations (the maximum water rising), and using more baffles results in more decrease in water level rising. However, similar analyses by using other earthquake records, such as Tabas, Iran (1987) and Kocaeli, Turkey (1999) showed that using more than 3, and in some cases 2, baffles does not change the results so much. Therefore, it can be recommended that 2 baffles are used in tanks of the sizes around the size of the studied tank.

6 NEURAL NETWORK AND ITS TRAINING FOR SLOSHING RESPONSE PREDICTION

To train a neural network for prediction of the sloshing response to earthquake excitations, the results of Kocaeli (1999), Tabas (1987), and Chi-Chi (Chy024 component -1999) earthquakes were used. The values of pseudo velocities corresponding to the 1st, 2nd, and 3rd sloshing modes in the tank, along with the number of baffles were used and the input data, and the ratio of water level increase to the water depth was used as the output data (Table 2).

Table 2: Input and output data used for training the considered neural network

	Name of Earthq.	X ₁ =Number of baffle(s)	X ₂ =Pseudo velocity	Water level increase (cm)	Y ₁ =Water level increase / Water depth

32			0.7192	36	0.642857143
33			0.4451	36	0.642857143
34		3	0.6337	34.5	0.633027523
35			0.7192	34.5	0.633027523
36			0.4451	34.5	0.633027523

Based on the data given in Table 2, and by considering a neural network with one intermediate or hidden layer [8] (Figure 17), the network was trained. After training the neural network, to test its capability in response prediction, another earthquake (Chi-Chi, Chy101 component) was considered, whose displacement record is shown in Figure 17.

Figure 17: the neural network with one intermediate (hidden) layer [8]

Figure 17: Displacement time history of Chi-Chi earthquake (CHY101 component)

The results, obtained by FE element analysis of the sloshing response of the tank, subjected to the test record are given in Table 3.

Table 3: Input and output data obtained from the test record for checking the trained neural network

	Name of Earthq.	X_1 =Number of baffle(s)	X_2 =Pseudo velocity	Water level increase (cm)	Y_1 =Water level increase / Water depth
1	Chi-Chi (CHY101)	0	0.5358	33*	0.622641509
2			0.4025	33	0.622641509
3			0.3115	33	0.622641509
4		1	0.5358	27	0.574468085
5			0.4025	27	0.574468085

9			0.3115	18	0.473684211
10		3	0.5358	18	0.473684211
11			0.4025	18	0.473684211
12			0.3115	18	0.473684211

* Results are related to the tank with actual size.

Figure 18 shows the results obtained by the trained neural network in comparison with those obtained by the time history analysis of the numerical FE model.

Figure 18: The results of the trained neural network in comparison with those of the FE analysis

It can be seen in Figure 18 that the trained neural network can predict the sloshing response with satisfactory precision.

7 CONCLUSIONS

Based on the numerical finite element analysis of the tanks in this study and the proposed neural network response prediction method, it can be concluded that:

- Using scaled down numerical models of tanks, which results in shorter time steps, and accordingly shorter durations, for time history analyses lead to significant reduction of the analysis required time.
- When the excitation is in one of the main directions of the rectangular tank, the width of tank can be chosen as small as 10 cm. This also will lead to reduction of the analysis required time.
- Using 2 to 4 vertical baffles, equally spaced along the rectangular tanks, can reduce the sloshing effect to a great extent.
- The proposed neural network can be used for predicting the sloshing response in tanks with satisfactory precision, and therefore, it is recommended that this approach is used for studying the sloshing problem in tanks instead of time history analysis, which is very time consuming.

Abstract. *In view of reasons like the size and complicatedness of current civil and structural engineering projects, and the lack of sufficient knowledge about exact, versatile, and robust analysis methods and solutions, the computational issues of structural and earthquake engineering are in considerable attention. Considering this and the limitations existing on the financial sources and facilities supporting research projects, proper allocation of facilities is of vital importance. Accordingly, in order to dedicate the sources and facilities in a more optimized and appropriate manner, budget the research funds in a better way, and clarify the main streams of research, it is meaningful to study the importance of computational issues in earthquake engineering. Consequently, the objective, in this paper, is to take a step forward towards better knowledge on the contribution of computational issues in earthquake engineering.*

1 INTRODUCTION

The size of civil and structural engineering projects and their complicatedness are in every day increase. By considering this and the stochastic nature of natural hazards, e.g. earthquakes, tsunamis, tornados, etc., the importance and essentiality of further study regarding better understanding of structures behaviors, for instance against earthquakes, can be simply explained. For arriving at further knowledge about the seismic behaviors of structural systems, implementing computational methods is inevitable. Meanwhile, limitations exist on facilities and financial sources supporting the research projects, specifically in earthquake engineering as a non-directly profitable branch of science and engineering. Consequently, an overview on the contribution and importance of the computational methods in earthquake engineering would be helpful. With such an insight, regarding the contributions of computational issues, the financial supports and facilities can be allocated in a better way, and more reasonable programming and budgeting on sources would be possible.

In this paper, the objective is to take a step in this direction. The contributions are compared based on the number of relevant literature, according to a unique search engine. In Section 2, two available search engines are compared, and the one, more appropriate, is set as the search engine, throughout the study. In Section 3, the phrases to be searched are set, the searches are done throughout the interval 1981-2010, the outcomes are reported, and a brief discussion is presented; and with a set of the conclusions the paper is ended, in Section 4.

2 SELECTION OF SEARCH ENGINE

The two search engines available for the authors of this paper were Google Scholar and Scirus, respectively available from:

- a. <http://scholar.google.com/schhp?hl=en&tab=ws>
- b. <http://scirus.com>

In an investigation on the reliability of the number of literature found by the two search engines, shortcomings were observed. The main points are as noted below:

1. The "with at least one of the words" box, hereafter addressed as Box A, in Google Scholar, seems not working properly. A simple example is reported in Table 1,

The phrase in the Box A	Number of Literature found
Apple	1,360,000
Tree	3,070,000
apple tree	2,780,000

Table 1: An example for the first problem existing in the Google Scholar search engine.

where, apparently, different from what expected, the number in the forth row is less than the number in the third row.

2. Likewise, the first shortcoming, the "OR" search tip, in Google Scholar, seems not working properly; see Table 2.

The phrase in the Box "find articles with all of the words"	Number of Literature found
Apple	1,360,000
Tree	3,070,000
apple OR tree	2,780,000

Table 2: An example for the second problem existing in the Google Scholar search engine.

Besides, as correctly mentioned, in the Google Scholar report page, the number of literature found by Google Scholar is merely an approximation. However, the amount of this approximation is such that, when the numbers of literature found in two searches are considerably different, the logical combination of the searches might be meaningless.

Scirus does not suffer from the problems above, see Table 3 and 4 .

apple	2,819,569
tree	7,142,515
apple OR tree	9,601,404

Table 3: The results of the searches corresponding to Tables 1 and 2 in Scirus.

Scirus		Google Scholar	
Photosynthesis	461,368	photosynthesis	610,000
Cell	22,826,734	Cell	5,940,000
photosynthesis OR cell	23,056,129	photosynthesis OR cell	5,620,000
Photosynthesis AND cell	231,973	Photosynthesis AND cell	352,000

Table 4: A comparison between logical combinations in Scirus and Google Scholar, when the numbers of the two main searches are considerably different.

where, regarding Table 3, as expected, from mathematics [1],

$$\text{Max}(2,819,569, 7,142,515) \leq 9,601,404 \leq 2,819,569 + 7,142,515 \quad (1)$$

and, for meaningless computations, in view of Table 4,

$$\begin{aligned} \text{Scirus : } & 22,826,734 + 461,368 - 231,973 = 23,056,129 \\ \text{Google Scholar : } & 5,940,000 + 610,000 - 352,000 = 6,198,000 \neq 5,620,000 \end{aligned} \quad (2)$$

(Since, the settings in the search engines are kept as defaults, the differences between the corresponding numbers in Table 1-4 are not meaningful.)

In a further control on the Scirus search engine, the authors could not find some the contributions [2-4] of the first author. In an e-communication with the authorities in the Scirus search engine, the reason is the not collaboration of some publishers with Scirus [5].

In view of the objective of this study, since, some of the searches, in this study, may include logical operators, e.g. OR, and some may not, the shortcomings, of Google Scholar might be more effective on the consequences, while the shortcoming, of Scirus would likely scale the numerically obtained graphs. Considering these, Scirus is set as the search engine to be implemented in the investigations, in this paper.

3 FROM PHRASES SELECTION TO BRIEF DISCUSSION ON THE OUTCOMES OF THE SEARCHES

In order to check the contribution of numerical analyses in earthquake engineering research, first the number of articles found for a search on the phrase below:

$$\text{"earthquake" OR "strong motion" OR "seismic"} \quad (3)$$

hereafter, addressed as X, is compared with the number of the articles for the search below:

$$(X \text{ AND "computational efficiency"}) \text{ OR } (X \text{ and "computational cost"}) \text{ OR } (X \text{ AND "approximate computation"}) \quad (4)$$

The results of the two searches, in different years, are as depicted in Figure 1, respectively in black and orange. Though there may exist ambiguities regarding the selected phrases, the trends of changes in Figure 1, considered together with the large number of research areas in earthquake engineering, e.g. steel buildings, concrete dams, liquefaction, performance based

Figure 1: An approximate, based on number of articles, illustration for the contribution of computational issues in earthquake engineering research throughout 1981-2010.

design, masonry and historical buildings, etc. clearly reveals the proper and robust growth of research on the computational issues in earthquake engineering; see the almost constant distant between the two graphs in Figure 1. Then, in order to compare the importance of computational issues with that of the other subjects in earthquake engineering, the search is repeated for the phrase below:

$$(X \text{ AND "passive control"}) \text{ OR } (X \text{ and "active control"}) \quad (5)$$

considering, structural control as a typical important research issue in earthquake engineering. The results of the searches implied in equations (4) and (5) lead to Figure 2. Similar to Figure 1, the trend of the graphs in Figure 2 imply the considerable contribution of computational issues in earthquake engineering, from some other point of view. Extending the study to both article and non-article literature, leads to Figures 3 and 4 respectively corresponding to Figures 1 and 2, clearly revealing the considerable significance of computational issues, even compared to issues like structural control.

Figure 2: An approximate, based on number of articles, comparison between the contributions of computational issues and structural control in earthquake engineering research, throughout 1980-2010.

Figure 3: An extension of the study reported in Figure 1 to article and non-article literature.

Figure 4: An extension of the study reported in Figure 2 to article and non-article literature.

The observations can be simply explained by paying attention to the fact that computational methods and experimental studies are two main alternatives in structural behavior study, with completely different level of price and financial needs, very important nowadays.

4 CONCLUSION

In this paper, the contribution of computational issues in earthquake engineering is studied, in view of the Scirus search engine, throughout 1981-2010. Scirus is selected as the search engine based on the reliability of the number of the literature found in the searches. After selecting the phrases to be searched, and carrying out the searches, the main observations are as noted below:

- . Considering the number of issues and branches in earthquake engineering, computational issues are of considerable importance and contribution in earthquake engineering; see Figures 1 and 3.
- . The contribution of computational issues in earthquake engineering is in gradual increase; see Figure 3.
- . The contribution of computational issues in earthquake engineering is comparable with important issues like structural control; see Figures 2 and 4.

The main reasons of the observations are:

- . the everyday increasing size and complicatedness of structural systems,
- . the low price of structural behavior study by computational methods compared to experimental work, also related to
- . the fact that computational, numerical, and approximate analyses, become cheaper everyday by the accelerated improvement of electronics and computer hardware engineering.

Keywords: Earthquake Engineering, Computational Issues, Research, Countries, Seismic Hazard, Financial Potential.

Abstract. *Further research on different issues of earthquake engineering is a major tool in global seismic protection. Considering the different, including financial, supports needed for carrying out appropriate researches, the nature of earthquakes, and the fact that the disastrous effects are not limited to one country or even region, financing earthquake engineering researches, in an international manner, is reasonable. Nevertheless, for materializing the financing, it is essential, especially in the nowadays hard financial situation, after the financial crisis, few years ago, to make an idea about the sections of the research in further need of support. As a seemingly staring step in this regard, the objective in this paper is to compare the need of further seismic research in different countries. And, in view of the considerable role of computational issues in other areas of earthquake engineering and meanwhile the title of the COMPDYN 2011 conference, the main attention in this paper is on the computational issues of earthquake engineering and comparing the essentialities of further researches in several countries based on their seismic hazard, carried out researches, and financial capabilities. As a main conclusion, Italy is the country with least essentiality and Chile and Iran are the countries with most essentialities for further research on the computational issues of earthquake engineering.*

1 INTRODUCTION

Earthquake is a natural disaster causing the most losses both in the number of human beings death and also from a financial point of view (see also Fig.1), e.g. the financial (export, im

Figure1: A comparison between losses originated in natural disasters, from 1955-1999 [1].

port,...), ecological (radiation, air pollution . . .) . . . inter-connections between different countries and neighboring regions of the globe, the effects of an earthquake is not limited to the country, where the earthquake has occurred, or even, in cases, to the neighboring countries; for instance, consider the effects of the March 11 th, 2011 earthquake and Tsunami at Japan. Consequently, international financing on different issues of earthquake engineering research is meaningful; and hence, considering the nowadays hard financial situations (originating in the financial crisis, few years ago), and the fact that there are many earthquake engineering (including seismological) issues, special and local for each country (e.g. seismicity, some types of construction, some geotechnical problems), it is reasonable to investigate and compare the research needs in different countries, such that, to also dedicate the international and even national financial supports, in a better and when possible optimized manner.

The explanation above, the significant role of research on the computational issues of earthquake engineering on other issues and branches of earthquake engineering, and the title of the COMPDYN 2011 conference, together, lead to the essentiality of the objective of this paper implied in its title. The aim of this paper is to investigate the superiorities (between countries), for further research on computational issues of earthquake engineering. Based on the seismic risk, amount of researches carried out, and the financial potentials, the key idea is explained in Section 2, the comparisons are made in Section 3, the reasons of the observations are briefly explained and led to an extension of the observations in Section 4, some complementary discussion is stated in Section 5, and eventually, the paper is concluded in Section 6.

2 THEORY

2.1 Key idea

Considering the seismic hazards and financial potentials in different countries and regions, a reasonable expectation is more researches in countries, subjected to more seismic hazard and with more financial potentials. For a robust improvement (and also as seen in a separate

study [2]), the expectation of more research, noted above, is not only regarding research on earthquake engineering, but also, is valid for the relevant computational issues. Hence, by following the procedure below:

1. Selection of some countries/regions, with considerable earthquake hazard and different financial potentials.
2. Studying the amount of researches on earthquake engineering and the computational issues, in each country/region.
3. Based on the selections and achievements in the two stages above, making an idea about the countries/regions with more essentiality of further research on earthquake engineering and the relevant computational issues.

we would be able to materialize the objective of this paper.

2.2 Some selections

2.2.1 Countries/regions

Since the outcomes of researches are in general being reflected in publications, indexed, with their titles, the name of authors/coauthors, affiliations, keywords, and titles of journals/scientific events, in this likely first study on the subject, it is much simpler to select and consider some countries from different parts of the globe, as representative of the regions they are located in. In this regard, Chile, Greece, Iran, Italy, Japan, Mexico, and USA are the seven countries under consideration in this paper.

2.2.2 How to determine the amount of researches

2.2.2.1 Approach

In order to evaluate the amount of researches, an appropriate approach (in view a slight assumption) is to study the number of relevant documents in the literature; also see [2]. For materializing this approach, a scientific search engine, reliable, regarding the number of documents, is to be selected. In view of the existing literature, www.scirus.com and its advanced version provides the capability of reliable searches [2, 3], and hence is herein set as the search engine.

2.2.2.2 Phrases to be implemented in the search

Consider the phrase X , defined below:

$$X: \text{"earthquake" OR "strong motion" OR "seismic"} \quad (1)$$

and its combination with names of the countries, set in Section 2.2.1, as:

$$X_i: X \text{ and } \textit{name of country} \quad , \quad i=1, 2, 3 \dots 7 \quad (2)$$

where,

$$\begin{aligned} i=1: \textit{name of country} &= \text{"Chile"} \\ i=2: \textit{name of country} &= \text{"Greece"} \\ i=3: \textit{name of country} &= \text{"Iran"} \\ i=4: \textit{name of country} &= \text{"Italy"} \\ i=5: \textit{name of country} &= \text{"Japan"} \\ i=6: \textit{name of country} &= \text{"Mexico"} \\ i=7: \textit{name of country} &= \text{"USA"} \end{aligned} \quad (3)$$

and, obviously X_i implies the amount of the researches carried out on earthquake engineering in the i th country. In order to study the amount of researches on the computational issues of earthquake engineering, we can consider the phrase:

$$Y: \text{"computational efficiency"} \text{ OR } \text{"computational cost"} \text{ OR } \text{"approximate computation"} \quad (4)$$

and define the search phrase below:

$$Y_i: X_i \text{ AND } Y, \quad i=1, 2, 3 \dots 7 \quad (5)$$

as the amount of the researches carried out on the computational issues of earthquake engineering.

2.2.2.3 Type of the documents and the scope of search

"Any information type" is selected as the type of literature document ("content sources") to be searched for, in www.scirus.com (advanced version), and the scope is set, by selecting the two alternatives "Earth and planetary sciences" and "Engineering, Energy and Technology" as the "subjects area" in the www.scirus.com.

2.2.2.4 Time interval

Lack of literature in a single year and/or abrupt changes of the existing literature in consecutive years may cause problems in arriving at reliable achievements and ideas. Hence, it is meaningful to carry out the searches throughout years. Considering this, the comparisons are based on the literature searches carried out in the interval 1981-2010 (see also [2]).

3 EVALUATIONS

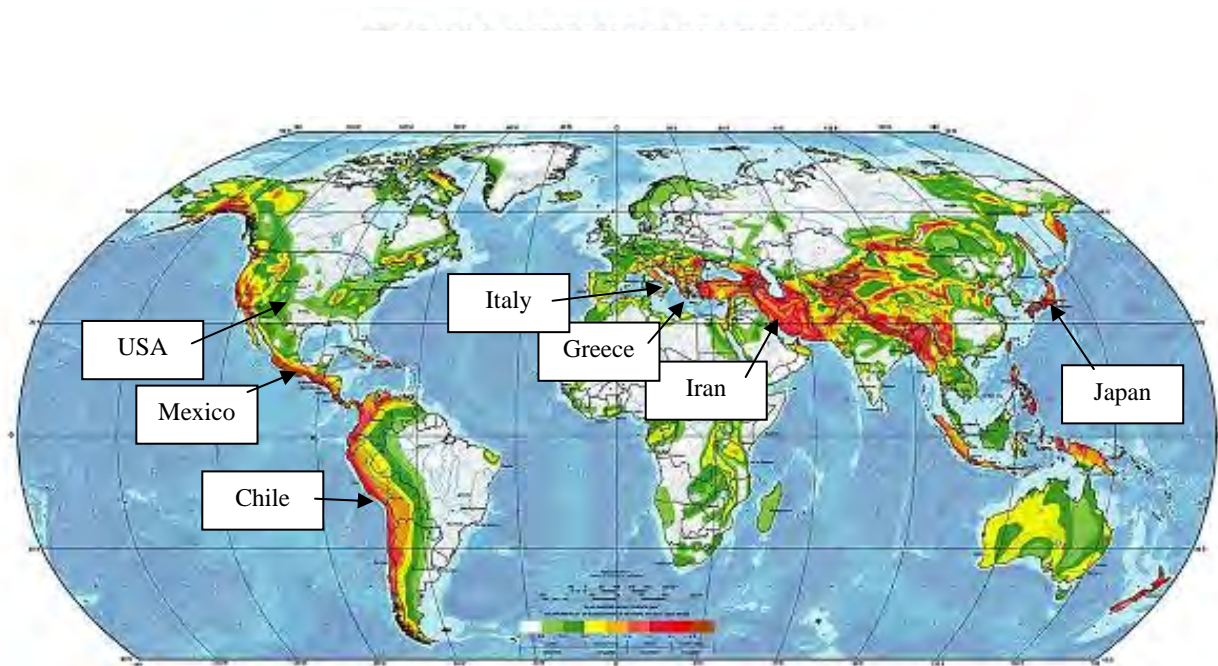

Figure 2: World seismic hazard map with the selected countries highlighted (taken from internet).

of the seven countries are roughly compared in Table 1, after some personal talks with some experts. The outcomes of the searches are compared in Fig. 3 and Table 2. In view of Fig. 3 and Tables 1 and 2, Chile and Iran are the countries with more essentiality of further research on earthquake engineering and the computational issues in earthquake engineering.

Chile (1)	Mexico, Greece, Japan (2, 5, 6)	Italy, Iran (3, 4)	USA (7)
<p style="text-align: center;">  More financial potential </p>			

Table 1: A rough comparison between financial potentials of the seven countries, selected in Section 2.1.

Country	1	2	3	4	5	6	7
Percentage of the earthquake engineering research relevant to computational issues	38	61	38	72	56	44	73

Table 2: The earthquake engineering research dedicated/involved in computational issues, in different countries.

Figure 3: Number of literature on earthquake engineering and the relevant computational issues in countries.

Specifically, considering the financial conditions, notified in Table 1, Iran is the country, where, acceleration of research on the computational issues of earthquake engineering is not only essential but can have a much simpler explanation. On the other end of the spectrum, Italy is the country, where, the amount of research is comparatively good; still further research is surely recommended.

4 FROM EXPLANATION TO EXTENSION

Obviously at countries with high seismic hazard, more research is essential (especially, when the existing financial potentials are considerable). Nevertheless, when the countries are not well developed, the financial potentials are not being implemented in research projects, sufficiently, and in an appropriate manner; hence, further financings become essential. On the other hand, at developed countries, with moderate seismic hazard, and moderate financial potential, the developments of the countries lead to good managements of the financial potentials, towards the not considerable research needs (the seismic hazards are moderate), and hence, less essentiality of further research is being observed.

Researches on earthquake engineering and the relevant computational issues, in the past decades, were in very similar growth [2]. Meanwhile, many issues in earthquake engineering are being affected by the results of research on the computational issues. Considering these, the explanations in the previous paragraph sounds valid, for both earthquake engineering and the computational issues of earthquake engineering, not only for the countries taken under consideration here, but also, for arbitrary country/region in the world.

5 COMPLEMENTARY REMARKS

The approaches and achievements in the previous sections are rough. Ambiguities regarding number of countries, selection of countries and the relation between the need to further research, seismic hazard and financial potentials exist, all, implying the essentiality of more through study on the subject, briefly discussed in this paper.

6 CONCLUSION

Under some simplifying assumptions, the existing amount of research on computational issues of earthquake engineering is evaluated in view of the need to progress and research (seismic hazard) and financial potential. As a consequence,

1. Further research is essential in less developed regions/countries, subjected to high seismic hazard, e.g. Iran and Chile. Such a research can be simply explained when the financial potentials are considerable.
2. Regions/countries subjected to moderate seismic hazard, possessing moderate or good financial capabilities, specifically, when developed, e.g. Italy, are in the best conditions of research on earthquake engineering and the computational issues.
3. Countries/regions with high seismic hazard and moderate or good financial capabilities are also generally in a good condition regarding research on earthquake engineering and the computational issues of earthquake engineering.

Still, further research is recommended, in all conditions, with emphasis on the essentiality of further research in less developed countries under high seismic hazard.

ACKNOWLEDGEMENT

The authors sincerely appreciate the kind guidance of Dr. S. Esghi, regarding the first reference and especially Fig. 1.

Keywords: Linear dynamic analysis, Time history analysis, Building structure, 3-component earthquake, Computational cost, Accuracy.

Abstract. Time integration is the most versatile tool to analyze and recognize dynamic behavior of structures. However, besides the versatility and simplicity, the resulting responses are accompanied by many approximations, while the computational efforts are considerable. The main parameter controlling the accuracy and computational cost is the integration step size, a positive definite parameter, uniformly controlling the size of integration steps throughout the integration interval. For an efficient time integration analysis it is conventional to implement integration step sizes as much as small enough to provide sufficient accuracy. An exceptional case is time integration of structural systems, subjected to digitized excitations, when the digitization step size is smaller than the size essential for sufficient accuracy. In such analyses, additional computational cost should be spent, merely to consider the digitized excitations. Recently, a technique to overcome the deficiency is proposed and successfully implemented in time integration analysis of different practical cases, e.g. simple linear and nonlinear examples, tall buildings, bridges, silos, reservoirs. However, in all examples the seismic excitations are considered as one-component records. The aim of this study is to examine the performance of the recently proposed technique in dynamic time history analysis of a building structure subjected to a three-component earthquake record.

1 INTRODUCTION

In many cases, in order to evaluate real performance of civil engineering structures during extra loadings, in general, using the time integration analysis is inevitable. Nowadays, seismic evaluations and retrofitting design process need deep understanding of the real behavior especially seismic behavior of buildings and bridges during strong ground motions. In this regard, understanding of building performances against natural disaster are only achieved by considering their dynamic time history analysis. Such analyses need some special features like detailed modeling of the building, recognizing realistic loadings may happen in the future, and a comprehensive and consistent analysis method. Also, we know that considering unusual behavior of infrastructures during environmental loadings may not be simplified to static or even pseudo-static evaluations. On the other hand, performing a dynamic time history analysis in real world is accompanied by some errors causing the results to be inexact representing of the real behavior but only an approximate one. Difficulties emerge when we do not know values and sources of errors. Now, it is clearly recognized that in any numerical method, the magnitude of the selected time steps is strongly affect the accuracy and also stability of the step-by-step integration methods. Many analysis methods to ensure satisfying stability criteria need assigning small time steps. Hence, selection of the proper time increment, Δt , is an important problem. Among various effective parameters the two following factors should be carefully considered: (1) the period of the last effective mode of the structure, which should be considered in the analysis; (2) the digitization steps of the seismic excitations. If the nonlinear behavior of the system is included in the analysis, nature of the changes of the stiffness and damping matrices during the following steps may be an effective parameter influence on the selection of time step [1].

In general, it is known that sufficiently accurate results can be obtained if the time increment is selected to be no longer than one-tenth of the period of the last effective mode of the structure. However, using step-by-step time integration analyses with so small time step significantly increase the computational costs. Hence, if we can lengthen time steps such that it guarantees the accuracy and stability of the analysis, the size of time step is limited to the values by which, the excitation is recorded. Recently, a technique by Soroushian [2] is proposed for decreasing the computational cost in which, size of the time steps of a recorded earthquake ground motion is lengthen without changing other characteristics of the record. In 2010, Soroushian [3] used this method for considering linear and nonlinear behavior of a single degree of freedom excited by an earthquake record. In this paper, we aim to evaluate this method for a 3-component earthquake when applied to an 8-story 3-dimensional building using conventional time integration methods. A brief review of the recent technique is presented in the following section.

2 THE RECENT TECHNIQUE IN BRIEF

According to Soroushian [2], in order to replace the original excitation with a new digitized excitation with larger steps such that the responses rate of convergence is preserved four steps are designed as follows:

- 1- The excitation steps, Δt_i $i = 1, 2, \dots$, are equally sized,
- 2- The integration steps, Δt_i $i = 1, 2, \dots$, are equally sized,
- 3- The excitation steps are embedded by the integration steps (the first time station, i.e. t_0 , is a station for both excitation and integration),
- 4- If we assumed that $\mathbf{f}(t)$ is a digitized representation of an actual excitation we can replace it with a new excitation, $\tilde{\mathbf{f}}$, digitized at steps equal to n times larger, according to:

$$\begin{aligned}
t_i = 0 : \quad & \tilde{\mathbf{f}}_i = \mathbf{f}(t_i), \\
0 < t_i < t_{end} : \quad & \tilde{\mathbf{f}}_i = \frac{1}{2}\mathbf{f}(t_i) + \frac{1}{4n'} \sum_{k=1}^{n'} [\mathbf{f}(t_{i+k/n}) + \mathbf{f}(t_{i-k/n})], \\
t_i = t_{end} : \quad & \tilde{\mathbf{f}}_i = \mathbf{f}(t_i),
\end{aligned} \tag{1}$$

where,

$$\begin{aligned}
t = \Delta t : \quad & n' = n - 1 \\
\Delta t < t < t_{end} - \Delta t : \quad & n' = \begin{cases} \frac{n}{2} & n = 2j \quad j \in \mathbb{Z}^+ \\ \frac{n-1}{2} & n = 2j+1 \quad j \in \mathbb{Z}^+ \end{cases} \\
t = t_{end} - \Delta t : \quad & n' = n - 1
\end{aligned} \tag{2}$$

and Δt and n ($n \in \mathbb{Z}^+$) are the largest values such that accuracy of the results and stability of the method are satisfied with generally accepting a small loss of accuracy in time integration. Since, the new excitation, $\tilde{\mathbf{f}}$, is digitized at steps equal to $n_f \Delta t$, when considered instead of the original excitation, can lead to a reduction in computational cost including the time spent and memory, which is essential for the analysis.

3 STRONG GROUND MOTION

On Jun-20-1990, a destructive earthquake occurred in Gilan and Zanjan provinces. The strongest ground motions of this earthquake have been recorded at the Abbar station at a 10 km distant from earthquake fault. [4]. In this research, the three components of this earthquake, *i.e.* longitudinal, transversal, and vertical directions, which are digitized by a time step equal to 0.005 sec is used as the strong ground motion. Using the new proposed method [2] the three components of the Abbar earthquake records are digitized at steps 2, 3, 4, and 10 times larger than the steps in the original records, *i.e.* 0.01, 0.015, 0.02, 0.05 sec. Filtering or baseline correction are not applied on the new digitized records. The acceleration records derived from the longitudinal direction of the earthquake record for various time steps are separately shown in Figure 1. By visual comparing the new digitized records in Figure 1, it can be seen that configuration of the records are preserved except for the last one, *i.e.* time step 0.05 sec. The time history of the velocity and displacements derived from the acceleration digitized records by carrying out a numerical integration process, are shown in Figure 2. It is mentioned that the velocity and displacement of the digitized record with 0.05 sec. step size, show slight and major differences respectively with respect to the other related results. It emphasizes our previous visual conclusion.

In order to better understanding the changes occurred in the new digitized records their other characteristics of this direction are compared. The response spectra of the digitized records are considered in Figure 3. This figure shows the maximum acceleration response of a single degree of freedom system against the longitudinal direction of the digitized records. It is seen that large time steps, like 10 times larger, may lessen the power of the short periods of the main record. It is because if sampling rate of the new digitized record is assumed to be 0.05 sec, the Nyquist frequency is 10 Hz, the modes with periods shorter than 0.1 sec are not considered in the record, and they may produce conflict in the results. This may observe in the acceleration and velocity responses of systems. So, we expect that the results related to this record because unexciting high frequency modes of the building model in comparison to the other digitized records produce farther results with respect to the original record.

Figure 1: The digitized acceleration records of the longitudinal direction with various step sizes.

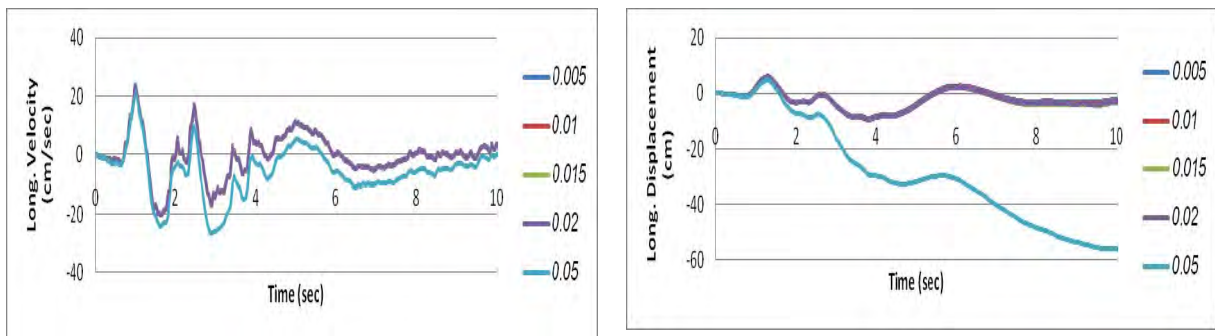

Figure 2: The digitized velocity (left) and displacement (right) records of the longitudinal direction with various step sizes.

Figure 3: The response spectrum of the longitudinal direction of the digitized records with various step sizes.

Arias intensity drawn in Figure 4 (left side), is a ground motion parameter that captures the potential destructiveness of an earthquake as the integral of the square of the acceleration-time history. It correlates well with commonly used demand measures of structural performance, and several demands related to geotechnical appearances like liquefaction and seismic slope stability. Arias intensities in Figure 4, shows that we may suppose that the performance of the building against digitized records with various time steps are not so different. Energy flux drawn in Figure 4 (right side) is the total rate of energy transfer through a surface. The results show that the rate of transferring energy to the building due to the digitized record by time step equal to 0.05 sec is completely different from the other records. Hence, it may cause the response of the building to be more excited at the end of the mentioned record. It is emphasized that performance of the building due to the other digitized records will be very similar.

Figure 4: Arias intensity (left) and energy flux (right) related to the longitudinal direction of the digitized records with various step sizes.

The maximum acceleration, velocity, and displacement of the digitized records with various time steps presented in Table 1 are compared with the values of the original record. The results show that the main characteristics of the digitized records with time steps even 4 times larger than the original one are not seriously changed. It refers to the power of the new proposed method to re-digitized records by using larger time steps [2]. Hence, it is recognizable that the response of the building may not so change until time steps 4 times larger but it may completely different when using 10 times larger time step. Meanwhile, using combination of the three components of the earthquake records may slightly affect our guesses.

Table 1: The maximum ground acceleration, velocity, and displacement of the records digitized by various time step sizes.

Time step (Sec)	0.005			0.015			0.020			0.05

4 NUMERICAL STUDY

In this section, seismic behavior of an 8-story 3-dimensional steel structure against different 3-component earthquake records digitized by assuming various time steps is presented.

The building is symmetric about X and Y directions, includes four special moment resisting frame in each direction, and eight equal height floors. It has three equal spans 5 meters length in each direction, and each floor height is assumed to be 3 meters. This building is designed according to the Iranian codes [5-7]. Using the linear dynamic time history analysis, seismic evaluation of the building against the 3-component original earthquake records and the digitized earthquake records with 2, 3, 4, and 10 times larger than the original step size are carried out. The acceleration and displacement responses of the top floor of the building in X-direction due to the different 3-component digitized earthquake records are shown in Figure 5. Although, one may observe some dispersion in the acceleration response of the top floor due to unconsidered higher modes, but the displacement response is very smooth and similar for different time steps such that the differences of maximum values in each cycle are not assessable. It is because the displacement responses are highly influenced by the excitation of the lower modes of the building.

Figure 5. The acceleration (up) and displacement (below) responses of the top floor in X-direction during different 3-component digitized earthquake records.

The base shear responses of the building in X-direction due to the different 3-component digitized records are shown in Figure 6. It appears that they are almost identical. It is reasonable because the base shear variations to a great extent follow changes in the displacement responses. So, we may expect that almost all the results show good agreement with the responses of the building due to the original 3-component earthquake record.

Figure 6. The base shear responses of the building structure in X-direction during different 3-component digitized earthquake records.

Figure 7 shows the maximum displacements of the even floors in positive (right) and negative (left) directions. The values are very similar even for step size 10 times larger. There is only a slight decrease in the responses due to 4 and 10 times larger time steps. But, its differences are not recognizable. Hence, it may conclude that except for the acceleration responses, even using 10 times larger time step may be acceptable and meet the designers' goals.

Figure 7. Maximum displacements of the even floors of the building structure in X-direction during different 3-component digitized earthquake records.

Now, we consider the error percentages of the acceleration and displacement responses of the top and the 1st floors due to the earthquake records digitized by various time steps. The results are tabulated in Table 2. It is clear that the values of the displacement responses for positive and negative side are very similar to the correct values. It is noticeable that the error related to the step size 4 times larger is greater than that of 10 times larger. However, considering the acceleration responses show that rapidly incorrect increasing the values of the acceleration responses may happen as the step size of the original earthquake record increases. It is because the higher modes are not considered in the analysis.

Table 2: The error percentages of the top and the 1st floors responses due to the earthquake records digitized by various time steps.

Error Value %		0.01	0.015	0.02	0.05
Top floor acceleration response	right side	-3.0	-7.0	-8.2	-11.8
	left side	-3.4	-3.6	-8.2	-6.6
1st floor acceleration response	right side	-4.0	-5.6	-20.2	-18.7
	left side	-4.4	-3.2	-9.0	-43.8
Top floor displacement response	right side	-1.4	-2.9	-4.4	-3.2
	left side	-1.9	-3.8	-5.8	-5.4
1st floor displacement response	right side	-1.4	-2.9	-4.5	-2.6
	left side	-1.1	-2.2	-3.6	-2.2

Finally, the overall time consuming for each analysis are compared in Table 3. Since, the building structure belongs to relative short height building, differences are not effective. Based on the results represented in Tables 2 and 3, it seems using step size 3 times larger presents the best corrected results and decreased time needed for analysis. But, if the acceleration response has not influence in our considering, it may use step size 10 times larger.

Table 3: The time consumes during linear dynamic time history analysis due to the earthquake records digitized by various time steps.

Time Step (sec)	0.005	0.01	0.015	0.02
Run Time	37' 33"	18' 40"	15' 20"	12' 14"

Discussion presented by considering the differences occurred in the inherent characteristics of the new digitized records does not necessarily result in predetermined performance of the building. Because, it is strongly related to the parameter of the considered building, characteristics of the original earthquake even including 1, 2, or 3 components in the analysis, and finally to the conditions and assumptions of the analysis. Some discrepancies may be related to the records before and after regeneration are not corrected by baseline procedure. This may slightly change the characteristics of the digitized earthquakes and influence the performance of the building. But overall, considering the results show that the new proposed method has effective influence on decreasing time consuming and memory used by preserving correctness of the building performance.

5 CONCLUSIONS

In this paper, a new proposed method to regenerating earthquakes by larger step sizes and its influence on seismic performance of a 3-dimensional 8-story special moment resisting frame steel structure is examined. Considered earthquake is the first 10 sec of the 3 components of the Abbar earthquake records. The results are not filtered or baseline corrected. Evaluation of the different parameters and characteristics of the records show that the proposed method using step size until 4 times of the original record almost not change the original features of the earthquake records. Considering responses of the building shows that using large time steps cannot significantly change the base shear and displacement responses of the building but may strongly affect the acceleration responses, which is excited by eliminating higher modes of the building. On the other hand, the new method can significantly reduce the computational cost and used memory.

These results are related to the linear dynamic time history analysis of a 3-dimensional steel structure due to more than one component earthquake records. However, these results may be changed if different parameters are included, like material and/or geometric nonlinearities, P-delta effect, using different numerical method with other convergence speed, structure with complex modes, closeness of the modal characteristics, and finally parameters of earthquake records especially include intense changes during short times.

ACKNOWLEDGEMENT

We are sincerely grateful to Dr. A. Soroushian for his help to generating new earthquake records using various time steps. Also, Mr. A. Mahmoodian Aghdam is greatly acknowledged for carrying out computer analyses regarding the main characteristics of generated earthquake records.

Abstract. *The existence of some geometrically imperfect members in space structures are almost inevitable, beside that there are some imperfections in botching the structures and the fact that they are effective in producing internal forces is undeniable. When a compressing member yields, in spite of that, continues bearing a lot of load, on the other hand the buckled compressive member goes to a critical situation and losses its stiffness and shed its load on the other members, causing a progressive collapse. Double layer barrel vaults which have statically highly indeterminate degree, may cause this phenomena because of unsuitable members. As the members initial curvature is the most popular geometric imperfection which is common in practical structures, in this thesis has chosen as an effective imperfection for research. We have tried to study this effect on the load bearing capacity of model structure. The selected model is a double layer barrel vault which is subjected to uniform concentrated load applied vertically downward to each node of the upper layer and members assumed to be pin-ended. The ratio of pure height of structure to pure opening mouth is 0.22 and the kind of layers decoration is a square on square. Two forms of analysis carried out; one for monotonous imperfections and the other for 30 cases of random imperfections which based on Monte Carlo Methods. After analysis, the ratio of maximum reduction to common case was about %41, also the suitable way of certain conclusion is presented with Monte Carlo Method.*

1 INTRODUCTION

Double layer reticulated structures are generally indeterminate from statically point of view. As occasionally there will not be any problem in stability and structure efficiency even with elimination of structure elements 15% to 25%, sometimes this preconception causes the engineers misleading about the estimation of structure safety factor [9] When one of the compressive element yields, truss stiffness decreases. After the buckling of compressive element, its force is shed among the other elements [3]. Consequently other bars are buckled and lead to progressive collapse phenomenon which imposes impact dynamic effect on the structure [2, 4]. While the development of double-layer reticulated shells on the architectural /executive ground, the buckling issue of such structures has not completely solved yet. Reticulated shells have the same specification with the reticulated and shell structures, so they will encounter with both structures problems and these problems will resonate and combine [7]. In a truss system, the structure elements are essentially under the axial forces and the element of the structures may be collapsed either under being yield of tension or buckling under compress. If one of the elements of the structure buckles the behavior of its element will conform the post critical characteristics [5, 12]. So in the case of determining behavior of tensional and compressive elements after reaching the critical load, the structure can be analyzed and continue the analysis until the overall collapse of the structure occur. On the other hand, having post critical characteristics the behavior of tensional and compressive element of the structure analysis will be possible between the ranges of the first local buckle to the total structure buckling. Usually when a tensional element reaches yield load, its load capacity increases somehow due to strain hardening [8], but when a compressive element buckles load capacity decreases with increasing axial shortening. I.e., the element cannot resist and consequently sheds its load into the other structure elements. The stiffness of post buckling compressive element has an effective influence on the total behavior of the element. It means that, if compressive element becomes unstable and abruptly shed its load to the other elements, its effect will be worse than when the load gradually sheds on the other elements [6]. Presentation of the compressive element behavior has an essential role in the buckling analysis. In the most buckling methods, first of all the load-displacement behavior of compressive element should be determined, and then the results can be used in the modeling of nonlinear compressive elements behavior. Hence, in order to determine the compressive element behavior, the behavior of post buckling element should be determined. There will be three collapse mechanisms for the structures as mentioned below: overall collapse, local collapse with dynamic snap through, local collapse without snap –through [2].

The essential factors in determining compressive buckling element and general structure behavior are the material and the geometric imperfections and there are several geometric varieties such as: nodal imperfections, increase or decrease in element length rather than desired length and element initial curve which is considered as an effective imperfection. In fact the imperfection effect of capacity rather than double layer barrel vault space structure is the main problem of this study. Fundamental theory of this study is based on the existing geometric imperfection which causes the decrease in load capacity and overall /local instability. In this study as double layer barrel vault load increases incrementally in top nodes of double layer grid, the load bearing capacity of the structure decreases. Also, distribution of existing imperfection has been done randomly. In the distribution of imperfect elements in the critical area Monte Carlo analysis standards [16] has been considered. Finally, in order to determine safety factor for structures load bearing capacity a new method is offered.

2 SPACE TRUSS FOR OBSERVATION AND ANALYTICAL METHOD

As the element of the space trusses are usually manufactured in factory, involving some nonstandard products about 1% of space trusses. In order to simplifying the study five types of imperfections for elements are use. Of course, practically due to the diversity of imperfection elements, the distribution will be continuum based on gamma distribution.

2.1 Modeling

The double-layer barrel vault truss includes the pin-ended connections. The dimension of the structure plan is 20*21.3 meters which is almost square on square. The distance between two layers is 1.63meter.also; the ratio of net height to net bay is 0.22. Double-layer grid is designed as all of the lower and upper elements have 2 meters length with a diagonal 2.4 meter length. In this model internal length of structure is 4.42 meters and net bay is 19.38 meters. (Figure 1)

Figure1. Layout of studied space trusses

2.1.1 Material specifications

The material is steel and its yield stress is 360 Mpa and yang module is 210000 Mpa.

2.1.2 Elements specifications

Regarding to 1.5 ton/joint loading for all upper layer nodes and the structure linear analysis, all profiles are selected from steel tube with an external radius of 41.275mm and a wall thickness of 9.52 mm.

2.1.3 Imperfection specifications

The kind of used imperfection is geometrical imperfection with an initial deviation [5]. The maximum initial deviation of the member at mid-point from the chord line was taken to be ε .

2.1.4 Computer program specifications

In order to carry out nonlinear pre-buckling and post-buckling analysis, Lusas software including BM3 for compressive element modeling has been used. [1]

2.1.5 Loading specification:

The starting point of incremental loading is 100N and has been continued until structure collapse. (Figure2)

2.1.6 Supporting specifications:

All of the supports are pin-ended and positioned along with the lower layer edges. (Figure2)

Figure2. Truss loading & linear edged support position

2.2 Determining the buckling behavior of compressive element in a finite element method

In order to do nonlinear analysis of the modeled structure, determining load-displacement relationship in pre-buckling and post buckling stage of structural members with consideration of its imperfection is essential [5]. Applying tubular profile in the space structures is typical. So as it already mentioned, using linear analysis, profile sections with the 41.275mm radius and with the wall thickness of 9.52mm in the 2.4 and 2 lengths have been selected.

2.2.1 The assumptions of analyses of compressive elements in the finite element method are:

- Complete elasto-plastic stress-strain relationship for material is considered and regardless of hardening effect, we assume symmetric relationship for stress-strain diagram. [4]
- We assume the element section prismatic and symmetric.
- We generalize each element to ten equal parts to achieve precious and reliable results.
- We use the Kirchhoff thin beam model to determine the behavior of the compressive elements regardless of the shear deforming effect.

-If the compressive elements become straight with homogenous material, pure compressive condition will be occurred. But there would not be any ideal compressive elements with the mentioned characteristics. Somehow some imperfections such as the following ones may create bending moment in the compressive elements and decrease the load bearing capacity.

-Initial element deviation, eccentric loading, diversity of local specifications, being inhomogeneous, residual stress in element section

-In this study merely the compressive element initial curvature as a geometric imperfection has been considered. It is assumed that, maximum initial deviation of the member at mid-point from the chord line was taken to be ε and it is symmetric as well. For imperfection ($\varepsilon=0.0005L$, $\varepsilon=0.001L$, $\varepsilon=0.005L$, $\varepsilon=0.01L$ and $\varepsilon=0.02L$), the elements behavior have been determined.

-We assume that compressive elements do not have local instability. In order to determine compressive element load-displacement relationship; we can use a statically large deformation elasto-plastic nonlinear analysis and both material and geometric nonlinearity in analysis have been used [7]. (Figure3)

Figure3. Effects of nonlinearities

-Drawing an equilibrium nonlinear route until reaching the buckling load has been done by Newton-Raphson repetitive method as this method has been diverged due to being singular stiffness matrix adjacent to buckling critical point; consequently it would not be efficient. So, in order to draw balanced route adjacent with critical point, we have used arc length method.

-The quantity of compressive element critical load is calculated for member initial maximum imperfection and the obtained quantities will be reliable if the load is less than Euler buckling load. Otherwise, the initial buckling load will be considered.

2.2.2 Drawing stress-strain relationship based on the above assumptions

Members length has been analyzed with the imperfections ($\varepsilon=0.0005L$, $\varepsilon=0.001L$, $\varepsilon=0.005L$, $\varepsilon=0.01L$ and $\varepsilon=0.02L$) and all behavior were compared [10, 11]. The slenderness of the elements is medium and stress-strain curvature has been calculated according to the force-displacement which their diagram have been illustrated below. Note that, sometimes the above diagrams have been illustrated based on 1000 case of incremental loading. Determining of these points to structure analysis for finite elements program may be time consuming. In this study nonlinear curves have been considered in calculation with 6 points. (Figure 4, 5)

Figure4. Axial force-displacement diagram for 2and 2.4 members

Figure5. Stress-strain diagram for 2and 2.4 members

According to the depicted diagrams, it is clear that the applicable elements behaviors are brittle. Hence, final strength of such elements has been decrease with increase in the imperfection as a result ductile behavior is formed.

2.3 Double layer barrel vault truss analysis

Analyze the barrel vault in two manners. Firstly under uniform imperfection for all elements and secondly under random imperfection about 30 cases

2.3.1 Analyzing under uniform imperfection for all elements

Study the truss under Quadra imperfections ($\epsilon=0.0005L$, $\epsilon=0.001L$, $\epsilon=0.005L$, $\epsilon=0.01L$).it is assumed that, all of the elements have the same imperfection and the result of the analysis have been drawn in a displacement-load diagrams. It is clear that, with increasing the imperfections quantity in a current mode, total structure strength is influenced effectively. (Figure 6)

Figure6. Behavior of the truss under uniform geometrical imperfections

2.3.2 Analyzing truss under random imperfections distributions

Due to being time consuming of nonlinear analysis and likelihood of all possible imperfections, 30 analysis cases based on Monte Carlo standards have been used to estimate load capacity. For each analysis, consider a different distribution for imperfections consequently; use a program in visual basic to determine the random imperfections distributions. Note that, the purpose of complete status or comparative standards, is ($\epsilon=0.001L$) total imperfections for all elements. Also as linear analysis result show that, lower layer and diagonal elements cannot reach the plastic stage so they would not be critical. Consequently critical area is selected in the critical area of truss upper layer. (Figure7)

Figure7. The position of randomly distributed elements of the truss top layer in the critical area

2.3.2.1 The method of determining the quantity of each existing imperfection

The quantity of each existing imperfections resulting from gamma distribution has been selected [13] according to the following diagram. (Figure8)

Figure8.Quantity-imperfection diagram via gamma distribution

2.3.2.2 Consideration of random analysis result

We compared the obtained results of random analysis to achieve the quantity of strength decline according to changes in imperfection elements locations. (Figure9)

Figure9. Node mid-point Load-displacement behavior for 30 random and a perfect modes

2.3.2.3 The structure sensitivity

The structure sensitivity rather than imperfection distribution of truss in the critical area is completely evident. According to the analysis, the strength average of structure for different conditions is 10795004.07 N and strength decline diagram is drawn based on random analysis. (Figure10)

Figure10. Descending strength according to structure number

According to analysis based on Monte Carlo criteria and its accordance with normal distribution the diagrams are

- 1-frequency-strength related to quantity of resulted strength. (Figure11)
- 2-probability density function diagram

Figure11. Histograms of the structure load bearing capacity for 30 random analyses

Figure12. Analysis density distribution function

As a result based on the illustrated diagrams and regarding to the possibility of desired occurrence, estimating of the structure strength would be possible. This method for determining safety factor has been mentioned in [14], [15] references.

3 SUMMERY AND CONCLUSION

According to the analysis, we conclude that:

-The applied imperfections in the critical area have not have a remarkable effect on the structure initial stiffness. Indeed, the most important effect of such measurements is decreasing the maximum load bearing capacity.

-The double layer barrel vault space structure is sensitive to geometric imperfections.

-For different modes of randomly imperfections distributions, in the worst mode the structure has shown 41% strength decline.

-In this study the only geometric imperfections is initial deviation contributed in the result. Furthermore, the other imperfections effect and the combination of the local instabilities have not been considered. Randomly distribution of the imperfections in the critical area based on Monte Carlo method, leads to finding a suitable method way to estimate the structure actual and practical strength.

-Based on the analysis of Monte Carlo method and drawing related curvature (including strength-possibility and frequency-strength), the possibility of desired strength occurrence is assessed.

4 RECOMMENDATIONS

The main logical method in such structures, having more accuracy in manufacturing and controlling the parts before assembly. So, if there are more member imperfections, they should not be used in the compressive critical area. In the double layer barrel vault space structure, the critical member located in upper layer and these members are much more sensitive to the geometric imperfection; so, more strengthening the members in the critical area of the truss leads to increasing the structure load bearing capacity and decline the structure sensitivity to the imperfection as well. In summary it is not possible to monitor the structure in all conditions so, it is recommended to apply fuzzy logic and artificial neural network in future studies.

5 ACKNOWLEDGEMENTS

Keywords: RKPM, multiscale, microcrack, damage model, ultra high-strength concrete, penetration

Abstract. *Impact and penetration events involve complex response phenomena such as damage and fragmentation, which present particular challenges to numerical methods like the finite element method. Further, the commonly used phenomenological damage law gives no direct consideration to the evolution of continuum-scale damage with respect to microcrack formation and growth within the substructure. In this work, we introduced the reproducing kernel particle method (RKPM) to impact and penetration problems, and a hierarchical multiscale modeling technique under the framework of RKPM is proposed. A multiscale damage model is developed based on homogenization of a cracked microscopic cell, which is termed the microcrack-informed damage model (MIDM). Bridging between scales is accomplished by a novel energy equivalence approach. Application of the MIDM to a specific ultra high-strength concrete material is discussed, and results from the analysis of a benchmark penetration problem are presented.*

1 INTRODUCTION

Impact and penetration events represent a class of complex physical problems that are of significant interest in both military and commercial applications. These can generally be considered as “strong dynamics” problems, which exhibit high strain rates (10^3 - 10^7 s⁻¹ for ballistic events [1]), large velocity gradients, and fast-evolving strong and weak discontinuities that lead to extensive material and structural damage and fragmentation. The level of complexity is further enhanced when considered in the context of concrete structures due to concrete’s brittle response and highly heterogeneous microstructure. In particular, material fragmentation poses a significant challenge to structured-mesh-based methods such as the finite element method (FEM). Due to extensive material deformation and separation, techniques such as element erosion have been commonly implemented to circumvent instabilities resulting from excessive mesh distortion. However, erosion is not consistent with the physical event, and subsequently precludes accurate modeling of certain effects such as debris generation from the impact zone. Therefore new meshfree methods, which do not exhibit the structured-mesh dependency of FEM, can provide significantly enhanced capabilities for impact and penetration modeling.

Accurate mathematical description of material softening, degradation and failure processes plays a dominant role in the accuracy of penetration modeling. The typical phenomenological description of damage evolution at the continuum scale lacks a direct link to the underlying microstructure processes. Damage processes in brittle solids such as concrete are driven by the distribution of microcracks and their evolution, and thus the applicability of continuum damage models requires further enhancement. In this work, a multiscale approach is introduced to link the continuum damage evolution to substructure crack propagation based on an energy bridging approach. This multiscale model is developed under the framework of the meshfree reproducing kernel particle method to model concrete penetration. The resulting multiscale damage evolution model has been termed the microcrack-informed damage model (MIDM) [7]. An ultra high-strength concrete developed by the U.S. Army Engineer Research and Development Center (ERDC) was adopted as a material for use in the formulation development.

The purpose of this paper is to provide an overview of the RKPM formulation for penetration modeling and discuss the development of the microcrack-informed damage model. Organization of the paper is as follows. Section 2 provides an overview of RKPM utilizing a semi-Lagrangian formulation, and Section 3 discusses the microcrack-informed damage model formulation. Section 4 presents implementation of the MIDM into a concrete constitutive model developed for penetration, and a benchmark penetration problem is analyzed in Section 5. Concluding remarks are given in Section 6.

2 REPRODUCING KERNEL PARTICLE METHOD

The reproducing kernel particle method (RKPM) [2,3] is a meshfree method in which the approximation and domain discretization of a partial differential equation are accomplished by a set of nodes related through domains of influence, also known as support zones. The support zones are non-conforming, which alleviates many of the structured-mesh dependent problems associated with FEM. This minimization of mesh dependency provides a distinct advantage when applying RKPM to impact and penetration problems, where very large material deformation and/or separation are common. A typical RKPM discretization is

shown in Figure 1a, where the non-conforming support zone of node **I** is highlighted. The corresponding shape function over the i^{th} node's compact support is shown in Figure 1b.

Figure 1. a) Non-conforming, compact support of i^{th} node, b) RKPM shape function for i^{th} node

2.1 Semi-Lagrangian RKPM

In the following discussions, we use the general d -dimensional notation, where $x^\alpha = x_1^{\alpha_1} \dots x_d^{\alpha_d}$ and $|\alpha| = \sum_{i=1}^d \alpha_i$. For the subject of interest, we consider the reproducing kernel (RK) approximation of degree p of a displacement field, \mathbf{u} , denoted by \mathbf{u}^h as

$$\mathbf{u}^h(\mathbf{x}) = \sum_{l=1}^n C(\mathbf{x}; \mathbf{x}_l) \Phi_a(\mathbf{x} - \mathbf{x}_l) \mathbf{d}_l \equiv \sum_{l=1}^n \Psi_l(\mathbf{x}) \mathbf{d}_l \quad (1)$$

where $\Psi_l(\mathbf{x})$ is the RK shape function, $\Phi_a(\mathbf{x} - \mathbf{x}_l)$ is a scalar-valued kernel function with compact support (for example, the cubic B-spline function), \mathbf{d}_l are the RK approximation coefficients for displacement, and $C(\mathbf{x}; \mathbf{x}_l)$ is the correction function expressed as

$$C(\mathbf{x}; \mathbf{x}_l) = \mathbf{H}^T(\mathbf{x} - \mathbf{x}_l) \mathbf{b}(\mathbf{x}) \quad (2)$$

where $\mathbf{H}^T(\mathbf{x} - \mathbf{x}_l) = \{(\mathbf{x} - \mathbf{x}_l)^\alpha\}_{|\alpha| \leq p}$ is a vector of monomial basis functions of degree p , and $\mathbf{b}^T(\mathbf{x}) = \{b_\alpha(\mathbf{x})\}_{|\alpha| \leq p}$ is a vector of unknown coefficients to be solved by using the reproducing conditions

$$\sum_{l=1}^n \Psi_l(\mathbf{x}) \mathbf{x}_l^\alpha = \mathbf{x}^\alpha \quad \alpha \leq p \quad (3)$$

Utilizing the reproducing condition of (3), $\mathbf{b}(\mathbf{x})$ may be solved by

$$\mathbf{b}(\mathbf{x}) = \mathbf{M}^{-1}(\mathbf{x}) \mathbf{H}(\mathbf{0}) \quad (4)$$

where $\mathbf{H}^T(\mathbf{0}) = [1, 0, 0 \dots 0]$ and $\mathbf{M}(\mathbf{x})$ is a moment matrix defined as

$$\mathbf{M}(\mathbf{x}) = \sum_{l=1}^n \mathbf{H}(\mathbf{x} - \mathbf{x}_l) \mathbf{H}^T(\mathbf{x} - \mathbf{x}_l) \Phi_a(\mathbf{x} - \mathbf{x}_l) \quad (5)$$

Utilizing (2) and (4) in conjunction with (1), the complete RK approximation is given as

$$\mathbf{u}^h(\mathbf{x}) = \sum_{l=1}^n \mathbf{H}^T(\mathbf{0}) \mathbf{M}^{-1}(\mathbf{x}) \mathbf{H}(\mathbf{x} - \mathbf{x}_l) \Phi_a(\mathbf{x} - \mathbf{x}_l) \mathbf{d}_l \quad (6)$$

The RK approximation may be formulated in a Lagrangian [4] or semi-Lagrangian [5] form, based on update of the support zone for each node. In the Lagrangian formulation, the support of each node is defined in the initial configuration, as shown in Figure 2a. This determines a “list” of neighboring nodes contained within the i^{th} node's support zone. The

definition of nodal support is not modified during the calculation, so that the same nodes remain in the i^{th} node's support throughout. As a result, the support zones deform with the material, as shown in Figure 2b. However, the Lagrangian formulation and discretization of conservation laws breaks down when mapping between the initial and current configurations is no longer one-to-one. This occurs under conditions such as new free surface formation (i.e. material separation) or free-surface closure, which commonly exist in damage processes of geomaterials.

Similar to the Lagrangian formulation, in the semi-Lagrangian formulation the nodal support conditions are first defined in the initial configuration. However, in the semi-Lagrangian formulation the neighboring node list is incrementally updated based on the material deformation and readjustment of support size. As a result, in the semi-Lagrangian formulation nodes are allowed to move in and out of the i^{th} node's support. Consequently, the nodal support zones do not deform with the material, as shown in Figure 2c. This property is necessitated in impact and penetration problems due to material separation and moving contact surfaces [6].

According to [5], the semi-Lagrangian RK shape function is expressed as

$$\Psi_I^{SL}(\mathbf{x}) = \mathbf{H}^T(\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)) \mathbf{b}(\mathbf{x}) \phi_a(\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)) \quad (7)$$

where $\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)$ indicates distance measurements taken in the current configuration and $\Psi_I^{SL}(\mathbf{x})$ is used to denote the semi-Lagrangian shape function. Let the velocity approximation be expressed by the semi-Lagrangian RK shape function

$$\dot{\mathbf{u}}^h(\mathbf{x}, t) = \mathbf{v}^h(\mathbf{x}, t) = \sum_{I=1}^n \Psi_I^{SL}(\mathbf{x}) \mathbf{v}_I(t) \quad (8)$$

where $\dot{\mathbf{u}}^h$ is the time derivative of \mathbf{u}^h and $\mathbf{v}_I(t)$ are the RK approximation coefficients for velocity. Taking the time derivative of (8) gives the approximation of acceleration as

$$\ddot{\mathbf{u}}^h(\mathbf{x}, t) = \dot{\mathbf{v}}^h(\mathbf{x}, t) = \sum_{I=1}^n [\Psi_I^{SL}(\mathbf{x}) \dot{\mathbf{v}}_I(t) + \Psi_I^*(\mathbf{x}) \mathbf{v}_I(t)] \quad (9)$$

where

$$\Psi_I^*(\mathbf{x}) = C(\mathbf{x}; \mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)) \dot{\phi}_a(\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)) \quad (10)$$

$$\dot{\phi}_a\left(\frac{\|\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)\|}{a}\right) = \phi_a'\left(\frac{\|\mathbf{x} - \mathbf{x}(\mathbf{X}_I, t)\|}{a}\right) \frac{\mathbf{n} \cdot (\mathbf{v} - \mathbf{v}_I)}{a} \quad (11)$$

In (10), $\dot{\phi}_a(\cdot)$ is the time derivative of the kernel function which takes into account the nodal transport effect in the semi-Lagrangian formulation.

3 MICROCRACK-INFORMED DAMAGE MODEL

A microcrack informed damage model (MIDM) is proposed for describing the softening behavior of brittle solids, in which damage evolution is treated as a consequence of microcrack propagation [7]. The homogenized stress-strain relation in a cracked microscopic cell defines the degradation tensor, which can be obtained by the equivalence between averaged Helmholtz free energy (HFE) of the microscopic cell and HFE of the damaged continuum, $\bar{\Psi}$, as follows (with reference to Fig. 3).

$$\bar{\Psi} = \frac{1}{V_y} \left(\int_{\Omega_y} \Psi^\varepsilon d\Omega + \frac{1}{2} \oint_{\Gamma_c} \mathbf{u}^\varepsilon \cdot \mathbf{h} ds \right) \quad (12)$$

Here superscript “ ε ” is used for the fine scale variables, \mathbf{u}^ε is the displacement field in the microscopic cell, \mathbf{h} is the cohesive traction acting on the crack surface Γ_c , Ψ^ε is the HFE of the microscopic cell, and V_y is the volume of the microscopic cell with domain Ω_y . This energy equivalence relationship serves as an energy bridging vehicle between the damaged continuum and the cracked microstructure.

Figure 3. Homogenization of microscopic cell with fluctuating fields

By introducing bridging based on HFE, the damage tensor for the continuum can be obtained. Recall (12), and let $\bar{\Psi}$ computed from the microscopic cell be related to the damaged continuum by

$$\bar{\Psi} = \frac{1}{2} \bar{\mathbf{e}} : (\mathbf{I} - \mathbf{D}) : \bar{\mathbf{C}}_0 : \bar{\mathbf{e}} \quad (13)$$

where $\bar{\mathbf{e}}$, $\bar{\mathbf{C}}_0$, and \mathbf{D} are the homogenized strain tensor, undamaged material response tensor, and the continuum damage tensor, respectively. The damage energy release rate is defined as

$$\mathbf{Y} = -\frac{\partial \bar{\Psi}}{\partial \mathbf{D}} = \frac{1}{2} \bar{\mathbf{e}} : \bar{\mathbf{C}}_0 : \bar{\mathbf{e}} \quad (14)$$

By taking the derivative of the HFE of the microscopic cell in (12) with respect to the damage energy release rate, \mathbf{Y} , we obtain the damage tensor

$$\mathbf{D} = \mathbf{I} - \frac{\partial \bar{\Psi}}{\partial \mathbf{Y}} \approx \mathbf{I} - \frac{\Delta \bar{\Psi}}{\Delta \mathbf{Y}} \quad (15)$$

Here a finite difference approach could be used in (15) to obtain the fourth-order damage tensor using $\Delta \bar{\Psi}$ and $\Delta \mathbf{Y}$. This general approach can be reduced to scalar or bi-scalar damage models as discussed in [7].

4 IMPLEMENTATION

The MIDM was implemented into the Advanced Fundamental Concrete (AFC) model, developed by the U.S. Army ERDC [8]. The AFC model is a 3-invariant plasticity model which incorporates damage evolution, strain rate effects, and a nonlinear pressure-volume relationship. In the original AFC model, a single-scalar damage variable was used for failure surface evolution as a function of volumetric and effective deviatoric plastic strains. As an enhancement, in this work the damage variable was decomposed into two terms, one to consider damage in compression and another to consider damage in tension. The compression damage term, d_c , was calculated using the original AFC damage evolution equation. The tensile damage term, d_t , was calculated from the MIDM.

For use during implementation of the MIDM, an ultra high-strength, fiber-reinforced concrete known as CorTuf [9] was considered. CorTuf is reinforced with approximately 30-mm long, randomly distributed steel fibers, the effects of which were considered in the microscopic cell analysis.

4.1 Microscopic cell analysis

To determine the microcrack-informed tensile damage evolution function, the microscopic cell analysis was based on Mode I crack propagation in a center-cracked cell. Crack propagation in the cell was modeled using a cohesive crack model with a modified cohesive law. The conventional cohesive crack law applies cohesive stresses over a fracture processing zone near the crack tip, which extends from the so-called mathematical crack tip to the physical tip. The cohesive law is then expressed as the relationship between cohesive stresses and crack opening displacement (COD), and the area under the resulting curve is equal to the fracture energy, G , of the material. The modified cohesive law was formulated to consider the effect of fiber bridging in CorTuf, such that cohesive stresses extend beyond the typical fracture processing zone. Based on a Griffith-type crack formation, the cohesive stress versus COD relationship was assumed to consist of a constant stress region which represents fiber bridging effects and a softening region which corresponds to a region of fiber failure. Fracture energy of the modified law was equivalent to experimentally determined values.

Solving the microscopic cell problem by RKPM, the average microscopic cell strain, stress, and HFE were determined. Utilizing the microscopic cell results in conjunction with the homogenization relationships in Section 3, the tensile damage parameter versus homogenized continuum strain relationship was determined, as shown in Figure 4. Here nonlinearity of the microcrack-informed tensile damage evolution function is noted.

Figure 4. Microcrack-informed tensile damage evolution function for CorTuf concrete

Evolution of the AFC model yield surfaces with and without the microcrack-informed tensile damage function are shown in Figure 5. Sign convention is adopted such that $(+)I_1$ indicates compression and $(-)I_1$ indicates tension. From Figure 5a, it is seen that when a single scalar damage term is used, the tension and compression yield surfaces contract together with damage evolution. However, from Figure 5b it is observed that when the damage variables are separated, the tensile yield surface may evolve independently of the compression yield surface.

Figure 5. AFC model yield surface with a) compression damage only ($d_c=0.5$) b) separated tension and compression damage ($d_c=0, d_t=0.5$); (I_1 =first stress invariant, J_2 =second deviatoric stress invariant)

5 BENCHMARK PROBLEM

The multiscale RKPM formulation for penetration and impact was implemented into the *Nonlinear Meshfree Analysis Program (NMAP)* parallel code [10], which was used to analyze a series of benchmark penetration problems. The benchmark problems followed penetration experiments performed by ERDC in their small-caliber ballistic test facility [11]. The experiments were conducted by firing spherical projectiles (S2 tool steel) into thin-panel CorTuf targets where impact velocity, projectile size and panel thickness were varied to achieve a range of terminal ballistic conditions. Results from one of these experiments are presented here, where an 11-mm diameter projectile with a mass of 86 grains was fired into an approximately 25-mm-thick panel. Impact velocity of the projectile was 538 m/s. The projectile exited the panel's back face, but with insufficient velocity to reach the exit-face-velocity measuring devices.

For the *NMAP* model, the projectile and panel were discretized using 1,163 nodes and 190,000 nodes, respectively. This provided a nodal spacing of approximately 1 mm on the surface of the projectile and 1.4 mm in the impact region of the panel. The projectile was modeled using a J2 plasticity model with isotropic hardening, with material model parameters as given in Table 1. The CorTuf target was modeled using both the original AFC model and the MIDM-enhanced formulation.

parameter	value
Young's modulus, E	200 GPa
Poisson's ratio, ν	0.26
yield stress, σ_y	2400 MPa
hardening modulus, H	2500 MPa
density	7806 kg/m ³

Table 1. J2 plasticity model parameters for projectile

Snapshots from the penetration process are shown in Figure 6. Notable is the debris generated from the exit face. Because each “flying” node contains velocity and mass data, this can be directly translated to momentum and energy of debris generated from the impact event.

Figure 6. Penetration process using MIDM-enhanced AFC formulation a) 300 μ sec after impact, b) 1000 μ sec after impact.

Exit velocity, velocity reduction, and mass loss of the projectile are compared in Table 2. As seen from the data, both sets of numerical results are in excellent agreement with the experimental data. The MIDM-enhanced formulation predicted a marginally higher exit velocity than the original AFC formulation, but both solutions were within approximately 0.3 percent of the experimental results. In terms of projectile mass loss, both models slightly under predicted the experimental result. This is due to the fact that damage was not included in the projectile material model. However, as with the exit velocities, the numerically predicted projectile mass loss is still in good agreement with the experimental results.

	impact velocity, m/s	exit velocity, m/s	velocity reduction, %	projectile mass loss, %
experiment	538	~0	~100	0.2
original AFC	538	1.2	99.8	0
MIDM-enhanced AFC	538	1.7	99.7	0

Table 2. Comparison of results

Experimental and numerical damage patterns on the panel faces are compared in Figure 7. Simulation data are shown for the MIDM-enhanced model, where edges of the experimentally measured craters are shown in black. As seen, the calculated zones of heavy damage generally matched the crater limits, with some additional damage extending beyond. Extension of panel damage beyond the crater limits is commonly observed in this type of penetration experiments, indicating generally good agreement between the experimental and numerical results. Notably, damage zones calculated without the multiscale enhancement were smaller, and did not appear to capture the panel damage as well.

Figure 7. Comparison of experimental and numerical damage patterns (tensile damage parameter plotted).
a) experimental impact face, b) experimental exit face, c) numerical impact face, d) numerical exit face.

6 CONCLUSIONS

In this research an RKPM formulation was developed for penetration modeling, which was successfully used to model the penetration of ultra high-strength concrete targets. From the benchmark problem, it was seen that due to the reduced mesh-dependency of RKPM, large-scale material failure and separation was captured without problem. This implies that the method not only has capability to accurately model terminal ballistic effects within the target, but can also accurately capture secondary effects such as behind-target debris – which is of great interest in certain applications.

A multiscale model for damage evolution in ultra high-strength concrete was also developed and implemented into the RKPM-based *NMAP* code. The basic approach was to utilize a microscale calculation to determine constitutive model parameters (in this case the damage evolution function) which otherwise would be phenomenologically determined. Therefore, in essence the microscopic cell analysis serves as a microscale numerical experiment, where microcrack propagation within the material can be modeled explicitly. Scale bridging is used to link the microscale cracking to continuum-scale damage evolution, and as a result damage evolution in the continuum is based on a more fundamental aspect of material response. A novel energy-bridging method was also developed for scale bridging, which provides a more computationally efficient link between the micro- and macroscales. Note that for the example given, the multiscale model was used to define tensile damage evolution, and therefore the microscopic cell analysis only considered Mode I crack

propagation. However, more complex conditions within the microscopic cell could also be addressed under this multiscale modeling framework. This is a topic of ongoing research within the program.

From results of the benchmark problem, it was seen that both the original AFC model and the MIDM-enhanced model were in excellent agreement with the experimentally measured exit velocity. The MIDM-enhanced AFC model also provided a very good prediction of panel damage on both the impact and exit faces, while the original AFC model tended to predict smaller damage areas.

ACKNOWLEDGEMENT

Permission to publish was granted by Director, Geotechnical and Structures Laboratory. Simulations were partly performed on the Department of Defense Super Computing Resource Center high performance computers.

Keywords: Explosives, Blast, Equation of State, Detonation, Security.

Abstract. *There is an increasing emphasis on the modeling of security related blast events that produce both fragmentation and blast loading. The Jones-Wilkins-Lee-Baker (JWL-B) thermodynamic equation of state was originally developed to more accurately describe overdriven detonation, while maintaining an accurate description of high explosive products early expansion work output associated with metal pushing and fragmentation. The equation of state is more mathematically complex than the Jones-Wilkins-Lee equation of state, as it includes an increased number of parameters to describe the principle isentrope, as well as a Gruneisen parameter formulation that is a function of specific volume. Although the increased mathematical complexity over JWL was originally implemented in order to model both overdriven detonation and early volume expansion work output, it has been found that this increased mathematical complexity also allows the flexibility to parameterize higher volume work output associated with blast output. As increased numbers of parameters can mean increased calibration complexity and does not guarantee increased accuracy for practical problems of interest, calibration techniques have been developed to provide robust detonation products equation of state parameters that are applicable to the broad range of high explosive work output associated with overdriven detonation (wave shapers), early volume expansion (metal pushing) and late volume expansion (blast). This paper presents a method of parameter calibration: formal optimization using JAGUAR thermo-chemical predictions to cylinder test and high volume total work output associated with blast overpressure and impulse. The calibration procedure details are presented, along with equation of state parameter sets and ALE3D modeling comparisons. Although reasonable agreement to empirically based peak overpressures is achieved, the results indicate that an explosive products afterburning model is required to achieve further agreement with empirically based peak overpressures and impulse.*

1 INTRODUCTION

There is an increasing emphasis on the modeling of security related blast events that produce both fragmentation and blast loading. The combined loading of blast and fragments, caused by explosions, is known to often produce damage greater than the sum of the damage caused by the blast and fragment loading treated separately. This phenomenon is well known and is pointed out in literature and design manuals within the area of protective design [1]. However, due to a lack of more sophisticated modeling [2] and the complex nature of combined blast and fragment loading, the design manuals normally disregard the effect or treat it in a very simplified manner [1]. One missing aspect for combined blast and fragment loading modeling, is the development of detonation products equations of state that are accurate for a broad range of volume expansions. This is required in order to predict the fragmentation characteristics produced at early detonation products volume expansion, as well as to predict the total work output produced at very high detonation products volume expansions. The Jones-Wilkins-Lee-Baker (JWL) thermodynamic equation of state was investigated in an effort to accurately predict both early volume expansion and highly expanded behavior associated with air blast. In this study, the explosives TNT and LX-14 were used for computational investigations.

2 JONES-WILKINS-LEE EQUATION OF STATE

The Jones-Wilkins-Lee-Baker (JWL) thermodynamic equation of state was originally developed to more accurately describe overdriven detonation, while maintaining an accurate description of high explosive products early expansion work output associated with metal pushing and fragmentation [3]. The equation of state is more mathematically complex than the Jones-Wilkins-Lee equation of state, as it includes an increased number of parameters to describe the principle isentrope, as well as a Gruneisen parameter formulation that is a function of specific volume. The JWL mathematical form is:

$$P = \sum_n A_n \left(1 - \frac{\omega}{R_n V^*} \right) e^{-R_n V^*} + \frac{\lambda E}{V^*} \quad (1)$$

$$\lambda = \sum_i (A_{\lambda i} V^* + B_{\lambda i}) e^{-R_{\lambda i} V^*} + \omega \quad (2)$$

where V^* is the relative volume, E is the product of the initial density and specific internal energy and λ is the Gruneisen parameter. Although the increased mathematical complexity over JWL was originally implemented in order to model both overdriven detonation and early volume expansion work output, it has been found that this increased mathematical complexity also allows the flexibility to parameterize higher volume work output associated with blast output. As increased numbers of parameters can mean increased calibration complexity and does not guarantee increased accuracy for practical problems of interest, calibration techniques have been developed to provide robust detonation products equation of state parameters that are applicable to the broad range of high explosive work output associated with early volume expansion (metal pushing) and late volume expansion (blast).

3 JWL EQUATION OF STATE CALIBRATION

For this study, the JWL equation of state was parameterized for early volume expansion through the use of JAGUAR thermo-chemical equation of state calculations for detonation properties and associated cylinder test velocities. Formal optimization was used to parameterize JWL for TNT and LX-14. The early volume detonation state and early volume expan-

sion cylinder velocities were held constant, while the high volume work output associated with isentropic expansion was adjusted to increasingly higher values in order to approximate the energy output associated with explosive products afterburning.

3.1 Detonation and Cylinder Velocity Calculations

JAGUAR analytical procedures have been developed for the accurate calculation of detonation properties and cylinder test products expansion for H-C-N-O near ideal explosives. These routines use extended JCZ3 thermo-chemical equation of state procedures with EXP-6 potentials for H-C-N-O detonation products [4]. An analytic cylinder test model has long been used by ARDEC for explosive equation of state calibration and verification [5]. This analytic model has been shown to provide close agreement to high rate continuum modeling. The analytic model is based on adiabatic expansion along the principle isentrope from the Chapman-Jouguet state. Figure 1 presents a sketch of the analytic cylinder test model and ALE3D modeling of a cylinder test.

Figure 1. Analytic cylinder model (left) and ALE3D cylinder test modeling (right).

ALE3D high rate continuum modeling was compared to analytic cylinder test modeling using identical JWL-B equations of state for TNT and LX-14. The JWL-B equations of state were parameterized using JAGUAR thermo-chemical equation of state modeling [5]. Two different copper cylinder thicknesses, 1.2" OD, 1" ID 10" long and 1.3" OD, 1" ID 10" long, was modeled using the Johnson-Cook material model. Figure 2 presents the comparison of the analytic cylinder test model to the ALE3D modeling for TNT and LX-14 respectively.

Figure 2. TNT (left) and LX-14 (right) analytic cylinder model results compared to ALE3D calculations.

For each pair of curves, the higher curve represents the velocity history of the inside of the copper cylinder and the lower curve represents the velocity history of the outside of the cylinder. The analytic cylinder model slightly under predicts the velocities at 2 and 3 inside area expansions, but is in very close agreement by 6 and 7 inside area expansions. This is consistent with the fact that this analytic modeling approach neglects initial acceleration due to shock processes. Strong shock effects are typically observed in the 2 to 3 volume expansion region and are significantly damped out by 6 volume expansions, where very close agreement between the analytic model and ALE3D results are observed.

3.2 High Volume Products Expansion and Blast Calibration

For the modified total work output JWL equations of state, the detonation state and early volume expansion cylinder velocities were held constant, while the high volume work output associated with isentropic expansion to ambient pressure was adjusted to increasingly higher values. This increased total work output was incorporated in order to approximate the energy output associated with explosive products afterburning, as both TNT and LX-14 are negatively oxygen balanced (TNT: -74%, LX-14: -29.5%). Table 1 presents the standard TNT JWL parameters. Table 2 presents the TNT and LX-14 JWL parameters for the modified total work output study. Table 3 presents the analytically predicted cylinder velocities and associated predicted Gurney constants associated with each of the modified total work output JWL parameter sets using a 1" ID and 1.2" OD copper cylinder. The presented cylinder velocities and Gurney energies demonstrate that although the modified work output JWL parameter sets have increased total work output E0 values, the equation of states maintain the same predicted cylinder velocities and associated early volume expansion characteristics.

3.3 Blast Calculations

ALE3D was used to model the explosive detonation and subsequent blast produced by using standard JWL equations of state and modified total work output JWL equations of state. Air was modeled using the ideal gas equation of state with an adiabatic gamma of 1.4. A 13.85 cm diameter sphere of high explosive was detonated in the center of a high resolution mesh consisting of 5 million cells on a 200 cm cube. Tracer particles were placed at 9 positions evenly spaced from 2.5 foot (76.2 cm) to 6.5 foot (198.1 cm) from the charge center. Figure 3 presents pressure color plots from the computations at 30, 200 and 500 microseconds.

4 CONCLUSIONS

It is possible to produce increased total work output using the JWLB equation of state, while maintaining agreement accepted detonation characteristics and cylinder test data. This was done in an attempt to account for explosive detonation products afterburning with air, while avoiding the use of potentially inaccurate and computationally expensive air mixing, diffusion and combustion models. This modified equation of state approach seems reasonable, as it can be viewed as an analogous approach to the currently used empirical blast scaling. It is clear from the computational results, that agreement with empirical peak blast overpressures can be achieved and that the trend moving towards agreement incident blast impulse occurs as the total work output is increased. However, reasonable parameter sets become increasingly difficult to achieve as the total work output is increased. This is due to the difficulty in maintaining agreement with cylinder velocity values consistent with early detonation products expansion up to 7 times the initial unreacted explosive volume. Although reasonable agreement to the empirically based peak overpressures can be achieved, the results indicate that an explosive products afterburning model is required to achieve further agreement with empirically based peak overpressures and impulse. There is clear evidence of the effect of afterburning [7] with limited practical high rate continuum model development [8, 9] to date. One potential simplified approach is to use a partial equilibrium equation of state that was previously used successfully for the modeling of combined effects explosives aluminum reaction [10].

Key words: Structural Dynamics, Dynamic Load Allowance, Reinforced Concrete Bridges

Abstract. *A dynamic load allowance (DLA) is a quantitative measure of dynamic effects exerted in addition to static loads by moving vehicles on highway bridges. The American Association of State Highway and Transportation Officials (AASHTO) recommends using 33% as a maximum value of DLA [1]. The paper presents results of extensive investigation of DLA, which was carried out for the Florida Department of Transportation (FDOT) for a broad class of prestressed reinforced concrete bridges. FDOT manages over 6400 such bridges and precise information about their performance, due to heavy (so called: permit) vehicles, is critical for its Maintenance Office. Two parallel tracks: experimental and analytical, were designed and implemented as integral parts of this research. Each track resulted in data which was used to calculate DLA. Comparison of these results showed a good correlation between experiments and analyses, and was used to verify and validate finite element (FE) models developed.*

All experimental tests were carried out on a selected, typical, prestressed, reinforced concrete bridge #500133 on US 90 in north eastern Florida. It was a newer bridge, built in 1999 with three simply supported spans and AASHTO type III girders. A selected span of the bridge was instrumented with: (a) two linear variable displacement transformers (LVDT), (b) 38 strain gauges and (c) 14 accelerometers installed at the top of the bridge deck. 35 static and dynamic tests were carried out with the speed of 48 km/hr and 80 km/hr. Three representative permit vehicles were used for the tests. Data acquisition from experimental testing allowed for calculation of DLA.

The second research track consisted of FE model development and computational analysis using LS-DYNA computer code. In addition to the bridge #500133, two other local, prestressed, reinforced concrete bridges were selected for analytical studies of DLA. Their superstructure consisted of AASHTO type II and IV prestressed reinforced concrete girders. The FE model of the bridge #500133 was validated and verified using experimental data. DLA factors were calculated for all bridges as functions of vehicle types and their velocities. They were determined based on maximum displacements and strains. Several factors were identified as triggering significant DLA. They included: surface imperfections (as joint abutments and bridge approach depression), loosely attached cargo producing so called hammering effect, and characteristics of the vehicle suspension. This paper presents the latest results of the project, for which some earlier data was reported in [2] through [4].

1. INTRODUCTION

The Florida Department of Transportation (FDOT) has set a mission to rehabilitate the state transportation system, including roads highways and highway bridges. This research project responds to the call from the FDOT to improve the transportation system and to meet the needs for providing safer transportation. The state will need a huge investment over the next years to improve the transportation system. To decrease the total investment needed, the FDOT needs to significantly improve the operation and make sure that the proper maintenance of highway bridges is performed. In order to achieve this, more knowledge about certain effects resulting from dynamic loading of bridges is imperative. The information not only will help the FDOT make decisions on heavy vehicle permitting but also to establish permissible weight limits for bridges.

Traditional methods used for analysis of dynamic live loads on bridges use simplifications. This results in dynamic loads tending to be very conservative if not ignored. Ignoring the dynamic nature of live loads is not very convenient, and may result in premature damage of the bridge structure or a decrease in the bridge lifespan.

Dynamic live loads are taken into account by using dynamic load allowances (DLA), which is a factor to scale up the magnitude of the static load. By using a DLA engineers usually ignore vibrations and other damaging effects induced by heavy vehicles into bridges.

Reinforced concrete bridges usually have a behavior that is hard to explain, and applying advanced structural analysis to this type of structure is not simple. With advances in computational power and methods in computational mechanics, newer methods to analyze complex structures like bridges are coming to light. This advances in computer technology and computational capabilities, followed by development of commercial finite element (FE) software have made 3-D dynamic analysis of bridge structures more effective.

Further development of FE software in material models, and different applications of constraint and damping allows the software to more accurately represent the actual behavior of the bridge structure. The vast variety of element and material types allow for a better representation of vehicle components like the suspension system, which is critical in the interaction between vehicle and bridge. All these advancements in FE model software provide a powerful tool for the assessment of complex structural and mechanical phenomena such as a wheel rolling on the pavement. Most important for this type of analysis is the dependence of moving live loads varying with time caused by dynamic interaction of masses for the vehicle and the bridge components.

Experimental testing of bridges in the field is expensive and can only provide a limited amount of data. This project seeks to conduct comprehensive research on transient analysis of the dynamic interaction between heavy vehicles and prestressed concrete bridges using computational mechanics. Such approach offers less expensive and more accurate ways to conduct this research on dynamic load allowance factors.

Verification and validation of numerical models is a process that builds the credibility of the model. It is usually done by comparing a numerical model of a phenomena to the data obtained from the actual physical tests. Validated FE models can provide accurate information about the behaviour of the structure which are expensive and difficult if only experiments are used. This paper focuses on the use of validated FE models for the assessment of DLA of reinforced concrete bridges.

Three heavy permit vehicles were selected for analysis and their FE models were developed. The vehicles were selected based on their span length, number of axles, weight

distribution, and suspension characteristics. The vehicle FE models were verified and validated through experimental testing of the vehicles crossing over a speed bump.

Three reinforced concrete bridges were also selected from the northern part of Florida and their FE models were also developed. The selected bridges varied in span length, width, and girder type. The FE models of the bridges included road surface irregularities to assess the influence of the road surface imperfections on the bridge response. The FE models of the bridges were verified and validated through experimental tests conducted on one of the bridges.

The analyses performed in the project were based on explicit, dynamic, non-linear finite element computational mechanics using LS-DYNA computer code [8].

2. FE MODELS OF PERMIT VEHICLES

The FE models of the vehicles were simple but still reliable, with a good geometrical and physical representation of the actual trucks. The simplicity of the model reduced the necessary calculation time needed for numerical simulations and increased the performance and stability of the simulations.

Three vehicles were selected for analysis and FE models of them were developed. The vehicles selected were: a CH613 truck tractor with a single drop lowboy trailer, a Terex T-340 Crane, and a FDOT truck.

The FE models of the selected vehicles were developed using direct measurement and constant inspection of the vehicle, as blueprints or files with the data for the selected vehicles were not available. Extended efforts were made on the development of the vehicle's components which have a significant influence in the interaction with the road. Some of these components include: the vehicle's elastic tires, wheels, suspension system, single and tandem axles, and the chassis.

The first vehicle, the tractor-trailer, was selected because of its well designed suspension system, its length, and uniform weight distribution. The FE model of the tractor-trailer was developed using 2-D 3- and 4-node shell elements, and 3-D 6- and 8- node fully integrated solid elements for most of the vehicle component. The suspension system was modelled using 1-D discrete beam elements, with discrete spring and damper material models. Constitutive material models included elastic material for the truck frame, and fabric and rubber material for the wheels. Other components of the vehicle which were modelled as rigid parts include the driver cab, hood, and engine. The FE model of the tractor-trailer is summarized in Table 1 and is presented in Figure 1.

Specification		Specification	
Number of parts	204	Number of elements	26,194
Number of nodes	19,941	- solid elements	1128
Number of material models	38	- shell elements	24,790
		- beam elements	248
		- discrete elements	22
		- mass elements	6

Table 1: Summary of complete FE model of tractor-trailer [5].

Figure 1: An FE model of the tractor-trailer.

The second vehicle, the Terex crane, was selected because of its short length, and heavy load. The distribution of the heavy load over a short span created a compact setup which was very different from that of the tractor-trailer. The FE model of the Terex crane was developed using the same technique as for the tractor-trailer with the same material models with slight variation on the properties of steel. This FE model was the simplest one with most of its components being rigid. More detailed information about the development of the FE model of the Terex crane is available in [5]. The FE model of the Terex crane is summarized in Table 2 and is presented in Figure 2.

Specification		Specification	
Number of parts	153	Number of elements	20,837
Number of nodes	17,401	- solid elements	1,338
Number of material models	29	- shell elements	19,323
		- beam elements	142
		- discrete elements	28
		- mass elements	6

Table 2: Summary of complete FE model of Terex crane [5].

Figure 2: An FE model of the Terex crane.

The third vehicle, the FDOT truck, was chosen because of its purposely designed stiff suspension. The FDOT truck was custom-built for the FDOT to conduct dynamic tests on bridge structures and so was designed with the worst possible suspension characteristics to test the worst case dynamic loadings. The truck consists of a very simple suspension system

with two tandem axles which were easy to model. The FE model of the FDOT truck was developed using the same technique as the other two vehicles, with the same material models and element types. The FE model of the FDOT truck is summarized in Table 3 and is presented in Figure 3.

Specification		Specification	
Number of parts	181	Number of elements	18,569
Number of nodes	13,031	- solid elements	926
Number of material models	25	- shell elements	17,137
		- beam elements	440
		- discrete elements	58
		- mass elements	8

Table 3: Summary of complete FE model of FDOT truck [5].

Figure 3: An FE model of the FDOT truck.

3. VERIFICATION AND VALIDATION OF VEHICLE FE MODELS

Verification and validation of the vehicle's FE model was obtained through comparison with data obtained from experimental testing on the actual vehicles. For the purpose of validation of the vehicle mass, each vehicle axle loads were measured using scales. Each axle of the FE models was then dropped into planar rigid walls for which LS-DYNA [8] allows an easy measurement of the load. The final measurements of the experiment and the virtual trucks are summarized in Table 4.

A test was designed and conducted in Broadmoor Estate in Tallahassee for validation of the suspension system of the vehicles. The vehicles were equipped with displacement gauges and accelerometers, and then driven over a speed bump at speeds varying from 8 to 32 km/h. Lower velocities were used to ensure the driver's safety and preserve the testing equipment, which is a common practice found in the literature. The test measured the acceleration of a point in the frame and the change in distance between a point in the frame and the axle. The test was then replicated virtually with the vehicles driven over the same speed bump at the same speeds. To ensure the numerical analysis matched the actual test, the asphalt speed bump was modelled using the exact geometry of the bump which was obtained from an Optech's Intelligent Laser Ranging and Imaging System (ILRIS) scanner. More detailed information about the development of the speed bump FE model is available in [5]. Experimental and virtual results of the tractor-trailer are compared in Figure 4.

Axle No.	Axle type	Axle load (kN)		Relative error (%)
		Measurements	FE model	
1	Front steer axle	42.184	42.291	0.25
2	Forward tandem drive axle	89.440	89.439	0.00
3	Rear tandem drive axle	94.957	95.008	0.05
4	First trailer axle	94.601	93.946	-0.69
5	Second trailer axle	98.517	97.908	-0.62
6	Third trailer axle	100.831	101.754	0.92
TOTAL		520.530	520.346	-0.04

Table 4: Axle loads for the tractor trailer in experiment and FE analysis [5].

Figure 4: Time histories from experiment and FE analysis of the tractor trailer at 24 km/h.

The load measurements of the truck and its FE model were matched quantitatively; this was obtained by adding discrete mass points in the FE model and making changes in material densities.

The spring and damper coefficients for the FE models were initially obtained from the manufacturer's websites. The results of the test were matched with the numerical analysis quantitatively by modifying the spring stiffness until there was conformity between the two. The process was done carefully to keep the proper distribution of sprung and unsprung mass, as well as to maintain the proper length of the springs in its static configuration. This process was applied to all the FE models of the permit vehicles used in this study. The vehicles were then considered to be validated.

4. FE MODELS OF REINFORCED CONCRETE BRIDGES

FE modelling of 3-D bridges became more common over the past decade [3], [4], [5], [6]. The models are becoming more sophisticated due to the increased efficiency and capability of computer software.

Three highway bridges near Tallahassee were selected for analysis of DLA factors. These bridges were selected because they consisted of prestressed reinforced concrete girders according to the American Association of State Highway and Transportation Officials

(AASHTO) [1]. Data for one span of each of the three bridges selected for analysis is summarized in Table 5.

Bridge Name	Bridge No.	AASHTO Girder Type	Span Length (m)	Width (m)
No Name Creek	#540074	II	12.1	11.6
Chattahoochee	#500133	III	21.0	13.1
St. Mark's	#590056	IV	29.3	12.6

Table 5: Summary of selected bridges for analysis.

An FE model of one span of each bridge was developed. The bridge model included six different components such as: bearing pads, concrete girders, diaphragm, concrete deck, bridge barriers, and bridge approach surface. The components were modelled according to geometric data obtained from one of the bridge's blueprints provided by the FDOT. The other two bridges were modelled using measurements obtained in situ.

Unreinforced neoprene bearing pads were used to support the FE model of the girders at each end. The bearing pads were modelled using 3-D 8-node fully integrated solid elements with a viscoelastic material model selected for analysis. The material properties of the neoprene pads were inspected and assessed in [7].

The FE model of the concrete girders was developed using 3-D 8- and 6-node fully integrated solid elements. An elastic material model was used for analysis with properties for concrete obtained from cylinder testing of the girders by the FDOT Structures Research Laboratory.

Reinforcement of the girders included reinforcing bars and prestressing strands, which were modelled using 1-D beam and rod elements respectively.

Each AASHTO girder included two No. 9 strands at the top and 24 No. 13 strands at the bottom. One equivalent strand at the top and eleven equivalent strands at the bottom were modeled due to the discrete location of the nodes in the FE model cross section. Selected strands were grouped and their properties were lumped together as presented in Figure 5. The process was done to make sure that the FE model accurately behaved like the real beam.

A special material model (MAT_CABLE_DISCRETE_BEAM) was applied to the strands which allowed an introduction of prestressing forces, and allowed the cables to carry tensile loads without any stiffness for compression [8].

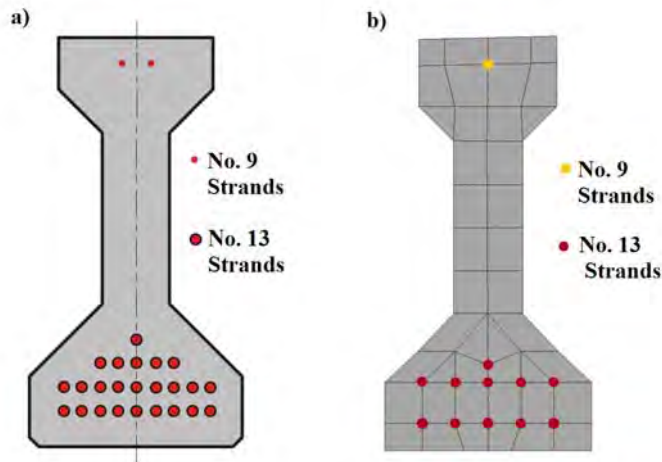

Figure 5: Prestressing strands: a) actual location in girder, b) equivalent location in FE model.

The FE model of the diaphragm, concrete deck, and bridge barriers were modelled using 3-D fully integrated solid elements. The elastic material model was selected for analysis, with their actual properties for concrete as tested. Reinforcement of these components was modelled using 1-D beam elements for the reinforcing bars. Elastic material models with specific properties for steel were used for the reinforcements according to the blueprint information.

The bridge approach surfaces of all three bridges were inspected and the surface with the worst deterioration of the three was selected. The surface of bridge #500133 exhibit an area characterized by two distinct ruts made in the asphalt by passing vehicles, with the adjacent stronger concrete deck not showing such wear and tear damage. As a result there was a difference in elevation between the asphalt and the concrete which was found to be around 15 to 20 mm. The approach surface was found to have a pronounced effect in the dynamic response of the bridge; therefore the same approach surface was used on all three bridges to make use of the worst conditions available. The bridge approach surface was modelled as is, with the exact geometry obtained using Optech's ILRIS scanner. More detailed information on the development of the bridge approach surface model is available in [5].

The final FE model of the bridge consisted of 145,604 finite elements. A similar process was used for the development of the other two bridges. The final FE model of one of the bridges is presented in Figure 6.

Figure 6: An FE model of bridge #500133.

5. VALIDATION AND VERIFICATION OF FE BRIDGE MODELS

Validation of the concrete bridges was obtained by experimental testing of one of the selected bridges. All experimental tests were carried out on bridge #500133 on US 90 in north eastern Florida. This newer bridge was built in 1999 with three simply supported spans and with six AASHTO type III girders in each span. The bridge was tested twice, first in 2003 with an FDOT truck, and then in 2008, including two additional vehicles: the tractor trailer and the Terex crane. One span of the bridge was instrumented with two linear variable displacement transformers (LVDT), 38 strain gauges, and 14 accelerometers installed at the top of the bridge deck. Over 35 static and dynamic tests were carried out at speeds ranging from 48 to 80 km/h. Data obtained from the experimental testing allowed for calculation of DLA, and comparison to results from the numerical model. Detailed description of the tests carried out on the bridge and the results are available in [5].

The tests were virtually replicated, with strains and displacements obtained from the same points as in the experiment. Figure 7 shows result of the experiment and numerical analysis for one case, in which the tractor trailer crosses the bridge in the center of the westbound lane at a speed of 80 km/h.

Figure 7: Time histories from experiment and FE analysis at 80 km/h over bridge #500133.

It is observed that the strain values are between ranges of measurement error. Results for displacements show a largest discrepancy which is attributed to the lack of zeroing of the displacement meters before each test. Still with some of the error observed, the values are accepted as qualitatively rather than quantitatively. The complete results of the tests are available in [5]. The same process was carried out with all three vehicles, and the FE model of the bridge was considered to be validated.

6. ANALYSIS OF DYNAMIC LOAD ALLOWANCE

DLA factors were calculated for all three bridges loaded with all three vehicles. DLAs were determined based on maximum displacement and strains in the bottom of the girder in the middle of the bridge span. DLA factors based on maximum strains proved to be more reliable, and closer to the experimental data, as well as recommended values by AASHTO [1]. The largest strains and displacements were recorded in girders no. 4 and 5 located

directly underneath the path of the vehicle during the tests. Over ninety different tests with the numerical models were conducted to study the effect of the velocity on the DLA factor. As an illustration, DLA variation due to the vehicle speed is presented for one of the cases in Figure 8.

Figure 8: DLA factor vs. speed for the tractor trailer on bridge #500133.

Figure 8 illustrates the fact that DLA factors do not necessarily monotonically increase as vehicle speed increases. For this case of the tractor-trailer crossing over the bridge, the maximum DLA factor observed was at speed of about 88 km/h with a value of about 14%. DLA factors were calculated for every case with the same observation in all the cases.

The suspension system of the vehicles was one of the most influential characteristics that affected the dynamic response of the bridge. Results of DLA factors for the three vehicles crossing over bridge #500133 at a specified speed are presented in Table 6.

Vehicle	Speed (km/h)	DLA (%)
Tractor-trailer	80	6.6
Terex crane	80	32.7
FDOT truck	80	35.4

Table 6: Analysis of vehicles traveling over bridge #500133.

Another feature identified as triggering an increased DLA is a loosely attached cargo that is able to bounce on top of the trailer, producing a so called hammering effect. The tractor trailer model was modified to allow the bouncing of the cargo on top of the trailer. The cargo was detached from the trailer and seatbelt elements were introduced to act as tying chains. Final results of the testing of the tractor-trailer on bridge #500133 are presented in Figure 9.

Figure 9: Deflection of the bridge girder #4 from FE analyses at 80 km/h.

It can be seen from Figure 9 that with the modifications made to the tractor-trailer model, the bridge was subjected to a larger displacement, which was caused by an additional pounding of the bouncing load on the bridge. Qualitatively both time histories look the same, but there is an additional frequency observed in the modified model of about $f = 4.8$ Hz. This pounding frequency was consistent with those observed earlier during the experimental testing of bridge #500133.

The quality of the bridge approach depression was also found to have a significant impact on the DLA factors calculated. The bridge approach depression of the FE model of bridge #500133 was replaced by a perfectly flat approach surface. The virtual experiment used the Terex crane travelling at a speed of 80 km/h. Strain measurements from the virtual tests are presented in Figure 10. The strain for the case in which the vehicle travels over the flat approach shows a decrease in magnitude.

Figure 10: Longitudinal strains from FE analyses for girder #4 at 80 km/h.

7. CONCLUSIONS

This paper presented a comprehensive analysis of vehicle-bridge dynamic systems. The complete analysis consisted of computational mechanics and experimental parts. Three FE models of highway bridges and three FE models of heavy vehicles were used. Analysis of DLA factors was conducted for all bridges depending on vehicle speed and type. Efforts were made to develop realistic vehicle models for they account as much as 20% of the total mass of the vehicle-bridge system. Representing them as concentrated loads would not provide accurate data on the real system.

Considering the analysis was of dynamic nature, the vehicles springs and dampers were accounted for through a careful modelling process of the suspension systems. Rotating wheels and tires were also modelled carefully due to their influence on the vehicle-bridge dynamic system. The accuracy of the results obtained is credited to the development of the innovative finite element models and is supported with data from experimental tests. From the analysis several factors were found to have a significant influence on the DLA such as:

1. Vehicle suspension system: the very stiff suspension from FDOT resulted in the worst DLA factors in most of the cases.
2. Road surface condition: faults in the abutment joint and surface imperfections such as cracks and ruts; when compared to a flat surface result in a much higher DLA factor.
3. Loosely attached cargo which is able to bounce on top of the trailer: an additional pounding frequency is observed with a higher dynamic response on the bridge.

These were the factors that had the most influence on the magnitude of the DLA factors. From the variety of tests conducted in computational analysis, some other observations were also made, such as:

1. AASHTO recommendation value of $DLA = 33\%$ appeared to be a reasonable approximation with only five cases surpassing it, but at relatively high speeds as presented in Figure 11.

Figure 11: Summary of FE analyses of all the vehicle-bridge interactions.

2. The DLA factor does not monotonically increase as the vehicle speed increases; a lower vehicle speed in certain cases resulted in a higher DLA factor.
3. The bridge dynamic response is dependent on a combination of span length, width, and girder type which specifies the structure natural frequency.
4. The DLA factors also depend on the bridge natural frequency, and vibrations transferred in the interaction with the heavy vehicle.

ACKNOWLEDGEMENTS

This study was completed under direction and in cooperation with the Florida Department of Transportation Structures Laboratory. Thanks to all the professionals who helped in conducting all the experimental tests including Marc Ansley, Stephen Eudy, William Potter and Paul Tighe. All the comments, advice, guidance, and technical support provided by this group of professionals were essential in the development of the project and are highly appreciated. Thanks are also due to Blueprint 2000 office in Tallahassee for making Broadmoor Estate available free of charge for speed bump testing. Opinions and views expressed in this paper are those of the authors and not necessarily those of the sponsoring Agency.

Key words: Flexural-Torsional Analysis, Dynamic analysis, Wagner's coefficients, Nonlinear analysis, Shortening Effect, Boundary element method.

Abstract. *In this paper a boundary element method is developed for the nonlinear flexural-torsional dynamic analysis of beams of arbitrary, simply or multiply connected, constant cross section, undergoing moderate large deflections and rotations under general boundary conditions, taking into account the effects of rotary and torsional warping inertia. Four boundary value problems are formulated with respect to the transverse displacements, to the axial displacement and to the angle of twist and solved using the Analog Equation Method, a BEM based method. The geometric, inertia, torsion and warping constants are evaluated employing the Boundary Element Method. The proposed model takes into account, both the Wagner's coefficients and the shortening effect. Numerical examples are worked out to illustrate the efficiency, wherever possible the accuracy, the range of applications of the developed method as well as the influence of the nonlinear effects to the response of the beam.*

1 INTRODUCTION

In engineering practice, we often come across the analysis of beam structures subjected to vibratory loading. This problem becomes much more complicated in the case the cross section's centroid does not coincide with its shear center (asymmetric beams), leading to the formulation of the flexural-torsional vibration problem. Besides, when arbitrary torsional boundary conditions are applied either at the edges or at any other interior point of the bar due to construction requirements, this bar under the action of general twisting loading is leaded to nonuniform torsion. Moreover, since weight saving is of paramount importance, frequently used thin-walled open section beams have low flexural and/or torsional stiffness and their deformations can be of such magnitude that it is not adequate to treat the cross section displacements and its angle of rotation as small. In these cases, the study of nonlinear effects on these members becomes essential, where this non-linearity results from retaining the nonlinear terms in the strain–displacement relations (finite displacement – small strain theory). When finite displacements are considered, the flexural-torsional dynamic analysis of bars becomes much more complicated, leading to the formulation of coupled and nonlinear flexural, torsional and axial equilibrium equations.

When the displacement components of a member are small, a wide range of linear analysis tools, such as modal analysis, can be used and some analytical results are possible. As these components become larger, the induced geometric nonlinearities result in effects that are not observed in linear systems. In such situations the possibility of an analytical solution method is significantly reduced and is restricted to special cases of beam boundary conditions or loading.

During the past few years, the nonlinear dynamic analysis of beams undergoing large deflections has received a good amount of attention in the literature. More specifically, Rozmarynowski and Szymczak in [1] studied the nonlinear free torsional vibrations of axially immovable thin-walled beams with doubly symmetric open cross section, employing the Finite Element Method. In this research effort only free vibrations are examined, the solution is provided only at points of reversal of motion (not in the time domain), no general axial, torsional or warping boundary conditions (elastic support case) are studied, while some nonlinear terms related to the finite twisting rotations as well as the axial inertia term are ignored. Crespo Da Silva in [2-3] presented the nonlinear flexural-torsional-extensional vibrations of Euler-Bernoulli doubly symmetric thin-walled closed cross section beams, primarily focusing to flexural vibrations and neglecting the effect of torsional warping. Pai and Nayfeh in [4-6] studied also the nonlinear flexural-torsional-extensional vibrations of metallic and composite slewing or rotating closed cross section beams, primarily focusing to flexural vibrations and neglecting again the effect of torsional warping. Simo and Vu-Quoc in [7] presented a FEM solution to a fully nonlinear (small or large strains, hyperelastic material) three dimensional rod model including the effects of transverse shear and torsion-warping deformation based on a geometrically exact description of the kinematics of deformation. Qaisi in [8] obtained nonlinear normal modes of free vibrating geometrically nonlinear beams of various edge conditions employing the harmonic balance analytical method. Moreover, Pai and Nayfeh in [9] studied a geometrically exact nonlinear curved beam model for solid composite rotor blades using the concept of local engineering stress and strain measures and taking into account the in-plane and out-of-plane warpings. Di Egidio et al. in [10-11] presented also a FEM solution to the nonlinear flexural-torsional vibrations of shear undeformable thin-walled open beams taking into account in-plane and out-of-plane

warpings and neglecting warping inertia. In this paper, the torsional-extensional coupling is taken into account but the inextensionality assumption leads to the fact that the axial boundary conditions are not general. Mohri et. al. in [12] proposed a FEM solution to the linear vibration analysis of pre- and post- buckled thin-walled open cross section beams, neglecting warping and axial inertia, considering geometrical nonlinearity only for the static loading and presenting examples of bars subjected to free vibrations and special boundary conditions. Machado and Cortinez in [13] presented also a FEM solution to the linear free vibration analysis of bisymmetric thin-walled composite beams of open shaped cross section, taking into account static initial stresses and deformations considering geometrical nonlinearity only for the static loading and presenting examples of bars subjected to special boundary conditions. Avramov et. al. [14-15] studied the free flexural-torsional vibrations of beams and obtained nonlinear normal modes by expansion of the equations of motion employing the Galerkin technique and neglecting the cross-section warping. Lopes and Ribeiro [16] studied also the nonlinear flexural-torsional free vibrations of beams employing a FEM solution and neglecting the longitudinal and rotary inertia as well as the cross-section warping. Duan [17] presented a FEM formulation for the nonlinear free vibration problem of thin-walled curved beams of asymmetric cross-section based on a simplified displacement field. Finally, the boundary element method has also been used for the nonlinear flexural [18-20] and torsional [21] dynamic analysis of only doubly symmetric beams. To the authors' knowledge the general problem of coupled nonlinear flexural – torsional free or forced vibrations of asymmetric beams has not yet been presented.

In this paper, a boundary element method is developed for the nonlinear flexural-torsional dynamic analysis of beams of arbitrary, simply or multiply connected, constant cross section, undergoing moderate large deflections and twisting rotations under general boundary conditions, taking into account the effects of rotary and warping inertia. The beam is subjected to the combined action of arbitrarily distributed or concentrated transverse loading in both directions as well as to twisting and/or axial loading. Four boundary value problems are formulated with respect to the transverse displacements, to the axial displacement and to the angle of twist and solved using the Analog Equation Method [22], a BEM based method. Application of the boundary element technique leads to a system of nonlinear coupled Differential – Algebraic Equations (DAE) of motion, which is solved iteratively using the Petzold-Gear Backward Differentiation Formula (BDF) [23], a linear multistep method for differential equations coupled to algebraic equations (DAE). The geometric, inertia, torsion and warping constants are evaluated employing the Boundary Element Method. The essential features and novel aspects of the present formulation compared with previous ones are summarized as follows.

- i. The cross section is an arbitrarily shaped thin or thick walled one. The formulation does not stand on the assumption of a thin-walled structure and therefore the cross section's torsional and warping rigidities are evaluated “exactly” in a numerical sense.
- ii. The beam is subjected to an arbitrarily distributed or concentrated transverse loading and bending moments in both directions as well as to axial loading.
- iii. The beam is supported by the most general boundary conditions including elastic support or restraint.
- iv. For the first time in the literature, the effects of rotary and warping inertia are taken into account on the nonlinear flexural-torsional dynamic analysis of asymmetric beams subjected to arbitrary loading and boundary conditions.

- v. The transverse loading can be applied at any arbitrary point of the beam cross section. The eccentricity change of the transverse loading during the torsional beam motion, resulting in additional torsional moment is taken into account.
 - vi. The proposed model takes into account the coupling effects of bending, axial and torsional response of the beam as well as the Wagner's coefficients and the shortening effect.
 - vii. The proposed method employs a BEM approach (requiring boundary discretization for the cross sectional analysis) resulting in line or parabolic elements instead of area elements of the FEM solutions (requiring the whole cross section to be discretized into triangular or quadrilateral area elements), while a small number of line elements are required to achieve high accuracy.
- Numerical examples are worked out to illustrate the efficiency, wherever possible the accuracy, the range of applications of the developed method as well as the influence of the nonlinear effects to the response of the beam.

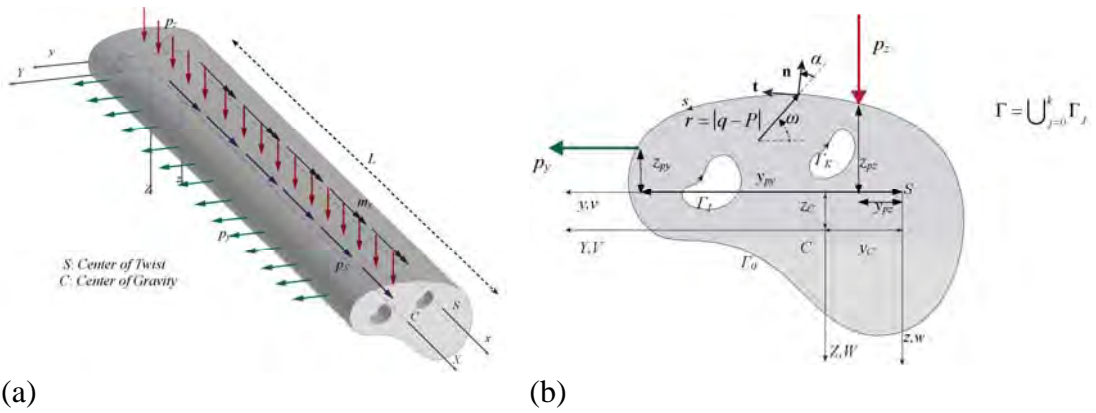

Figure1: Prismatic beam in axial - flexural - torsional loading (a) of an arbitrary cross-section occupying the two dimensional region Ω (b).

3 STATEMENT OF THE PROBLEM

Let us consider a prismatic beam of length L (Fig.1), of constant arbitrary cross section of area A . The homogeneous isotropic and linearly elastic material of the beam's cross section, with modulus of elasticity E , shear modulus G and Poisson's ratio ν occupies the two dimensional multiply connected region Ω of the y, z plane and is bounded by the Γ_j ($j=1,2,...,K$) boundary curves, which are piecewise smooth, i.e. they may have a finite number of corners. In Fig. 1 CYZ is the principal bending coordinate system through the cross section's centroid C , while y_c, z_c are its coordinates with respect to the Syz shear system of axes through the cross section's shear center S , with axes parallel to those of the CYZ system. The beam is subjected to the combined action of the arbitrarily distributed or concentrated, time dependent and conservative axial loading $p_x = p_x(X, t)$ along X direction, twisting moment $m_x = m_x(x, t)$ along x direction and transverse loading $p_y = p_y(x, t)$, $p_z = p_z(x, t)$ acting along the y and z directions, respectively, applied at distances y_{p_y}, z_{p_y} and y_{p_z}, z_{p_z} , with respect to the Syz shear system of axes (Fig. 1b). It is worth here noting that the aforementioned transverse loading can be applied at any arbitrary point of the beam's cross section and not necessarily at its centroid or at its shear center. In the case of a linear analysis, where the beam deflections and rotations

are considered to be small, in order to overcome the fact that the external transverse loading is usually applied as tractions upon the surface of the beam, the superposition principle is adopted and the actual applied system of forces is replaced by a statically equivalent one, acting on the centroid or on the shear center of the beam (Fig. 2a). However in nonlinear analysis, where twisting rotations are considered to be large, the occurring change of eccentricity (Fig. 2b) may have substantial influence on the beam response and must be taken into account.

Figure 2: Superposition principle in linear analysis (a) and change of eccentricity of the transverse force p_z during the twisting motion of the cross section in nonlinear analysis (b).

Under the action of the aforementioned loading and employing the Euler-Bernoulli assumption, the displacement field of an arbitrary point of the cross section can be derived with respect to those of the shear center as [12]

$$\bar{u}(x, y, z, t) = u(x, t) - (y - y_c)\theta_z(x, t) + (z - z_c)\theta_y(x, t) + \theta'_x(x, t)\phi_S^P(y, z) \quad (1a)$$

$$\bar{v}(x, y, z, t) = v(x, t) - z \sin(\theta_x(x, t)) - y[1 - \cos(\theta_x(x, t))] \quad (1b)$$

$$\bar{w}(x, y, z, t) = w(x, t) + y \sin(\theta_x(x, t)) - z[1 - \cos(\theta_x(x, t))] \quad (1c)$$

$$\theta_y(x, t) = v'(x, t) \sin(\theta_x(x, t)) - w'(x, t) \cos(\theta_x(x, t)) \quad (1d)$$

$$\theta_z(x, t) = v'(x, t) \cos(\theta_x(x, t)) + w'(x, t) \sin(\theta_x(x, t)) \quad (1e)$$

where \bar{u} , \bar{v} , \bar{w} are the axial and transverse beam displacement components with respect to the Syz shear system of axes; $u(x, t) = \frac{1}{A} \int_A \bar{u}(x, y, z, t) dA$ denotes the average axial displacement of the cross section [24] and $v = v(x, t)$, $w = w(x, t)$ are

the corresponding components of the shear center S ; $\theta_y(x, t)$, $\theta_z(x, t)$ are the angles of rotation of the cross section due to bending, with respect to its centroid; $\theta'_x(x, t)$ denotes the rate of change of the angle of twist $\theta_x(x, t)$ regarded as the torsional curvature and ϕ_S^P is the primary warping function with respect to the shear center S [25]. Employing the strain-displacement relations of the three-dimensional elasticity for moderate displacements [26, 27], the strain components can be written as

$$\begin{aligned} \varepsilon_{xx} = & u' + (z - z_C)(v'' \sin \theta_x - w'' \cos \theta_x) - (y - y_C)(v'' \cos \theta_x + w'' \sin \theta_x) + \\ & + \theta_x'' \phi_S^P - \theta_x' (z_C (v' \cos \theta_x + w' \sin \theta_x) + y_C (v' \sin \theta_x - w' \cos \theta_x)) + \\ & + \frac{1}{2} \left(v'^2 + w'^2 + (y^2 + z^2) (\theta_x')^2 \right) \end{aligned} \quad (2a)$$

$$\gamma_{xy} = 2\varepsilon_{xy} = \left(\frac{\partial \phi_S^P}{\partial y} - z \right) \theta_x' \quad (2b)$$

$$\gamma_{xz} = 2\varepsilon_{xz} = \left(\frac{\partial \phi_S^P}{\partial z} + y \right) \theta_x' \quad (2c)$$

while considering strains to be small, the non vanishing stress components of the second Piola – Kirchhoff stress tensor are obtained as

$$\begin{aligned} S_{xx} = & E \left[u' + (z - z_C)(v'' \sin \theta_x - w'' \cos \theta_x) - (y - y_C)(v'' \cos \theta_x + w'' \sin \theta_x) + \right. \\ & + \theta_x'' \phi_S^P - \theta_x' (z_C (v' \cos \theta_x + w' \sin \theta_x) + y_C (v' \sin \theta_x - w' \cos \theta_x)) + \\ & \left. + \frac{1}{2} \left(v'^2 + w'^2 + (y^2 + z^2) (\theta_x')^2 \right) \right] \end{aligned} \quad (3a)$$

$$S_{xy} = G \cdot \theta_x' \cdot \left(\frac{\partial \phi_S^P}{\partial y} - z \right) \quad (3b)$$

$$S_{xz} = G \cdot \theta_x' \cdot \left(\frac{\partial \phi_S^P}{\partial z} + y \right) \quad (3c)$$

In order to establish the nonlinear equations of motion, the principle of virtual work

$$\delta W_{\text{int}} + \delta W_{\text{mass}} = \delta W_{\text{ext}} \quad (4)$$

where

$$\delta W_{\text{int}} = \int_V (S_{xx} \delta \varepsilon_{xx} + S_{xy} \delta \gamma_{xy} + S_{xz} \delta \gamma_{xz}) dV \quad (5a)$$

$$\delta W_{\text{mass}} = \int_V \rho (\ddot{u} \delta \bar{u} + \ddot{v} \delta \bar{v} + \ddot{w} \delta \bar{w}) dV \quad (5b)$$

$$\delta W_{\text{ext}} = \int_L (p_x \delta \bar{u}_C + p_y \delta \bar{v}_{p_y} + p_z \delta \bar{w}_{p_z} + m_x \delta \theta_x) dx \quad (5c)$$

under a Total Lagrangian formulation, is employed. In the above equations, $\delta(\cdot)$ denotes virtual quantities, $(\dot{\cdot})$ denotes differentiation with respect to time, V is the volume of the beam, \bar{u}_C is the axial displacement of the centroid and \bar{v}_{p_y} , \bar{w}_{p_z} are the transverse displacements of the points where the loads p_y , p_z , respectively, are applied. It is worth here noting that the aforementioned relation of the external work δW_{ext} (eqn. (5c)) is expressed in terms of the applied external forces and virtual quantities of the kinematical components in the deformed configuration of the beam. This expression takes into account the change of the eccentricity of the external conservative transverse loading, arising from the cross section torsional rotation, inducing additional (positive or negative) torsional moment (Fig. 2b). Substituting the expressions of virtual quantities in eqn. (5c), the external work can be written as

$$\delta W_{ext} = \int_L \left[p_x \delta u + p_y \delta v + p_z \delta w + \left(p_y \left(-z_{p_y} \cos \theta_x - y_{p_y} \sin \theta_x \right) + p_z \left(y_{p_z} \cos \theta_x - z_{p_z} \sin \theta_x \right) + m_x \right) \delta \theta_x \right] dx \quad (6)$$

Expanding the trigonometric functions in terms of Taylor series and keeping the first two terms [12], the following approximate expressions are obtained

$$\cos \theta_x = 1 - \frac{\theta_x^2}{2!} = 1 - \frac{\theta_x^2}{2} \quad (7a)$$

$$\sin \theta_x = \theta_x - \frac{\theta_x^3}{3!} = \theta_x - \frac{\theta_x^3}{6} \quad (7b)$$

Using equations (7), equation (6) can be written as

$$\delta W_{ext} = \int_L \left[p_x \delta u + p_y \delta v + p_z \delta w + \left(p_y \left(-z_{p_y} - y_{p_y} \theta_x + \frac{1}{2} \theta_x^2 z_{p_y} + \frac{1}{6} \theta_x^3 y_{p_y} \right) + p_z \left(y_{p_z} - z_{p_z} \theta_x - \frac{1}{2} \theta_x^2 y_{p_z} + \frac{1}{6} \theta_x^3 z_{p_z} \right) + m_x \right) \delta \theta_x \right] dx \quad (8)$$

As it can be observed from equation (8), neglecting all the nonlinear terms leads to the well known linear expression of the external twisting moment, arising from the superposition principle. In the present study, these terms are retained, so that the change of eccentricity is taken into account. Moreover, the stress resultants of the beam can be defined as

$$N = \int_{\Omega} S_{xx} d\Omega \quad (9a)$$

$$M_Y = \int_{\Omega} S_{xx} Z d\Omega \quad (9b)$$

$$M_Z = - \int_{\Omega} S_{xx} Y d\Omega \quad (9c)$$

$$M_t^P = \int_{\Omega} \left[S_{xy} \left(\frac{\partial \phi_s^P}{\partial y} - z \right) + S_{xz} \left(\frac{\partial \phi_s^P}{\partial z} + y \right) \right] d\Omega \quad (9d)$$

$$M_w = -\int_{\Omega} S_{xx} \phi_s^P d\Omega \quad (9e)$$

$$M_R = \int_{\Omega} S_{xx} (y^2 + z^2) d\Omega \quad (9f)$$

where M_t^P is the primary twisting moment [25, 28] resulting from the primary shear stress distribution S_{xy} , S_{xz} , M_w is the warping moment due to torsional curvature and M_R is a higher order stress resultant. Substituting the expressions of the stress components (3) into equations (9a-9f), the stress resultants are obtained as

$$N = EA \left[u' + \frac{1}{2} \left(v'^2 + w'^2 + \frac{I_s}{A} \theta_x'^2 \right) - \theta_x' \left(z_c \left(v' \cos \theta_x + w' \sin \theta_x \right) + y_c \left(v' \sin \theta_x - w' \cos \theta_x \right) \right) \right] \quad (10a)$$

$$M_Y = -EI_Y \left(w'' \cos \theta_x - v'' \sin \theta_x - \beta_z \theta_x'^2 \right) \quad (10b)$$

$$M_Z = EI_Z \left(v'' \cos \theta_x + w'' \sin \theta_x - \beta_Y \theta_x'^2 \right) \quad (10c)$$

$$M_t^P = GI_t \theta_x' \quad (10d)$$

$$M_w = -EC_s \left(\theta_x'' + \beta_{\omega} \theta_x'^2 \right) \quad (10e)$$

$$M_R = N \frac{I_s}{A} - 2EI_Z \beta_Y \left(v'' \cos \theta_x + w'' \sin \theta_x \right) - 2EI_Y \beta_Z \left(w'' \cos \theta_x - v'' \sin \theta_x \right) + 2EC_s \beta_{\omega} \theta_x'' + \frac{1}{2} E \left(I_R - \frac{I_s^2}{A} \right) \theta_x'^2 \quad (10f)$$

where the area A , the polar moment of inertia I_s with respect to the shear center S , the principal moments of inertia I_Y , I_Z with respect to the cross section's centroid, the fourth moment of inertia I_R with respect to the shear center S , the torsion constant I_t and the warping constant C_s with respect to the shear center S , are given as

$$A = \int_{\Omega} d\Omega \quad (11a)$$

$$I_s = \int_{\Omega} (y^2 + z^2) d\Omega \quad (11b)$$

$$I_Y = \int_{\Omega} Z^2 d\Omega \quad (11c)$$

$$I_Z = \int_{\Omega} Y^2 d\Omega \quad (11d)$$

$$I_R = \int_{\Omega} (y^2 + z^2)^2 d\Omega \quad (11e)$$

$$C_s = \int_{\Omega} (\phi_s^P)^2 d\Omega \quad (11f)$$

$$I_t = \int_{\Omega} \left(y^2 + z^2 + y \frac{\partial \phi_s^P}{\partial z} - z \frac{\partial \phi_s^P}{\partial y} \right) d\Omega \quad (11g)$$

while the Wagner's coefficients β_z , β_y and β_ω are given as

$$\beta_z = \frac{1}{2I_y} \int_{\Omega} (z - z_c)(y^2 + z^2) d\Omega \quad (12a)$$

$$\beta_y = \frac{1}{2I_z} \int_{\Omega} (y - y_c)(y^2 + z^2) d\Omega \quad (12b)$$

$$\beta_\omega = \frac{1}{2C_s} \int_{\Omega} (y^2 + z^2) \varphi_s^p d\Omega \quad (12c)$$

Employing the expressions of strain obtained in equations (2), the expressions of stress resultants given in equations (10) and applying the principle of virtual work (eqn. (4)), the equations of motion of the beam can be derived. The arising set of equations is coupled and highly complicated. Simplification can be achieved by neglecting the axial inertia of the beam, denoted by the term $\rho A \ddot{u}$, and employing the approximate expressions given in equations (7). Thus, using the aforementioned approximations and ignoring the nonlinear terms of the fourth or greater order [12], the governing partial differential equations of motion for the beam at hand can be written as

$$\begin{aligned} -EA \left[u'' + w'w'' + v'v'' + \frac{I_s}{A} \theta_x' \theta_x'' - z_c \left(\theta_x \theta_x' w'' + \theta_x \theta_x'' w' + \theta_x'' v' + \theta_x' v'' + \theta_x'^2 w' \right) - \right. \\ \left. - y_c \left(\theta_x \theta_x'' v' + \theta_x \theta_x' v'' - \theta_x'' w' - \theta_x' w'' + \theta_x'^2 v' \right) \right] = p_X \end{aligned} \quad (13a)$$

$$\begin{aligned} EI_Z v''' - N \left[-z_c \theta_x'' - y_c \left(\theta_x'^2 + \theta_x'' \theta_x \right) + v'' \right] + \\ + (EI_Z - EI_Y) \left(w''' \theta_x + 2w'' \theta_x' + w' \theta_x'' - v''' \theta_x^2 - 4v'' \theta_x \theta_x' - 2v' \theta_x \theta_x'' - 2v \theta_x'^2 \right) + \\ + EI_Z \beta_Y \left(-2\theta_x' \theta_x''' - 2\theta_x''^2 \right) + EI_Y \beta_Z \left(2\theta_x' \theta_x''' \theta_x + 2\theta_x''^2 \theta_x + 5\theta_x'^2 \theta_x'' \right) + \rho A \ddot{v} + \\ + \rho \left[(I_Z - I_Y) \left(\theta_x v'' + \theta_x' v' \right) - I_Z w'' - A \left(y_c \theta_x + z_c - \frac{l}{2} z_c \theta_x^2 \right) \right] \ddot{\theta}_x + \rho (I_Z - I_Y) \cdot \\ \cdot \left[2\theta_x \theta_x' \ddot{v}' + \theta_x^2 \ddot{v}'' + 2 \left(\theta_x' \dot{\theta}_x + \theta_x \dot{\theta}_x' \right) \dot{v}' + 2\theta_x \dot{\theta}_x \ddot{v}'' - \theta_x' \ddot{w}' - \theta_x \ddot{w}'' + v' \theta_x \ddot{\theta}_x' \right] + \rho I_Z \cdot \\ \cdot \left[-w' \ddot{\theta}_x' - \ddot{v}'' - 2\dot{\theta}_x \dot{w}'' + v'' \dot{\theta}_x^2 + 2v' \dot{\theta}_x \dot{\theta}_x' - 2\dot{\theta}_x' \dot{w}' \right] - \rho A (y_c - z_c \theta_x) \dot{\theta}_x^2 = p_y - \\ - p_X \left(v' - y_c \theta_x' \theta_x - z_c \theta_x' \right) \end{aligned} \quad (13b)$$

$$\begin{aligned} EI_Y w''' - N \left[w'' + y_c \theta_x'' - z_c \left(\theta_x'^2 + \theta_x \theta_x'' \right) \right] + \\ + (EI_Z - EI_Y) \left(v''' \theta_x + 2v'' \theta_x' + v' \theta_x'' + w''' \theta_x^2 + 4w'' \theta_x \theta_x' + 2w' \theta_x \theta_x'' + 2w \theta_x'^2 \right) + \end{aligned}$$

$$\begin{aligned}

$$\theta_x(x, 0)=\theta_{x0}(x) \quad \dot{\theta}_x(x, 0)=\dot{\theta}_{x0}(x) \tag{18a,b}$$

together with the corresponding boundary conditions of the problem at hand, which are given as

$$a_1 u(x, t) + \alpha_2 N(x, t) = \alpha_3 \quad (19)$$

$$\beta_1 v(x, t) + \beta_2 V_y(x, t) = \beta_3 \quad \bar{\beta}_1 \theta_z(x, t) + \bar{\beta}_2 M_z(x, t) = \bar{\beta}_3 \quad (20a, b)$$

$$\gamma_1 w(x, t) + \gamma_2 V_z(x, t) = \gamma_3 \quad \bar{\gamma}_1 \theta_Y(x, t) + \bar{\gamma}_2 M_Y(x, t) = \bar{\gamma}_3 \quad (21a, b)$$

$$\delta_1 \theta_x(x, t) + \delta_2 M_t(x, t) = \delta_3 \quad \bar{\delta}_1 \theta'_x(x, t) + \bar{\delta}_2 M_w(x, t) = \bar{\delta}_3 \quad (22a, b)$$

at the beam ends $x=0, l$, where V_y , V_z and M_z , M_Y are the reactions and bending moments with respect to y , z or to Y , Z axes, respectively, given by the following relations (ignoring again the nonlinear terms of the fourth or greater order)

$$\begin{aligned} V_y = & N \left(v' - z_c \theta'_x - y_c \theta_x \theta'_x \right) + \\ & + EI_z \left(v''' \theta_x^2 - w'' \theta'_x - w''' \theta_x - v''' + 2v'' \theta_x \theta'_x + 2\beta_Y \theta'_x \theta''_x \right) + \\ & + EI_Y \left(w''' \theta_x + w'' \theta'_x - 2v'' \theta_x \theta'_x - v''' \theta_x^2 - \beta_Z \theta_x'^3 - 2\beta_Z \theta_x \theta'_x \theta''_x \right) \end{aligned} \quad (23a)$$

$$\begin{aligned} V_z = & N \left(w' + y_c \theta'_x - z_c \theta'_x \theta_x \right) + \\ & + EI_Y \left(w''' \theta_x^2 + v''' \theta_x - w''' + v'' \theta'_x + 2w'' \theta_x \theta'_x + 2\beta_Z \theta'_x \theta''_x \right) - \\ & - EI_z \left(v'' \theta'_x + w''' \theta_x^2 + v''' \theta_x + 2w'' \theta_x \theta'_x - 2\beta_Y \theta_x \theta'_x \theta''_x - \beta_Y \theta_x'^3 \right) \end{aligned} \quad (23b)$$

$$M_z = EI_z \left(w'' \theta_x - \beta_Y \theta_x'^2 + v'' - v'' \theta_x^2 \right) + EI_Y \left(-w'' \theta_x + v'' \theta_x^2 + \beta_Z \theta_x'^2 \theta_x \right) \quad (23c)$$

$$M_Y = EI_z \left(-w'' \theta_x^2 + \beta_Y \theta_x'^2 \theta_x - v'' \theta_x \right) + EI_Y \left(\beta_Z \theta_x'^2 - w'' + w'' \theta_x^2 + v'' \theta_x \right) \quad (23d)$$

while M_t and M_w are the torsional and warping moments at the boundary of the bar, respectively, given as

$$\begin{aligned} M_t = & GI_t \theta'_x - EC_s \theta_x''' + N \left(-z_c w' \theta_x + y_c w' - y_c v' \theta_x - z_c v' + \frac{I_s}{A} \theta'_x \right) + \\ & + EI_z \beta_Y \left(-2\theta'_x v'' - 2\theta'_x w'' \theta_x \right) + EI_Y \beta_Z \left(-2\theta'_x w'' + 2\theta'_x v'' \theta_x \right) + \frac{1}{2} E \left(I_R - \frac{I_s^2}{A} \right) \theta_x'^3 \end{aligned} \quad (24a)$$

$$M_w = -EC_s \left(\theta_x'' + \beta_\omega \theta_x'^2 \right) \quad (24b)$$

Finally, α_k , β_k , $\bar{\beta}_k$, γ_k , $\bar{\gamma}_k$, δ_k , $\bar{\delta}_k$ ($k=1,2,3$) are time dependent functions specified at the boundaries of the bar ($x=0, l$). The boundary conditions eqns. (19)-(22) are the most general boundary conditions for the problem at hand, including also the elastic support. It is apparent that all types of the conventional boundary

conditions (clamped, simply supported, free or guided edge) can be derived from these equations by specifying appropriately these functions (e.g. for a clamped edge it is $\alpha_1 = \beta_1 = \gamma_1 = \delta_1 = 1$, $\bar{\beta}_1 = \bar{\gamma}_1 = \bar{\delta}_1 = 1$, $\alpha_2 = \alpha_3 = \beta_2 = \beta_3 = \gamma_2 = \gamma_3 = \delta_2 = \delta_3 = \bar{\beta}_2 = \bar{\beta}_3 = \bar{\gamma}_2 = \bar{\gamma}_3 = \bar{\delta}_2 = \bar{\delta}_3 = 0$). In a case of eccentric axial loading or additional concentrated or distributed bending or warping moments, additional terms in governing equations (13) would arise. These terms could be taken into account without any special difficulty, by modifying appropriately equations (5c), (6), (8).

4 INTEGRAL REPRESENTATIONS-NUMERICAL SOLUTION

4.1 Evaluation of the axial displacement $u(x,t)$, the transverse displacements $v(x,t)$, $w(x,t)$ and the angle of twist $\theta_x(x,t)$

According to the precedent analysis, the nonlinear flexural-torsional vibration problem of a beam reduces in establishing the axial displacement component $u(x,t)$ having continuous partial derivatives up to the second order and the transverse displacement components $v(x,t)$, $w(x,t)$ and the angle of rotation $\theta_x(x,t)$ having continuous partial derivatives up to the fourth order with respect to x and up to the second order with respect to t , satisfying the nonlinear initial boundary value problem described by the coupled governing differential equations of motion (eqns. (13)) along the beam, the initial conditions (eqns. (15)-(18)) and the boundary conditions (eqns. (19)-(22)) at the beam ends $x=0, l$. Eqns. (13) and (15)-(22) are solved using the Analog Equation Method [22] as it is developed for hyperbolic differential equations in [29, 30].

5 NUMERICAL EXAMPLES

On the basis of the analytical and numerical procedures presented in the previous sections, a computer program has been written and representative examples have been studied to demonstrate the validation, the efficiency, wherever possible the accuracy and the range of applications of the developed method. The numerical results have been obtained employing 21 nodal points (longitudinal discretization) and 400 boundary elements (cross section discretization).

Example 1

In the first example, for comparison reasons, the forced vibrations of a steel-I beam (Fig. 3), ($E = 2,1 \times 10^8 \text{ kN/m}^2$, $G = 8,0769 \times 10^7 \text{ kN/m}^2$, $\rho = 7,85 \text{ tn/m}^3$, flange width $t_f = 0,03 \text{ m}$, web width $t_w = 0,012 \text{ m}$, total height $h = 0,56 \text{ m}$, total width $b = 0,30 \text{ m}$) having geometric constants presented in Table 1, under three load cases, are examined. In the first load case (case (a), Fig. 3a), a beam with hinged-hinged ends, of length $l = 10 \text{ m}$ is considered. The beam is subjected to a uniformly distributed 'static' loading $p_z(t) = p_{z0}(t/t_1)$ for $0 \leq t \leq t_1$ and $p_z(t) = p_{z0}$ for $t \geq t_1$ ($t_1 = 0,02 \text{ sec}$, $p_{z0} = 3000 \text{ kN/m}$), as this is shown in Fig. 3a. In Fig. 4 the time histories of the displacements $u(x_0, t)$, $w(x_0, t)$ at $x_0 = 6,9048 \text{ m}$ are presented, respectively, as compared with those obtained from a BEM solution [20], noting the accuracy of the proposed method.

$A = 2,4 \times 10^{-2} m^2$	$I_R = 1,14831 \times 10^{-4} m^6$
$I_Y = 1,39035 \times 10^{-3} m^4$	$I_t = 5,38871 \times 10^{-6} m^4$
$I_Z = 1,35072 \times 10^{-4} m^4$	$C_S = 9,48415 \times 10^{-6} m^6$
$I_S = 1,5254 \times 10^{-3} m^4$	

Table 1: Geometric constants of the beam of example 1.

	Linear Analysis	Nonlinear Analysis					
		Load case (b)			Load case (c)		
		Present study	FEM 960 solid elements [31]	FEM 2080 shell elements [31]	Present study	FEM 960 solid elements [31]	FEM 2080 shell elements [31]
$u(l)_{\max}$	0,0000	-0,0033	-0,0034	-0,0037	-0,0031	-0,0032	-0,0032
$v(l)_{\max}$	0,0000	0,0615	0,0603	0,0675	0,0331	0,0329	0,0328
$w(l)_{\max}$	0,2040	0,2045	0,2108	0,2114	0,2040	0,2108	0,2078

Table 2: Maximum values of the kinematical components $u(l,t)$ (m), $v(l,t)$ (m) and $w(l,t)$ (m) of the cantilever beam of example 1 for load cases (b), (c).

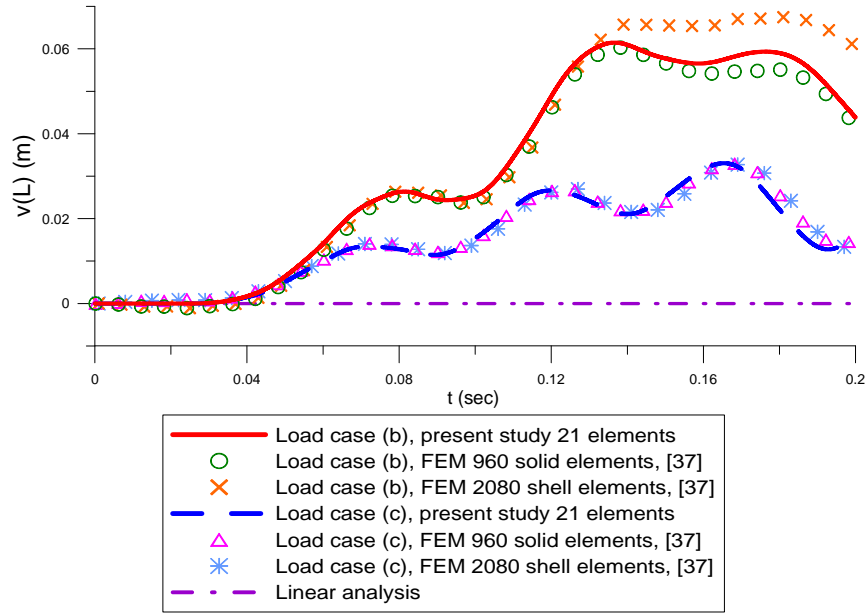

Figure 6: Time history of the displacement v at the tip of the cantilever beam of example 1 for load cases (b), (c).

Figure 7: Time history of the displacement w at the tip of the cantilever beam of example 1 for load cases (b), (c).

Moreover, in order to demonstrate the influence of the loading position upon the cross section, a cantilever beam of the same cross section of length $l = 8\text{ m}$, undergoing a uniformly distributed ‘static’ loading ($t_1 = 0,02\text{ sec}$, $p_{z0} = 60\text{ kN/m}$) is examined for the load cases (b), (c) (Figs. 3b,c). In Figs. 5-7 the time histories of the kinematical components $u(l,t)$, $v(l,t)$ and $w(l,t)$, respectively, at the tip cross section of the cantilever beam are presented as compared with those obtained from a FEM solution [31, 32], employing either shell or solid finite elements. In Fig. 8 the deformed configurations of the beam at the time instant $t = 0,1\text{ sec}$ for the load case (b) and at $t = 0,067\text{ sec}$ for the load case (c) are presented as compared with those obtained from a FEM solution [31, 32]. Finally, in Table 2 the maximum values of the

kinematical components $u(l,t)$, $v(l,t)$ and $w(l,t)$ of the present study are presented together with those obtained from the aforementioned FEM solutions [31, 32]. From these figures and table the accuracy of the proposed method is demonstrated. Moreover, as it can easily be observed, the loading position may have important influence on the dynamic response of the beam.

Example 2

In order to investigate the influence of eccentricity change of the transverse loading in nonlinear flexural-torsional vibrations, the forced vibration of a cantilever beam ($E = 2,1 \times 10^8 \text{ kN/m}^2$, $G = 8,0769 \times 10^7 \text{ kN/m}^2$, $\rho = 7,85 \text{ tn/m}^3$, $l = 1 \text{ m}$) of a monosymmetric thin-walled open shaped cross section (its geometric constants are presented in Table 3), as this is shown in Fig. 9, has been studied. More specifically, the beam is subjected to a suddenly applied concentrated force $P_z(t) = 16 \text{ kN}$ having a slight eccentricity $e = 0,0028 \text{ m}$ with respect to the shear center of the tip cross section (Fig. 9b). In Figs. 10-12 the time histories of the transverse displacements $v(l,t)$, $w(l,t)$ and the angle of twist $\theta_x(l,t)$ of the cantilever beam, respectively, in Table 4 the maximum values of its kinematical components and in Fig. 13 the deformation of the cantilever beam at the time instant $t = 0,02$ sec , are presented. From these figures and table, the influence of the relatively small ‘imperfection’ of the application point of the transverse loading to the beam response is remarked.

$A = 5,1 \times 10^{-2} m^2$	$\theta = -0,41330 rad$
$I_Y = 9,64614 \times 10^{-4} m^4$	$I_t = 2,6965 \times 10^{-4} m^4$
$I_Z = 3,90079 \times 10^{-4} m^4$	$C_S = 4,6911 \times 10^{-6} m^6$
$I_S = 1,58177 \times 10^{-3} m^4$	$\beta_y = 8,56633 \times 10^{-2} m$
$I_R = 7,14223 \times 10^{-5} m^6$	$\beta_z = -8,89913 \times 10^{-3} m$
$y_c = 6,20527 \times 10^{-2} m$	$\beta_w = 0,39404$
$z_c = -2,45329 \times 10^{-2} m$	

Table 5: Geometric constants of the beam of example 3.

Example 3

In order to demonstrate the range of applications of the developed method, in this final example the forced vibration of a hinged-hinged (axially immovable ends) beam of length $l = 3,5 m$ ($E = 3,0 \times 10^7 kN/m^2$, $G = 1,25 \times 10^7 kN/m^2$, $\rho = 2,5 tn/m^3$) having an asymmetric closed shaped cross section (its geometric constants are presented in Table 5), subjected to a uniformly distributed suddenly applied loading $p_{\bar{y}} = 1000 kN/m$, as this is shown in Fig. 14, is examined. In Figs. 15-17 the time histories of the transverse displacements $\tilde{v}(l/2, t)$, $\tilde{w}(l/2, t)$ and the angle of twist $\theta_x(l/2, t)$, respectively, in Table 6 the maximum values of its kinematical components and in Fig. 18 the deformation of the hinged-hinged beam at the time instant $t = 0,017 sec$, are presented. As it can be observed, in this case, the eccentricity change did not affect significantly the dynamic response of the beam, while geometrical nonlinearity due to axially immovable ends had important influence, especially on the transverse displacements \tilde{v} , \tilde{w} .

6 CONCLUSIONS

In this paper a boundary element method is developed for the nonlinear elastic flexural-torsional dynamic analysis of beams of arbitrary cross section, undergoing moderately large displacements and angles of twist, taking into account the effects of rotary and warping inertia and the change of eccentricity of transverse loads during torsional rotation. The main conclusions that can be drawn from this investigation are:

- The numerical technique presented in this investigation is well suited for computer aided analysis of beams of arbitrary simply or multiply connected cross section supported by the most general boundary conditions and subjected to the combined action of arbitrarily distributed or concentrated time dependent loading.
- The geometrical nonlinearity leads to strong coupling between the axial, torsional and bending equilibrium equations, resulting a significantly different response of the beam compared with this obtained from a linear analysis.
- The change of eccentricity of the transverse loading during the torsional rotation of the cross section affects significantly the torsional response of the beam
- Different loading positions upon the cross section may alter significantly the torsional response of the beam.
- Accurate results are obtained using a relatively small number of nodal points along the beam.
- The developed procedure retains most of the advantages of a BEM solution over a FEM approach, although it requires longitudinal domain discretization.

Keywords: Modal Analysis, Multilayer FGM Beams, 1st and 2nd Order Beam Theory, Shear Correction Function, Large Axial Force, Spatial Variation of Material Properties.

Abstract. *A differential equation of the homogenized functionally graded material (FGM) beam deflection will be presented which will be used for free vibration analysis of the beams with continuous longitudinal and transversal variation of material properties. The FGM beams with continuous spatial variation of material properties of double symmetric cross-section have been transformed into the multilayer FGM beams. Symmetrical layering according the neutral plane in transversal direction is assumed: the corresponding layers have the same height and material properties. The material properties vary continuously in longitudinal direction, but they are constant along the height and width of competent layers. The FGM beams are considered to be resting on longitudinal variable (Winkler) elastic foundation. The first and second order beam theories have been used for establishing the kinematics and kinetic equations. Not only the shear force deformation effect and the effect of consistent mass distribution and mass moment of inertia have been taken into account, but also the effect of large axial forces have been considered. Numerical experiments were performed to calculate the eigenfrequencies and corresponding eigenmodes of chosen FGM beams. The solution results are discussed and compared with those obtained using a very fine mesh of two-dimensional solid finite elements. The effects of material properties variation, layering fineness, the shear force correction factor and large axial forces have been evaluated and discussed.*

1 INTRODUCTION

Nowadays, the interaction between FGM beams and elastic foundations is an important issue in the study of beam behavior. Ying et al. [1] presented exact two-dimensional elasticity solution for the bending and free vibration of FGM beams on a Winkler – Pasternak foundation. The beam is assumed orthotropic at any point, and the material properties are taken as exponential functions of the thickness coordinate. The elastic foundation modules have been assumed as a constant. Pradhan et al. [2] presented thermo-mechanical vibration analysis of FGM beams resting on a variable Winkler foundation and two-parameter elastic foundation. The FGM material properties of these beams are assumed to be varying in thickness direction. In [3], the free vibration analysis of FGM beams has been presented. Spatial variation of material properties of these beams has been assumed. The shear force deformation effect and the effect of consistent mass distribution and mass moment of inertia have been taken into account. In [4], the paper [3] was extended by the effect of large axial forces. The solution results confirmed a very strong effect of large axial forces: the tensional axial force increased and the compression axial force decreased the level of eigefrequencies significantly. Many other authors investigate with free vibration of FGM beams with constant or transversal variation of material properties, e.g. [5], [6], [7]. In [8], the nonlinear dynamic analysis of partially supported beam-columns on non-linear elastic foundation including shear deformation effect has been discussed.

In [9], a differential equation of the homogenized functionally graded material (FGM) beam deflection has been proposed to be in a further free vibration analysis of multilayer and sandwich FGM beams of rectangular cross-section. The FGM beam was considered to be resting on longitudinal variable (Winkler) elastic foundation. In the contribution [10], an extension of paper [9] was presented, where not only the shear force deformation effect, the effect of consistent mass distribution as well as mass moment of inertia have been taken into account, but also the effect of large axial forces was considered.

In this contribution, which is a continuation of the paper [10], the differential equations of the 1st and 2nd order beam theory of the homogenized functionally graded material (FGM) beam deflection will be presented which will be used in the modal analysis of FGM beams with continuous longitudinal and transversal variation of material properties. The FGM beam with spatial variation of material properties will be transformed to multilayer beam. Symmetric layering along the neutral plane in transversal direction is assumed. The material properties vary continuously in longitudinal direction, but they are constant along the height and width of each layer. The multilayer beam will be then transformed to one layer homogenized beam with longitudinal variation of effective material properties. The FGM beams are considered to be resting on longitudinal variable (Winkler) elastic foundation. Numerical experiments were performed to calculate the eigenfrequencies and corresponding eigenmodes of chosen FGM beams with continuous spatial variation of material properties. The shear correction function has been derived from which the average shear correction factor has been calculated. The effects of the average shear correction factor, the large axial force, the variation of material properties and the layering fineness have been studied and compared with those obtained using a very fine mesh of a plane solid finite elements.

2 MATERIAL PROPERTIES HOMOGENIZATION AND DIFFERENTIAL EQUATION DERIVATION

Let us consider a two nodal straight beam element with predominantly rectangular cross-sectional area A and quadratic moment of inertia I (Fig. 1).

The composite material of this beam/link arises from mixing two components (matrix and fibres) that are approximately of the same geometrical form and dimensions (e.g. by powder metallurgy or plasma spraying).

Both, the fibre volume fraction $v_f(x, y)$ and the matrix volume fraction $v_m(x, y)$ are chosen as polynomial functions of x with continuous and symmetrical variation through its height h in respect to the neutral plane of the beam. The volume fractions are assumed constant through the cross-sectional depth b . At each point of the beam it holds: $v_f(x, y) + v_m(x, y) = 1$.

The values of the volume fractions at the nodal points are denoted by indices i and j .

The material properties of the constituents (fibres - $p_f(x, y)$ and matrix - $p_m(x, y)$) can vary analogically (in dependence on inhomogeneous temperature field for example) as defined by the variation of volume fractions. Homogenization of the material properties (the reference volume is the volume of the whole beam) will be done in two steps. In the first step, the real beam (Figure 1a) will be transformed to a multilayered beam (Figure 1b). Material properties of the layers will be calculated via the extended mixture rules [11]. Each layer will have constant volume fractions and material properties of the constituents through the beam height. They are calculated as an average value from boundary values of the respective layer. Polynomial variation of these parameters will appear in the longitudinal direction. Sufficient accuracy of the substitution of the continuous lateral variation of material properties with the layer-wise constant lateral distribution of material properties will be reached when the division to layers is fine enough. In the second step, the effective longitudinal material properties of the homogenized beam will be derived using laminate theory. These homogenized material properties are constant through the beam height but they vary continuously along the longitudinal beam axis. Finally, a differential equation for calculation of the effective beam variables for homogenized beam (Figure 1c) will be established.

One thin layer of the composite or FGM is depicted in Figure 2 with a constant rectangular cross-section considered. The layer length is L . Longitudinal variation of the constituent volume fractions and longitudinal variation of the constituent elasticity modules will be assumed. These parameters will be considered constant along the layer height and width. The fibers (constituent 1) volume fraction $v_f(x)$ is chosen as a polynomial function of x :

$$v_f(x) = 1 - v_m(x) = v_{fi} \eta_{vf}(x) = v_{fi} \left(1 + \sum_k \eta_{vfk} x^k \right) \quad (1)$$

Then the matrix (constituent 2) volume fraction $v_m(x)$ is

$$v_m(x) = 1 - v_f(x) = v_{mi} \eta_{vm}(x) = v_{mi} \left(1 + \sum_k \eta_{vmk} x^k \right) \quad (2)$$

where v_{fi} and v_{mi} are the fibre and the matrix volume fractions at node i and $\eta_{vf}(x)$ and $\eta_{vm}(x)$ are the polynomials of fibre and matrix volume fractions variation, respectively. Constants η_{vfk} and η_{vmk} , ($k = 1, \dots, r$), and the order r of these polynomials depends on the fibre and matrix volume fractions variation.

Figure 1: FGM beam with spatial variation of the material properties.

Figure 2: One thin layer of FGM.

Also the fibre material property $p_f(x)$ and the matrix material property $p_m(x)$ are chosen as polynomial functions of x :

$$p_f(x) = p_{fi} \eta_{pf}(x) = p_{fi} \left(1 + \sum_k \eta_{pfk} x^k \right) \quad (3)$$

$$p_m(x) = p_{mi} \eta_{pm}(x) = p_{mi} \left(1 + \sum_k \eta_{pmk} x^k \right) \quad (4)$$

where p_{fi} and p_{mi} are the fibre and matrix material properties at node i and $\eta_{pf}(x)$ is the polynomial of fibre material property variation. Its constants η_{pfk} , where $k = 1, \dots, r$, and the order r of this polynomial depend on the fibre material property variation. $\eta_{pm}(x)$ is the polynomial of matrix material property variation. The constants η_{pmk} , where $k = 1, \dots, s$, and the order s of this polynomial depend on the matrix material property variation.

Then the effective material property of the composite one-layer beam is given by

$$p_L(x) = v_f(x) p_f(x) + v_m(x) p_m(x) \quad (5)$$

Similarly to (4), we can write

$$p_L(x) = p_{Li} \eta_{pL}(x) \quad (6)$$

Here, p_{Li} is the effective longitudinal material property at node i , and

$$\eta_{pL}(x) = \frac{p_L(x)}{p_{Li}} \quad (7)$$

is the polynomial of effective longitudinal material property variation.

The indices are: $p \equiv E$ and ρ - for elasticity modulus and mass density, respectively.

Expressions (5 - 7) can be used in the effective material properties calculation for single-layer FGM beams.

Let us replace the initial beam (Fig. 1a) by a multilayered beam (Fig. 1b). Lamination is symmetric according to the geometry of the layers and material properties as well. This symmetry allows the application of the elementary theory of the homogeneous isotropic beam for all solutions when the material properties are replaced by their effective values [12]. From the mechanical coupling point of view, axial loading is not coupled with transversal loading.

Individual layers are built of composite layers with longitudinal variation of volume fractions and material properties of the constituents as described above.

Homogenization of material properties of the multilayered beam will be done using the theory of laminates [12], [13], [14]. In this way we get one layer beam with longitudinal variation of homogenized longitudinal material properties. Main dimensions of the beam such as the length L , height h and width b remain conserved.

a) Homogenized elastic properties

If we denote the effective longitudinal elasticity modulus of a chosen layer with superscript k , then, according to (6), it holds

$$E_L^k(x) = E_{Li}^k \eta_{E_L^k}(x) \quad (9)$$

Index $k \in \langle 1, n \rangle$ represents the layer number in the upper and lower symmetrical part of the beam/link. The number of layers of the symmetrical part is n . If the cross-sectional area of the k^{th} layer is A^k , then the volume fraction of the pair of these symmetrical areas is $v^k = 2A^k/A$.

Then, the effective longitudinal elasticity modulus for axial loading of the homogenized sandwich can be derived using the expression

$$E_L^{NH}(x) = E_{Li}^{NH} \eta_{E_L^{NH}}(x) = \sum_{k=1}^n v^k E_L^k(x) \quad (10)$$

where $E_{Li}^{NH} = \sum_{k=1}^n E_L^k v^k$ is the effective longitudinal elasticity modulus for axial loading of the homogenized beam at node i , and $\eta_{E_L^{NH}}(x) = E_L^{NH}(x) / E_{Li}^{NH}$ is the polynomial of its variation.

This effective longitudinal elasticity modulus has to be used for calculation of an axial free vibration of the FGM beam.

According to the notation in Figure 1, the effective longitudinal elasticity modulus for flexural loading of the homogenized beam of rectangular cross-section has been derived [15]:

$$E_L^{MH}(x) = \frac{12}{h^3} \sum_{k=1}^n \left(\frac{h_k^3}{6} + 2d_k^2 h_k \right) E_L^k(x) = E_{Li}^{MH} \eta_{E_L^{MH}}(x) \quad (11)$$

where E_{Li}^{MH} is the value of the effective longitudinal elasticity modulus for flexural loading of the homogenized beam/link at node i , and $\eta_{E_L^{MH}} = E_L^{MH}(x) / E_{Li}^{MH}$ is the polynomial of its longitudinal variation. This effective longitudinal elasticity modulus has to be used in the calculation of a flexural free vibration of the FGM beam.

In a similar way, the effective longitudinal elasticity modules can be derived for beams with different other types of cross-sections.

b) Homogenized mass density

If we denote ρ with superscript k the effective longitudinal mass density of a chosen layer k , then, according to (5), (6) and (7), it holds

$$\rho_L^k(x) = \rho_{Li}^k \eta_{\rho_L^k}(x) \quad (12)$$

Index k , the cross-sectional area of the k^{th} layer A^k , and the volume fraction $v^k = 2A^k/A$ have the same meanings as in the elastic properties derivation.

Accordingly, the homogenized effective longitudinal mass density is

$$\rho_L^H(x) = \rho_{Li}^H \eta_{\rho_L^H}(x) = \sum_{k=1}^n v^k \rho_L^k(x) \quad (13)$$

where $\rho_{Li}^H = \sum_{k=1}^n \rho_{Li}^k v^k$ is the effective longitudinal mass density at node i of the homogenized beam, and $\eta_{\rho_L^H}(x) = \rho_L^H(x) / \rho_{Li}^H$ is the polynomial of its longitudinal variation.

All the homogenized effective longitudinal properties are denoted by upper right index H in this chapter. As assumed, their variation along the homogenized beam is polynomial.

Sufficient accuracy of substituting the continuous lateral variation of material properties by a layer-wise constant lateral distribution of material properties will be reached when the layer-division is fine enough. The constant value of the material property in the assumed layer at position x will be calculated as a mean value from its values at the top and the bottom of this layer. The same approach will be used in the calculation of the components volume fractions in the competent layer.

Variations of the homogenized beam properties and the loading are shown in Fig. 3.

Figure 3: Variation of the beam parameters.

$\mu = \rho A$ is the mass distribution, $\bar{\mu} = \rho I$ is the mass moment of inertia distribution, $\rho = \sum_{j=0}^{p_\rho} \rho_j a_j = \rho_L^H(x)$ is the homogenized varying mass density (also defined by (13), indices L, H are omitted for simplicity), A is the cross-sectional area, I is the moment of inertia, $EI = \sum_{j=0}^{p_e} EI_j a_j = B$ is the varying bending stiffness caused by varying elasticity

modulus $E \equiv E_L^{MH}(x)$, $G\bar{A} = \sum_{j=0}^{p_G} G\bar{A}_j a_j$ is the varying shear stiffness with $G = G_L^H(x)$,

and $\varsigma = \frac{EI}{G\bar{A}} = \text{const.}$, $k(x)$ is the longitudinally varying Winkler elastic foundation modulus, and finally, $a_j = \frac{x^j}{j!}$ is the polynomial function. The same longitudinal polynomial

variation of the homogenized shear modulus G has been assumed as stated by the homogenized elasticity modulus E . The assumption $\varsigma = \frac{EI}{G\bar{A}} = \text{const.}$ is a simplification which holds exactly only for single-layer FGM beams with only longitudinal variation of material properties. In addition, the condition $\frac{E}{G} = \text{const.}$ must be fulfilled. For the initial beam

(Fig. 1a) both the shear correction factor $k^s = \frac{\bar{A}}{A} = k^s(x)$ and consecutive the factor $\varsigma = \varsigma(x)$ are functions of x . In our consideration, the parameters k^s and ς will be assumed as average values of their functional variation. The assumption $\varsigma = \varsigma(x)$ would make the differential equation of the beam deflection very complicated. In the following derivation of the differential equation, indices L, M, H have been also omitted for simplicity.

In Fig. 4 the distributed loads and the nodal internal forces are shown at the beam increment dx in the deformed configuration of the beam increment. In Fig. 5 the internal forces and nodal displacements at position x are shown.

 Figure 4: Distributed loads and internal forces in R – formulation.

 Figure 5: Internal forces and displacements at point x in Q - and R – formulation, respectively.

Here, M is the bending moment, N is the axial force, Q is the shear force, R is the transversal force, φ is the angle of cross-section rotation, w is the deflection perpendicular to the undeformed longitudinal beam axis and u is the longitudinal displacement, ω is the circular frequency. The inertia forces in x – direction has not been assumed in the following considerations. N^{II} is the 2nd order beam theory constant axial force, which is of a system character and it is a known variable.

The differential equilibrium equations of a harmonic free vibration of 2nd order beam theory according to the undeformed longitudinal beam axis (the R - formulation) are (the superscript “’” denotes the differentiations d/dx):

$$R' = (k - \omega^2 \mu)w \quad (14)$$

$$M' = Q + \bar{\mu}\omega^2 \varphi \quad (15)$$

The dependence between the shear and transversal force can be expressed as [16]: $Q = R - N^{II}w'$.

The kinematical differential equations are:

$$\varphi' = -\frac{M}{B} \quad (16)$$

$$w' = \varphi + \frac{Q}{GA} = \varphi + \varsigma \frac{Q}{B} \quad (17)$$

After some mathematical operations the homogeneous differential equation of the 4th order of the homogenized functionally graded material (FGM) beam deflection has been obtained. Its form is:

$$\eta_4 w'''' + \eta_3 w''' + \eta_2 w'' + \eta_1 w' + \eta_0 w = 0 \quad (18)$$

After the boundary conditions application, the equation (18) can be used for the modal analysis of the multilayer FGM beams resting on the elastic Winkler foundation, with above mentioned effects.

The non constant parameters of the differential equation of the 4th order (18) are:

$$\begin{aligned} \eta_0 = & (\omega^2 \mu - k) \left(\varsigma B (B'' - \omega^2 \bar{\mu}) - \varsigma B'^2 + B^2 \right)^2 + \varsigma B k \Omega B'' - \varsigma \omega^2 B \mu \Omega B'' + \varsigma B \Omega B' (\omega^2 \mu' - k') \\ & - \varsigma B k \Gamma B' + \varsigma k \Omega B'^2 + \varsigma \omega^2 B \Gamma \mu B' - \varsigma \omega^2 \mu \Omega B'^2 - \varsigma B^2 \Omega k'' + \varsigma B^2 \Gamma (k' - \omega^2 \mu') + \varsigma \omega^2 B^2 \Omega \mu'' \\ \eta_1 = & -B \left(\Omega (B' (\omega^2 (- (2\mu + \varsigma \mu)) + \varsigma k + 2N'')) + \varsigma N'' (B''' - \omega^2 \bar{\mu}') \right) + \varsigma N'' \Gamma \Delta + \\ & \varsigma N'' B' \left(\Omega (\omega^2 \bar{\mu} + B'') - \Gamma B' \right) + B^2 \left(\Gamma (\omega^2 (- (\bar{\mu} + \varsigma \mu)) + \varsigma k + N'') + \Omega (\omega^2 (\bar{\mu}' + 2\varsigma \mu') - 2\varsigma k') \right) \\ \eta_2 = & B \left(B \left(\Omega (\omega^2 (\bar{\mu} + \varsigma \mu)) + B'' - \varsigma k - N'' \right) - \Gamma B' \right) + \Omega \left(\varsigma N'' \omega^2 \bar{\mu} - 2\varsigma N'' B'' + 2B'^2 \right) + \varsigma N'' \Gamma B' \\ \eta_3 = & B \left(\Omega B' (4B + \varsigma N'') - B \Gamma (B + \varsigma N'') \right) \\ \eta_4 = & B^2 \Omega (B + \varsigma N'') \end{aligned} \quad (19)$$

$$\Gamma = \varsigma B' (\omega^2 \bar{\mu} + B'') + B (\varsigma \omega^2 \bar{\mu}' - \varsigma B''' - 2B')$$

$$\Omega = \varsigma B (\omega^2 \bar{\mu} - B'') + \varsigma B'^2 - B^2$$

$$\Delta = \omega^2 \bar{\mu} - B''$$

After integration of the differential equation the transfer relations will be obtained for the vertical displacement, angle of cross-section rotation, bending moment and transversal force. The 4 transfer relations have been transformed to the transfer matrix method form:

$$\begin{bmatrix} w(x) \\ \varphi(x) \\ M(x) \\ R(x) \\ 1 \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{13} & A_{14} & 0 \\ A_{21} & A_{22} & A_{23} & A_{24} & 0 \\ A_{31} & A_{32} & A_{33} & A_{34} & 0 \\ A_{41} & A_{42} & A_{43} & A_{44} & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} w_i \\ \varphi_i \\ M_i \\ R_i \\ 1 \end{bmatrix} \quad (20)$$

The kinematical and kinetic variables at node i are denoted by index “ i ” in (20). The parameters of the transfer matrix are not expressed in detail here from space spending point of view. After implementation of the applied boundary conditions, the homogenous equations system will be obtained for the calculation of internal forces and deformations. Hence, eigenvalue problems can be solved for circular eigenfrequencies and subsequently, the eigenfrequencies $f_n = \omega_n / 2\pi$ can be obtained (index n denotes the frequency number).

If the axial force N^H is set to zero in equations (14) – (20), then $R = Q$ and the equation of the 1st order beam theory has been obtained.

3 NUMERICAL EXPERIMENTS

3.1 Modal analysis of the FGM beam: Case I

A FGM beam has been considered as shown in Fig. 6. Its square cross-section is constant with height $h = 0.2$ m and width $b = 0.2$ m. Length of the beam is $L = 3$ m. Material of the beam consists of two components: NiFe – named as a matrix and denoted with index m ; Tungsten – named as a fibre and denoted with index f .

Figure 6: Composite beam with spatial variation of material properties.

Material properties of the components are constant and their values are: Tungsten (fibres) – elasticity modulus $E_f = 400$ GPa, mass density $\rho_f = 19300$ kg·m⁻³; NiFe (matrix) – elasticity modulus $E_m = 255$ GPa, mass density $\rho_m = 9200$ kg·m⁻³ [11]. The cross-sectional area $A = 0.04$ m²; the moment of inertia $I = bh^3 / 12 = 0.2^4 / 12$ m⁴; and the reduced cross-sectional area $\bar{A} = k^s A$ [m²]. The shear correction factor k^s can be computed so that the strain energy of the classical transverse shear stress equals the strain energy computed using the first order shear deformation theory [12], [17]]. According the notation in Fig. 1, it is possible to extend the calculation of shear stresses for a symmetrically layered beam with longitudinal variation of material properties of the layers [15]. The shear stress at point (x, y) of the relevant layer is a function of position of this point and it varies through the height and length of the layer. There is no jump of the shear stresses on the interface of the layers. Especially, for a rectangular

cross-section – see Fig.1, the shear stress in the k^{th} layer for $k \in \langle 1, n \rangle$ and $y \in \langle d_k - h_k / 2, d_k + h_k / 2 \rangle$ is

$$\tau_k(x, y) = \frac{Q(x)}{D(x)} \left(\frac{E_L^k(x)}{2} \left(\left(d_k + \frac{h_k}{2} \right)^2 - y^2 \right) + \sum_{j=k}^n \frac{E_L^{j+1}(x)}{2} \left(\left(d_{j+1} + \frac{h_{j+1}}{2} \right)^2 - \left(d_j + \frac{h_j}{2} \right)^2 \right) \right) \quad (21)$$

where $Q(x)$ is the shear force, $D(x)$ is the effective bending stiffness of the multilayer FGM beam at position x [15]. Using the expression (21) for the calculation of the strain energy in the cross-sectional area of the multilayered beam and putting it equal to the strain energy of the first order shear deformation theory, the shear correction factor function $k^s(x)$ (which is originally studied in [18]) can be calculated (because of longitudinal variation of the material properties in the layers, the shear correction factor is a function of x as well). Its average value

$$k^{sm} = \frac{1}{L} \int k^s(x) dx \quad (22)$$

has been used in calculation of the constant parameter ς included in the differential equation (19):

$$\varsigma = \frac{EI}{k^{sm} GA} \quad (23)$$

If the shear force effect is neglected, the factor $\varsigma = 0$. If the non-continuous distribution of the shear stresses (21) and the longitudinal variation of material properties in the layers is not accounted, then $k^s = 0.833334$. Otherwise, the shear correction function and the average shear correction factor (22) depend on the layering fineness. By increasing numbers of layers, the average shear correction factor will converge to the value which approximately fits the continuous variation of the material properties in transversal and longitudinal direction.

The fiber volume fraction, in this case, varies linearly and symmetrically according to the $x - z$ neutral plane in transversal direction at node i ($v_{fi} \in \langle 0.5, 1.0 \rangle$), and continues linearly in the longitudinal direction to the constant value at node j .

Both halves of the height h of this beam have been divided symmetrically to the beam neutral plane to $n = 5$, and $n = 10$ layers in such a way that all the layers have the same thickness h^k , where $k \in \langle 1, n \rangle$. The transversally constant fiber volume fractions of the assumed layers have been calculated from their values at the top and the bottom of the competent layer.

Pairs of the symmetrical layers in all cases were built as a mixture of the two components. The volume fraction of the components is constant along the height and width of the competent layer but it varies linearly along the layer length:

$$v_{fi}^k(x) = v_{fi}^k (1 + \eta_1^k x) = 1 - v_m^k(x) \quad (24)$$

where index k is the number of the symmetrical layers, v_{fi}^k is the volume fraction of the fibres in the k^{th} layer at node i , and η_1^k is a parameter of variation of the fibres volume fraction. The list of these parameters for $n = 5$ is given in Table 1. The fibres volume fraction in the layers at node j is a constant and it is equal to $v_{fj}^k = 0.3$, $v_m^k(x)$ is the matrix volume fraction in layer k .

Layer k	1	2	3	4	5
$v_{fi}^k (-)$	0.55	0.65	0.75	0.85	0.95
$\eta_i^k (-)$	-4.545	-5.384	-6.000	-6.470	-6.842

Table 1: Parameters of the fibres volume fractions variation for $n = 5$.

With expressions (9) and (12) the effective longitudinal elasticity modules and the mass densities of the layers can be calculated. Subsequently, the effective elasticity modulus for transversal loading, the effective mass density and the average shear stress correction factor of the homogenized multilayer beam have been calculated by using of the expressions (10), (11) (13) and (22), and we have got:

a) for $n = 5$ layers

$$E_L^{MH}(x) = 381.15 - 27.55x \text{ [GPa]}; \rho_L^H(x) = 16775.0 - 1515.0x \text{ [kgm}^{-3}\text{]}; k^{sm} = 0.836594 [-];$$

b) for $n = 10$ layers

$$E_L^{MH}(x) = 381.69 - 27.73x \text{ [GPa]}; \rho_L^H(x) = 16775.0 - 1515.0x \text{ [kgm}^{-3}\text{]}; k^{sm} = 0.836798 [-].$$

The shear stress correction functions $k^s(x)$ have non-linear longitudinal distribution (see Fig. 9): its value is equal to 0.83934 for $n = 5$, and 0.839714 for $n = 10$ at point i ; and it is equal to 0.833334 at point j for the both divisions (the material properties are the same at this point in each layer).

If the homogenized material properties have been calculated by direct integration method (without division into layers), following parameters have been obtained:

$$E_L^{MH} = 381.875 - 27.79x \text{ [GPa]} \quad k^{sm} = 0.836868$$

As can be seen, the homogenized material properties converge very fast to the values obtained by the direct integration methods.

The ratio $\frac{E_L^{MH}(x)}{G_L^H(x)} = 2.6$ has been used for the effect of shear forces assumption in this example. Longitudinal distributions of the homogenized elasticity modulus and the effective elasticity modules in the respective layers for $n = 5$ are shown in Fig. 7.

Figure 7: Longitudinal distributions of the homogenized elasticity modulus and the effective elasticity modules in respective layers for $n = 5$

Longitudinal distributions of the mass density in the homogenized beam and the effective mass densities distribution in respective layers of the multilayer beam for $n = 5$ are shown in Fig. 8.

Figure 8. Effective mass density distribution along the homogenized beam and the effective elasticity mass density in respective layers for $n = 5$.

Figure 9: Shear correction function for $n = 5$ and $n = 10$.

The varying Winkler elastic foundation modulus is chosen as a linear function: $k(x) = 5000 - 1000x$ [kN/m²].

The homogenized simply supported beam (Fig. 6) has been studied by modal analysis. The first three bending eigenfrequencies have been found using the differential equation (18) and the appropriate boundary conditions. The buckling critical forces have been calculated by [19], and they are: $N_{Ki}^{II} = -52172.0$ kN for $n = 5$ layers; and $N_{Ki}^{II} = -52209.7$ kN for $n = 10$ layers.

The axial force (tension and compression) $N^{II} \equiv N$ will be chosen as a part of the critical buckling force N_{Ki}^{II} . In all cases, the applied axial force N was smaller than the critical buck-

ling force. The effects of the shear stress correction factor and the large axial force have been studied and evaluated.

The same problem has been solved using a very fine mesh – 12000 of 2D PLANE42 elements and 401 COMBIN14 elements of the FEM program ANSYS [20] where each element has material properties equal to their value at the (x,z) location of the element center. The results of ANSYS as well as the results of the differential equations solution (using the software MATHEMATICA [21] and denoted by DIF) are presented in Tables 2 – 5. The shear force deformation effect and the effect of axial force (tension and compression) on the eigefrequencies have been studied.

The Table 2 presents the eigenfrequency results for tensional axial force when the average shear correction factors k^{sm} have been considered by DIF solution. In the second column of this table, the 1st order beam theory results obtained by DIF solution are presented.

$N^H = N$ [kN]		1 st order DIF $N = 0$	DIF $N =$ 13000	ANSYS $N =$ 13000	DIF $N =$ 26000	ANSYS $N =$ 26000	DIF $N =$ 39000	ANSYS $N =$ 39000

	$n = 10$	187.86	181.18	174.23
f_3 [Hz]	$n = 5$	426.14	419.68	413.13
	$n = 10$	426.31	419.85	413.30

Table 5: Eigenfrequencies in the Case I for compression axial force without the shear correction factors

Dependence of the 1st eigenfrequency on the applied axial force (with and without the shear correction factor and for $n = 10$) is shown in Fig. 9

As we can see in Tab. 2 to Tab. 5, and in Fig. 9, the solution results obtained by our new differential equation agree very well with the ones obtained by very fine mesh of the PLANE42 solid elements. As expected, inclusion of the shear force deformation effect makes the results more accurate. But this effect is not significant in this example. This effect will grow with higher variation of non-linearities in material properties in transversal and longitudinal direction. As expected, increasing compression axial force decreases the values of eigenfrequency and, on the other hand, increasing tensional force increases the eigenfrequency. The influence of the large axial force is significant in calculated cases. This fact can be utilized by the control and tuning of dynamic properties of beam structures.

Foundation elastic properties have not been studied in this contribution.

Figure 9: Dependence of the eigenfrequencies in the Case I for $n = 10$.

3.2 Modal analysis of the FGM beam: Case II

An FGM beam has been considered as shown in Fig. 10. Its geometry and material properties of the constituents are the same as in Case I. Only the variation of fibre volume fractions has been changed.

Fig. 10. FGM beam with spatial variation of material properties

The fibre volume fraction at node i varies linearly and symmetrically according to the neutral plane in the transversal direction ($v_{fi} \in \langle 1.0, 0.5 \rangle$) and continuous linearly in the longitudinal direction to the value $v_{ff} = 0.3$.

By the same approach described in chapter 2 the fibres volume fraction have been obtained - see Table 6.

Layer k	5	4	3	2	1
$v_{fi}^k (-)$	0.55	0.65	0.75	0.85	0.95
$\eta_1^k (-)$	-4.545	-5.384	-6.000	-6.470	-6.842

Table 6: Parameters of the fibres volume fractions variation for $n = 5$

With expressions (9) and (12) the effective longitudinal elasticity modules and the mass densities of the layers can be calculated. Following, the effective elasticity modulus for transversal loading, the effective mass density and the average shear stress correction factor of the homogenized multilayer beam have been calculated using expressions (10), (11) (13). The effective elasticity modulus and the average shear correction factor of the homogenized multilayer beams for transversal loading have been calculated via expressions (11) and (29), and we have got:

a) for $n = 5$ layers

$$E_L^{MH}(x) = 345.88 - 15.79x \text{ [GPa]}; \rho_L^H(x) = 16775.0 - 1515.0x \text{ [kgm}^{-3}\text{]}; k^{sm} = 0.828612 \text{ [-]};$$

b) for $n = 10$ layers

$$E_L^{MH}(x) = 345.74 - 15.74x \text{ [GPa]}; \rho_L^H(x) = 16775.0 - 1515.0x \text{ [kgm}^{-3}\text{]}; k^{sm} = 0.829386 \text{ [-]}.$$

The shear stress correction function $k^s(x)$ has non-linear longitudinal distribution (see Fig. 11): its value is equal to 0.824329 for $n = 5$ and 0.82579 for $n = 10$ at point i ; and it is equal to 0.833334 at point j for the both divisions (the material properties are the same at this point in each layer).

The ratio $\frac{E_L^{MH}(x)}{G_L^H(x)} = 2.6$ has been used to express the effect of shear forces assumption in this example.

Figure 11: Shear correction function for $n = 5$ and $n = 10$, and direct integration.

Homogenized material properties obtained by direct integration (without division into layers) give following parameters:

$$E_L^{MH}(x) = 345.625 - 15.70x \text{ [GPa]} \quad k^{sm} = 0.829478$$

The above listed parameters show that the division of the beam into $n = 10$ layers gives enough accurate results which agree very well with the ones obtained by the direct integration method.

The ratio $\frac{E_L^{MH}(x)}{G_L^H(x)} = 2.6$ has been used to express the effect of shear forces assumption in this example.

Longitudinal distributions of the homogenized elasticity modulus and the effective elasticity modules in respective layers for $n = 5$ are shown in Fig. 12.

Fig. 12. Longitudinal distributions of the homogenized elasticity modulus and the effective elasticity modules in respective layers for $n = 5$.

Longitudinal distributions of the homogenized elasticity modules for division into $n = 10$ layers are shown in Fig. 13.

Fig. 13. Longitudinal distributions of the homogenized elasticity modules for $n = 10$ layers.

The homogenized mass density has been calculated by expressions (12) and (13): $\rho_L^H(x) = 16775.0 - 1515.0x$, $[\text{kg}\cdot\text{m}^{-3}]$; this value is the same for any number of divisions n as it was in the Case I. Distribution of the mass density in the layers is similar to the one displayed in Fig. 8 but the ordering of layers is in contrary series. The same varying Winkler elastic foundation has been chosen as in the Case I.

The homogenized simply supported beam (Fig. 10) has been studied using modal analysis. The first three bending eigenfrequencies have been found using the differential equation (18) and the appropriate boundary conditions. The buckling critical forces have been calculated by [19], and they are: $N_{Ki}^H = -49711.3$ kN for $n = 5$ layers; and $N_{Ki}^H = -49701.6$ kN for $n = 10$ layers. The axial force (tension and compression) $N^H \equiv N$ will be chosen as a part of the critical buckling force N_{Ki}^H . In all cases, the applied axial force N was smaller than the critical buckling force. The effects of the shear stress correction factor and the large axial force have been studied and evaluated. The same problem has been solved using a very fine mesh – 12000 of 2D PLANE42 elements and 401 COMBIN14 elements of the FEM software ANSYS [20] – with a variation of material properties (in competent layers) as displayed in Fig. 7 and Fig. 8. The results from ANSYS as well as the results of the differential equations solution (using the software MATHEMATICA [21] and denoted by DIF) are presented in Tables 7 – 10. The shear force deformation effect and the effect of axial force (tension and compression) on the eigenfrequencies have been investigated.

The Table 7 presents the eigenfrequency results for tensional axial force when the average shear correction factors k^{sm} have been considered in the DIF solution. In the second column of this table, the 1st order beam theory results obtained by DIF solution are presented.

$N^H = N$ [kN]		1 st order DIF $N = 0$	DIF $N =$ 13000	ANSYS $N =$ 13000	DIF $N =$ 26000	ANSYS $N =$ 26000	DIF $N =$ 39000	ANSYS $N =$ 39000

Table 10: Eigenfrequencies in the Case II for compression axial force without the shear correction factors

Dependence of the 1st eigenfrequency on the applied axial force (with and without the shear correction factor and for $n = 10$) is shown in Fig. 14.

As we can see in Tab. 7 to Tab. 10 and in Fig. 14, the effects and conclusions are similar to the ones in the previous Case I. In addition, also the changed variation of material properties influenced the eigenfrequencies of the FGM beams. The eigenfrequencies are higher in the Case I due a variation of material properties making the beam stiffer.

Figure 14: Dependence of the eigenfrequencies on the axial force in the Case II for $n = 10$.

4 CONCLUSIONS

Differential equation of the homogenized functionally graded material (FGM) beam deflection was established for 2nd the order beam theory, which has been used in a modal analysis of FGM beams of rectangular cross-sections with continuous spatial variation of material properties. The FGM beams are considered to be resting on longitudinally variable (Winkler) elastic foundation. Homogenization of material properties has been done by the multilayer method and by direct integration. By the multilayer method, the FGM beam with continuous spatial variation of material properties has been transformed into a multilayer beam. Symmetrical layering along the neutral plane in transversal direction has been assumed: the corresponding layers having the same height and material properties variation. The material properties vary continuously in longitudinal direction but they are constant along the height and width of each layer. By the second one the direct integration of the varying material properties over the height and length of the beam has been used. Increasing numbers of layers make the homogenized material properties converge to the ones obtained by a direct integration.

Not only the shear force deformation effect and the effect of consistent mass distribution and mass moment of inertia but also the effect of a large axial force has been taken into account. Large axial force has a system character: if set to zero in the derived differential equation, the 1st order beam theory differential equation will be obtained. The shear correction function has been derived and an average shear correction factor has been calculated to express the shear force effect. Effects of variation of elastic foundation properties are not subject of this contribution.

Numerical experiments were performed to calculate the eigenfrequencies of the chosen FGM beams. The solution results are discussed and compared with those obtained using a very fine mesh of two-dimensional solid finite elements.

The main conclusions that can be drawn from this investigation are:

- the large axial force has a significant effect on the eigenfrequency value also in the case of a beam resting on an elastic foundation;
- increasing compression axial force decreases the eigenfrequency and increasing tensional force increases the eigenfrequency;

- inclusion of the shear force deformation effect makes the results more accurate (the shear correction function has been derived for calculation of the average shear correction factor);
- not only transversal but also longitudinal variation of material properties affects the dynamic properties of the FGM beams;
- the results obtained by solution of the differential equation agree very well with these obtained by an FEM solution using a very fine mesh of the solid finite elements.

The presented differential equation is suitable for an effective modal analysis of beams with continuous spatial variation of material properties resting on a Winkler elastic foundation with longitudinally varying material properties. Results of such analyses can be used not only as a benchmark solution in comparison of results obtained by other numerical method but also in modal analysis of the real FGM beams.

Keywords: Torsion, piezoelectric rod, piezoelectric actuation, piezoelectric sensor, macro fiber composites

Abstract. *This paper concerns a computational study on the realization of piezoelectric torsional actuators and sensors. Exemplarily, a rod with rectangular solid cross-section is considered consisting of a linear elastic substrate material on which orthotropic piezoelectric layers are bonded. On the one hand side, piezoelectric actuation is obtained by applying voltage to the electrodes of the piezoelectric layer. Secondly, the layers can be used as sensors by measuring the voltage on the electrodes which is caused by external torsional loads. Three material types are compared for possible realisations: ammonium dihydrogen phosphate (ADP) and two types of macro fiber composites (MFC). In the framework of Saint Venant's theory of torsion, the actuator and sensor equations are formulated: The actuating torsional moment is proportional to the applied voltage, and the sensor voltage is proportional to the torsional angle. Finally, the results are validated by means of three-dimensional Finite Element computations.*

1 INTRODUCTION

Recently, interest in active vibration compensation using piezoelectric materials has gained more and more. Possible applications can be found for instance in the fields of robotics and light-weight structures. Piezoelectric layers can either be integrated into structures, or applied on the surfaces of structures. Such layers can be used as sensors and actuators, utilizing the direct and converse piezoelectric effect, respectively, [1].

The topic of this paper is the application of piezoelectric materials for sensing and actuation of torsional rod vibrations. Exemplarily, a rod of rectangular cross-section made of aluminium is considered which is subject to an external torsional couple. On the top and bottom of the rod, piezoelectric layers are attached, such that a sandwich structure is obtained. Each layer can be used as a sensor by measuring the voltage on the electrodes, or as an actuator by prescribing the voltage. The main scope is the derivation of the sensor and actuator equations, and to perform numerical investigations in order to find a suitable configuration for an experimental setup.

Torsional actuation and sensing is either based on the piezoelectric extension or on the shear mode. In the first case, torsional actuation is obtained by piezoelectric normal strains acting at an angle of 45° degrees to the rod axis, c.f. Park and Chopra [2]. In the second case, piezoelectric shear strains cause a resulting actuating torque, [3]-[9]. On the other hand, in torsional sensors the strains corresponding to the piezoelectric mode cause the sensor voltage at the electrodes. In this paper two types of materials are investigated: (a) Shear mode: Piezo-ceramic material ammonium dihydrogen phosphate (ADP) and (b) Extension mode: Macro fiber composites (MFC) consisting of lead zirconate titanate (PZT) fibers embedded within an epoxy-substrate. Two types of MFCs are compared utilizing either the transversal d_{31} -effect or the longitudinal d_{33} -effect of the PZT fibers. For the MFC transducers effective homogenized material properties are used, which have been obtained by applying mixing rules according to Deraemaeker et al. [10].

In order to investigate the influence of piezoelectricity on torsion, Saint Venant's theory has been extended by Zehetner [5] and Zehetner and Krommer [7]. The main extension is the consideration of the additional cross-sectional warping caused by piezoelectric strains. In this paper, the theory is adapted for studying the behaviour of the three materials mentioned above. It turns out that for the three configurations the sensor and actuator equations only differ with respect to some coefficients referring to the material properties. It also turns out that for an experimental realization MFCs are more practicable because of higher sensitivity and efficiency of actuation. Finally, the theoretical results are validated by means of three-dimensional Finite Element computations performed with *ANSYS* and *ABAQUS* showing a good coincidence.

2 PIEZOELECTRIC SHEAR ACTUATORS AND SENSORS

In this paper two kinds of materials suitable for torsional sensing and actuation are investigated: Figure 1a shows a homogenous layer made of the piezoceramic ammonium dihydrogen phosphate (ADP), z is the thickness direction, and x is the axial direction of the rod. The second type of material is shown in Figure 1b, a macro fiber composite (MFC) consisting of piezoceramic fibers (lead zirconate titanate, PZT) which are embedded into an epoxy-substrate at an angle of 45° with respect to the axial direction x of the rod.

The compliance matrices S of the two materials are stated in Eq. (1). In layers made of ADP, the shear strains correspond to the shear stresses only. The same behavior is obtained for MFC's, if the coordinate frame coincides with the axes of material symmetry. On the contrary, for the investigated case with a ply angle of 45° , the shear strains are coupled to normal stresses

by the compliance components S_{16} and S_{36} .

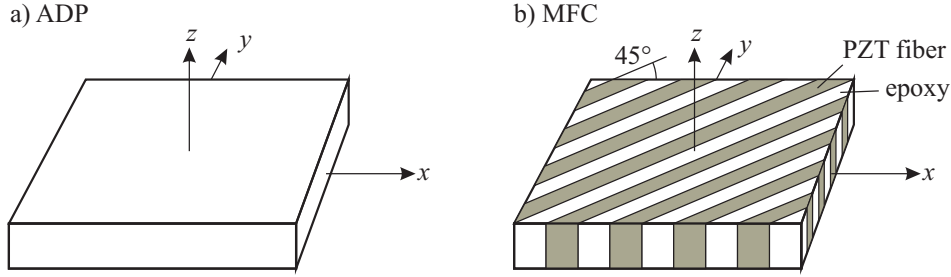

Figure 1: Piezoelectric materials

$$\begin{aligned}
 \text{a) ADP} \quad \mathbf{S} &= \begin{bmatrix} S_{11} & S_{12} & S_{13} & 0 & 0 & 0 \\ S_{12} & S_{11} & S_{13} & 0 & 0 & 0 \\ S_{13} & S_{13} & S_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{55} & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & S_{66} \end{bmatrix}, \quad \text{b) MFC} \quad \mathbf{S} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & 0 & 0 & S_{16} \\ S_{12} & S_{11} & S_{13} & 0 & 0 & S_{16} \\ S_{13} & S_{13} & S_{33} & 0 & 0 & S_{36} \\ 0 & 0 & 0 & S_{55} & S_{45} & 0 \\ 0 & 0 & 0 & S_{45} & S_{55} & 0 \\ S_{16} & S_{16} & S_{36} & 0 & 0 & S_{66} \end{bmatrix}. \quad (1)
 \end{aligned}$$

Three configurations are considered as shown in Figure 2: (a,b) A layer made of ADP or MFC type 1 (d_{31} -effect) is polarized in thickness direction, and the electrodes are bonded on the top and bottom surfaces, (c) A layer made of MFC type 2 (d_{33} -effect) is polarized in longitudinal direction of the fibers, and the electrodes are normal to this direction.

Figure 2: Electrodes and polarization direction

The matrices \mathbf{d} of piezoelectric coefficients d_{ij} for the three configurations are specified in Eq. (2). In layers made of ADP only piezoelectric shear strains are induced, such that pure torsional actuation is possible. On the contrary, in MFC's also normal eigenstrains arise, which can excite elongation and bending modes of the rod. In the following, the bending mode is avoided due to a symmetrical set-up, and the elongation is neglected.

$$\begin{aligned}
 \text{a) ADP} \quad \mathbf{d} &= \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ d_{25} & 0 & 0 \\ 0 & d_{25} & 0 \\ 0 & 0 & d_{36} \end{bmatrix}, \quad \text{b) MFC type 1} \quad \mathbf{d} = \begin{bmatrix} 0 & 0 & d_{13} \\ 0 & 0 & d_{13} \\ 0 & 0 & d_{33} \\ d_{25} & d_{15} & 0 \\ d_{15} & d_{25} & 0 \\ 0 & 0 & d_{36} \end{bmatrix}, \quad \text{c) MFC type 2} \quad \mathbf{d} = \begin{bmatrix} d_{11} & d_{12} & 0 \\ d_{12} & d_{11} & 0 \\ d_{13} & d_{13} & 0 \\ 0 & 0 & d_{35} \\ 0 & 0 & d_{35} \\ d_{16} & d_{16} & 0 \end{bmatrix}. \quad (2)
 \end{aligned}$$

3 TORSION OF PIEZO-LAMINATED RODS

Figure 3 shows the cross-section of a laminated rod with length L , width B and total height H . The rod consists of an isotropic aluminum layer with height h on which two piezoelectric layers with height h_L are ideally bonded. The rod is subject to the external torsional couple M_x^e . A Cartesian coordinate system is introduced such that the x -axis represents the longitudinal axis of the rod, and the axes y and z form the cross-sectional plane. The cross-sectional area of the piezoelectric layers is denoted as A_L , the interface between the layers i and j by ∂I_{ij} , A is the total cross-sectional area, and ∂A the boundary of the cross-section.

Figure 3: Cross-section of the laminated rod

3.1 Kinematical assumptions

According to Saint Venant's theory of torsion, the elastic deformation of the rod is composed of a rigid-body rotation of the cross-section about the torsional angle $\chi = \chi(x, t)$ and an axial displacement due to cross-sectional warping. It has been shown by Zehetner [5] that under the presence of piezoelectric shear strains the displacement components can be expressed by

$$u_x = \chi' \varphi + \phi^0, \quad u_y = -z\chi, \quad u_z = y\chi, \quad (3)$$

where $\varphi = \varphi(y, z)$ is Saint Venant's warping function, and the additional warping function $\phi^0 = \phi^0(y, z, t)$ represents the additive influence of the piezoelectric strains on the axial displacement. In order to obtain continuity at the interfaces, the warping functions have to satisfy the compatibility relations

$$\partial I_{ij} : \quad \llbracket \varphi(y, z) \rrbracket = 0, \quad \llbracket \phi^0(y, z) \rrbracket = 0, \quad (4)$$

where the notation $\llbracket \cdot \rrbracket$ stands for the jump of the respective quantity at the interface ∂I_{ij} . Note that due to the interface conditions the additional warping function is defined for the whole cross-section. With Eq. (3) and the assumption that $\chi'' = 0$ in case of unconstrained warping, the only non-vanishing linearized strain components are the shear angles

$$\gamma_{xz} = \chi' \left(\frac{\partial \varphi}{\partial z} + y \right) + \frac{\partial \phi^0}{\partial z}, \quad \gamma_{xy} = \chi' \left(\frac{\partial \varphi}{\partial y} - z \right) + \frac{\partial \phi^0}{\partial y}. \quad (5)$$

3.2 Constitutive Relations

The constitutive relations for the considered materials have been stated in section 2. Assuming, that the piezoelectric layers are thin, the normal stress σ_{zz} in thickness and the shear stress τ_{yz} are neglected, such that the mechanical constitutive relations can be written in the generalized form

$$\begin{bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \tau_{xz} \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 & Q_{16} \\ Q_{12} & Q_{11} & 0 & Q_{16} \\ 0 & 0 & Q_{55} & 0 \\ Q_{16} & Q_{16} & 0 & Q_{66} \end{bmatrix} \left(\begin{bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \gamma_{xz} \\ \gamma_{xy} \end{bmatrix} - \begin{bmatrix} \varepsilon_{xx}^0 \\ \varepsilon_{yy}^0 \\ \gamma_{xz}^0 \\ \gamma_{xy}^0 \end{bmatrix} \right), \quad (6)$$

where Q_{ij} are the coefficients of the effective stiffness matrix, ε_{ii}^0 and γ_{ij}^0 are piezoelectric eigenstrains. From the kinematical assumptions in section 3.1 follows that $\varepsilon_{xx} = \varepsilon_{yy} = 0$, such that the constitutive equations reduce to

$$\tau_{xz} = Q_{55}(\gamma_{xz} - \gamma_{xz}^0), \quad \tau_{xy} = Q_{66}(\gamma_{xy} - \gamma_{xy}^0). \quad (7)$$

Note that the constitutive relations for the isotropic substrate (aluminium) follows from Eq. (7) by setting $\gamma_{xz}^0 = \gamma_{xy}^0 = 0$ and $Q_{55} = Q_{66} = G$. For the piezoelectric materials in section 2 we obtain the effective shear moduli

$$Q_{55} = S_{55}^{-1}, \quad Q_{66} = \begin{cases} S_{66}^{-1} & \text{for ADP,} \\ (S_{11} + S_{12})(S_{11}S_{66} - S_{16}^2 + S_{12}S_{66})^{-1} & \text{for MFC.} \end{cases} \quad (8)$$

For the considered piezoelectric materials the effective eigenstrains can be expressed by

$$\gamma_{xz}^0 = 0, \quad \gamma_{xy}^0 = d_{xy}E_{\parallel}, \quad (9)$$

where E_{\parallel} is the component of the electric field parallel to the polarization direction, and d_{xy} is the effective piezoelectric coefficient, which depends on the material type, i.e.

$$d_{xy} = \begin{cases} d_{36} & \text{for ADP,} \\ d_{36} - 2d_{31}S_{16}(S_{11} + S_{12})^{-1} & \text{for MFC type 1,} \\ \sqrt{2}d_{16} - \sqrt{2}(d_{11} + d_{12})S_{16}(S_{11} + S_{12})^{-1} & \text{for MFC type 2.} \end{cases} \quad (10)$$

Assuming that the distance δ between the electrodes is relatively small, the parallel electric field component is proportional to the applied voltage V , but the normal component vanishes,

$$E_{\parallel} = \frac{V}{\delta}, \quad E_{\perp} = 0. \quad (11)$$

The electrical constitutive relations for the piezoelectric materials are given by

$$D_{\parallel} = \eta_{\parallel}(E_{\parallel} - E_{\parallel}^0), \quad (12)$$

where D_{\parallel} is the dielectric displacement component in direction of the polarization, η_{\parallel} the permittivity, and E_{\parallel}^0 the electric eigenfield representing the direct piezoelectric effect,

$$E_{\parallel}^0 = -\frac{d_{xy}}{\eta_{\parallel}}\tau_{xy}. \quad (13)$$

Inserting Eqs. (5), (9) and (11) into Eq. (7) yields the shear stresses in the piezoelectric layers as

$$\begin{aligned}\tau_{xz} &= Q_{55} \left[\left(\frac{\partial \varphi}{\partial z} + y \right) \chi' + \frac{\partial \phi^0}{\partial z} \right], \\ \tau_{xy} &= Q_{66} \left[\left(\frac{\partial \varphi}{\partial y} - z \right) \chi' + \frac{\partial \phi^0}{\partial y} - \frac{d_{xy}}{\delta} V \right].\end{aligned}\quad (14)$$

Note that the stresses in the isotropic substrate layer are obtained by setting $Q_{55} = Q_{66} = G$ and $V = 0$. Integrating over the cross-sectional area yields the internal torsional moment

$$M_x = C_{11} \chi' - M_x^a \quad (15)$$

with the torsional stiffness C_{11} and the actuating torsional moment M_x^a ,

$$C_{11} = \int_A \left[Q_{55} \left(\frac{\partial \varphi}{\partial z} + y \right) y - Q_{66} \left(\frac{\partial \varphi}{\partial y} - z \right) z \right] dA, \quad (16)$$

$$M_x^a = - \int_A \left(Q_{55} \frac{\partial \phi^0}{\partial z} y - Q_{66} \frac{\partial \phi^0}{\partial y} \right) dA - 2V \int_{A_L} Q_{66} \frac{d_{xy}}{\delta} z dA. \quad (17)$$

3.3 Warping functions

Inserting Eq. (14) into the equilibrium equations of elastostatics,

$$\frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} = 0, \quad \partial A : \tau_n = 0, \quad \partial I_{ij} : \llbracket \tau_n \rrbracket = 0, \quad (18)$$

where τ_n is the projection of the shear stress on the outer normal of the boundary and interface, yields boundary value problems for the warping functions φ and ϕ^0 , c.f. Zehetner [5]. For the cross-section in Figure 3 the Saint Venant warping function φ follows to

$$\begin{aligned}Q_{66} \frac{\partial^2 \varphi}{\partial y^2} + Q_{55} \frac{\partial^2 \varphi}{\partial z^2} &= 0, \\ \partial A_h : \frac{\partial \varphi}{\partial z} &= -y, \quad \partial A_v : \frac{\partial \varphi}{\partial y} = z, \quad \partial I_{ij} : \llbracket Q_{55} \frac{\partial \varphi}{\partial z} \rrbracket = 0, \quad \llbracket \varphi \rrbracket = 0,\end{aligned}\quad (19)$$

where ∂A_h denotes the horizontal boundary at the top and bottom, and ∂A_v the vertical boundary. Solutions of Eq. (19) are given in Rand and Rovenski [11]. A similar boundary value problem is obtained for the additional warping function. Using the separation

$$\phi_0(y, z, V(t)) = \frac{d_{xy}}{\delta} V(t) \bar{\phi}^0(y, z) \quad (20)$$

yields the boundary value problem

$$\begin{aligned}Q_{66} \frac{\partial^2 \bar{\phi}^0}{\partial y^2} + Q_{55} \frac{\partial^2 \bar{\phi}^0}{\partial z^2} &= 0, \\ \partial A_h : \frac{\partial \bar{\phi}^0}{\partial z} &= 0, \quad \partial A_v : \frac{\partial \bar{\phi}^0}{\partial y} = 1, \quad \partial I_{ij} : \llbracket Q_{55} \frac{\partial \bar{\phi}^0}{\partial z} \rrbracket = 0, \quad \llbracket \bar{\phi}^0 \rrbracket = 0.\end{aligned}\quad (21)$$

A solution of Eq. (21) has been given in Zehetner [5]. Note that $\varphi(y, z)$ and $\bar{\phi}^0(y, z)$ only depend on geometric and material properties.

4 SENSOR AND ACTUATOR EQUATIONS

Inserting Eq. (20) into Eq. (17) yields the actuator equation

$$M_x^a(t) = c_A V(t), \quad (22)$$

i.e. the actuating moment is proportional to the applied voltage with the actuator constant

$$c_A = \int_A \left[Q_{55} \frac{\partial \bar{\phi}^0}{\partial z} y - Q_{66} \frac{\partial \bar{\phi}^0}{\partial y} z \right] dA - 2 \int_{A_L} Q_{66} \frac{d_{xy}}{\delta} z dA. \quad (23)$$

Following the strategy presented by Zehetner and Krommer [7] yields the sensor equation

$$V(t) = -c_S \chi_L(t), \quad (24)$$

i.e. the measured voltage is proportional to the tip torsional angle with the sensor constant

$$c_S = \frac{d_{xy} Q_{66} \delta}{L} \frac{\int_{A_{el}} \left(\frac{\partial \varphi}{\partial y} - z \right) dA}{\int_{A_{el}} \left[\left(\frac{\partial \bar{\phi}^0}{\partial y} - 1 \right) d_{xy}^2 Q_{66} + \eta_{\parallel} \right] dA}. \quad (25)$$

Note that the actuator constant depends on cross-sectional properties only, but the sensor constant is a function of the rod length.

5 NUMERICAL EXAMPLES

5.1 Results of rod theory

In this section the expressions for torsional stiffness, actuator and sensor constants given in Eqs. (16), (23) and (25) are evaluated using the numerical values of table 1, $\eta_0 = 8.854 \cdot 10^{-12}$ F/m is the permittivity of vacuum. The results are compared in table 2. The highest actuator constant is obtained for MFC type 2, and the highest sensor constant for ADP.

property	unit	ADP	MFC type 1	MFC type 2
Q_{55}	N/m^2	$8.6207 \cdot 10^9$	$2.3059 \cdot 10^9$	$2.2959 \cdot 10^9$
Q_{66}	N/m^2	$6.0241 \cdot 10^9$	$4.2484 \cdot 10^9$	$3.8188 \cdot 10^9$
d_{xy}	C/N	$5.17 \cdot 10^{-11}$	$1.7234 \cdot 10^{-10}$	$5.1495 \cdot 10^{-10}$

Table 2: Rod Theory: Sensor and actuator constants

5.2 Finite Element Results

In the following these results of rod theory are verified by means of three dimensional Finite Element computations using the model presented in Zehetner [5]. The model has been implemented within *ABAQUS* and *ANSYS*. The following steps have been performed:

1. The torsional stiffness C_{11} is obtained by applying an external torsional couple $M_x^e = 100$ Nm to the rod and evaluating the torsional tip angle χ_L for $V = 0$. The stiffness is then obtained from Eq. (15),

$$C_{11} = \frac{M_x^e L}{\chi_L}. \quad (26)$$

2. For evaluating the actuator constant c_A the external torsional couple is set to $M_x^e = 0$ and the voltage $V = 100$ V is prescribed. Equation (15) yields

$$c_A = \frac{C_{11} \chi_L}{V} \frac{L}{L}. \quad (27)$$

3. The sensor constant c_S is obtained by applying an external torsional couple M_x^e to the rod and evaluating the torsional angle and the sensor voltage V . From Eq. (24) follows that

$$c_S = \frac{V}{\chi_L}. \quad (28)$$

The deformed rod for load case 2 with an actuator voltage of $V = 100$ V is shown in Figure 4, where the displacements have been scaled by a factor of 1000. The figure shows that the largest actuation is obtained for MFC type 2.

Figure 4: Deformed rod, displacements scaled by a factor of 1000

The results for Eqs. (26)-(28) obtained with *ABAQUS* and *ANSYS* are shown in Tables 3 and 4, respectively.

load case	constant	unit	ADP	MFC type 1	MFC type 2

	χ_L	rad	$7.24 \cdot 10^{-5}$	$7.77 \cdot 10^{-5}$	$7.08 \cdot 10^{-5}$
	c_S	V/rad	$3.494 \cdot 10^4$	$3.976 \cdot 10^3$	$1.634 \cdot 10^4$

Table 4: Results of the ANSYS analysis

The results of rod theory in Section 5.1 are confirmed: The highest actuator constant is obtained for MFC type 2, and the highest sensor constant for ADP. The slight differences between *ABAQUS* and *ANSYS* result from some minor discrepancies in the Finite Element models. A better adjustment of the models is a topic for further investigations.

5.3 Comparison of rod theory and FEM

Finally, the results of rod theory and Finite Element computations are compared in Figure 5. The relative difference of Finite Element and rod theory solutions are shown in Table 5.

Figure 5: Comparison of the results for C_{11} , c_A and c_S

constant		ADP	MFC type 1	MFC type 2
C_{11}	<i>ABAQUS</i>	1.0 %	0.4 %	0.8 %
	<i>ANSYS</i>	0.5 %	0.6 %	6.1 %
C_A	<i>ABAQUS</i>	0.0 %	4.9 %	0.6 %
	<i>ANSYS</i>	0.6 %	2.3 %	0.3 %
C_S	<i>ABAQUS</i>	0.3 %	3.8 %	6.9 %
	<i>ANSYS</i>	1.4 %	2.5 %	7.3 %

Table 5: Comparison of theory and Finite Element solutions: Relative difference

The maximum difference of 7.3% is obtained for the sensor constant of MFC type 2. The differences in Table 5 result from the assumptions of the presented rod theory, e.g. the kinematical assumptions and the neglect of some coupling terms. All in all Figure 5 shows a good coincidence of the results, such that the presented rod theory can be utilized for finding a suitable configuration for the planned experimental verification.

6 CONCLUSIONS

In this paper it has been shown how three kinds of piezoelectric materials can be used for actuating and sensing of torsional vibrations. An extension of Saint Venant's theory of torsion has been used to derive sensor and actuator equations. A numerical evaluation has shown high sensitivity of the investigated configurations, but relative small efficiency for actuation. The highest sensor constant is obtained for the ADP layer, and the highest actuator constant for MFC type 2.

Keywords: Honeycomb sandwich, Elastic wave propagation, periodic media, Bloch wave transformation.

Abstract. *The present work is devoted to a theoretical analysis and numerical modeling of the phenomena of high-frequency wave propagation in honeycomb-type periodic media. A one-dimensional periodic elastic rod model and a two-dimensional periodic elastic beam hexagonal model are considered. The Bloch wave direct and inverse transformations are applied to find general or particular solutions. By identifying eigenfrequencies and the corresponding eigenmodes of the periodic systems, important information, such as the frequency bandgaps and the diffracted waves caused by the periodic cells, is obtained. The aims are to improve our understanding of how HF waves are transmitted and attenuated in the studied periodic media and to link the theoretical analyses to our numerical assessments.*

1 INTRODUCTION

Sandwich shells using honeycomb-type core are very useful composite materials to design lightweight but high-strength structures, especially in aerospace and aeronautics industries, for the honeycomb core provides an efficient solution to increase bending stiffness without significant increase in structural weight. When high-frequency (HF) flexural waves propagating in such sandwich shells, the involved wavelengths are of the same order of the characteristic lengths of the honeycomb cells, or even shorter, the honeycomb cellular microstructure can interact with the waves and highly perturb the propagation phenomena, as they are governed by the geometry and the material properties of the cells. Indeed, due to the periodic geometric and material discontinuities within the cellular structure, waves can propagate completely or be attenuated even stopped, depending upon the involved frequencies and upon the spatial direction, so we observe the existence of passing and stop bands in frequency domain ([1]). As the classical homogenized models cannot take into account this kind of interaction, they fail to correctly describe the transient flexural behaviors of the sandwich shells in HF ranges ([2]). Therefore, relevant analytical and numerical models should be established by understanding how HF waves propagate in a honeycomb thin layer and interact with its cellular structure.

To simplify and optimize numerical models but still taking into account the detail characteristics of the cellular microstructure, the Bloch wave theory is more and more widely used now. The basic idea is to transform a non-periodic function defined in a periodic structure to a set of periodic functions having the same periodicity as the structure. Therefore the study of the original function in the whole structure can be replaced by considering the periodic functions in a unique cell. The theory was firstly applied in the quantum mechanics to solve the Schrödinger equation in periodic lattice of particles ([3]). Now it has been introduced to the structural mechanics. In the literature, the dispersion equations relating the frequency to the Bloch wave vector have been given for several types of honeycomb cells composed by beams and the effects of the cellular characteristics, for example the slenderness ratio and the internal angle, have been discussed in [4] and [5].

The honeycomb thin layer that we are interested is composed by thin-walled hexagonal regular cells, which give rise to an in-plane two-dimension periodic hexagonal cellular microstructure. Each hexagonal cell has two parallel sides whose thickness is doubled due to the manufacturing process, which forms ribbons with a semi-hexagonal profile and bonds them together in pairs to obtain hexagonal cells. These doubled thickness walls result in plane anisotropic properties of the honeycomb thin layer. Our first research works presented herein consist in the development of theoretical and numerical modeling tools based on the Bloch wave theory and then in their validation by application to a one-dimensional (1D) periodic elastic rod model and a two-dimensional (2D) elastic beam hexagonal model, for which the previously mentioned double thickness aspect is considered. The Bloch wave modes inside one cell are considered and the dispersion equations are obtained.

The paper is organized as follows: The section 2 introduces the direct and inverse Bloch wave transformations. The section 3 is devoted to the theoretical and numerical analyses of the wave propagation in a 1D periodic structure composed by elastic rods. The modeling of a more complex 2D periodic structure composed by elastic beams is then presented in the section 4, before some concluding remarks in the section 5.

2 BLOCH WAVE THEORY

Let us consider a periodic structure Ω of space dimension N , a *primitive cell* Q_0 and a set of basis vector \mathbf{e}_i ($i=1, \dots, N$), called *direct cell basis*, are defined so that the entire structure Ω can be obtained by repeating the primitive cell along the direct cell basis. Dual to the primitive cell Q_0 , a *reciprocal cell* Q_0^* and a *reciprocal cell basis*, \mathbf{e}_j^* , are defined, which satisfies the following relation:

$$\mathbf{e}_i \cdot \mathbf{e}_j^* = \delta_{ij} \quad (1)$$

where δ_{ij} is the Kronecker delta. The reciprocal cell is also called the *first Brillouin zone* [6]. The areas of Q_0 and Q_0^* verify the following equation:

$$\text{volume}(Q_0)\text{volume}(Q_0^*) = 1 \quad (2)$$

For any non periodic function $\mathbf{V}(\mathbf{x})$ defined on Ω , the Bloch wave theory states that, for each wave vector \mathbf{k} restricted in the first Brillouin zone Q_0^* , the Bloch transformation $\mathbf{V}^B(\mathbf{x}, \mathbf{k})$ of $\mathbf{V}(\mathbf{x})$ is a periodic function having the same periodicity as the periodic structure, which is also called *Bloch wave function*:

$$\mathbf{V}^B(\mathbf{x}, \mathbf{k}) = \sum_{\mathbf{n}} \mathbf{V}(\mathbf{x} + \mathbf{n}_i \lambda_i \mathbf{e}_i) e^{i\mathbf{k} \cdot (\mathbf{x} + \mathbf{n}_i \lambda_i \mathbf{e}_i)} \quad (3)$$

Then, $\mathbf{V}(\mathbf{x})$ can be recovered by the following inverse Bloch transformation:

$$\mathbf{V}(\mathbf{x}) = \frac{1}{\text{volume}(Q_0^*)} \int_{Q_0^*} \mathbf{V}^B(\mathbf{x}, \mathbf{k}) e^{-i\mathbf{k} \cdot \mathbf{x}} d\mathbf{k} \quad (4)$$

By virtue of the Bloch wave transformation, the propagation phenomena of HF elastic waves, transmission, reflection, conversion and attenuation, through the periodic microstructure can be understood by investigating the Bloch wave modes within the primitive cell, which allows to save lots of the efforts when doing analysis and simulation.

3 WAVE PROPAGATION IN 1D ELASTIC ROD MODEL

The first periodic structure considered herein is a 1D elastic rod model, which is a topology of a primitive cell composed by two rigidly jointed elastic rods respectively of lengths l_1 and l_2 , therefore the period of the 1D medium is $\lambda = l_1 + l_2$ (Figure 1).

Figure 1: 1D elastic rod model

The equilibrium eigen equation of the i -th rod ($i=1, 2$) reads as:

$$\frac{d}{dx} \left[E_i \frac{dU(x)}{dx} \right] = -\rho_i \omega^2 U(x) \quad (5)$$

where (E_i, ρ_i) denote the Young's Modulus and the density, ω the eigenfrequency and $U(x)$ the corresponding eigenmode. By applying Bloch wave transformation to (5), the following Bloch eigen equation is obtained:

$$E_i \frac{\partial^2 U^B(x, k)}{\partial x^2} - 2ikE_i \frac{\partial U^B(x, k)}{\partial x} - E_i k^2 U^B(x, k) = -\rho_i \omega^2 U^B(x, k) \quad (6)$$

with $k \in Q_0^* = [0, 2\pi/\lambda]$ the Bloch wave vector. Given k , the goal is to find the eigenvalue ω and the corresponding Bloch eigenmode $U^B(x, k)$ of the eigen problem (6). It is straightforward that the general solution of (6) has the following analytical form:

$$U_i^B(x, k) = a_i e^{i\left(k + \frac{\omega}{c_i}\right)x} + b_i e^{i\left(k - \frac{\omega}{c_i}\right)x} \quad (7)$$

where, for the i -th rod, $c_i = \sqrt{E_i/\rho_i}$ is the wave velocity and (a_i, b_i) are four constants to be determined.

3.1 Dispersion equation

To calculate the four constants (a_i, b_i) , ($i=1, 2$), we consider the following the interface conditions between the two rods inside the primitive cell and the periodic conditions on its extremities:

$$\begin{aligned} U^B(0^-) &= U^B(0^+), \quad N^B(0^-) = N^B(0^+) \\ U^B(-l_1) &= U^B(l_2), \quad N^B(-l_1) = N^B(l_2) \end{aligned} \quad (8)$$

where $N^B = dU^B/dx - ikU^B$ denotes the 1D Bloch axial force vector. Substituting the general solution form (7) to these conditions (8), a system of four linear equations is obtained. To ensure that system admits nontrivial solutions, its determinant must vanish, which finally gives a relation between k and ω , called *dispersion equation*.

For our 1D rod model, the following analytical dispersion equation can be obtained:

$$\cos(\lambda k) = \cos(\omega T_1) \cos(\omega T_2) - \left(\frac{Z_1}{2Z_2} + \frac{Z_2}{2Z_1}\right) \sin(\omega T_1) \sin(\omega T_2) \quad (9)$$

where $Z_i = \rho_i c_i$ denotes the characteristic acoustic impedance and $T_i = l_i / c_i$ the time for wave to propagate through the whole i -th rod. Using (9), for each given frequency ω , a Bloch wave vector $k = k_r + i k_{im}$ can be found and result in the following Bloch eigenmode in the i -th rod:

$$U_i^B(x, k) = a_i e^{i\left(k_r + \frac{\omega}{c_i}\right)x} e^{-k_{im}x} + b_i e^{i\left(k_r - \frac{\omega}{c_i}\right)x} e^{-k_{im}x} \quad (10)$$

Therefore, when k is real ($k_{im} = 0$), the Bloch wave mode U_i^B is a propagating mode, which is transmitted to the adjacent cells with the same amplitude and there is no energy losing when propagating through the periodic medium. Otherwise, when k is complex or pure imaginary ($k_{im} \neq 0$), U_i^B is an evanescent Bloch wave mode, it vanishes rapidly when propagating to the adjacent cells and the pure energy exchanging between periodic cells is equal to zero ([1]).

The frequency ranges that give real values of k is called *passing band* and the others *stop band*. The figure 2 gives the frequency bandgap of the 1D model: The red curves plot the two real solutions of k and so indicate the passing bands, while the blue curves present the stop

bands, by plotting the imaginary part k_{im} of the two complex solutions of $k: \frac{j\pi}{\lambda} + i k_{im}$, ($j=0,1$). We remark that the location and the width of the stop bands mainly depend on the ratio between the two characteristic acoustic impedances Z_1/Z_2 ([7]).

Figure 2: Dispersion relation of eigenfrequency on k , $Z_1/Z_2 = \sqrt{5}$

3.2 Diffracted wave analysis

Now, we consider an incident plane wave $u_0(x, t) = e^{i(k_0 x - \omega_0 t)}$ and investigate how its propagation through the 1D periodic structure that is perturbed by the periodic cells. To do this, the wave solution $u(x, t)$ is decomposed into two parts:

$$u(x, t) = [e^{ik_0 x} + u_d(x)]e^{-i\omega_0 t} \quad (11)$$

where (k_0, ω_0) are the wave vector and the angular frequency of the incident wave. We are interested in finding $u_d(x)$, the diffracted wave caused by the periodicity of the cells, which indicate us in fact what's the difference between the wave motion in a periodic medium and in a homogenous medium.

By substituting the equation (11) in the equilibrium eigenequation (5), we get:

$$\frac{d}{dx} \left[E_i \frac{du_d(x)}{dx} \right] + \underbrace{\left\{ \frac{d}{dx} \left[E_i \frac{du_0(x)}{dx} \right] + \rho_i \omega_0^2 u_0(x) \right\}}_{f_e} = -\rho_i \omega_0^2 u_d(x) \quad (12)$$

where the second term of the left member is considered as an external loading f_e due to the incident wave. By expanding $u_d(x)$ as a linear combination of eigenmode $U(x)$:

$$u_d(x) = \sum_n \alpha_n U_n(x) \quad (13)$$

the Bloch diffracted wave u_d^B reads as:

$$u_d^B(x, k) = \sum_n \alpha_n(k) U_n^B(x, k) \quad (14)$$

where $U^B(x, k)$ is the Bloch eigenmode and $\alpha_n(k)$ the Bloch coefficient.

Since we have already calculated $U^B(x, k)$, we look for $\alpha_n(k)$ now. Applying the Bloch wave transformation to the equation (12) to get Bloch equilibrium eigenequation and substituting the equation (14) into it, we get:

$$\sum_n \rho_i (\omega^2 - \omega_0^2) \alpha_n(k) U_n^B(x, k) = f_e^B(x, k) \quad (15)$$

where f_e^B is the Bloch external loading that can be expanded using the same Bloch modes $U^B(x, k)$:

$$f_e^B(x, k) = \sum_n F_n(k) U_n^B(x, k) \quad (16)$$

Therefore α_k can be obtained in the following way:

$$\alpha_n(k) = \frac{F_n(k)}{\rho_i (\omega^2 - \omega_0^2)} \quad (17)$$

Subsequently the u_d^B is got using (14) and finally u_d is obtained using the inverse Bloch transformation (4).

The figure 3 illustrates the ratio of amplitude between u_0 and u_d with two incident waves with having respectively two different frequencies $f_0=2.5$ kHz and $f_0=10$ kHz, whose corresponding wave lengths in the first rod, λ_0 , are respectively 0.3 and 0.075 times of the period. We observe an important amplification of wave propagation phenomena due to diffracted wave caused by the periodicity of the cells and the amplification level is not affected a lot by the frequency of the incident wave.

Figure 3: Diffracted wave inside the primitive cell.

4 WAVE PROPAGATION IN 2D ELASTIC BEAM MODEL

The second periodic structure considered here is a 2D elastic beam model (Figure 4). It is a topology of a primitive cell composed by three rigidly jointed elastic beams ([8]) with the same length s . The Lamé constants and the density of the beams are (λ, μ, ρ) . The thickness of beam (1) is twice of the thickness of the other two beams (2) and (3) (see Figure 4). Each beam is firstly considered in its local basis (s, n) , in which the unit vector s is parallel to the beam's axis and the unit vector n is perpendicular to the beam's axis. Then the entire model is considered in a global basis (x, y) .

Figure 4: 2D elastic periodic structure composed by beams

4.1 Dispersion relation

The well-known Timoshenko kinetics for thick beams is used, so the displacement $\mathbf{u}(s, t)$ in each beam reads as:

$$\mathbf{u}(s, t) = u_{01}(s)\mathbf{s} + u_{02}(s)\mathbf{n} + t u_{13}(s)\mathbf{s} \quad (18)$$

where $u_{01}(s)$ and $u_{02}(s)$ are the displacement fields of the middle line in direction \mathbf{s} and \mathbf{n} and $u_{13}(s)$ is the rotation of the fibers.

For each beam, the Bloch equilibrium eigenequations of the 2D model are:

$$\begin{aligned} \frac{d^2 U_{01}^B}{ds^2} - 2i(\mathbf{k} \cdot \mathbf{s}) \frac{dU_{01}^B}{ds} - (\mathbf{k} \cdot \mathbf{s})^2 U_{01}^B &= -\frac{\rho\omega^2}{\lambda + 2\mu} U_{01}^B \\ \frac{d^2 U_{02}^B}{ds^2} - 2i(\mathbf{k} \cdot \mathbf{s}) \frac{dU_{02}^B}{ds} - (\mathbf{k} \cdot \mathbf{s})^2 U_{02}^B + \frac{dU_{13}^B}{ds} &= -\frac{\rho\omega^2}{\mu} U_{02}^B, \quad (m = 0, 1) \\ \frac{d^2 U_{13}^B}{ds^2} - 2i(\mathbf{k} \cdot \mathbf{s}) \frac{dU_{13}^B}{ds} - \left[(\mathbf{k} \cdot \mathbf{s})^2 + \frac{12\mu}{(\lambda + 2\mu)H_m^2} \right] U_{13}^B - \frac{12\mu}{(\lambda + 2\mu)H_m^2} \frac{dU_{02}^B}{ds} &= -\frac{\rho\omega^2}{\lambda + 2\mu} U_{13}^B \end{aligned} \quad (19)$$

with $(U_{01}^B, U_{02}^B, U_{13}^B)$ the Bloch eigenmode and $\mathbf{k} \in Q_0^*$ the Bloch wave vector. In this 2D model, the first Brillouin zone Q_0^* is also a hexagonal cell. Similar to the analysis we did for the 1D model, giving \mathbf{k} , we look for the eigenvalues and the corresponding Bloch eigenmodes of the equation (19).

According to the interface conditions between the beams inside the primitive cell and the periodic conditions on their extremities as following:

$$\begin{aligned} U_{01}^{B(1)} + U_{02}^{B(1)} &= U_{01}^{B(2)} + U_{02}^{B(2)} = U_{01}^{B(3)} + U_{02}^{B(3)} \\ U_{13}^{B(1)} &= U_{13}^{B(2)} = U_{13}^{B(3)} \\ N^{B(1)} + Q^{B(1)} + N^{B(2)} + Q^{B(2)} + N^{B(3)} + Q^{B(3)} &= 0 \\ M^{B(1)} &= M^{B(2)} = M^{B(3)} \end{aligned} \quad (20)$$

where \mathbf{N}^B is the Bloch axial force vector, \mathbf{Q}^B is the Bloch transverse shear force vector and \mathbf{M}^B is the Bloch bending moment, we get a system of 18 linear equations. Let the determinant

of the system equal to zero, we can get finally the dispersion equations between \mathbf{k} and ω . Unfortunately, in the 2D model, we are not able to explicit the dispersion equation and we can only plot the dispersion surface numerically (Figure 5). We find that the ratio of H_0/H_1 largely affects the width of the stop bands and the bandgap will move to HF range if we shorter the lengths of the beams.

Figure 5: Dispersion surface of eigenfrequency upon Bloch wave vector.

5 CONCLUSIONS

The classical homogenized models fail to correctly describe the HF transient flexural behavior of the honeycomb-type sandwich shells. It is necessary to look into the effects coming from the periodic microstructure of the honeycomb thin layer. The Bloch wave theory has been adopted in order to take into account the characteristics of the honeycomb cells while optimizing numerical models and saving calculation costs.

Theoretical analyzing and numerical modeling tools base on the Bloch wave theory and the FE method has been developed. They are at first applied to a 1D periodic structure composed by elastic rods and validated. By considering only the primitive cell, the dispersion equation is obtained, which allows identifying the passing and stopping bands of frequency. With an incident plane wave, the diffracted wave due to the periodicity of the cells is calculated and amplification phenomena are observed independently from the frequency of the incident wave.

Then, a 2D periodic hexagonal regular structure composed by elastic beams is investigated. The first result of eigenfrequency bandgap is obtained.

Our current research work is to apply our theoretical and numerical tools to the honeycomb-type thin layer composed of periodic thin-walled hexagonal regular cells.

Keywords: Bi-hierarchical finite element, double hierarchical increment, shells of revolution, linearly varying thickness, non – axisymmetric, free vibration.

Abstract. *A new hierarchical finite element is developed to analyze the free vibration of isotropic shells of revolution with linear varying thickness. It is a bi-hierarchical four nodes quadrilateral element with three degrees of freedom (three displacements) by node. The specificity of this element is a double increase of the hierarchical mode number independently according to both axial and radial directions. The advantage is that the solution is accurate for high ratio dimensions as well flattened axisymmetric (plates) shells that slim ones (high cylindrical shells) with different shapes and boundary conditions. The second advantage is the possibility of using only one element to idealize regular shape shells. Through the application of this element to some numerical examples, the comparisons with other studies show clearly that this element gives good results accuracy with simple idealization for axisymmetric and non-axisymmetric shells vibration (thick and thin).*

1 INTRODUCTION

The propose of this work is to present a new bi-hierarchical finite element to idealize isotropic shells of revolution with linear varying thickness. Shells of revolution can be of different shape and dimensions. Thin and thick plates and cylindrical shells cannot be idealized by the same finite elements in standard or hierarchical method. The dimensions ratio and the shape of the shell influence on the choice of the finite element and the mesh. For modeling for example a storage tank, one must have two elements, one for the cylinder and the other for the plate. The new proposed element can idealize the two shells.

The literature on finite element approximation of shells of revolution is huge. Let us just mention a few different approaches. Bodies of revolution compounds of thin shell segments, thick shell segments, and rings have been analyzed by using quadrilateral isoparametric elements of revolution of eight nodes [1] and Mindlin Reissner axisymmetric finite elements which take in account the shearing strains and the rotational inertia effects [2]. Other methods were implemented of which a three-dimensional method of analysis to determine the frequencies and eigen modes of paraboloid solids and paraboloid shells of revolution with variable thickness [3] and a spline finite element method for the analysis of the free vibration of shells of revolution which is based on the theory of the thin shells [4].

The proposed element in this work is a four nodes volumetric and axisymmetric bi-hierarchical finite element with only displacements as degrees of freedom. The word "bi-hierarchical" comes from the fact that this element has two hierarchical mode numbers, one in the axis direction and the second in the radius direction. These two hierarchical mode numbers increase independently. This element can than idealize flattened shells like plates and high shells like cylinders and conic shells (thins and thicks) or structures composed of them. For the first kind of shells, the radius direction hierarchical mode number is increased to have the accuracy of the results, and for the second kind, the axis hierarchical mode number is increased.

2 POTENTIAL ENERGY

The potential energy stored in the shell is in the form of strain energy due to the effect of both stretching and bending. The strain energy expression can be written as

$$U(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} (\sigma_r \varepsilon_r + \sigma_z \varepsilon_z + \sigma_\theta \varepsilon_\theta + \tau_{rz} \gamma_{rz} + \tau_{r\theta} \gamma_{r\theta} + \tau_{z\theta} \gamma_{z\theta}) r dr dz d\theta \quad (1)$$

And in matrix form
$$U(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} \{\varepsilon\}^T \{\sigma\} r dr dz d\theta \quad (2)$$

Where $\{\varepsilon\} = \begin{Bmatrix} \varepsilon_r \\ \varepsilon_z \\ \varepsilon_\theta \\ \gamma_{rz} \\ \gamma_{r\theta} \\ \gamma_{z\theta} \end{Bmatrix} \quad (3-a) \quad \text{and} \quad \{\sigma\} = \begin{Bmatrix} \sigma_r \\ \sigma_z \\ \sigma_\theta \\ \tau_{rz} \\ \tau_{r\theta} \\ \tau_{z\theta} \end{Bmatrix} \quad (3-b) \quad \text{are the stain and stress vectors}$

Figure 1: Shell of revolution

The constitutive relationship between stress and strain is the generalized Hooke's law. For an isotropic homogeneous structure, it is given as

$$\{\sigma\} = [D]\{\varepsilon\} \quad (4)$$

Where $[D]$ is the elasticity matrix, E is Young's modulus, and ν is Poisson ratio of the structure.

Eq. (4) into Eq. (2), the potential energy is given in terms of strain as

$$U(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} (\{\varepsilon\}^T [D] \{\varepsilon\}) r dr dz d\theta \quad (5)$$

The strain-displacement relations are given by:

$$\{\varepsilon\} = \begin{Bmatrix} \varepsilon_r \\ \varepsilon_z \\ \varepsilon_\theta \\ \gamma_{rz} \\ \gamma_{r\theta} \\ \gamma_{z\theta} \end{Bmatrix} = \begin{Bmatrix} \frac{\partial u}{\partial r} \\ \frac{\partial v}{\partial z} \\ u + \frac{1}{r} \frac{\partial w}{\partial \theta} \\ \frac{\partial u}{\partial z} + \frac{\partial v}{\partial r} \\ \frac{1}{r} \frac{\partial u}{\partial \theta} + \frac{\partial w}{\partial r} - \frac{w}{r} \\ \frac{1}{r} \frac{\partial v}{\partial \theta} + \frac{\partial w}{\partial z} \end{Bmatrix} \quad (6)$$

The strain vector can be expressed in terms of the displacement vector as follows:

$$\{\varepsilon\} = [d]\{\delta\} \quad (7)$$

Where

$$\{\delta\} = \{u, v, w\} \quad (8)$$

and $[d]$ is a differential operator matrix

The stress vector can be expressed in terms of the displacement vector, as:

$$\{\sigma\} = \frac{E}{(1+\nu)(1-2\nu)} \cdot \begin{Bmatrix} (1-\nu) \frac{\partial u}{\partial r} + \nu \left(\frac{\partial v}{\partial z} + \frac{u}{r} + \frac{1}{r} \cdot \frac{\partial w}{\partial \theta} \right) \\ (1-\nu) \frac{\partial v}{\partial z} + \nu \left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{1}{r} \cdot \frac{\partial w}{\partial \theta} \right) \\ (1-\nu) \left(\frac{u}{r} + \frac{1}{r} \cdot \frac{\partial w}{\partial \theta} \right) + \nu \left(\frac{\partial u}{\partial r} + \frac{\partial v}{\partial z} \right) \\ \frac{1-2\nu}{2} \left(\frac{\partial u}{\partial z} + \frac{\partial v}{\partial r} \right) \\ \frac{1-2\nu}{2} \left(\frac{1}{r} \cdot \frac{\partial u}{\partial \theta} + \frac{\partial w}{\partial r} - \frac{w}{r} \right) \\ \frac{1-2\nu}{2} \left(\frac{1}{r} \cdot \frac{\partial v}{\partial \theta} + \frac{\partial w}{\partial z} \right) \end{Bmatrix} \quad (9)$$

3 KINETIC ENERGY

The kinetic energy of the shell can be written as

$$T(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} \rho \cdot \left[\left(\frac{\partial u(r, z, \theta, t)}{\partial t} \right)^2 + \left(\frac{\partial v(r, z, \theta, t)}{\partial t} \right)^2 + \left(\frac{\partial w(r, z, \theta, t)}{\partial t} \right)^2 \right] r \cdot dr \cdot dz \cdot d\theta \quad (10)$$

where ρ is the density. Equation can be written as follows

$$T(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} \rho \cdot \{\dot{\delta}\}^T \cdot \{\dot{\delta}\} r \cdot dr \cdot dz \cdot d\theta \quad (11)$$

where $\{\delta\}$ is the displacement vector defined by Eq. (8), and differentiation is with respect to the time, t .

4 HIERARCHICAL FINITE ELEMENT FORMULATION

The hierarchical finite element method known under the name of the p-version of the finite element method is more precise and its convergence is faster than that of the h-method. Indeed, when the exact solution is analytical everywhere the rate of convergence is exponential, whereas that of the h-method is only algebraic. The quality of the solutions is not very sensitive to the distortions of the elements, which allows the use of flattened elements or great ratio on sides without penalizing the precision too much. In addition, as a hierarchical formulation is adopted for the representation of displacements, the matrix of stiffness relative to a given degree imbricates those of lower degrees. This makes it possible to obtain in an economic way a sequence of solutions instead of only one solution as it is the case of the h-method [5], [6] et [7].

The hp version of the finite element method has as a characteristic to increase the precision by increasing both the degree of the polynomial of interpolation and the number of finite elements as for the standard finite element method [7].

4.1 Idealization of the shell

The shell is divided into four nodes hierarchical axisymmetric quadrilateral isoparametric finite elements (Fig.1). The element size is arbitrary. They may all be of the same size or may

all be different. The shell can also be idealized by only one element if the thickness of the shell is varying linearly or if it is constant.

Figure 2: Displacements of a shell point

The equation of motion of the shell admit the representation of the Radial, circumferential and axial displacement components u , v , and w following respectively R , Z and θ in the following form

$$\begin{cases} u(r, z, \theta) = \bar{u}(r, z) \cos n\theta \\ v(r, z, \theta) = \bar{v}(r, z) \cos n\theta \\ w(r, z, \theta) = \bar{w}(r, z) \sin n\theta \end{cases} \quad (12)$$

The displacement functions $\bar{u}(r, z)$, $\bar{v}(r, z)$ and $\bar{w}(r, z)$ can be expressed in terms of the nodal displacements of the finite elements by means of an appropriate set of interpolation functions. title should be written centered, in 14pt, boldface Roman, all capital letters. It should be single spaced if the title is more than one line long.

4.2 Shape functions selection

The hierarchical shape functions are generally selected in the Serendipity space. In this paper, the shape functions are built from the shifted Legendre orthogonal polynomials introduced by [8]. They are so different from those introduced by [9]. These polynomials are defined in the interval $[0, 1]$.

They can be classified in three categories, nodal shape functions, side shape functions, internal shape functions. Their recurring form is:

$$\begin{cases} f_i(x) = 1 - x \\ f_i(x) = x \\ f_{i+2}(x) = \int_0^x P_i(\alpha) d\alpha \end{cases} \quad (13)$$

where $P_i(\alpha)$ are the shifted Legendre polynomials defined by :

$$\left\{ \begin{array}{l} P_0(\alpha) = 1 \\ P_1(\alpha) = 2\alpha - 1 \\ P_{i+1}(\alpha) = \frac{1}{i+1} \cdot [(-2i-1 + (4i+2)\alpha) \cdot P_i(\alpha) - i \cdot P_{i-1}(\alpha)] \end{array} \right. \quad i = 1, 2, 3, \dots \quad (14)$$

The shape functions are given on the basis of one-dimensional hierarchical finite element. The origin of the non-dimensional coordinates is at the left end of the element. For the C^0 continuous problems, the first two linear shape functions of the standard finite element method are retained. The higher order C^0 shape functions vanish at each end of the elements, they are used to describe the displacement function inside the element. These functions are generated by using the recursive formula (16).

Having the shape functions, the displacement functions $\bar{u}(r, z)$, $\bar{v}(r, z)$ and $\bar{w}(r, z)$ can be expressed:

$$\left\{ \begin{array}{l} \bar{u}(r, z) = \sum_{i=1}^n N_i(r, z) u_i \\ \bar{v}(r, z) = \sum_{i=1}^n N_i(r, z) v_i \\ \bar{w}(r, z) = \sum_{i=1}^n N_i(r, z) w_i \end{array} \right. \quad (15)$$

where

$$N_i(r, z) = f_k(r) g_l(z) \quad (16)$$

with: $k = 1, \dots, p+1$ et $l = 1, \dots, q+1$

p : Hierarchical modes number according to ξ ,

q : Hierarchical modes number according to η , f , g : Shape functions

The matrix form of the expression (15) is:

$$\{\bar{\delta}\} = [N] \{q\} \quad (17)$$

Where:

$$\{\bar{\delta}\} = \left\{ \begin{array}{l} \bar{u}(r, z) \\ \bar{v}(r, z) \\ \bar{w}(r, z) \end{array} \right\} \quad (18)$$

is the generalized displacement vector,

$$\{q\} = \{u_1, v_1, w_1, \dots, u_i, v_i, w_i, \dots\}^T \quad (19)$$

With $i=1, \dots, (p+1)(q+1)$

is the nodal displacement vector

$$[N] = [[N_1], [N_2], \dots, [N_i], \dots, [N_{(p+1)(q+1)}]] \quad (20)$$

is the shape functions matrix, where $[N_i]$ is a sub-matrix given by:

$$[N_i] = \begin{bmatrix} f_k(r)g_l(z) & 0 & 0 \\ 0 & f_k(r)g_l(z) & 0 \\ 0 & 0 & f_k(r)g_l(z) \end{bmatrix} \quad (21)$$

$f_k(r)$ and $g_l(z)$ are the nodal, edge and internal shape functions of the element.

4.3 Shell stiffness matrix

Defining the stiffness properties of the shell is reduced to evaluating the stiffness of a typical element.

Expression (12) can be written

$$\{\delta\} = [\theta_n] \{\bar{\delta}\} \quad (22)$$

Where

$$[\theta_n] = \begin{bmatrix} \cos n\theta & 0 & 0 \\ 0 & \cos n\theta & 0 \\ 0 & 0 & \sin n\theta \end{bmatrix} \quad (23)$$

Substitute Eq. (22) into Eq. (7), then one can write

$$\{\varepsilon\} = [d]\{\delta\} = [d][\theta_n]\{\bar{\delta}\} = [\bar{d}]\{\bar{\delta}\} \quad (24)$$

Where $[\bar{d}]$ is an operator vector .Eq. (24) into Eq. (5), the potential energy can be written, as

$$U(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} \left([\bar{d}]\{\bar{\delta}\} \right)^T [D][\bar{d}]\{\bar{\delta}\} r dr dz d\theta \quad (25)$$

To evaluate the stiffness matrix of an element, the global cylindrical coordinates (r , z) may be expressed in terms of the local non-dimensional coordinates (ξ , η) which are varying from 0 to 1 whose origin is the node lower right of the element.

After transformations, the potential energy can be written, as

$$U(t) = \frac{k\pi}{2} \int_0^1 \int_0^1 \left(\{q\}^T [N]^T [\bar{d}]^T [D][\bar{d}][N]\{q\} \right) r |J| d\xi d\eta = \frac{1}{2} \{q\}^T [K]\{q\} \quad (26)$$

Where

$$[K_e] = k\pi \int_0^1 \int_0^1 \sum_{i=1}^{p+1} \sum_{j=1}^{q+1} \left([B_i]^T [D][B_j] \right) r |J| d\xi d\eta \quad (27)$$

is the element stiffness matrix.

$[B] = [\bar{d}][N]$ and $k = 2$ for $n = 0$ and $k = 1$ for $n = 1, 2, \dots$ (n : circumferential wave number),

4.4 Mass matrix

The kinetic energy can be written

$$T(t) = \frac{1}{2} \int_{R_i}^{R_e} \int_0^H \int_0^{2\pi} \rho \cdot \left\{ \bar{\delta} \right\}^T [\theta_n]^T [\theta_n] \left\{ \bar{\delta} \right\} r \cdot dr \cdot dz \cdot d\theta = \frac{1}{2} \{\dot{q}\}^T [M_e] \{\dot{q}\} \quad (28)$$

Where

$$[M_e] = k\pi \cdot \int_0^1 \int_0^1 \rho \cdot \sum_{i=1}^{p+1} \sum_{j=1}^{q+1} [N_i]^T [N_j] |J| \cdot r \cdot d\xi \cdot d\eta \quad (29)$$

is the element mass matrix

4.5 Numerical integration

The double integral appearing in the forms of the mass and stiffness matrices results in a numerical integration. For his implementation, one uses the Gauss quadrature expressed by:

$$\int_0^1 f(x) d(x) = \sum_{i=1}^N W_i \cdot f(x_i) \quad (30)$$

Where N is the integration points number. After having tested several integration points numbers, the number which is a compromise between the computing time and the precision is:

$$N_{int} = p + 2 \quad (31)$$

5 RESULTS AND DISCUSSIONS

The convergence and comparison studies must be carried out to ensure the reliability of the results. The vibration frequency ω is expressed in terms of the frequency parameter

$$\Omega = \omega \cdot \sqrt{\frac{2\rho(1+\nu)}{E}} \quad (32)$$

5.1 Convergence

The bi-hierarchical finite element is used for the first time, to study the free vibration of a very thin cylindrical shell with free boundary conditions. The external and internal radius are respectively $R_e=1$ and $R_i=0.99$, the shell height is $H=2$. Table 1 show the convergence study of the first six modes with an increasing of the two hierarchical mode numbers p and q following respectively the radius and the axis directions for two and four elements.

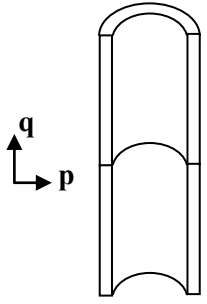

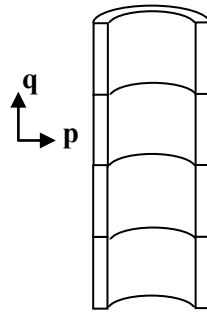

Element number	q	p	DOF	Modes number					
				1	2	3	4	5	6

Table 1: Convergence and comparison study of frequency parameter Ω for a free cylindrical shell ($Re=1$, $Ri=0.99$, $H=2$)

The results are compared with those of the boundary collocation method [10] and those of ANSYS (20 harmonic and axisymmetric structural element solid with eight nodes). For the two idealization, two and four elements, an accuracy of three digits after the comma is reached for the first two modes for $p=2$ and $q=2$.

For modes 3, 4, 5; the convergence is reached for $p=6$ and $q=3$ for a 2 elements model, and for $p=4$ and $q=2$ for a 4 elements model. The sixth mode reaches the convergence for $p=8$ and $q=3$ for 2 elements, and $p=6$ and $q=2$ for 4 elements.

It is apparent that by increasing the number of elements, the hierarchical mode numbers p and q necessary to reach convergence are smaller. But the degrees of freedom number becomes more important. Indeed for mode 6 this number is of 300 for 4 elements whereas it is only of 189 for 2 elements.

The matrices size is smaller if one increases p and q rather than the elements number. Table (2) shows that the number of degrees of freedom can be easily decreased by modifying the values of p and q according to the shell geometry.

5.2 Comparison with other methods

In order to verify the accuracy of the bi-hierarchical finite element in solving the vibration of shells of revolution, a comparison study is conducted for different shells. A thick and a very thin cylindrical shells, a hollow cylindrical shell with varying thickness and a very thin

plate. The results are compared with those of the boundary collocation method BCM, [10] and with those obtained by ANSYS where the harmonic and axisymmetric structural element solid with eight nodes is used.

circumferential wave's number	Method	Modes					
		1	2	3	4	5	6
0	Present	2.298	2.512	3.237	4.138	4.502	6.352
	BCM	2.299	2.513	3.237	4.137	4.500	6.347
	ANSYS	2.300	2.514	3.239	4.141	4.508	6.368
1	Present	2.124	2.716	3.305	3.448	3.892	4.645
	BCM	2.123	2.716	3.304	3.447	3.890	4.645
	ANSYS	2.125	2.718	3.307	3.452	3.895	4.650
2	Present	1.371	1.444	3.142	3.143	4.195	4.626
	BCM	1.371	1.441	3.139	3.140	4.194	4.622
	ANSYS	1.370	1.442	3.142	3.143	4.199	4.630
3	Present	2.820	3.079	3.762	4.285	5.531	5.716
	BCM	2.818	3.071	3.758	4.279	5.526	5.711
	ANSYS	2.818	3.074	3.761	4.286	5.538	5.727

Table 2: Comparison of frequency parameters Ω for free thick cylindrical shell ($R_e=1/3$, $R_i=1$, $H=4/3$, $p=8$, $q=8$)

The comparison of the frequency parameters Ω with those of the boundary collocation method [10] and ANSYS (32 harmonic and axisymmetric structural element solid with eight nodes) for a free thick cylindrical shell is given in table 1. The inner radius is $R_i=1/3$, the outer radius is $R_e=1$ and the shell height is $H=4/3$. Considering that the results accuracy is quickly reached for a low number of elements if one increases the number of hierarchical modes, the shell is idealized by only four bi-hierarchical finite elements with the same hierarchical modes numbers p and q according to the axial and radial directions. For this very thick cylindrical shell, $p=q=8$.

The results given in table 2 are in good agreement with those of the two other methods, as well for the axisymmetric case as for the non-axisymmetric case. For the high frequencies the results approach more those of the BCM than those of ANSYS. The reason is that the warping of cross-sections is important and thus the interpolation polynomials degree must be larger to describe these modes. It is easily and automatically possible by using this bi-hierarchical finite element.

circumferential wave's number	Method	Modes					
		1	2	3	4	5	6
0	Present	2.006	2.193	2.366	2.844	3.273	3.880
	BCM	2.007	2.195	2.367	2.839	3.279	3.896
	ANSYS	2.007	2.193	2.367	2.846	3.275	3.889
1	Present	1.629	1.996	2.518	2.832	3.370	3.382
	BCM	1.627	2.002	2.518	2.835	3.370	3.384
	ANSYS	1.629	1.997	2.519	2.839	3.373	3.386
2	Present	0.644	0.761	1.853	2.466	2.967	3.309
	BCM	0.646	0.760	1.861	2.464	2.963	3.308
	ANSYS	0.644	0.761	1.855	2.468	2.976	3.312
3	Present	1.641	1.762	2.444	3.356	3.767	4.228
	BCM	1.641	1.755	2.449	3.348	3.761	4.228
	ANSYS	1.642	1.763	2.448	3.365	3.774	4.239

Tableau 3: Comparison of frequency parameters Ω for a free thick hollow cylindrical shell of varying thickness (R_e varying, $R_i=0.6$, $H=2$, $p=8$, $q=8$)

Finally, a thick free hollow cylindrical shell with varying thickness is considered. Along the axis the inner radius is $R_i=0.6$ and the outer radius is varying from $R_e=0.8$ at the edges to $R_e=1$ at the middle height. The height is $H=2$. The shell being thick, one takes the same hierarchical modes numbers the $p=q=8$. Each half cylindrical shell is idealized by one bi-hierarchical finite. Comparison Results with those of the BCM [10] and those of ANSYS (16 elements) are given in table 3. The same observation is made as for the two other examples. The results agree very well with those of the BCM and those of ANSYS, which shows the power of this element.

6 CONCLUSION

The bi-hierarchical finite element presented in this study is able to give accurate frequencies for shells of revolution of an unspecified shape. The results show clearly that this element can be easily used for the extreme cases of very thin or very thick shells of revolution. With this element one is not constrained any more to have the same number of hierarchical modes in the two main directions of the radial and axial shells of revolution. Indeed, if the shapes and dimensions change (thick or thin shells) the hierarchical modes number can change very easily. This element can also be used to idealize a composed shell, plate linked to cylindrical shell for example. Finally this bi-hierarchical finite element allows triple increase in the accuracy, finite elements number, and radial and axial hierarchical modes numbers.

Keywords: Finite Element Methods, Dynamic Analysis, Model Order Reduction, Discrete Equivalence

Abstract. *In dynamic structural analyses, in order to improve the analyses performance, model order reduction methods are applied to mathematical models obtained by computational techniques to reduce the size of the associated problems. There are various techniques for model order reduction with different performance levels applying to complex problems. In this study, model order reduction approaches based on discrete equivalent principle are compared with some methods given in literature.*

Newly developed discrete equivalent model order reduction approach is based on that the response of the original and reduced order model is equal to each other at discrete time steps. In the proposed model order reduction approach, the degrees-of-freedom (DOFs) that give responses conforming with the original system are the main criteria at the selection of the DOFs which are transferred into the reduced system as the active DOFs.

The developed model order reduction method was applied to create some sample structures by using some Matlab codes and the results of the model order reduction analyses are compared with the original system response. In the same Matlab codes, responses of some other model order reduction methods were also compared with the original system responses. Damping characteristics of the systems are taken into account in all these comparisons and the results of analyses with different model orders are evaluated in terms of calculation time and performance.

To develop computational models, finite element methods are employed. It is observed that as the damping of the original system decreases, the accuracy of the model order reduction process decreases. In simulation studies, the inputs for the sample systems are selected to be external forces applied to some nodes. If the input force is smooth enough then the performance of model order reduction process based on discrete equivalent methods improves substantially.

1 INTRODUCTION

Model order reduction methods have been the subject of significant number of recent studies, e.g., see [1] for an overview and discussion. Many techniques have been proposed to obtain reduced order finite element models by reducing the orders of mass and stiffness matrices. One class of techniques such as [2, 3, 4, 5, 6, 7, 8, 9, 10] uses a direct reduction of physical model coordinates by omitting some selected degrees-of-freedom (DOF), whose accuracy is very sensitive to the selection of active DOF. The second class of methods such as the works [11] and [12] is the modal methods having better accuracy, yielding decoupled equations and giving a better insight into the problems; however, they have the following disadvantages: computation of the modes may be costly if too many modes are needed in the analyses and their results may be unacceptable due to the effects of truncated modes. In order to overcome this drawback, quasi-static compensation (QSC) method studied in [13, 14, 15, 16, 17, 18] was developed. The third class of methods is the Ritz vector methods (e.g., see [1, 19, 20, 21, 22, 23, 24, 25, 27, 28]) developed to eliminate the need to compute costly eigenvalue problems and to improve the accuracy in cases where eigenvectors are not the best choice; these methods can be regarded as a generalized approach replacing the eigenvectors by more generally defined Ritz vectors. Juanmin Gu et. al. in [29] used the data recovery techniques in dynamic analyses to recover the physical response from the modal response obtained by using the mode-displacement method. In [30], the frequency and time domain responses of some popular model order reduction methods such as QSC, quasi-static mode synthesis (QSM) method [19], subspace based identification [31] and nonlinear least square (NLS) fit in frequency domain [32, 33] are compared.

In this paper, a family of model order reduction techniques is derived in time domain based on the principle that the exact solution of the semi-discrete equation of a system and the solution of the reduced order model match at discrete time steps. It is sufficient to pursue exact match at discrete time steps, i.e., discrete equivalence, since the solutions of semi-discrete equations are obtained only at the time steps. Numerical examples are presented to compare the performance of the proposed approach with that of exact solution. It is shown that proposed methods have certain advantages over conventional methods.

2 DEFINITIONS

A linear time-invariant discrete-time system is represented by the transfer function obtained by the ratio of the Z-transform of input to the Z-transform of output as follows

$$G_z(z) = \frac{D_z(z)}{F_z(z)} = \frac{num(z)}{den(z)} \quad (1)$$

where $D_z(z)$ and $F_z(z)$ are respectively Z-transforms of output and input, $num(z) = n_k z^k + n_{k-1} z^{k-1} + \dots + n_1 z + n_0$, $den(z) = d_l z^l + d_{l-1} z^{l-1} + \dots + d_1 z + d_0$ and z is the complex Z-transform variable [34]. For a signal having the discrete values $u_0, u_1, u_2, \dots, u_k$, the Z-transform is defined as follows

$$U(z) = Z\{u(k)\} = \sum_{k=-\infty}^{\infty} u_k z^{-k} \quad (2)$$

On the other hand, a linear time-invariant continuous-time system is represented by the transfer function in terms of the complex Laplace transform variable s as follows

$$G_s(s) = \frac{D_s(s)}{F_s(s)} = \frac{num(s)}{den(s)} \quad (3)$$

where $D_s(s)$ and $F_s(s)$ are respectively Laplace transforms of the output and input, $num(s) = n_k s^k + n_{k-1} s^{k-1} + \dots + n_1 s + n_0$ and $den(s) = d_l s^l + d_{l-1} s^{l-1} + \dots + d_1 s + d_0$. For a time varying signal $u(t)$, the Laplace transform is defined as follows

$$U(s) = L\{u(t)\} = \int_0^{\infty} u(t) e^{-st} dt \quad (4)$$

3 DISCRETE EQUIVALENCE PRINCIPLE

It is common to study a time integration algorithm by considering the single modal equation. Accordingly, the following continuous-time transfer function $G_s(s)$ of the first-order single modal equation of a parabolic problem is considered

$$G_s(s) = \frac{1}{s + \lambda} \quad (5)$$

where λ is the modal parameter. For the second-order structural systems, $G_s(s)$ is equal to

$$G_s(s) = \frac{1}{s^2 + 2\xi\Omega s + \Omega^2} \quad (6)$$

where Ω is the undamped natural frequency and ξ the damping ratio. Note that Ω and λ belong to the finite element discretization, and they are usually denoted by the superscript h in literature that is omitted in this article for brevity. Let $G_z(z)$ denote the discrete-time transfer function of a time integration method which is unknown to us. Suppose that we have a forcing term $f(t)$ that is applied to the semi-discrete equation and we want to integrate the semi-discrete equation via the time integration method. Let $F_z(z) = \{f(k)\}$ and $F_s(s) = \{f(t)\}$ denote the Z-transform and Laplace transform of the forcing term $f(t)$, respectively. Then, if the solution of the time integration method is equal to the exact solution of the semi-discrete equation at discrete time steps, the following equation should hold:

$$Z^{-1}\{G_z(z)F_z(z)\} = L^{-1}\{G_s(s)F_s(s)\}_{t=k\Delta t} \quad (7)$$

Equivalently,

$$G_z(z) = \frac{1}{F_z(z)} Z\{L^{-1}\{G_s(s)F_s(s)\}_{t=k\Delta t}\} \quad (8)$$

where $Z^{-1}\{\}$ and $L^{-1}\{\}$ are, respectively, the inverse Z-transform and inverse Laplace transform operators, Δt time step and k an integer denoting the time step number. Note that (8) guarantees that the solution of the time integration method matches with the exact solution at discrete time steps no matter what the time step is; however, the frequency response of this time integration method cannot match with that of the original semi-discrete equation. Therefore, time integration methods obtained by using (8) are called discrete equivalent methods. Now, (8) can be used to find the unknown discrete-time transfer function $G_z(z)$ of the time integration method, e.g., see [30] for details.

4 DESIGN OF TIME INTEGRATION METHODS BY USING DISCRETE EQUIVALENCE PRINCIPLE

Consider two systems having the following semi-discrete equations

$$M\ddot{d} + C\dot{d} + Kd = f \quad (9)$$

$$\hat{M}\ddot{\hat{d}} + \hat{C}\dot{\hat{d}} + \hat{K}\hat{d} = \hat{f} \quad (10)$$

where (9) represents the original system and (10) represents the system obtained by a model order reduction method. It is noteworthy that in general the solutions $d(t)$ and $\hat{d}(t)$ are different [35]. Suppose that even though (9) and (10) represent two different systems, certain outputs of these systems obtained by discrete equivalence principle (7) are equal to each other at discrete time steps. That is, at a discrete time step $t=k\Delta t$, we have

$$\hat{d}_k = E d_k \quad \text{and} \quad \hat{f}_k = E f_k \quad (11)$$

where E is the transformation matrix defined by

$$E = \begin{bmatrix} e_i^T \\ e_j^T \\ \vdots \\ e_k^T \end{bmatrix} \quad (12)$$

and e_i is the unit vector in the i th direction whose elements are zero except for the i th element which is 1 as follows

$$e_i = [0 \quad 0 \quad \dots \quad 0 \quad 1 \quad 0 \quad \dots \quad 0]^T \quad (13)$$

where superposed T denotes transpose. Thus, the outputs of systems represented by (9) and (10) that correspond to the unit vectors e_i in (12) are equal to each other at discrete time steps. Note that the transformation matrix is in general rectangular and by definition $EE^T = I$ due to $e_i e_j^T = \delta_{ij}$ is equal to the Kronecker delta function.

Consider the following semi-discrete equations of a parabolic problem

$$M\dot{d} + Kd = f \quad (14)$$

where M is the mass matrix, K stiffness matrix, f load vector, d displacement vector and \dot{d} time derivative of d . Note that M and K are symmetric, M positive definite and K positive semidefinite. The load vector f is the function of time denoted by $f=f(t)$ for $t \in [0, T]$. The purpose of the initial value problem defined by (14) is to find the solution $d=d(t)$ satisfying the initial condition $d(0)=d_0$. Next, we will apply “response invariant” time integration methods to the system represented by (14).

Suppose that we would like to have that the impulse response of the original system represented by (9) obtained by IRI method [6] is equal to the exact solution of (9) at discrete time steps. Consider the following single DOF modal equation of (9)

$$\ddot{d} + \lambda d = f \quad (15)$$

The discrete-time solution of the time integration method is equal to $f_d(k\Delta t) = Z^{-1}\{G_z(z)\}$, and the corresponding continuous-time impulse response of the semi-discrete equation is equal to $f_c(t) = L^{-1}\{G_s(s)\}$; then, $f_d(k\Delta t) = \Delta t f_c(t)|_{t=k\Delta t}$ [6]. On the other hand, since

$$G_z(z) = Z\{f_d(k\Delta t)\} = Z\{f_c(t)\}\Delta t = Z\{L^{-1}\{G_s(s)\}\}\Delta t \quad (16)$$

where $G_s(s)$ is given by (5); then, (16) yields

$$G_z(z) = \frac{D_z(z)}{F_z(z)} = Z\left\{L^{-1}\left\{\frac{1}{s + \lambda}\right\}\right\}\Delta t = \frac{z}{z - e^{-\lambda\Delta t}} \Delta t \quad (17)$$

where z is the time shift operator such that $z^n d_k = d_{k+n}$ where d_k is the output value at the k th time step, i.e., $t = k\Delta t$, then (12) yields that

$$d_{k+1} = e^{-\lambda\Delta t} d_k + \Delta t f_{k+1} \quad (18)$$

5 TOTAL ENERGY EQUIVALENCE METHOD

The main criteria in newly proposed model order reduction method is based on principal that “The total energy level of the model order reduced system should be equal to the total energy level of the original system.”. In this approach, the main method accuracy criteria comes from the comparison of total energy levels of both systems. In order to reach the total energy, the kinetic and potential energy of the original system can firstly be given as,

$$\text{Kinetic energy: } H_k = \frac{1}{2} \dot{d}_k^T M \dot{d}_k \quad (19)$$

$$\text{Potential energy: } P_k = \frac{1}{2} d_k^T K d_k \quad (20)$$

By using (19) and (20), total energy is obtained as

$$\text{Total energy: } T_k = H_k + P_k \quad (21)$$

To obtain the lowest deviation on the total energy error of both systems, system transformation formulation is developed and then system mass M and system stiffness K matrices by finite element methods are produced.

To calculate the total energy, forward difference integration method is applied to (21) by d_k and d_{k+1} .

By using $\dot{d}_k \cong \frac{d_{k+1} - d_k}{\Delta t}$ statement, kinetic energy of original model can be written,

$$H_k = \frac{1}{2\Delta t^2} (d_{k+1}^T - d_k^T) M (d_{k+1} - d_k) \quad (22)$$

and (21) equation can be orientated again by (20), original model total energy (22) yields,

$$T_k = H_k + P_k = \frac{1}{2} d_k^T K d_k + \frac{1}{2\Delta t^2} [d_{k+1}^T M d_{k+1} - d_{k+1}^T M d_k - d_k^T M d_{k+1} + d_k^T M d_k] \quad (23)$$

The matrix form of (23) is given by,

$$T_k = \frac{1}{2} \begin{bmatrix} d_k^T & d_{k+1}^T \end{bmatrix} \begin{bmatrix} K + \frac{M}{\Delta t^2} & -\frac{M}{\Delta t^2} \\ -\frac{M}{\Delta t^2} & \frac{M}{\Delta t^2} \end{bmatrix} \begin{Bmatrix} d_k \\ d_{k+1} \end{Bmatrix} \quad (24)$$

The total energy of the model order reduced system is similarly formed as,

$$\hat{T}_k = \frac{1}{2} \begin{bmatrix} \hat{d}_k^T & \hat{d}_{k+1}^T \end{bmatrix} \begin{bmatrix} \hat{K} + \frac{\hat{M}}{\Delta t^2} & -\frac{\hat{M}}{\Delta t^2} \\ -\frac{\hat{M}}{\Delta t^2} & \frac{\hat{M}}{\Delta t^2} \end{bmatrix} \begin{Bmatrix} \hat{d}_k \\ \hat{d}_{k+1} \end{Bmatrix} \quad (25)$$

If (25) is modified, below equation is obtained,

$$\hat{T}_k = \frac{1}{2} \begin{bmatrix} d_k^T & d_{k+1}^T \end{bmatrix} E^T \begin{bmatrix} \hat{K} + \frac{\hat{M}}{\Delta t^2} & -\frac{\hat{M}}{\Delta t^2} \\ -\frac{\hat{M}}{\Delta t^2} & \frac{\hat{M}}{\Delta t^2} \end{bmatrix} E \begin{Bmatrix} d_k \\ d_{k+1} \end{Bmatrix} \quad (26)$$

When the active DOFs of original and model order reduced systems is taken into consideration, because total energy equivalence $T_k \equiv \hat{T}_k$ is desired, the identical parameters of the matrices should be equal (energy saving algorithm). Thus,

$$E^T \begin{bmatrix} \hat{K} + \frac{\hat{M}}{\Delta t^2} & -\frac{\hat{M}}{\Delta t^2} \\ -\frac{\hat{M}}{\Delta t^2} & \frac{\hat{M}}{\Delta t^2} \end{bmatrix} E = \begin{bmatrix} K + \frac{M}{\Delta t^2} & -\frac{M}{\Delta t^2} \\ -\frac{M}{\Delta t^2} & \frac{M}{\Delta t^2} \end{bmatrix} \quad (27)$$

and, the first elements of the matrices are considered equal as below,

$$E^T \hat{K} E + E^T \frac{\hat{M}}{\Delta t^2} E = K + \frac{M}{\Delta t^2} \quad (28)$$

the second parameters should be equal.

$$E^T \frac{\hat{M}}{\Delta t^2} E = \frac{M}{\Delta t^2} \quad (29)$$

On the other hand, if (29) is premultiplied by the transformation matrix E , and then also postmultiplied by the transpose of transformation matrix E^T , and using the fact that $EE^T = I$, we obtain

$$\hat{M} = EME^T \quad (30)$$

Similarly from the equality of the first parameters of (28), and by using pre and post multiplying, we get

$$\hat{K} = EKE^T \quad (31)$$

Note that (30) and (31) determine respectively the mass and stiffness matrices for the reduced order system whose certain outputs are equal to those of the exact solution at discrete time steps for which the Total Energy Equivalence Method is used as the time integration method; namely, their impulse responses should be identical at discrete time steps for certain outputs defined by the transformation matrix E . Note that the second order systems could be cast in the state space form by defining the state-space matrices appropriately.

6 NUMERICAL EXAMPLE

The results of the example system will be presented in this section such as a cantilever beam. More examples and argument can be found in [35]. By considering the cantilever planar beam, the model order reduction method is applied to the beam given in Figure 1 by using the programs developed in Matlab environment.

Figure 1: The Euler-Bernoulli beam system on which model order reduction is applied.

In the planar beam element, each node has 1 axial, 1 vertical and 1 rotational DOF. The length of the beam is 0.5 m, cross-sectional area is $4 \times 10^{-4} \text{ m}^2$, beam height is $2 \times 10^{-2} \text{ m}$, area moment of the cross-section is $1.33 \times 10^{-8} \text{ m}^4$, density of the material of the beam is 7850 kg/m^3 and material elasticity modulus is 210 GPa (steel material). The loading is applied to

the beam tip downward having the magnitude of 100 N as shown in Figure 1. By considering the proportional Rayleigh damping $C = \beta K$, the reduced model order system is created and then the analyses are repeated for different Rayleigh damping ratios as $\beta=0, 0.00008, 0.001, 0.01$ and 0.1 .

Different element number combinations were studied as seen at Table 1. Through these studies, impulse and sinusoidal forces were separately loaded. The results of the beam having 5 elements are presented here. The impulse responses and forced responses for the input of $f(t)=100*\sin(2*time)+50*\sin(5*time)$ are presented in Figures 2 and 3.

Figure 2: The beam tip displacement (in meter) for the impulse response where $\beta=0.001$.

Figure 3: The beam tip displacement (in meter) for the sinusoidal input response where $\beta=0.001$.

Note that other simulation studies were also carried out whose results were not presented here for brevity. In sum, as the damping coefficient β reduces, the accuracy also reduces. Moreover, the accuracy of the response for the sinusoidal input is always superior to that of impulse response.

In order to compare the performance of the proposed model order reduction method, the CPU times of the original system and other systems obtained by using the existing model order reduction methods are listed in Table 1, where the damping coefficient β and number of elements are changing. In sum, creating the reduced order model is always beneficial by considerable time.

7 CONCLUSIONS

A model order reduction techniques –Total Energy Equivalence Method- is derived in time domain based on the principle that the exact solution of the semi-discrete equation of a system and the solution of the reduced order model match at discrete time steps. It is sufficient to pursue exact match at discrete time steps, i.e., discrete equivalence, since the solutions of semi-discrete equations are obtained only at the time steps. A numerical example is presented to show the advantages of the proposed method and to compare the performance of them with that of some popular methods. The proposed method is applied to a sample problem and the results are compared with exact solutions. It is shown that proposed methods have certain advantages. It is concluded that characteristics of the responses of discrete equivalent reduced order models are similar as well no matter what the magnitude of the damping is. In

order to improve the convergence, the DOFs neighboring the DOFs to which forces are applied and outputs are computed should be selected as active DOFs. It was determined that especially, in case of the sudden input force changes like impulse or step functions, performance of the model order reduction process based on discrete equivalent methods decreases. More examples and discussion about the presented approach can be found in [35]. In the future, this method would be applied to other kinds of problems and will be tested further.

Keywords: Dynamic contact, Tire-road, Green function, Traffic noise, Road texture, Convolution

Abstract. *Tire/road contact represents the major source of traffic noise with driving speed above 50 km/h. One of the most important problems is to take into account the contact conditions and to calculate the contact forces in an accurate way. As a general approach, the dynamic response of the tire is calculated by convolving the contact forces with the Green function of the tire. The disadvantage of this method is that the computation can be time consuming. In this paper, an alternative which is a modal decomposition model is used. The developed method allows quicker calculations than the traditional convolution. It consists, at the first stage, on an approximation of the pre-calculated Green function on a series of modal contributions with the Least Square Complex Exponential (LSCE) algorithm then, on the calculation of the dynamic response in the time domain as a series of SDoF systems response. For verification, the approach is tested by using a Single Degree of Freedom (SDoF) oscillator where the system moves through a sinusoidal road profile with a constant speed. Then, it is applied to the Ring on Elastic Foundation (REF) Model.*

1 Introduction

In many advanced structures, the contact impact problems present an important interest. In numerical modeling of the effect of contact on structures, two classic approaches can be used. The Lagrange multiplier method [1] and the penalty method [2] are most commonly used in dynamic contact problems.

The dynamic contact problems can also be treated by using the Green's functions. In this approach the dynamic response is calculated by convolving the Green's functions with the contact forces. The convolution technique for contact problems is used by many authors : M. McIntyre al. [3] have applied the approach to the string/bow contact to study large-amplitude oscillations of musical instruments. C. Wang and J. Kim. [4],[5] have used the same approach for a thin beam impacting against a stop, A. Nordborg [6] for the wheel/rail contact problem and many other authors have used this technique in the tyre/road contact [7, 8, 9, 10].

The convolution technique for contact problems presents the advantage of simple implementation and is relatively less time consuming than classical methods. However, the time calculation for the convolution can be improved. G. Beylkin has developed [11] a fast convolution with free space Helmholtz Green's function. The convolution combines the spatial and Fourier domains. In the space domain, the Green's function is approximated by a sum of decaying Gaussians with positive coefficients and in the Fourier domain by a multiplication by a band-limited kernel.

In this paper, we present a fast convolution in which the Green's function in the frequency domain is approximated by a sum of modal contributions. The modal parameters are identified by LSCE algorithm and used in the time domain to construct a fast and accurate algorithm for computing convolutions with Green's functions. Two examples illustrate the efficiency of the method : first a SDoF system moving on a sinusoidal profile and in the second a MDoF on a random profile.

2 Structural Green's function

2.1 Standard convolution

A linear discretized dynamic problem can be generally expressed by a second order differential equation in the time domain:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{q}(t) \quad (1)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass matrix, the damping matrix and the stiffness matrix, respectively. In the frequency domain, the problem can be written:

$$[-\omega^2\mathbf{M} + j\omega\mathbf{C} + \mathbf{K}] \mathbf{U}(\omega) = \mathbf{Q}(\omega) \quad (2)$$

The resolution of equation (1) first needs to search a general solution $\mathbf{u}_g(t)$ of the associated homogeneous equation and then to find a particular solution of the full equation. The computation of the Green's function $\mathbf{G}(\omega)$ is a systematic tool to get this particular solution. The traditional method when the time Green's function $\mathbf{g}(t)$ is known, is to

calculate the dynamic response of the system by convolving the contact forces with the Green's function:

$$\mathbf{u}(t) = \mathbf{u}_g(t) + \int_0^t \mathbf{g}(t - \tau) \mathbf{q}(\tau) d\tau \quad (3)$$

When the system is at rest until a certain time taken as origin $t = 0$, the solution of the homogeneous problem is null ($\mathbf{u}_g(t) = \mathbf{0}$), and the solution is reduced to the relation:

$$\mathbf{u}(t) = \int_0^t \mathbf{g}(t - \tau) \mathbf{q}(\tau) d\tau \quad (4)$$

Equation (4) can be discretized as follows:

$$\mathbf{u}_k = \sum_{m=0}^k \mathbf{g}_{k-m} \mathbf{q}_m \quad (5)$$

Where \mathbf{u}_k is the displacement at the time $k\Delta t$.

Let's note N_t the number of time steps used to calculate the displacement, and N_g the number of time steps for the influencing Green's function. The effect of the Green's function is neglected when the amplitudes of oscillation at time greater than $N_g\Delta t$ are hundred times smaller than the maximum of the Green's function $g(t)$.

Equation (5) is reduced to :

$$u_k = \sum_{m=0}^{\min(k, N_g)} g_{k-m} q_m \quad (6)$$

The number of arithmetic operations necessary to obtain the displacement until the time $N_t\Delta t$ is of the same order as $N_t N_g$.

2.2 Modal decomposition

The idea is to express the Green's function as a sum of modal contributions, and through numerical manipulations, the modal parameters can be identified. The Green's function $G(\omega)$ is supposed to be known, and $g(t)$ denotes its inverse Fourier transform. For the sake of simplicity, we restrict to one component for the displacement, in this case the Green's function $G(\omega)$ can be approximated as follows.

$$G(\omega) \simeq \sum_{k=1}^{k=N} \left[\frac{R_k}{j\omega - \lambda_k} + \frac{R_k^*}{j\omega - \lambda_k^*} \right] \quad (7)$$

One seeks to identify the modal parameters (residues A_k , damping ξ_k and frequencies ω_k). There exist several methods to deal with this kind of problems. The LSCE method

(Least Square Complex Exponential) remains the reference in the applications of experimental modal analysis. Equation (7) can be written in the equivalent form

$$G(\omega) \simeq \sum_{k=1}^{k=N} \frac{A_k}{-\omega^2 + 2j\xi_k\omega\omega_k + \omega_k^2} \quad (8)$$

The LSCE algorithm is used for the decomposition.

To check the accuracy of estimated modal data, the Green's function is regenerated. This method aims to find the best estimates of modal data that minimizes the error defined in equation (9)

$$E = \frac{\int_0^{\omega_{max}} |G(\omega) - \sum_{k=1}^{k=N} \frac{A_k}{-\omega^2 + 2j\xi_k\omega\omega_k + \omega_k^2}| d\omega}{\int_0^{\omega_{max}} |G(\omega)| d\omega} \quad (9)$$

3 Fast convolution

After finding the modal parameters A_k , ω_k and ξ_k , then truncating the decomposition to an order N , the Green's function in the time domain can be written in the form of a sum of the contribution of each mode:

$$g(t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k\omega_k t} \sin(\omega_k^d t) \quad (10)$$

with

$$\omega_k^d = \omega_k \sqrt{1 - \xi_k^2}$$

The displacement can be calculated by a convolution product

$$u(t) = \int_0^t g(\tau) q(t - \tau) d\tau = \int_0^t g(t - \tau) q(\tau) d\tau \quad (11)$$

Replacing $g(t)$ by its decomposition in equation (10) yields

$$u(t) = \int_0^t \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k\omega_k (t-\tau)} \sin(\omega_k^d (t - \tau)) q(\tau) d\tau \quad (12)$$

By separating the variables t and τ , then rearranging the terms, we can write the displacement in the form

$$u(t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k\omega_k t} [\sin(\omega_k^d t) \alpha^k(t) - \cos(\omega_k^d t) \beta^k(t)] \quad (13)$$

where $\alpha^k(t)$ and $\beta^k(t)$ are given as

$$\alpha^k(t) = \int_0^t e^{\xi_k \omega_k \tau} \cos(\omega_k^d \tau) q(\tau) d\tau \quad (14)$$

$$\beta^k(t) = \int_0^t e^{\xi_k \omega_k \tau} \sin(\omega_k^d \tau) q(\tau) d\tau \quad (15)$$

$$(16)$$

At the time $n\Delta t$ the discrete displacement is written

$$u(n\Delta t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k \omega_k n\Delta t} [\sin(\omega_k^d n\Delta t) \alpha^k(n\Delta t) - \cos(\omega_k^d n\Delta t) \beta^k(n\Delta t)] \quad (17)$$

The coefficients $\alpha^k(n\Delta t)$ and $\beta^k(n\Delta t)$ are calculated by the recurrence equations

$$\alpha^k((n+1)\Delta t) = \alpha^k(n\Delta t) + e^{\xi_k \omega_k n\Delta t} \cos(\omega_k^d n\Delta t) q(n\Delta t) \Delta t \quad (18)$$

$$\beta^k((n+1)\Delta t) = \beta^k(n\Delta t) + e^{\xi_k \omega_k n\Delta t} \sin(\omega_k^d n\Delta t) q(n\Delta t) \Delta t \quad (19)$$

The number of arithmetic operations necessary to obtain the displacement until the time $N_t \Delta t$ is of the same order than $N_t N_m$, where N_m is the number of modes used to represent the Green's function.

4 Contact models using Green's functions

4.1 General procedure

To illustrate the approach presented above, let us consider a simple dynamic contact problem. The purpose of this example is to test the fast convolution method and to compare it with the traditional convolution. So we consider a mechanical system represented by its Green's function. The system is moving with a constant speed on a surface without slipping.

The displacement $u(t)$ at time t , depends on the contact forces history $f_c(t)$ imposed by the texture of the surface. Two situations arise: either, there is a contact between the system and the surface and the displacement of the system equals the height of the surface $u_r(t)$, or there is no contact and in this case the contact force is null and the displacement of the system is strictly higher than that of the surface. Only vertical displacements are considered here.

The ideal conditions of unilateral contact are given by:

$$u(t) = u_r(t) ; f_c(t) > 0 \quad (20)$$

$$u(t) > u_r(t) ; f_c(t) = 0 \quad (21)$$

The procedure of the computation is described in the following.

1. First the displacement history $u^h(n\Delta t)$ is computed by assuming no contact $f_c(n\Delta t) = 0$.

$$u^h(n\Delta t) = \Delta t \sum_{k=0}^{n-1} f_c(k\Delta t) g((n-k)\Delta t) \quad (22)$$

2. The displacement history is compared with the profile altitude:

$$\Delta x(n\Delta t) = u_r(n\Delta t) - u^h(n\Delta t) \quad (23)$$

3. If the assumption of no contact ($\Delta x < 0$) is satisfied, the displacement is:

$$u(n\Delta t) = u^h(n\Delta t) \quad (24)$$

Then the procedure is repeated by assuming no contact for the next time step ($f_c((n+1)\Delta t) = 0$).

4. If $\Delta x \geq 0$, the contact force is computed from the cinematic conditions described below.
5. The procedure is repeated by assuming no contact condition for the next time step ($f_c((n+1)\Delta t) = 0$).

The same procedure is used for the modal decomposition model, but the displacement history $u^h(n\Delta t)$ is computed by

$$u^h(n\Delta t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k \omega_k n\Delta t} \left[\sin(\omega_k^d n\Delta t) \alpha^k((n-1)\Delta t) - \cos(\omega_k^d n\Delta t) \beta^k((n-1)\Delta t) \right] \quad (25)$$

4.1.1 Cinematic condition

The standard convolution can be written as following

$$\begin{aligned} u(t) &= \int_0^{t-\Delta t} g(t-\tau) q(\tau) d\tau + \int_{t-\Delta t}^t g(t-\tau) q(\tau) d\tau \\ &= \underbrace{\int_0^{t-\Delta t} g(t-\tau) q(\tau) d\tau}_{u_h(t)} + \int_0^{\Delta t} g(\tau) q(t-\tau) d\tau \\ &= u_h(t) + \int_0^{\Delta t} g(\tau) q(t-\tau) d\tau \end{aligned} \quad (26)$$

We derive the equation (26)

$$\begin{aligned}
 v(t) = u'(t) &= \int_0^{t-\Delta t} g'(t-\tau)q(\tau)d\tau + \int_{t-\Delta t}^t g'(t-\tau)q(\tau)d\tau \\
 &= \underbrace{\int_0^{t-\Delta t} g'(t-\tau)q(\tau)d\tau}_{v_h(t)} + \int_0^{\Delta t} g'(\tau)q(t-\tau)d\tau \\
 &= v_h(t) + \int_0^{\Delta t} g'(\tau)q(t-\tau)d\tau
 \end{aligned} \tag{27}$$

let's note $\mathbf{Y} = [u(t) \ v(t)]^T$ and $\mathbf{Y}_h = [u_h(t) \ v_h(t)]^T$, we can write

$$\mathbf{Y} = \mathbf{Y}_h + \Psi(q) \tag{28}$$

where Ψ is an integral operator which reflects the influence of efforts at the present moment.

Where there is contact, the displacement is imposed by the rigid profile. We suppose that the contact point follows the profile. We can write the following contact conditions

$$u(t) = u_r(t) \tag{29}$$

$$v(t) = \frac{du_r(t)}{dt} \tag{30}$$

$$\tag{31}$$

In the vectorial form

$$\mathbf{Y} = \mathbf{Y}_r = [u_r(t) \ \frac{du_r(t)}{dt}]^T \tag{32}$$

Using the modal decomposition convolution we have

$$u(t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k \omega_k t} [\sin(\omega_k^d t) \alpha^k(t) - \cos(\omega_k^d t) \beta^k(t)] \tag{33}$$

and

$$\begin{aligned}
 v(t) = & - \sum_{k=1}^{k=N} \frac{A_k \xi_k \omega_k}{\omega_k^d} e^{-\xi_k \omega_k t} [\sin(\omega_k^d t) \alpha^k(t) - \cos(\omega_k^d t) \beta^k(t)] \\
 & + \sum_{k=1}^{k=N} A_k e^{-\xi_k \omega_k t} [\cos(\omega_k^d t) \alpha^k(t) + \sin(\omega_k^d t) \beta^k(t)]
 \end{aligned} \tag{34}$$

Equations (33) and (34), can be written in the matrix form

$$\mathbf{Y} = \sum_{k=1}^{k=N} \mathbf{B}_k \mathbf{x}_k \tag{35}$$

where

$$\mathbf{x}_k = [\alpha^k(t) \ \beta^k(t)]^T \quad (36)$$

and

$$\mathbf{B}_k = A_k e^{-\xi_k \omega_k t} \begin{bmatrix} \frac{\sin(\omega_k^d t)}{\omega_k^d} & -\frac{\cos(\omega_k^d t)}{\omega_k^d} \\ \cos(\omega_k^d t) - \frac{\xi_k \omega_k}{\omega_k^d} \sin(\omega_k^d t) & \sin(\omega_k^d t) + \frac{\xi_k \omega_k}{\omega_k^d} \cos(\omega_k^d t) \end{bmatrix} \quad (37)$$

The contact conditions are

$$\mathbf{Y}_r = \mathbf{Y}^h + \Psi(\mathbf{q}) \quad (38)$$

The purpose is to find the contact force that verify simultaneously the conditions (32). Contact forces are related to displacements and velocities by the operator Ψ .

$$\begin{aligned} \Delta \mathbf{Y} &= \mathbf{Y}_r - \mathbf{Y}^h \\ &= \begin{bmatrix} \int_0^{\Delta t} g(t-\tau) q(\tau) d\tau \\ \int_0^{\Delta t} g'(t-\tau) q(\tau) d\tau \end{bmatrix} \end{aligned} \quad (39)$$

Integrals can be computed using two Gauss points. The values of the contact force at the two Gauss points are then calculated by inverting the operator Ψ

$$\mathbf{q} = \begin{bmatrix} q_1 \\ q_2 \end{bmatrix} \quad (40)$$

$$= \Psi^{-1}(t_1, t_2) \Delta \mathbf{Y} \quad (41)$$

The operator Ψ is given by

$$\Psi = \begin{bmatrix} g(t-t_1) & g(t-t_2) \\ g'(t-t_1) & g'(t-t_2) \end{bmatrix} \Delta t \quad (42)$$

where,

$$g(t) = \sum_{k=1}^{k=N} \frac{A_k}{\omega_k^d} e^{-\xi_k \omega_k t} \sin(\omega_k^d t) \quad (43)$$

On a time interval $[t \ t + \Delta t]$, the contact force is the medium of its two values at the two Gauss points t_1 and t_2 .

where

$$t_1 = t + \left(1 - \frac{1}{\sqrt{3}}\right) \frac{\Delta t}{2} \quad (44)$$

$$t_2 = t + \left(1 + \frac{1}{\sqrt{3}}\right) \frac{\Delta t}{2} \quad (45)$$

Knowing the values of the contact force at the Gauss points t_1 and t_2 we can compute the parameters $\alpha_k(t + \Delta t)$ and $\beta_k(t + \Delta t)$ by the recursion equations

$$\alpha^k(t + \Delta t) = \alpha_h^k(t) + \frac{f^c(t_1)q_1 + f^c(t_2)q_2}{2}\Delta t \quad (46)$$

$$\beta^k(t + \Delta t) = \beta_h^k(t) + \frac{f^s(t_1)q_1 + f^s(t_2)q_2}{2}\Delta t \quad (47)$$

where

$$f^s(t) = e^{\xi_k \omega_k t} \sin(\omega_k^d t) \quad (48)$$

$$f^c(t) = e^{\xi_k \omega_k t} \cos(\omega_k^d t) \quad (49)$$

5 Examples

5.1 Case of a single DoF system

The simplest dynamic system considered in vibration problems is the Single Degree of Freedom (SDoF) oscillator as shown in Figure (1). The analysis of this system is used to compare the standard convolution with the developed approach.

In this example, the system moves through a profile $u_r(x)$ with a constant speed $V_0 = 0.1 \text{ m.s}^{-1}$. It is supposed that the displacement is done without slipping as shown in figure (1).

Figure 1: SDof mass-spring system on a sinusoidal surface

Consider a sinusoidal profile

$$u_r = A_0 \sin(\omega_r x) = A_0 \sin\left(\frac{2\pi}{\lambda_r} V_0 t\right) \quad (50)$$

where $\lambda_r = 25 \text{ mm}$ is the wavelength of the profile and $A_0 = 5 \text{ mm}$ its amplitude.

The system verifies the equations:

$$M\ddot{u} + C\dot{u} + Ku = -Mg + F_c \quad (51)$$

$$u(t) \geq u_r(t) \quad (52)$$

$$F_c \geq 0 \quad (53)$$

with the initial conditions:

$$u_0 = u(0) = u_r(0) \quad (54)$$

$$v_0 = \left. \frac{du(t)}{dt} \right|_{t=0} = 0 \quad (55)$$

If the mass is above the surface, there is no contact. The displacement and contact forces are given by

$$u(t) = e^{-\xi\omega_0(t-t_c)} \left[u_c \cos(\omega_d(t-t_c)) + \frac{v_c + \xi\omega_0 u_c}{\omega_d} \sin(\omega_d(t-t_c)) \right] \quad (56)$$

$$F_c(t) = 0 \quad (57)$$

where u_c and v_c are respectively the displacement and velocity at the last contact moment t_c .

If the mass is below the surface, there is contact and the contact force is computed from the cinematic conditions described previously.

The parameters used in the model for the simulations are given in Table (1).

$M[\text{Kg}]$	$K[\text{N/m}]$	ξ
1	$4 \cdot 10^5$	0.02

Table 1: SDoF parameters used in the simulations

Figures (2) and (3) show respectively the displacements $u(t)$ and the contact forces $F_c(t)$ calculated by the standard convolution method and the modal decomposition method. Both methods give the same result. In the part where there is contact, we notice that the displacement and contact force curves are fitting the shape of the surface. When this contact force is null, the system enters on a free vibration regime.

Using standard convolution is costly in terms of computing time, especially with a small time step. Indeed, from equations (5) and (17) we can see that in the case of a classical convolution, the number of calculation operations is proportional to the number of time steps N and to the size of the Green's functions N_g while in the modal decomposition it is proportional to N and to the approximation order. Table (2) shows a comparison of computing times between both methods.

5.2 Ring on Elastic Foundation Model

Modelling complex tire structures in details is a hard task. In the literature the ring on elastic foundation model was frequently used. In this model, the main dynamical

properties of the tire are taken into account. The tread is modelled by a circular Euler-Bernoulli beam, the elastic properties of the sidewalls and the rim are modelled by distributed springs as shown in Figure (4).

Figure 4: Ring on Elastic Foundation Model

The Green functions of the system is given by [12]:

$$\mathbf{G}(\omega) = \begin{bmatrix} G_{\theta\theta} & G_{\theta z} \\ G_{z\theta} & G_{zz} \end{bmatrix} = \sum_{n=-\infty}^{+\infty} [-\omega^2 \mathbf{M} + j\omega \mathbf{C} + \mathbf{L}_n]^{-1} e^{jn\theta} \quad (58)$$

where \mathbf{M} the mass matrix, \mathbf{C} the gyroscopic matrix and \mathbf{L}_n the matrix defined by equation (60):

$$\mathbf{M} = \rho S \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} ; \quad \mathbf{C} = 2\rho S \Omega \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \quad (59)$$

$$\mathbf{L}_n = \begin{pmatrix} \left(\left(\frac{EI}{R^4} + \frac{K}{R^2} + \frac{pb}{R} + \rho S \Omega^2 \right) n^2 + \frac{pb}{R} + k_\theta \right) & -j \left[\frac{EI}{R^4} n^3 + \left(\frac{K}{R^2} + \frac{2pb}{R} + 2\rho S \Omega^2 \right) n \right] \\ j \left[\frac{EI}{R^4} n^3 + \left(\frac{K}{R^2} + \frac{2pb}{R} + 2\rho S \Omega^2 \right) n \right] & \frac{EI}{R^4} n^4 + \left(\frac{pb}{R} + \rho S \Omega^2 \right) n^2 + \frac{K}{R^2} + \frac{pb}{R} + k_z \end{pmatrix} \quad (60)$$

Only the normal component G_{zz} of the Green function is computed for the contact problem. The parameters used for the simulation are given in Table (3).

We assume that the contact line contains three points $A(\theta = -\pi/100)$, $B(\theta = 0)$ and $C(\theta = \pi/100)$. The matrix of Green functions is calculated at these three points. Figure (5) shows the Green functions in the frequency rang $[0 \text{ } 1000 \text{ Hz}]$. The figures (6) and (7) show the displacements and the contact forces at the three contact points.

6 Conclusion

A unilateral contact dynamic model has been presented in this contribution. The model is based on a fast convolution using a modal decomposition of the Green functions. First, the Green function is approximated by a sum of a SDoF Green functions using the LSCE algorithm, then the identified modal parameters are used to construct a fast convolution. By exploiting the cinematic condition, the fast convolution can be inverted to calculate the contact forces when the contact occurs. Two examples are presented to prove the efficiency of the model.

Keywords: Wave Propagation, Dispersion Analysis, B-spline based finite element method.

Abstract. *The spatial discretization of elastic continuum by finite element method (FEM) introduces dispersion errors to numerical solutions of wave propagation tasks. For higher order Lagrangian as well as Hermitian elements there are optical modes in their frequency spectra leading to spurious oscillations of shock induced responses in a vicinity of propagating wavefronts. Furthermore, the behavior of classical higher order elements accounts for discontinuities in their spectra as well as for false representation of maximum frequency, the error of which increases with element order. For brevity this property is called the divergent behavior in the text. The recent innovations in finite element analysis rely on spline-based shape functions, taking inspiration in CAD (Computer Aided Design) approaches where the B-splines and mainly NURBS (non-uniform rational B-spline) representations are regularly employed. B-spline as well as NURBS curves are piecewise polynomial curves that are differentiable up to a prescribed order. The B-splines functions, employed as finite element shape functions, are examined in this paper, using the 1D stress wave modeling as a testing vehicle. It is shown that the employed approach leads to substantial minimization of dispersion errors; furthermore the errors decrease with increasing order of B-spline elements. It is believed that the B-spline based FE technology represents a promising tool allowing to increase reliability of numerical solutions of wave propagation problems.*

1 INTRODUCTION

The numerical solution of fast transient elastodynamics problems by the classical Lagrangian as well as Hermitian type of the finite element method (FEM) [1] is influenced by dispersion errors caused by both spatial and temporal discretizations [2]. A monochromatic harmonic stress wave propagates in unbounded elastic continuum regardless of its frequency and correspondingly a wave packet propagates without distortion. When these propagating phenomena are modeled by FEM the speed of a single harmonic wave depends on its frequency and thus a wave packet is distorted. The parasitic effects do not exist in 'ideal' unbounded continuum. The dispersive properties of one-dimensional Lagrangian and Hermitian elements were studied in Ref. [3]. Furthermore, the finite element (FE) mesh behaves as a frequency filter - higher frequencies are transferred with a strong attenuation.

The theoretical basis of the dispersion analysis of FEM for the solution of the hyperbolic partial differential equation has been laid in [4], where the Gibb's effect with the connection of FEM was observed. The oscillations near the wavefront or the stress jump change do not vanish for the fine-grained mesh. Fourier method as the dispersion analysis tool of the numerical solution of the hyperbolic partial differential equation is described in [5]. Very simple and efficient computational strategy of the complex wavenumber Fourier analysis of FEM is presented in Ref. [6].

In seismology the spectral finite elements [7] appeared recently. Spectral finite elements are of h-type finite elements, where nodes have special positions along the elements corresponding to the numerical quadrature schemes. But the displacements along element are approximated by the Lagrangian interpolation polynomials. The spectral finite elements improve dispersion errors for lower dispersion branches but not for upper ones.

A modern approach in the finite element analysis is the isogeometric analysis [8], where shape functions are based on varied types of splines. For example, Bézier representation, B-spline (basis spline), NURBS (non-uniform rational B-spline), PB-spline, T-spline and others are used for spatial discretization. This approach has an advantage that the geometry and approximation of the field of unknown quantities is prescribed by the same technique. Another benefit is that the approximation is smooth.

Dispersion of B-spline based finite elements was established for the same recurrent (uniform) B-spline basis functions [5] approximating one dimensional infinite domain. It was shown, that the optical modes did not exist and next, dispersion errors were reported to decrease with increasing order of B-spline shape functions [9]. This is a very good result for the explicit dynamics, where critical time step is bounded by the highest eigenfrequency of the whole system [10].

Generally, the B-spline or NURBS basis functions for bounded solids are not uniform. For this reason, the non-homogeneity of basis functions near the boundary of the domain produces the dispersion and attenuation behavior. These behavior can be controlled by parameterization of B-spline entity, by order of piecewise polynomials, etc. In this paper, the dispersion of B-spline based finite element will be determined for a one-dimensional elastic wave propagation problem. Numerical parameters of B-spline representation will be tested to show their dispersion and attenuation.

2 PROPAGATION OF ELASTIC WAVES IN ONE-DIMENSIONAL CASE

In one-dimensional case the classical equation governing linear elastic wave propagation [11] is given by

$$c_0^2 \frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial t^2} = 0, \quad \text{where } x \in (-\infty, \infty), t \in [0, \infty), \quad (1)$$

where c_0 denotes the wave propagation speed, $u(x, t)$ is the displacement field, x is the position and t is the time. The unbounded one-dimensional continuum is assumed, therefore boundary conditions are not prescribed. The 1D continuum can be realized as a 'thin' elastic bar, the material of which is characterized by Young's modulus E and mass density ρ . For a 'thin' elastic bar, the wave speed is given by $c_0 = \sqrt{E/\rho}$. In case of constant E and ρ , the wave speed is as well constant. Moreover, the value of wave speed is independent of the wavenumber or frequency of wave. This continuum is called non-dispersive [11].

3 B-SPLINE BASED FINITE ELEMENT METHOD

Firstly, the B-spline basis functions will be mentioned, see details in Ref. [12]. For a given knot vector Ξ , the B-spline basis functions are defined recursively starting with piecewise constants ($p = 0$)

$$N_{i,0}(\xi) = \begin{cases} 1 & \text{if } \xi_i \leq \xi \leq \xi_{i+1}, \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

The basis functions $N_{i,0}(\xi)$ are step functions, equal to zero everywhere except on the half-open interval $\xi = [\xi_i, \xi_{i+1})$, where ξ is parameter usually chosen so, that $\xi = [0, 1]$.

Figure 1: Example of cubic B-spline basis functions for ten control points $n = 10$ and uniform knot vector Ξ . Red lines correspond to non-uniform basis functions and blue lines correspond to uniform (homogeneous) basis functions. The number of non-uniform basis functions depends on the polynomial order.

For $p = 1, 2, 3, \dots$, they are defined by

$$N_{i,p}(\xi) = \frac{\xi - \xi_i}{\xi_{i+p} - \xi_i} N_{i,p-1}(\xi) + \frac{\xi_{i+p+1} - \xi}{\xi_{i+p+1} - \xi_{i+1}} N_{i+1,p-1}(\xi). \quad (3)$$

This is referred to as the Cox-de Boor recursion formula [12]. A knot vector in one dimensional case is a non-decreasing set of coordinates in the parameter space, written $\Xi = \{\xi_1, \xi_2, \dots, \xi_m\}$,

where $\xi_i \in R$ is the i -th knot, i is the knot index, $i = 1, 2, \dots, m$, where $m = n + p + 1$, p is the polynomial order, and n is the number of basis functions used to construct a B-spline curve. Equation (3) can yield the quotient $0/0$, for this case the quotient is prescribed zero. The main properties of $N_{i,p}$, defined by (2) and (3), are introduced in Ref. [12]. Example of cubic B-spline basis functions for ten control points $n = 10$ and uniform knot vector is displayed in Fig. 1.

Figure 2: Example of cubic B-spline curve for ten control points and uniform knot vector. The corresponding control polygon is depicted.

In CAD technology [13] a B-spline curve is given by linear combination of B-spline basis functions $N_{i,p}$ [12]

$$\mathbf{C}(\xi) = \sum_{i=1}^n N_{i,p}(\xi) \mathbf{B}_i, \quad (4)$$

where $\mathbf{B}_i, i = 1, 2, \dots, n$ are corresponding control points. Piecewise linear interpolation of control points gives the so-called control polygon. Example of cubic B-spline curve with its control polygon is shown in Fig. 2.

The open B-spline curve interpolating end points is used, where the knot vector is prescribed as

$$\Xi = \{a, \dots, a, \xi_{p+2}, \dots, \xi_n, b, \dots, b\}, \quad (5)$$

where values are usually set as $a = 0$ and $b = 1$. The multiplicity of the first and last knot value is $p + 1$. If the values ξ_{p+1} up to ξ_{n+1} are chosen uniformly, the knot vector Ξ is called uniform knot vector, otherwise non-uniform, for more details see Ref. [12]. The B-spline curve for the knot vector given by (5) is passed through the end points of the control polygon.

Analogously, the spatial coordinate for a one-dimensional continuum can be approximated by linear combination of B-spline basis functions $N_{i,p}$

$$x(\xi) = \sum_{i=1}^n N_{i,p}(\xi) x_i^B, \quad (6)$$

where $x_i^B, i = 1, 2, \dots, n$ are positions of control points in the x-direction. Furthermore, the approximation of the displacement field u^h by the B-spline approach is given by

$$u^h(\xi) = \sum_{i=1}^n N_{i,p}(\xi) u_i^B, \quad (7)$$

where u_i^B is the component of the vector of control variables – displacements corresponding to the control points.

A scheme of a admissible dependence of a one dimensional displacement field based on B-spline representation is presented in Fig. 3. Generally, the displacement field discretized by B-spline technology in one-dimensional case can be controlled by following parameters:

- length of element patch h (h -refinement),
- polynomial order p (p -refinement),
- number of control points n (k -refinement),
- positions of control points x_i^B , $i = 1, 2, \dots, n$, (choice of parameterization),
- components of the knot vector Ξ and their multiplicities,
- continuity between patches C^m , $m \leq p - 1$ order of continuity.

Figure 3: Scheme for permissible spatial discretization of a one-dimensional domain by B-spline based FE. h_i denotes a length of B-spline segment, u_i^B are control variables, n_i is number of control points, p_i denotes polynomial order, Ξ_i denotes a knot vector for i -th B-spline segment. C_{ij}^m marks order of continuity between i -th and j -th B-spline segment. Spatial coordinate $x(\xi)$ and corresponding displacement $u(\xi)$ are parametric functions of parameter ξ .

In this paper, C^0 continuity between B-spline segments with the identical length h is considered. The number of control points n , their positions and polynomial order p are the same. The knot value appears only once in the knot vector, but the first and last knot values appear $p + 1$ times. Of course, the continuity of the displacement field inside the B-spline segment is C^{p-1} .

In the following text, the continuous Galerkin's approximation method [1] for the solution of partial differential equations is employed. Spatial discretization of elastodynamics problems by finite elements leads to the second order ordinary differential system in the form [1]

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{R}. \quad (8)$$

Here, \mathbf{M} is the mass matrix, \mathbf{K} the stiffness matrix, \mathbf{R} is the time-dependent load vector, \mathbf{u} and $\ddot{\mathbf{u}}$ contain nodal displacements and accelerations. Neglecting the loading we have $\mathbf{R} = \mathbf{0}$. A lot of discrete time direct integration methods for the system (8) were developed [1]. However, the time is considered continuous in this work.

The element mass and stiffness matrices are given by

$$\mathbf{M}^e = \int_{h^e} \rho \mathbf{H}^T \mathbf{H} dx \quad (9)$$

and

$$\mathbf{K}^e = \int_{h^e} E \mathbf{B}^T \mathbf{B} dx \quad (10)$$

where h^e denotes the finite element length or length of B-spline segment, \mathbf{B} is the strain-displacement matrix, \mathbf{H} stores the displacement interpolation (shape) functions h_i [1]. For case of B-spline based FEM, shape functions are denoted $N_{i,p}$. Integrations (9) and (10) are carried over the element domain. If the theory of linear elastodynamics is considered, then mass matrix \mathbf{M}^e (9) and stiffness matrix \mathbf{K}^e (10) are constant. Global matrices are assembled in the usual fashion. Mass matrix defined by (9) is called consistent mass matrix and this mass matrix is employed in the following text. The stiffness matrix \mathbf{K} and mass matrix \mathbf{M} is computed numerically by the Gauss-Legendre quadrature formula [1].

4 DISPERSION ANALYSIS

The complex wavenumber dispersion analysis was performed for one-dimensional finite elements in Ref. [6]. In Fourier analysis [5], the displacement u_i^h corresponding to given spatial discretization is prescribed in the form of wave solution

$$u_i^h = A_i e^{i(\omega t - \psi^h x_i)}, \quad (11)$$

where A_i is displacement amplitude, ω is angular velocity, imaginary unit $i = \sqrt{-1}$ and x_i is the position. The discrete (numerical) wavenumber k^h equals to the real part of ψ^h , $k^h = \text{Re } \psi^h$. Imaginary part $b^h = \text{Im } \psi^h$ has a physical meaning of the attenuation intensity.

In Fourier analysis, the assumed solution of (11) is inserted to the equation (1) and the dispersion relation $\omega = f(k^h)$ is obtained. The dispersion errors can be measured by non-dimensional numerical phase speed c^h/c_0 , where numerical phase speed is defined by the relationship $c^h = \omega/k^h$. Mostly, the dispersion errors are depicted as a function of the non-dimensional numerical wavenumber $k^h h$, where h is characteristic length of finite element domain or B-spline segment.

5 RESULTS OF DISPERSION ANALYSIS FOR B-SPLINE BASED FEM

In this section, the dispersion diagrams for B-spline based FEM are shown for different number of control points with linear or non-linear parameterization and for different polynomial order, respectively. These graphs are compared with results for classical Lagrangian finite elements.

5.1 Uniform B-spline FEM versus classical finite element

Dispersion of one-dimensional Lagrangian FE was been studied in [3], [6]. The normalized dispersion errors in phase speed are depicted in Fig. 4 (on the left). These errors are divergent with the polynomial order of approximation of a displacement field. In Fig. 4 (on the left), h denotes the length of Lagrangian finite element. Nevertheless, the distances between uniformly-spaced nodes are h/p . The wavenumbers are normalized, being divided by appropriate polynomial order p . Thus, the non-dimensional numerical wavenumbers are in the range $k^h h/p = [0, \pi]$. The horizontal jumps in the dispersion graph on Fig. 4 (on the left) correspond to the attenuating solution [14]. For higher order Lagrangian finite elements, the optical modes are

occurred [2]. These vibration modes produce the spurious oscillations in numerical solutions of transient elastodynamics problems.

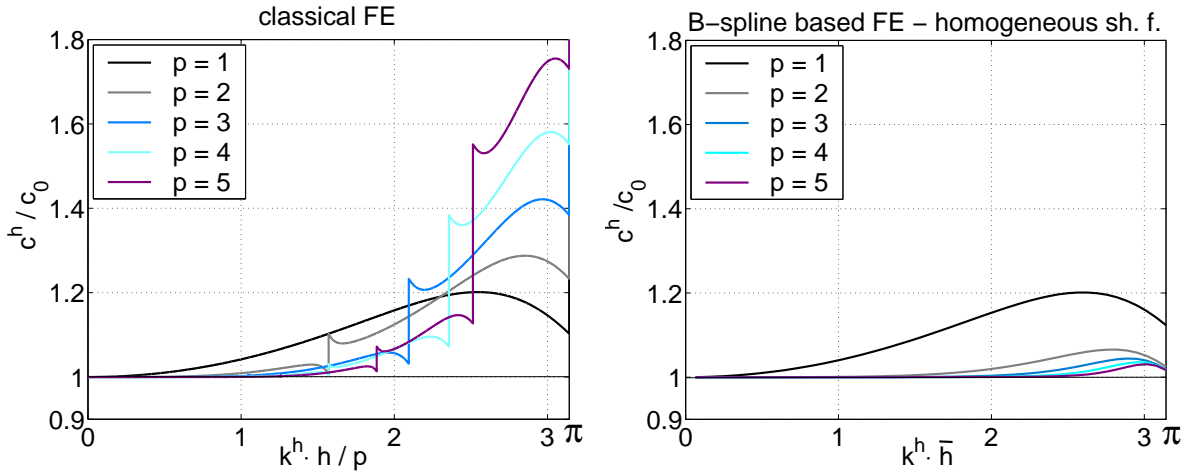

Figure 4: Dispersion errors for Lagrangian FE (on the left) [3], [6] and B-spline based FE (on the right) [9] for different polynomial order p . h denotes the finite element length, \bar{h} is the distance of uniformly-spaced control points.

In Ref. [8], the errors of eigenfrequency of an elastic fixed-fixed bar computed by classical FEM and B-spline based FEM are compared. The dependence of eigenfrequency ω^h/ω on the corresponding counter has the same character as the dependence c^h/c_0 on the corresponding non-dimensional wavenumber $k^h h$. It is a consequence of the duality principle accomplished in Ref. [9].

The dispersion analysis of B-spline based FEM has been investigated in Ref. [5], where uniform basis shape functions are employed. This case is in agreement with a model of an infinite elastic 'thin' bar. The dispersion graph for uniform B-spline based FEM is presented in Fig. 4 (on the right), where the high mode behavior is convergent with the polynomial order p of B-spline approach. The dispersion errors are decreasing with increasing polynomial order. The permissible values of numerical wavenumber $k^h \bar{h}$ are in the range $[0, \pi]$. In Fig. 4 (on the right), \bar{h} denotes distance of uniformly-spaced control points. The optical modes and attenuating solution in the right-open range $k^h \bar{h} = [0, \pi)$ do not exist, but for $k^h \bar{h} = \pi$ the attenuating solution arises. The spatial resolution limit corresponds to the numerical wavenumber is $k^h \bar{h} = \pi$, where positions of control points are in the 'saw tooth' oscillation form. The uniform B-spline based finite element for discretization of a one-dimensional domain produces better dispersion dependence without optical modes and band gaps [14] with respect to the Lagrangian classical FEM [9].

REMARK: Another solution of wave equation (1) discretized by uniform B-spline based FEM exists [9]. This solution is called evanescent solution [14]. This solution of discretized system is characteristic by non-zero imaginary parts of ψ^h and for the numerical wavenumber is valid $k^h \bar{h} \neq i\pi, i = 0, 1, 2, \dots, p$, simultaneously. The number of the evanescent solutions is $p - 1$, see Ref. [9]. The evanescent solutions do not have practically meaning in the numerical solution of wave equation due to their attenuating effect.

5.2 Non-linear parameterization - uniformly-spaced control points

This section deals with the dispersion analysis for B-spline segments with polynomial order p , different number of uniformly-spaced control points. And also with the uniform knot vector and for case, where individual B-spline segments are connected only with C^0 continuity with their neighbouring B-spline segments. In Fig. 5 (on the left), dispersion errors c^h/c_0 of the quadratic ($p = 2$) B-spline based FE are drawn. In Fig. 5 (on the right) there are presented the dispersion errors for cubic ($p = 3$) B-spline based FE with different number of control points, where h denotes the patch length of B-spline (see Fig. 3). For increasing number of control points, the dispersion errors are convergent to value of wave speed c_0 – i.e. to the exact solution for continuum.

The vertical jumps pertain to the decay solution with non-zero attenuation. These parts of the dispersion dependencies depict quantitatively the passing and band gaps in the frequency range [14]. Thereby, the band gaps exist also for the B-spline based element method with C^0 continuity between B-spline segments. With increasing number of control points the band gap range is decreasing and the maximal band gap range occurs in higher dispersion branches. It can be shown, that dispersion errors are influenced by shape (basis) functions $N_{i,p}$ defined in the vicinity of patch domain boundary, see Fig. 1. The corresponding shape functions are not homogeneous due the interpolation of end points [12].

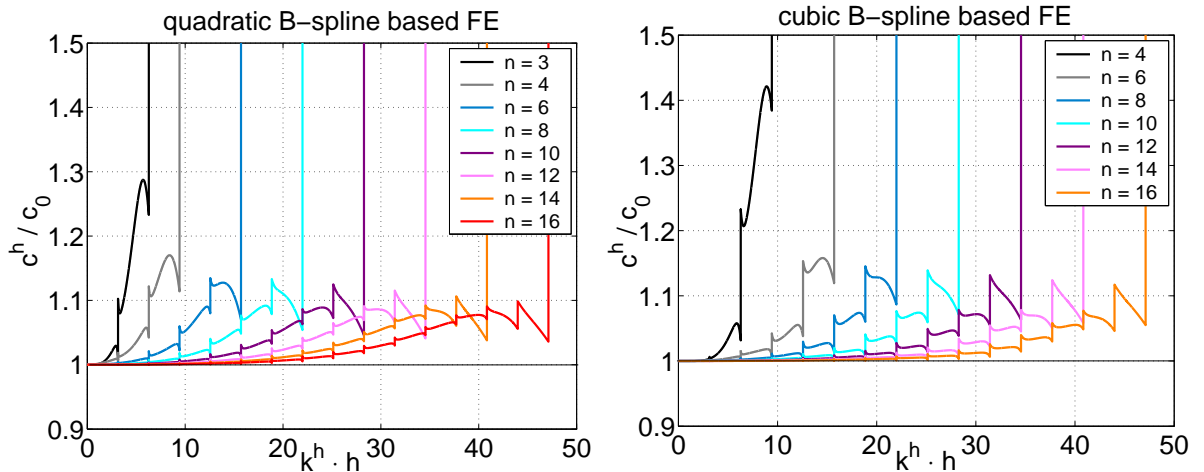

Figure 5: Dispersion errors for quadratic (on the left) and cubic (on the right) B-spline based FE with different number of control points. The red line corresponds to homogeneous shape functions [9].

The dispersion dependencies in Fig. 5 can be redrawn to the normalized non-dimensional wavenumber $k^h h / (n - 1)$. Which means that the abscissa variables are divided by the appropriate number of distances of control points, i.e. $n - 1$. The distance between uniformly-spaced control points is $\bar{h} = h / (n - 1)$. It is the averaged distance of control points. The normalized numerical wavenumbers are in the range $k^h h / (n - 1) \in [0, \pi]$. The normalized dispersion errors are depicted in Fig. 6, where corresponding dispersion errors for uniform B-spline shape functions (Fig. 4 (on the right)) are added. The normalized dispersion errors for quadratic B-spline are shown in Fig. 6 (on the left) and for cubic B-spline are represented in Fig. 6 (on the right). For clarity the number of control points in Fig. 6 is different from that appearing in Fig. 5. It is of interest that the mentioned normalized dispersion errors are approaching to those of the uniformly (homogeneous) B-spline shape functions (Fig. 4).

For minimization of dispersion errors, the increasing number of control points (*k-refinement*) is better than the partition of the B-spline segments (*h-refinement*). The higher order of continuity inside the B-spline produces more reliable dispersion behavior.

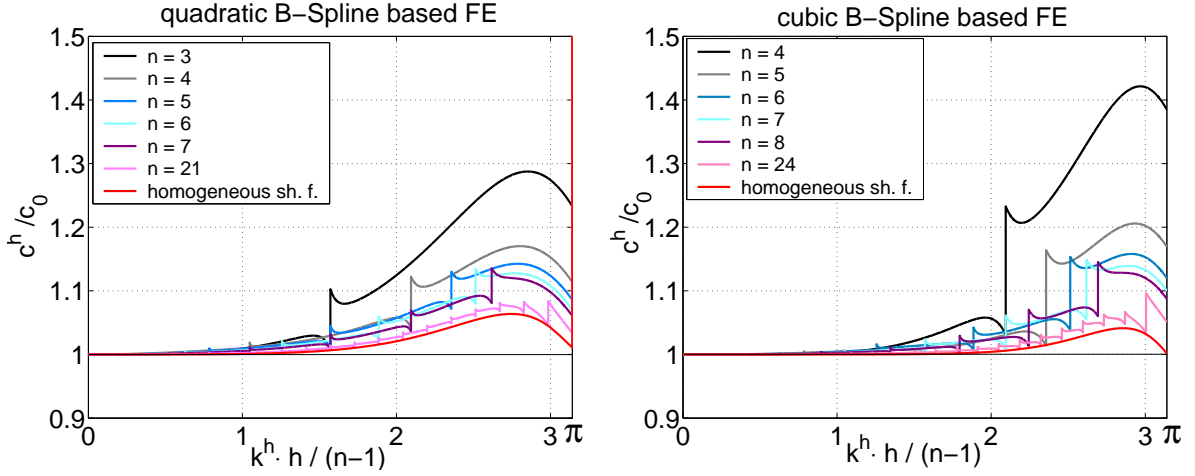

Figure 6: Normalized dispersion errors for quadratic (on the left) and cubic (on the right) B-spline based FE with different number of control points. The red line corresponds to homogeneous shape functions [9].

REMARK: For situations, where number of control points is $n = p + 1$ and B-spline segments are only connected with C^0 continuity, the dispersion dependencies are identical with those of Lagrangian finite elements (Fig. 4 (on the left)).

5.3 Linear parameterization - Graviile abscissa

The simple modification of the previously shown B-spline non-linear parameterization is based on a choice of special positions of control points. Good interpolation properties of B-splines can also be obtained by so called Graviile abscissa. In such a case the abscissa is associated with the knot vector Ξ . See [15] and [16] for details. Thus, the control points are given by the formula

$$x_i^*(\xi) = \frac{\xi_{i+1} + \dots + \xi_{i+p}}{p}, \quad i = 1, 2, \dots, n. \quad (12)$$

The set of control points positions obtained this way (12) is usually called the set of averaged collocation points or Greville collocation points. If the knot vector is chosen so, that $a = 0$, $b = 1$ in (5) and the outside knots are with $p + 1$ multiplicity, then the boundary control points are located on $x_1^* = 0$ and $x_n^* = 1$. B-spline displacement field is passed through end points. Therefore, the coordinates $x_i, i = 1, 2, \dots, n$ of control points of B-spline segment with length h are given by

$$x(\xi) = x_i^*(\xi) \cdot h. \quad (13)$$

The fundamental property of this parameterization based on the Greville abscissa is such, that Jacobians of the transformation from the parametric space to the physical space are constant for arbitrary parameter ξ , i.e. $\frac{dx(\xi)}{d\xi} = \text{const}$ for $\forall \xi \in [0, 1]$ [16]. This parameterization is called linear.

The normalized dispersion errors c^h/c_0 versus non-dimensional wavenumber $k^h h / (n - 1)$ for quadratic B-spline with linear parameterization are shown in Fig. 7 and for cubic B-spline

with linear parameterization are in Fig. 8, where influence of the number of control points is displayed. The dispersion graphs are normalized with respect to the averaged distance between the control points prescribed by relationship (12) and (13), respectively. The details of $c^h - k^h$ -curves presented in Figs. 7 (on the left) and 8 (on the left) are enlarged in Figs. 7 (on the right) and 8 (on the right). The band gap ranges for this parameterization are rapidly disappearing.

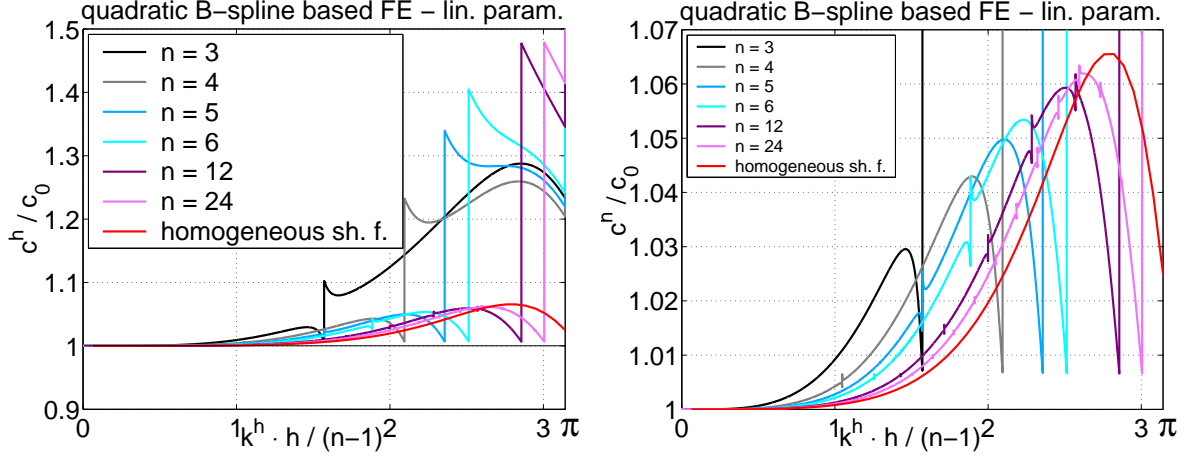

Figure 7: Normalized dispersion errors for quadratic B-spline based FE with linear parameterization. The red line corresponds to homogeneous shape functions [9].

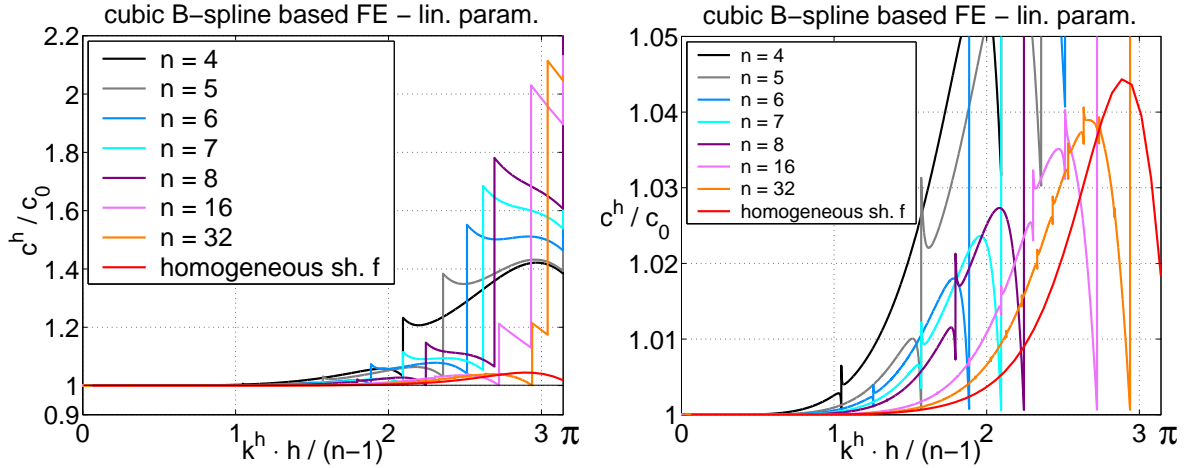

Figure 8: Normalized dispersion errors for cubic B-spline based FE with linear parameterization. The red line corresponds to homogeneous shape functions [9].

The dispersion curves for linear parameterization converge to the solution employing uniform (homogeneous) B-spline basis functions. For large number of control points, approximately $n \geq 10$, the $p - 1$ highest dispersion branches ω versus k^h display a constant behavior. From it follows that the group speed $c_g^h = d\omega/dk^h = 0$ and the dependence of phase speed $c^h = \omega/k^h$ is a linear function with the negative slope. The wave corresponding to the last $p - 1$ dispersion branches are not propagated through a elastic bar discretized by B-spline approach. The linear parameterization rapidly minimize the dispersion errors. The maximal error in phase speed for quadratic B-spline discretization is less than 7% and for cubic B-spline less than 4% thanks to the linear parametrization. This is very good property of B-spline based finite element method for case, where connection between several B-spline segments are only C^0 .

6 CONCLUSIONS

It was shown that the dispersion errors of B-spline based finite element method for increasing number of control points converge to the continuum solution. The solution with high number of control points is near by the solution for uniform B-spline shape functions. On the other hand, its dependence is with jumps from the reason of existing of passing and band gaps. Moreover, the spurious modes are reduced by the B-spline based spatial discretization thanks to higher order of continuity of approximation of a unknown quantity (in this case displacement). Further, the dispersion errors and ranges of band gaps can be similarly eliminated by a special choice of positions of control points, for example, by the Greville abscissa. It is valid as well in the case, where individual B-spline segments are only connected with C^0 continuity. B-splines basis functions as shape functions have a potential for using in high performance and accurate finite element analysis of elastic wave propagation problems.

Keywords: Explicit integration, Courant number, Critical time step, Wave propagation, Dispersion.

Abstract. *The critical Courant number limiting the length of time step in explicit integration schemes is inversely proportional to the maximum natural frequency of a finite element mesh. The well known recommendation $Co = 1$ for linear finite elements is deemed to be best. In fact, for some configurations this choice may dangerously overestimate the critical time step. It was shown in an earlier paper that by increasing the number of elements in the finite element mesh one will paradoxically improve the mesh's stability towards its theoretical limit. The present paper refines some details, presenting small scale numerical tests. The first test involves a long truss/bar consisting of one row of elements whose critical Courant number changes as elements are added one after another. Since this increases the critical number one may pick up a time step such that it is supercritical to a certain mesh but becomes subcritical by merely adding one element. In a similar fashion, a square area is tested in the second example, using different arrangements of edge supports. It turns out that the numerical solutions to wave propagation may be strongly influenced by small variation of distant boundary conditions, which should normally be physically insignificant.*

1 INTRODUCTION

Detailed analysis of accuracy and stability of finite element wave propagation solutions was presented in review paper [1] and references cited therein for various finite elements including consistent and lumped mass matrices. The critical Courant number limiting the length of the time step in explicit integration schemes, namely the central difference method, follows from the famous formula

$$Co_{crit} = \frac{2}{\bar{\omega}} \quad (1)$$

where $\bar{\omega}$ is the dimensionless frequency

$$\bar{\omega} = \frac{\omega_{max} H}{c_1} \quad (2)$$

with ω_{max} being the maximum natural frequency of a finite element mesh, H the element size, and c_1 the speed of the fastest wave propagating in a continuum, typically the longitudinal wave. Nearly equally famous recommendation $Co = 1$ (or slightly less to be on the safe side) for linear finite elements, also known to engineers as “rule of thumb” is deemed to be best. In fact, this observation comes from dispersion analysis but, as it has been shown in Ref. [1], for some configurations it may dangerously overestimate the critical time step. It was also shown that by increasing the number of elements, N , in the finite element mesh one will improve the mesh’s stability towards $Co_{crit} = 1$ as $N \rightarrow \infty$, which is rather a paradoxical finding.

The present paper refines these details, presenting small scale numerical tests, which exemplify some peculiarities. The first test involves a long truss/bar consisting of one row of elements whose critical Courant number changes as elements are added one after another. Since this increases the critical number one may pick up a time step such that it is supercritical to a certain mesh but becomes subcritical by merely adding one element. In a similar fashion, a square area is tested in the second example, using different arrangements of edge supports. It turns out that the numerical solutions to wave propagation may be strongly influenced by small variation of distant boundary conditions, which should normally be physically insignificant. Finally, the third illustration shows the direct numerical results relevant to the above mentioned choices of sub and supercritical times steps.

2 PROBLEM DESCRIPTION

This section concerns with essentials of wave propagation in homogeneous solids, finite element technology and dispersion computation.

2.1 Propagation of waves in an elastic isotropic continuum

The i th equation of motion in linear elastodynamics reads

$$(\Lambda + G)u_{j,ji} + Gu_{i,jj} = \rho \ddot{u}_i \quad (3)$$

In this equation, Λ and G are Lamé’s constants, ρ is the mass density and u_i is the i th component of the displacement vector. Furthermore, a comma placed before subscripts refers to spatial differentiation whereas the superimposed dots denote the time derivatives. The summation convention on repeated indices is assumed. The Lamé constants Λ , G may be related to engineering constants E , ν as

$$\Lambda = \frac{\nu E}{(1 + \nu)(1 - 2\nu)}, \quad G = \frac{E}{2(1 + \nu)} \quad (4)$$

where E and ν are Young's modulus and Poisson's ratio.

In an unbounded isotropic continuum, two types of planar waves exist: the longitudinal wave and two transversal waves, featuring mutually orthogonal polarisation. The longitudinal wave propagates with the speed

$$c_1 = \sqrt{\frac{\Lambda + 2G}{\rho}} \quad (5)$$

The speed of the two transversal waves is

$$c_2 = \sqrt{\frac{G}{\rho}} \quad (6)$$

The standard continuum is said to be *non-dispersive*. This is, by d'Alembert's solution, because the wave profile (wavelength) does not affect the velocity of propagation.

As a special case, one may consider a plane harmonic solution to Eqn. (3) as

$$u_i = U_i(\mathbf{x}) \exp(i\mathbf{k} \cdot \mathbf{x} \pm ct) \quad (7)$$

or its equivalent form

$$u_i = U_i(\mathbf{x}) \exp(i(\mathbf{k} \cdot \mathbf{x} \pm \omega t)) \quad (8)$$

where $i = \sqrt{-1}$ is the imaginary unit; \mathbf{x} is a position vector; t is time; k is the wave number; \mathbf{p} is the unit normal to the wave front; \mathbf{k} is the wave vector, $\mathbf{k} = k\mathbf{p}$; c is the phase velocity; ω is the angular velocity; and U_i is the i th component of the amplitude vector at the point defined by the position vector \mathbf{x} . For a given wavelength λ , the wave number k may be computed from

$$k = \frac{2\pi}{\lambda} \quad (9)$$

The phase velocity c is related to ω and k by

$$c = \frac{\omega}{k} \quad (10)$$

Finally, the group velocity c_g is defined as

$$c_g = \frac{d\omega}{dk} \quad (11)$$

In non-dispersive systems, c is a constant and since $\omega = ck$, we get $c_g = c$. Thus, in the absence of dispersion the group velocity equals the phase velocity. On the other hand, $c_g \neq c$ indicates dispersion.

2.2 Finite element method

Spatial discretization by the finite element of an elastodynamic problem introduces the ordinary differential system

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{R} \quad (12)$$

Here, \mathbf{M} is the mass matrix, \mathbf{K} the stiffness matrix, \mathbf{R} is the time-dependent load vector, and \mathbf{u} and $\ddot{\mathbf{u}}$ contain nodal displacements and accelerations. The element mass and stiffness matrices are given by

$$\mathbf{M}_e = \int_V \rho \mathbf{H}^T \mathbf{H} dV \quad (13)$$

and

$$\mathbf{K}_e = \int_V \mathbf{B}^T \mathbf{C} \mathbf{B} \, dV \quad (14)$$

where \mathbf{C} is the elasticity matrix, \mathbf{B} is the strain-displacement matrix, \mathbf{H} stores the displacement interpolation functions and integration is carried over the element domain. Global matrices are assembled in the usual fashion. Under plane strain conditions, the elastic matrix \mathbf{C} takes the form

$$\mathbf{C} = \frac{E}{1-\nu^2} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu^2}{2(1+\nu)} \end{bmatrix} \quad (15)$$

The mass matrix defined by Eqn. (13) is called the consistent mass matrix.

Explicit integration methods, such as the central difference method discussed later, require the mass matrix inverted. Thus, it is advantageous to have it diagonal or *lumped*. In contrast to consistent matrices, which are uniquely defined by the variational formulation, lumping procedures are not strictly prescribed. The only common principle is the ability of FEM to assemble diagonal global matrix from the element mass matrices, thus, lumping may be performed on an element basis. Out of many methods rendering the mass matrix diagonal we shall refer to the simplest: the row sum method (RS) for bilinear elements and the Hinton-Rock-Zienkiewicz method (HRZ) for quadratic elements—see Ref [1].

In the subsequent analysis, a regular $H_x \times H_y$ mesh composed of plane rectangular elements is considered with H_x and H_y measuring the length of element edges aligned with coordinate axes. It proves useful to define reference matrices $\bar{\mathbf{M}}_e$, $\bar{\mathbf{K}}_e$ for a parent element having unit properties E and ρ , unit thickness b and unit length $H_x = 1$. Then performing integration over the reference domain $1 \times r$ one gets

$$\mathbf{M}_e = br H_x^2 \rho \bar{\mathbf{M}}_e \quad (16)$$

and

$$\mathbf{K}_e = bE \bar{\mathbf{K}}_e \quad (17)$$

Therefore, a class of problems is defined by two constants: the Poisson ratio ν and the aspect ratio $r = H_y/H_x$. Within this class, the reference stiffness matrix $\bar{\mathbf{K}}_e$ is a function of ν and r whereas the reference mass matrix $\bar{\mathbf{M}}_e$ is independent of both. Denote by $\bar{\omega}_e$ the maximum natural frequency of a *single* element described by these unit matrices. For example, one may compute $\bar{\omega}_e = 2.39$ for the bilinear RS elements or $\bar{\omega}_e = 7.61$ for the quadratic serendipity HRZ elements.

2.3 Dispersion computation

The smooth solutions, Eqn. (7) and (8), no longer apply to discretized system (12). In this case, the speed of propagation of an harmonic wave depends on its angular frequency. According to Ref. [1], such dependence may be manifested by the dispersion plot shown in Fig. 1. In general, dispersion behaviour is investigated by considering an harmonic wave train travelling through unbounded mesh, which may be accomplished by prescribing periodic boundary conditions. Thus, the normalized frequencies read off the plot actually represent the limit natural frequencies corresponding to a very large (theoretically infinite) finite element mesh.

As in the preceding section, denote by $\bar{\omega}_\lambda$ the supreme value of the normalized angular frequency in Fig 1, e.g. $\bar{\omega}_\lambda = 2.00$ for bilinear elements and $\bar{\omega}_\lambda = 7.37$ for quadratic elements. It is worth mentioning that $\bar{\omega}_\lambda < \bar{\omega}_e$ in every case. It should also be noted that the dispersion

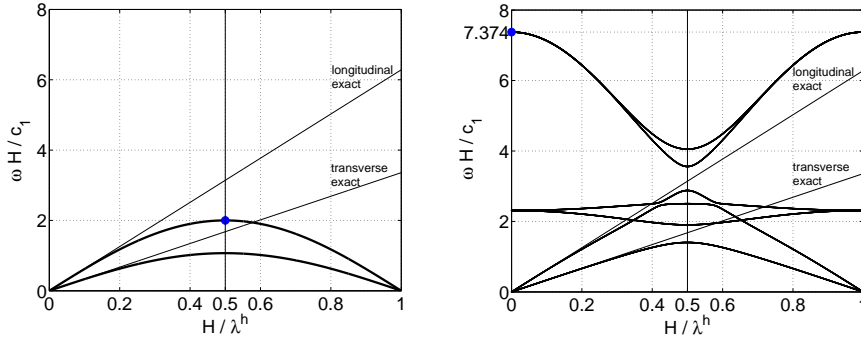

Figure 1: Dispersion curves for bilinear (left) and serendipity (right) elements.

diagrams discussed in this text are entirely due to spatial dispersion, neglecting effects of time integration—refer to paper [1] for complete treatise. This by no means oversimplifies actual problems since they are namely these theoretical values that enter stability criteria.

2.4 Explicit time integration and numerical stability

As a representative of explicit schemes, reviewed in Reference [2], the central difference method (CDM) will be discussed. Its discrete operator reads

$$\frac{1}{\Delta t^2} \mathbf{M} \mathbf{u}^{t+\Delta t} = \mathbf{R}^t - \left(\mathbf{K} - \frac{2}{\Delta t^2} \mathbf{M} \right) \mathbf{u}^t - \frac{1}{\Delta t^2} \mathbf{M} \mathbf{u}^{t-\Delta t} \quad (18)$$

where \mathbf{R}^t contains forces acting on the nodal points at time t . It is well known that CDM is only conditionally stable, Ref. [3], that is

$$\Delta t \leq \frac{2}{\omega_{\max}} \quad (19)$$

where ω_{\max} is the maximum eigenfrequency of the finite element mesh. The highest frequency can be computed by the standard FE software, aiming at the lowest eigenvalue with \mathbf{K} and \mathbf{M} swapped. This method was indeed employed in all the numerical computations presented here. Alternatively, the critical time step may be estimated analytically as in Ref. [4].

At this point, it is convenient to introduce the Courant dimensionless number defined as

$$\text{Co} = \frac{c_1 \Delta t}{H} \quad (20)$$

In elastodynamics, c_1 is the velocity of the longitudinal wave. Using the latter definition and that of $\bar{\omega}$ in Eqn. (2), the stability condition (19) can be rephrased as

$$\text{Co} \leq \frac{2}{\bar{\omega}} \quad (21)$$

or, defining Co_{crit} , in the form of Eqn. (1). Inequality $\text{Co} \leq 1$ then exactly manifests the Courant-Friedrichs-Levy stability condition for the linear truss element [2] but for other elements it may not be generally valid. On the other hand, we know, by Fried's theorem [5], which is a direct consequence of Sturm's polynomial separation property, that the maximum frequency is bounded by $\bar{\omega}_e$ obtained as the maximum eigenvalue taken over all the elements in the FE mesh.

If the mesh is regular, composed only of rectangular elements of the same aspect ratio (the so-called structured mesh), one may devise another estimate of the critical time step, which lends some interesting insight into the problem of numerical stability in general. One asymptotic case arises for the infinite mesh, when ω_{\max} equals the supremum taken over all the dispersion curves for the particular element, i.e., $\bar{\omega}_\lambda$ is exploited. Tentatively, one may conjecture

$$\bar{\omega}_\lambda \leq \bar{\omega} \leq \bar{\omega}_e \quad (22)$$

This expression is indeed valid for an arbitrary body with free boundary, $\Gamma_u = \emptyset$, but *does not hold* for a constrained mesh, for instance, if some displacement boundary conditions are prescribed. The meaning of the statement (22) will be clarified in full by examples shown in the next section.

Finally, it should be pointed out, that precisely because of the inequality (22), the true frequency of a real mesh will probably be higher than the estimate stemming from dispersion theory. Hence, the popular formula $c_1 \Delta t = H$ for the determination of time step length is not entirely safe.

3 NUMERICAL EXPERIMENTS

Unit dimensions were set in the numerical tests as follows: mass density $\rho = 1$, Poisson's ratio $\nu = 0.3$, and Young's modulus $E = 0.7428 \dots$ so that $c_1 = 1$ and $c_2 = 0.5345 \dots$. Furthermore, plane strain square bilinear elements with edge length $H = 1$ and unit thickness, $b = 1$, were employed. The reason for choosing linear rather than quadratic elements to illustrate stability properties is that the difference between $\bar{\omega}_\lambda = 2.00$ and $\bar{\omega}_e = 2.39$ is greater for these elements. Having N elements in the mesh, the total mass is $m = N\rho H^2 b = N$.

3.1 Plane strain bar

As the first example we consider a plane strain bar whose length is variable depending on the number of elements used. Fig 2 shows the eigenmode corresponding to the bar's maximum frequency for 40×1 discretization. The value of frequencies computed for various N s are listed in Tab. 1.

Figure 2: Eigenvector corresponding to the highest frequency of a bar with free ends.

One important observation following the inspection of Tab. 1 is that starting from the 20×1 bar, the maximum frequency does not change within the first 8 digits, which suggests an existence of the limit. Alas, this limit, $\bar{\omega} = 2.16$, differs from the theoretical value $\bar{\omega}_\lambda = 2.00$. On the one hand, our sequence correctly starts at $\bar{\omega}_e = 2.39$ for 1×1 discretization, but on the other, the asymptotics $C_{o_{\text{crit}}} = 1$ has never been reached. Why is it so? The answer lies in Fig 2. Since only the free ends vibrate, the maximum eigenvalue does not depend on the bar's length but solely on this boundary effect. The limit solution will not fit the periodical boundary conditions characteristic of the dispersion approach.

N	$\bar{\omega}$	$C_{o_{crit}}$

Table 1: Critical Courant numbers for the bilinear finite element mesh of a free bar.

Another interesting observation follows from the graphical representation depicted in Fig. 3 on the log scale. Apart from the limit, there is a pronounced gap between the three and four element configurations. Selecting $Co = 0.92$, the time step is stable for the 4×1 mesh but unstable for the smaller 3×1 mesh. This motivates the critical test defined in Fig. 4.

Figure 3: Distribution of the critical Courant number for the bar with free ends.

A three-element bar is loaded by the Heaviside step function $F(t) = 1$ for $t > 0$. Since $Co = 0.92 > C_{o_{crit}}$ one expects an incursion of instability after some time has elapsed but a stable solution if a four-element problem had been considered instead. In both the cases, parabolic displacement evolution

$$u(t) = \frac{F}{2m}t^2 = \frac{t^2}{2N} \quad (23)$$

applies to the motion of the whole body. The average acceleration, $1/N$, measured at the control point A for the 4×1 configuration equals 0.25. The existence of the stable solution is confirmed

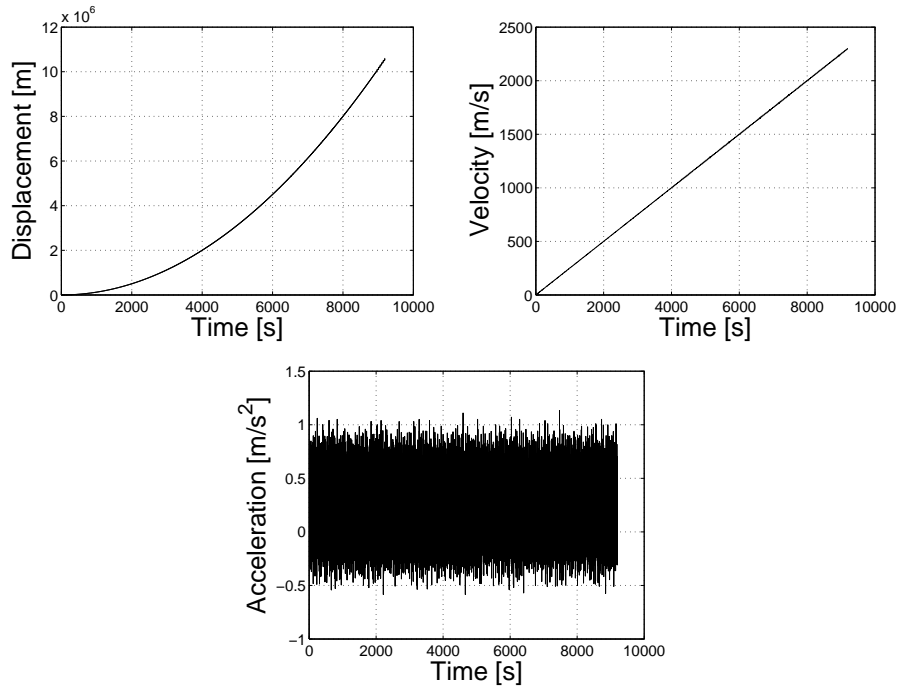

Figure 4: Transient problem with Heaviside load; unstable configuration.

by plots shown in Fig. 5. The oscillatory course of acceleration history is due to waves reflection about the mean value 0.25, which matches the rigid body motion. By contrast, the unstable 3×1

 Figure 5: Displacement, velocity and acceleration in the stable 4×1 computation.

problem exhibits the solution's uncontrolled blow up at about $t = 3000$, see Fig. 6. The instability commences even much earlier after several wave reflections, which is nicely captured in Fig. 7.

Let us return to the original eigenvalue problem shown in Fig. 2. This time the boundary conditions are modified by clamping the right end. The corresponding eigenvector and the frequencies computed are shown in Fig. 8 and Tab. 2, respectively. The same limit $\bar{\omega} = 2.16$ is reached already by the 8×1 discretization, which is not surprising. Indeed, the vibration modes roughly correspond to those of the free bar twice the length of the free-fixed bar. A more interesting fact is that the maximum frequency now *increases*. This is because the results converge to the same limit as before but for each N -element bar the constrained configuration has lower maximum frequency than the free one. The critical Courant number distribution is shown in Fig. 9

Table 2: Critical Courant numbers for the free-fixed bar.

We close our discussion concerning this example with the remark that the conjecture (22) does not hold for a constrained problem. For example, for the free-fixed bar $\bar{\omega}_\lambda > \bar{\omega}_{1 \times 1}$, because the maximum frequency has been reduced by the imposition of the boundary condition. Theoretically, one could even have had $\bar{\omega} = 0$ if all the nodes had been fixed. By contrast, $\bar{\omega}_e$ always forms the upper bound.

Figure 7: Detail of acceleration build up.

Figure 8: A free-fixed bar.

3.2 Plane strain square domain

Similar examples as in the preceding section may be analysed. Consider a plane strain square domain shown in Fig. 10 and the critical Courant number distributions for both (fixed and free) boundary configurations—Fig. 11.

In this case, convergence to the limit $C_{o_{crit}} = 0.99$ is observed. Similarly as for the free bar this number is slightly less than the theoretical value $C_{o_{crit}} = 1$. The reason can again be seen in Fig. 10, which suggests that it is the vibration of the corner elements that is responsible for the maximum frequency and is, in fact, independent of the mesh size.

A new phenomenon is detected with the constrained mesh. Comparing it with the free-fixed bar one notices that, here, zero displacements are prescribed along the whole boundary. This means that adding extra elements is merely equivalent to mesh refinement, which in turn implies the increase of the dimensionless maximum frequency. Since the mesh grading is regular and there are no boundary effects, monotonous convergence to the theoretical limit, $C_{o_{crit}} = 1$, follows. It is interesting to note that also in this situation $\bar{\omega} < \bar{\omega}_\lambda$, which violates condition (22) as the present problem is fully constrained.

4 CONCLUSIONS

It might seem at first glance that, except illustrating certain mathematical principles, the present study bears little importance to real-world computation. On the one hand, today's engineering problems are extremely large (rendering $N \rightarrow \infty$ effectively) and, on the other, one may safely use the upper bound by calculating the maximum eigenvalue of a single element.

It should be borne in mind that Fried's estimate, $\bar{\omega} \leq \bar{\omega}_e$, is only useful for a structured mesh when all the elements have the same spectrum. For an unstructured mesh, this information is hardly available and one must resort to other estimates. It is namely under such circumstances

Figure 9: Distribution of the Critical Courant number for the free-fixed bar.

Figure 10: Maximum eigenmode of a free square domain (left) and the domain with fixed edges (right).

that the analysts use the $\bar{\omega}_\lambda$ limit derived from dispersion diagrams often unaware of its pitfalls. It must be emphasised that for the reasons explained in the paper the frequent recommendation $c_1 \Delta t = H$ is not entirely safe.

The examples involving free bodies clearly demonstrated the way the vibration of corner elements changed the stability limits. Hence, we conclude that even distant boundary conditions, which should normally be physically insignificant, may considerably influence numerical solution.

Keywords: time integration, spurious oscillations, numerical dispersion

Abstract. *There are the following issues with existing numerical methods for elastodynamics problems (including wave propagation and structural dynamics problems): a) a large dispersion error of space-discretization methods may lead to a great error in space, especially in the 2-D and 3-D cases; b) due to spurious high-frequency oscillations, the lack of reliable numerical techniques that yield an accurate solution of wave propagation in solids; c) the treatment of the error accumulation for long-term integration; d) the selection of an effective time-integration method among known ones; e) the selection of the size of a time increment for a time-integration method with numerical dissipation; f) the increase in accuracy and the reduction of computation time for real-world dynamic problems. A new numerical approach for computer simulation of the dynamic response of linear elastic structures is suggested, resolves the issues listed and includes two main components: a) a new dispersion reduction technique for linear finite elements based on the extension of the modified integration rule method to elastodynamics problems, and b) a new two-stage time-integration technique with the filtering stage. The suggested two-stage time-integration technique includes the stage of basic computations and the filtering stage, new first-, second- and high-order accurate time-integration methods for elastodynamics, and a new calibration procedure for the selection of the minimum necessary amount of numerical dissipation for time-integration methods, new criteria for the selection of time-integration methods for elastodynamics. In contrast to existing approaches, the new technique does not require guesswork for the selection of numerical dissipation and does not require interaction between users and computer codes for the suppression of spurious high-frequency oscillations. Different discretization methods in space such as the finite element method, the spectral element method, the boundary element method, and others can be used with the suggested two-stage time-integration approach. 1-D and 3-D numerical examples show that the new approach used with the finite element method yields an accurate non-oscillatory solution for impact and wave propagation problems and considerably reduces the number of degrees of freedom and the computation time in comparison with existing methods.*

1 INTRODUCTION

The application of finite elements in space to transient acoustics or transient linear elastodynamics problems leads to a system of ordinary differential equations in time

$$\mathbf{M} \ddot{\mathbf{U}} + \mathbf{C} \dot{\mathbf{U}} + \mathbf{K} \mathbf{U} = \mathbf{R}, \quad (1)$$

where \mathbf{M} , \mathbf{C} , \mathbf{K} are the mass, damping, and stiffness matrices, respectively, \mathbf{U} is the vector of the nodal displacement, \mathbf{R} is the vector of the nodal load. The case of zero natural viscosity, $\mathbf{C} = \mathbf{0}$, is considered in the paper. It is known that even the exact solution to Eq. (1) contains the numerical dispersion error, which is also related to the space discretization error; e.g., see [1, 2, 3, 4, 5, 6, 7, 8, 9, 10] and others. The decrease in the space discretization error by the use of mesh refinement considerably increases computational costs. Therefore, several techniques have been proposed for the reduction in the numerical dispersion error. One simple approach for acoustic and elastic wave propagation problems is based on the use of the averaged mass matrix in Eq. (1) instead of the consistent or lumped mass matrix \mathbf{M} ; see [5, 6, 7, 8] and others. For linear finite elements, this technique reduces the relative error in the wave velocity for harmonic waves from the second order to the fourth order of accuracy in the 1-D case. However, these results are not valid in the general case of harmonic wave propagation for 2-D and 3-D problems (nevertheless, in the 2-D and 3-D cases, the averaged mass matrix yields more accurate results compared with the standard mass matrix). Another simple technique for linear finite elements, which is suggested in [9] for acoustic waves in the 2-D case, is based on the modified integration rule for the mass and stiffness matrices. In contrast to the averaged mass matrix, this approach increases the accuracy for the phase velocity from the second order to the fourth order in the general multi-dimensional case of acoustic waves. However, the applicability of the modified integration rule to linear elastodynamics problems has not been studied.

As we mentioned above, the analysis of numerical dispersion is based on propagation of harmonic waves. In the general case of loading (boundary conditions), the numerical study of the effectiveness of the finite element formulations with the reduced dispersion error is difficult due to the presence of spurious high-frequency oscillations in numerical solutions; e.g., see [3, 5].

In the current paper, we will apply two dispersion reduction techniques for linear finite elements to 1-D and 3-D impact problems. Similar to the classical finite element technique for elastodynamics, the finite element formulations with reduced dispersion also suffer spurious high-frequency oscillations in numerical solutions (e.g., see below). Therefore, for obtaining accurate numerical results and for the numerical study of the effectiveness of the dispersion reduction techniques applied to elastodynamics problems with general loading, the two-stage time-integration technique with the filtering stage (developed in our previous papers [11, 12, 13]) is used along with the finite elements with reduced dispersion. This technique identifies and removes spurious high-frequency oscillations from numerical solutions. 1-D and 3-D impact problems for which all frequencies of the semi-discrete system, Eq. (1), are excited are solved with the standard and new techniques. Numerical results show that compared with the standard mass and stiffness matrices, the simple dispersion reduction techniques lead to a considerable reduction in the number of degrees of freedom and computation time at the same accuracy, especially for multi-dimensional problems.

2 NUMERICAL TECHNIQUE

2.1 Dispersion reduction of linear finite elements (see [14])

We will use two numerical techniques which reduce the dispersion error of linear finite elements at the space discretization. The first approach is based on the use of the mass matrix \mathbf{M} calculated as a weighted average of consistent and lumped mass matrices with the weighting factor γ (similar to that used in [5, 6, 8])

$$\mathbf{M} = \mathbf{M}^{lump}\gamma + \mathbf{M}^{cons}(1 - \gamma) \quad (2)$$

where γ is the parameter to be determined. The second technique is the extension of the modified integration rule to the case of elastodynamics suggested in our paper [14]. For the dispersion reduction of linear finite elements, the mass and stiffness matrices of each finite element are calculated with the modified integration rule (similar to those used in [9])

$$\mathbf{M}^e = \int_{-1}^1 \mathbf{N}^T(s) \mathbf{N}(s) \det(\mathbf{J}) ds \approx \sum_{i=1}^2 \mathbf{N}^T((-1)^i \alpha_M) \mathbf{N}((-1)^i \alpha_M) \det(\mathbf{J}), \quad (3)$$

$$\mathbf{K}^e = \int_{-1}^1 E \mathbf{B}^T(s) \mathbf{B}(s) \det(\mathbf{J}) ds \approx \sum_{i=1}^2 E \mathbf{B}^T((-1)^i \alpha_K) \mathbf{B}((-1)^i \alpha_K) \det(\mathbf{J}) \quad (4)$$

in the 1-D case,

$$\begin{aligned} \mathbf{M}^e &= \int_{-1}^1 \int_{-1}^1 \int_{-1}^1 \mathbf{N}^T(s, t, q) \mathbf{N}(s, t, q) \det(\mathbf{J}) ds dt dq \\ &\approx \sum_{i=1}^2 \sum_{j=1}^2 \sum_{p=1}^2 \mathbf{N}^T((-1)^i \alpha_M, (-1)^j \alpha_M, (-1)^p \alpha_M) \mathbf{N}((-1)^i \alpha_M, (-1)^j \alpha_M, (-1)^p \alpha_M) \det(\mathbf{J}), \end{aligned} \quad (5)$$

$$\begin{aligned} \mathbf{K}^e &= \int_{-1}^1 \int_{-1}^1 \int_{-1}^1 \mathbf{B}^T(s, t, q) \mathbf{D} \mathbf{B}(s, t, q) \det(\mathbf{J}) ds dt dq \\ &\approx \sum_{i=1}^2 \sum_{j=1}^2 \sum_{p=1}^2 \mathbf{B}^T((-1)^i \alpha_K, (-1)^j \alpha_K, (-1)^p \alpha_K) \mathbf{D} \mathbf{B}((-1)^i \alpha_K, (-1)^j \alpha_K, (-1)^p \alpha_K) \det(\mathbf{J}) \end{aligned} \quad (6)$$

in the 3-D case. Here, \mathbf{N} and \mathbf{B} are the standard finite element shape and B matrices; \mathbf{D} is the matrix of elastic coefficients; \mathbf{J} is the Jacobian matrix ($\det(\mathbf{J}) = dx/2$; $dx^2/4$; $dx^3/8$ in the 1-D case, in the 2-D case for square elements and in the 3-D case for cubic elements, respectively; dx is the length of a finite element); E is Young's modulus; s, t, q are the isoparametric coordinates; α_M and α_K are the coordinates of the integration points for the mass and stiffness matrices to be determined (2 and $2 \times 2 \times 2 = 8$ integration points are used for linear elements in the 1-D and 3-D cases, respectively); e.g., see [15] for the derivation of finite element matrices. The integration error related to the application of the modified integration rule for the mass and stiffness matrices does not change the convergence rate of finite element solutions; see [9].

The analytical study of numerical dispersion shows (see our paper [14]) that the use of the averaged mass matrix with $\gamma = 0.5$ increases the accuracy in the calculation of the wave velocity from the second order to the fourth order in the 1-D case. Completely equivalent results for the numerical dispersion reduction are obtained with the modified integration rule in the 1-D case

with $\alpha_M = \sqrt{\frac{2}{3}}$. However, in the multi-dimensional cases with the presence of compressional and shear waves, these results are valid only under some specific conditions. For example, for the averaged mass matrix ($\gamma = 0.5$), the increase in the order of accuracy for the phase velocity is valid only for the waves propagating along the coordinate axes of uniform meshes. The modified integration rule with $\alpha_M = \sqrt{\frac{2}{3}}$ and $\alpha_K = \sqrt{\frac{4(2\nu-1)}{3(4\nu-3)}}$ (ν is Poisson's ratios) additionally allows the extension of the results of the 1-D case only for the compressional waves or only for the shear waves propagating in any direction in the 2-D case and propagating in any direction within the coordinate planes of uniform meshes in the 3-D case.

2.2 The two-stage time-integration technique with filtering spurious oscillations (see [11, 12, 13])

The standard finite elements and the finite elements with reduced dispersion described in the previous section lead to the appearance of spurious high-frequency oscillations at time integration of Eq. (1) for wave propagation and impact problems. Below we briefly describe the approach developed in our previous papers [11, 12, 13] which, for the standard finite elements and for the finite elements with reduced dispersion, allows accurate numerical solutions of elastodynamics problems without spurious oscillations. It includes the two-stage time-integration technique with the stage of basic computations and the filtering stage, the implicit time-continuous Galerkin (TCG) method with large numerical dissipation and the calibration procedure for the selection of the minimum necessary amount of numerical dissipation (in terms of a time increment) for the implicit TCG method; see also the Appendix.

The idea of the two-stage time-integration technique is very simple. Because for linear elastodynamics problems there is no interaction between different modes during time integration (they are integrated independently of each other; e.g., see [12, 13]), the most accurate time-integration method (usually without numerical dissipation or artificial viscosity) should be used at the stage of basic computations, especially for a long-term integration. This means that all modes including high-frequency modes are integrated very accurately and the solution includes spurious high-frequency oscillations after basic computations. For the damping out of spurious high modes, a time-integration method with large numerical dissipation (or artificial viscosity) is used for a number of time increments for the filtering of spurious oscillations (the filtering stage). A small number of time increments for implicit time-integration methods is sufficient for the filtering stage, with negligible error accumulation at low modes (e.g., 10 time increments with the implicit TCG with large numerical dissipation is used with the proposed technique at the filtering stage for all elastodynamics problems; see [13]).

The main advantages of the developed approach are as follows. The suggested numerical technique: a) allows the selection of the best time-integration method for basic computations from simple criteria (the most important one being the accuracy of the method); b) includes pre-, or/and post-processing for filtering spurious high-frequency oscillations, which requires little computation time compared with that for the stage of basic computations (a small number of time increments with the implicit TCG method with large numerical dissipation is used for the filtering stage); c) yields no error accumulation due to numerical dissipation (or artificial viscosity) at the stage of basic computations; d) allows the calibration of spurious oscillations at different observation times (see [12, 13] and the Appendix below) and does not require any guesswork for the selection of numerical dissipation or artificial viscosity as do existing approaches. Thus, the approach can be easily incorporated in computer codes and does not require interaction with users for the suppression of spurious high-frequency oscillations.

Summarizing, in contrast to existing approaches with one time integration method, the described technique is based on the application two different time integration methods to Eq. (1): one method is used for accurate integration of a semi-discrete system at the stage of basic computations and allows spurious oscillations; another method is used for filtering spurious oscillations at the pre-, or/and post-processing stage. At mesh refinement, the numerical solutions obtained with the two-stage time-integration technique include more modes (because a finer mesh requires smaller numerical dissipation; see Eqs. (13)-(15) in the Appendix), exclude spurious high modes, and converge to exact solutions.

In the current paper, we will use the standard implicit trapezoidal rule with small time increments for basic computations in order to obtain an accurate solution of the semi-discrete elastodynamics problem, Eq. (1), with a negligible error in time (this solution contains spurious high-frequency oscillations). We should mention that other known implicit or explicit time-integration methods can also be used for basic computations with very small time increments (the trapezoidal rule is the most accurate second-order time-integration method). For filtering spurious oscillations, the implicit TCG method with large numerical dissipation developed in [12, 13] and briefly described in the Appendix is used at the filtering stage (the post-processing stage).

3 NUMERICAL MODELING

The new numerical approach is implemented into the finite element code FEAP [16]. 1-D and 3-D impact linear elastodynamics problems will be considered below. Due to spurious high-frequency oscillations, these problems cannot be accurately solved by existing time-integration methods based on the introduction of artificial viscosity (or numerical dissipation) at each time increment, especially in the case of long-term integration. For the filtering of spurious oscillations in the problems solved below, the filtering stage will be used with the TCG method with $N = 10$ time increments (5 positive plus 5 negative time increments) the size of which is calculated according to Eqs. (13) - (15) with $\Omega_{0.1}(N = 10) = 0.81$ (see [12, 13, 17] and the Appendix below).

3.1 1-D impact of an elastic bar against a rigid wall

First, the impact of an elastic bar of the length $L = 4$ against a rigid wall is considered in the 1-D case (see Fig. 1a). Young's modulus is chosen to be $E = 1$ and the density to be $\rho = 1$. The following boundary conditions are applied: the displacement $u(0, t) = t$ (which corresponds to the velocity $v(0, t) = v_0 = 1$) and $u(4, t) = 0$ (which corresponds to the velocity $v(4, t) = 0$). Initial displacements and velocities are zero; i.e., $u(x, 0) = v(x, 0) = 0$. The analytical solution to this problem includes the continuous variation of displacements $u_a(x, t) = t - x$ for $t \geq x$ and $u_a(x, t) = 0$ for $t \leq x$, and the piecewise continuous variation of velocities and stresses $v_a(x, t) = -\sigma^a(x, t) = 1$ for $t \geq x$ and $v_a(x, t) = \sigma^a(x, t) = 0$ for $t \leq x$ (at the interface $x = t$, jumps in stresses and velocities occur). The observation time is chosen to be $T = 18$. During this time the velocity pulse travels within the bar with two reflections from each end of the bar.

It is known that the application of traditional semi-discrete methods to this problem leads to oscillations in velocities and stresses due to the spurious high-frequency response [11, 18, 19]. As we will see (e.g., from Fig. 1b), finite elements with reduced numerical dispersion reduce these oscillations after basic computations but they do not completely remove them from the numerical solution. Therefore, the two-stage procedure with the filtering stage as described in

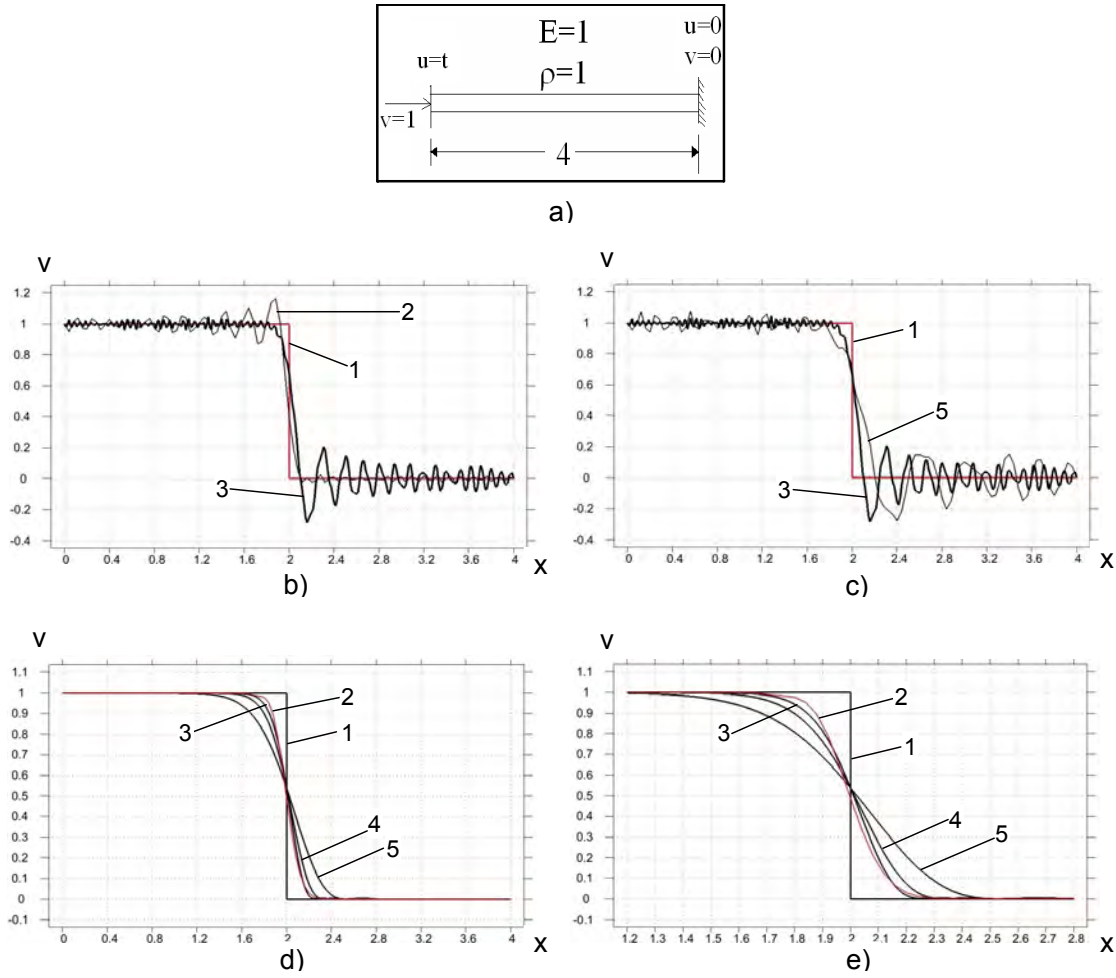

Figure 1: Impact of an elastic bar of length $L = 4$ against a rigid wall (a). Velocity distribution along the bar at observation time $T = 18$ after basic computations (b, c) and after post-processing (d, e). Curves 1 correspond to the analytical solution. Curves 2 correspond to the numerical solution with the averaged mass matrix ($\gamma = 0.5$) on a uniform mesh with 100 linear 2-node finite elements. Curves 3, 4, 5 correspond to the numerical solutions with the consistent mass matrix on uniform meshes with 300, 200 and 100 linear 2-node finite elements, respectively. e) shows the zoomed graph d) in the range $1.2 < x < 2.8$.

Section 2.2 will be applied for accurate and non-oscillatory solutions. The 1-D impact problem with propagating discontinuities in stresses and velocities can be considered a good benchmark problem for the testing of new numerical methods for wave propagation problems.

The problem is solved on uniform meshes with 100, 200 and 300 $Q2$ linear finite elements with the consistent and averaged ($\gamma = 0.5$) mass matrices as well as on uniform meshes with 50 and 70 $Q3$ quadratic finite elements with the consistent mass matrix. We should mention that the techniques based on the modified integration rule with $\alpha_M = \sqrt{2/3}$ and the averaged mass matrix with $\gamma = 0.5$ are completely equivalent and yield the same results in the 1-D case. Because in the paper we study the improvement of the spatial accuracy due to the reduction in the numerical dispersion error, for the time integration of Eq. (1) at basic calculations we will use the trapezoidal rule with very small time increments $\Delta t = 0.001$. A further reduction of time increments does not practically affect the numerical results for the meshes used; i.e., the error in time is very small and can be neglected.

Figure 2: Velocity distribution along the bar at observation time $T = 18$ after post-processing. Curve 1 corresponds to the analytical solution. Curves 2, 3, 4, 5 correspond to the numerical solutions with the averaged mass matrix ($\gamma = 0.5$) on uniform meshes with 1000, 300, 200 and 100 linear 2-node finite elements, respectively. b) shows the zoomed graph a) in the range $1.2 < x < 2.8$.

Fig. 1 shows the numerical results for linear elements obtained with the consistent and averaged mass matrices after basic computations and after the filtering stage (post-processing). The use of the formulation with the reduced dispersion error reduces the amplitudes of spurious oscillations (see curve 2 in Fig. 1b) and yields a more accurate slope of the wave front at $x = 2$ (see curve 2 in Fig. 1b and curve 5 in Fig. 1c for the consistent mass matrix obtained at the same numbers of elements). However, the presence of spurious high-frequency oscillations makes it difficult to compare numerical results. After the filtering of spurious oscillations, we can see that for the selected observation time and at the same accuracy, the use of the averaged mass matrix reduces the number of degrees of freedom by a factor of three as compared with the case with the standard consistent mass matrix (see curves 2 and 3 in Fig. 1d,e). We should also mention that after basic computations the slopes of the wave front in the numerical solutions obtained on a uniform mesh with 100 elements and the averaged mass matrix and obtained on a uniform mesh with 300 elements and the consistent mass matrix are approximately the same (see curves 2 and 3 in Fig. 1b). After the filtering stage, the numerical results obtained with the averaged mass matrix converge to the analytical solution at mesh refinement; see Fig. 2. These numerical results for the 1-D impact problem after the filtering stage are similar to those obtained in [18] by the use of special non-linear discontinuity-capturing operators.

Fig. 3 shows that for the standard mass and stiffness matrices, quadratic finite elements yield more accurate results than linear finite elements (e.g., compare curves 4 and 5 obtained on the meshes with the same numbers of degrees of freedom). However, at the same numbers of degrees of freedom, the linear elements with the averaged mass matrix (or the modified integration rule) are more accurate than the quadratic elements with the consistent mass matrix (e.g., compare curves 2 and 4 in Fig. 3 obtained on the meshes with the same numbers of degrees of freedom). The comparison of curves 2 and 3 in Fig. 3 also shows that for the selected observation time and at the same accuracy, the linear elements with the reduced dispersion error reduces the number of degrees of freedom by a factor of 1.4 as compared with the case of the quadratic elements with the consistent mass matrix. In addition to this advantage, numerical solutions with linear elements require less computation time compared with that for quadratic elements because at the same numbers of degrees of freedom, the bandwidth of the mass and stiffness matrices for quadratic elements is twice of that for linear elements.

Remark. It is interesting to note that the range of frequencies in numerical solutions after

Figure 3: Velocity distribution along the bar at observation time $T = 18$ after post-processing. Curve 1 corresponds to the analytical solution. Curves 2 and 5 correspond to the numerical solutions on a uniform mesh with 100 linear 2-node finite elements with the averaged mass matrix ($\gamma = 0.5$) and with the consistent mass matrix, respectively. Curves 3 and 4 correspond to the numerical solutions with the consistent mass matrix on uniform meshes with 70 and 50 quadratic 3-node finite elements, respectively. b) shows the zoomed graph a) in the range $1.6 < x < 2.4$.

the filtering stage is indirectly determined by the size of the time increments calculated by Eqs. (13) - (14) (see the Appendix). The numerical results show that if the time increments calculated according to Eqs. (13) - (14) for the filtering stage are close to each other for the formulations with the consistent and averaged mass matrices on different uniform meshes, then the numerical solutions obtained on these different uniform meshes are close to each other. This means that Eqs. (13) - (14) allow the quantitative estimation of the advantage of the averaged mass matrix ($\gamma = 0.5$) compared with the consistent mass matrix. For example, for a uniform mesh with 100 linear finite elements and the averaged mass matrix ($\gamma = 0.5$), the size of the time increments at the filtering stage is $\Delta t_1 = 0.03447$ according to Eqs. (13) - (14). For a uniform mesh with 300 linear finite elements and the consistent mass matrix, the size of the time increments at the filtering stage is $\Delta t_2 = 0.03908$ according to Eqs. (13) - (14). Because Δt_2 is close to Δt_1 , then curves 2 and 3 in Fig. 1d,e are close to each other (curve 2 is slightly more accurate because Δt_1 is slightly smaller than Δt_2); see also the analytical solution, curve 1. For a uniform mesh with 70 $Q3$ quadratic elements and the consistent mass matrix, the size of the time increments at the filtering stage is $\Delta t_3 = 0.03465$ according to Eqs. (13) - (14). Because Δt_3 is close to Δt_1 , then curves 2 and 3 in Fig. 3 are close to each other.

3.2 3-D impact of an elastic bar against a rigid wall

A solid 3-D bar of length $L = 2$ with a square cross section $a \times a$ ($a = 2$) under impact loading at the left end $ACEM$ is considered; see Fig. 4. Due to symmetry, the problem is solved for a quarter of the bar $ACEMNFB$ where planes $ABDC$ and $ABNM$ are the planes of symmetry. Young's modulus is chosen to be $E = 1$, Poisson's ratio to be $\nu = 0.3$, and the density to be $\rho = 1$. The following boundary conditions are applied: along the left end $ACEM$: $u_n = t$ (which corresponds to the instantaneous application of velocity $v_{load}(t) = v_0 = 1$) and $\tau_n = 0$; along planes $BDFN$, $CDEF$ and $EFNM$: $\sigma_n = 0$ and $\tau_n = 0$ (free surfaces); along planes $ABDC$, $ABNM$: $u_n = 0$ and $\tau_n = 0$ where u_n , v_n , and σ_n are the normal displacements, velocities and the tractive forces, respectively; τ_n are the tangential tractive forces. The observation time is chosen to be $T = 7$. During this time the velocity pulse travels within the bar with multiple reflections from the ends of the bar and from the external surfaces $CDFE$ and $EFNM$. We should mention that with the dimensionless coordinates \tilde{x} ,

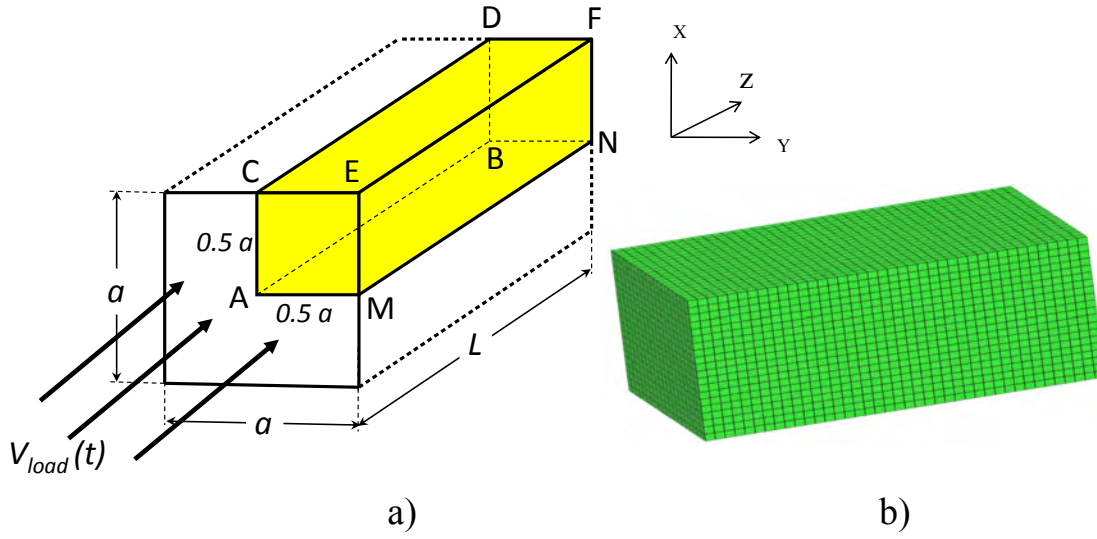

Figure 4: Impact of an elastic 3-D square bar of length $L = 2$ and width $a = 2$ against a rigid wall (a). A uniform mesh with $20 \times 20 \times 40 = 16000$ linear $Q8$ finite elements (b).

\tilde{y} and \tilde{z} and the dimensionless time \tilde{t}

$$\tilde{x} = \frac{x}{a}, \quad \tilde{y} = \frac{y}{a}, \quad \tilde{z} = \frac{z}{a}, \quad \tilde{t} = \frac{tc_0}{a},$$

and with the normalized displacements \tilde{u}_i , velocities \tilde{v}_i , stresses $\tilde{\sigma}_{ij}$ and strains $\tilde{\varepsilon}_{ij}$

$$\begin{aligned} \tilde{u}_i &= \frac{u_i c_0}{a v_0}, & \tilde{v}_i &= \frac{v_i}{v_0}, & \tilde{\varepsilon}_{ij} &= \frac{\varepsilon_{ij} c_0}{v_0}, \\ \tilde{\sigma}_{ij} &= \frac{\sigma_{ij} c_0 \sqrt{(1+\nu)(1-\nu)(1-2\nu)}}{\sqrt{2\nu E} v_0}, & i, j &= x, y, z \end{aligned}$$

numerical results are independent of Young's modulus, the density, the amplitude of the velocity v_0 and the size a of a cross-section, and depend on Poisson's ratio ν and the dimensionless length of the bar L/a . Here, $c_0 = \sqrt{\frac{E}{\rho}}$ is the wave velocity in the 1-D case.

The problem is solved on uniform meshes with $10 \times 10 \times 20 = 2000$ and $20 \times 20 \times 40 = 16000$ linear quadrilateral $Q8$ elements with the modified integration rule for the mass and stiffness matrices ($\alpha_M = \sqrt{\frac{2}{3}}$ and $\alpha_K = \sqrt{\frac{4(2\nu-1)}{3(4\nu-3)}}$) as well as with the consistent and averaged ($\gamma = 0.5$) mass matrices. Similar to the 1-D impact problem, for the time integration of Eq. (1) at basic calculations we use the trapezoidal rule with very small time increments ($\Delta t = 0.001$). A further reduction of time increments does not practically affect the numerical results for the meshes used; i.e., the error in time is very small and can be neglected.

Figs. 5 and 6 show the distribution of the axial velocity along lines EF and AB at observation time $T = 7$. Similar to the previous 1-D impact problem, the numerical results after basic computations with the standard mass and stiffness matrices and the formulations with reduced numerical dispersion contain spurious oscillations; see Fig. 5. Fig. 6 shows the convergence of numerical results at mesh refinement after the filtering stage for the cases of the modified integration rule and the averaged mass matrix (these results do not contain spurious oscillations).

Figure 5: The distribution of the axial v_z (curves 1, 2, 3) velocity components along lines EF (a) and AB (b) (see Fig. 4) after basic computations at time $T = 7$ on a uniform mesh with $20 \times 20 \times 40 = 16000$ linear $Q8$ finite elements. The Poisson's ratio is $\nu = 0.3$. Curves 1, 2 and 3 correspond to the numerical solutions obtained by the use of the modified integration rule, the averaged mass matrix with $\gamma = 0.5$ and the consistent mass matrix, respectively.

The difference between the numerical results obtained with the modified integration rule and with the averaged mass matrix is small and can be neglected compared with the change in the numerical results at mesh refinement; see Fig. 6. Fig. 6 also shows that for the selected observation time $T = 7$, the use of the modified integration rule (or the averaged mass matrix) reduces the number of degrees of freedom by a factor of 8 (see curves 3, 4 and 5 in Fig. 6). Similar to the 1-D case, the size of the time increments at post-processing calculated by Eqs. (13) - (15) allows the quantitative estimation of the advantage of the modified integration rule (or the averaged mass matrix) compared with the consistent mass matrix. For example, for a uniform mesh with $10 \times 10 \times 20 = 2000$ finite elements and the modified integration rule (or the averaged mass matrix), the size of the time increments at the filtering stage is $\Delta t_1 = 0.084951$ according to Eqs. (13) - (15). For a uniform mesh with $20 \times 20 \times 40 = 16000$ finite elements and the consistent mass matrix, the size of the time increments at the filtering stage is $\Delta t_2 = 0.091410$ according to Eqs. (13) - (15). Because Δt_2 is close to Δt_1 , then curves 3, 4 and 5 in Fig. 6 are close to each other (curves 3, 4 are slightly more accurate because Δt_1 is slightly smaller than Δt_2 ; see also curves 1 and 2 for the numerical solutions on a finer mesh).

4 CONCLUDING REMARKS

Two dispersion reduction techniques for linear finite elements has been applied to the to 1-D and 3-D impact problems, along with the filtering technique developed in our previous papers [11, 12, 13]. The considered finite element formulations with reduced numerical dispersion increase the accuracy of numerical solutions for elastodynamics problems; however, they do not remove all spurious high-frequency oscillations for wave propagation problems. These spurious oscillations make it difficult to estimate the effectiveness of the finite element formulations with reduced numerical dispersion applied to engineering elastodynamics problems. In the paper, this issue has been overcome by the use of the two-stage time-integration technique with the filtering stage [11, 12, 13], which identifies and removes spurious oscillations. Despite the fact that the modified integration rule yields a smaller numerical dispersion error compared with that for the averaged mass matrix, the numerical results after the filtering stage show that the difference between the numerical solutions obtained with the modified integration rule and with the averaged mass matrix is small and can be neglected compared with the change in

Figure 6: The distribution of the axial v_z (curves 1, 2, 3) velocity components along lines EF (a) and AB (b) (see Fig. 4) after post-processing at time $T = 7$. The Poisson's ratio is $\nu = 0.3$. Curves 1, 2, 5 and 3, 4 correspond to the numerical solutions on uniform meshes with $20 \times 20 \times 40 = 16000$ and $10 \times 10 \times 20 = 2000$ linear $Q8$ elements, respectively. The modified integration rule (curves 1 and 3), the averaged mass matrix with $\gamma = 0.5$ (curves 2 and 4) and the consistent mass matrix (curves 5) are used.

the numerical results at mesh refinement. The numerical results after the filtering stage also show that compared with the use of linear finite elements with the consistent mass matrix and the standard stiffness matrix, the finite element formulations with reduced numerical dispersion reduce the number of degrees of freedom for uniform meshes by a factor of $n = 2 \sim 3$ in the 1-D case and $n = 8 \sim 27$ in the 3-D case depending upon the material properties and the observation time. This leads to a huge reduction in computation time, especially for multi-dimensional elastodynamics problems. We should also mention that for the standard mass and stiffness matrices, quadratic finite elements yield more accurate results than linear elements; e.g., see [3, 13] and the numerical results in Section 3.1. However, the linear elements with reduced dispersion are more accurate than the quadratic elements with the standard mass and stiffness matrices. It is interesting to note that the range of frequencies in numerical solutions after the filtering stage is indirectly determined by the size of the time increments calculated by Eqs. (13) - (15) (see the Appendix). Numerical experiments show that if for uniform meshes with different numbers of degrees of freedom and with different types of finite elements, the time increments calculated according to Eqs. (13) - (15) are close to each other then the numerical solutions obtained on these meshes after the filtering stage are close to each other as well. This means that Eqs. (13) - (15) allow the quantitative estimation of the effectiveness of the finite element formulations with reduced numerical dispersion compared with the standard mass and stiffness matrices (the effectiveness is different for different observation times).

Appendix. The implicit TCG method for filtering spurious high-frequency oscillations and the selection of the minimum necessary amount of numerical dissipation

Let us describe the implicit TCG method with large numerical dissipation suggested in [12, 13] that is used for the step-by-step time integration of the semi-discrete elastodynamics equations (1) at the filtering stage of the two-stage time-integration technique. The method is based on the linear approximations of displacements $U(t)$ and velocities $V(t)$ within a time

step Δt ($0 \leq t \leq \Delta t$)

$$\mathbf{U}(t) = \mathbf{U}_0 + \mathbf{U}_1 t, \quad \mathbf{V}(t) = \mathbf{V}_0 + \mathbf{V}_1 t, \quad (7)$$

and has the first order of accuracy. Here \mathbf{U}_0 and \mathbf{V}_0 are the known initial nodal displacements and velocities, and the unknown nodal vector \mathbf{V}_1 can be expressed in terms of the unknown nodal vector \mathbf{U}_1 as follows:

$$\mathbf{V}_1 = \frac{1}{a_1} \mathbf{U}_1 - \frac{1}{a_1} \mathbf{V}_0. \quad (8)$$

Finally, the following system of algebraic equations is solved for the determination of \mathbf{U}_1

$$(\mathbf{M} + a_1 \mathbf{C} + a_1^2 \mathbf{K}) \mathbf{U}_1 = -a_1 \mathbf{K} \mathbf{U}_0 + \mathbf{M} \mathbf{V}_0 + \mathbf{R}_1, \quad (9)$$

where

$$a_1 = \frac{m+2}{m+3} \Delta t, \quad (10)$$

$$\mathbf{R}_1 = \frac{(m+2)^2}{(m+3)\Delta t^{m+1}} \int_0^{\Delta t} \mathbf{R}(t) t^{m+1} dt. \quad (11)$$

The parameter m is responsible for the amount of numerical dissipation. After the calculation of \mathbf{U}_1 from Eq. (9), the values of displacements and velocities at the end of a time increment Δt are calculated using Eqs. (7) and (8) for $t = \Delta t$:

$$\mathbf{U}(\Delta t) = \mathbf{U}_0 + \mathbf{U}_1 \Delta t, \quad \mathbf{V}(\Delta t) = \mathbf{V}_0 + \mathbf{V}_1 \Delta t. \quad (12)$$

The maximum numerical dissipation corresponds to $m = \infty$. For the case $m = \infty$, the parameter $a_1 = \Delta t$, and \mathbf{R}_1 should be calculated analytically; see Eqs. (11). However, in order to avoid the analytical calculation of \mathbf{R}_1 at $m = \infty$, a value $m \geq 15$ can be used in computations (the difference in numerical dissipation for $m = \infty$ and $m \geq 15$ is not very essential). Numerical examples show that the first-order accurate implicit TCG method suppresses spurious high-frequency oscillations for 10 time steps and retains good accuracy of a numerical solution at low modes. In order to have a numerical solution before and after the filtering stage at the same observation time, the first five uniform time increments are taken positive, and the last five uniform time increments are taken negative (the boundary conditions and external forces are zero during the filtering stage).

For the selection of minimum necessary amount of numerical dissipation for filtering spurious oscillations, a special calibration procedure was developed in [13]. The procedure was based on the analysis of spurious high-frequency oscillations for the 1-D impact problem for which the analytical solution is known (see [12, 13] for details). The following empirical formula for the selection of time increments for an implicit time-integration method with large numerical dissipation (the size of a time increment is related to the amount of numerical dissipation) is suggested in [12, 13] for 1-D elastodynamics problems:

$$\Delta t = \alpha(N_1) \frac{\Delta x \Omega_{0.1}(N)}{c}, \quad (13)$$

where $c = c_o = \sqrt{\frac{E}{\rho}}$ is the wave velocity; Δx is the size of a finite element; $\Omega_{0.1}(N)$ is the value of $\Omega = w\Delta t$ at which the spectral radius has the value 0.1 for the selected number N of time

increments; w is the frequency of vibration for a system with a single degree of freedom; $\Omega_{0.1}$ is used to scale spectral radii calculated at different numbers of time increments N ; $\alpha(N_1)$ is the empirical coefficient depending on the time-integration method, the order of finite elements, and on the number N_1 of elements which are passed through by the wave front (this number can be expressed as $N_1 = \frac{cT}{\Delta x}$; see [12, 13]). For example, for the first-order implicit TCG method ($m = 15$), the following explicit expression is suggested in [13] for the coefficient $\alpha(N_1)$:

$$\alpha\left(\frac{cT}{\Delta x}\right) = a_1 \left(\frac{cT}{\Delta x}\right)^{a_2}. \quad (14)$$

The coefficients a_1 and a_2 for linear and quadratic elements with the consistent mass matrix are calculated in [13]. Using the calibration procedure described in [13], we found the following coefficients for linear elements with the averaged ($\gamma = 0.5$) mass matrix: $a_1 = 0.2942$ and $a_2 = 0.2104$ (see [14]); for linear elements with the standard consistent mass matrix: $a_1 = 0.2986$ and $a_2 = 0.3461$ (see [13]); for quadratic elements with the standard consistent mass matrix: $a_1 = 0.1948$ and $a_2 = 0.234$ (see [13]).

For the selection of the size of time increments for the filtering stage of 2-D and 3-D problems, the following modification of Eq. (13) can be used

$$\begin{aligned} \Delta t &= \max_{i,j} \left[\alpha\left(\frac{c_i T}{\Delta x_j}\right) \frac{\Delta x_j}{c_i} \right] \Omega_{0.1}(N) = \max_{i,j} \left[\frac{\Delta x_j}{c_i} \right]^{1-a_2} a_1 T^{a_2} \Omega_{0.1}(N) \\ &= \left[\frac{\max_j \Delta x_j}{\min_i c_i} \right]^{1-a_2} a_1 T^{a_2} \Omega_{0.1}(N) = \left[\frac{\Delta x_{max}}{c_2} \right]^{1-a_2} a_1 T^{a_2} \Omega_{0.1}(N), \end{aligned} \quad (15)$$

where $c_2 = \min_i c_i$ ($i = 1, 2$) is the minimum value between the velocities of the compressional wave $c_1 = \sqrt{\frac{\lambda+2\mu}{\rho}}$ and the shear wave $c_2 = \sqrt{\frac{\mu}{\rho}}$, $\Delta x_{max} = \max_j \Delta x_j$ is the maximum dimension of finite elements along the axes x_j ($j = 1, 2$ for 2-D problems and $j = 1, 2, 3$ for 3-D problems). Eq. (15) is based on Eqs. (13) and (14) with the selection of the maximum size of a time increment with respect to the compressional and shear waves, and the dimensions of a finite element along the coordinate axes. For 2-D and 3-D uniform meshes with linear quadrilateral elements, we use the coefficients a_1 and a_2 obtained for the 1-D case; see Eq. (14). As shown in [12], Eq. (15) is the necessary condition for the selection of the amount of numerical dissipation in the multi-dimensional case.

Abstract. *In this paper we study numerically different methods to impose contact constraints in explicit dynamics. The traditional methods, the penalty method and the more recent forward increment Lagrange multiplier method, are compared, in their performance and accuracy, to a direct elimination method based on the theory of manifolds. The idea of the method is that when a contact constraint is active the solution lies on the boundary of the contact manifold generated by contact constraints. Then the contact problem can be solved with the elimination of additional degrees of freedom. This elimination technique can be viewed as a parameterization of the contact manifold. We show numerically that in the case of a rigid impactor, the elimination method is highly more efficient than the forward Lagrange multiplier method since the latter leads to a coupled system of equations for solving the Lagrange multipliers while both methods produce similar results. In the present work the elimination method is also developed for the impact problem of deformable bodies and the performance of the different methods are compared in numerical simulations of the longitudinal impact of thick bars. The modified Euler method is employed in solving the equations of motion in time.*

1 INTRODUCTION

The traditional method to impose contact constraints in explicit transient dynamics is the penalty function method. It is, however, an approximate method and has an adverse effect on the numerical stability of explicit integration. For this reason, Carpenter et al. [1] introduced a modification of Lagrange multiplier method, called Forward Increment Lagrange Multiplier method (FILM), which is compatible with explicit time integrators and does not affect the stability of integration. The idea of the method is to refer the kinematic contact constraints one time step ahead of the equations of motion and the Lagrange multipliers. With general contact interfaces, this method leads to a coupled system of equations for the Lagrange multipliers. Therefore, if the number of contact pairs is large it is not effective.

In this paper we present an alternative and efficient method for impact modeling in explicit transient dynamics. The method, called here DME (Direct Manifold Elimination method) is based on the theory of manifolds. Contact constraints, i.e. the displacement inequalities, generate a constraint manifold with a boundary [2]. When a contact constraint is active the solution lies on the boundary of the contact manifold. This method was employed by Saksala & Mäkinen [3] in case of a rigid piston impacting an elasto-viscoplastic damaging domain. In that case, the contact constraints, i.e. the impenetrability conditions between the piston node and rock surface nodes, were eliminated. In the present paper, this formulation is also performed in the case of a deformable impactor and the node-to-node contact interface.

The developed technique is implemented in 2D (axisymmetric) case. In the numerical examples involving impacts between linear elastic bodies and dynamic indentation by a rigid indenter, the accuracy and efficiency of the manifold method is compared to the penalty function method and the forward increment Lagrange multiplier method. The modified Euler explicit integrator is used for solving the FE discretized equations of motion in time.

2 IMPOSITION OF CONTACT CONSTRAINTS

In this section we describe the traditional methods, the penalty method and the more recent forward increment Lagrange multiplier method, as well as the manifold method to impose kinematic contact constraints in explicit time integration setting. The background for the manifold method is elaborated only to the level required for understanding how the method arises. Linear elasticity and small displacements are assumed for simplicity.

2.1 Modified Euler method for explicit time integration

The explicit modified Euler time integrator is chosen for solving the equations of motion. The response of the system using this method is computed by [4]:

$$\begin{aligned}\ddot{\mathbf{u}}^t &= \mathbf{M}^{-1}(\mathbf{f}_{\text{ext}}^t - \mathbf{C}\dot{\mathbf{u}}^t - \mathbf{f}_{\text{int}}^t) \\ \dot{\mathbf{u}}^{t+\Delta t} &= \dot{\mathbf{u}}^t + \Delta t \ddot{\mathbf{u}}^t \\ \mathbf{u}^{t+\Delta t} &= \mathbf{u}^t + \Delta t \dot{\mathbf{u}}^{t+\Delta t}\end{aligned}\tag{1}$$

where \mathbf{M} is the lumped mass matrix, \mathbf{C} is the damping matrix (set zero here), \mathbf{f}_{int} , \mathbf{f}_{ext} are the internal and external force vectors, respectively, and \mathbf{u} is the displacement vector while a dot above it denotes time derivative.

2.2 Forward increment Lagrange multiplier and penalty method

The classical Lagrange multiplier method is incompatible with explicit time integrators. For this reason, Carpenter et al. [1] introduced a modification, called here forward increment

Lagrange multiplier method, which is compatible with explicit methods. The idea of the method is to refer the kinematic contact constraints one time step ahead of Lagrange multipliers as:

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{u}}^t + \mathbf{C}\dot{\mathbf{u}}^t + \mathbf{f}_{\text{int}}^t &= \mathbf{f}_{\text{ext}}^t - \mathbf{G}^T \boldsymbol{\lambda}^t \\ \mathbf{G}\mathbf{u}^{t+\Delta t} - \mathbf{b} &= \mathbf{0} \end{aligned} \quad (2)$$

where \mathbf{b} is the vector containing the initial distances between the contact node pairs (which are known in advance), \mathbf{G} is the kinematic contact constraint matrix consisting, usually, of the normal vectors of the contact surfaces, and $\boldsymbol{\lambda}$ is the Lagrange multiplier vector having the physical interpretation of contact forces. On substituting (1) into (2) gives, after some algebra:

$$\begin{aligned} \ddot{\mathbf{u}}^t &= \tilde{\ddot{\mathbf{u}}}^t - \mathbf{M}^{-1} \mathbf{G}^T \boldsymbol{\lambda}^t \\ \dot{\mathbf{u}}^{t+\Delta t} &= \dot{\mathbf{u}}^t + \Delta t \ddot{\mathbf{u}}^t \\ \mathbf{u}^{t+\Delta t} &= \mathbf{u}^t + \Delta t \dot{\mathbf{u}}^t + \frac{\Delta t^2}{2} \ddot{\mathbf{u}}^t \end{aligned} \quad (3)$$

where

$$\begin{aligned} \tilde{\ddot{\mathbf{u}}}^t &= \mathbf{M}^{-1} (\mathbf{f}_{\text{ext}}^t - \mathbf{C}\dot{\mathbf{u}}^t - \mathbf{f}_{\text{int}}^t) \\ \tilde{\mathbf{u}}^{t+\Delta t} &= \mathbf{u}^t + \Delta t \dot{\mathbf{u}}^t + \frac{\Delta t^2}{2} \tilde{\ddot{\mathbf{u}}}^t \\ (\Delta t^2 \mathbf{G} \mathbf{M}^{-1} \mathbf{G}^T) \boldsymbol{\lambda}^t &= \mathbf{G} \tilde{\mathbf{u}}^{t+\Delta t} - \mathbf{b} \rightarrow \boldsymbol{\lambda}^t \end{aligned} \quad (4)$$

This method belongs to the class of predictor-corrector methods in that, first, the acceleration and displacement of the system are predicted as if there were no contacts. Then, the contact forces are solved based on the virtual penetration. Finally, the acceleration is corrected by subtracting the contribution of the contact forces and the response of the system is updated.

It should be noted that this method is fully explicit only when the node-to-node contact interface is used. In this case, with the lumped mass matrix, the equations for solving the Lagrange multipliers in (4) are uncoupled, i.e. matrix $\Delta t^2 \mathbf{G} \mathbf{M}^{-1} \mathbf{G}^T$ is diagonal. With more general contact interfaces a coupled system of equations must be solved. Thus, computational efficiency of this method considerably depends on the type of contact interface. The efficiency can be, however, greatly increased, at the expense of accuracy and stability however, if the Penalty method is employed in the contact force calculation. Accordingly, the third equation in (4) and Lagrange multiplier in (3) is replaced by

$$\mathbf{f}_{\text{cont}}^t = p (\mathbf{G} \tilde{\mathbf{u}}^{t+\Delta t} - \mathbf{b}) \quad (5)$$

where p is the problem dependent penalty coefficient. Other equations go unaltered.

2.3 Direct elimination method based on theory of manifolds

Different kinematic relations of constraint equations are shown in Figure 1, where geometric constraints include all holonomic and the unilateral constraints, which are given by inequality equations with the function of time and a generalized place vector only. Unilateral constraints arise when modeling a kinematic relation between bodies in contact.

Contact constraints, i.e. the displacement inequalities, generate a contact manifold with a boundary. When a contact constraint is active the solution lies on the boundary of the contact manifold. Next, the formal definition of the contact manifold is given.

Figure 1: Geometric interpretation of constraints.

Definition for contact manifold: The geometric constraint equations induce a d -manifold that is defined by:

$$\mathbf{M} := \{ \mathbf{t} \times \mathbf{u} \in \mathbf{R} \times \mathbf{E}^n \mid \mathbf{h}(\mathbf{t}, \mathbf{u}) \leq \mathbf{0} \in \mathbf{E}^{n-d} \} \quad (6)$$

The contact manifold is a d -dimensional smooth manifold with time as 1-parameter family. The contact manifold at fixed time $t = t_0$ is denoted by \mathbf{M}_{t_0} .

In our case, the unilateral constraint equations are simply $\mathbf{h}(\mathbf{t}, \mathbf{u}) = \mathbf{G}\mathbf{u}^t - \mathbf{b}$. The Lagrange multiplier method and the penalty method, described in the previous section, are conventional methods to impose the contact constraints. However, the contact problem can also be solved with the elimination of additional degrees of freedom. This elimination technique can be viewed as a parameterization of the contact manifold.

In the present paper, we have only node-to-node contacts with straight interfaces (lines) between bodies A and B and both bodies can be deformable or one of them can be rigid depending on the application. In both cases, the solution procedure begin with the detection of active contacts by checking the violation of the equation

$$\mathbf{G}\tilde{\mathbf{u}}^{t+\Delta t} - \mathbf{b} \geq \mathbf{0} \quad (7)$$

where the predicted displacement is as in Equation (4). Next, two different schemes to compute the nodal displacements, velocities and accelerations are presented. The first one is for the case in which the other body is rigid, thus representing usually a tool used for indentation, and the second is for the impact of deformable bodies.

Case 1 (B is a rigid body, say a punch): If any contact constraint is active, say i , then this nodal displacement u_i^A of the body A is eliminated by solving the active constraint equation (7) with respect to u_i^A as:

$$\begin{aligned}
 u_i^A &= u_i^B - b_i \\
 \dot{u}_i^A &= \dot{u}_i^B \\
 \ddot{u}_i^A &= \ddot{u}_i^B = \sum f_{\text{tot},i} / M_i
 \end{aligned} \tag{8}$$

where $\sum f_{\text{tot},i}$ and $M_i = \sum m_i$ are the total force and mass related to the active contact constraints, i.e. the summation is over the degrees of freedom of the active constraints i .

Figure 2: Illustration of node-to-node contact interface.

Case 2 (A and B are deformable bodies): When an active contact pair, say i , is detected according to Equation (7), the acceleration and displacement in the vertical degrees of freedom (dof_B^i and dof_A^i in Figure 2) of the nodes in contact are calculated as:

$$\begin{aligned}
 \hat{u}_i^B &= \hat{u}_i^A = \frac{1}{2}(u_i^B + u_i^A) \\
 \ddot{u}_i^B &= \ddot{u}_i^A = f_{\text{tot},i} / (m_i^A + m_i^B)
 \end{aligned} \tag{9}$$

where $f_{\text{tot},i} = \mathbf{f}_{\text{tot}}(dof_A^i) + \mathbf{f}_{\text{tot}}(dof_B^i)$ and $m_i^A + m_i^B = \mathbf{M}(dof_A^i) + \mathbf{M}(dof_B^i)$ are the total force and mass related to the active contact pair i with m_i^A and m_i^B being the nodal point masses of the active constraint i for the body A and B, respectively.

As to the velocities, they can be solved from the equations provided by elementary physics of colliding rigid bodies:

$$\begin{aligned}
 m_i^A \dot{u}_i^A + m_i^B \dot{u}_i^B &= m_i^A \hat{u}_i^A + m_i^B \hat{u}_i^B \\
 e(\dot{u}_i^A + \dot{u}_i^B) &= \hat{u}_i^A + \hat{u}_i^B
 \end{aligned} \tag{10}$$

where e is the coefficient of restitution with $e = 1$ for elastic collision and $e = 0$ for perfectly inelastic collision. By the elimination technique presented, the degrees of freedom of the problem reduce by one for each active constraint.

Finally, the detection of separation of the active contact constraint can be examined via the nodal internal forces. The separation occurs when the nodal internal force is a tractive force. The tractive force converts the active constraint inactive.

3 NUMERICAL EXAMPLES

In this section the performance of the different methods to impose contact constraints are compared in numerical simulations involving low-velocity impact. First, the performance of the manifold method is demonstrated in the rigid punch indentation problem with varying number of contact constraints. Then, the problem of longitudinal impact of thick cylindrical bars is simulated and the accuracy of the methods is compared with each other and to the analytical solution as well. The material is assumed rigid and/or linear elastic. All the simulations are performed with self-written Matlab (64-bit 2009a version) codes using a Windows Vista pc equipped with 2.60 GHz AMD Phenom™ II X3 710 processor and 8.0 GB of RAM.

3.1 Rigid punch indentation problem

The indentation problem with a rigid punch described in Figure 3 is solved with the FILM, DME and Penalty methods. Axisymmetry of the problem is exploited and CST elements are used in the mesh. The material of the indented domain is linear elastic. The punch is assumed rigid while it is modeled as a single node.

Figure 3: Indentation with a rigid punch.

The external stress pulse, $\sigma(t)$, is used to simulate the impact of the rigid punch to the deformable domain B . As multiplied by the cross sectional area of the indenter A_{punch} , an external force, F_{ext} , to be applied to the punch node is obtained. Moreover, the force that resists the punch penetration into domain B , the contact force F_{punch} , needs to be solved during the solution process. Thus, the equation of motion for the punch node, with its motional degrees of freedom $u_{p,x}$, $u_{p,z}$, to be added to the FE discretized equation of motion, can be written as:

$$m_p \ddot{u}_{p,z} = F_{\text{ext}} - F_{\text{punch}} \quad (11)$$

where m_p is a computational mass attached to the punch node. The value of this mass must be small enough so that it doesn't affect the solution and big enough to maintain the mass matrix well-conditioned.

The geometry of the punch (indenter) is defined as b_i , i.e. the distances between the punch node and the contact nodes on the indented domain boundary. Thus, using the notation in Figure 3, the kinematic contact constraints can be written in form:

$$u_{c,z} - u_{p,z} = b_i \quad (12)$$

Equations of this form are written for all contact nodes and, consequently, the constraint equation of form $\mathbf{Gu} = \mathbf{b}$ is obtained. As there is only one DOF (friction is not taken into account) associated to the punch node, the system of constraint equations is coupled. This system is solved (when using the FILM method) using the Matlab backslash operation. The contact computations are performed as explained in Section 2.

Next, the problem described in Figure 3 is simulated with varying number of contact constraints (achieved easily by different values of radius R_z) using the mesh consisting of 22060 CST elements shown in Figure 4.

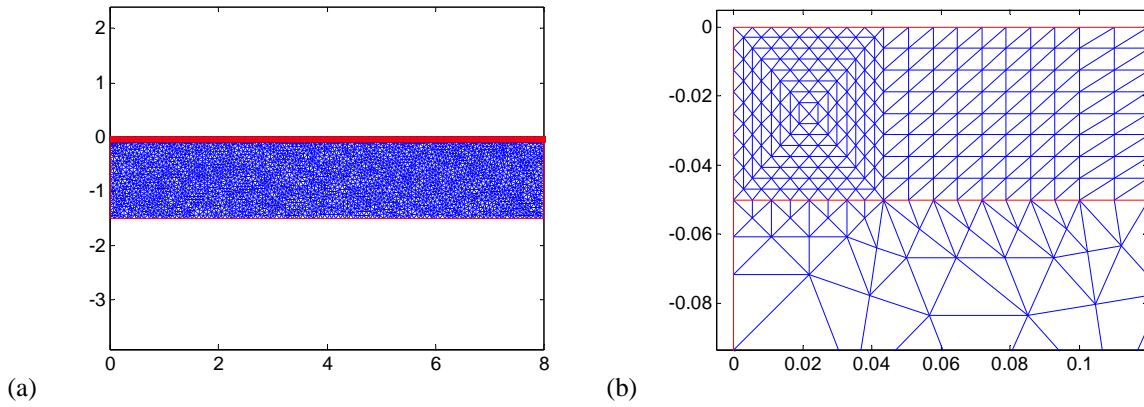

Figure 4: CST mesh (a) and a detail (b).

The material parameters are: $E = 200$ GPa, $\nu = 0.3$ and $\rho = 7850$ kg/m³. A computational mass of 0.1 kg is used for the punch node mass m_p . A time step $\Delta t = 3.64 \times 10^{-7}$ s is chosen to keep the computations stable. Three different simulations are carried out in what follows, corresponding to three different number of contact constraints: Sim1 with 107 ($R_z = 1$ m), Sim2 with 308 ($R_z = 3$ m) and Sim3 with 610 ($R_z = 6$ m) contact constraints. The analysis time is $400\Delta t = 1.457 \times 10^{-4}$ s. The stress pulse amplitude is 200 MPa while its duration, rise and descent times are 1×10^{-4} s, 1×10^{-5} s, respectively. The results of the simulations for Sim1 are presented in Figure 5.

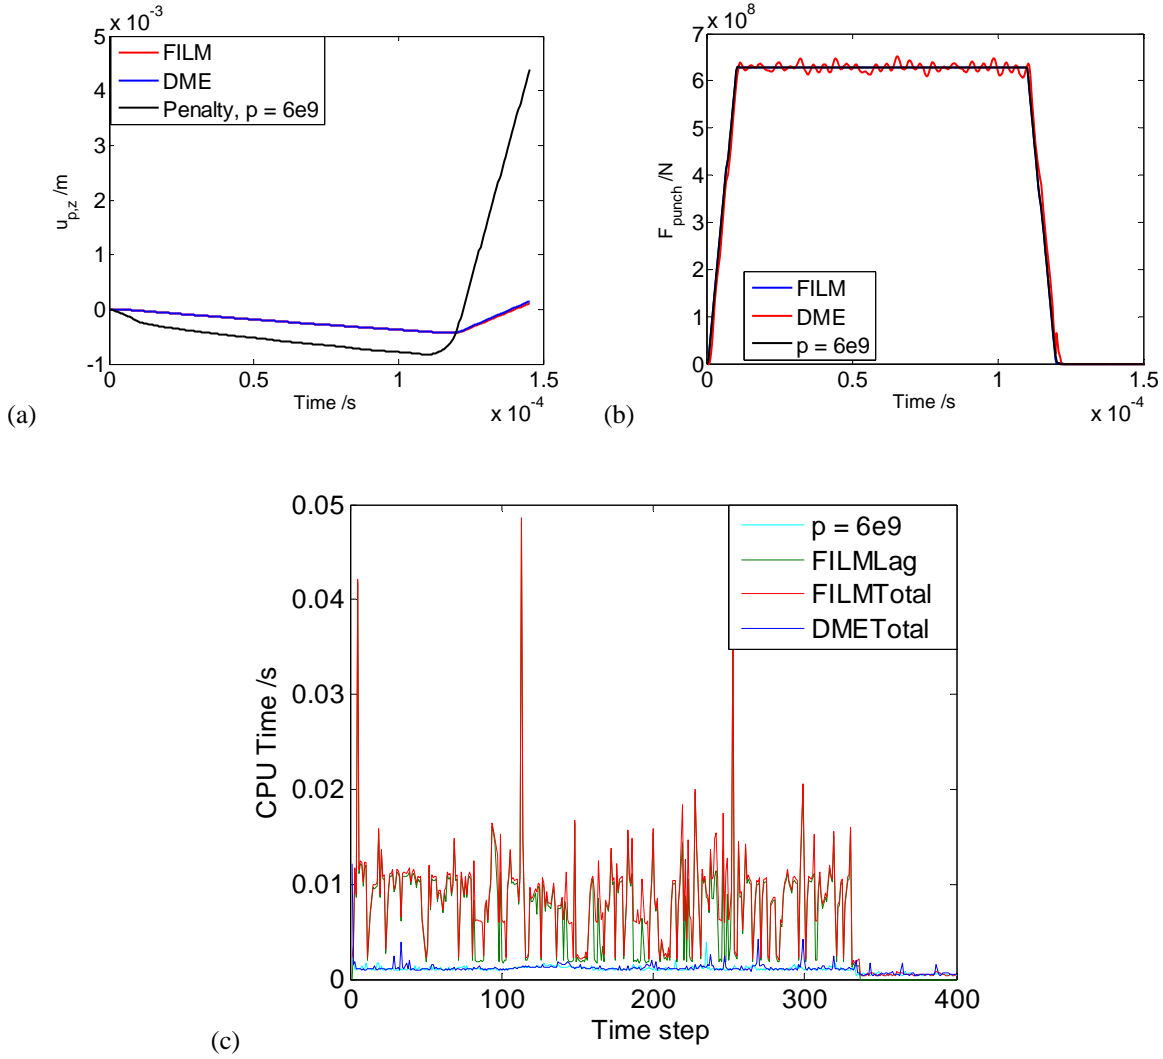

Figure 5: Punch penetration (a), contact force (b) and CPU times for contact solution (c) in Sim1.

According to Figure 5a the FILM and DME (Case 1) methods produce equal punch displacement during loading phase but slight, barely noticeable difference occurs during unloading. In contrast, the vertical displacement by Penalty method deviates considerably from the other methods. The value $p = 6 \times 10^9$, found by trial and error, gave the best results in this problem. The force resisting penetration, F_{punch} , is also quite similar to all methods besides the oscillations seen in the DME curve in Figure 5b. As for the CPU times (measured by Matlab tic function), it is seen that the time spend for contact computations by the DME and Penalty methods (DMETotal and $p = 6e9$) is about half of the lowest times by the FILM method. Moreover, most of the total time used by the FILM method is consumed in solving for the Lagrange multipliers from Equation (4), (compare the FILMLag and FILMTotal curves in Figure 5c). Finally, the FILM method displays heavy variations in CPU times which are attested by the high peaks in Figure 5c. Next, the results for Sim2 and Sim3 are shown in Figure 6.

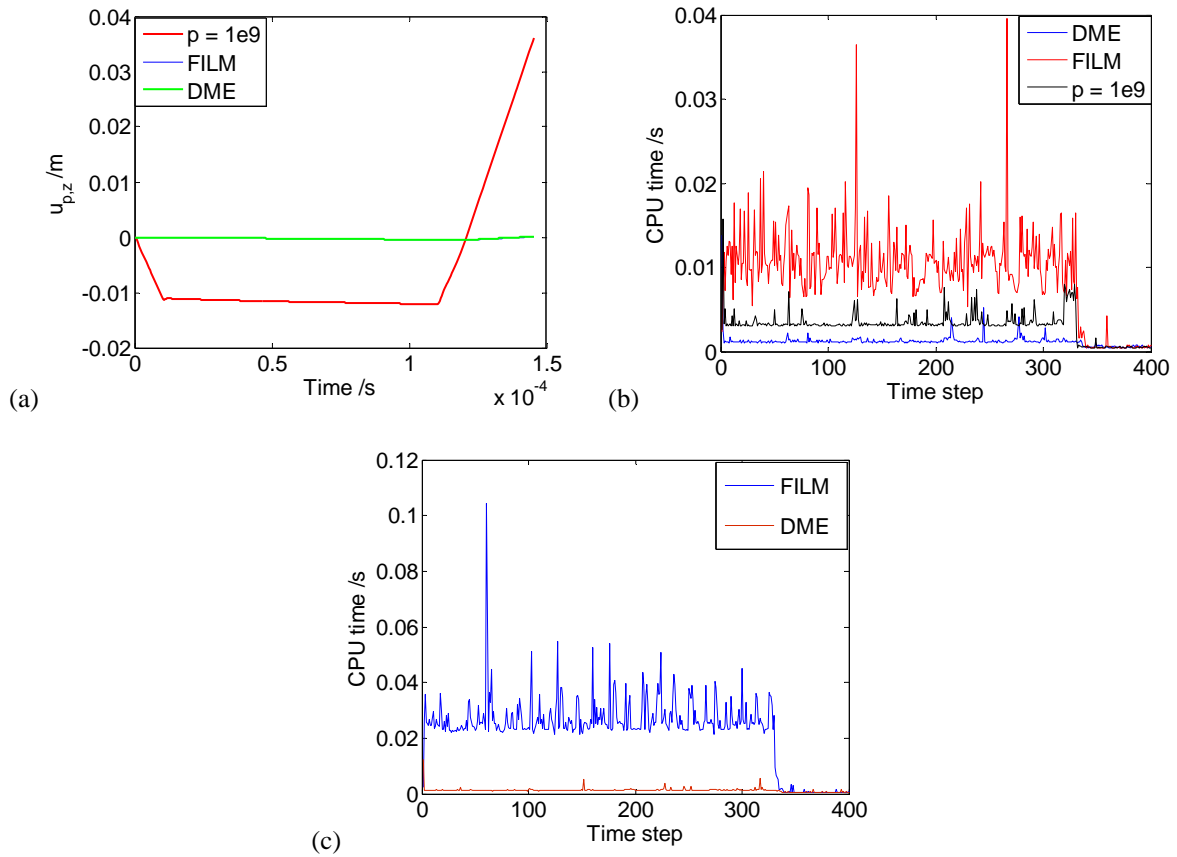

Figure 6: Punch penetration (a) and CPU times (b) in Sim2, and CPU times for contact solution (c) in Sim3

As the number of contact constraints increase, the Penalty method becomes more ill-behaving as seen in Figure 6a. In fact, no value of penalty coefficient giving reasonable results for punch displacement, $u_{p,z}$, was found in Sim3, i.e. when the number of contact constraints is 610. This deficiency of the penalty method is related to the relatively long contact interface in this problem: a value of the penalty coefficient giving good results close to the axis of symmetry is far too small, by many orders of magnitude, further away from it.

As to the CPU times spent in the contact computations, the DME method is clearly the most efficient one. Indeed, in Sim3, see Figure 6c, it is at least 20 times faster than the FILM method. It is also twice as fast as the Penalty method, as seen in Figure 6b.

In this specific problem, having 23036 DOFs, the second most time consuming operation during a time step is the computation of the internal force vector by $\mathbf{f}_{int} = \mathbf{K}\mathbf{u}$ where \mathbf{K} is the global linear elastic stiffness (sparse) matrix. In the present simulations this time varied between 1 to 2 ms which is approximately of the same magnitude as the time needed to perform the contact computations with the DME method. Therefore, the efficiency of contact computations is crucial in this kind of explicit transient elasto-dynamics involving contact-impact.

3.2 Longitudinal impact of cylindrical bars

The problem of longitudinal impact of thick cylindrical bars described in Figure 7a is solved with the FILM, DME and Penalty methods in order to compare their performance. Axisymmetry of the problem is exploited and CST mesh shown for the left bar in Figure 7b is used. Relatively coarse mesh, with 406 for the left and 426 elements for the right bar is used.

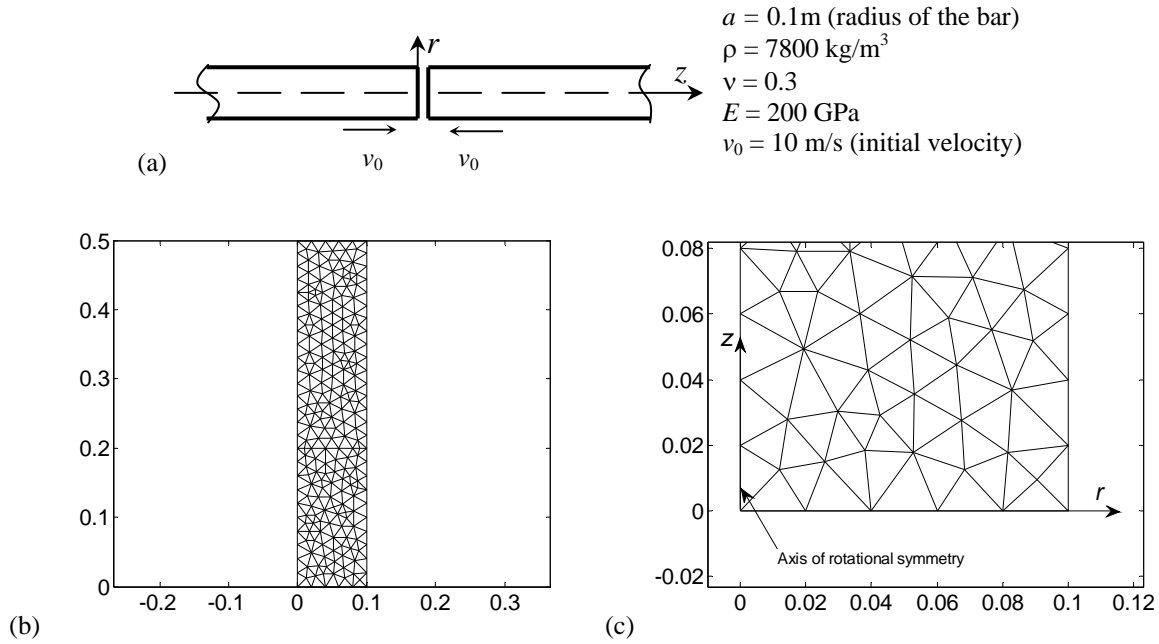

Figure 7: Longitudinal impact of thick bars (a), the CST mesh (b) and a detail (c).

The node-to-node contact interface is employed here and the contact computations are performed as explained in Section 2. The number of contact pairs is very small, 6 pairs, which is insignificant from the computational point of view. A time step $\Delta t = 1 \times 10^{-6}\text{ s}$ is chosen to keep the computations stable. As the matrix $\Delta t^2 \mathbf{G} \mathbf{M}^{-1} \mathbf{G}^T$ is diagonal for the node-to-node contact interface, the average of its entries, 1.19×10^{10} , is taken for the penalty parameter. In the results in Figures 8-10, the gap computed as $\mathbf{G} \mathbf{u}^t - \mathbf{b}^t$ and contact forces are plotted at the contact nodes as a function of time for different methods.

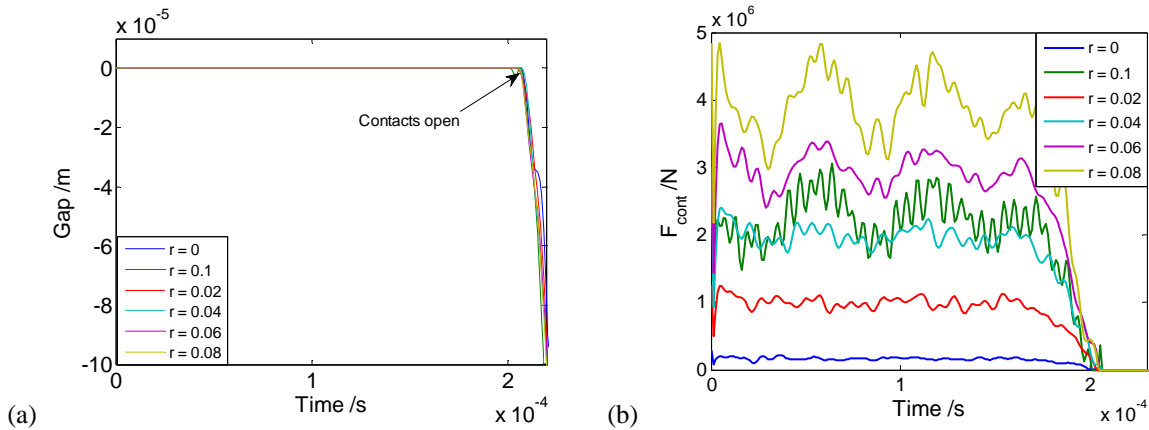

Figure 8: Simulation results with FILM method: gap (a), and contact forces (b).

According to the results in Figure 8, the impenetrability condition is accurately satisfied, i.e. the gap is zero all the time bars are in contact, with the FILM method. As the stress waves reflected at the free ends of the bars reach the contact surfaces, the contacts open and bars start to retreat. This event is indicated in Figure 8a. Next, the same results are presented for the Penalty method in Figure 9.

Figure 9: Simulation results with Penalty method ($p = 1.19 \times 10^{10}$): gap (a), and contact forces (b).

As expected, the Penalty method does not satisfy the impenetrability condition. Indeed, penetration occurs and the contact force is based on this penetration. Finally, the same results are presented for the DME method with the perfectly inelastic collision scheme ($e = 0$) in Figure 10.

Figure 10: Simulation results with DME method: gap (a), and contact forces (b).

The results for the DME method with the perfectly inelastic collision assumption satisfy the impenetrability condition accurately, as attested by the zero gap values (see Figure 10a) until the arrival of the stress wave reflected from the free end of the bar. The contact forces in Figure 10b are somewhat similar to those produced with the FILM method.

Next, the methods are compared to the analytical solution of the problem by Valeš et al. [5]. The dimensionless axial stress at the location $r = 0.1$ m and $z = 0.2$ m, a location close enough to the contact surfaces so that the differences in the results between the methods are still visible (and not smoothed too much by the Saint-Venant principle). In addition, the different schemes for calculating the velocity of contact nodes with the DME method, Equation (10), are compared. The results are shown in Figure 11.

Figure 11: Analytical solution for dimensionless axial stress [5] (a), simulation results with different methods (b) and results with different velocity schemes of DME method (c).

As seen in Figure 11b, the axial stress predicted with the FILM and DME ($e = 0$) methods are identical. The result with the elastic collision scheme for velocity (DME, $e = 1$) deviates slightly from these. These methods predict the analytical solution with a good accuracy. For example, the arrivals of the different wave types are clearly identifiable in the numerical results as well. In contrast, the Penalty method with the value $p = 1.19 \times 10^{10}$ is quite poor when compared to the analytical solution. With the higher value, $p = 5 \times 10^{10}$, the Penalty method seems to perform slightly better first but then, after time station $c_1 t/a = 5$, overshooting oscillations develop in the response. Moreover, this value provided poor results at the contact nodes.

4 CONCLUSIONS

- Different methods, including the forward increment Lagrange multiplier method (FILM), the Penalty method and the direct manifold elimination method (DME), to impose contact constraints in transient explicit dynamics were numerically compared in this paper.
- A method based on direct elimination of the contact constraints was developed and tested for the node-to-node contact interface. The theoretical background of the method based on the theory of manifolds was elaborated with some detail.
- In the numerical simulation of the indentation problem with a rigid punch, the DME method was found to be overwhelmingly more efficient than the FILM method while both methods provided similar results. As to the Penalty method, while efficient, it failed to produce reasonable results when the contact interface was relatively wide. It is more suitable for point-like contact problems. Moreover, the Penalty method has an adverse effect on the numerical stability of the explicit integration and the problem specific pain to find the correct value of the parameter.

- In the impact problem of longitudinal bars, the FILM and DME methods predicted the analytical solution for axial stress with a good accuracy. These methods, the DME with the perfectly inelastic collision assumption, satisfied the impenetrability condition accurately and predicted identical results for axial stress. In contrast, the results with the Penalty method deviated from the analytical solution and from the other methods as well.
- Due to its efficiency and accuracy, the DME method can be regarded as superior to the FILM method in problems where the FILM method requires a solution of coupled system of equations for the Lagrange multiplier. These problems include the rigid punch indentation simulated in this paper and problems with a more general contact interface.
- In the future developments of the DME method, it will be formulated for more general node-to-segment contact interfaces.

Abstract. Near-fault ground motions are characterized by high values of the ratio α_{PGA} between the peak value of the vertical acceleration, PGA_V , and the analogous value of the horizontal acceleration, PGA_H , which can notably modify the axial force demand in columns (e.g. producing both tension and high compressive forces larger than the balanced force) and the bending moment demand in girders (e.g. plastic hinges are expected along the span of r.c. girders, especially in the upper storeys). At present, the Italian seismic code (NTC08) does not consider the effects of near-fault ground motions in the design of a r.c. framed structure. In order to check the effectiveness of current code provisions, six- and twelve-storey r.c. spatial framed structures are designed according to the provisions of NTC08, considering the horizontal seismic loads acting alone or in combination with the vertical ones. A numerical investigation is carried out considering the nonlinear response of the test structures subjected to horizontal and vertical accelerograms, representative of near-fault ground motions with different values of the acceleration ratio α_{PGA} . A lumped plasticity model (LPM) based on the Haar-Kàrmàn principle is proposed to model the inelastic behaviour of the r.c. frame members. Specifically, the lumped plasticity model for a column (LPMC) includes a piecewise linearization of the bounding surface of the axial load-biaxial bending moment elastic domain, at the end sections where inelastic deformations are expected. On the other hand, the lumped plasticity model for a girder (LPMG) takes into account the potential plastic hinges along the span, due to the vertical ground motion, modifying the uniaxial plastic moments of the end-sections and so avoiding the computational effort required by the sub-discretization of the frame member.

1 INTRODUCTION

Structural damage of reinforced concrete (r.c.) framed buildings, designed according to recent seismic codes and located in a near-fault area, has been observed during near-fault ground motions [1] and experimentally verified [2]. Generally, the design provisions of current seismic codes are not very accurate for assessing near-fault effects, because only far-fault ground motions are considered. At present, the Italian [3] and European [4] seismic codes do not consider the effects of the vertical component of near-fault ground motions in the design of a r.c. framed structure. These motions are characterized by high values of the ratio between the peak value of the vertical acceleration (PGA_V) and the analogous value of the horizontal acceleration (PGA_H) [5]. More specifically, high values of the acceleration ratio α_{PGA} can notably modify the axial load in r.c. columns, producing undesirable phenomena in these elements [6]: e.g., reduction in the shear capacity, buckling of the longitudinal bars, brittle failure in compression, bond deterioration or failure under tension. Moreover, plastic hinges are expected along the span of the girders, especially if rather long [7], and in the upper storeys, where the effects of the gravity loads generally prevail over those of the horizontal seismic loads and an amplification of the vertical motion is expected [8].

In order to establish if suitable additional code guidelines are needed, it is very important to study the nonlinear response of r.c. spatial frames subjected to near-fault ground motions. The high computational effort required to obtain accurate results by finite elements or fibre models has encouraged the development of simplified approaches [9]. In the present work, a lumped plasticity model (LPM) based on the Haar-Kàrmàn principle is proposed to model the inelastic behaviour of r.c. frame members. Specifically, the lumped plasticity model for a r.c. column (LPMC) includes a piecewise linearization of the bounding surface of the axial load-biaxial bending moment elastic domain, at the end sections where inelastic deformations are expected. Each flat surface corresponds to a plastic strain mechanism for the section, defined by axial strains and curvatures. This type of element represents a good choice for the response simulation of structural members, like columns, that may experience inelastic deformations at the end sections. On the contrary, the lumped plasticity model for a r.c. girder (LPMG) takes into account the potential plastic hinges along the span of the girders, due to the vertical ground motion, modifying the uniaxial plastic moments of the end-sections depending on the top and bottom plastic moments of selected critical intermediate sections and so avoiding the computational effort required by the sub-discretization of the frame member [10].

Six- and twelve-storey r.c. spatial frames are assumed as test structures and designed according to the provisions of the Italian seismic code (NTC08) considering (besides the gravity loads) the horizontal seismic loads acting alone or in combination with the vertical ones. Horizontal and vertical accelerograms, representative of near-fault ground motions with different values of the acceleration ratio α_{PGA} , are considered for the numerical investigation.

2 LUMPED PLASTICITY MODELING

The nonlinear dynamic analysis of a spatial framed structure can be carried out adopting a numerical step-by-step procedure based on an initial stress-like iterative procedure [11]. At each step of the analysis, the elastic-plastic behaviour of a beam element is described using the Haar-Kàrmàn principle, without satisfying nodal equilibrium conditions, once the initial state and the incremental load in the step are known. Then, an implicit two-parameter integration scheme is adopted in order to satisfy the global dynamic equilibrium of the overall structure. Each frame member is modeled by a LPM composed of two parallel elements, one elastic-perfectly plastic and the other linearly elastic, assuming a bilinear moment-curvature ($M-\chi$) law, depending on the axial load in the case of a column. The elastic component is cha-

characterized by the flexural stiffness pEI , p being the hardening ratio of the $(M-\chi)$ law. Torsional strains are assumed to be fully elastic while shear strains are neglected. Distributed masses are considered along the girders to evaluate the influence of the vertical vibrations.

2.1 Frame members in biaxial bending with axial force

The nonlinear behaviour of r.c. structural elements under biaxial bending with axial force is generally based on the knowledge of the bounding surface of the cross-sections, resulting from the plastic moments obtained for different values of the axial force [12]. A lumped plasticity model, labelled as LPMC, is proposed for a r.c. column, assuming that the bounding surface of the elastic domain is described by means of flat surfaces. More specifically, the inelastic deformations, supposed as lumped at the end cross-sections, are represented by the axial strain ε_p , along the longitudinal axis x , and the curvatures χ_{py} and χ_{pz} , along the principal axes y and z , collected in the vector

$$\boldsymbol{\varepsilon}_p = [\varepsilon_p, \chi_{py}, \chi_{pz}]^T \quad (1)$$

and referring to the (geometric) centroid of the cross-section. Denoting the corresponding generalized stresses at the end section by the vector

$$\boldsymbol{\sigma} = [N, M_y, M_z]^T \quad (2)$$

and the plastic stresses, related to $\boldsymbol{\varepsilon}_{pk} = \mathbf{n}_k$, by $\boldsymbol{\sigma}_{pk}$, the elastic domain $g(\boldsymbol{\sigma}) = 0$ can be approximated by n_{fs} flat surfaces $g_k(\boldsymbol{\sigma})$, each defined by a different (normal) direction \mathbf{n}_k .

As suggested in [13], a satisfactory representation of the axial load-biaxial bending moment bounding surface of the elastic domain can be obtained considering 26 flat surfaces, including: 6 surfaces normal to the principal axes x , y and z (Figure 1a); 12 surfaces normal to the bisections of the y - z , x - y and x - z principal planes (Figure 1b); 8 surfaces normal to the bisections of the octants (Figure 1c). The piecewise linearized elastic domain is characterized by the corresponding 26 columns of the matrix

$$\mathbf{N} = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & c_{yx} & c_{yx} & -c_{yx} & -c_{yx} & c_{zx} & c_{zx} & -c_{zx} & -c_{zx} \\ 0 & 0 & 1 & -1 & 0 & 0 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & c_{yz} & c_{yz} & -c_{yz} & -c_{yz} & 0 & 0 & 0 & 0 & 1 & -1 & 1 & -1 \\ c'_{yz} & c'_{yz} & -c'_{yz} & -c'_{yz} & c'_{yz} & c'_{yz} & -c'_{yz} & -c'_{yz} & c'_{yz} & c'_{yz} & -c'_{yz} & -c'_{yz} & c'_{yz} & c'_{yz} & -c'_{yz} & -c'_{yz} & c'_{yz} & c'_{yz} \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ c_{yz} & c_{yz} & c_{yz} & c_{yz} & -c_{yz} & -c_{yz} & -c_{yz} & -c_{yz} & c_{yz} & c_{yz} & c_{yz} & c_{yz} & -c_{yz} & -c_{yz} & -c_{yz} & -c_{yz} & c_{yz} & c_{yz} \end{bmatrix} \quad (3)$$

where each column represents a vector \mathbf{n}_k defined starting from

$$c_{yx} = \frac{\|\boldsymbol{\sigma}_{p3} - \boldsymbol{\sigma}_{p4}\|}{\|\boldsymbol{\sigma}_{p1} - \boldsymbol{\sigma}_{p2}\|}, \quad c_{zx} = \frac{\|\boldsymbol{\sigma}_{p5} - \boldsymbol{\sigma}_{p6}\|}{\|\boldsymbol{\sigma}_{p1} - \boldsymbol{\sigma}_{p2}\|}, \quad c_{yz} = \frac{\|\boldsymbol{\sigma}_{p3} - \boldsymbol{\sigma}_{p4}\|}{\|\boldsymbol{\sigma}_{p5} - \boldsymbol{\sigma}_{p6}\|}, \quad c'_{yz} = \frac{\|\boldsymbol{\sigma}_{p7} - \boldsymbol{\sigma}_{p10}\|}{\|\boldsymbol{\sigma}_{p1} - \boldsymbol{\sigma}_{p2}\|} \quad (4)$$

which refer to the plastic generalized stresses

$$\begin{aligned} \boldsymbol{\sigma}_{p1} &= \begin{bmatrix} N_{p1} \\ 0 \\ 0 \end{bmatrix}, \boldsymbol{\sigma}_{p2} = \begin{bmatrix} N_{p2} \\ 0 \\ 0 \end{bmatrix}, \boldsymbol{\sigma}_{p3} = \begin{bmatrix} N_{p3} \\ M_{py3} \\ 0 \end{bmatrix}, \boldsymbol{\sigma}_{p4} = \begin{bmatrix} N_{p4} \\ M_{py4} \\ 0 \end{bmatrix}, \boldsymbol{\sigma}_{p5} = \begin{bmatrix} N_{p5} \\ 0 \\ M_{pz5} \end{bmatrix}, \boldsymbol{\sigma}_{p6} = \begin{bmatrix} N_{p6} \\ 0 \\ M_{pz6} \end{bmatrix} \\ \boldsymbol{\sigma}_{p7} &= \begin{bmatrix} N_{p7} \\ M_{py7} \\ M_{pz7} \end{bmatrix}, \boldsymbol{\sigma}_{p8} = \begin{bmatrix} N_{p8} \\ M_{py8} \\ M_{pz8} \end{bmatrix}, \boldsymbol{\sigma}_{p9} = \begin{bmatrix} N_{p9} \\ M_{py9} \\ M_{pz9} \end{bmatrix}, \boldsymbol{\sigma}_{p10} = \begin{bmatrix} N_{p10} \\ M_{py10} \\ M_{pz10} \end{bmatrix} \end{aligned} \quad (5)$$

In particular, once the plastic strain mechanism of the cross-section corresponding to the vector \mathbf{n}_k ($k=1..n_{fs}$) is considered, the maximum compressive strain in concrete (ε_{cmax}) and the maximum tensile strain in longitudinal steel reinforcement (ε_{smax}) are evaluated, avoiding values greater than the corresponding ultimate ones (e.g. $\varepsilon_{cu}=0.35\%$ and $\varepsilon_{su}=1\%$). In this way, the position of the neutral axis and the area of the compressed concrete section (A_c) being known, the components of the generalized plastic stress vector σ_{Pk} can be evaluated by the equilibrium equations:

$$N_{Pk} = \int_{A_c} \sigma_c dA + \sum_{i=1}^{n_b} A_{si} \sigma_{si}, \quad M_{Pyk} = - \int_{A_c} \sigma_c z dA - \sum_{i=1}^{n_b} A_{si} \sigma_{si} z_i, \quad M_{Pzk} = \int_{A_c} \sigma_c y dA + \sum_{i=1}^{n_b} A_{si} \sigma_{si} y_i \quad (6)$$

where $\sigma_c = \sigma_c(\varepsilon)$ and $\sigma_{si} = \sigma_{si}(\varepsilon)$. In Eq. (5) n_b is the number of longitudinal bars while (y_i, z_i) and A_{si} define, respectively, the position and area of each bar. Elastic-perfectly plastic constitutive laws are assumed for both concrete ($\sigma_c - \varepsilon_c$) and steel ($\sigma_s - \varepsilon_s$), assuming stresses and strains with the appropriate signs (i.e. negative for compression and positive for tension).

At each step of the analysis, the elastic-plastic behaviour of a column, once the initial state and the incremental load are known, can be obtained by using the Haar-Kàrmàn principle. It states that, among all the generalized stress fields σ satisfying equilibrium, the elastic-plastic solution σ_{EP} is that with minimum distance, in terms of complementary energy Π_c , from the elastic solution σ_E [11]

$$\Pi_c(\sigma_{EP}) = \frac{L}{2} \int_0^1 (\sigma_{EP} - \sigma_E)^T D_c^{-1} (\sigma_{EP} - \sigma_E) d\xi = \min. \quad (7)$$

$\xi(=x/L)$ being a nondimensional abscissa, L the length of the beam element and D_c the elastic matrix of a column. The plastic admissibility conditions

$$g_k(\sigma_{EP}) \leq 0 \quad \text{for } k=1..n_{fs} \quad (8)$$

also have to be satisfied at the end sections of the beam element. The elastic-plastic solution corresponds to the tangent point between a level curve of $\Pi_c(\sigma_{EP})$ and the piecewise approximation of the bounding surface of the elastic domain. Moreover, when the elastic solution lies within the fan limited by the planes normal to the boundaries of the flat surfaces, the elastic-plastic solution corresponds to a point along the corner line resulting from the intersection between these surfaces.

Figure 1: Flat surfaces approximating the elastic domain for the end sections of a column.

2.2 Frame members in uniaxial bending without axial force

A lumped plasticity model, already proposed by the authors [10], is adopted for a r.c. girder and labelled as LPMG. The elastic-plastic solution is evaluated only at the end sections (i and j) in the vertical plane (i.e. x - z plane) of bending. Moreover, the potential inelastic de-

formations lumped at n_s intermediate sections along the span, due to the vertical ground motions, are also checked. In order to avoid the computational effort due to the sub-discretization of the frame member, the elastic solution at the end section i (j) is modified taking into account the possible inelastic effects occurring at an intermediate section s ($s=1..n_s$), besides those at the end section j (i). Specifically, when a plastic (flexural) distortion

$$\Delta\phi_{Pys} = \Delta M_{EPys} \left(\frac{4EI_y(1-p)}{L} \left(3\left(\frac{x_s}{L}\right)^2 - 3\left(\frac{x_s}{L}\right) + 1 \right) \right)^{-1} \quad (9)$$

consequent to an elastic-plastic moment M_{EPys} greater than the corresponding plastic moment occurs at an intermediate section of abscissa x_s , the corresponding moments at the end sections can be evaluated as

$$\Delta M_{EPyi}^{(s)} = \frac{2EI_y(1-p)}{L} \left(3\left(\frac{x_s}{L}\right) - 2 \right) \Delta\phi_{Pys}, \quad \Delta M_{EPyj}^{(s)} = \frac{2EI_y(1-p)}{L} \left(3\left(\frac{x_s}{L}\right) - 1 \right) \Delta\phi_{Pys} \quad (10a,b)$$

With reference to the bending moment along the principal axis y and neglecting the inflection along the principal axis z , the generalized stresses of a girder are denoted by the vector

$$\boldsymbol{\sigma} = [M_{yi}, M_{yj}]^T \quad (11)$$

Then the elastic-plastic solution satisfying equilibrium is obtained, according to the Haar-Kàrmàn principle, minimizing the complementary energy

$$\Pi_c(\boldsymbol{\sigma}_{EP}) = \frac{L}{2} \int_0^1 (\boldsymbol{\sigma}_{EP} - \boldsymbol{\sigma}_E - \Delta\boldsymbol{\sigma}_{EP}^{(s)})^T \mathbf{D}_g^{-1} (\boldsymbol{\sigma}_{EP} - \boldsymbol{\sigma}_E - \Delta\boldsymbol{\sigma}_{EP}^{(s)}) d\xi = \min. \quad (12)$$

where \mathbf{D}_g is the elastic matrix of a girder. Moreover, the plastic admissibility condition

$$g(\boldsymbol{\sigma}_{EP}) \leq 0 \quad (13)$$

also has to be satisfied at the end sections of the beam element. Specifically, the (uniaxial) top (T) and bottom (B) plastic moments at the end sections

$$\boldsymbol{\sigma}_{P,T} = [M_{Pyi,T}, M_{Pyj,T}]^T, \quad \boldsymbol{\sigma}_{P,B} = [M_{Pyi,B}, M_{Pyj,B}]^T \quad (14a,b)$$

are modified during the nonlinear analysis, assuming the following values when a plastic distortion occurs at an intermediate section (see Figure 2)

$$\bar{\boldsymbol{\sigma}}_{P,T} = [\bar{M}_{Pyi,T}, \bar{M}_{Pyj,T}]^T, \quad \bar{\boldsymbol{\sigma}}_{P,B} = [\bar{M}_{Pyi,B}, \bar{M}_{Pyj,B}]^T \quad (15a,b)$$

The elastic-plastic solution of the problem defined by the Equations (12) and (13) can be obtained by a predictor-corrector procedure. It is triggered evaluating the elastic-plastic solution at an end section (e.g. end section i) by the formula:

$$M_{EPyi}^{(0)} = \max \left(-\bar{M}_{Pyi,T}, \min \left(\bar{M}_{Pyi,B}, M_{Eyi} + \sum_{s=1}^{n_s} \Delta M_{EPyi}^{(s)} \right) \right) \quad (16)$$

Afterwards the elastic-plastic solution is alternately evaluated at the end section i (j) and j (i)

$$M_{EPyj}^{(k)} = \max \left(-\bar{M}_{Pyj,B}, \min \left(\bar{M}_{Pyj,T}, M_{Eyj} + \sum_{s=1}^{n_s} \Delta M_{EPyj}^{(s)} - \frac{M_{Eyi} + \sum_{s=1}^{n_s} \Delta M_{EPyi}^{(s)} - M_{EPyi}^{(k-1)}}{2} \right) \right) \quad (17)$$

$$M_{EPyi}^{(k+1)} = \max \left(-\bar{M}_{Pyi,T}, \min \left(\bar{M}_{Pyi,B}, M_{Eyi} + \sum_{s=1}^{n_s} \Delta M_{EPyi}^{(s)} - \frac{M_{Eyi} + \sum_{s=1}^{n_s} \Delta M_{EPyi}^{(s)} - M_{EPyi}^{(k)}}{2} \right) \right) \quad (18)$$

In cases where the intermediate sections experience inelastic deformations, Eqns. (17) and (18) are solved iteratively until, in these sections, at the iteration loop k the differences between the plastic moments and the elastic-plastic moments evaluated by the equilibrium, starting from the elastic-plastic solution at the end sections, become less than a prefixed tolerance.

Figure 2: Bounding surface of the elastic domain for the end sections of a girder.

3 LAYOUT AND DESIGN OF THE R.C. FRAMED BUILDINGS

Typical six- and twelve-storey residential buildings with r.c. framed structures, whose symmetric plan is shown in Figure 3, are considered as test structures. Deep girders are placed along the perimeter of the building together with infilled walls assumed as non-structural elements regularly distributed in elevation; deep and flat girders, perpendicular and parallel to the floor slab direction, respectively, are assumed inside the building. Geometric dimensions of the girders and columns are shown in Table 1. Moreover, the vibration periods corresponding to the high-participation modes with prevailing components in the horizontal and vertical directions are: $T_{IX}=0.576s$, $T_{IY}=0.698s$ and $T_{IZ}=0.064s$, for the six-storey buildings; $T_{IX}=0.993s$, $T_{IY}=1.249s$ and $T_{IZ}=0.103s$, for the twelve-storey buildings. The gravity loads used in the design are represented by dead- and live-loads, equal respectively to: 4.8 kN/m^2 and 2 kN/m^2 , for the top floor; 5.7 kN/m^2 and 2 kN/m^2 , for the other floors. The weight of the perimeter masonry-infills is taken into account considering a gravity load of 2.7 kN/m^2 . A cylindrical compressive strength of 25 N/mm^2 for the concrete and a yield strength of 450 N/mm^2 for the steel are considered.

The proportioning of the test structures has been done according to the Italian seismic code (Technical Regulations for Constructions 2008, NTC08 [3]) assuming, besides the gravity loads, the horizontal seismic loads acting alone or in combination with the vertical ones. Each building (B) is identified by two symbols: the first one (6 or 12) indicates the number of storeys, the second one refers to the design seismic loads which are considered (i.e.: H, when considering only the horizontal component of the seismic loads; HV, when also considering

the vertical component of the seismic loads). The following assumptions have been made: medium subsoil (class B, subsoil parameters: $S_{SH}=1.13$ in the horizontal direction and $S_{SV}=1$ in the vertical one); flat terrain (class T1, topographic parameter: $S_T=1$).

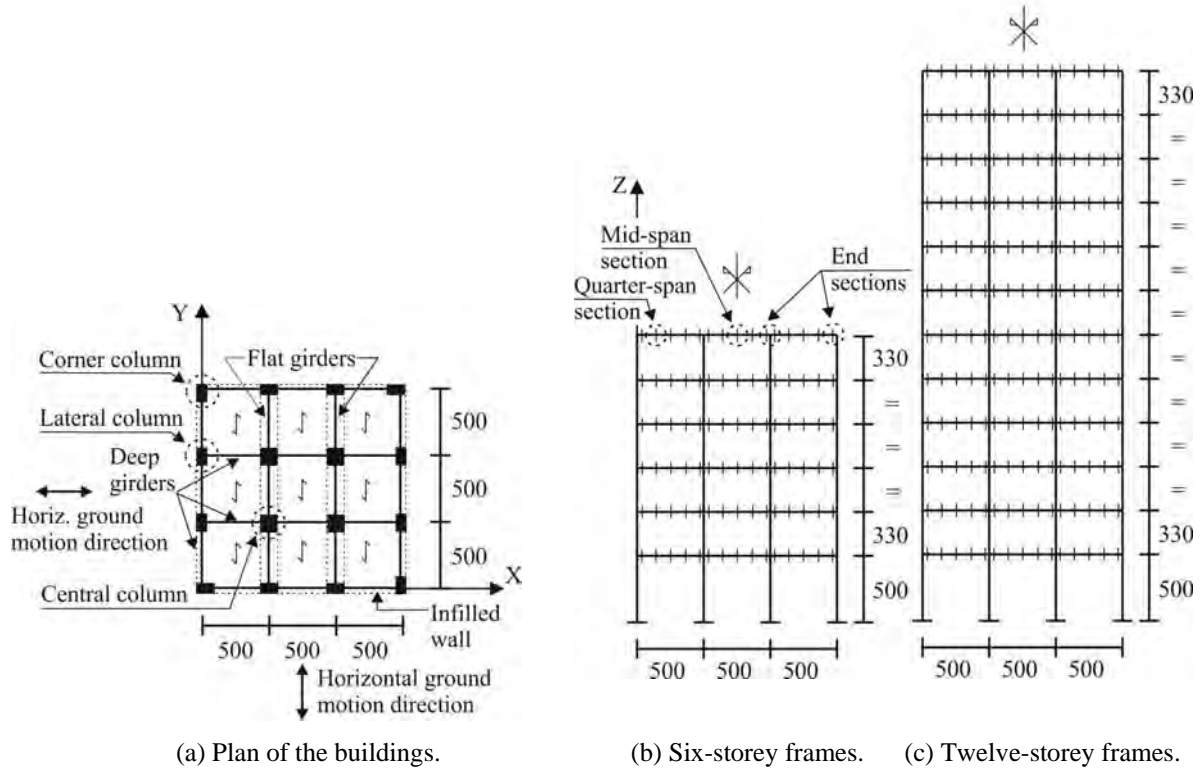

Figure 3: R.c. test structures (dimensions in cm).

Storey	Corner columns	Lateral columns	Central columns	Deep girders	Flat girders
12	30x30	30x40	40x40	30x50	50x25
11	30x30	30x40	40x40	30x50	50x25
10	30x40	30x50	40x40	30x50	60x25
9	30x40	30x50	40x40	30x60	60x25
8	35x40	35x60	50x50	30x60	70x25
7	35x40	35x60	50x50	30x60	70x25
6	40x50 (30x50)	45x60 (30x50)	60x60 (40x40)	40x65 (30x50)	80x25 (50x25)
5	40x50 (30x50)	45x60 (30x50)	60x60 (40x40)	40x65 (30x50)	80x25 (50x25)
4	50x60 (30x60)	50x70 (40x60)	70x70 (50x50)	40x65 (30x60)	90x25 (60x25)

1	50x70 (40x70)	50x90 (50x80)	80x80 (60x60)	40x70 (40x60)	100x25 (70x25)

Table 1: Section dimensions (in cm) of the six- (in brackets) and twelve-storey r.c. buildings.

The design is carried out to comply with the ultimate limit state (ULS) of life safety, according to the horizontal and vertical elastic response spectra whose main data are reported in Table 2: i.e. return period (T_r) corresponding to a nominal life of the structure equal to 50 years; peak ground accelerations in the horizontal (PGA_H) and vertical (PGA_V) directions; amplification factors defining the maximum horizontal (F_o) and vertical (F_v) spectral acceleration on rock-site; upper limit of the period of the constant spectral acceleration branch in the horizontal direction (T_C^*). Six- and twelve-storey structures have to be classified as regular in plan and irregular in elevation, according to the criteria imposed by NTC08. As a consequence, a low ductility class is considered, assuming: behaviour factor for the horizontal seismic loads, $q_H=3.12$; behaviour factor for the vertical seismic loads, $q_V=1.5$. Finally, the

serviceability limit state (SLS) of damage is also controlled, checking that, under the horizontal seismic loads corresponding to the elastic response spectra whose main parameters are shown in Table 2, the inter-storey drift is less than 0.5% of the storey height. Detailing for local ductility is also imposed to satisfy minimum conditions for the longitudinal bars of the r.c. frame members. Finally, capacity design rules regarding the beam-column moment ratio and shear forces and local ductility requirement of girders and columns are also satisfied.

Limit state	T_r (years)	PGA_H (g)	PGA_V (g)	F_o	F_v	T_c^* (s)
ULS (Life safety)	475	0.312	0.276	2.44	1.73	0.370
SLS (Damage)	50	0.108	-	2.28	-	0.301

4 NUMERICAL RESULTS

In order to evaluate the effects produced by the combination of the horizontal and vertical components of near-fault ground motions on the response of r.c. spatial frames, a computer code has been implemented according to the LPMs proposed in Section 2. A bilinear moment-curvature law is adopted, assuming a hardening ratio $p=5\%$. In the Rayleigh hypothesis, the damping matrix is assumed as a linear combination of the mass and stiffness matrices, assuming a viscous damping ratio equal to 5% or 2% with reference to the two vibration periods corresponding to high-participation modes with components prevailing in the Y (T_{1Y}) or Z (T_{1Z}) direction, respectively. In this way, an intermediate value of the damping ratio is achieved in the range of vibration periods $T_{1Z}-T_{1Y}$, while the higher frequency modes, which do not contribute significantly to the dynamic response, are practically eliminated due to their high damping ratio. Plastic conditions are checked at the end sections of the columns, considering an approximation with flat surfaces of the axial force-biaxial bending moment bounding surface of the elastic domain (see Section 2.1). Three intermediate sections (i.e. the two quarter-span sections and the mid-span section) are checked along the span of the girders, in addition to the end sections (Figure 3b) even if, according to the model proposed in Section 2.2, girders are discretized with only one element instead of four sub-elements, reducing the computational effort of the discretization by about 2/3.

The nonlinear dynamic response of the B6H, B6HV, B12H and B12HV test structures, which are described in Section 3, is studied with reference to the records of the Imperial Valley earthquake, available in the Pacific Earthquake Engineering Research center database [14]. More specifically, ground motions recorded at different stations placed at close range to one another and exhibiting high values of the acceleration ratio $\alpha_{PGA}(=PGA_V/PGA_H)$ are considered. It is worth mentioning that the accelerograms are characterized by a PGA_H value approximately comparable, for one of the two horizontal directions, with the one adopted in the design of the test structures (i.e. $PGA_H=0.312g$ in Table 2). In Table 3 the main data of the selected near-fault ground motions are reported: recording station, closest distance to fault rupture (D); magnitude (M_s), peak ground acceleration for the horizontal components ($PGA_{H,1}$ and $PGA_{H,2}$) and the vertical one (PGA_V) and acceleration ratios ($\alpha_{PGA,1}$ and $\alpha_{PGA,2}$). As can be observed, α_{PGA} has a maximum value of 2.009 for the El Centro Differential Array (D.A.) station as opposed to the value 1.13 prescribed by NTC08 in the examined case (see Table 2).

Station	D	M_s	$PGA_{H,1}$	$PGA_{H,2}$	PGA_V	$\alpha_{PGA,1}$	$\alpha_{PGA,2}$
El Centro Array #5	1.0 km	6.9	0.379g	0.519g	0.537g	1.417	1.035
El Centro Array #7	0.6 km	6.9	0.338g	0.463g	0.544g	1.609	1.175
El Centro Differential Array	5.3 km	6.9	0.352g	0.480g	0.707g	2.009	1.473

Table 3: Main data of the selected near-fault ground motions (Imperial Valley, 15/10/1979).

The elastic (normalized) response spectra of acceleration in the horizontal ($S_{aH,1}$ and $S_{aH,2}$) and vertical (S_{aV}) directions are plotted in Figure 4, assuming an equivalent viscous damping ratio in the horizontal direction, ξ_H , equal to 5%, and an analogous ratio in the vertical direction, ξ_V , equal to 2% due to the low damping capacity of the structure expected in this direction [1]. The response spectra of these motions are compared with the corresponding target NTC08 response spectra for a high-risk seismic region and a medium subsoil class (class B): i.e. $PGA_H=0.312g$ and $PGA_V=0.276g$. It is interesting to note that in the vertical direction the spectral values for the El Centro ground motions (Figure 4c) are much greater than those corresponding to NTC08, at least in the range of the vibration periods which are more relevant for the test structures.

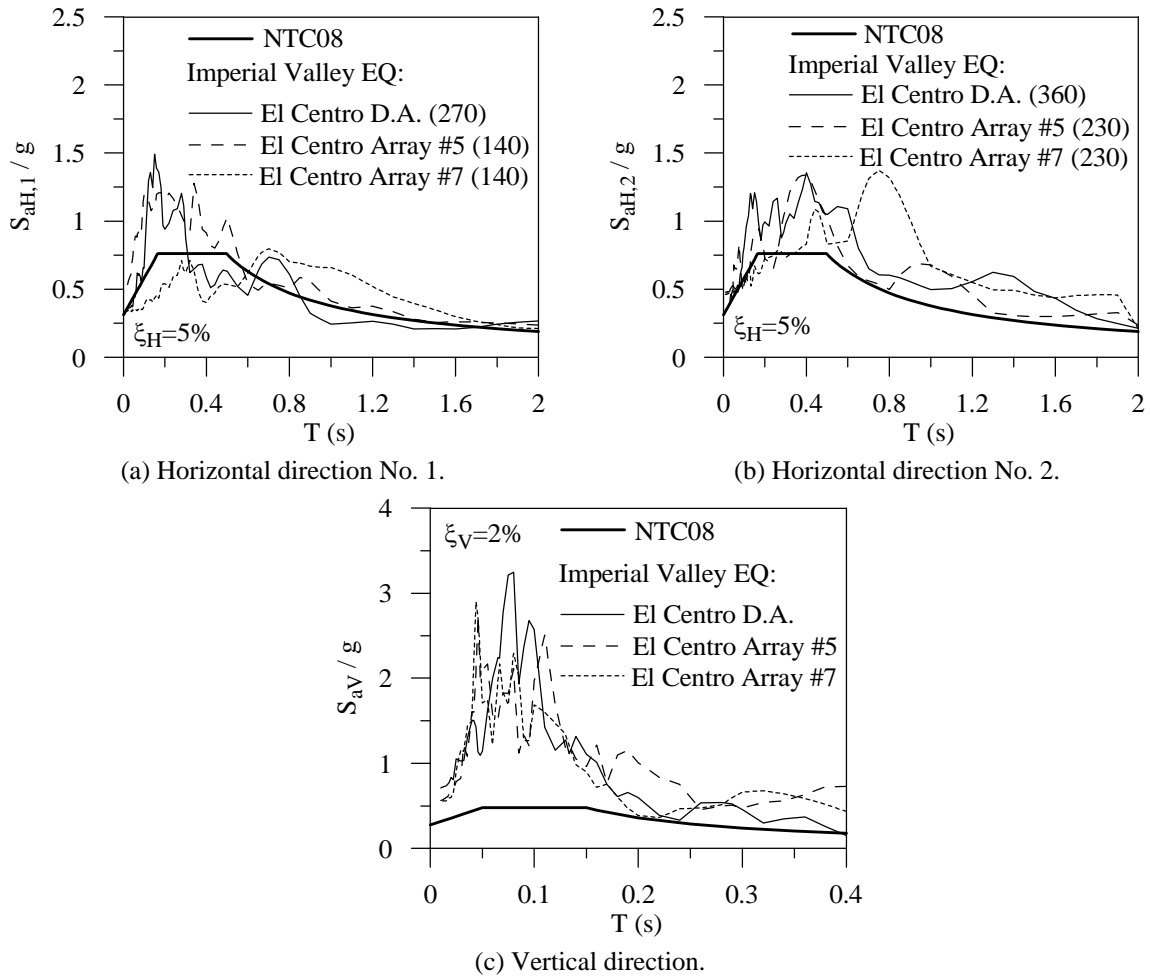

Figure 4: Acceleration (elastic) response spectra.

To emphasize the importance of also considering the vertical ground motion, the main response parameters affected by this component are considered: i.e. curvature ductility demand at the potentially critical sections (i.e. end, quarter span and mid-span sections) of the girders, for each of the two loading directions; curvature ductility demand, at the end sections, and axial force demand for the columns. More specifically, the ductility demand for a column is evaluated with reference to the radial direction defined by the bending moment axis vector

$$\mu_{max,r} = \frac{\chi_{max,r}}{\chi_{Er}} = \frac{\sqrt{(\chi_{Ey} + \sum \Delta \chi_{Py})^2 + (\chi_{Ez} + \sum \Delta \chi_{Pz})^2}}{M_{Pr}[N_V]/(EI_r)} \quad (19)$$

where $\chi_{max,r}$ and $\chi_{E,r}$ represent the maximum and yielding curvatures, respectively, in the radial direction. Plastic curvatures at each step of the analysis (i.e. $\Delta\chi_{Py}$ and $\Delta\chi_{Pz}$) are accumulated and added to the yielding curvatures at the current step (i.e. χ_{Ey} and χ_{Ez}). Finally, the plastic moment (M_{Pr}) is calculated considering the axial force due to the gravity loads only (N_V) and referring to the radial direction identified by $\chi_{max,r}$.

In order to compare the response of the test structures designed for the horizontal seismic loads only (i.e. B6H and B12H structures) with that of the analogous structures designed also for the vertical seismic loads (i.e. B6HV and B12HV structures), the mean values of the ductility demand of girders and columns are reported in Figures 5 and 6. The results below were obtained as an average of the maximum (local) curvature ductility demand attained at the most critical sections of the structures subjected to the selected Imperial Valley ground motions (see Table 3). The numerical investigation is carried out considering the horizontal components of motion acting alone (H), for B6H and B12H structures, or contemporaneously with the corresponding vertical component (H+V), for B6HV and B12HV structures. Moreover, the horizontal accelerogram with $PGA_{H,1}$ ($PGA_{H,2}$) is applied twice, once along the principal axis X (Y) and the other along the principal axis Y (X) of the building plan.

The curves in Figures 5a and 6a correspond to the mean ductility demand for the end sections and quarter-span sections of the interior deep girders, perpendicular to the floor slab direction shown in Figure 3a. As shown, the effects of the vertical component of ECDA, ECA#5 and ECA#7 ground motions proved to be more evident at the upper floors where bending moments due to vertical seismic loads are more important than those due to the horizontal seismic loads. More specifically, the end sections, at the top side, and quarter-span sections, at the bottom one, proved to be the more stressed sections. This kind of behaviour can be explained observing that the ductility demand at these sections, in contrast to the mid-span ones, already appears under the horizontal components of the Imperial Valley ground motions. Moreover, the bottom plastic moments of the quarter-span sections, at the upper floors, were less than or equal to those assumed at the mid-span sections. This result emphasizes the need to take into account the vertical ground motion in the design of the girders, especially at the upper storeys. Further results, omitted for the sake of brevity, highlighted that flat girders, parallel to the floor slab direction, exhibit plastic deformations at the end sections due to the horizontal components of the ground motion, but the intermediate sections are practically independent of the vertical component due to their small tributary mass.

Figure 5: Mean ductility demand of B6H and B6HV structures subjected, respectively, to the horizontal components (H) and horizontal and vertical components (H+V) of the Imperial Valley earthquakes.

Successively, the maximum values of the mean ductility demand at the end sections of the columns are evaluated with reference to the same cases as discussed above. As can be observed, the effects of the vertical ground motion are negligible for the B6HV structure (Figure 5b) and generally limited to the upper storeys for the B12HV structure (Figure 6b). However, note that the mean ductility demand at each storey is shown for the (central, lateral or corner) column section exhibiting the maximum value, but in many cases the section where the maximum ductility value is attained is different, when the horizontal ground motions alone (H) or in combination with the vertical ground motion (H+V) are considered. As expected, a “strong-column weak-beam” mechanism is achieved, with acceptable maximum values of the ductility demand for the columns of all the storeys.

Figure 6: Mean ductility demand of B12H and B12HV structures subjected, respectively, to the horizontal components (H) and horizontal and vertical components (H+V) of the Imperial Valley earthquakes.

Finally, attention was focused on the axial force attained by the columns, in order to check whether failure phenomena occur: i.e. failure under compression or tension, due to the attainment of the corresponding ultimate compressive load, N_{cu} , or tensile load, N_{tu} ; brittle failure under a compressive load greater than the balanced load N_b . For this purpose, the minimum (N_{min}) and maximum (N_{max}) values attained by the axial load (assuming positive to be a compressive load) in the corner and central columns of B6H and B6HV structures subjected, respectively, to the horizontal (H) and horizontal and vertical (H+V) components of ECDA ground motion are plotted in Figure 7. Analogous curves are also plotted in Figure 8 with reference to B12H and B12HV structures subjected, respectively, to the H and H+V components of ECA#5 ground motion. As can be observed, the axial-force variation induced a rather high compressive force, which in many columns was greater than the balanced load, thus produc-

ing a reduction in both the ultimate bending moment and available ductility. It should be noted that a compressive load greater than N_b does not necessarily imply a brittle failure, because it depends on the value attained by the bending moment, which may be less than the ultimate moment corresponding to the current axial load. Nevertheless, caution is needed when the compressive load is greater than N_b . It is also useful to note that NTC08 requires that, in the case of medium ductility class, the maximum compressive load for the columns should not be greater than 65% of the corresponding ultimate load N_{cu} .

Figure 7: Typical values of column axial forces for the corner and central columns of B6H and B6HV structures subjected to El Centro D.A. records.

Figure 8: Typical values of column axial forces for the corner and central columns of B12H and B12HV structures subjected to El Centro Array #5 records.

The overturning moment due to the horizontal components of ECDA and ECA#5 ground motions induced an evident variation of the axial load in the corner columns of B6H (Figure 7a) and B12H (Figure 8a) structures. On the other hand, for the central columns, having the greatest tributary mass (i.e. their tributary mass in a storey is about four times the analogous mass corresponding to the corner columns, respectively), the addition of the vertical ground motion produced an evident variation in the axial force giving rise even to a tensile force, which in many sections of B6HV (Figure 7b) and B12HV (Figure 8b) structures is very close to the ultimate tensile force N_{tu} .

5 CONCLUSIONS

An efficient nonlinear beam model based on the Haar–Kàrmàn principle has been proposed for the analysis of r.c. spatial frames subjected to the vertical component of near-fault ground motions. Specifically, the lumped plasticity model for a column (LPMC) includes a piecewise linearization of the bounding surface of the elastic domain corresponding to axial load-biaxial bending moment interaction. A satisfactory compromise between accuracy and computational efficiency has been attained considering 26 flat surfaces: i.e., 6 surfaces normal to the principal axes; 12 surfaces normal to the bisections of the principal planes; 8 surfaces normal to the bisections of the octants. Moreover, the lumped plasticity model for a girder (LPMG) takes into account the potential plastic hinges along the span of the girders, due to the vertical ground motion, modifying the uniaxial plastic moments of the end-sections depending on the top and bottom plastic moments of selected critical intermediate sections. LPMG allowed a reduction in the computational effort due to the sub-discretization of the girders by about 2/3.

Afterwards, a computer code was developed on the basis of the proposed LPMC and LPMG, in order to investigate the effects of the vertical component of near-fault ground motions on the inelastic behavior of r.c. spatial frames. To this end, six- and twelve-storey r.c. framed buildings were designed assuming, besides the gravity loads, the horizontal seismic loads acting alone or in combination with the vertical ones. In order to emphasize the effects due to the vertical component, the numerical investigation was carried out with reference to cases in which the considered horizontal components of the motion acted alone or contemporaneously with the corresponding vertical component. The numerical results showed that the frame members should be designed to also take into account the vertical ground motion. Specifically, the ductility demand increased in many end sections and quarter-span sections of deep girders, while for flat girders it did not depend on the vertical component due to their small tributary mass. As regards the columns, a large variation in the axial force occurred producing even tension (close to the ultimate tensile force) and high compressive forces (larger than the balanced force) which are more evident, respectively, at the upper and lower storeys of the test structures.

Keywords: FEM, Contact-Impact Problems, Local Contact Search, Quasi-Newton Methods

Abstract. *The essential part of the solution of a contact problem in the finite element method is to locate probable contact areas reliably and efficiently. Most contact searching algorithms are based on the definition of master and slave contact surfaces, when the slave nodes/integration points are checked on against master segments for penetration. The present paper deals with the local search problem which comprises the calculation of the exact position of the slave node/integration point with respect to a given master segment. Since the analytical solution for finding the distance does not exist for a general quadrilateral contact segment, the iterative numerical procedure is solved. Several methods for the solution of non-linear algebraic systems are tested: the Newton-Raphson procedure, the least square projection, the steepest descent method, Broydens method, BFGS method, DFP method and the simplex method. The effectiveness of methods is tested by means of a contact-impact problem of two colliding thick plates, for which analytical solution is available.*

1 INTRODUCTION

The key issue in the numerical treatment of contact problem in the finite element method is to locate contact areas reliably and efficiently. Most contact algorithms are based on the master-slave concept, when the position of slave node is checked on against the master segment for penetration. The contact detection can be usually divided into two phases: the global search for finite elements/segments which actually intersect and the local search for projections of slave points (nodes/quadrature points) onto master surfaces.

An overview of global search algorithms might be found in Refs. [1, 2]. When the global search is successfully done, the local search is performed. There are several possibilities to deal with this problem.

The most frequently used approach for local contact searching is described in Ref. [3]. The contact point is defined on the master segment as the point closest to the slave point. Its parametric coordinates are calculated by solving the minimization problem. There is an analytical solution for linear triangular segments, however, a bilinear quadrilateral as well as higher order elements have to be solved numerically. The Newton-Raphson method is applied for solving the simple non-linear equations.

In order to increase efficiency, in Ref. [4] each quadrilateral segment is broken into four triangles with their common vertex at the centre of the master segment. The contact point is calculated by determining which triangle is closest to the slave node and projecting the slave node onto it. Although efficiency of this approach is undeniable, it is not adequate for distorted elements which can occur within post-buckling calculations [5].

For node-to-segment contact design the algorithm based on the definition of a mesh normal was proposed in Ref. [6]. The mesh normal vector of a node is defined as the average normal vector for all surfaces which adjacent to the node. The inside-outside algorithm [7] employs this vector to determine whether the projection of a node is located inside or outside of a surface. Since no iterations are involved the algorithm is very fast. However, a lack of continuity on the boundary of surfaces called the deadzone problem was observed. In order to overcome this drawback, the free-form-surface (FFS) algorithm was proposed in Ref. [2]. The contact area is approximated with the FFS patch, which ensures smoothness. The accuracy can be increased by subdividing of the surface patch.

In this paper, we focused on the solution of a minimization problem between slave integration (quadrature) point and the master segment of the three-dimensional quadratic serendipity element. The solution of resulting non-linear equations is not trivial, especially when higher order finite elements are taken into account. First, the formulation of a minimization problem is presented in Section 2. Various numerical methods for the solution of this problem are presented in Section 3. First, the convergence difficulties of the Newton-Raphson method are analyzed. Next, the least square projection constructed as the linearized Newton-Raphson scheme [5] is mentioned. Then, the line search strategy is presented [8], utilized in the steepest descent method, Broyden's method, BFGS and DFP method [9]. The last three methods belong to an alternative approach to the Newton-Raphson method, known as quasi-Newton methods. Finally, the Nelder-Mead simplex method [10] is discussed as an interesting alternative to preceding methods. The effectiveness of methods is compared in Section 3.9, followed by the numerical example of the longitudinal impact of two thick plates in Section 4.

2 FORMULATION OF THE MINIMIZATION PROBLEM

Let us consider the slave quadrature point $\mathbf{y}_s \in \mathbb{E}^3$ and the master segment γ_c . The aim of the local contact search is to calculate the parametric coordinates $\xi_1, \xi_2 \in [-1, 1]$ corresponding to projection $\bar{\mathbf{y}}(\xi_1, \xi_2) \in \mathbb{E}^3$ of the quadrature point \mathbf{y}_s (see Fig. 1).

Figure 1: Formulation of the minimization problem.

Such a point has to satisfy

$$\bar{\mathbf{y}} = \min_{\mathbf{y} \in \gamma_c} \{(\mathbf{y}_s - \mathbf{y}) \cdot (\mathbf{y}_s - \mathbf{y})\} \quad (1)$$

where the minimization of the inner product on \mathbb{E}^3 instead of more natural Euclidean norm has been used. Hence, the minimized function is defined as

$$f = (\mathbf{y}_s - \mathbf{y}) \cdot (\mathbf{y}_s - \mathbf{y}) \quad (2)$$

The necessary condition for local extremum is

$$\begin{aligned} (\mathbf{y}_s - \mathbf{y}) \cdot \frac{\partial \mathbf{y}}{\partial \xi_1} &= 0 \\ (\mathbf{y}_s - \mathbf{y}) \cdot \frac{\partial \mathbf{y}}{\partial \xi_2} &= 0 \end{aligned} \quad (3)$$

The master segment γ_c is parametrized by

$$\mathbf{y}(\xi_1, \xi_2) = \sum_{i=1}^n N_i(\xi_1, \xi_2) \mathbf{Y}_i \quad (4)$$

where $N_i(\xi_1, \xi_2) : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$ are the shape functions, n is the number of nodes and $\mathbf{Y}_i \in \mathbb{E}^3$ are the global coordinates of nodes. Note that the partial derivations are constant and Eqn. (3) is system of linear equations for linear triangular segments. If higher order elements are taken into account, Eqn. (3) results in the system of non-linear algebraic equations. The inequality constraints $|\xi_1|, |\xi_2| \leq 1$ for isoparametric segment γ_c are not explicitly imposed. The solution of the unconstrained problem lying outside the permissible range indicates that the integration point does not penetrate onto the master segment. Therefore, methods for unconstrained optimization can be employed [8, 9].

3 METHODS FOR UNCONSTRAINED OPTIMIZATION

For the purpose of this section, some notation will be introduced. First, the vector of the isoparametric coordinates is defined as

$$\mathbf{x}^k = \begin{Bmatrix} \xi_1^k \\ \xi_2^k \end{Bmatrix} \quad (5)$$

where the superscript k is the iteration counter. Then, the gradient of the minimized function is denoted by

$$\nabla f^k = \begin{Bmatrix} (\mathbf{y}_s - \mathbf{y}) \cdot \frac{\partial \mathbf{y}}{\partial \xi_1} \\ (\mathbf{y}_s - \mathbf{y}) \cdot \frac{\partial \mathbf{y}}{\partial \xi_2} \end{Bmatrix} \quad (6)$$

and the Hessian matrix of second partial derivations is

$$\mathbf{H}^k = \begin{bmatrix} \frac{\partial^2 f^k}{\partial \xi_1^2} & \frac{\partial^2 f^k}{\partial \xi_1 \partial \xi_2} \\ \frac{\partial^2 f^k}{\partial \xi_1 \partial \xi_2} & \frac{\partial^2 f^k}{\partial \xi_2^2} \end{bmatrix} \quad (7)$$

3.1 Newton-Raphson method

The numerical scheme of the Newton-Raphsons method is based on the first-order Taylor's series expansion of (3) about \mathbf{x}^k . The numerical scheme can be written in the form

$$\mathbf{x}^{k+1} = \mathbf{x}^k - (\mathbf{H}^k)^{-1} \cdot \nabla f^k \quad (8)$$

Generally, there are two constructions of the Newton-Raphson method. First, the method can be thought as the root-finding algorithm of the residuals (3). The matrix \mathbf{H}^k is considered as the tangent matrix and the point $\mathbf{x}^k + 1$ is understood as the intersection of hyperplanes with constraint $f(\mathbf{x}^k) = 0$. Second, the Newton-Raphson is taken as an quadratic interpolation in point \mathbf{x}^k

$$Q = \frac{1}{2} (\mathbf{H}^k \cdot \Delta \mathbf{x}^k) \cdot \Delta \mathbf{x}^k + \nabla f^k \cdot \Delta \mathbf{x}^k + f^k, \quad \Delta \mathbf{x}^k = \mathbf{x}^{k+1} - \mathbf{x}^k \quad (9)$$

Then, new iteration \mathbf{x}^{k+1} is minimizer of this quadratic function

$$\mathbf{H}^k \cdot \Delta \mathbf{x}^k + \nabla f^k = 0 \quad (10)$$

Indeed, for convex functions the Newton-Raphson produces only positive definite matrices \mathbf{H}^k , for which the quadratic function (9) is paraboloid. Minimization of such interpolation embodies quadratic convergence [8]. On the other hand, for general non-linear functions the positive definiteness of \mathbf{H}^k cannot be guaranteed. In case of indefinite Hessian matrix, next iteration \mathbf{x}^k could bounce, because hyperbolic paraboloid, which represents indefinite matrix, could have the minimum (saddle point) far from \mathbf{x}^{k+1} . Consequently, the solution could converge to another local minimum or even diverge. The necessary condition for the convergence of the Newton-Raphson method is positive definiteness of the Hessian matrix \mathbf{H}^k . The rigorous proof can be found in [8]. It should be pointed out that the convergence property of the Newton-Raphson iteration is difficult to achieve since the Hessian matrix of the distance function (2) to be minimized is not positive definite in general. Therefore, several methods will be discussed in the following sections.

3.2 Least squares projection

Whereas the Newton-Raphson linearizes the minimized function (2), the least squares projection linearizes the master contact segment (4)

$$\mathbf{y} = \mathbf{y}^k + \left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} \cdot \Delta \mathbf{x}^k \quad (11)$$

For given point \mathbf{x}^k the necessary condition for local extremum (3) becomes linear

$$\left(\mathbf{y}_s - \mathbf{y}^k + \left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} \cdot \Delta \mathbf{x}^k \right) \cdot \left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} = 0 \quad (12)$$

By rearranging

$$\left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} \cdot \left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} \cdot \Delta \mathbf{x}^k = - \left. \frac{\partial \mathbf{y}}{\partial \mathbf{x}} \right|_{\mathbf{x}^k} \cdot (\mathbf{y}_s - \mathbf{y}^k) \quad (13)$$

and introducing the matrix notation, we obtain

$$\begin{Bmatrix} \frac{\partial \mathbf{y}^k}{\partial \xi_1} \\ \frac{\partial \mathbf{y}^k}{\partial \xi_2} \end{Bmatrix} \cdot \begin{Bmatrix} \frac{\partial \mathbf{y}^k}{\partial \xi_1} & \frac{\partial \mathbf{y}^k}{\partial \xi_2} \end{Bmatrix} \cdot \begin{Bmatrix} \Delta \xi_1^k \\ \Delta \xi_2^k \end{Bmatrix} = - \begin{Bmatrix} \frac{\partial \mathbf{y}^k}{\partial \xi_1} \\ \frac{\partial \mathbf{y}^k}{\partial \xi_2} \end{Bmatrix} \cdot \{\mathbf{y}_s - \mathbf{y}^k\} \quad (14)$$

Benson et al. [5] recommends three iterations of this method to generate an initial guess for the Newton-Raphson. We try to use the least squares projection as fully-fledged method. The global convergence was attained for arbitrary initial guess [11]. Nevertheless, the global minimum lies outside the permissible range in most cases and therefore this method is not feasible for local search.

3.3 Line search strategy

In each iteration of a line search method a search direction is computed $\mathbf{p}^k \in \mathbb{R}^n$ and then decided how far to move along that direction. The iteration is given by

$$\mathbf{x}^{k+1} = \mathbf{x}^k + t^k \mathbf{p}^k \quad (15)$$

where the positive scalar $t^k \in \mathbb{R}$ is called the step length. The success of a line search method depends on the effective choices of both the direction \mathbf{p}^k and the step length parameter t^k . Most line-search algorithms require \mathbf{p}^k to be a descent direction for which $\mathbf{p}^k \cdot \nabla f^k < 0$. The search direction often has the form

$$\mathbf{p}^k = -\mathbf{D}^k \cdot \nabla f^k \quad (16)$$

where $\mathbf{D}^k \in \mathbb{R}^{n,n}$ is a suitable matrix. Let us consider that \mathbf{D}^k is positive definite. Multiply Eqn. (16) by ∇f^k yields

$$\mathbf{p}^k \cdot \nabla f^k = -(\mathbf{D}^k \cdot \nabla f^k) \cdot \nabla f^k < 0 \quad (17)$$

Thus, the positive definiteness of \mathbf{D}^k guarantee a descent direction of \mathbf{p}^k . The methods of computation of the matrix \mathbf{D}^k will be discussed in following sections. Note that for $\mathbf{D}^k = (\mathbf{H}^k)^{-1}$ and $t^k = 1$ one can obtain the Newton-Raphson method. We now turn attention to

the choice of the step length parameter t^k . Its computation is based on the restriction of the minimized function $f(\mathbf{x})$ to the ray from a point \mathbf{x}^k in the search direction \mathbf{p}^k

$$\varphi(t) = f(\mathbf{x}^k + t\mathbf{p}^k), \quad t > 0 \quad (18)$$

Apparently, the exact minimization of this function is computationally expensive. In order to find even a local minimizer of $\varphi(t)$ it generally requires too many evaluations of the minimized function $f(\mathbf{x})$. In Ref. [8], more sophisticated strategies are mentioned to perform an inexact line search to identify a step length that achieves reductions of $f(\mathbf{x})$. In proposed algorithm the step length is computed analytically by the one-dimensional minimizer of the quadratic function along the direction $\mathbf{x}^k + t\mathbf{p}^k$

$$t^k = -\frac{\nabla f^k \cdot \mathbf{p}^k}{(\mathbf{p}^k \cdot \mathbf{H}^k) \cdot \mathbf{p}^k} \quad (19)$$

3.4 Steepest descent method

The steepest descent method is the simplest line search method, for which \mathbf{D}^k is the identity matrix and so the search direction \mathbf{p}^k is the negative gradient. Thus, the iteration scheme is

$$\mathbf{x}^{k+1} = \mathbf{x}^k - t^k \nabla f^k \quad (20)$$

Since the Hessian matrix is not employed the steepest descent method does not converge to the saddle points.

3.5 Broyden's method

The Broyden's method is a generalization of the 1D secant method to multiple dimensions as well as the Newton-Raphson is a generalization of the Newton's tangent method. The Broyden's sequence $\{\mathbf{x}^k\}$ is defined by the recurrent formula [9]

$$\mathbf{x}^{k+1} = \mathbf{x}^k - t^k (\mathbf{D}^k)^{-1} \nabla f^k \quad (21)$$

where the update of \mathbf{D}^k is computed by

$$\mathbf{D}^{k+1} = \mathbf{D}^k + \frac{(\nabla f^{k+1} - \nabla f^k) - \mathbf{D}^k (\mathbf{x}^{k+1} - \mathbf{x}^k)}{(\mathbf{x}^{k+1} - \mathbf{x}^k) \cdot (\mathbf{x}^{k+1} - \mathbf{x}^k)} \otimes (\mathbf{x}^{k+1} - \mathbf{x}^k) \quad (22)$$

3.6 BFGS method

A very effective minimization method is the Broyden-Fletcher-Goldfarb-Shenno (BFGS) method. This method requires no evaluation of the Hessian matrix. Moreover, the BFGS method was developed so that the search direction \mathbf{p}^k has always a descent direction. Thus, the positive definiteness of the matrix \mathbf{D}^k is guaranteed. The BFGS iteration scheme is defined by the recurrence [9]

$$\mathbf{x}^{k+1} = \mathbf{x}^k - t^k (\mathbf{D}^k)^{-1} \nabla f^k \quad (23)$$

The update of \mathbf{D}^k is computed by

$$\mathbf{D}^{k+1} = \mathbf{D}^k + \frac{\mathbf{y}^k \otimes \mathbf{y}^k}{\mathbf{d}^k \cdot \mathbf{y}^k} - \frac{\mathbf{D}^k \mathbf{d}^k \otimes \mathbf{D}^k \mathbf{d}^k}{\mathbf{d}^k \cdot \mathbf{D}^k \mathbf{d}^k} \quad (24)$$

where $\mathbf{d}^k = \mathbf{x}^{k+1} - \mathbf{x}^k$ and $\mathbf{y}^k = \nabla f^{k+1} - \nabla f^k$.

3.7 DFP method

Another famous method is the Davidon-Fletcher-Powell (DFP) method. Instead of updating the matrices \mathbf{D}^k

$$\mathbf{x}^{k+1} = \mathbf{x}^k - t^k (\mathbf{D}^k)^{-1} \nabla f^k \quad (25)$$

as in the BFGS method, the DFP method updates their inverses and retains the features of a secant method. The DFP method sequence $\{\mathbf{x}^k\}$ is defined by the recurrent formula

$$\mathbf{x}^{k+1} = \mathbf{x}^k - t^k \mathbf{D}^k \nabla f^k \quad (26)$$

The update of \mathbf{D}^k is computed by

$$\mathbf{D}^{k+1} = \mathbf{D}^k + \frac{\mathbf{d}^k \otimes \mathbf{d}^k}{\mathbf{y}^k \cdot \mathbf{d}^k} - \frac{\mathbf{D}^k \mathbf{y}^k \otimes \mathbf{D}^k \mathbf{y}^k}{\mathbf{y}^k \cdot \mathbf{D}^k \mathbf{y}^k} \quad (27)$$

where $\mathbf{d}^k = \mathbf{x}^{k+1} - \mathbf{x}^k$, $\mathbf{y}^k = \nabla f^{k+1} - \nabla f^k$.

3.8 Nelder-Mead simplex method

In geometry context, the simplex is a generalization of the motion of a triangle or tetrahedron to arbitrary dimension. Specifically, an n -simplex is an n -dimensional polytope with $n + 1$ vertices whereas the distance between each of them is equal. The examples of such a simplex is shown in Fig. 2. The minimized function is evaluated in all vertices of simplex. The algorithm

Figure 2: The examples of simplex.

of the simplex method is based on the three rules [10]. The first rule says that the vertex with the maximum value is released. Alternatively, it is replaced by new one according to Fig. 3. In

Figure 3: First rule of the simplex method.

case that the value in new vertex is maximum again, the second rule (see Fig. 4) holds. It is not allowed to return the vertex back in the subsequent iteration due to runaway loop. Instead, the

Figure 4: Second rule of the simplex method.

vertex with second highest value is released. Finally, the third rule treats the case when one of the vertices has still the same position. This situation indicates that the simplex rotates above a local extremum. Therefore, the simplex edge length a is halved after m iterations. The number of iteration m can be estimated by the empiric formula

$$m = 1.65n + 0.05n^2 \quad (28)$$

where n is the number of dimensions. Fig. 5 shows two-dimensional case ($n = 2$).

Figure 5: Third rule of the simplex method.

3.9 Comparison of methods for local contact search

A numerical test was performed for three different positions of slave point with respect to the deformed master segment topology. The first estimation was gained by one iteration of the least squares projection. Then, the origin of isoparametric coordinates was taken. Finally, the corners of the master segment were tested as the initial guesses. The results are summarized in Tab. 1, where the number of iterations n and normalized time t are shown. The normalized time is defined as the CPU time related to CPU time for the Newton-Raphson for the initial guess $(0.83, -0.62)$. The criterion of convergence was set $\|\mathbf{x}^k - \mathbf{x}^{k-1}\| \leq 10^{-10}$. Note that the superscript sp denotes the solutions which converged to a saddle point.

	Initial guess											
	(0.83,-0.62)		(0,0)		(-1,-1)		(1,-1)		(1,1)		(-1,1)	
	n	t	n	t	n	t	n	t	n	t	n	t
N-R	28	1.00	5	0.20	12	0.45	17 ^{sp}	0.61	5 ^{sp}	0.20	12 ^{sp}	0.44
LSP	133	0.44	134	0.45	137	0.46	124	0.42	116	0.39	134	0.46
SD	51	4.50	71	6.10	28	2.52	14	1.22	29	2.60	1543	142.97
Broyden	9	0.48	11	0.58	10	0.51	9	0.46	11 ^{sp}	0.55	14900	819.15
BFGS	8	0.37	8	0.42	8	0.41	7	0.36	9 ^{sp}	0.48	23	1.22
DFP	7	0.35	8	0.39	8	0.40	7	0.36	9 ^{sp}	0.45	26	1.28
Simplex	190	6.75	200	7.13	192	6.75	184	6.84	210	7.61	196	6.91

Table 1: n - number of iteration, t - normalized CPU time.

It clear that the best results were obtained for BFGS and DFP methods. The Broyden's as well as the steepest descent methods gave only average results. Due to facts mentioned in Section 3.2 the least squares projection was not efficient for the solution of this problem. In comparison to other methods the advantage of the Nelder-Mead simplex method is insensitivity to the convergence to saddle points. Finally, it should be pointed out that the convergence property of the Newton-Raphson iteration was difficult to achieve in general. It is illustrated by the difference between NR iterations for the first and the second initial point.

In conclusion, the most fitting turned out the conjunction of the simplex method for coarse searching and the quasi-Newton solvers BFGS or DFP for fine tuning of numerical solution. The performance of new local contact search procedure was tested by means of a contact-impact problem of two colliding thick plates. The results are presented in following Section 4.

4 LONGITUDINAL IMPACT OF THICK PLATES

The longitudinal impact of two thick plates was studied, for which the analytical solution was available [12]. Despite the problem is two-dimensional one it could be used for testing three-dimensional local contact search procedure. The plates dimensions were: thickness $2d = 5$ mm, length 2.5 mm. Young's modulus, Poisson's ratio and density, respectively, were $E = 2.1 \times 10^5$ MPa, $\nu = 0.3$, $\rho = 7800$ kg/m³. The plates made contact with initial velocity $v_0 = 1$ m/s prescribed at time $t = 0$ s (Fig. 6).

Figure 6: Longitudinal impact of two plates.

The analytical solution [12] utilizing the Laplace transform is rather complex. The distributions of displacements and stresses are cast in the form of infinite series of improper integrals which are evaluated numerically. For illustration, theoretical positions of wave fronts for a short time after impact are plotted in Fig. 7. At the instant the faces of the plates come into contact there are aroused elementary dilatation waves at all points of the contact area. The envelope of these waves is represented by a wave with a plane wave front, propagating in both directions at speed of dilatation waves c_1 . From the boundary points A, D of the contact area emanates a reflected wave which continues propagating in perpendicular direction to x, y plane at speed c_1 . Behind the dilatation wave the transversal waves proceeds at speed c_2 . In the region bounded by plane wave fronts of the dilatation wave and by circular wave fronts of the wave starting from

the points A and D, the state of stress is the same as that encountered by a longitudinal impact of half-spaces.

Figure 7: Theoretical position of wave fronts for $c_1t/d = 0.56$ after [12].

In view of symmetry, only one half of the plates was discretized using 100×100 eight-node linear brick elements per each plate. For the integration of equilibrium equations, the central difference with the lumped mass matrix was employed. The time step was chosen very small corresponding to the dimensionless Courant number $Co = 0.125$.

Figure 8: Longitudinal stress distribution σ_x^* along x -axis for $z/d = 0$.

The normalized longitudinal stress distribution $\sigma_x^* = \sigma_x c_1 / \Lambda v_0$ (Λ is Lamé's constant) along x -axis is drawn in Fig. 8. The results are plotted for normalized time $c_1t/d = 0.56$ and coordinate $z/d = 0$, for which no reflections from boundaries occur. Except the contact analysis a symmetric reference calculation was performed, where the longitudinal displacements of the

front-end nodes of the plate were fixed. In Fig. 8 the contact solution is plotted by red line while the solution based on the reference calculation is denoted by blue line. In addition, the theoretical solution corresponding to uniaxial strain condition is plotted by the black line in Fig. 8. It is clear that the numerical solution is influenced by dispersion errors caused by both FE spatial and time discretization. In comparisons with the continuum solution the speed of the longitudinal wave is slower. This fact follows from the theoretical dispersion diagrams for the bilinear four-node and serendipity elements (e.g. Ref. [13]). Quite a good agreement between the contact and reference calculation was observed. Furthermore, it should be emphasized that the symmetry of longitudinal stress distributions was perfectly preserved in contact analysis.

The normalized transversal stress distribution $\sigma_z^* = \sigma_z c_1 / \Lambda v_0$ along z -axis is drawn in Fig. 9. In contrast to graphs in previous Fig. 8 these distributions are strongly influenced by the longitudinal and transversal waves reflected from the boundary of plate. Before the arrival of these waves the solution is identical to the constant values $\sigma_z^* = -1$ corresponding to a half-space impact problem. Quite a good agreement between the contact and reference calculation versus the analytical solution was observed. It should be pointed out that the accuracy of analytical solution is strongly influenced by the number of terms included in the series of improper integrals [12]. The analytical solution plotted in this paper was derived from the summation of the first 300 terms of this series.

Figure 9: Transversal stress distribution σ_z^* along z -axis for $x/d = 0.4$.

Engineering

amashhk@gmail.com

Keywords: Dynamic analysis, Nonlinear analysis, Composite plate, Finite element method

Abstract: *A nonlinear finite element method is adopted for the large displacement dynamic analysis of anisotropic plates under in-plane compressive loads. The analysis is based on the two-dimensional layered approach with higher order shear deformation theory with five, seven, nine, and eleven degrees of freedom per node, nine-node Lagrangian isoparametric quadrilateral elements are used for the discretization of the laminated plates. A complete bond between the layers is assumed (no delamination occurs). A consistent mass matrix is used in the present study. Damping property is considered by using Rayleigh type damping which is linearly related to the mass and the stiffness matrices. Newmark integration method and Harmonic acceleration method are used for solving the dynamic equilibrium equations. The effects of number of layers, damping factor, and number of degree of freedom per node on the large displacement dynamic analysis are considered. From the present study, noticed that the central deflection increase with increasing the degree of freedom per node.*

1. GENERAL

Certain civil engineering structures are designed to carry their own dead load plus superimposed loads which are immovable and unvarying with time, that is, superimposed static loads. In such cases, the stress analysis involves only principles of statics. More often the design of a civil engineering structure involves not only static loads but also superimposed loads which are either moving or movable and may vary with time as in superimposed dynamic loads. In such cases, the stress analysis properly should involve principles of dynamics to determine the effect of dynamic loading. However, in many of these cases, experience has shown that the dynamic effect makes a minor contribution to the total load which must be provided for the design and therefore the dynamic effect need not be evaluated precisely. In such cases, the dynamic effect may be handled by the use of an equivalent static load, or by an impact factor or by a modification of the factor of safety⁽³⁾.

There have been a number of developments which have led to growing interest in a more precise evaluation of the effects produced by the dynamic portion of the loading. Among these are the imposition of more severe live load conditions (that is, machinery and vehicles moving at high speeds), the construction of high towers and long bridges involving more severe and important wind-loading conditions, the necessity of developing blast resistant constructions, and the desire to improve earthquake resistance of constructions. These are some aspects where it may be necessary to consider more precisely the response produced by dynamic loading.

The ability of thin-walled structures to absorb the energy of dynamic transient loading has led to its utilization for several classes of important structures, such as aerodynamic structures, power plant structure, bridge structures, etc. These types of structures are designed under these loads to maintain the overall structural integrity with irreversible deformation analysis. In the present study a computational modeling is developed for the nonlinear dynamic analysis of laminated composite plates using finite element method. The dynamic equilibrium Equation and the derivation of mass and damping matrices will be presented. A Newmark direct time integration method is adopted. In [1993], **Kommineni** and **Kant** presented a C^0 -continuous finite element formulation of a higher order displacement theory for predicting linear and geometrically nonlinear behavior in the sense of von-Karman transient response of composite and sandwich plates. **Azevedo** and **Awruch** [1999] presented a geometric nonlinear dynamic analysis of plates and shells using eight-node hexahedral isoparametric elements. The main features of their study are: (1) the element matrices were obtained by using reduced integrations with hourglass control; (2) an explicit Taylor-Galerkin scheme was used to carry out the dynamic analysis by solving the corresponding equations of motion in terms of velocity components. **Tao, et al.** [2004] presented a simple solution of the dynamic buckling of stiffened plates under impact loading. Based on large deflection theory, a discretely stiffened plate model had been used. The tangential stresses of stiffeners and their in-plane displacements were neglected.

2. LAMINATED PLATE THEORIES

A laminated plate is a series of laminas bonded together to act as an integral structural element. Thus, a laminate is not a material but instead a structural element with essential features of both material properties and geometry. The stiffness and strength of such a composite material with structural configuration are obtained from the properties of the constituent laminas, and thus the macromechanical behavior of a laminate is the main topic of this section. The lamination so described can be considered as a single layer with "rule of mixtures" representation of the interaction between the multiple laminas in a plate or shell⁽⁶⁾.

Figure (1): Laminated plate with several lamina orientations⁽⁶⁾

In the analysis of the laminated plates, there are two categories of theories, equivalent single layer and three dimensional elasticity theories. In the first category, the material properties of the constituent layer are smeared to form a hypothetical single layer whose properties are equivalent to through thickness integrated sum of its constituents, and this category contains classical lamination theory, first order shear deformation theory, and higher order shear deformation theory as will be given in the following section:

2.1 Classical lamination theory

Classical laminated plate theory is also often called "classical laminated theory (CLT)" which is based on the Kirchhoff-Love hypothesis for plates and shells ⁽⁶⁾. The assumptions of classical laminated plate theory are as follows:

- 1- The plate is thin. That is the thickness (h) is small compared to the other physical dimensions.
- 2- The displacements $u(x, y, z)$, $v(x, y, z)$ and $w(x, y, z)$ are small compared to the plate thickness.
- 3- The in-plane strains $\epsilon_x^o, \epsilon_y^o$ and γ_{xy}^o are small compared to unity.
- 4- The transverse normal stress σ_z is negligible.
- 5- The transverse shear stresses τ_{xz}, τ_{yz} are negligible.

2.2 First order shear deformation theory (FSDT)

Timoshenko deep beam theory, which includes transverse shear deformation and rotary inertia effect, has been extended to isotropic plates by **Reissner** and **Mindlin**, and to laminate anisotropic plates by **Yang, et. al.** and their theory, also called "First order shear deformation theory (FSDT)", takes into account the effect of transverse shear deformation and assume it constant through the plate thickness. Thus, a shear correction factor is used ⁽³⁾. The assumptions of First order shear deformation theory (FSDT) are as follows:

- 1- The in-plane displacements are linear functions of z (plane cross sections remaining plane after deflection).
- 2- The displacements $u(x, y, z)$, $v(x, y, z)$ and $w(x, y, z)$ are small compared to the plate thickness.
- 3- The in-plane strains ϵ_x, ϵ_y and γ_{xy} are small compared to unity.
- 4- The transverse normal stress σ_z is negligible.
- 5- The transverse shear stresses τ_{xz} , and τ_{yz} are considered to be constant through the plate thickness.

2.3 Higher order shear deformation theory (HSDT)

In general, a layered composite plate exhibits coupling between the in-plane displacements, transverse displacements and shear rotations. However, due to the low transverse shear modulus relative to the in-plane Young's modulus of each lamina, the transverse shear deformation effect is more pronounced in composite than in isotropic plates. Hence, several types of shear deformation theories have been introduced.

The higher order shear deformation theories are more efficient to represent the transverse shear deformation, through-thickness displacement and strains. The assumption of a higher order plate theory can also be used within the equivalent layer formulation⁽⁶⁾.

The assumptions of higher order shear deformation are as follows:

- 1- The plate may be moderately thick.
- 2- The in-plane displacements $u(x, y, z)$, $v(x, y, z)$ are cubic functions of z .
- 3- The transverse shear stresses τ_{xz} , and τ_{yz} are parabolic in z , no shear correction factor is necessary.
- 4- The in-plane stresses σ_x , σ_y , and τ_{xy} are cubic functions of z .
- 5- The normals to the mid-surface before deformation are straight, but not necessarily remain normal to it the mid-surface after deformation.
- 6- The transverse normal stress σ_z is negligible.

Figure (2) briefly shows, the basic difference between the classical and the first order theories with the higher order theories.

Figure (2): Kinematics of deformation of a plate in various plate theories⁽¹⁾

All the prescribed theories are considered in the present study in order to study the effect of these theories on the accuracy and the time consumption in the analysis. In the present study, three types of displacement equations were considered. Firstly the displacement representation for this theory with five degrees of freedom per node is as follows:

$$\begin{aligned}
 u(x, y, z, t) &= u_o(x, y, t) + z\theta_x(x, y, t) \\
 v(x, y, z, t) &= v_o(x, y, t) + z\theta_y(x, y, t) \\
 w(x, y, z, t) &= w_o(x, y, t)
 \end{aligned} \tag{1}$$

in which t denotes the time; and u_o , v_o , and w_o are the components of the mid-plane displacements for a generic point (x,y,z) having displacements u , v , and w in x , y , and z directions, respectively. Here, θ_x and θ_y are rotations of transverse normals in the (xz) and (yz) planes, respectively.

The strain-displacement relations after differentiating Equation (1) are:

$$\begin{aligned}
 \varepsilon_x &= \frac{\partial u}{\partial x} = \varepsilon_x^o + z\kappa_x \\
 \varepsilon_y &= \frac{\partial v}{\partial y} = \varepsilon_y^o + z\kappa_y \\
 \gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \gamma_{xy}^o + z\kappa_{xy} \\
 \gamma_{xz} &= \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} = \varphi_x \\
 \gamma_{yz} &= \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} = \varphi_y
 \end{aligned} \tag{2}$$

where

$$\begin{aligned}
 \varepsilon_x^o &= \frac{\partial u_o}{\partial x}, \quad \varepsilon_y^o = \frac{\partial v_o}{\partial y}, \quad \gamma_{xy}^o = \frac{\partial u_o}{\partial y} + \frac{\partial v_o}{\partial x} \\
 \kappa_x &= \frac{\partial \theta_x}{\partial x}, \quad \kappa_y = \frac{\partial \theta_y}{\partial y}, \quad \kappa_{xy} = \frac{\partial \theta_x}{\partial y} + \frac{\partial \theta_y}{\partial x} \\
 \varphi_x &= \theta_x + \frac{\partial w_o}{\partial x} \\
 \varphi_y &= \theta_y + \frac{\partial w_o}{\partial y}
 \end{aligned} \tag{3}$$

All the strains above are defined in the middle plane of the laminate and substitution these Equations into the stress-strain relations. Secondly the higher order shear deformation theory (HSDT) with seven degrees of freedom per node was considered. The strain expressions derived from the displacement field was considered by **Mallikarjuna**, and **Kant** [1988], and by **Ali** [2004] with seven degrees of freedom per node as follows:

$$\begin{aligned}
 u(x,y,z,t) &= u_o(x,y,t) + z\theta_x(x,y,t) + z^3\theta_x^*(x,y,t) \\
 v(x,y,z,t) &= v_o(x,y,t) + z\theta_y(x,y,t) + z^3\theta_y^*(x,y,t) \\
 w(x,y,z,t) &= w_o(x,y,t)
 \end{aligned} \tag{4}$$

in which $(u, v, w, \theta_x$, and $\theta_y)$ are defined previously, θ_x^* and θ_y^* are the corresponding higher order terms in Taylor's series expression and also defined at the middle plane. The strain-displacement relations after differentiating Equation (4) are:

$$\begin{aligned}
\varepsilon_x &= \frac{\partial u}{\partial x} = \varepsilon_x^o + z\kappa_x + z^3\kappa_x^* \\
\varepsilon_y &= \frac{\partial v}{\partial y} = \varepsilon_y^o + z\kappa_y + z^3\kappa_y^* \\
\gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \gamma_{xy}^o + z\kappa_{xy} + z^3\kappa_{xy}^* \\
\gamma_{xz} &= \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} = \varphi_x + z^2\varphi_x^* \\
\gamma_{yz} &= \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} = \varphi_y + z^2\varphi_y^*
\end{aligned} \tag{5}$$

where the parameters $(\varepsilon_x^o, \varepsilon_y^o, \gamma_{xy}^o, \kappa_x, \kappa_y, \kappa_{xy}, \varphi_x, \varphi_y)$ are defined previously.

$$\begin{aligned}
\kappa_x^* &= \frac{\partial \theta_x^*}{\partial x}, \kappa_y^* = \frac{\partial \theta_y^*}{\partial y}, \kappa_{xy}^* = \frac{\partial \theta_x^*}{\partial y} + \frac{\partial \theta_y^*}{\partial x} \\
\varphi_x^* &= 3\theta_x^* \\
\varphi_y^* &= 3\theta_y^*
\end{aligned} \tag{6}$$

Also, all the strains above are defined in the middle-plane of the laminate and substitution these Equations into the stress-strain relations.

Thirdly, Higher order shear deformation theory (HSDT) with nine degrees of freedom per node was considered. The strain expressions derived from the displacement field were considered by [Ali, 2004] with nine degrees of freedom per node as follows:

$$\begin{aligned}
u(x, y, z, t) &= u_o(x, y, t) + z\theta_x(x, y, t) + z^2u_o^*(x, y, t) + z^3\theta_x^*(x, y, t) \\
v(x, y, z, t) &= v_o(x, y, t) + z\theta_y(x, y, t) + z^2v_o^*(x, y, t) + z^3\theta_y^*(x, y, t) \\
w(x, y, z, t) &= w_o(x, y, t)
\end{aligned} \tag{7}$$

in which the parameters $(u, v, w, \theta_x, \theta_y, \theta_x^*, \text{ and } \theta_y^*)$ are defined previously, u_o^* , and v_o^* are the corresponding higher order terms in Taylor's series expression and they are also defined at the middle plane. The strain-displacement relations after differentiating Equation (7) are:

$$\begin{aligned}
\varepsilon_x &= \frac{\partial u}{\partial x} = \varepsilon_x^o + z\kappa_x + z^2\varepsilon_x^{o*} + z^3\kappa_x^* \\
\varepsilon_y &= \frac{\partial v}{\partial y} = \varepsilon_y^o + z\kappa_y + z^2\varepsilon_y^{o*} + z^3\kappa_y^* \\
\gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \gamma_{xy}^o + z\kappa_{xy} + z^2\gamma_{xy}^{o*} + z^3\kappa_{xy}^* \\
\gamma_{xz} &= \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} = \varphi_x + z\gamma_{xz}^o + z^2\varphi_x^* \\
\gamma_{yz} &= \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} = \varphi_y + z\gamma_{yz}^o + z^2\varphi_y^*
\end{aligned} \tag{8}$$

where $(\epsilon_x^o, \epsilon_y^o, \gamma_{xy}^o, \kappa_x, \kappa_y, \kappa_{xy}, \kappa_x^*, \kappa_y^*, \kappa_{xy}^*, \phi_x, \phi_y, \phi_x^*, \phi_y^*)$ are defined previously.

$$\begin{aligned}\epsilon_x^{o*} &= \frac{\partial u_o^*}{\partial x}, \quad \epsilon_y^{o*} = \frac{\partial v_o^*}{\partial y}, \quad \gamma_{xy}^{o*} = \frac{\partial u_o^*}{\partial y} + \frac{\partial v_o^*}{\partial x} \\ \gamma_{xz}^{o*} &= 2u_o^* \\ \gamma_{yz}^{o*} &= 2v_o^*\end{aligned}\quad (9)$$

Also, all the strains above are defined in the middle-plane of the laminate. By substitution from Equation (8) into the stress-strain relations, after complete integration, the stress-resultant/strain relations of the laminate are as follows:

$$\begin{bmatrix} N_x \\ N_y \\ N_{xy} \\ N_x^* \\ N_y^* \\ N_{xy}^* \\ M_x \\ M_y \\ M_{xy} \\ M_x^* \\ M_y^* \\ M_{xy}^* \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & D_{11} & D_{12} & D_{16} & B_{11} & B_{12} & B_{16} & E_{11} & E_{12} & E_{16} \\ A_{12} & A_{22} & A_{26} & D_{12} & D_{22} & D_{26} & B_{12} & B_{22} & B_{26} & E_{12} & E_{22} & E_{26} \\ A_{16} & A_{26} & A_{66} & D_{16} & D_{26} & D_{66} & B_{16} & B_{26} & B_{66} & E_{16} & E_{26} & E_{66} \\ D_{11} & D_{12} & D_{16} & F_{11} & F_{12} & F_{16} & E_{11} & E_{12} & E_{16} & G_{11} & G_{12} & G_{16} \\ D_{12} & D_{22} & D_{26} & F_{12} & F_{22} & F_{26} & E_{12} & E_{22} & E_{26} & G_{12} & G_{22} & G_{26} \\ D_{16} & D_{26} & D_{66} & F_{16} & F_{26} & F_{66} & E_{16} & E_{26} & E_{66} & G_{16} & G_{26} & G_{66} \\ B_{12} & B_{12} & B_{16} & E_{11} & E_{12} & E_{16} & D_{11} & D_{12} & D_{16} & F_{11} & F_{12} & F_{16} \\ B_{12} & B_{22} & B_{26} & E_{12} & E_{22} & E_{26} & D_{12} & D_{22} & D_{26} & F_{12} & F_{22} & F_{26} \\ B_{16} & B_{26} & B_{66} & E_{16} & E_{26} & E_{66} & D_{16} & D_{26} & D_{66} & F_{16} & F_{26} & F_{66} \\ E_{11} & E_{12} & E_{16} & G_{11} & G_{12} & G_{16} & F_{11} & F_{12} & F_{16} & H_{11} & H_{12} & H_{16} \\ E_{12} & E_{22} & E_{26} & G_{12} & G_{22} & G_{26} & F_{12} & F_{22} & F_{26} & H_{12} & H_{22} & H_{26} \\ E_{16} & E_{26} & E_{66} & G_{16} & G_{26} & G_{66} & F_{16} & F_{26} & F_{66} & H_{16} & H_{26} & H_{66} \end{bmatrix} \begin{bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \\ \epsilon_x^{o*} \\ \epsilon_y^{o*} \\ \gamma_{xy}^{o*} \\ \kappa_x \\ \kappa_y \\ \kappa_{xy} \\ \kappa_x^* \\ \kappa_y^* \\ \kappa_{xy}^* \end{bmatrix} \quad (10)$$

and,

$$\begin{bmatrix} Q_x \\ Q_y \\ S_x \\ S_y \\ Q_x^* \\ Q_y^* \end{bmatrix} = \begin{bmatrix} A_{55} & A_{45} & B_{55} & B_{45} & D_{55} & D_{45} \\ A_{45} & A_{44} & B_{45} & B_{44} & D_{45} & D_{44} \\ B_{55} & B_{45} & D_{55} & D_{45} & E_{55} & E_{45} \\ B_{45} & B_{44} & D_{45} & D_{44} & E_{45} & E_{44} \\ D_{55} & D_{45} & E_{55} & E_{45} & F_{55} & F_{45} \\ D_{45} & D_{44} & E_{45} & E_{44} & F_{45} & F_{44} \end{bmatrix} \begin{bmatrix} \phi_x \\ \phi_y \\ \gamma_{xz}^{o*} \\ \gamma_{yz}^{o*} \\ \phi_x^* \\ \phi_y^* \end{bmatrix} \quad (11)$$

All coefficients in A, B, D, E, F, G , and H groups are defined as follows:

$$A_{ij} = \sum_{L=1}^{NL} Q_{ij} (h_L - h_{L-1}) \quad i, j = 1, 2, 6 \text{ or } i, j = 4, 5 \quad (12 \text{ a})$$

$$B_{ij} = (1/2) \sum_{L=1}^{NL} Q_{ij} (h_L^2 - h_{L-1}^2) \quad i, j = 1, 2, 6 \text{ or } i, j = 4, 5 \quad (12 \text{ b})$$

$$D_{ij} = (1/3) \sum_{L=1}^{NL} Q_{ij} (h_L^3 - h_{L-1}^3) \quad i, j = 1, 2, 6 \text{ or } i, j = 4, 5 \quad (12 \text{ c})$$

$$E_{ij} = (1/4) \sum_{L=1}^{NL} Q_{ij} (h_L^4 - h_{L-1}^4) \quad i, j = 1, 2, 6 \text{ or } i, j = 4, 5 \quad (12 \text{ d})$$

$$F_{ij} = (1/5) \sum_{L=1}^{NL} Q_{ij} (h_L^5 - h_{L-1}^5) \quad i, j = 1, 2, 6 \text{ or } i, j = 4, 5 \quad (12 \text{ e})$$

$$G_{ij} = (1/6) \sum_{L=1}^{NL} Q_{ij} (h_L^6 - h_{L-1}^6) \quad i, j = 1, 2, 6 \quad (12 \text{ f})$$

$$H_{ij} = (1/7) \sum_{L=1}^{NL} Q_{ij} (h_L^7 - h_{L-1}^7) \quad i, j = 1, 2, 6 \quad (12 \text{ g})$$

Figure (3): Geometry of an NL-layered laminate [Jones,1999]⁰

DYNAMIC EQUILIBRIUM EQUATION

The dynamic equilibrium Equations are obtained by using the principle of virtual work which states that for any arbitrary kinematically consistent set of displacements, the internal virtual work done by stresses through virtual strains must be equal to that done by the external forces irrespective of the material behavior as [Cook, 1995]⁽⁸⁾:

$$\int_v (d\epsilon)^T \sigma dv = \int_{s_t} (du)^T P_t ds + \int_v (du)^T (P_b - \rho \ddot{u} - C \dot{u}) dv \quad (13)$$

where du is a vector of virtual displacements, $d\epsilon$ is the vector of associated virtual strains and σ is the vector of actual stresses. The term P_t is a vector of surface tractions acting on the portion s_t of the boundary S . Vectors P_b , $\rho \ddot{u}$ and $C \dot{u}$ are the body, inertial and damping forces respectively. The symbol $(\dot{})$ denotes differentiation with respect to time. ρ is the mass density and C is the damping parameter.

For the finite element representation, the displacements, velocities and accelerations u, \dot{u} and \ddot{u} can be defined in terms of the nodal variables d, \dot{d} and \ddot{d} by the expressions:

$$u = \sum_{i=1}^m N_i(\xi, \eta) d_i = Nd, \quad du = N \delta d \quad (14)$$

$$\dot{u} = \sum_{i=1}^m N_i(\xi, \eta) \dot{d}_i = N \dot{d} \quad (15)$$

$$\ddot{u} = \sum_{i=1}^m N_i(\xi, \eta) \ddot{d}_i = N \ddot{d} \quad (16)$$

where $u = \sum_{i=1}^m N_i(\xi, \eta) d_i = Nd$, N_i is the shape functions for i node, and m is the number of nodes.

With standard strain-nodal displacement matrix $[B]$, the virtual strain vector can be related to the nodal displacements as:

$$d\epsilon = \sum_{i=1}^m [B]_i \delta d_i = [B] \delta d \quad (17)$$

Upon substitution of Equations (14-17) into Equation (13) then:

$$\delta d^T [[M]\ddot{d} + [C]\dot{d} + [K]d] = \delta d^T \{f_e(t)\} \quad (18)$$

in which the mass matrix $[M]$, the damping matrix $[C]$, the stiffness matrix $[K]$ and the external applied vector $\{f_e(t)\}$ have the following element contributions:

$$[M_e] = \int_{V_e} N^T \rho N dV \quad (19)$$

$$[C_e] = \int_{V_e} N^T C N dV \quad (20)$$

$$[K_e] = \int_{V_e} [B]^T [D] [B] dV \quad (21)$$

$$f_e(t) = \int_{s_e} N^T P_t ds + \int_{V_e} N P_b dV \quad (22)$$

where s_e and V_e denote the surface and volume of the element under consideration. As δd^T is arbitrary, then Equation (18) may be written as:

$$[M]\{\ddot{d}\} + [C]\{\dot{d}\} + [K]\{d\} = \{f_e(t)\} \quad (23)$$

Equation (23) is the dynamic equilibrium Equation for a single or multi-degree of freedom system.

FORMULATION OF ELEMENT MASS MATRIX

The kinetic energy of the element (e) can be expressed as follows:

$$TI^e = \frac{1}{2} \int_A \{\dot{d}\}^T [m] \{\dot{d}\} dA \quad (24)$$

The velocity vector within an element is discretized such that:

$$\{\dot{d}\} = \sum_{i=1}^{NN} N_i \{\dot{d}_i\}, \text{ NN: number of nodes.} \quad (25)$$

By substituting Equation (25) into Equation (24), one gets:

$$TI^e = \frac{1}{2} \sum_{i=1}^{NN} \{\dot{d}_i\}^T \int_A N_i^T [m] N_i dA \{\dot{d}_i\} \quad (26)$$

Thus,

$$[M]^e = \int_A [N]^T [m] [N] dA = \int_{-1}^1 \int_{-1}^1 [N]^T [M] [N] |d\xi d\eta| \quad (27)$$

The mass matrix for nine degrees of freedom per node is:

$$[m]_{9 \times 9} = \begin{bmatrix} I_1 & & & & & & & & 0 \\ & I_1 & & & & & & & \\ & & I_1 & & & & & & \\ & & & I_2 & & & & & \\ & & & & I_2 & & & & \\ & & & & & I_3 & & & \\ & & & & & & I_3 & & \\ & & & & & & & I_4 & \\ 0 & & & & & & & & I_4 \end{bmatrix} \quad (28)$$

For layered plates, the element mass matrix can be written as follows:

$$[M] = \sum_{L=1}^{NL} [M]^e \quad (29)$$

where in the above Equation (28), I_1 , I_2 , I_3 , and I_4 are translation inertia, rotary inertia, and respectively higher order inertia terms, and these are given by:

$$(I_1, I_2, I_3, I_4) = \sum_{L=1}^{NL} \int_{h_{L-1}}^{h_L} (1, z^2, z^4, z^6) \rho^L dz \quad (30)$$

where ρ^L is material density of L-th layer.

FORMULATION OF DAMPING PROPERTIES

The most common form for the representation of the damping matrix $[C]$ is the so-called Rayleigh-type damping⁽³⁾ which was given as;

$$[C] = a_o [M] + a_1 [K] \quad (31)$$

in which (a_o and a_1) are arbitrary proportionality factors, which make the damping matrix satisfy the orthogonality condition with respect to the modal matrix $[\Phi]$ in the same way of the orthogonality conditions for the mass and stiffness matrices that is⁽⁵⁾:

$$\begin{aligned} \{\Phi\}^T [M] \{\Phi\} &= [I] \\ \{\Phi\}^T [K] \{\Phi\} &= [\Lambda] \\ \{\Phi\}^T [C] \{\Phi\} &= 2[\gamma][\Lambda]^{1/2} \end{aligned} \quad (32)$$

where

$\{\Phi\}$: The modal matrix whose columns represent the natural modal shapes and the superscript (T) denotes transpose.

$[I]$: Identity matrix.

$[\Lambda]$: Spectral matrix, which is a diagonal matrix with elements representing the squares of the natural frequencies (ω_i^2).

$[\gamma]$: Modal damping matrix which is also a diagonal matrix with elements representing the damping ratios for the system modes (γ_i)

Premultiplying Equation (37) by $\{\Phi\}^T$ and postmultiplying it by $\{\Phi\}$ yields:

$$\{\Phi\}^T [C] \{\Phi\} = a_o \{\Phi\}^T [M] \{\Phi\} + a_1 \{\Phi\}^T [K] \{\Phi\} \quad (33)$$

Substituting Equations (38) into Equation (39) gives;

$$2[\gamma][\Lambda]^{1/2} = a_o [I] + a_1 [\Lambda] \quad (34)$$

The two factors, a_o and a_1 can be determined by specifying the damping ratios for two modes for example 1 and 2, and substituting into Equation (34) as⁽¹²⁾:

$$2\gamma_1 \omega_1 = a_o + a_1 \omega_1^2 \quad (35)$$

$$2\gamma_2 \omega_2 = a_o + a_1 \omega_2^2 \quad (36)$$

where ω_1 and ω_2 are the natural frequencies for modes 1 and 2 respectively. By solving the above two Equations one can get:

$$a_o = \frac{2\omega_1 \omega_2 (\omega_2 \gamma_1 - \omega_1 \gamma_2)}{(\omega_2^2 - \omega_1^2)} \quad (37)$$

$$a_1 = \frac{2(\omega_2 \gamma_2 - \omega_1 \gamma_1)}{(\omega_2^2 - \omega_1^2)} \quad (38)$$

Then, the values of a_o and a_1 are substituted into Equation (31) to get the required damping matrix.

FORCED VIBRATION ANALYSIS

The calculation of the nonlinear dynamic response of structure of structures including instability or buckling phenomena has received considerable attention and a good amount of literature has appeared on this subject. The nonlinear dynamic analysis depends largely on solving the following Equations:

$$[M] \{\ddot{d}(t)\} + [C] \{\dot{d}(t)\} + [K_T] \{d(t)\} = \{F(t)\} \quad (39)$$

in which $[K_T]$ is the tangent stiffness matrix of the plate (or structure) and depends on the current displacements and stresses. The most conventional implicit time integration procedures is **Newmark** method. After solving Equation (39) at time $(t+\Delta t)$ for displacements, velocities, and accelerations, the following equation as:

$$([K_T] + a_o [M] + a_1 [C]) \{d\}_{t+\Delta t} = \{F(t)\}_{t+\Delta t} + [M] (a_2 \{\dot{d}\}_t + a_3 \{\ddot{d}\}_t) + [C] (a_4 \{\dot{d}\}_t + a_5 \{\ddot{d}\}_t) \quad (40)$$

For convenience, the following is used:

$$[K_T]_{eff} = [K_T] + a_o [M] + a_1 [C] \quad (41)$$

and,

$$\{F(t)\}_{eff} = \{F(t)\}_{t+\Delta t} + [M] (a_2 \{\dot{d}\}_t + a_3 \{\ddot{d}\}_t) + [C] (a_4 \{\dot{d}\}_t + a_5 \{\ddot{d}\}_t) \quad (42)$$

So, Equation (42) may be written in the form:

$$[K_T]_{eff} \{d\}_{t+\Delta t} = \{F(t)\}_{eff} \quad (43)$$

For a linear system, $[K_T]_{eff}$ will be constant during the analysis at any time, while in the nonlinear analysis, $[K_T]_{eff}$ is a function of current displacement vector $\{d\}$. Therefore, an iterative procedure must be used to define $[K_T]_{eff}$. In the nonlinear analysis, it is more useful to put Equation (43) in increment form. For such purpose, Equation (43) may be rewritten as:

$$[\hat{K}_T] \{\Delta d\} = \{\Delta \hat{F}(t)\} \quad (44)$$

in which $[\hat{K}_T]$ is the effective stiffness matrix and $\{\Delta \hat{F}(t)\}$ is the effective load vector. Equation (44) is solved by an iterative procedure like Equation (40). It may be noted that Equation (40) may be used for solving linear problems, while for nonlinear problems, Equation (44) should be used.

Solving Equation (44) for $\{\Delta d\}$, approximate values for accelerations, velocities and displacements may be given as:

$$\begin{aligned} \{\ddot{d}\}_{t+\Delta t} &= a_o \{\Delta d\} - a_2 \{\dot{d}\}_t - a_3 \{\ddot{d}\}_t \\ \{\dot{d}\}_{t+\Delta t} &= a_1 \{\Delta d\} - a_4 \{\dot{d}\}_t - a_5 \{\ddot{d}\}_t \\ \{d\}_{t+\Delta t} &= \{d\}_t + \{\Delta d\} ; \end{aligned} \quad (45)$$

where

$$\begin{aligned} a_o &= \frac{1}{\beta(\Delta t)^2}, \quad a_1 = \frac{\gamma}{\beta(\Delta t)}, \quad a_2 = \frac{1}{\beta(\Delta t)}, \quad a_3 = \frac{1}{2\beta} - 1 \\ a_4 &= \frac{\gamma}{\beta} - 1, \quad a_5 = \frac{\Delta t}{2} \left(\frac{\gamma}{\beta} - 2 \right) \end{aligned}$$

APPLICATIONS AND DISCUSSIONS

Several plates are analyzed to study the different effects on the large displacement dynamic behavior of plates with some comparison with other researchers.

Comparison with available theoretical investigation of composite plate

Clamped supported square angle-ply laminated plate under transverse suddenly applied constant dynamic loading

A square angle-ply ($0^\circ/45^\circ/90^\circ/\text{core}/90^\circ/45^\circ/30^\circ/0^\circ$) sandwich laminated plate with clamped edges and subjected to a suddenly applied uniformly transverse load was analyzed and compared with **Kommineni** and **Kant [1993]**⁰. The following layer material properties are used in the analysis: for face sheets (Graphite/epoxy prereg system) ($E_1=130.8$ GPa; $E_2=10.6$ GPa $G_{12}=G_{13}=6$ GPa; $G_{23}=3.9$ GPa; $\nu_{12}=0.28$; and $\rho=15.8$ kN.sec²/m⁴); for core sheet (US Commercial al. honeycomb, 1/4 in cell size, 0.003 in foil) ($G_{13}=0.5206$ GPa; $G_{23}=0.1772$ GPa; $\rho=1.009$ kN.sec²/m⁴). The time step is ($\Delta t=0.000025$ sec), and applied load ($q=50$ kN/m²). The geometry properties are ($a=1.0$ m, $a/b=1$, and $h=0.01$ m, at top three stiff layers, thickness of each layer= 0.025 h , at bottom four stiff layer, thickness of each layer= 0.08125 h , and thickness of core= 0.6 h). **Kommineni** and **Kant** used nine-node isoparametric Lagrangian

elements with nine-node degrees of freedom per node and divided the full plate into (4×4) element mesh.

In the present study, the full laminated plate is modeled by (4×4) element mesh with nine-node isoparametric Lagrangian element and nine degrees of freedom per node. A consistent mass matrix and **Newmark** integration method with $\alpha=1/2$, and $\beta=1/4$ were used in the present study.

Figure (4) shows the time history curve for the clamped angle-ply laminated plate under transverse suddenly applied load. From this figure, it can be noticed that good agreement with other study exists with a difference not exceeding (1%).

Figure (4): Central deflection ratio-time curve of a clamped square sandwich composite plate under transverse constant dynamic loading, ($b/h=100$, $\Delta t=0.000025\text{sec}$, $q=50\text{ kN/m}^2$)

A simply supported square plate with slenderness ratio ($b/h=100$), and with symmetric cross-ply and antisymmetric cross-ply arrangements, were chosen to study the effect of number of layers on the large displacement dynamic behavior of a laminated composite plate under in-plane constant dynamic loading. The initial imperfection is ($w_0/h=0.1$) by which the shape is considered to be a sinusoidal curve.

Figures (5) and (6) present the time history curve and show that for the same volume of the plate, the response (deflection) will decrease about (15%) for the symmetric cross-ply and about (29%) for the antisymmetric cross-ply plates where with increasing the number of layers (3-10) for the symmetric cross-ply and (2-10) for the antisymmetric cross-ply arrangements, the stiffness increase may be related to the increase of the number of the reinforced layers. Thus, extension and bending stiffness will increase; and therefore, the amplitude will decrease. Also, the increase of the number of layers will give a better distribution of orthogonal stiffness through the depth. From these figures, it can be seen that the increase of the number of layers more than (8 layers) for the symmetric cross-ply and the antisymmetric cross-ply plates have slight effect on increasing the stiffness of the plate.

Figure (5): Effect of number of layers on the large displacement analysis of symmetric cross-ply laminated plate under in-plane constant dynamic loading ratio ($P_x/P_u=0.4$), ($b/h=100$, $t=0.0001$, $w_o/h=0.1$)

Figure (6): Effect of number of layers on the large displacement analysis of antisymmetric cross-ply laminated plate under in-plane constant dynamic loading ratio ($P_x/P_u=0.4$), ($b/h=100$, $t=0.0001$, $w_o/h=0.1$)

To study the effect of shear deformation on the large displacement dynamic analysis of a laminated composite plate under in-plane constant dynamic loading, a simply supported square plate with slenderness ratio ($b/h=20$), and with symmetric cross-ply antisymmetric cross-ply arrangements and with eight layers was analyzed. The initial imperfection is ($w_o/h=0.1$) by which the shape is considered to be a sinusoidal curve.

Figures (7) and (8) present the time history curves for the symmetric cross-ply, and for the antisymmetric cross-ply laminated composite plates by taking the through-thickness shear deformation through the degrees of freedom of the element. From these figures, it can be noticed that increasing the number of degrees of freedom per node from five degrees to nine degrees will increase the central deflection about (16%) for symmetric cross-ply and about (20%) for antisymmetric cross-ply plates.

Figure (7): Effect of transverse shear deformation on the large displacement analysis of symmetric cross-ply laminated plate under in-plane constant dynamic loading ratio ($P_x/P_u=0.3$), ($b/h=20$, $t=0.0001$, $w_o/h=0.1, P_u=18563$ kN/m)

Figure (8): Effect of transverse shear deformation on the large displacement analysis of antisymmetric cross-ply laminated plate under in-plane constant dynamic loading ratio ($P_x/P_u=0.3$), ($b/h=20$, $t=0.0001$, $w_o/h=0.1, P_u=16347$ kN/m)

To study the effect of damping on the large displacement elastic-plastic dynamic behavior of composite plates, two examples are considered. The first one is a simply

supported square plate with symmetric cross-ply lamination with eight layers and under in-plane dynamic loading. The second one is a simply supported square plate with antisymmetric cross-ply lamination with eight layers and under in-plane dynamic loading. Different values of damping factor (0.05-0.1) are considered in the present study. The initial imperfection shape is considered to be a sinusoidal curve. The following geometry and layer material properties of high graphite epoxy are used in the analysis: ($E_1=172.5$ GPa; $E_2=7.08$ GPa; $G_{12}=G_{13}=3.45$ GPa, $G_{23}=1.38$ GPa; $\rho=15.8$ kN.sec²/m⁴)⁰. The geometry properties are ($a=1.0$ m, $a/b=1$).

Figure (9) and (10) present the time history curve for a simply supported square plate with symmetric and antisymmetric cross-ply lamination under in-plane constant loading. It is noticed that the response (deflection) decreases with the increase of the damping factor. Also, the plate shows no oscillation about the static deflection position, this means that the plate is under the critical damping ratio

Figure (9):Effect of damping factor on the large displacement analysis of a simply supported square symmetric cross-ply plate under in-plane constant dynamic loading, ($b/h=100$, $t=0.0001$, $w_0/h=0.1$, $P_x/P_u=0.65$, $P_u=972.4$ kN/m)

Figure (10):Effect of damping factor on the large displacement analysis of a simply supported square antisymmetric cross-ply plate under in-plane constant dynamic loading, ($b/h=100$, $t=0.0001$, $w_0/h=0.1$, $P_x/P_u=0.65$, $P_u=960$ kN/m)

CONCLUSIONS

A nonlinear finite element method is adopted for the large displacement dynamic analysis of anisotropic plates under in-plane compressive load. Damping property is considered by using Rayleigh type damping which is linearly related to the mass and the stiffness matrices. Newmark integration method is used for solving the dynamic equilibrium equations. The effects of initial imperfection, orthotropy of individual layers, fiber's orientation angle, type of loading, damping factor, and on the large displacement dynamic analysis are considered. The conclusion it is shown that the antisymmetric cross-ply laminated plate has a damping rate faster than the symmetric cross-ply laminated plate and if damping is considered and if the response of the plate shows no oscillation about the static deflection position, it means that the damping factor is below the critical damping factor. So, noticed that the central deflection increasing with increasing the degree of freedom per node.

Keywords: Scaled boundary finite element method, h -hierarchical adaptivity, subdivision of subdomains, mesh mapping, elastodynamics

Abstract. *This study develops a posterior h -hierarchical adaptive scaled boundary finite element method for transient elastodynamic problems using a mesh refinement procedure which subdivides subdomains. In a time step, the fields of displacement, stress, velocity and acceleration are all semi-analytical and the kinetic energy, strain energy and energy errors are all semi-analytically integrated in subdomains. This makes mesh mapping very simple but accurate. Mesh refinement is very simple, flexible and efficient because only a small number of subdomains are subdivided due to the high accuracy of the SBFEM. The results of an example with stress wave propagation were presented. It is shown that the developed method is capable of capturing the propagation of steep stress regions and calculating accurate dynamic responses, but only using a fraction of degrees of freedom required by adaptive finite element methods.*

1 INTRODUCTION

A few adaptive spatial discretisation methods based on finite element method (FEM) and *posteriori* error estimators have been developed to efficiently simulate elastodynamic problems with stress wave propagation [1, 2]. However, there still exist two major difficulties in adaptive finite element method (AFEM). First, automatic remeshing to capture the stress wave propagation usually involves complicated and time-consuming topological changes on a large number of small-sized elements, especially for large-scale problems. This may also lead to ill-shaped elements resulting in inaccurate responses. Second, mesh mapping after remeshing to transfer state variables from the old mesh to the new one is approximate, which may lead to high accumulative errors in later time steps. In addition, identifying the old element where a new node is located may be time-consuming as well because a large number of finite elements need to be checked.

The scaled boundary finite element method (SBFEM) developed in 1990s [3, 4] is a semi-analytical method combining the advantages of the FEM and the boundary element method (BEM). It models an analysis domain by a small number of large-sized subdomains and only the subdomain boundaries are discretised, and the modeled dimensions are reduced by one as the BEM, but no fundamental solutions or singular integrations are needed. Therefore, the FEM's wide applicability and the BEM's simplicity in remeshing are both retained.

This study aims to further extend the applicability of the SBFEM by developing an adaptive SBFEM (ASBFEM) for transient elastodynamic problems using a simple subdomain subdivision procedure. A simply-supported beam under impact was modeled to validate the developed ASBFEM.

2 METHODOLOGY

2.1 The scaled boundary finite element method

A domain of analysis is illustrated in Figure 1(a) as an example. The domain is divided into three subdomains whose geometry and dimensions are defined by a few vertices. Figure 1(b) shows the details of Subdomain 1. The subdomain is represented by scaling a defining curve S relative to a scaling centre. A normalized radial coordinate ξ is defined, varying from zero at the scaling centre and unit value on S . A circumferential coordinate η is defined around the defining curve S . A curve similar to S defined by $\xi=0.5$ is shown in Figure 1b. The coordinates ξ and η form a local coordinate system used in all the subdomains and simple transformation equations between the local and global coordinates can be identified with ease for each subdomain:

$$x = x_0 + \xi \left(\frac{x_1 + x_2 - 2x_0}{2} + \frac{(x_2 - x_1)\eta}{2} \right) \quad (1)$$

$$y = y_0 + \xi \left(\frac{y_1 + y_2 - 2y_0}{2} + \frac{(y_2 - y_1)\eta}{2} \right) \quad (2)$$

where (x_1, y_1) and (x_2, y_2) are nodal coordinates of a two-node element on the boundary and (x_0, y_0) are the coordinates of the scaling centre. The displacements of any point (ξ, η) in a subdomain are assumed as

$$\mathbf{u}(\xi, \eta) = \mathbf{N}(\eta)\mathbf{u}(\xi) \quad (3)$$

where $\mathbf{u}(\xi)$ are the displacements along the radial lines and are analytical with respect to ξ . $\mathbf{N}(\eta)$ is the shape function matrix in the circumferential direction.

Figure 1 The concept of the scaled boundary finite element method

For linear elastic materials, the stress vector in a subdomain is calculated by

$$\boldsymbol{\sigma}(\xi, \eta) = \mathbf{D}\mathbf{B}^1(\eta)\mathbf{u}(\xi)_{,\xi} + \frac{1}{\xi}\mathbf{D}\mathbf{B}^2(\eta)\mathbf{u}(\xi) \quad (4)$$

where $\mathbf{B}^1(\eta)$ and $\mathbf{B}^2(\eta)$ are coefficient matrixes, and \mathbf{D} is the elasticity matrix.

2.2 Solutions in time domain

In elastodynamics, the dynamic equilibrium equation of a subdomain is derived as [5]

$$\mathbf{M}_s \ddot{\mathbf{u}}_b + \mathbf{K}_s \mathbf{u}_b = \mathbf{p}_s \quad (5)$$

where \mathbf{u}_b is the displacement vector and $\ddot{\mathbf{u}}_b$ is the acceleration vector on the subdomain boundary, \mathbf{p}_s the subdomain load vector, \mathbf{K}_s the subdomain stiffness matrix and \mathbf{M}_s the subdomain mass matrix.

Assembling Eq. (5) for all subdomains lead to the global equation system

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{P} \quad (6)$$

where \mathbf{M} and \mathbf{K} are the assembled global mass and stiffness matrices, \mathbf{P} is the global load vector, \mathbf{U} and $\ddot{\mathbf{U}}$ are the nodal displacement and acceleration vectors respectively.

The Newmark integration scheme [6] is used to solve Eq. (6). At time step n , the state variables are calculated by

$$(a_1\mathbf{M} + \mathbf{K})\mathbf{U}_n = \mathbf{F}_n + \mathbf{M}(a_1\mathbf{U}_{n-1} + a_2\dot{\mathbf{U}}_{n-1} + a_3\ddot{\mathbf{U}}_{n-1}) \quad (7a)$$

$$\ddot{\mathbf{U}}_n = a_1(\mathbf{U}_{n-1} - \mathbf{U}_{n-1}) - a_2\dot{\mathbf{U}}_{n-1} - a_3\ddot{\mathbf{U}}_{n-1} \quad (7b)$$

$$\dot{\mathbf{U}}_n = \dot{\mathbf{U}}_{n-1} + a_4\ddot{\mathbf{U}}_{n-1} + a_5\ddot{\mathbf{U}}_n \quad (7c)$$

$$a_1 = \frac{1}{\beta(\Delta t)^2}, \quad a_2 = \frac{1}{\beta\Delta t}, \quad a_3 = \frac{1}{2\beta} - 1, \quad a_4 = \Delta t(1 - \gamma), \quad a_5 = \gamma\Delta t \quad (8)$$

where Δt is the time increment, β and γ are the Newmark parameters. In this study, $\beta = 0.25$ and $\gamma = 0.5$ are used for all the examples with unconditional stability.

The subdomain displacement and stress field are

$$\mathbf{u}(\xi, \eta) = \mathbf{N}(\eta) \sum_{i=1}^N c_i \xi^{\lambda_i} \boldsymbol{\varphi}_i \quad (9)$$

$$\boldsymbol{\sigma}(\xi, \eta) = \mathbf{DB}^1(\eta) \left(\sum_{i=1}^N c_i \lambda_i \xi^{\lambda_i-1} \boldsymbol{\varphi}_i \right) + \mathbf{DB}^2(\eta) \left(\sum_{i=1}^N c_i \xi^{\lambda_i-1} \boldsymbol{\varphi}_i \right) \quad (10)$$

where λ_i and $\boldsymbol{\varphi}_i$ ($i=1-N$) are eigen values and eigen vectors from solving a standard eigen problems [7]. $\mathbf{c}=\{c_1, c_2, \dots, c_N\}^T$ are constants dependent on boundary conditions, and N is the number of degrees of freedom (DOFs) of the subdomain.

The velocity and acceleration fields in a subdomain are calculated by differentiating Eq. (9) with respect to time

$$\dot{\mathbf{u}}(\xi, \eta) = \mathbf{N}(\eta) \sum_{i=1}^N \dot{c}_i \xi^{\lambda_i} \boldsymbol{\varphi}_i \quad (11)$$

$$\ddot{\mathbf{u}}(\xi, \eta) = \mathbf{N}(\eta) \sum_{i=1}^N \ddot{c}_i \xi^{\lambda_i} \boldsymbol{\varphi}_i \quad (12)$$

From Eqs. (9)-(12) it is clear that the displacements, stresses, velocities and accelerations in a subdomain are all analytical with respect to the radial coordinate ξ .

3 DYNAMIC ENERGY ERROR ESTIMATOR

The energy norm of the total energy is

$$\|\mathbf{u}\| = \left(\|\mathbf{u}\|_k^2 + \|\mathbf{u}\|_s^2 \right)^{1/2} \quad (13)$$

where

$$\|\mathbf{u}\|_k = \left(\sum_{s=1}^{NS} \int_{V_s} \dot{\mathbf{u}}(\xi, \eta)^T \rho \dot{\mathbf{u}}(\xi, \eta) dV \right)^{1/2} \quad (14)$$

$$\|\mathbf{u}\|_s = \left(\sum_{s=1}^{NS} \int_{V_s} \boldsymbol{\sigma}(\xi, \eta)^T \mathbf{D}^{-1} \boldsymbol{\sigma}(\xi, \eta) dV \right)^{1/2} \quad (15)$$

are the energy norm of the kinetic energy and the strain energy respectively. NS is the number of subdomains.

A recovered stress field can be used to calculate the strain energy semi-analytically [8]

$$\|\mathbf{u}\|_s \approx \left(\sum_{s=1}^{NS} \sum_{i=1}^N \sum_{j=1}^N \frac{c_i c_j}{\lambda_i + \lambda_j} \int_{S_s} \boldsymbol{\sigma}_i^*(\eta)^T \mathbf{D}^{-1} \boldsymbol{\sigma}_j^*(\eta) |J| d\eta \right)^{1/2} \quad (16)$$

And the kinetic energy is [9]

$$\|\mathbf{u}\|_k = \left(\sum_{s=1}^{NS} \sum_{i=1}^N \sum_{j=1}^N \frac{\rho \dot{c}_i \dot{c}_j}{\lambda_i + \lambda_j + 2} \int_{S_s} (\dot{\mathbf{u}}_i(\eta))^T \dot{\mathbf{u}}_j(\eta) |J| d\eta \right)^{1/2} \quad (17)$$

where $\boldsymbol{\sigma}_i^*$ is the recovered stresses of i th mode at the boundary nodes, $\dot{\mathbf{u}}_i(\eta)$ is the velocity vector of i th mode along the subdomain boundary.

Substituting Eqs. (16) and (17) into Eq. (13) yields

$$\|\mathbf{u}\| = \left(\sum_{s=1}^{NS} \sum_{i=1}^N \sum_{j=1}^N \left(\frac{\rho \dot{c}_i \dot{c}_j}{\lambda_i + \lambda_j + 2} \int_{S_s} (\dot{\mathbf{u}}_i(\eta))^T \dot{\mathbf{u}}_j(\eta) |J| d\eta + \frac{c_i c_j}{\lambda_i + \lambda_j} \int_{S_s} \boldsymbol{\sigma}_i^*(\eta)^T \mathbf{D}^{-1} \boldsymbol{\sigma}_j^*(\eta) |J| d\eta \right) \right)^{1/2} \quad (18)$$

The domain energy error can be evaluated as [8]

$$\|\mathbf{e}\| \approx \left(\sum_{s=1}^{NS} \|\mathbf{e}\|_s^2 \right)^{1/2} \quad (19)$$

where

$$\|\mathbf{e}\|_s \approx \sum_{i=1}^N \sum_{j=1}^N \frac{c_i c_j}{\lambda_i + \lambda_j} \int_{S_s} \mathbf{e}_{\sigma_i}^*(\eta)^T \mathbf{D}^{-1} \mathbf{e}_{\sigma_j}^*(\eta) |J| d\eta \quad (20)$$

is the energy error of a subdomain and

$$\mathbf{e}_\alpha^*(\eta) = \mathbf{N}(\eta)\boldsymbol{\sigma}_i^* - \mathbf{D}(\lambda_i\mathbf{B}^1(\eta) + \mathbf{B}^2(\eta))\boldsymbol{\varphi}_i \quad (21)$$

The dynamic energy error estimator is defined as

$$\delta = \frac{\|\mathbf{e}\|}{\|\mathbf{u}\|} \times 100\% \quad (22)$$

4 THE ADAPTIVE PROCEDURE

4.1 Remeshing

The aim of the adaptive procedure is to make each subdomain contribute equally to the domain energy error. The average limit of the subdomain error is defined as

$$\|\mathbf{e}\|_s^{\text{lim}} = \bar{\delta} \left(\frac{\|\mathbf{u}\|^2}{NS} \right)^{1/2} \quad (23)$$

where $\bar{\delta}$ is the target error estimator of the domain.

A parameter θ is employed to identify the subdomains that should be refined

$$\theta = \frac{\|\mathbf{e}\|_s}{\|\mathbf{e}\|_s^{\text{lim}}} \quad (24)$$

Figure 2 The remeshing procedure

In each time step, a very simple mesh refinement procedure applies to all subdomains with $\theta > 1$, as illustrated in Figure 2 where two subdomains in the whole domain are shown. Subdomain 1 needs to be refined and Subdomain 2 represents those connected with Subdomain 1. Figure 2a shows the two subdomains with vertices only after nodes are removed. Subdomain 1 is first subdivided into four smaller subdomains by adding a vertex at the scaling centre and a vertex at the middle point of each of the four edges, as shown in Figure 2b. The old subdomain 1 is then deleted and the topologies of the four smaller subdomains are generated. The topology of Subdomain 2 is updated with the addition of one vertex. A global seed of elemental size is then assigned to the five subdomains to generate nodes on their edges, resulting in Figure 2c for analysis.

The estimator is updated based on the new mesh until the following condition is satisfied

$$\delta < \bar{\delta} \quad (25)$$

4.2 Mesh mapping

Once a new mesh is obtained, nodal state variables, including displacement, velocity and acceleration, are transferred from the old mesh to the new one as initial conditions of the following time step. For a point or a node located at coordinates (x_0, y_0) in the new mesh after remeshing, the subdomain in the old mesh within which the point (x_0, y_0) is located is first found. The coordinates (x_0, y_0) are then easily transformed to SBFEM coordinates (ξ_0, η_0) by Eqs. (1) and (2) in this subdomain. Because the properties of this subdomain (eigenvalues λ_i , eigenvectors $\boldsymbol{\varphi}_i$ and constants c_i) are known, the displacements, velocities and accelerations at (ξ_0, η_0) in the old mesh or (x_0, y_0) in the new mesh can be calculated by Eq. (9), Eq. (11) and Eq. (12), respectively ($\xi = \xi_0, \eta = \eta_0$). This procedure is also very accurate because Eqs (9, 11-12) are semi-analytical. In addition, because the SBFEM discretises a domain by a few large-sized subdomains, it takes little time to locate the old subdomain for the newly-generated nodes.

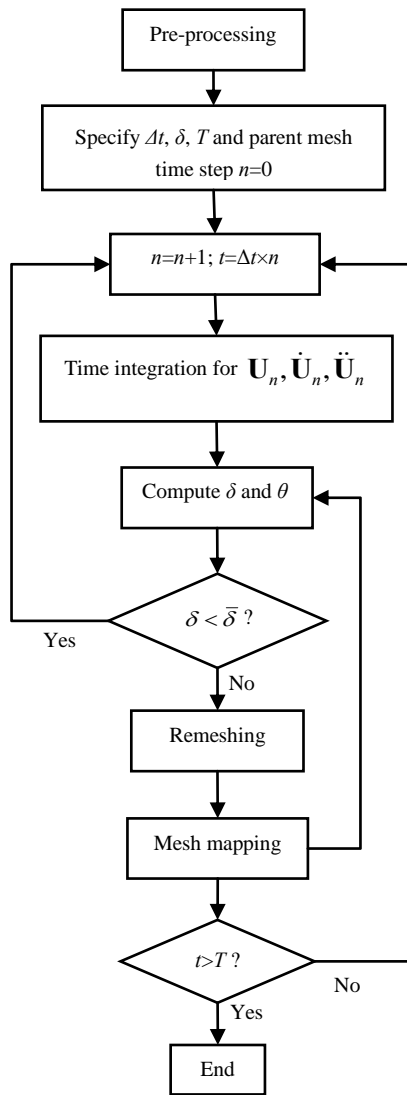

Figure 3 Flow chart of the adaptive procedure

regular mesh (mesh 1) and an irregular mesh (mesh 2) are employed as the parent mesh, as shown in Figure 5. The target error estimator is $\bar{\delta}=15\%$. The same example was modeled in [2] using AFEM.

Figure 5 Parent meshes of the beam

4.3 The flow chart

Figure 3 illustrates the flow chart of the adaptive procedure. A parent mesh consisting of relatively large-sized subdomains and a target error estimator $\bar{\delta}$ are input first. At time step n , the state variables $\mathbf{U}_n, \dot{\mathbf{U}}_n, \ddot{\mathbf{U}}_n$ are solved by the Newmark integration method using the old mesh at the end of time step $(n-1)$ and the error estimator δ is calculated. If δ exceeds the target, the adaptive procedure is triggered to identify a new mesh, starting from the parent mesh. The nodal state variables are then mapped from the old mesh to the new mesh as the initial conditions. After the state variables are solved, Eq. (25) is checked again. This iteration is repeated until an optimal adaptive mesh satisfying Eq. (25) is identified.

5 NUMERICAL EXAMPLE

Figure 4 Dimensions of the simply-supported beam

The numerical example examined is a simply-supported beam subjected to an impact loading on the beam top face. The dimensions and material properties are shown in Figure 4. The dynamic responses in a time period of $(0, 1.2\text{s})$ were calculated with a constant time increment $\Delta t=0.02\text{s}$. A

Figures 6(a) and 6(b) show the horizontal stress contours and corresponding adaptive meshes at $t=0.04\text{s}$ & 0.10s respectively. It can be observed that, with the stress wave propagation, the mesh is refined from the ends to the mid-span of the beam.

Figure 7 shows the histories of vertical displacement at point A. It can be seen that the results of non-adaptive SBFEM for both meshes gradually deviate away from the results of FEM [2] using a very fine mesh which can be considered as exact.

The results of the developed ASBFEM are better than AFEM reported in [2] and very close to FEM. Figure 8 shows the horizontal stress at point B. It can also be seen that the results of the present method agree well with FEM and better than the non-adaptive SBFEM.

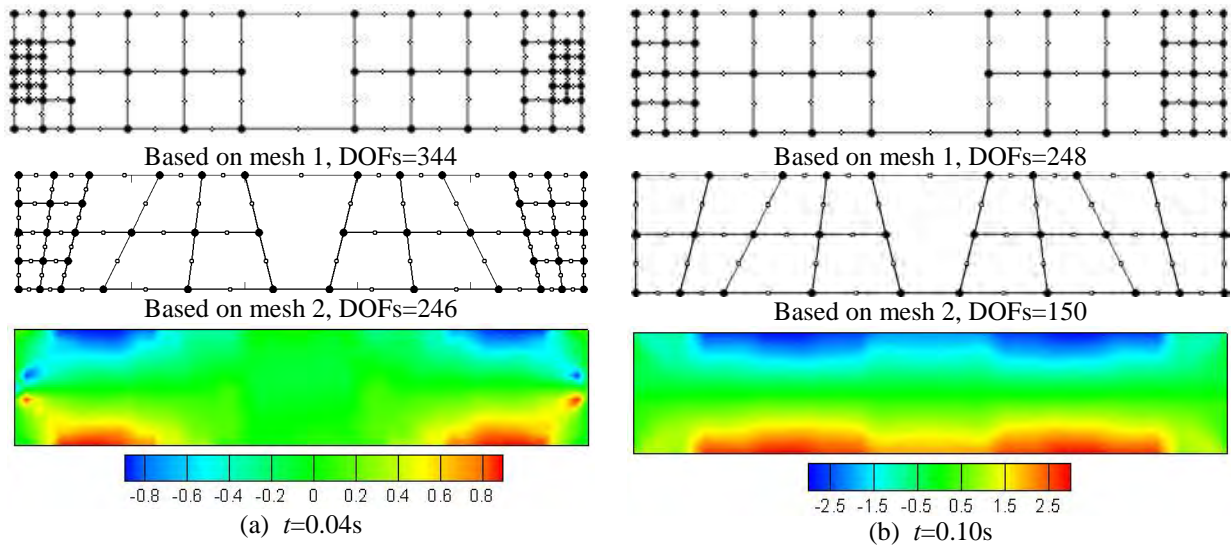

Figure 6 Adaptive meshes and the horizontal stress contours

Figure 7 Histories of the vertical displacement at A

Figure 8 Histories of horizontal stress at B

Figure 9 Histories of the energy error estimator δ

Figure 10 Histories of degrees of freedom

Figure 9 shows the histories of the energy error estimator calculated by non-adaptive SBFEM and the present method. It can be observed that the present method is able to control the estimator under the target 15% in most stages, while the estimators of the former are around 20% based on mesh 1 and 25% based on mesh 2 respectively.

Figure 10 shows the degrees of freedom used in the present ASBFEM. For this example, 150 DOFs are used in most stages while about 2,000 DOFs were used in AFEM [2].

6 CONCLUSIONS

An adaptive scaled boundary finite element method subdividing subdomains has been developed for elastodynamic problems in this study. It uses a semi-analytically integrated posteriori error estimator, and a simple and efficient mesh refinement procedure with accurate mesh mapping to adaptively identify an optimal mesh that captures stress wave propagation. An example under impact load was modelled. It has been demonstrated that the developed method is capable of computing accurate dynamic responses and effectively capturing stress wave propagation while using a fraction of degrees of freedom that are needed by adaptive finite element methods. The developed method thus provides a strong competitor in adaptive modelling of elastodynamic problems.

Keywords: Theory of anisotropic shells, Shell theory of Paliy-Spiro, Shell theory of Rodionova-Titaev-Chernykh.

Abstract. *In [1] the stiffness of bridges and cantilevers made of natural chrysotile asbestos nanotubes has been studied by means of scanning probe microscopy. The stiffness is defined as a ratio the value of local load (applied to the tube) to the value of the displacement. The nanotubes with different materials for fillings are analyzed. The experiments show that the stiffness of the tube depends on the materials for filling. The tubes with water are softer than the tubes without filling materials and the tubes filled with mercury are more rigid than tubes without filling materials. It was shown in [1] that the classical theory of beam bending can not explain the experimental results, but the experimental results well agree with the Timoshenko-Reissner theory (at least qualitatively), when interlaminar shear modulus of elasticity changes for different filling materials. When additional factors such as lamination of structure and cylindrical anisotropy are taken into account [2] the theory of Rodionova-Titaev-Chernykh (RTC) permits to obtain much more reliable results. In this work the authors also applied one more nonclassical shell theory, namely the shell theory of Paliy-Spiro (PS) developed for medium - thickness shells and considered radial pressure. The comparison of nonclassical shell theories (RTC and PS) with experimental data and FEM calculations are presented in the report.*

1 INTRODUCTION

It is known [3] that mechanical characteristics corresponding to nano-dimensional structure elements such as beams, plates and shells can differ from mechanical characteristics corresponding to structures of the same material, which have "normal" geometrical sizes. There is a possibility of appearance of the anisotropy of nanoobjects. In [1], [2] results of experiments, which examined mechanical properties of nanotubes made of natural chrysolite asbestos are discussed. The diameter of nanotubes is approximately equal to 30nm, internal diameter is 5nm. The inner cavity of a tube was filled with water, mercury or tellurium under pressure. The rigidity of nanotubes was measured with the use of scanning probing microscopy. The rigidity was understood as the ratio between applied strain and value of bridge deflection formed by the nanotube, which blocked an opening in porous bottom layer. (Conditions of the experiment are described in detail in [1]). The experiments showed that tube filled with water is substantially softer than a "dry" tube (tube without any filler) and tubes filled with mercury are slightly more rigid than "dry" tubes. In [1] experimental data and the results of modeling were compared. The simplest classical models of isotropic beams and non-classical transversal isotropic models were considered. In [2] the problem of nanotubes deformation was solved with the use of the Rodionova-Titaev-Chernykh (RTCH) theory of anisotropic shells [4], which permits to take into account layered structure of asbestos and cylindrical anisotropy as well. In this work deformation of a multilayered tube under locally applied load (Fig. 1) is found with the use of the theory of anisotropic shells of moderate thickness, which is developed in [5]. There was made a comparison of the results obtained with the use of the Timoshenko-Reissner (TR) theory [6], RTCH theory, the Paliy-Spiro theory and FEM calculations in ANSYS code.

2 PROBLEM DEFINITION

Let α and β be cylindrical coordinates on a shell surface, α — the polar angle, β — coordinate along the tube's generatrix, $h^{(i)}$ — thicknesses, $R^{(i)}$ — radii of medium surfaces of the shell layers, and L — tube's length. For definition of coefficients we will use symbol $A_j^{(i)}$. Low index j denotes curvilinear coordinate corresponding to the value A , upper index i — denotes to which layer it corresponds, i.e. if $i = 1$ then A corresponds to the first inner layer, if $i = N$ then A corresponds to the last outer layer. $E_1^{(i)}, E_2^{(i)}, E_3^{(i)}$ are modules of elasticity in tangential and normal directions, $\nu_{jk}^{(i)}$ are the Poisson's ratios.

Figure 1: Geometrical model of the tube

We studies the stress-strain state of a multilayered tube under locally applied load with the use of the new improved iterative theory of anisotropic shells of Rodionova-Titaeva-Chernykh [4], the theory by Paliy-Spiro suggested in [5], the Timoshenko-Reissner theory.

The improved iterative RTCH theory is based on the following hypotheses:

1. transverse tangential and normal stresses are distributed on shell's thickness according to quadratic and cubic laws respectively;
2. tangential and normal components of the displacement vector are distributed on the shell thickness according to quadratic and cubic laws respectively.

This theory takes into account turns of fibers, their deviation and change of their length.

Functions which describe displacement of the shell's layer $u_1(\alpha, \beta, z)$, $u_2(\alpha, \beta, z)$, $u_3(\alpha, \beta, z)$ according to the Rodionova-Chernykh theory are suggested to be found as series of Legendre polynomials P_0, P_1, P_2, P_3 in normal coordinate $z \in \left[-\frac{h}{2}, \frac{h}{2}\right]$

$$\begin{aligned} u_1(\alpha, \beta, z) &= u(\alpha, \beta)P_0(z) + \gamma_1(\alpha, \beta)P_1(z) + \theta_1(\alpha, \beta)P_2(z) + \varphi_1(\alpha, \beta)P_3(z), \\ u_2(\alpha, \beta, z) &= v(\alpha, \beta)P_0(z) + \gamma_2(\alpha, \beta)P_1(z) + \theta_2(\alpha, \beta)P_2(z) + \varphi_2(\alpha, \beta)P_3(z), \\ u_3(\alpha, \beta, z) &= w(\alpha, \beta)P_0(z) + \gamma_3(\alpha, \beta)P_1(z) + \theta_3(\alpha, \beta)P_2(z), \end{aligned} \quad (1)$$

$$P_0(z) = 1, \quad P_1(z) = \frac{2z}{h}, \quad P_2(z) = \frac{6z^2}{h^2} - \frac{1}{2}, \quad P_3(z) = \frac{20z^3}{h^3} - \frac{3z}{h}, \quad (2)$$

where u, v, w are the components of the displacement vector for points of the middle surface of the shell, γ_3 and θ_3 characterize change in length of the normal to this surface, γ_1 and γ_2 are angles of rotation of the normal in planes (α, z) , (β, z) correspondingly. The variables θ_1 and φ_1 , describe normal curvature of the fiber in plane (α, z) , quantities θ_2, φ_2 , normal curvature in plane (β, z) before deformation they were perpendicular to the shell middle surface.

The Paliy-Spiro shells theory [5] is a theory of shells of moderate thickness, which assumes the following hypotheses:

1. straight fibers of the shell, which are perpendicular to its middle surface before deformation, remain also straight after deformation;
2. cosine of the slope angle of these fibers shell's slope to the middle surface of the deformed shell is equal to the averaged angle of transverse shear.

Mathematical formulation of these hypotheses gives following equalities:

$$\begin{aligned} u_1(\alpha, \beta, z) &= u(\alpha, \beta) + \phi(\alpha, \beta)z, & u_2(\alpha, \beta, z) &= v(\alpha, \beta) + \psi(\alpha, \beta)z, \\ u_3(\alpha, \beta, z) &= w(\alpha, \beta) + F(\alpha, \beta, z), \\ \phi(\alpha, \beta) &= \gamma_1(\alpha, \beta) + \phi_0(\alpha, \beta), & \psi(\alpha, \beta) &= \gamma_2(\alpha, \beta) + \psi_0(\alpha, \beta), \\ \phi_0(\alpha, \beta) &= -\frac{1}{A_1} \frac{\partial w(\alpha, \beta)}{\partial \alpha} + k_1 u(\alpha, \beta), & \psi_0(\alpha, \beta) &= -\frac{1}{A_2} \frac{\partial w(\alpha, \beta)}{\partial \alpha} + k_2 v(\alpha, \beta), \end{aligned} \quad (3)$$

where ϕ and ψ are angles of normal's rotation in planes (α, z) , (β, z) ; ϕ_0, ψ_0, γ_1 and γ_2 — are angles of normal's rotation to the median surface and angles of displacement in the same planes. The function $F(\alpha, \beta, z)$ characterizes change of length of the normal to the median surface.

The Lamé's coefficients and curvature coefficients, which determine geometry of the cylindrical shell have the following form

$$A_1^{(i)} = R^{(i)}, \quad A_2^{(i)} = 1, \quad k_1^{(i)} = \frac{1}{R^{(i)}}, \quad k_2^{(i)} = 0 \quad (4)$$

Let us introduce the following dimensionless variables:

$$\begin{aligned}
 \tilde{R}^{(i)} &= \frac{A_1^{(i)}}{A_2^{(i)}}, \quad \tilde{h}^{(i)} = \frac{h}{R^{(i)}}, \\
 \{ \tilde{u}^{(i)}, \tilde{v}^{(i)}, \tilde{w}^{(i)}, \tilde{\gamma}_{1,2,3}^{(i)}, \tilde{\theta}_{1,2,3}^{(i)}, \tilde{\varphi}_{1,2}^{(i)}, \tilde{\phi}_{,0}^{(i)}, \tilde{\psi}_{,0}^{(i)} \} \\
 &= \frac{1}{h} \{ u^{(i)}, v^{(i)}, w^{(i)}, \gamma_{1,2,3}^{(i)}, \theta_{1,2,3}^{(i)}, \varphi_{1,2}^{(i)}, \phi_{,0}^{(i)}, \psi_{,0}^{(i)} \}, \\
 \tilde{E}_{2,3} &= \frac{E_{2,3}}{E_1}, \quad \tilde{G}_{13,12,23} = \frac{G_{13,12,23}}{E_1}, \\
 \tilde{Pin}_{1,2,3}^{(i)} &= \frac{Pin_{1,2,3}^{(i)}}{E_1}, \quad \tilde{Pout}_{1,2,3}^{(i)} = \frac{Pout_{1,2,3}^{(i)}}{E_1}, \\
 \{ \tilde{T}_{0,1,2}^{(i)}, \tilde{Q}_{1,2}^{(i)}, \tilde{m}_{1,2,3}^{(i)} \} &= \frac{\{ T_{0,1,2}^{(i)}, Q_{1,2}^{(i)}, m_{1,2,3}^{(i)} \}}{R^{(i)} E_1}, \\
 \{ \tilde{M}_{0,1,2}^{(i)} \} &= \frac{\{ M_{0,1,2}^{(i)} \}}{R^{(i)} E_1 h}, \quad \{ \tilde{q}_{1,2,3}^{(i)} \} = \frac{\{ q_{1,2,3}^{(i)} \}}{E_1},
 \end{aligned} \tag{5}$$

where $Pout_x$, Pin_x are the values of the pressure on the internal and external shell surfaces. For simplicity we introduce the following parameters:

$$\begin{aligned}
 E_{11} &= \frac{1}{1 - \nu_{12}\nu_{21}}, \quad E_{12} = \frac{\tilde{E}_2}{1 - \nu_{12}\nu_{21}}, \quad E_{22} = \frac{\nu_{12}}{1 - \nu_{12}\nu_{21}}, \\
 E_z &= \frac{\tilde{E}_3}{1 - \nu_{13}\mu_1 - \nu_{23}\mu_2}, \quad \mu_1 = \frac{\nu_{31} + \nu_{21}\nu_{32}}{1 - \nu_{12}\nu_{21}}, \quad \mu_2 = \frac{\nu_{32} + \nu_{21}\nu_{31}}{1 - \nu_{12}\nu_{21}}, \\
 K_{11} &= -E_{11}\tilde{h}^{(i)}, \quad K_{12} = E_{22}\tilde{h}^{(i)}, \quad K_{21} = \frac{3}{2}E_{11}\tilde{h}^{(i)}\mu_1, \quad K_{22} = \frac{3}{2}E_{22}\tilde{h}^{(i)}\mu_2, \\
 K_{13} &= E_{11}\frac{\tilde{h}^{(i)}}{2}(\mu_2 + 2\nu_{12}\mu_1), \quad K_{23} = E_{11}\frac{\tilde{h}^{(i)}}{2}(\nu_{12}\mu_1 + 2\mu_2), \\
 \tilde{m}_x^{(i)} &= \frac{\tilde{h}^{(i)}}{2}\tilde{Pout}_x^{(i)}\left(1 + \frac{\tilde{h}^{(i)}}{2}\right) + \frac{\tilde{h}^{(i)}}{2}\tilde{Pin}_x^{(i)}\left(1 - \frac{\tilde{h}^{(i)}}{2}\right), \quad (x = 1, 2, 3), \\
 \tilde{q}_x^{(i)} &= \tilde{Pout}_x^{(i)}\left(1 + \frac{\tilde{h}^{(i)}}{2}\right) - \tilde{Pin}_x^{(i)}\left(1 - \frac{\tilde{h}^{(i)}}{2}\right), \quad (x = 1, 2, 3)
 \end{aligned} \tag{6}$$

3 CORRELATIONS OF THE RODIONOVA-TITAEV-CHERNYKH SHELL THEORY AND THE PALIY-SPIRO THEORY

Shell deformations of the theories under consideration are expressed through the components of displacements with the use of the following equations.

Deformation components those are different for the theories are underlining. Below we present the relations for moments, strains and deformation components for the RTCH theory, which were converted for the case of a cylindrical shell. Substituting the given dependencies in expression (7), we can receive an equation, which characterizes their connection to components of the displacement.

Rodionova-Titaev-Chernykh theory		Paliy-Spiro theory	
$\tilde{\varepsilon}_1^{(i)} = \tilde{h}^{(i)} \left(\frac{\partial \tilde{u}^{(i)}}{\partial \alpha^{(i)}} + \tilde{w}^{(i)} \right),$	$\tilde{\varepsilon}_2^{(i)} = \frac{\partial \tilde{v}^{(i)}}{\partial \beta^{(i)}},$	$\tilde{\varepsilon}_1^{(i)} = \tilde{h}^{(i)} \left(\frac{\partial \tilde{u}^{(i)}}{\partial \alpha^{(i)}} + \tilde{w}^{(i)} \right),$	$\tilde{\varepsilon}_2^{(i)} = \frac{\partial \tilde{v}^{(i)}}{\partial \beta^{(i)}},$
$\tilde{\eta}_1^{(i)} = \tilde{h}^{(i)} \left(\frac{\partial \tilde{\gamma}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{\gamma}_3^{(i)} \right),$	$\tilde{\eta}_2^{(i)} = \frac{\partial \tilde{\gamma}_2^{(i)}}{\partial \beta^{(i)}},$	$\tilde{\eta}_1^{(i)} = \tilde{h}^{(i)} \left(\frac{\partial \tilde{\phi}^{(i)}}{\partial \alpha^{(i)}} \right),$	$\tilde{\eta}_2^{(i)} = \frac{\partial \tilde{\psi}^{(i)}}{\partial \beta^{(i)}},$
$\tilde{\varepsilon}_{13}^{(i)} = \tilde{h}^{(i)} \frac{\partial \tilde{w}^{(i)}}{\partial \alpha^{(i)}} - \tilde{h}^{(i)} \tilde{u}^{(i)} + 2\tilde{\gamma}_1^{(i)},$		$\tilde{\varepsilon}_{13}^{(i)} = 0,$	
$\tilde{\varepsilon}_{23}^{(i)} = \frac{\partial \tilde{w}^{(i)}}{\partial \beta^{(i)}} + 2\tilde{\gamma}_2^{(i)},$		$\tilde{\varepsilon}_{23}^{(i)} = 0,$	
$\tilde{\omega}_1^{(i)} = \tilde{h}^{(i)} \frac{\partial \tilde{v}^{(i)}}{\partial \alpha^{(i)}},$	$\tilde{\omega}_2^{(i)} = \frac{\partial \tilde{u}^{(i)}}{\partial \beta^{(i)}},$	$\tilde{\omega}_1^{(i)} = \tilde{h}^{(i)} \frac{\partial \tilde{v}^{(i)}}{\partial \alpha^{(i)}},$	$\tilde{\omega}_2^{(i)} = \frac{\partial \tilde{u}^{(i)}}{\partial \beta^{(i)}},$
$\tilde{\tau}_1^{(i)} = \tilde{h}^{(i)} \frac{\partial \tilde{\gamma}_2^{(i)}}{\partial \alpha^{(i)}},$	$\tilde{\tau}_2^{(i)} = \frac{\partial \tilde{\gamma}_1^{(i)}}{\partial \beta^{(i)}},$	$\tilde{\tau}_1^{(i)} = \tilde{h}^{(i)} \frac{\partial \tilde{\psi}^{(i)}}{\partial \alpha^{(i)}},$	$\tilde{\tau}_2^{(i)} = \frac{\partial \tilde{\phi}^{(i)}}{\partial \beta^{(i)}},$
$\tilde{\tau}^{(i)} = \tilde{\tau}_1^{(i)} + \tilde{\tau}_2^{(i)}, \tilde{\omega}^{(i)} = \tilde{\omega}_1^{(i)} + \tilde{\omega}_2^{(i)}$			

Table 1: Deformation components in two theories

$$\begin{aligned}
 \tilde{T}_1^{(i)} &= E_{11} \tilde{h}^{(i)} \varepsilon_1^{(i)} + E_{12} \tilde{h}^{(i)} \varepsilon_2^{(i)} + \mu_1^{(i)} \tilde{T}_0^{(i)}, \quad \tilde{T}_2^{(i)} = E_{12} \tilde{h}^{(i)} \varepsilon_1^{(i)} + E_{22} \tilde{h}^{(i)} \varepsilon_2^{(i)} + \mu_2^{(i)} \tilde{T}_0^{(i)}, \\
 \tilde{M}_1^{(i)} &= \frac{\tilde{h}^{(i)}}{6} (E_{11} \eta_1^{(i)} + E_{12} \eta_2^{(i)}) + \mu_1^{(i)} \tilde{M}_0^{(i)}, \quad \tilde{M}_2^{(i)} = \frac{\tilde{h}^{(i)}}{6} (E_{12} \eta_1^{(i)} + E_{22} \eta_2^{(i)}) + \mu_2^{(i)} \tilde{M}_0^{(i)}, \\
 \tilde{T}_{12}^{(i)} &= \tilde{T}_{21}^{(i)} = \tilde{G}_{12}^{(i)} \tilde{h}^{(i)} \tilde{\tau}^{(i)}, \quad \tilde{M}_{12}^{(i)} = \tilde{M}_{21}^{(i)} = \frac{1}{6} \tilde{G}_{12}^{(i)} \tilde{h}^{(i)} \tilde{\omega}^{(i)}, \\
 \tilde{Q}_1^{(i)} &= \frac{5\tilde{h}^{(i)} \tilde{G}_{13}^{(i)}}{6} \varepsilon_{13}^{(i)} + \frac{\tilde{m}_1^{(i)}}{6} - (\tilde{h}^{(i)})^2 \frac{\tilde{G}_{13}^{(i)}}{6} \frac{\partial \theta_3^{(i)}}{\partial \alpha^{(i)}}, \\
 \tilde{Q}_2^{(i)} &= \frac{5\tilde{h}^{(i)} \tilde{G}_{23}^{(i)}}{6} \varepsilon_{23}^{(i)} + \frac{\tilde{m}_2^{(i)}}{6} - \tilde{h}^{(i)} \frac{\tilde{G}_{23}^{(i)}}{6} \frac{\partial \theta_3^{(i)}}{\partial \beta^{(i)}}, \\
 \tilde{T}_0^{(i)} &= \tilde{m}_3^{(i)} + \frac{(\tilde{h}^{(i)})^2}{12} \left(\frac{\partial \tilde{q}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)} \frac{\partial \tilde{q}_2^{(i)}}{\partial \beta^{(i)}} \right) - \tilde{h}^{(i)} \tilde{M}_1^{(i)}, \\
 \tilde{M}_0^{(i)} &= \frac{(\tilde{h}^{(i)})^2}{10} \tilde{q}_3^{(i)} + \frac{\tilde{h}^{(i)}}{60} \left(\frac{\partial \tilde{m}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)} \frac{\partial \tilde{m}_2^{(i)}}{\partial \beta^{(i)}} \right) - \frac{\tilde{h}^{(i)}}{60} \tilde{T}_1^{(i)}
 \end{aligned} \tag{7}$$

Let us substitute the following relations (8) for six components of the displacement in formulas (7). Thus we reduce them to dependence on the five main components of the displacement $u, v, w, \gamma_1, \gamma_2$:

$$\begin{aligned}
 \tilde{\theta}_1^{(i)} &= \frac{\tilde{q}_1^{(i)}}{12\tilde{G}_{13}} - \frac{\tilde{h}^{(i)}}{6} \frac{\partial \tilde{\gamma}_3^{(i)}}{\partial \alpha^{(i)}}, & \tilde{\varphi}_1^{(i)} &= \frac{m_1^{(i)} - \tilde{Q}_1^{(i)}}{10\tilde{h}^{(i)} \tilde{G}_{13}^{(i)}} - \frac{\tilde{h}^{(i)}}{10} \frac{\partial \tilde{\theta}_3^{(i)}}{\partial \alpha^{(i)}}, \\
 \tilde{\theta}_2^{(i)} &= \frac{\tilde{q}_2^{(i)}}{12\tilde{G}_{23}} - \frac{\tilde{h}^{(i)}}{6\tilde{R}^{(i)}} \frac{\partial \tilde{\gamma}_3^{(i)}}{\partial \beta^{(i)}}, & \tilde{\varphi}_2^{(i)} &= \frac{m_2^{(i)} - \tilde{Q}_2^{(i)}}{10\tilde{h}^{(i)} \tilde{G}_{23}^{(i)}} - \frac{\tilde{h}^{(i)}}{\tilde{R}^{(i)}} \frac{\partial \tilde{\theta}_3^{(i)}}{\partial \beta^{(i)}}, \\
 \tilde{\gamma}_3^{(i)} &= \frac{1}{2\tilde{h}^{(i)}} \frac{\tilde{T}_0^{(i)}}{\tilde{E}_z^{(i)}} - \frac{1}{2} \left(\mu_1 \varepsilon_1^{(i)} + \mu_2 \varepsilon_2^{(i)} \right), & \tilde{\theta}_3^{(i)} &= \frac{1}{\tilde{h}^{(i)}} \frac{\tilde{M}_0^{(i)}}{\tilde{E}_z^{(i)}} - \frac{1}{6} \left(\mu_1 \eta_1^{(i)} + \mu_2 \eta_2^{(i)} \right)
 \end{aligned} \tag{8}$$

The same transformation for Paliy-Spiro theory gives:

$$\begin{aligned}
 \tilde{T}_1^{(i)} &= E_{11}\tilde{h}^{(i)}\varepsilon_1^{(i)} + E_{12}\tilde{h}^{(i)}\varepsilon_2^{(i)} + \frac{\tilde{h}^{(i)}}{12}((K_{11} - K_{12})\tilde{\eta}_1^{(i)} - K_{13}\tilde{\eta}_2^{(i)}) + \mu_1^{(i)}\frac{q_3^i}{2}\tilde{h}^{(i)}, \\
 \tilde{T}_2^{(i)} &= E_{12}\tilde{h}^{(i)}\varepsilon_1^{(i)} + E_{22}\tilde{h}^{(i)}\varepsilon_2^{(i)} + \frac{\tilde{h}^{(i)}}{12}((K_{21} - K_{22})\tilde{\eta}_2^{(i)} - K_{23}\tilde{\eta}_1^{(i)}) + \mu_2^{(i)}\frac{q_3^i}{2}\tilde{h}^{(i)}, \\
 \tilde{T}_{12}^{(i)} &= \tilde{G}_{12}^{(i)}\tilde{h}^{(i)}\left(\tilde{\omega}_1^{(i)} + \tilde{\omega}_2^{(i)} - \frac{(\tilde{h}^{(i)})^2}{12}\tilde{\tau}_1^{(i)}\right), \\
 \tilde{T}_{21}^{(i)} &= \tilde{G}_{12}^{(i)}\tilde{h}^{(i)}\left(\tilde{\omega}_1^{(i)} + \tilde{\omega}_2^{(i)} + \frac{(\tilde{h}^{(i)})^2}{12}\tilde{\tau}_2^{(i)}\right), \\
 \tilde{M}_1^{(i)} &= \frac{\tilde{h}^{(i)}}{6}(E_{11}\eta_1^{(i)} + E_{12}\eta_2^{(i)} + (K_{11} - K_{12})\tilde{\varepsilon}_1^{(i)} - K_{23}\tilde{\varepsilon}_2^{(i)}) + \mu_1^{(i)}\frac{q_3^i}{8}\tilde{h}^{(i)}, \\
 \tilde{M}_2^{(i)} &= \frac{\tilde{h}^{(i)}}{6}(E_{12}\eta_1^{(i)} + E_{22}\eta_2^{(i)} + (K_{21} - K_{22})\tilde{\varepsilon}_2^{(i)} - K_{13}\tilde{\varepsilon}_1^{(i)}) + \mu_2^{(i)}\frac{q_3^i}{8}\tilde{h}^{(i)}, \\
 \tilde{M}_{12}^{(i)} &= \tilde{G}_{12}^{(i)}\frac{\tilde{h}^{(i)}}{12}(\tilde{\tau}_1^{(i)} + \tilde{\tau}_2^{(i)} - (\tilde{h}^{(i)})^2\tilde{\omega}_1^{(i)}), \\
 \tilde{M}_{21}^{(i)} &= \tilde{G}_{12}^{(i)}\frac{\tilde{h}^{(i)}}{12}(\tilde{\tau}_1^{(i)} + \tilde{\tau}_2^{(i)} + (\tilde{h}^{(i)})^2\tilde{\omega}_2^{(i)}), \\
 \tilde{Q}_1^{(i)} &= \tilde{G}_{13}^{(i)}\tilde{h}^{(i)}\gamma_1^{(i)}, \quad \tilde{Q}_2^{(i)} = \tilde{G}_{23}^{(i)}\tilde{h}^{(i)}\gamma_2^{(i)}, \\
 \sigma_{33} &= \frac{\tilde{P}_{out3}^{(i)}\left(1 + \frac{\tilde{h}^{(i)}}{2}\right)\left(0.5 + \frac{z}{h^{(i)}}\right) - \tilde{P}_{in3}^{(i)}\left(1 - \frac{\tilde{h}^{(i)}}{2}\right)\left(0.5 - \frac{z}{h^{(i)}}\right)}{1 + \frac{z}{R^{(i)}}}, \\
 \tilde{F}(\alpha, \beta, z)^{(i)} &= \int_0^z \frac{\sigma_{33}}{E_z} dz - (\mu_1\varepsilon_1 + \mu_2\varepsilon_2)z - \left[\mu_1\left(\eta_1 - \frac{\varepsilon_1}{R^{(i)}}\right) + \mu_2\eta_2\right]\frac{z^2}{2} + \left(\frac{\mu_1\eta_1}{R^{(i)}}\right)\frac{z^3}{3}.
 \end{aligned} \tag{9}$$

By using Table 1 we obtain moments and strains as functions of the displacement $u, v, w, \gamma_1, \gamma_2$. By substituting these relations into equilibrium equation of the cylindrical shell

$$\begin{aligned}
 \frac{\partial \tilde{T}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)}\frac{\partial \tilde{T}_{21}^{(i)}}{\partial \beta^{(i)}} + \tilde{Q}_1^{(i)} + \tilde{q}_1^{(i)} &= 0, \quad \frac{\partial \tilde{T}_{12}^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)}\frac{\partial \tilde{T}_2^{(i)}}{\partial \beta^{(i)}} + \tilde{q}_2^{(i)} = 0, \\
 \frac{\partial \tilde{Q}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)}\frac{\partial \tilde{Q}_2^{(i)}}{\partial \beta^{(i)}} - \tilde{T}_1^{(i)} + \tilde{q}_3^{(i)} &= 0, \\
 \frac{1}{\tilde{h}^{(i)}}\left(\frac{\partial \tilde{M}_1^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)}\frac{\partial \tilde{M}_{21}^{(i)}}{\partial \beta^{(i)}}\right) - \tilde{Q}_1^{(i)} + \tilde{m}_1^{(i)} &= 0, \\
 \frac{1}{\tilde{h}^{(i)}}\left(\frac{\partial \tilde{M}_{12}^{(i)}}{\partial \alpha^{(i)}} + \tilde{R}^{(i)}\frac{\partial \tilde{M}_2^{(i)}}{\partial \beta^{(i)}}\right) - \tilde{Q}_2^{(i)} + \tilde{m}_2^{(i)} &= 0
 \end{aligned} \tag{10}$$

one can get a system of five partial differential equations with five unknown functions for both theories. For the Rodionova-Titaev-Chernykh theory this system of equations is 14 order, and for the Paliy-Spiro theory is of 10 order. Substituting corresponding components of the deformation in formulas (1)-(3) one can get all components of the stress-deformed state of the shells under consideration.

4 TIMOSHENKO-REISSNER THEORY

In the first approximation the nanotube could be considered as a beam. If we use the Timoshenko-Reissner theory then the solution for beams with the freely supported edges has the following [6] form

$$w(L_v) = \frac{FL_v^2(L - L_v)^2}{3LEJ} \left(1 + \frac{1}{GS} \frac{3nEJ}{L_v(L - L_v)}\right). \tag{11}$$

where L_v is a coordinate of the load application, $J = \frac{\pi R^4}{4}$ is moment of inertia for circular cross-section, $n = 5/6$ is coefficient in the formula Zhuravsky, $S = \pi R^2$ is cross-sectional area.

5 NUMERICAL METHOD

For solving the system of equations (10) in the displacements we will use the following series:

$$\begin{aligned} (u^{(i)}(\alpha, \beta)), (\gamma_1^{(i)}(\alpha, \beta)) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} (u_{nm}^{(i)}), (\gamma_{nm}^{(i)}) \sin[n\alpha] \sin[\bar{m}\beta], \\ (v^{(i)}(\alpha, \beta)), (\gamma_2^{(i)}(\alpha, \beta)) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} (v_{nm}^{(i)}), (\gamma_{nm}^{(i)}) \cos[n\alpha] \cos[\bar{m}\beta], \\ w^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} w_{nm}^{(i)} \cos[n\alpha] \sin[\bar{m}\beta], \quad \bar{m} = (\pi m)/L, \end{aligned} \quad (12)$$

These formulas take into account the symmetry of the shell deformation in regard to plane $\alpha = 0$ and provide zero displacements u , γ_1 and w while $\beta = 0, L$. Expressions for v , γ_2 do not satisfy zero boundary conditions but this displacements are small. External and internal forces, which act on the shell surface can be represented as a product of sectional forces expanded in series. Let $X1_{mn}^{(i+1)}$, $X2_{mn}^{(i+1)}$, $X3_{mn}^{(i+1)}$ — be components of the pressure on the external surface of i^{th} shell, and $X1_{mn}^{(i)}$, $X2_{mn}^{(i)}$, $X3_{mn}^{(i)}$ pressure on its internal surface. Then expressions for the load and moments become:

$$\begin{aligned} \tilde{m}_1^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{\tilde{h}^{(i)}}{2} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) + X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \sin[n\alpha] \sin[\bar{m}\beta], \\ \tilde{q}_1^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) - X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \sin[n\alpha] \sin[\bar{m}\beta], \\ \tilde{m}_2^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{\tilde{h}^{(i)}}{2} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) + X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \cos[n\alpha] \cos[\bar{m}\beta], \\ \tilde{q}_2^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) - X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \cos[n\alpha] \cos[\bar{m}\beta], \\ \tilde{m}_3^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \frac{\tilde{h}^{(i)}}{2} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) + X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \cos[n\alpha] \sin[\bar{m}\beta], \\ q_3^{(i)}(\alpha, \beta) &= \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \left(X1_{nm}^{(i+1)} \left(1 + \frac{\tilde{h}^{(i)}}{2} \right) - X1_{nm}^{(i)} \left(1 - \frac{\tilde{h}^{(i)}}{2} \right) \right) \cos[n\alpha] \sin[\bar{m}\beta] \end{aligned} \quad (13)$$

Index $i = 1$ corresponds to the internal, and $i = N + 1$ to the external surface of the tube, which consists of N layers. Following [4], we accept the condition of rigidly bound layers:

$$\tilde{u}_k^{(i)}(\alpha, \beta, h/2) = \tilde{u}_k^{(i+1)}(\alpha, \beta, -h/2), \quad k = 1, 2, 3 \quad (14)$$

The load localized in a small rectangular area can be represented in the form of a product of the Fourier series of two loading functions in cross-section and longitudinal section:

$$Pa[\alpha] = P \left(\frac{C}{L} + \frac{2}{L} \sum_{n=0}^{\infty} \frac{L}{n\pi} \sin\left(\frac{n\pi}{L}C\right) \cos\left(\frac{n\pi}{L}\alpha\right) \right) \quad (15)$$

Pressure in longitudinal section of the tube is equal to

$$Pb[\beta] = P \left(\frac{4}{L} \sum_{m=0}^{\infty} \frac{L}{m\pi} \sin\left(\frac{m\pi}{L}C\right) \sin\left(\frac{m\pi}{L}L_v\right) \sin\left(\frac{m\pi}{L}\beta\right) \right), \quad (16)$$

where L_v is a center of load application, $2C$ is a size of load application area, P is pressure in the area. Pressure area is described by function of the product of the series:

$$Pd[\alpha, \beta] = Pa[\alpha] * Pb[\beta] \quad (17)$$

The load is applied to the outer surface of the tube:

$$X1_{nm}^{(N+1)} = 0, \quad X2_{nm}^{(N+1)} = 0, \quad X3_{nm}^{(N+1)} = Pd[\alpha, \beta] \quad (18)$$

Pressure on the internal surface of the tube is absent:

$$X1_{nm}^{(1)} = 0, \quad X2_{nm}^{(1)} = 0, \quad X3_{nm}^{(1)} = 0 \quad (19)$$

Substituting dependencies (11),(12) and (16) in the system (10) and in conditions (13) we obtain a system of $8N-3$ linear algebraic equations for $5N$ deformation components and $3N-3$ forces of interaction between layers of shells. Each of the obtained coefficients $u_{nm}^{(i)}, v_{nm}^{(i)}, w_{nm}^{(i)}, \gamma1_{nm}^{(i)}, \gamma2_{nm}^{(i)}, X1_{nm}^{(i)}, X2_{nm}^{(i)}, X3_{nm}^{(i)}$ is a member of the Fourier series of functions of deformation and loading functions.

For realization of the aforementioned numerical method we developed a program based on code Mathematica 7.0.

6 NUMERICAL RESULTS

In [4] deformation of a nanotube was considered with the following parameters: thickness of each of the 100 layers $h = 0,135$ nm, inner tube radius $R=2.5$ nm, outer $R=16$ nm, length of the tube $L=500$ nm. For values of the modulus of elasticity of the shell $E_{1,2,3} = 1.75 * 10^{11}$ Pa, and relatively small value of the shear modulus $G_{13} = G_{12} = G_{23} = 2.3 * 10^7$ Pa. Poisson ratios $\nu_{12} = \nu_{21} = \nu_{32} = \nu_{31} = \nu_{23} = \nu_{13} = 0.3$.

The table 2 shows the values of deflection of the described tube, obtained by RTCH, TR theory and theory of PS. Calculation of the functions of displacement was done with external force $F_v = 10$ nN. The area of applied load is $[40 * 40]$ nm². For comparison we present values of deflections of a transversal-isotropic tube, which were received in code Ansys 11 where 3-dimensional 20 knots element Solid 186 was used. Lines "TR1", "Ansys1" correspond to tube with a hole; lines "TR2", "Ansys2" correspond to solid tube.

L_v	250	220	200	170	150	120	100	70	40

Table 2: Deflection of the many-layer nanotube.

Let us compare results obtained by the three-dimensional theory that is used in code Ansys 11 with results obtained by the aforementioned non-classical theories of shells for single-layer cylindrical shell. We consider a shell with constant outer radius and gradually increase the thickness of the shell (and consequently reduce a radius of the middle surface of the shell). The following table lists the values of deflections at the center of considered shells.

Figures 2 present functions of the upper layer displacement of the shell when the load is applied to the center of the tube.

Table 3 gives the values of the deflections of shells. Other values that characterize the stress-strain state of shells are also similar. With increasing the relative thickness of the shell, values of deflection obtained with the PS theory are closer to the values obtained with the finite element method.

h/R	1/15	1/10	1/5	1/4	1/3	1/2
TR1	46.33	31.91	17.55	14.71	11.88	9.13

Keywords: Pneumatic Textile Structures, Anisotropic Toroidal Membrane, Nonlinear Deformation, Asymptotic and Numerical Solutions.

Abstract. *Nonlinear axisymmetric deformation of a toroidal shell under action of internal pressure is considered. The shell is made of neo-Hookean material and is reinforced by two system of threads located on parallels and meridians. The nonlinear theory of membranes is used. For the evaluating deformations and displacements of a membrane the system of the ordinary differential equations of the fourth order is obtained. The method of asymptotical integration in the case when the meridian radius is much smaller than the parallel one is elaborated. Comparison of asymptotic and numerical results is performed.*

1 INTRODUCTION

Textile composites and pneumatic structures have become increasingly popular for a variety of applications in a civil engineering, architecture, aerospace engineering, etc. [1]. Typical examples of inflatable toroidal shells include tires, pneumatic jacks and inflatable pools. In this paper the axisymmetric nonlinear deformation under internal pressure of the toroidal shell reinforced of fibers is studied. The bending of an inflatable cylindrical membrane was considered in the paper [2].

2 MAIN ASSUMPTIONS

It is supposed that the toroidal shell is made of a cylindrical textile composite pipe which contains two systems of threads located on parallels and meridians. The lengths of not deformed threads are equal accordingly L and l (see Figure 1a).

Figure 1: Transformation of the cylindrical pipe into toroidal membrane.

We assume that the fibers are disposed frequently enough. After averaging we get the two-dimensional elastic medium. This medium we consider as an anisotropic membrane. Let's close end faces of a pipe and create inside of it the pressure q . Connecting end faces of a pipe, we get a membrane like the toroidal one (see Figure 1b).

All fibers going on membrane meridians are stretched, but some fibers going on parallels are compressed if $q < q_*$, where q_* is the minimal value of pressure at which all parallels are stretched. A membrane can not hold the compression stresses. Therefore in case $q < q_*$ the part of its surface is covered by folds. If the internal pressure q increases then the area covered by folds decreases. At $q = q_*$ all shell will be stretched.

3 BASIC EQUATIONS

The theory of elastic membranes is a particular case of nonlinear theory of shells developed in the work of W.T. Koiter, W. Pietraszkiewicz, K.Z. Galimov, A. Libai and J.G. Simmonds [3]. The nonlinear membrane theory has the satisfactory accuracy for sufficiently thin shells.

For a toroidal membrane the following geometrical relations are valid:

$$\begin{aligned} \lambda_1 &= \frac{ds}{ds_0}, & \lambda_2 &= \frac{r}{R}, & R &= \frac{L}{2\pi}, \\ \frac{dr}{ds} &= -\sin \theta, & \frac{d\hat{z}}{ds} &= \cos \theta, & \frac{1}{R_1} &= \frac{d\theta}{ds}, & \frac{1}{R_2} &= \frac{\cos \theta}{r}, \end{aligned} \quad (3.1)$$

where $s_0 \in [0, l]$ and $s(s_0)$ are the length of the meridian arch before and after deformation, $r(s_0)$ is the radius of a parallel, $\hat{z}(s_0)$ is the height of a parallel above a point O , $\lambda_1(s_0)$ and

$\lambda_2(s_0)$ are the stretch ratios of meridians and parallels, R_1 and R_2 are the radii of curvature of a surface, θ is the angle between a tangent to a meridian and the vertical direction (see Figure 2).

Figure 2: Toroidal membrane.

The equilibrium equations in a projection to the tangent to a meridian and the normal to the membrane give

$$\frac{d(rT_1)}{ds} + T_2 \sin \theta = 0, \quad \frac{T_1}{R_1} + \frac{T_2}{R_2} = q, \quad (3.2)$$

where q is the internal pressure, T_1 and T_2 are stress resultants.

Assume that the shell and threads are made of incompressible homogeneous isotropic materials with elastic potentials

$$G_i \Phi_i(\lambda_1, \lambda_2, \lambda_3), \quad i = 1, 2, 3, \quad (3.3)$$

where G_i are constants of a material. For the threads going on meridians and parallels $i = 1$ and $i = 2$ accordingly, and $i = 3$ for a material of the shell. In case of small deformations G_i is the shear modulus.

Whereas the material is incompressible, equality $\lambda_1 \lambda_2 \lambda_3 = 1$ is valid. Besides for the threads going on meridians $\lambda_2 = \lambda_3$. Therefore the potential (3.3) becomes

$$G_1 \Phi_1(\lambda_1, \lambda_1^{-1/2}, \lambda_1^{-1/2}) = G_1 \Psi_1(\lambda_1).$$

For the threads going on parallels $\lambda_1 = \lambda_3$ and

$$G_2 \Phi_2(\lambda_2, \lambda_2^{-1/2}, \lambda_2^{-1/2}) = G_2 \Psi_2(\lambda_2).$$

For the shell potential (3.3) have the form

$$G_3 \Phi_3(\lambda_1, \lambda_2, (\lambda_1 \lambda_2)^{-1}) = G_3 \Psi_3(\lambda_1, \lambda_2).$$

The stress resultants entering into equations (3.2) are the sums of the tensile thread forces and the stresses arising as result of a deformation of the shell:

$$T_1 = \frac{G_1 N_1 S_1}{\lambda_2} \frac{d\Psi_1}{d\lambda_1} + \frac{G_3 h_0}{\lambda_2} \frac{\partial \Psi_3}{\partial \lambda_1}, \quad T_2 = \frac{G_2 N_2 S_2}{\lambda_1} \frac{d\Psi_2}{d\lambda_2} + \frac{G_3 h_0}{\lambda_1} \frac{\partial \Psi_3}{\partial \lambda_2}, \quad (3.4)$$

where N_1 , N_2 and S_1 , S_2 are numbers of threads on unit of length in a cross-sectional direction and the areas of cross-section of threads in the state before deformation for meridians and parallels correspondingly, h_0 is the thickness of the shell before deformation.

If at $\varphi \in [\varphi_*, \pi]$ formula (3.4) gives $T_2 < 0$ then according to membrane hypotheses it is necessary to put $T_2 = 0$ in system (3.2) when $\varphi \in [\varphi_*, \pi]$.

4 DIMENSIONLESS VARIABLES

Let's enter dimensionless variables by formulas

$$\begin{aligned} z &= \frac{\hat{z}}{R}, \quad s_0 = \rho\varphi, \quad \rho = \frac{l}{2\pi}, \quad \mu = \frac{\rho}{R}, \quad Q = \frac{qR}{G_0 h_0}, \\ t_1 &= \frac{T_1 \lambda_2}{G_0 h_0}, \quad t_2 = \frac{T_2 \lambda_1}{G_0 h_0}, \quad g_i = \frac{G_i N_i S_i}{G_0 h_0}, \quad i = 1, 2, \quad g_3 = \frac{G_3}{G_0}, \end{aligned} \quad (4.1)$$

where G_0 is any number, $\mu < 0.5$, and parameters g_i characterize relative stiffness of treads in comparison with one of the shell. Due to a choice G_0 any of values g_i can be taken equal 1.

Using formulas (3.1), (3.2) and (4.1) we get the following system for unknown variables $\theta(\varphi)$, $t_1(\varphi)$, $\lambda_2(\varphi)$ and $z(\varphi)$

$$\begin{aligned} \frac{d\theta}{d\varphi} &= \frac{\mu}{t_1}(\lambda_1 \lambda_2 Q - \hat{t}_2 \cos \theta), \quad \frac{dt_1}{d\varphi} = -\mu \hat{t}_2 \sin \theta, \\ \frac{d\lambda_2}{d\varphi} &= -\mu \lambda_1 \sin \theta, \quad \frac{dz}{d\varphi} = \mu \lambda_1 \cos \theta, \\ \hat{t}_2 &= \max\{t_2, 0\}, \quad 0 \leq \varphi \leq 2\pi. \end{aligned} \quad (4.2)$$

The function

$$\Phi(\lambda_1, \lambda_2, \lambda_3) = \frac{1}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3)$$

corresponds to neo-Hookean material. Assume that $\Phi_1 = \Phi_2 = \Phi_3 = \Phi$. Then after the introduction of dimensionless variables (4.1) formulas (3.4) take the form

$$t_1 = g_3 \left(\lambda_1 - \frac{1}{\lambda_1^3 \lambda_2^2} \right) + g_1 \left(\lambda_1 - \frac{1}{\lambda_1^2} \right), \quad t_2 = g_3 \left(\lambda_2 - \frac{1}{\lambda_1^2 \lambda_2^3} \right) + g_2 \left(\lambda_2 - \frac{1}{\lambda_2^2} \right). \quad (4.3)$$

Owing to the symmetry of the problem to the plane $z = 0$, to find its periodic solution it is enough to find the solution of system (4.2), (4.3) satisfying the boundary conditions

$$\theta(0) = 0, \quad z(0) = 0, \quad \theta(\pi) = \pi, \quad z(\pi) = 0. \quad (4.4)$$

5 THE APPROXIMATE SOLUTION FOR COMPLETELY STRETCHED MEMBRANE

Assume that $\mu \ll 1$, $t_2 \geq 0$ for $\varphi \in [0, \pi]$ and introduce the new variables

$$\alpha = \mu^{-1} t_1, \quad \beta = \mu^{-1}(\lambda_1 - 1), \quad \gamma = \mu^{-1}(\lambda_2 - 1), \quad \delta = \mu^{-1} t_2, \quad \zeta = \mu^{-1} z. \quad (5.1)$$

Equations (4.2), (4.3) and boundary conditions (4.4) take the form

$$\begin{aligned} \frac{d\alpha}{d\varphi} &= -\mu \delta \sin \theta, \quad \frac{d\theta}{d\varphi} = \frac{1}{\alpha}[(1 + \mu\beta)(1 + \mu\gamma)Q - \mu\delta \cos \theta], \\ \frac{d\zeta}{d\varphi} &= (1 + \mu\beta) \cos \theta, \quad \frac{d\gamma}{d\varphi} = -(1 + \mu\beta) \sin \theta. \end{aligned} \quad (5.2)$$

$$\begin{aligned} \mu\alpha &= (g_1 + g_3)(1 + \mu\beta) - \frac{g_1}{(1 + \mu\beta)^2} - \frac{g_3}{(1 + \mu\beta)^3(1 + \mu\gamma)^2} \\ \mu\delta &= (g_2 + g_3)(1 + \mu\gamma) - \frac{g_2}{(1 + \mu\gamma)^2} - \frac{g_3}{(1 + \mu\gamma)^3(1 + \mu\beta)^2} \end{aligned} \quad (5.3)$$

$$\theta(0) = \zeta(0) = \zeta(\pi) = 0, \quad \theta(\pi) = \pi. \quad (5.4)$$

Substitute into (5.2)–(5.4) the asymptotic expansions

$$\begin{aligned} \alpha &= \alpha_0 + \mu\alpha_1, & \beta &= \beta_0 + \mu\beta_1, & \gamma &= \gamma_0 + \mu\gamma_1, \\ \delta &= \delta_0 + \mu\delta_1, & \theta &= \theta_0 + \mu\theta_1, & \zeta &= \zeta_0 + \mu\zeta_1. \end{aligned} \quad (5.5)$$

In the zeroth approximation we get

$$\begin{aligned} \alpha_0 &= Q, & \theta_0 &= \varphi, & \zeta_0 &= \sin \varphi, & \gamma_0 &= \cos \varphi + a_0, \\ \beta_0 &= A_1 - A_2\gamma_0, & \delta_0 &= A_3\gamma_0 + A_4, \end{aligned} \quad (5.6)$$

where a_0 is the arbitrary constant which can be found at the construction of the first approximation,

$$A_1 = \frac{Q}{4g_3 + 3g_1}, \quad A_2 = \frac{2g_3A_1}{Q}, \quad A_3 = 4g_3 + 3g_2 - 2g_3A_2, \quad A_4 = QA_2.$$

It follows from formulas (4.1), (5.1) and (5.6) that in the zeroth approximation a cross-section of the membrane is the circumference of the radius ρ . The distance between the center of this circumference and the center of the torus is equal to $R + a_0\rho$.

The solutions of equations of the first approximation

$$\begin{aligned} \frac{d\alpha_1}{d\varphi} &= -\delta_0 \sin \varphi, & \frac{d\theta_1}{d\varphi} &= \beta_0 + \gamma_0 - \frac{\alpha_1}{Q} - \frac{\delta_0}{Q} \cos \varphi, \\ \frac{d\zeta_1}{d\varphi} &= \beta_0 \cos \varphi - \theta_1 \sin \varphi, & \frac{d\gamma_1}{d\varphi} &= -\beta_0 \sin \varphi - \theta_1 \cos \varphi, \end{aligned} \quad (5.7)$$

satisfy the boundary conditions

$$\theta_1(0) = \zeta_1(0) = \theta_1(\pi) = \zeta_1(\pi) = 0. \quad (5.8)$$

First equation (5.7) has solution

$$\alpha_1 = (A_3a_0 + A_4) \cos \varphi + \frac{A_3}{2} \cos^2 \varphi + a_1Q, \quad (5.9)$$

where a_1 is the arbitrary constant. Substitution expressions (5.9) in second equation (5.7) and taking first condition (5.8) into account we get

$$\theta_1 = (A - 3c)\varphi + B \sin \varphi - \frac{c}{2} \sin 2\varphi,$$

where

$$A = A_1 + a_0(1 - A_2) - a_1, \quad B = 1 - A_2 - \frac{2(a_0A_3 + A_4)}{Q}, \quad c = \frac{A_3}{4Q}.$$

Equality $\theta_1(\pi) = 0$ holds if

$$A = 3c. \quad (5.10)$$

The solution of the third equation (5.7) satisfying the boundary condition $\zeta_1(0) = 0$ has the form

$$\zeta_1 = -\frac{1}{2}(B + A_2)\varphi + (A_1 - a_0A_2) \sin \varphi + \frac{B - A_2}{4} \sin 2\varphi + c \sin^3 \varphi.$$

Taken into account the condition $\zeta_1(\pi) = 0$ we get equality $B + A_2 = 0$. Hence

$$a_0 = \frac{Q - 2A_4}{2A_3}.$$

The substitution of the expression for a_0 in formula (5.10) allows one to find a_1 :

$$a_1 = A_1 + \frac{(1 - A_2)(Q - 2A_4)}{2A_3} - 3c.$$

The expression for the function γ_1 contains the constant term a_2 which can be found at the construction of the second approximation.

The condition $t_2 \geq 0$ at $\varphi \in [0, \pi]$ is necessary for a correctness of the obtained solution. After the substitution into the inequality $t_2 \geq 0$ the approximate expression $t_2 \simeq \mu\delta_0$, we get $Q \geq Q_0$, where $Q_0 = 2A_3$. The number Q_* for which by means of the asymptotic method the approximate expression Q_0 is obtained, represents a characteristic value of dimensionless pressure Q . In case of $Q < Q_*$ the part of the membrane is covered by folds, and at $Q > Q_*$ the membrane is completely stretched.

6 THE APPROXIMATE SOLUTION FOR PARTLY STRETCHED MEMBRANE

Assume that $t_2 > 0$ when $\varphi \in [0, \varphi_*]$ and $t_2 < 0$ when $\varphi \in [\varphi_*, \pi]$. Then in the area $\varphi \in [0, \varphi_*]$ all fibers going on parallels are stretched and the part of the membrane surface $\varphi \in [\varphi_*, \pi]$ is covered by folds. At these assumptions equalities

$$t_2(\varphi_*) = 0, \quad \delta(\varphi_*) = 0 \quad (6.1)$$

take place.

At $\varphi \in [0, \varphi_*]$ the axisymmetric deformation of a toroidal membrane describe equation (5.2), (5.3). The function α' , β' , γ' , θ' and ζ' define on the interval $\varphi \in [\varphi_*, \pi]$ satisfy the following equation

$$\begin{aligned} \frac{d\alpha'}{d\varphi} &= 0, \quad \frac{d\theta'}{d\varphi} = \frac{Q}{\alpha'}[(1 + \mu\beta')(1 + \mu\gamma')], \\ \frac{d\zeta'}{d\varphi} &= (1 + \mu\beta') \cos \theta', \quad \frac{d\gamma'}{d\varphi} = -(1 + \mu\beta') \sin \theta'. \end{aligned} \quad (6.2)$$

$$\mu\alpha' = (g_1 + g_3)(1 + \mu\beta') - \frac{g_1}{(1 + \mu\beta')^2} - \frac{g_3}{(1 + \mu\beta')^3(1 + \mu\gamma')^2} \quad (6.3)$$

We search the solutions of equations (5.2), (5.3) and (6.2), (6.3) satisfying boundary conditions

$$\theta(0) = \zeta(0) = 0, \quad \theta'(\pi) = \pi, \quad \zeta'(\pi) = 0, \quad (6.4)$$

$$\alpha(\varphi_*) = \alpha'(\varphi_*), \quad \theta(\varphi_*) = \theta'(\varphi_*), \quad \gamma(\varphi_*) = \gamma'(\varphi_*), \quad \zeta(\varphi_*) = \zeta'(\varphi_*), \quad (6.5)$$

in the form (5.5). To find the approximate value of the unknown number φ_* we use the asymptotic expansion $\varphi_* = \varphi_0 + \mu\varphi_1$.

In the zeroth approximation we get the same results, as in case when the toroidal membrane is completely stretched:

$$\begin{aligned} \alpha_0 &= \alpha'_0 = Q, \quad \theta_0 = \theta'_0 = \varphi, \quad \zeta_0 = \zeta'_0 = \sin \varphi, \\ \gamma_0 &= \gamma'_0 = \cos \varphi + a_0, \quad \beta_0 = \beta'_0 = A_1 - A_2\gamma_0. \end{aligned}$$

It follows from second equality (6.1) that

$$a_0 = -\cos \varphi_0 - \frac{A_4}{A_3}.$$

The number φ_0 will be found at the construction of the first approximation.

If $\varphi \leq \varphi_0$ then for the construction of the first approximation we can use equations (5.7). In case $\varphi \geq \varphi_0$ equations of the first approximation have the form

$$\begin{aligned} \frac{d\alpha'_1}{d\varphi} &= 0, \quad \frac{d\theta'_1}{d\varphi} = \beta_0 + \gamma_0 - \frac{\alpha'_1}{Q}, \\ \frac{d\zeta'_1}{d\varphi} &= \beta_0 \cos \varphi - \theta'_1 \sin \varphi, \quad \frac{d\gamma'_1}{d\varphi} = -\beta_0 \sin \varphi - \theta'_1 \cos \varphi. \end{aligned} \quad (6.6)$$

The solutions of equations (5.7) and (6.6) satisfy the boundary conditions

$$\theta_1(0) = \zeta_1(0) = \theta'_1(\pi) = \zeta'_1(\pi) = 0, \quad (6.7)$$

$$\alpha_1(\varphi_0) = \alpha'_1(\varphi_0), \quad \theta_1(\varphi_0) = \theta'_1(\varphi_0), \quad \zeta_1(\varphi_0) = \zeta'_1(\varphi_0), \quad \gamma_1(\varphi_0) = \gamma'_1(\varphi_0). \quad (6.8)$$

In a considered case formulas (5.7) and (5.8) suit for the definition of the functions $\alpha_1(\varphi)$ and $\theta_1(\varphi)$. Taken into account first equation (6.6) and first condition (6.8) we get

$$\alpha'_1 = \alpha_1(\varphi_0) = -\frac{A_3}{2} \cos^2 \varphi_0 + a_1 Q.$$

It follows from second equation (6.6) and third condition (6.7) that

$$\theta'_1 = (A + 2c \cos^2 \varphi_0) (\varphi - \pi) + (1 - A_2) \sin \varphi, \quad (6.9)$$

The substitution of expressions (5.8) and (6.9) into second condition (6.8) gives the equality

$$(A/c + 2 \cos^2 \varphi_0) \pi = 3\varphi_0 - 5 \sin \varphi_0 \cos \varphi_0 + 2\varphi_0 \cos^2 \varphi_0. \quad (6.10)$$

Whereas for partly stretched toroidal membrane equality (5.9) is not valid, the expression for the function $\zeta_1(\varphi)$ differs from the expression obtained in the previous section:

$$\zeta_1 = (A_1 - a_0 A_2) \sin \varphi + (A - 3c)(\varphi \cos \varphi - \sin \varphi) - \frac{1}{2}(B + A_2)\varphi + \frac{B - A_2}{4} \sin 2\varphi + c \sin^3 \varphi. \quad (6.11)$$

The solution $\zeta'_1(\varphi)$ of the third equation (6.6) satisfying last boundary condition (6.7) has the form

$$\zeta_1 = (A_1 - a_0 A_2) \sin \varphi + (A - 2c \cos^2 \varphi_0) [(\varphi - \pi) \cos \varphi - \sin \varphi] + \frac{1}{2}(\pi - \varphi) + \frac{1 - 2A_2}{4} \sin 2\varphi. \quad (6.12)$$

Substitute equalities (6.11) and (6.12) into third condition (6.8). Taking in account formula (6.10) after transformations we obtain the following equation for the evaluating φ_0 :

$$\sin \varphi_0 - \varphi_0 \cos \varphi_0 = \pi p, \quad p = \frac{Q}{Q_0}. \quad (6.13)$$

Equation (6.13) has no an explicit solution, however its root $\varphi_0 \in [0, \pi]$ depends only on one parameter $p \in [0, 1]$. Therefore for the estimation of the value of this root it is possible to use Figure 3.

Figure 3: Plot of the functions $\varphi_0(p)$.

7 RESULTS

Consider three cases:

- 1) $g_1 = g_2 = 1, g_3 = 0$; 2) $g_1 = g_2 = g_3 = 1/2$; 3) $g_1 = g_2 = 0, g_3 = 1$.

In the first case the stiffness of the threads only is taken into account, influence of the stiffness of the threads and the shell in the second case are equal and in the third case the threads are absent.

Table 1 lists the values of the dimensionless characteristic pressure Q_* for these cases. The second and third columns contain the values calculated by a numerical solution of equations (4.2) and (4.3) for $\mu = 0.1$ and $\mu = 0.01$. The last column contains the values $Q_0 = 2A_3$ found by the asymptotic approach. The error of the asymptotic formula $Q_* \simeq Q_0$ decreases with the parameter μ .

Case	Q_*		
	$\mu = 0.1$	$\mu = 0.01$	Asymptotics
1)	4.12	5.71	6.00
2)	4.59	6.15	6.43
3)	4.71	5.78	6.00

Table 1: The values of Q_* for three cases.

The boundaries φ_* of the area covered by folds for the case $g_1 = g_2 = g_3 = 1/2$ and for the different values of the dimensionless pressure Q are given in Table 2. The second and third columns contain the values calculated by a numerical solution of equations (4.2) and (4.3). The last column contains the root φ_0 of equation (6.13). The error of the asymptotic results decreases with the μ and Q .

8 CONCLUSIONS

The application of the asymptotic approach to the problem of the toroidal membrane deformation under internal pressure permits to obtain the simple approximate solution. In particular, the explicit expression Q_0 for the minimal dimensionless pressure Q_* at which folds on the shell are not formed is found. It is shown that the relative stiffness of treads influences value of the characteristic pressure Q_* a little.

Q	φ_*		
	$\mu = 0.1$	$\mu = 0.01$	Asymptotics
1	1.28	1.20	1.19
2	1.67	1.58	1.56
3	2.04	1.87	1.85
4	2.51	2.16	2.12

Table 2: The values of φ_* for the different Q .

The equation for the evaluating the boundary of the membrane area covered by folds φ_* is derived. This equation contains only one non-dimensional parameter Q/Q_0 . For $\mu = 0.1$ and $Q < 3$ the error of the asymptotic results for the boundary φ_* in comparison with numerical ones is less than 10%.

Keywords: Balloon Mechanics, Contact Problem, Balloon Squeezing, Visco-elasticity, Fender-ship Model.

Abstract. *A nonlinear planar model of visco-elastic balloon, interposed between a couple of moving rigid bodies, is formulated. The pneumatic structure is modeled as an initially circular cable, pre-stressed by an internal pressure, and constrained to remain in a planar domain. External pressure is assumed to be zero. The pushing bodies are modeled as a couple of frictionless rigid parallel bars, approaching each other normally, and causing squeezing of the pneumatic body. Motion is assumed slow, in such a way any inertial effects are negligible. Both cases of long and short bars are considered, the latter entailing the possibility of puncture of the deformable body. A thermoplastic polyurethane material behavior is considered, and proper constitutive relationships adopted. Several models are formulated, which differ for constitutive laws (inextensible, elastic, linearly or non linearly visco-elastic) and/or for kinematic analysis (small strains and displacements or finite kinematics). The governing mixed differential-algebraic equations are analytically or numerically integrated for several impressed motion time-histories and the main features of the phenomenon are investigated.*

1 INTRODUCTION

Pneumatic structures have many applications in different technical fields. Often, they consist in balloons interposed between bodies of higher stiffness, that cause their squeezing or puncture. Examples are given by fender-devices, gaskets, balloons for bulkheads control, blood vessels and angioplastic balloons. Fender-devices are used in nautical, as peer-fenders, ship-fenders and rollers; pressurized gaskets are interposed between bodies in contacts; balloons are used to lift-up bulkheads, to create artificial rapids for rafting; balloons are also extensively used for biomedical applications, e.g. to free narrowed arteries obstructed by cholesterol and fats in general.

In all these application, it is of interest to predict the evolution in time of the geometry of the balloon, of its stress, its strain and its internal pressure. Of course, the response of the balloon depends on several causes: (a) the stiffness and geometry of the in-contact bodies, (b) the type of friction at the contact, (c) the law of relative motion of the bodies, (d) the geometry of the balloon, (e) the constitutive law of the material of which the balloon is made. Here, a first attempt is made to approach the problem in a simple way, by using simple models, leading to analytical or semi-analytic solutions. The goal is to gain insights into the physics of the phenomenon, and to highlight the implications of different levels of approximation in the analysis. A long cylindrical balloon under internal pressure is considered, interposed between two rigid planar surfaces, slowly approaching each other normally. External pressure is assumed zero. By ignoring boundary effects, the problem is studied as planar, in the plane orthogonal to the cylinder axis. The structural model consists therefore in an initially circular cable, pre-stressed by an internal pressure, squeezed by two rigid and parallel bars, assumed frictionless [1]. Due to the prescribed motion of the bars, quasi-static variations of geometry, stress, and internal pressure occur. The configuration history is sketched in Fig 1, for both cases of ‘long’ (Fig 1a) and ‘short’ (Fig 1b) bars. Contact initially occurs at one point on each bar (phase I in Fig 1a,b), then it extends over a segment during the loading process (phases II in Fig 1a,b), while the free part of the cable keeps its circular shape, with modified unknown radius. These two phases are common to both kind of bars. If the bar are long, however, the process ends with a complete adhesion of cable to the bodies (phase III in Fig 1a). If the bars are short, in contrast, a critical configuration is observed (phases III in Fig 1b), in which a part of the cable is adherent to the bars for their entire length, but a remaining part is still free. Then, a partial puncture of the deformable body occurs (phase IV in Fig 1b) ending with a complete puncture (phase V in Fig 1b).

Different models are adopted for the balloon material behavior, namely (1) inextensible, (2) elastic, (3) linear visco-elastic, (4) large-strain visco-elastic, (5) fully non-linear visco-elastic. Models (3)-(5) differ in kinematic description (small strains and displacements regime, or finite kinematics) and in stress-strain-rate relationships (linear or nonlinear). In model (5), a thermoplastic polyurethane material is considered, and a properly simplified constitutive relationship adopted, deduced by the literature [2,3]. The five models are aimed to highlight the influence of the constitutive law and large displacements and strain on the overall response. For all the models considered, the formulation is illustrated, and the solution, analytical or numerical, given. Numerical results, relevant to different loading time-histories, are finally displayed and commented.

Figure 1: Evolution of the cable configuration: (a) long bars: (I) initial contact, (II) partial contact, (III) advanced configuration (close to total adhesion); (b) short bars: (I) initial contact, (II) partial contact, (III) critical configuration, (IV) punctured configuration, (V) final configuration (totally punctured).

2 MODEL FORMULATION

2.1 State-variables, pre- and post-critical states

The physical system is made of two components, the cable and the insufflated air. Its mechanical state is defined by quantities able to describe (a) the actual shape of the system (by configuration variables), (b) the state of strain (by extensive variables) and (c) the state of stress (by dual intensive variables). As it will be explained soon, since the cable is made of rectilinear and circular parts, two configuration variables are sufficient to describe the geometry. However, one of them must be taken as control parameter for the loading process, so that just one geometrical variable is unknown; it is convenient to take it as the radius R of the circular part. On the other hand, the state of the air is defined by its pressure P and by the volume V instantaneously included in the cable. The state of the cable is determined by the stress T and the strain ε , this latter measured with respect to a reference (or *initial*) configuration \mathcal{C}_I . Due to geometry, both these quantities are constant along the cable. By summarizing, the state is described by five scalar quantities (state-variables), $\mathbf{x} := (R, P, V, T, \varepsilon)$, all depending on time.

The state of first-contact between cable and rods (phase I in Fig 1) is taken as initial configuration. Here $\mathbf{x}_I := (R_I, P_I, V_I, T_I, \varepsilon_I)$ are assumed to be known quantities. Their evaluation, of

course, calls for solving a *pre-contact evolution problem*, in which the circular cable is free. This transformation leads the body from its natural state to the initial state, as a consequence of its own visco-elastic properties.

By accounting for the double symmetry of the system, only a quarter of the cable is considered, as shown in Fig 2, for the two cases of long bars (Fig 2a,b) and short bars (Fig 2c,d). In the initial configuration (Fig 2a,c) the cable is circular, of center O , and delimited by the (material) contact point A and the symmetry point C ; the volume subtended by this arc is $V_l = \pi R_l^2 / 4$. In the actual (or *varied*) configuration C_v (Fig 2b,c), a third point B is of interest, which separates the contact portion of cable (AB segment) from the circular part (BC arc). The projection of B on the horizontal symmetry axis is the new center O' of the arc. The varied configuration is determined once the radius R and the angle $\theta = \widehat{AO'B}$ are known. Although R coincides with the (assigned) semi-distance a between the two rods, it appears computationally more convenient to take the angle θ , instead of R , as control parameter for the loading process, by leaving to R the meaning of configuration variable. This state, that also occurs for short bars, will be referred to as *pre-critical*.

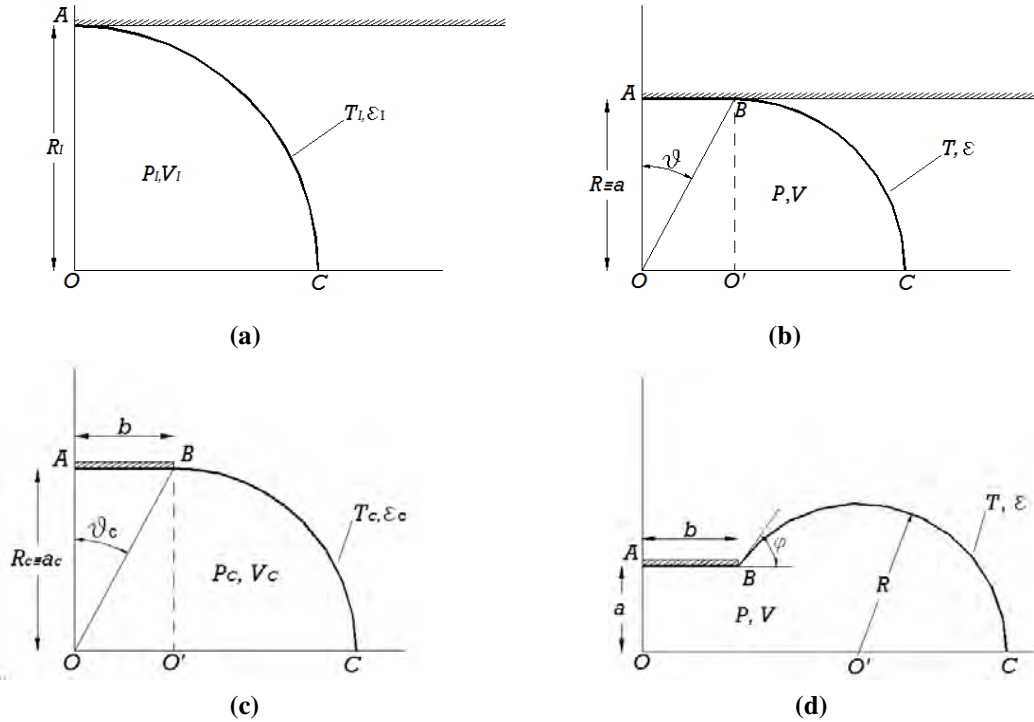

Figure 2: Configurations and state variables for long (a,b) and short (c,d) bars: (a) initial state; (b) actual state; (c) critical state; (d) actual (post-critical) configuration. θ, φ are control parameters.

If the bars are short, the system experiences a *critical state* C_c in which the contact point B coincides with an end of the bar (Fig 2c); in this configuration the quantities previously introduced assume the values $\mathbf{x}_c := (R_c, P_c, V_c, T_c, \varepsilon_c)$. A further approach between the bars causes the new geometrical structure of Fig 2d (punctured configuration). In order to describe how the phenomenon evolves, the new control parameter φ is chosen, which is the angle that the tangent at the circular arc at point B forms with the horizontal axis. The center of the arc, O' , is no more the projection of B , and therefore a and R are no more coincident, but $a = R \cos \varphi$.

In this phase, the state-variables will be still denoted by $\mathbf{x} := (R, P, V, T, \varepsilon)$, but the state will be referred to as *post-critical*. The history of these quantities, as well as the instant at which the system reaches the critical configuration, now depends on the bar semi-length b .

2.2 Governing equations

The formulation of the problem calls for establishing balance equations, geometric compatibility and constitutive equations. The balance equation expresses the equilibrium of an elementary material element belonging to the circular portion of the cable, namely:

$$T = PR \quad (1)$$

Equilibrium of the rectilinear part, indeed, is guaranteed by the fact that $T = \text{const}$ along the cable. Indeed, the internal pressure is balanced by the reactions normal to the contact, while no tangential forces act on the cable, since friction has been neglected.

As regards the constitutive laws, air is assumed to behave as perfect gas, and transformations are considered isothermal, for which:

$$PV = P_l V_l \quad (2)$$

The cable behavior, instead, is modeled in several ways. In the more general, visco-elastic case, the constitutive law assumes the form:

$$f(T, \dot{T}, \varepsilon, \dot{\varepsilon}) = 0 \quad (3)$$

where the dot denotes time-differentiation, and the initial conditions $T(0) = T_l$, $\varepsilon(0) = \varepsilon_l$ are prescribed.

The kinematics of the system requires writing two additional compatibility equations, expressing the two extensive variables, V, ε , in terms of the unique configuration variable R . They will be named the *volumetric* and *extensional* compatibility equations, respectively. Concerning volume, elementary calculations relevant to the shape assumed by the cable in Fig 2b,d, lead to:

$$V = \begin{cases} R^2 \left(\tan \theta + \frac{\pi}{4} \right) & \text{in pre-critical phase} \\ \frac{R^2}{4} (\sin 2\varphi + \pi + 2\varphi) + bR \cos \varphi & \text{in post-critical phase} \end{cases} \quad (4)$$

where, of course, the post-critical phase exists only if the bars are short. Concerning the strain, and defining it as the specific elongation $\varepsilon := (l/l_l) - 1$, with l and l_l being the total length of the cable in the actual and initial configuration, it follows, that:

$$\varepsilon = \begin{cases} \frac{R}{R_l} \left(1 + \frac{2}{\pi} \tan \theta \right) - 1 & \text{in pre-critical phase} \\ \frac{R}{R_l} \left(1 + \frac{2}{\pi} \varphi \right) + \frac{2b}{\pi R_l} - 1 & \text{in post-critical phase} \end{cases} \quad (5)$$

In the critical state is: $\tan \theta = b/R$, $\varphi = 0$, so that both the alternative expressions in Eqs (4) and (5) furnish $\varepsilon_c = R/R_l + (2b)/(\pi R_l)$ and $V_c = bR + \pi R^2/4$.

3 SPECIALIZED CONSTITUTIVE MODELS

The governing equations (1)-(5) are specialized ahead to different constitutive models of cable. Non-dimensional quantities are used, according to the following definitions:

$$\begin{aligned} p &:= P / P_I, \quad \tau = T / T_I, \quad v := V / V_I, \quad r := R / R_I \\ \alpha &= a / R_I, \quad \beta = b / R_I \end{aligned} \quad (6)$$

in which $T_I = P_I R_I$ holds, since \mathcal{C}_I is equilibrated.

3.1 Inextensible cable

The simplest model of material behavior is the inextensible model. Accordingly, the cable is considered perfectly flexible, but axially indeformable. In this case, no a constitutive law like Eq (3) exists, since the stress T assumes a reactive character. On the other hand, compatibility requires $\varepsilon = 0$, so that Eq (5) simplifies. Therefore, the relevant mechanical problem is governed by four equations in four unknowns. By using non-dimensional quantities, they read:

$$\tau = pr, \quad pv = 1, \quad v = \begin{cases} r^2 \left(1 + \frac{4}{\pi} \tan \theta \right) \\ r^2 \left(1 + \frac{2}{\pi} \varphi + \frac{1}{\pi} \sin 2\varphi \right) + \frac{4}{\pi} \beta r \cos \varphi \end{cases}, \quad \begin{cases} r \left(1 + \frac{2}{\pi} \tan \theta \right) = 1 \\ r \left(1 + \frac{2}{\pi} \varphi \right) + \frac{2}{\pi} \beta = 1 \end{cases} \quad (7)$$

in the pre-critical and post-critical phase, respectively.

3.2 Elastic cable

An improved model accounts for elasticity of the cable. By assuming that the body obeys to the Hooke law, and considering the initial stress, the constitutive relationship reads:

$$T = T_I + EA_I \varepsilon \quad (8)$$

where EA_I is the axial stiffness evaluated at \mathcal{C}_I . In non-dimensional form, the elastic problem (1)-(5) reads:

$$\begin{aligned} \tau &= pr, \quad pv = 1, \quad \tau = 1 + k\varepsilon, \\ v &= \begin{cases} r^2 \left(1 + \frac{4}{\pi} \tan \theta \right) \\ r^2 \left(1 + \frac{2}{\pi} \varphi + \frac{1}{\pi} \sin 2\varphi \right) + \frac{4}{\pi} \beta r \cos \varphi \end{cases}, \quad \varepsilon = \begin{cases} r \left(1 + \frac{2}{\pi} \tan \theta \right) - 1 \\ (r + 2\beta) \left(1 + \frac{2}{\pi} \varphi \right) - 1 \end{cases} \end{aligned} \quad (9)$$

in the two phases, respectively. In Eqs (9) the following non-dimensional elastic stiffness has been introduced:

$$k := EA_I / T_I \quad (10)$$

3.3 Linear visco-elastic cable

To account for slow-time effects and for internal energy dissipation of the cable, a visco-elastic constitutive model must be used. As a first, simplest approach to the problem, the well-known *linear* standard model (also called ‘three parameter model’, Fig 3) is adopted.

Figure 3: Standard visco-elastic model

The relevant constitutive relationship is:

$$\begin{cases} \dot{T} + \frac{K_2}{\eta} T = (K_1 + K_2) \dot{\varepsilon} + \frac{K_1 K_2}{\eta} \varepsilon \\ T(0) = T_I, \quad \varepsilon(0) = \varepsilon_I \end{cases} \quad (11)$$

where K_1, K_2 , are elastic moduli, and η a viscosity coefficient. In non-dimensional form, it reads:

$$\begin{cases} \dot{\tau} + \tau = (k_1 + k_2) \dot{\varepsilon} + k_1 \varepsilon \\ \tau(0) = 1, \quad \varepsilon(0) = \varepsilon_I \end{cases} \quad (12)$$

where:

$$\tilde{t} := (K_2 / \eta) t, \quad k_1 := K_1 / T_I, \quad k_2 := K_2 / T_I \quad (13)$$

have been introduced, and where the dot now denotes differentiation with respect the non-dimensional time \tilde{t} (tilde dropped ahead). The visco-elastic problem for the system is therefore governed by:

$$\tau = pr, \quad pv = 1, \quad v = \begin{cases} r^2 \left(1 + \frac{4}{\pi} \tan \theta \right) \\ r^2 \left(1 + \frac{2}{\pi} \varphi + \frac{1}{\pi} \sin 2\varphi \right) + \frac{4}{\pi} \beta r \cos \varphi \end{cases}, \quad \varepsilon = \begin{cases} r \left(1 + \frac{2}{\pi} \tan \theta \right) - 1 \\ (r + 2\beta) \left(1 + \frac{2}{\pi} \varphi \right) - 1 \end{cases} \quad (14)$$

$$\dot{\tau} + \tau = (k_1 + k_2) \dot{\varepsilon} + k_1 \varepsilon, \quad \tau(0) = 1, \quad \varepsilon(0) = \varepsilon_I$$

It is therefore a mixed differential-algebraic problem, whose solution calls for a numeric integration. It can be recast in the matrix form:

$$\begin{cases} \mathbf{A}(\mathbf{y}(t))\dot{\mathbf{y}}(t) + \mathbf{B}(\mathbf{y}(t))\mathbf{y}(t) = \mathbf{f}(t) \\ \mathbf{y}(0) = \mathbf{y}_0 \end{cases} \quad (15)$$

where \mathbf{A} and \mathbf{B} are 6×6 matrices, $\mathbf{y} = (\mathbf{x}; \theta)$ or $\mathbf{y} = (\mathbf{x}; \varphi)$ is an extended 6-vector of state variables, including the control parameter, and $\mathbf{f}(t) = (1, 1, 0, -1, 0; f(t))$ is a 6-vector of know-terms, in which $f(t)$ denotes the impressed time-history for $\theta(t)$ or $\varphi(t)$. Moreover $\mathbf{y}_0 = (r_I, p_I, v_I, \tau_I, \varepsilon_I; f(0))$. Equations (15) have been integrated by using a solver for singular and sparse matrices.

3.4 Large strain visco-elastic cable

An enhanced visco-elastic model is introduced, in which large strains are accounted for. The stretch $\lambda := 1 + \varepsilon$ (whose logarithm is known as the ‘true strain’) instead of the (engineering) elongation ε , is used as the strain measure, since this latter is not additive in finite kinematics¹. Reference is made again to the three-parameter model of Fig 3, in which A is the elastic part and B the visco-elastic part. Compatibility for the two parts requires $\lambda_A = \lambda_B =: \lambda$, while compatibility for part B calls for $\lambda = \lambda_i \lambda_e$, where $\lambda_{i,e}$ are the stretches of the in-series inelastic and elastic devices, respectively. Equilibrium requires that $T = T_A + T_B$ and $T_i = T_e =: T_B$. By still assuming linear constitutive laws for the single devices, namely:

$$T_A = K_1(\lambda - 1), \quad T_B = K_2(\lambda_e - 1), \quad T_B = \eta \dot{\lambda}_i \quad (16)$$

the following nonlinear stress-strain law is finally derived, with relevant initial conditions:

$$\begin{cases} \lambda \dot{T} - (K_1 + K_2 + T)\dot{\lambda} + \frac{K_2}{\eta} [T - K_1(\lambda - 1)] \left[1 - \frac{K_1}{K_2}(\lambda - 1) + \frac{T}{K_2} \right]^2 = 0 \\ T(0) = T_I, \quad \lambda(0) = \lambda_I \end{cases} \quad (17)$$

It should be noted that, for small strain and $T \ll K_2$, the squared bracket in Eq (17) tends to 1, so that Eq. (11) is recovered. In nondimensional variables, Eq. (17) reads:

$$\begin{cases} \lambda \dot{\tau} - (k_1 + k_2 + \tau)\dot{\lambda} + [\tau - k_1(\lambda - 1)] \left[1 - \frac{k_1}{k_2}(\lambda - 1) + \frac{\tau}{k_2} \right]^2 = 0 \\ \tau(0) = \tau_I, \quad \lambda(0) = \lambda_I \end{cases} \quad (18)$$

The visco-elastic problem for the large-strain cable model is therefore governed by the following set of equations:

¹ Indeed, if $\Delta l_1, \Delta l_2$ are two successive deformations of a segment of initial length l , then the final strain $\frac{\Delta l_1 + \Delta l_2}{l}$ differs from the sum of the two strains: $\varepsilon_1 = \frac{\Delta l_1}{l}, \varepsilon_2 = \frac{\Delta l_2}{l + \Delta l_1}$. In contrast, since $\lambda = \frac{l + \Delta l_1 + \Delta l_2}{l}, \lambda_1 = \frac{l + \Delta l_1}{l}, \lambda_2 = \frac{l + \Delta l_1 + \Delta l_2}{l + \Delta l_1}$, then $\lambda = \lambda_1 \lambda_2$.

$$\begin{aligned}
 \tau = pr, \quad pv=1, \quad v = \begin{cases} r^2 \left(1 + \frac{4}{\pi} \tan \theta \right) \\ r^2 \left(1 + \frac{2}{\pi} \varphi + \frac{1}{\pi} \sin 2\varphi \right) + \frac{4}{\pi} \beta r \cos \varphi \end{cases}, \quad \varepsilon = \begin{cases} r \left(1 + \frac{2}{\pi} \tan \theta \right) - 1 \\ (r + 2\beta) \left(1 + \frac{2}{\pi} \varphi \right) - 1 \end{cases} \\
 \lambda \dot{\tau} - (k_1 + k_2 + \tau) \dot{\lambda} + [\tau - k_1(\lambda - 1)] \left[1 - \frac{k_1}{k_2} (\lambda - 1) + \frac{\tau}{k_2} \right]^2 = 0, \quad \tau(0) = \tau_i, \quad \lambda(0) = \lambda_i
 \end{aligned} \tag{19}$$

The whole system is then rearranged as in Eqs (15), to be numerically integrated.

3.5 Fully-nonlinear visco-elastic cable

Although the previous model accounts for large strains, the constitutive laws (16) of the single components are still linear. To formulate a fully-nonlinear visco-elastic model (i.e. large-strain and mechanically nonlinear), it needs to more accurately describe the stress-strain-rate law. Here, reference is made to a thermoplastic polyurethane material, for which a proper 3D-constitutive law has been proposed in [2], still based on the model of Fig. 3. It involves all the eigenvalues $\lambda_1, \lambda_2, \lambda_3$ of the deformation gradient \mathbf{F} . To reduce the model to 1D, two hypotheses were introduced: (a) *each* parts *A* and *B* are incompressible, and (b) the material is transversally isotropic, these entailing $\lambda_2 = \lambda_3 = \pm 1/\sqrt{\lambda}$, with $\lambda := \lambda_1$ the longitudinal stretch. Although hypothesis (a) is quite strong (since isochoricity is more likely to hold on the two parts as a whole, rather than separately), it has been introduced here to keep the model the simplest possible. Based on this approximations, the following five-parameter visco-elastic, 1D-model were obtained in [1] (quite involved details are omitted here):

$$T_A = c_1 \left(\lambda^2 - \frac{1}{\lambda} \right), \quad T_B = c_2 \frac{\ln \lambda_e}{\lambda_e}, \quad T_B = c_3 \left(\lambda_e \sqrt{1 + \frac{2}{\lambda_e^3}} - 1 \right)^{c_4} \left(\frac{\dot{\lambda}_i}{\lambda_i} \right)^{c_5} \tag{20}$$

in which c_i are constant materials. By using compatibility and equilibrium as in the previous model, the final constitutive equation was derived. Together with Eqs (19₁₋₄), they govern the fully-nonlinear visco-elastic problem for the cable.

4 PRELIMINARY NUMERICAL RESULTS

The simplest inextensible and elastic models, governed by the algebraic Eqs (7) and (9), respectively, admit a closed-form solution, which is reported in the Appendix. In contrast, the mixed algebraic differential equations, governing all the visco-elastic models, call for numerical integrations. A sample numerical integration is shown here, in order to illustrate a typical time-history of a balloon (Fig 4). Three models have been considered, and the relevant results compared, namely elastic (*E*), linear visco-elastic (*LVE*) and fully nonlinear viscoelastic (*NLVE*). A fourth model, the large-strain visco-elastic, was disregarded, since it gave results very similar to the linear one. Figure 4 shows, for the three models, the strain (Fig 4a) and the stress (Fig 4b) time-histories. When $t < t_0$, the cable is at rest in its natural (unstressed, unstrained) configuration. At $t = t_0$ an internal pressure is instantaneously applied, by insufflating air, so that the cable undergoes the strain ε_0 and the tension T_0 . It should be noted that these state-variables relevant to *NLVE* differ from those relevant to *E* and *LVE*, due to the dif-

ferent elastic law adopted for the former. With the air-flow stopped, a time-interval $[t_0, t_I]$ is waited, in which, due to viscosity, the strain increases, while the stress decreases. In contrast, strain and stress remain constant in the elastic model. At the instant t_I , two (long) bars are juxtaposed to the balloon, touching it each in a single point, and a constant-rate motion approach is imposed to them. Both strain and stress decrease, up the critical configuration is reached at a point C , at an instant t_c which is different for each model. After that, the constant-rate motion is continued for an additional time interval, sufficient to move the system far from the critical condition. Then, at point P , a pulsating bar movement is started, of amplitude such that the balloon remains in post-critical phase. A remarkable different behavior is also appreciated in this phase for the three models.

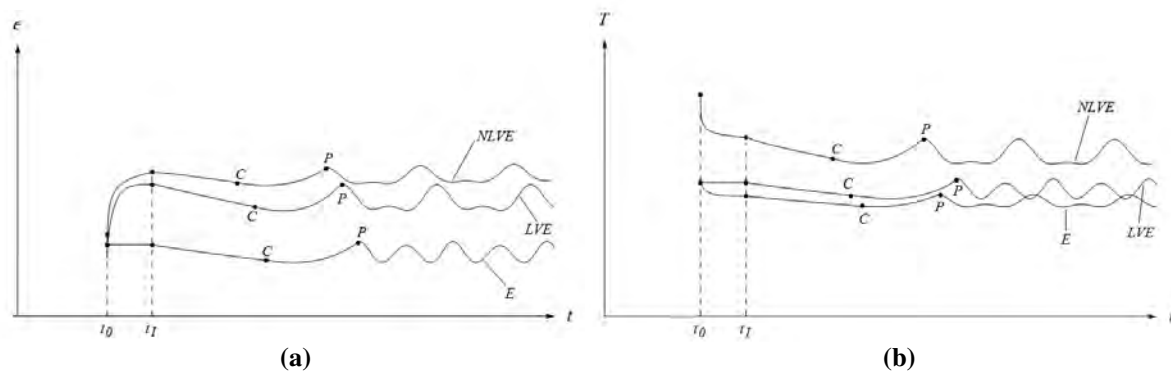

Figure 4: Time-histories of (a) strain and (b) stress; E :elastic, LVE : linear visco-elastic, $NLVE$: nonlinear visco-elastic; t_I start of the constant-rate motion; C : critical point; P : start of the pulsating motion.

5 CONCLUSIONS

A nonlinear planar model of visco-elastic balloon, interposed between two moving rigid bars, has been formulated. The problem has been found to be governed by five algebraic-ode equations in five state-variables (radius, strain, volume, stress, internal pressure), expressing equilibrium, compatibility and stress-strain-rate relationships. The distance between the two bars (or an equivalent geometrical magnitude) is taken as loading parameter, and an arbitrarily selected time-history, assigned. According to the ratio between the radius of the balloon and the length of the bars, a one-phase evolution problem (only squeezing, for long bars) or a two-phases evolution problems (squeezing and puncture, for short bars), occur. Five specific models have been derived, of increasing complexity: inextensible, linearly elastic, linear visco-elastic, large-strain visco-elastic, fully-nonlinear visco-elastic. Preliminary analytical and numerical results have been obtained, comparing the models for a sample time-history. More extended parametric analysis will be presented at the conference.

APPENDIX: Solution to the inextensible and elastic models

Equations (7), relevant to the inextensible model, admit a unique solution, that can be obtained in closed-form. It reads:

$$r = \frac{\pi}{\pi + 2 \tan \theta}, \quad v = \frac{\pi(4 \tan \theta + \pi)}{(2 \tan \theta + \pi)^2}, \quad p = \frac{(2 \tan \theta + \pi)^2}{\pi(4 \tan \theta + \pi)}, \quad \tau = 1 - \frac{2}{4 + \pi \cot \theta} \quad (21)$$

in the pre-critical phase, and:

$$r = \frac{\pi - 2\beta}{\pi + 2\varphi}, \quad v = \frac{(\pi - 2\beta)(4\beta(\pi + 2\varphi)\cos\varphi + (\pi - 2\beta)(\pi + 2\varphi + \sin 2\varphi))}{\pi(\pi + 2\varphi)^2}, \quad (22)$$

$$p = \frac{\pi(\pi + 2\varphi)^2}{(\pi - 2\beta)(4\beta(\pi + 2\varphi)\cos\varphi + (\pi - 2\beta)(\pi + 2\varphi + \sin 2\varphi))}, \quad \tau = \frac{\pi(\pi + 2\varphi)}{4\beta(\pi + 2\varphi)\cos\varphi + (\pi - 2\beta)(\pi + 2\varphi + \sin 2\varphi)}$$

in the post-critical phase.

Equations (9), relevant to the elastic model, can be solved analytically as well. Two distinct solutions were found; one of them, however, had to be disregarded, since physically not admissible ($\tau < 0$)(see [1]). The admissible solution, instead, is:

$$\tau = \frac{1}{2} \left(1 - k + \frac{\cos \theta \sqrt{\pi + 4 \tan \theta} \sqrt{(1+k)^2 \pi + 4(1+k^2) \tan \theta}}{\pi \cos \theta + 4 \sin \theta} \right),$$

$$p = \frac{(1+k^2)\pi + 4(1+(k-1)k) \tan \theta - (k-1)\sqrt{\pi + 4 \tan \theta} \sqrt{(1+k)^2 \pi + 4(1+k^2) \tan \theta}}{2\pi},$$

$$\varepsilon = \frac{1}{2} \left(-1 + \frac{-1 + \sqrt{\frac{(1+k)^2 \pi + 4(1+k^2) \tan \theta}{\pi + 4 \tan \theta}}}{k} \right), \quad (23)$$

$$v = \frac{\pi \left((1+k^2)\pi + 4(1+(k-1)k) \tan \theta + (k-1)\sqrt{\pi + 4 \tan \theta} \sqrt{(1+k)^2 \pi + 4(1+k^2) \tan \theta} \right)}{2k^2(\pi + 2 \tan \theta)^2},$$

$$r = \frac{\pi \left(-1 + k + \sqrt{\frac{(1+k)^2 \pi + 4(1+k^2) \tan \theta}{\pi + 4 \tan \theta}} \right)}{2k(\pi + 2 \tan \theta)}$$

in the pre-critical phase, and:

$$\tau = \frac{\beta(\pi + 2\varphi) - 2\beta(\pi + 2\varphi)\cos\varphi + \beta\sin 2\varphi + \frac{1}{2}A}{\pi(\pi + 2\varphi + \sin 2\varphi)},$$

$$p = \frac{1}{\pi^3 - 8\pi\beta^2 \cos \varphi} (\pi^3 + 2\pi^2\varphi + 2\beta^2\pi(1 - 2\cos\varphi) + 2\beta^2(2\varphi - 4\varphi\cos\varphi + \sin 2\varphi) + \beta A),$$

$$\varepsilon = \frac{(\beta - \pi)(\pi + 2\varphi) - 2\beta(\pi + 2\varphi)\cos\varphi + (\beta - \pi)\sin 2\varphi + \frac{1}{2}A}{\pi(\pi + 2\varphi + \sin 2\varphi)}, \quad (24)$$

$$v = \frac{1}{\pi(\pi + 2\varphi)^2} (\pi^3 + 2\pi^2\varphi + 2\beta^2\pi(1 - 2\cos\varphi) + 2\beta^2(2\varphi - 4\varphi\cos\varphi + \sin 2\varphi) - \beta A),$$

$$r = \frac{1}{(\pi + 2\varphi)(\pi + 2\varphi + \sin 2\varphi)} \left(-\beta\pi(1 + 2\cos\varphi) - 2\beta(\varphi + \cos\varphi(2\varphi + \sin\varphi)) + \frac{1}{2}A \right)$$

in the post-critical phase, where the following constant has been defined:

$$A = \sqrt{4(\pi + 2\varphi)(\pi^2 - 8\beta^2 \cos \varphi)(\pi + 2\varphi + \sin 2\varphi) + 4\beta^2((\pi + 2\varphi)(1 + 2\cos\varphi) + \sin 2\varphi)^2} \quad (25)$$

QUASI-STATIC SIMULATIONS OF THIN SPACE MEMBRANES, AIMING AT STABILITY ANALYSES OF BALLOON-LIKE STRUCTURES

Keywords: Space membranes, Inflation, Compressible medium, Quasi-static equilibrium, Stability, Path-following.

Abstract. *This paper discusses the evaluation of quasi-static equilibrium solutions for inflatable space membrane structures, such as balloons. A flat linearly interpolated triangular element is used for simulations, with a Mooney-Rivlin hyper-elastic material model, with variable constitutive constants. A compressible medium is used to introduce a one-parametric over-pressure loading within the membrane. Complex path-following procedures are used to find generalized equilibrium paths, with different parameterizations. Numerical examples show that the methods developed can give information on the stability of the structures, but that the medium and means for introducing the internal pressure is of importance for the interpretation of stability.*

1 INTRODUCTION

A large variety of thin three dimensional inflatable structures, i.e., balloons, are used in several engineering and medical contexts, e.g., [1, 2, 3]. These structures often show large deformations when subjected to distributed pressures. The bending stiffness can often be neglected and only a membrane state considered. Several analytical and numerical treatments for more or less general situations are available in literature, [4, 5, 6, 7, 8]. The treatment of these structures also leads to several accompanying aspects, such as the load descriptions, [9], contact formulations, [10], and instability aspects, [11, 12, 13].

Simulations of very thin membranes are often based on shell models, but these show important drawbacks in situations where the bending stiffness almost vanishes. The main problems lie in the treatment of large rotations, the aspect ratios of the elements, and the stiffness differences in membrane and bending action. As one remedy, rotation-free shell elements have been suggested by many researchers, [14, 15, 16, and others]. The main efforts have been related to non-local evaluation of the element curvatures, and to degenerated solid elements, [17]. Advantages and disadvantages of rotation-free shell elements are described in [18, 19].

For the balloon-like structures considered in the present work, an assumption has been that simulations of the inflation process can be based purely on the membrane behavior, disregarding the bending stiffness. This assumption will remove the numerical problems associated with shell formulations when thickness tends to zero, and also leads to efficient simulations. Some space membrane elements have been developed in literature for special applications. An interesting recent development is discussed by Pargana et al., [20], where an initially flat, quadratically interpolated 6-node membrane element is developed for ‘Tensioned Fabric’ structures. The element uses a total Lagrangian approach, and Green strains, but considers only cases where strains can be assumed as small.

The problems considered here, i.e., the inflation of balloon-like structures, are both geometrically non-linear due to finite deformations and materially non-linear through the constitutive relationship. A co-rotational (‘CR’) finite element form was developed in [21], where the local element is purely in an in-plane state. It was concluded that the CR formulation can be relevant and efficient for problems where the local behavior is sufficiently well described by an elastic formulation, but that the formulation became inefficient when hyper-elastic material models were introduced. In the present work, a hyper-elastic flat triangular membrane element based on a total Lagrangian (‘TL’) formulation was used for the analysis of thin space membrane structures, allowing different hyper-elastic forms.

The restrictions of the current formulation are primarily that all elements connecting to a node can not be co-planar at any stage, and that only surface-normal pressure loads are present. For physical relevance, the elements in the mesh must also be under tensile states at any solution. We also only consider quasi-static equilibrium situations, hypothesizing that the dynamics of a real inflation process is not primarily related to the inertia properties of the structure, but to the loading situations. The quasi-static assumption in this work means that any combination of pressure and volume can be immediately introduced, without dynamic or thermal effects.

The element formulation was tested for the structural class considered, noting that the present problems demand sophisticated path-following algorithms, with several aspects of instability detection and classification included. In particular, the generalized path-following in a parameter space with not just a single load factor was shown to be useful for the analyses.

2 COMPUTATIONAL MODELING

The basic quasi-static structural equilibrium situation is based on a one-parametric pressure loading. The formulation is thereby aimed at seeking a set of combinations (\mathbf{u}, ψ) satisfying:

$$\mathbf{F}(\mathbf{u}, \psi) \equiv \mathbf{f}(\mathbf{u}) - \mathbf{p}(\psi, \mathbf{u}) = \mathbf{0} \quad (1)$$

where \mathbf{f} , \mathbf{p} , and \mathbf{u} are vectors containing internal forces, external forces, and displacements, respectively, in the degrees of freedom of the structure considered. Also, ψ is a scalar value representing the over-pressure in the transversal direction. Element displacements \mathbf{u}^g are extracted from \mathbf{u} based on a topology defined, while \mathbf{f} and \mathbf{p} are assembled from element contributions \mathbf{f}^g and \mathbf{p}^g , respectively. The super-index g indicates that the element components are measured in the common degrees of freedom of the structure, which in the present case are translations in the three global axis directions.

The differential relation corresponding to Eq. (1) is:

$$\delta \mathbf{F} = \frac{\partial \mathbf{f}}{\partial \mathbf{u}} \delta \mathbf{u} - \frac{\partial \mathbf{p}}{\partial \mathbf{u}} \delta \mathbf{u} - \frac{\partial \mathbf{p}}{\partial \psi} \delta \psi = (\mathbf{K} - \mathbf{K}_p) \delta \mathbf{u} - \delta \psi \frac{\partial \mathbf{p}}{\partial \psi} \quad (2)$$

which gives a tangential stiffness matrix containing a load-dependent term, since the pressure load is acting on the deformed geometry.

2.1 Element formulation

The element used for large deflection space membrane simulations is based on the linearly interpolated constant strain triangle, ‘CST’, for in-plane analysis. When seen in a three-dimensional context, the nodes (i, j, k) are defined by initial coordinates \mathbf{x}_I^g , ($I = i, j, k$). The global displacement components are similarly \mathbf{u}_I^g . The element is assumed to be flat, and the initial nodal positions define a plane in space, with three initial element coordinate axes in an orthogonal matrix \mathbf{R}_0 , the third axis being an outwards normal direction to the flat element. Using the initial position of node i as the origin for a local coordinate system, the initial shape of the element is defined by local coordinates:

$$\mathbf{x}_I^e = \mathbf{R}_0^T (\mathbf{x}_I^g - \mathbf{x}_i^g) \quad (I = i, j, k) \quad (3)$$

where the third coordinate is zero for the three nodes, by construction. Relative to this initial element coordinate system, the displacements are:

$$\mathbf{u}_I^e = \mathbf{R}_0^T \mathbf{u}_I^g \quad (I = i, j, k) \quad (4)$$

The displacements of a point p within the element is interpolated as:

$$\mathbf{u}_p^e = \sum_I N_I(x_{p,1}^e, x_{p,2}^e) \mathbf{u}_I^e \quad (5)$$

with common shape functions for the CST element, representing a linear interpolation of all three local displacement components related to the initial element plane.

Corresponding to the element displacements \mathbf{u}_I^e , element internal forces \mathbf{f}_I^e are evaluated, which are then transformed into internal force contributions in global coordinate directions as:

$$\mathbf{f}_I^g = \mathbf{R}_0 \mathbf{f}_I^e \quad (I = i, j, k) \quad (6)$$

The evaluation of the internal forces in the element is assuming an incompressible isotropic hyper-elastic material model. Strains are described by the the right Cauchy-Green deformation tensor:

$$\mathbf{C} = \begin{bmatrix} C_{11} & C_{12} & 0 \\ C_{21} & C_{22} & 0 \\ 0 & 0 & C_{33} \end{bmatrix} \quad (7)$$

where the incompressibility condition $J = \det(\mathbf{C}) = 1$ relates C_{33} to the other components, and where initial element coordinates are used. Stresses are represented by the second Piola-Kirchhoff stress tensor:

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} & 0 \\ S_{21} & S_{22} & 0 \\ 0 & 0 & S_{33} \end{bmatrix} \quad (8)$$

where the assumption of a local plane-stress situation demands $S_{33} = 0$.

Introducing the constraints above, a convenient form can be derived based on considering the four components C_{11} , C_{22} , C_{12} and C_{21} , and the corresponding stress components. It is noted that the strains are non-linearly dependent on nodal displacements but constant over the element area. An incremental strain operator $\mathbf{B} = \mathbf{B}(\mathbf{x}_I^e, \mathbf{u}_I^e)$ gives variations in strain components from variations in element displacements.

The hyper-elastic model is characterized by a strain-energy relation, [22, 23]:

$$\mathbf{S} = -\rho \mathbf{C}^{-1} + 2 \frac{\partial W}{\partial \mathbf{C}} \quad (9)$$

where W is a strain energy function, and ρ a hydro-static pressure, which can also be seen as a Lagrange multiplier enforcing the strain and stress constraints above. With the incompressibility assumption, $I_3(\mathbf{C}) = 1$, the strain energy function is written:

$$W = W(I_1(\mathbf{C}), I_2(\mathbf{C})) \quad (10)$$

with the first and second invariants of the tensor \mathbf{C} . A Mooney-Rivlin form, [22] defines the stress-strain relation from two constitutive constants:

$$W = c_1(I_1(\mathbf{C}) - 3) + c_2(I_2(\mathbf{C}) - 3) \quad (11)$$

The above expressions were used to describe the relation between the stress and strain components considered:

$$\mathbf{S} = \mathbf{S}(\mathbf{C}, c_1, c_2) \quad (12)$$

and also the differential relation between increments in stress and strain. These give the internal force vector and the tangential stiffness matrix for the element at a current state of displacement; as all quantities are constant within each element, the required integration is simple.

A neo-Hookean form is a further specialization of the above expression, where a single constitutive constant is $c_1 = \mu/2$, half the shear modulus. A general demand on the constants is that the sum $c_1 + c_2 = \mu/2$, [22]. Different relations between the two constitutive constants were tested for the numerical examples below, and are in the examples represented as a ratio n_1/n_2 , where:

$$c_1 = \frac{n_1}{n_1 + n_2} \frac{\mu}{2} \quad (13)$$

$$c_2 = \frac{n_2}{n_1 + n_2} \frac{\mu}{2} \quad (14)$$

2.2 Loading assumptions

A membrane can be pressurized in several different ways. One important aspect is the medium introducing the pressure on the membrane. Typically, a gas is compressible and can be assumed to have zero density, whereas a liquid is incompressible and has a density. In particular for gases, the mechanism for introducing the medium into the membrane is of importance, where it is assumed that either a specified pressure can be introduced independent of the resulting volume, or a specific amount of gas is introduced leading to a balance between pressure and volume.

In the present work, it has been assumed that the pressure is introduced by a compressible gas, with zero density. This means that a one-parameter description of the over-pressure can be used, and this pressure is acting in a normal, outwards direction on all surfaces, with only positive over-pressures considered. The over-pressure ψ is seen as related to a constant surrounding pressure of the membrane ψ_0 . The total pressure within the membrane is thereby $\Psi = \psi_0 + \psi$.

The local displacement-dependent loading due to normal uniform over-pressure is evaluated as:

$$\mathbf{p}_I^e = \psi \frac{A}{3} (0, 0, 1)^T, \quad (I = i, j, k) \quad (15)$$

where ψ is the current surface pressure, and $A = A(\mathbf{x}_I^e, \mathbf{u}_I^e)$ is the current element area. The element contribution is transformed to global degrees of freedom and assembled to the structural pressure load vector.

The stiffness term \mathbf{K}_p in Eq. (2) is related to the displacement-dependent pressure loads. This aspect is extensively discussed in [11], and must be considered when simulating large deformations of a pressure-loaded structure. Assembled from element contributions \mathbf{K}_p^g , rather simple geometric consideration show that for the present formulation:

$$\mathbf{K}_p^g = \mathbf{R}_0 \begin{bmatrix} \mathbf{k}_{p,ii} & \mathbf{k}_{p,ij} & \mathbf{k}_{p,ik} \\ \mathbf{k}_{p,ji} & \mathbf{k}_{p,jj} & \mathbf{k}_{p,jk} \\ \mathbf{k}_{p,ki} & \mathbf{k}_{p,kj} & \mathbf{k}_{p,kk} \end{bmatrix} \mathbf{R}_0^T \quad (16)$$

where the submatrices are formulated in displaced local coordinates:

$$\mathbf{k}_{p,IJ} = \frac{\psi}{6} \begin{bmatrix} 0 & 0 & y_{d(J-1)} - y_{d(J+1)} \\ 0 & 0 & x_{d(J+1)} - x_{d(J-1)} \\ y_{d(J+1)} - y_{d(J-1)} & x_{d(J-1)} - x_{d(J+1)} & 0 \end{bmatrix} \quad (17)$$

The indices i, j, k are thereby introduced cyclically, and the coordinates are

$$\mathbf{x}_{dI} = \begin{pmatrix} x_{dI} \\ y_{dI} \\ z_{dI} \end{pmatrix} = \mathbf{x}_I^e + \mathbf{u}_I^e \quad (18)$$

The amount of gas contained by the membrane can be evaluated from the equation for an ideal gas, stated as:

$$\Psi V = NT \quad (19)$$

where Ψ is the total gas pressure, V the volume enclosed by the membrane, N an amount measure and T the absolute temperature. This expression can be used in different ways in the evaluation of membrane behavior, as indicated by the examples below.

2.3 Quasi-static equilibrium solutions

The pressurized membranes often show complicated non-linear responses to loading, with different instability states being important aspects. The solution of quasi-static equilibrium states thereby demands rather sophisticated solution algorithms. The present work has utilized one-dimensional path-following techniques based on variable parameterizations along the solution path, changing both the parameterizing component and the step length as functions of the path traversed, [24, 25]. The isolation of critical instability states is based on sequential bisections along the parameterized path, [26]. The response variables can also be seen as functions of, e.g., geometric or material parameters in the model, [27], where augmenting equations specify a subset of equilibrium states under variation of the additional parameters. In particular, the dependence of the critical states on the added parameters can be evaluated by methods from [28]. An interesting possibility, not yet utilized, is also to evaluate two-dimensional solution surfaces, where parametric combinations leading to certain response aspects can be evaluated and visualized, [29]. The general setting is thereby:

$$G(\mathbf{u}, \boldsymbol{\lambda}) \equiv \begin{pmatrix} \mathbf{f}(\mathbf{u}) - \mathbf{p}(\lambda_1, \mathbf{u}) \\ \mathbf{g}(\mathbf{u}, \boldsymbol{\lambda}) \end{pmatrix} = \mathbf{0} \quad (20)$$

where Eq. (1) gives the equilibrium equations between the displacements and the load-describing variable $\lambda_1 = \psi$, and the N_g augmenting equations $\mathbf{g}(\mathbf{u}, \boldsymbol{\lambda})$ define some extra relations for the interesting subset of equilibrium solutions, under the variations of the variables $\lambda_1, \dots, \lambda_{N_\lambda}$. The dimension of the solutions to the augmented system is then $N_\lambda - N_g$.

3 NUMERICAL EXAMPLES

We have performed some test with a spherical membrane, and a balloon-shaped membrane, both subjected to internal over-pressures. In both cases, we used an initial thickness of 0.1 mm, and a material with shear modulus $\mu = 0.4225$ MPa.

3.1 A sphere

A sphere with radius $r = 10$ mm under internal pressure was considered, [4, 22]. Boundary conditions were chosen to allow uniform expansion, cf Fig. 1. A mesh of the whole sphere with 5120 triangular elements was considered, based on successive subdivisions of a 20-corner icosahedron mesh; all nodes were moved radially to be placed on the sphere. The example was used to show the properties of the hyper-elastic formulation, with different ratios between c_1 and c_2 coefficients in the Mooney-Rivlin constitutive relation Eq. (11), described by (n_1, n_2) as in Eqs. (13)–(14).

The results from hyper-elastic models are given in Fig. 2. Re-drawn with the radial expansion u_D expressed as a stretch, the results visually agree with the analytical results given in [22], for $c_1 = 0.5\mu, c_2 = 0$ (‘neo-Hookean’) and for $c_1 = \frac{7}{16}\mu, c_2 = \frac{1}{16}\mu$ (‘Mooney-Rivlin’). No instabilities were noted in addition to the turning points with respect to pressure, [4].

Solutions with a sufficiently low c_2 constant show a maximum pressure state for small expansions. Even for very small non-zero values of c_2 , there will also be a (local) minimum pressure state, but the pressures will eventually increase with radial expansion; this was verified for a case with $(n_1/n_2) = 1023/1$, where the minimum limit pressure was found as $p = 0.528$ kPa at a radial expansion $u_D \approx 310$ mm. The pair of limit pressure states disappear between calculated solutions for $n_1/n_2 = 5/1$ and $n_1/n_2 = 4/1$.

Figure 1: Sphere under internal pressure. The figures shows an eighty element model, and sample points, but calculations were performed with an 5120 element mesh. Supports were given as: $u_A = v_A = v_B = u_C = v_C = w_C = 0$, with (u, v, w) the translations in global (x, y, z) directions.

Figure 2: Sphere under internal pressure. Radial expansion and internal over-pressure for different parameters in a Mooney-Rivlin model. Curve notation n_1/n_2 according to Eqs. (13)–(14).

3.2 A long balloon

Figure 3 shows a model with 672 triangular elements of an inflated balloon which is completely fixed in one end, $x = 0$, constrained to only axial movement of the farthest end (A), and subjected to a uniform internal pressure ψ , assuming a surrounding pressure of $\psi_0 = 100$ kPa. The initial geometry of the balloon was composed of a $L = 95$ mm cylinder with radius $r = 10$ mm and an end half-sphere. Sample points for deflections are marked in Fig. 3. Quasi-static equilibrium simulations were performed for refined models with 2688 and 10752 elements.

The pressure-expansion sequence was followed by a displacement-based iteration sequence for a 10752 element mesh, and different hyper-elastic material model, described by the ratio n_1/n_2 in Eqs. (13)–(14). The result is represented by the radial expansion v_D related to the internal over-pressure ψ in Fig. 4. A set of longitudinal sections through the inflated balloon are shown in Fig. 5. The profiles show the section of the balloon at $z = 0$, but the section $y = 0$

Figure 3: Inflation of balloon, 672 element model with sample points. All nodes at $x = 0$ were considered fully fixed in the simulations, the node at A could only move axially; all other nodes were completely free. Calculations were made with refined models (2688, 10752 elements), obtained from successive divisions of the figure elements into four triangles.

Figure 4: Inflation of balloon. Hyper-elastic material models, and 10752 element mesh. Quasi-static equilibrium paths, represented by internal over-pressure ψ and radial expansion at sample point D, v_D , Fig. 3. Curve notation n_1/n_2 according to Eqs. (13)–(14).

gives completely identical figures, as all solutions are rotationally symmetric. The sections were chosen when the radial expansion $v_D \approx 300$ mm for the different material models; the position of sample point D is marked by a circle in the figures. It is noted that these solutions refer to significantly different pressures ψ , cf. Fig. 4.

The dots on the sections in Fig. 5 show the displaced positions of the nodes on the symmetry line, which were close to evenly distributed initially. It is obvious that the neo-Hookean model $n_1/n_2 = 1/0$ will give a considerably different behavior than the other models, as it localizes the strains to the central parts of the balloon. This is an effect of the softening behavior with strain, whereas a non-zero c_2 coefficient will give a final stiffening of the material. This localization of the straining means that the mesh must be finer for the neo-Hookean material, in order to avoid behavior artifacts from the discretization. The 2688 element model was shown to be essentially free from such artifacts even for the neo-Hookean case.

Several of the material models showed a limit state with respect to internal over-pressure: a maximum load point, which was isolated to high accuracy. This limit state existed for all tested

Figure 5: Inflation of balloon. Hyper-elastic material models, and 10752 element mesh. Sections through inflated balloon, for solutions with $v_D \approx 300$ mm, for different parameters in a Mooney-Rivlin model. Curve notation n_1/n_2 according to Eqs. (13)–(14).

Figure 6: Inflation of balloon. Hyper-elastic material models, and 10752 element mesh. Radial expansion v_D related to the amount of gas injected, represented by product $(\psi_0 + \psi)V(\mathbf{u})$, for different parameters in a Mooney-Rivlin model. Curve notation n_1/n_2 according to Eqs. (13)–(14). Surrounding pressure $\psi_0 = 100$ kPa.

material models with ratios $n_1/n_2 \geq 5$, whereas no (local) maximum pressure state was found for $n_1/n_2 \leq 4$. Except for the neo-Hookean model, the maximum pressure state corresponded to a (local) minimum before the pressure started to increase monotonically with expansion. A loading situation where the pressure can be regulated would thus show a dynamic snap-through behavior in the inflation process for such materials.

The models showed bifurcation states for very large expansions. For the $n_1/n_2 = 7/1$ model with 10752 elements, this occurred at an overpressure $\psi = 43.9$ kPa, and a radial expansion $v_D = 2139$ mm with a mode corresponding to a torsion of the balloon. The same bifurcation was found for $\psi = 59.0$ kPa, $v_D = 1435$ mm when $n_1/n_2 = 3/1$. It is noted that some possible instability modes are restrained by the adopted kinematic constraints.

The results in Fig. 4 are represented as radial expansion v_D and product $(\psi_0 + \psi)V(\mathbf{u})$ in Fig. 6, for the assumed $\psi_0 = 100$ kPa, and the volume V calculated from the current displacements \mathbf{u} . For all material models, the expansion is monotonically increasing together with the injected amount of gas, so no instability would occur in the process for a loading situation where the inflow of gas is regulated. It is noted, however, that the evaluation of the injected amount of gas is significantly dependent on the assumed surrounding pressure.

As an alternative to the above solution, the solution of the inflation problem can also be

Figure 7: Inflation of balloon. Hyper-elastic material models, and 2688 element mesh. Solutions parameterized by amount measure, for different parameters in a Mooney-Rivlin model. Radial expansion v_D and internal over-pressure ψ , Fig. 3. Curve notation n_1/n_2 according to Eqs. (13)–(14). Surrounding pressure $\psi_0 = 100$ kPa.

parameterized by the amount of gas injected. Assuming isothermal conditions, a second control variable $\lambda_2 = N_t$ was used in addition to the over-pressure $\lambda_1 = \psi$, together with an augmenting equation:

$$g(\mathbf{u}, \boldsymbol{\lambda}) = (\psi_0 + \lambda_1)V(\mathbf{u}) - \lambda_2 = 0 \quad (21)$$

Driving the path-following with the λ_2 variable gave the results presented in Fig. 7, for different constitutive parameters c_1, c_2 . The solutions are identical to the ones obtained without the amount parameter.

The augmenting equation method was used to study the behavior of an inflated balloon under change of temperature. The problem was set up with three control variables $\boldsymbol{\lambda}^T = (\psi, N, T)$, with two augmenting equations beside the equilibrium equations:

$$g(\mathbf{u}, \boldsymbol{\lambda}) = \begin{pmatrix} (\psi_0 + \lambda_1)V(\mathbf{u}) - \lambda_2(\lambda_3 + 273) \\ \lambda_2 - N_0 \end{pmatrix} = \mathbf{0} \quad (22)$$

where N_0 is a constant, defined in each material model case from the primary solutions in Fig. 4 for an over-pressure of $\psi = 3.0$ kPa, and assuming that this situation was first achieved at $T = 20^\circ\text{C}$, whereafter the balloon was sealed. The solutions obtained for variable temperature are shown in Fig. 8

4 CONCLUDING REMARKS

In this paper, a faceted triangular membrane space element is used for the analysis of pressurized membrane structures, using a class of hyper-elastic, Mooney-Rivlin, material models. The loading was seen as a uniform over-pressure, representing a gas loading. Quasi-static conditions were assumed, neglecting dynamic effects primarily coming from the flow velocities within the volume. It is emphasized by examples that the pressurizing mechanism is of importance for the response, even when the analysis is restricted to gas as the pressurizing medium. Two simple ‘balloon-type’ membranes show that limit points can occur when the pressure variable is seen as the parameter for the inflation, whereas these limit states can disappear when the injected gas

Figure 8: Inflation of balloon. Hyper-elastic material models, and 2688 element mesh. Solutions parameterized by temperature, for different parameters in a Mooney-Rivlin model. Radial expansion v_D and internal over-pressure ψ , Fig. 3. Curve notation n_1/n_2 according to Eqs. (13)–(14). Surrounding pressure $\psi_0 = 100$ kPa.

volume is seen as the parameter. This difference thus has significance for the dynamic response of the membrane.

The results from the numerical examples indicate that the proposed formulation can be used for analysis of space membrane problems showing large displacements and large strains. The present study has been limited to uniform internal over-pressures, but other media or methods for introduction of the pressure, as well as partially filled structures, are interesting continuations of the project reported. A requirement for the model to be useful in the analysis of realistic structures is the development and verification of other non-linear material models.

A sophisticated path-following algorithm is needed for following the complex generalized equilibrium paths, which are used for the simulations. It is believed that the two-dimensional equilibrium surfaces discussed in [29] can be used for an improved understanding of membrane behavior under different classes of loadings.

Keywords: Fluid-Structure Interaction, Non-Matching Meshes, Mortar Method, Dual Lagrange Multipliers, Finite Elements.

Abstract. *Computational approaches for the simulation of fluid-structure interaction (FSI) problems have received much attention in recent years and their importance is still continuously growing. The main reason for this is that FSI problems are of great relevance in all fields of engineering (civil, mechanical, aerospace, bio, etc.) as well as in the applied sciences. In order to develop robust, reliable and efficient methods a number of challenges have to be met. This contribution focuses on the important question of how to treat the interface between solid and fluid. The topic is addressed by reviewing our novel, recently proposed method for dealing with non-matching grids in the context of moving grid FSI schemes. In contrast to available approaches in the literature, the proposed formulation is based on a mortar method with so-called dual Lagrange multipliers and handles the additional complexity of coupling non-matching interface meshes at negligible computational cost. Owing to its generality, the resulting FSI framework does not introduce any restriction on the particular choice of finite element formulations neither for fluid, ALE nor structure. It allows for the application of state-of-the-art iterative solution methods to the resulting system matrices in a straightforward manner and shows an excellent performance within monolithic FSI coupling algorithms.*

1 INTRODUCTION

The numerical simulation of fluid-structure interaction (FSI) phenomena has long been a field of intensive research owing to its many applications in civil, mechanical, aerospace and biomechanical engineering. Of particular interest is the interaction of incompressible flow with flexible structures undergoing finite deformations. We discuss here the most important features of our recently proposed dual mortar finite element method for dealing with non-matching interface meshes in the context of moving grid FSI schemes and monolithic coupling algorithms. The present contribution is thus a shortened version of our article [1] to which we refer for full technical details, more profound discussion of the methods and further numerical examples.

Possible solution strategies for FSI problems range from weakly coupled partitioned over strongly coupled partitioned to monolithic schemes. It could be shown that for some challenging numerical problems such as collapsible tubes [2], thin-walled structures in the hemodynamic or respiratory system [3] or balloon-like problems of human red blood cells [4], monolithic coupling schemes outperform partitioned approaches or are even the only feasible schemes to solve the problem at all. The issue of efficient and robust solvers for monolithic FSI scheme has among others been addressed in [5] where a novel algebraic multigrid preconditioner has been proposed. In general and also in [5], monolithic schemes are derived based on the assumption of a conforming interface discretization, i.e. fluid and structure share a common interface mesh. But only in very rare cases, this assumption will hold. Due to a manifold of reasons one generally has to deal with non-matching grids at the fluid-structure interface. Most often different resolution requirements in the different physical domains or quite simply the presence of complex interface geometries (e.g. in patient-specific biomechanics modeling) make the creation of matching fluid and structure meshes cumbersome or even impossible.

A possible remedy is provided by the mortar method, which has originally been introduced in the context of non-overlapping domain decomposition [6]. A characteristic feature of the mortar method is the imposition of interface constraints in a variationally consistent manner based on Lagrange multipliers. This approach has seen a great thrust of research over the past decade. New fields of application such as finite deformation contact analysis [7, 8, 9, 10] have been established and the mathematical understanding concerning the choice of adequate discrete Lagrange multiplier spaces has been deepened [11, 12, 13, 14].

Different other coupling methods for non-conforming interfaces in the framework of fluid-structure problems have been discussed for example in [15, 16, 17, 18, 19]. However, those contributions are limited to 2D analysis [16, 18] or only consider partitioned coupling schemes. The mortar method is referred to as a method with desirable mathematical and numerical properties [15, 17], but it has not yet been used for FSI computations in a competitive manner. It is obvious that a straightforward application of the standard mortar method will raise numerical issues in the case of monolithic FSI schemes. The Lagrange multiplier degrees of freedom lead to a global system matrix with increased size and saddle point structure. Especially the latter limits the practical use of this approach, since most iterative solvers rely on a matrix structure with only non-zero diagonal entries. A condensation could remedy this problem but would necessitate the inversion of a large matrix and is hence not feasible for practical purposes.

To overcome the numerical issues of the standard mortar method discussed above, we employ a so-called dual mortar method [11, 12, 13, 14] with discrete Lagrange multipliers that are constructed based on a biorthogonality relation with the primal shape functions at the fluid-structure interface. In contrast to standard mortar methods, the dual mortar approach allows for an elimination of the additional degrees of freedom by condensation at negligible computational

cost in the monolithic setting. This ensures that there are only non-zero diagonal entries in the global system matrix. We show that state-of-the-art iterative solvers for monolithic FSI systems with matching interface meshes as proposed in [5] can be applied to the resulting global system matrices without any conceptual changes.

The remainder of this article is organized as follows: The next section briefly introduces the mechanical problem and states the governing equations as well as the weak forms. In section 3 the resulting monolithic system of equations after discretization and consistent linearization is presented and we give some details on dual mortar coupling as well as on condensation of the Lagrange multiplier degrees of freedom. Section 4 demonstrates the validity of the proposed approach with a representative numerical example, and in section 5 we conclude the findings.

2 PROBLEM DESCRIPTION

FSI problems can formally be described as four field problems. To begin with, there are two physical fields, fluid and structure. Furthermore, to account for deformations of the fluid domain, an arbitrary Lagrangian-Eulerian (ALE) approach is employed, constituting a third, non-physical mesh field later also called ALE field. Fluid and structure share a common FSI interface Γ , but not necessarily a common finite element discretization of Γ . Therefore, coupling conditions are applied in a weak sense, introducing a field of Lagrange multipliers on Γ .

2.1 Fluid

The present FSI approach is not limited to a specific flow description. For the sake of brevity we assume a fluid field governed by the instationary, incompressible Navier-Stokes equations for a Newtonian fluid on a deformable fluid domain Ω^F . The unknown fluid domain deformation \mathbf{d}^G is defined by a unique mapping $\boldsymbol{\phi}$ given by

$$\mathbf{d}^G(\mathbf{x}, t) = \boldsymbol{\phi}(\mathbf{d}_\Gamma^G, \mathbf{x}, t) \quad \text{in} \quad \Omega^F \times (0, T), \quad (1)$$

based on the mesh interface displacement \mathbf{d}_Γ^G , that will later be related to the structure interface displacement \mathbf{d}_Γ^S . This mapping (1) is arbitrary and defines the domain velocity \mathbf{u}^G by

$$\mathbf{u}^G = \frac{\partial \boldsymbol{\phi}}{\partial t} \quad \text{in} \quad \Omega^F \times (0, T), \quad (2)$$

which has to match the fluid velocity \mathbf{u}_Γ^F at the interface Γ , i.e.

$$\mathbf{u}_\Gamma^F = \mathbf{u}_\Gamma^G \quad \text{in} \quad \Gamma \times (0, T). \quad (3)$$

Equation (2) allows for the definition of the ALE convective velocity $\mathbf{c} = \mathbf{u}^F - \mathbf{u}^G$, representing the fluid velocity relative to the arbitrarily moving fluid domain. The Navier-Stokes equations of the fluid field hence read

$$\frac{\partial \mathbf{u}^F}{\partial t} + \mathbf{c} \cdot \nabla \mathbf{u}^F - 2\nu \nabla \cdot \boldsymbol{\epsilon}(\mathbf{u}^F) + \nabla p^F = \mathbf{b}^F, \quad (4)$$

$$\nabla \cdot \mathbf{u}^F = 0, \quad (5)$$

both valid in $\Omega^F \times (0, T)$, where fluid velocity \mathbf{u}^F and kinematic fluid pressure p^F are unknown. In the momentum equation (4), \mathbf{b}^F denotes a body force, $\boldsymbol{\epsilon}(\mathbf{u}^F) = \frac{1}{2}(\nabla \mathbf{u}^F + (\nabla \mathbf{u}^F)^T)$ the strain rate tensor of the Newtonian fluid and ν its kinematic viscosity. Equation (5) states the fluid's

incompressibility deduced from the conservation of mass and a constant density ρ^F . The fluid system is completed by the usual Dirichlet and Neumann boundary conditions and an initial divergence-free velocity field \mathbf{u}_0^F .

The weak form of the incompressible Navier-Stokes equations (4) and (5) is obtained by testing these equations with test functions $\delta \mathbf{u}^F$ for velocity and δp^F for pressure and subsequent integration by parts

$$0 = \left(\delta \mathbf{u}^F, \frac{\partial \mathbf{u}^F}{\partial t} \right)_{\Omega^F} + (\delta \mathbf{u}^F, \mathbf{c} \cdot \nabla \mathbf{u}^F)_{\Omega^F} + (\nabla \delta \mathbf{u}^F, 2\nu \boldsymbol{\varepsilon}(\mathbf{u}^F))_{\Omega^F} - (\nabla \cdot \delta \mathbf{u}^F, p^F)_{\Omega^F} \\ - (\delta \mathbf{u}^F, \mathbf{b}^F)_{\Omega^F} - (\delta p^F, \nabla \cdot \mathbf{u}^F)_{\Omega^F} + (\delta \mathbf{u}^F, \bar{\mathbf{h}}^F)_{\Gamma_N^F} + \delta W_{\Gamma}^F, \quad (6)$$

where Γ_N^F denotes the Neumann boundary and δW_{Γ}^F denotes a contribution of the FSI interface that will be deduced in section 2.3.

2.2 Structure

In this work we assume a structure field governed by the nonlinear elastodynamics equation

$$\rho^S \frac{d^2 \mathbf{d}^S}{dt^2} = \nabla \cdot (\mathbf{F}\mathbf{S}) + \rho^S \mathbf{b}^S \quad \text{in } \Omega^S \times (0, T), \quad (7)$$

which states an equilibrium between the forces of inertia, internal forces and an external body force \mathbf{b}^S in the undeformed structural configuration Ω^S . Given the structural density ρ^S defined per unit undeformed volume, equation (7) has to be solved for the unknown structural displacements \mathbf{d}^S . The internal forces are expressed in terms of the second Piola-Kirchhoff stress tensor \mathbf{S} and the deformation gradient \mathbf{F} .

Different constitutive relations can be employed in this context, but for the sake of simplicity a hyperelastic material behavior with strain energy function Ψ is considered in the remainder of this paper. The second Piola-Kirchhoff stress tensor \mathbf{S} is thus defined as

$$\mathbf{S} = 2 \frac{\partial \Psi}{\partial \mathbf{C}}, \quad (8)$$

where the right Cauchy-Green tensor $\mathbf{C} = \mathbf{F}^T \mathbf{F}$ has been introduced. Dirichlet and Neumann boundary conditions as well as the usual initial boundary conditions, given initial displacements and velocities \mathbf{d}_0^S and $\dot{\mathbf{d}}_0^S$, respectively, have to be additionally satisfied.

Testing (7) with the virtual displacements $\delta \mathbf{d}^S$ and integration by parts yield the weak form

$$0 = \left(\delta \mathbf{d}^S, \rho^S \frac{d^2 \mathbf{d}^S}{dt^2} \right)_{\Omega^S} + (\nabla \delta \mathbf{d}^S, \mathbf{F}\mathbf{S})_{\Omega^S} - (\delta \mathbf{d}^S, \rho^S \mathbf{b}^S)_{\Omega^S} - (\delta \mathbf{d}^S, \bar{\mathbf{h}}^S)_{\Gamma_N^S} + \delta W_{\Gamma}^S, \quad (9)$$

where Γ_N^S denotes the Neumann boundary. The influence of the interface on the structure field is accounted for by δW_{Γ}^S , which will be discussed in the following subsection.

2.3 Fluid-Structure Interface

Coupling of the different fields is realized by enforcing kinematic and dynamic constraints at the fluid-structure interface Γ . Usually, the no-slip boundary condition

$$\frac{\partial \mathbf{d}_{\Gamma}^S}{\partial t} = \mathbf{u}_{\Gamma}^F \quad \text{in } \Gamma \times (0, T) \quad (10)$$

is applied, which prohibits both a mass flow across and a relative tangential movement of fluid and structure at the fluid-structure interface. In combination with (3) this condition (10) is equivalent to

$$\mathbf{d}_\Gamma^S = \mathbf{d}_\Gamma^G \quad \text{in } \Gamma \times (0, T), \quad (11)$$

stating that structural deformation and fluid movement (represented by the ALE based fluid domain deformation \mathbf{d}_Γ^G) must match on Γ . In addition, equilibrium of forces requires the surface tractions of fluid and structure to be equal, yielding

$$\mathbf{h}_\Gamma^S = -\mathbf{h}_\Gamma^F \quad \text{in } \Gamma \times (0, T). \quad (12)$$

In preparation of the mortar finite element discretization to follow, the method of weighted residuals is applied to the interface conditions. By introducing the Lagrange multiplier field $\boldsymbol{\lambda}$ and corresponding test functions $\delta \boldsymbol{\lambda}$ on the fluid-structure interface Γ , we obtain the weak form

$$(\delta \boldsymbol{\lambda}, \mathbf{d}_\Gamma^S - \mathbf{d}_\Gamma^G)_\Gamma = 0. \quad (13)$$

This adds an integral version of the continuity constraint (11) to the general problem definition. Furthermore, the unknown surface tractions introduced in (12) have to be imposed in a weak sense on the respective physical field, yielding the missing coupling terms in fluid weak form (6) and structure weak form (9)

$$\delta W_\Gamma^F = (\mathbf{h}_\Gamma^F, \delta \mathbf{u}_\Gamma^F)_\Gamma, \quad (14)$$

$$\delta W_\Gamma^S = (\mathbf{h}_\Gamma^S, \delta \mathbf{d}_\Gamma^S)_\Gamma. \quad (15)$$

Identifying the Lagrange multiplier field $\boldsymbol{\lambda}$ with the unknown surface traction $\mathbf{h}_\Gamma^S = -\mathbf{h}_\Gamma^F$, these coupling terms can be expressed as

$$\delta W_\Gamma^F = -(\boldsymbol{\lambda}, \delta \mathbf{u}_\Gamma^F)_\Gamma, \quad (16)$$

$$\delta W_\Gamma^S = (\boldsymbol{\lambda}, \delta \mathbf{d}_\Gamma^S)_\Gamma. \quad (17)$$

Thus, fluid-structure coupling is established in a weak sense, which formally leads to a four field FSI system.

3 DISCRETIZATION AND SOLUTION ALGORITHM

3.1 The monolithic FSI system

To derive the monolithic FSI system of equations, the governing equations stated above are discretized in space and time and the resulting non-linear equations are linearized consistently in order to apply a Newton-Raphson algorithm. Note that the presented algorithm is not limited to a particular choice of these discretizations. In general, we use finite element discretizations for fluid, ALE and structure fields and implicit time integration schemes.

The final linear system of equation for timestep $n + 1$ and iteration step i then emerges as

$$\begin{bmatrix}
 \mathbf{S}_{\text{II}} & \mathbf{S}_{\text{I}\Gamma} & & & & \\
 \mathbf{S}_{\Gamma\text{I}} & \mathbf{S}_{\Gamma\Gamma} & & & & \\
 & & \mathbf{F}_{\text{II}} & \mathbf{F}_{\text{I}\Gamma} + \frac{\Delta t}{2} \mathbf{F}_{\text{II}}^{\text{G}} & \mathbf{F}_{\text{II}}^{\text{G}} & \\
 & & \mathbf{F}_{\Gamma\text{I}} & \mathbf{F}_{\Gamma\Gamma} + \frac{\Delta t}{2} \mathbf{F}_{\Gamma\text{I}}^{\text{G}} & \mathbf{F}_{\Gamma\text{I}}^{\text{G}} & -\mathbf{C}_{\text{F}}^{\text{T}} \\
 & & \mathbf{0} & \frac{\Delta t}{2} \mathbf{A}_{\text{I}\Gamma} & \mathbf{A}_{\text{II}} & \\
 & \mathbf{C}_{\text{S}} & & -\frac{\Delta t}{2} \mathbf{C}_{\text{F}} & &
 \end{bmatrix}
 \begin{bmatrix}
 \Delta \mathbf{d}_{\text{I},i}^{\text{S},n+1} \\
 \Delta \mathbf{d}_{\Gamma,i}^{\text{S},n+1} \\
 \Delta \mathbf{u}_{\text{F},i}^{\text{F},n+1} \\
 \Delta \mathbf{u}_{\Gamma,i}^{\text{F},n+1} \\
 \Delta \mathbf{d}_{\text{I},i}^{\text{G},n+1} \\
 \boldsymbol{\lambda}_i^{n+1}
 \end{bmatrix}
 =
 \begin{bmatrix}
 \mathbf{f}_{\text{I},i}^{\text{S},n+1} \\
 \mathbf{f}_{\Gamma,i}^{\text{S},n+1} \\
 \mathbf{f}_{\text{F},i}^{\text{F},n+1} \\
 \mathbf{f}_{\Gamma,i}^{\text{F},n+1} \\
 \mathbf{0} \\
 \mathbf{0}
 \end{bmatrix}
 - \delta_{i0} \Delta t
 \begin{bmatrix}
 \mathbf{0} \\
 \mathbf{0} \\
 \mathbf{F}_{\text{II}}^{\text{G}} \mathbf{u}_{\Gamma}^{\text{F},n} \\
 \mathbf{F}_{\Gamma\text{I}}^{\text{G}} \mathbf{u}_{\Gamma}^{\text{F},n} \\
 \mathbf{A}_{\text{I}\Gamma} \mathbf{u}_{\Gamma}^{\text{F},n} \\
 \mathbf{C}_{\text{F}} \mathbf{u}_{\Gamma}^{\text{F},n}
 \end{bmatrix}, \quad (18)$$

where δ_{i0} denotes the Kronecker delta. In equation (18) the vector of unknowns and the right-hand side are split in quantities defined on the FSI interface denoted by \cdot_{Γ} and in the interior field denoted by \cdot_{I} . This split then propagates to the matrix block structure. The block structure of the structure stiffness matrix \mathbf{S} is defined as $\mathbf{S}_{\alpha\beta} = \partial \mathbf{f}_{\alpha}^{\text{S}} / \partial \mathbf{d}_{\beta}^{\text{S}}$, $\alpha, \beta \in \{\text{I}, \Gamma\}$, where \mathbf{f}^{S} denotes the residual vector and \mathbf{d}^{S} the vector of discretized nodal displacements. To shorten the notation for the fluid part, we have merged the pressure degrees of freedom into the vector of fluid interior unknowns. Fluid entries are then defined as $\mathbf{F}_{\alpha\beta} = \partial \mathbf{f}_{\alpha}^{\text{F}} / \partial \mathbf{u}_{\beta}^{\text{F}}$ and shape derivatives as $\mathbf{F}_{\alpha\beta}^{\text{G}} = \partial \mathbf{f}_{\alpha}^{\text{F}} / \partial \mathbf{d}_{\beta}^{\text{G}}$, $\alpha, \beta \in \{\text{I}, \Gamma\}$. Here, \mathbf{f}^{F} denotes the fluid residual, \mathbf{u}^{F} the vector of discretized fluid unknowns and \mathbf{d}^{G} the vector of fluid grid displacements. The ALE system matrix \mathbf{A} is split accordingly into blocks $\mathbf{A}_{\text{I}\Gamma}$ and \mathbf{A}_{II} .

The system is completed by coupling matrices \mathbf{C}_{S} and \mathbf{C}_{F} . The last row of (18) weakly imposes the continuity constraint (11) and thus represents the discrete version of (13). The contributions of the vector of discretized Lagrange multiplier values $\boldsymbol{\lambda}$, i.e. $-\mathbf{C}_{\text{F}}^{\text{T}} \boldsymbol{\lambda}$ and $\mathbf{C}_{\text{S}}^{\text{T}} \boldsymbol{\lambda}$, account for the additional surface tractions on the fluid and structure field, respectively, which result from the coupling at the FSI interface and correspond to (16) and (17).

3.2 Dual mortar coupling

Non-conforming finite element discretization brings about that fluid and structure surfaces at the FSI interface Γ do not match any more, as it is the case when using node-matching interface meshes. For making the following derivations more general, we define so-called *slave* and *master* sides Γ^{sl} and Γ^{ma} , introduce the displacement fields $\mathbf{d}_{\Gamma}^{\text{sl}}$ and $\mathbf{d}_{\Gamma}^{\text{ma}}$ and derive the dual mortar method as an abstract coupling strategy for two non-conforming meshes. The general form of slave and master displacement interpolation then reads

$$\mathbf{d}_{\Gamma}^{\text{sl}} = \sum_{k=1}^{n^{\text{sl}}} N_k^{\text{sl}} \mathbf{d}_k^{\text{sl}}, \quad \mathbf{d}_{\Gamma}^{\text{ma}} = \sum_{l=1}^{n^{\text{ma}}} N_l^{\text{ma}} \mathbf{d}_l^{\text{ma}}, \quad (19)$$

where shape functions N_k^{sl} , N_l^{ma} are obtained based on their trace space relationship with the underlying discretizations of the domains ‘behind’ the mortar interface (in this context fluid

Figure 1: Exemplary shape functions $N_1(\xi, \eta)$ and dual shape functions $\Phi_1(\xi, \eta)$.

and structure domains). Nodal displacements are represented by \mathbf{d}_k^{sl} , \mathbf{d}_l^{ma} . The total number of slave and master nodes is given by n^{sl} and n^{ma} , respectively.

Within the *dual* mortar method considered here, the Lagrange multiplier interpolation on the slave side of the interface is based on so-called dual shape functions Φ_j as

$$\boldsymbol{\lambda} = \sum_{j=1}^{n^{\text{sl}}} \Phi_j \boldsymbol{\lambda}_j, \quad (20)$$

with discrete nodal Lagrange multipliers $\boldsymbol{\lambda}_j$. The dual shape functions are constructed such that a biorthogonality condition, as introduced in [20, 13, 14], is satisfied, yielding

$$\int_{\Gamma^{\text{sl}}} \Phi_j N_k^{\text{sl}} d\Gamma = \delta_{jk} \int_{\Gamma^{\text{sl}}} N_k^{\text{sl}} d\Gamma, \quad (21)$$

where δ_{jk} is the Kronecker delta. Note that (21) demands an evaluation of shape function integrals on the actual (possibly distorted) surface element geometry in the reference configuration. Therefore, an *a priori* definition of dual shape functions is not possible in general, but these ansatz functions for Lagrange multiplier interpolation become element-specific. Fig. 1 exemplarily shows (standard) displacement shape functions and (dual) Lagrange multiplier shape functions for a 3-node triangular and for an undistorted 4-node quadrilateral surface element. For a more detailed overview and exemplary local calculations of element-specific dual shape functions for 3D mortar coupling, we refer to [11, 8].

For the sake of clarity, we temporarily ignore the weak continuity condition (13) already derived for the concrete FSI setting and instead consider the more general form

$$\left(\delta \boldsymbol{\lambda}, \mathbf{d}_{\Gamma}^{\text{sl}} - \mathbf{d}_{\Gamma}^{\text{ma}} \right)_{\Gamma} = 0 \quad (22)$$

in the following, which couples slave and master displacements of an abstract non-conforming interface. When the interpolations (19) and (20) are substituted into (22), the nodal blocks of two mortar integral matrices \mathbf{D} and \mathbf{M} emerge as

$$\mathbf{D}[j, k] = D_{jk} \mathbf{I}_3 = \int_{\Gamma^{\text{sl}}} \Phi_j N_k^{\text{sl}} d\Gamma \mathbf{I}_3, \quad (23)$$

$$\mathbf{M}[j, l] = M_{jl} \mathbf{I}_3 = \int_{\Gamma^{\text{sl}}} \Phi_j N_l^{\text{ma}} d\Gamma \mathbf{I}_3, \quad (24)$$

with the 3×3 identity matrix \mathbf{I}_3 . Herein, \mathbf{D} is a square $3n^{\text{sl}} \times 3n^{\text{sl}}$ matrix, whereas the definition of \mathbf{M} generally yields a rectangular matrix of dimensions $3n^{\text{sl}} \times 3n^{\text{ma}}$. Inserting the biorthogonality relation (21) into (23) allows for the advantageous simplification of \mathbf{D} to become a diagonal matrix with nodal blocks

$$\mathbf{D}[j, k] = D_{jk} \mathbf{I}_3 = \delta_{jk} \int_{\Gamma^{\text{sl}}} N_k^{\text{sl}} d\Gamma \mathbf{I}_3. \quad (25)$$

Finally, the discrete form of the general weak continuity condition (22) reads

$$\mathbf{D} \mathbf{d}_{\Gamma}^{\text{sl}} - \mathbf{M} \mathbf{d}_{\Gamma}^{\text{ma}} = \mathbf{0}, \quad (26)$$

which naturally defines a discrete projection from master to slave displacements as

$$\mathbf{d}_{\Gamma}^{\text{sl}} = \mathbf{D}^{-1} \mathbf{M} \mathbf{d}_{\Gamma}^{\text{ma}}. \quad (27)$$

Equation (27) illustrates one major advantage of the dual mortar approach as compared with standard mortar schemes. The discrete projection operator $\mathbf{P} = \mathbf{D}^{-1} \mathbf{M}$ at a non-conforming interface can be applied locally based on the trivial inversion of the diagonal matrix \mathbf{D} . Thus, evaluating (27) does not require the solution of a possibly large linear system of equations. This evades the high computational cost associated with standard mortar coupling of two non-conforming grids. Note that depending on the choice of structure or fluid as slave side for the mortar approach, the discrete coupling matrices \mathbf{C}_S and \mathbf{C}_F in (18) can be identified with the mortar matrices \mathbf{D} and \mathbf{M} .

3.3 Condensed linear system

The four-field linear system in (18) is in general very hard to solve numerically with parallel iterative linear solvers, because of the saddle point type structure of the problem. Since larger model sizes necessitate this type of solvers, the linear system is transformed into the same block-structure as the standard monolithic FSI system for conforming discretizations shown in [5]. The transformation is based on condensation of the Lagrange multipliers, which is only possible due to the dual mortar approach discussed in section 3.2.

Of course both choices for master and slave side of the mortar coupling are possible and result in viable algorithms as has been shown in great detail in [1]. For the sake of brevity, in this contribution only one possibility is discussed: we assume that the structure side of the FSI interface Γ serves as slave side for the mortar coupling. Thus the coupling matrices in (18) can be identified as $\mathbf{C}_F = \mathbf{M}$ and $\mathbf{C}_S = \mathbf{D}$.

The second row of (18) is solved for the Lagrange multipliers $\boldsymbol{\lambda}_i^{n+1}$, involving a trivial inversion of the diagonal matrix \mathbf{D} . The result can then be substituted into the fourth row of (18), so that the Lagrange multipliers are fully eliminated from the system. A further reduction can be obtained by a transformation of the last row of (18), which allows to express the structure interface displacement updates $\Delta \mathbf{d}_{\Gamma, i}^{\text{S}, n+1}$ in terms of fluid interface velocity updates $\Delta \mathbf{u}_{\Gamma, i}^{\text{F}, n+1}$.

Subsequent substitution and reordering yield the final reduced system of equations

$$\begin{bmatrix} \mathbf{S}_{\Pi} & \frac{\Delta t}{2} \mathbf{S}_{\Pi} \mathbf{P} \\ \mathbf{P}^T \mathbf{S}_{\Pi} & \frac{\Delta t}{2} \mathbf{P}^T \mathbf{S}_{\Pi} \mathbf{P} + \mathbf{F}_{\Pi} + \frac{\Delta t}{2} \mathbf{F}_{\Pi}^G \\ & \mathbf{F}_{\Pi} + \frac{\Delta t}{2} \mathbf{F}_{\Pi}^G \\ & \frac{\Delta t}{2} \mathbf{A}_{\Pi} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{d}_{I,i}^{S,n+1} \\ \Delta \mathbf{u}_{F,i}^{F,n+1} \\ \Delta \mathbf{u}_{F,i}^{F,n+1} \\ \Delta \mathbf{d}_{I,i}^{G,n+1} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{I,i}^{S,n+1} \\ \mathbf{f}_{F,i}^{F,n+1} + \mathbf{P}^T \mathbf{f}_{F,i}^{S,n+1} \\ \mathbf{f}_{F,i}^{F,n+1} \\ \mathbf{0} \end{bmatrix} + \delta_{i0} \Delta t \begin{bmatrix} \mathbf{S}_{\Pi} \mathbf{P} \mathbf{u}_{F,i}^{F,n} \\ (\mathbf{P}^T \mathbf{S}_{\Pi} \mathbf{P} + \mathbf{F}_{\Pi}^G) \mathbf{u}_{F,i}^{F,n} \\ \mathbf{F}_{\Pi}^G \mathbf{u}_{F,i}^{F,n} \\ \mathbf{A}_{\Pi} \mathbf{u}_{F,i}^{F,n} \end{bmatrix}. \quad (28)$$

4 EXAMPLE

To demonstrate the efficiency of the proposed method, different discretizations of the same fluid filled circular pipe with traveling pressure wave are considered. The example is motivated by [5, 21]. The tube is 0.1 m long, has an inner radius of 0.01 m and an outer radius of 0.011 m. The structure is described with a Neo-Hookean material law with Young's modulus $E = 10^5$ Pa, Poisson's ratio $\nu = 0.3$ and a density of $\rho^S = 1,200 \text{ kg/m}^3$. The Newtonian fluid inside the tube has a dynamic viscosity of $\mu = 0.003 \text{ Pa s}$ and a density of $\rho^F = 1,000 \text{ kg/m}^3$. The inflow surface is loaded with a surface traction of 1,000 Pa for 0.003 s. For the computation a timestep size of $\Delta t = 1.0 \times 10^{-4} \text{ s}$ is used and 250 timesteps are performed. The fluid is discretized with stabilized hexahedral finite elements, the structure with hexahedral solid shell elements proposed in [22].

We concentrate on four fluid discretizations denoted by A , B , C and D with different mesh sizes, which range from 2,080 to 130,560 elements. For all fluid mesh sizes corresponding conforming and non-conforming structure discretizations are considered. In the non-conforming versions the structure mesh is rotated such that the meshes overlap in circumferential direction by approximately a third of an element length, see Fig. 2(a). Furthermore, it contains two elements less than the fluid discretization across the length of the tube. The coarsest non-conforming model can be seen in Fig. 2.

Computations are performed in parallel on up to 12 processors. In order to study efficiency and scalability of the proposed approach, we distinguish not only between conforming and non-conforming (NC), but consider two solution methods for the conforming case: with mortar

Figure 2: Coarse, non-conforming mesh A for pressure wave example.

Table 1: Characteristics for the numerical solver averaged over timestep and number of processors used.

	Mesh	n_{dof}	n_{pr}	Newton	GMRES	time
A	(C)	19,413	4	2.97	29.2	4.44
A	(CM)	19,413	4	2.97	29.2	4.56
A	(NC)	19,221	4	2.97	36.1	6.09
B	(C)	140,291	8	2.98	30.0	22.99
B	(CM)	140,291	8	2.98	30.0	23.59
B	(NC)	139,715	8	2.98	32.8	27.1
C	(C)	377,857	12	2.97	30.9	41.09
C	(CM)	377,857	12	2.97	30.9	41.43
C	(NC)	376,705	12	2.97	37.1	50.68
D	(C)	1,045,553	12	2.78	33.9	99.44
D	(CM)	1,045,553	12	2.78	33.9	101.12
D	(NC)	1,043,663	12	2.78	42.7	121.68

coupling (CM) and with the standard approach (C) presented in [5]. In all cases the AMG(BGS) preconditioner introduced in [5] is employed to solve the linear system (28). The numerical behavior is assessed by the average number of Newton iterations, the average number of GMRES iterations and the average computation time per timestep. These quantities and the total number n_{dof} of degrees of freedom are listed in Tab. 1.

As could be expected the number of Newton iterations and linear iterations of the GMRES algorithm for the two conforming meshes coincide. The mortar approach and the corresponding explicit matrix-matrix products, which are needed to eliminate the discrete Lagrange multipliers and to set up the condensed system matrices, affect the numerical costs only very slightly. The average time spent for a timestep increases by less than 2% in all cases considered, which indicates the numerical efficiency of the proposed approach. Having to deal with non-conforming meshes (rows marked with 'NC' in Tab. 1) leads to an increase in computation time of approximately 25% for this example. This is completely due to linear systems of equations that are apparently harder to solve, which becomes obvious by comparing the average number of GMRES steps and Newton steps. The relative increase of iteration steps needed in the GMRES corresponds exactly to the relative increase in computation time, whereas the number of Newton iterations is unchanged. While this increase can not be neglected, it is however important to point out that the preconditioners have not been optimized for the non-conforming case but are simply carried over from the conforming case. The computational cost associated with the evaluation of dual mortar coupling itself is virtually zero. This is above all due to the fact that the mortar integrals (i.e. matrices \mathbf{D} and \mathbf{M}) only need to be evaluated once during problem initialization and remain unchanged during all FSI timesteps afterwards.

5 CONCLUSION

A novel mortar-based approach to efficiently simulate fluid-structure interaction phenomena allowing for independent discretization of fluid and structure domains has been presented. Owing to its generality, the proposed FSI framework does not introduce any restriction on the particular choice of finite element formulations neither for fluid, ALE nor structure. Implicit time integration is employed for all three physical fields. Consistent linearization within a Newton-Raphson scheme provides the fundamental building blocks of the monolithic system.

In contrast to available approaches in literature, the proposed formulation is based on a dual

mortar method and handles the additional complexity of non-matching interface meshes at negligible computational cost. The complete four-field monolithic system initially has a saddle point type structure, but is then transformed into a three-field system by condensation of the Lagrange multiplier degrees of freedom. The transformation requires the inversion of one of the coupling matrices, which is trivial due to its diagonal shape. This diagonality is a key feature of the dual mortar approach as opposed to standard mortar coupling schemes. Because of the transformation the application of state-of-the-art iterative solution methods to the resulting system matrices is straightforward.

In particular, block-specific preconditioners tailored for conforming monolithic FSI show excellent performance also in the non-conforming case, which is demonstrated with the well-known pressure wave example. It also shows that computational cost associated with the evaluation of dual mortar coupling itself and with the additional matrix-matrix multiplication necessary in some sub-blocks of the monolithic system is very low.

Keywords: Dynamics of Frames, VE Dampers, Rheological Models, Dynamic Characteristics.

Abstract. *Frame structures with viscoelastic (VE) dampers mounted on them are considered in this paper. Generalized rheological models are used to model the VE dampers. The finite element method is used to derive the equations of motion of a structure with dampers and such equations are written in terms of both physical and state-space variables. A solution to motion equations in the frequency domain is provided and the dynamic properties of the structure with VE dampers are determined as a solution to the appropriately defined eigenvalue problem. The dynamic characteristics of a relatively large structure with VE are determined and discussed.*

1 INTRODUCTION

Viscoelastic (VE) dampers are a passive type of energy dissipation devices, frequently used to mitigate excessive vibrations of structures due to winds or earthquakes. The properties of VE dampers, such as the possibility of energy dissipation and stiffness, are frequency and temperature dependent and are commonly defined in terms of experimentally obtained storage and loss modules. The frequency dependence of the properties of VE dampers can be accurately described by means of rheological models. Both the classical rheological models and the so-called rheological models with the fractional derivative are used [1, 2].

The dynamic analysis of frame or building structures with viscous and/or viscoelastic dampers are presented in a number of papers [3 - 14]. The most popular models of VE dampers are the simple rheological models, i.e., the Kelvin model and the Maxwell model. In papers [6 - 8] the simple Maxwell model was used. Moreover, in papers [7, 9, 13] the simple Kelvin model is used to describe the dynamic behavior of dampers. These simple models are used in [7, 12, 13] to solve the problem of optimum design of structures with VE dampers. However, as shown in [15], the simple Maxwell or Kelvin models cannot accurately approximate the frequency dependence of the storage modulus and the loss modulus of VE dampers. Recently, more advanced models of VE dampers have also been used when considering the dynamic analysis of structures with VE dampers. The dynamics of structures with VE dampers modeled by means of the generalized rheological models is very rarely discussed in the literature. These models are used in papers [4, 16] only. In papers [3, 5, 14] a three-parameter rheological model with the fractional-derivative model is used to model the VE dampers' behavior. Moreover, rational polynomial approximation modeling is used in paper [17] for an analysis of structures with VE dampers.

In this paper, frame structures equipped with VE dampers are considered. The frame is treated as a linear system while the generalized Kelvin model and the generalized Maxwell model are used to accurately describe the dynamic behaviour of VE dampers. The considered generalized models of VE dampers contain more parameters than the rheological models with the fractional derivative but lead to traditional differential equations of motion. The finite element method is adopted to write the equation of motion of the considered system in terms of both physical and state nodal variables. In particular, the solution of motion equation of a whole system in the frequency domain is considered and the dynamic properties of structure with VE dampers are determined. The frequencies of vibration, the non-dimensional damping ratios together with the corresponding eigenvectors are determined as a solution to the appropriately defined linear eigenvalue problem. Moreover, the frequency response functions are also determined. The results of typical calculations are presented and discussed.

Up to now, the dynamic characteristics of structures with VE dampers modeled by means of the generalized rheological models have not been considered or discussed in the available literature. Moreover, it was found that the VE damper model is not unique, i.e., both of the considered models can be used for modeling accurately the real damper for a sufficiently great number of model parameters.

2 THE GENERALIZED RHEOLOGICAL MODELS OF VE DAMPERS

The frequency dependence of the properties of VE dampers can be captured using generalized rheological models. The generalized Kelvin model and the generalized Maxwell model, as shown in Figs. 1 and 2, are used for modeling the VE dampers in this paper. The generalized Kelvin model is built of a spring and a set of the m Kelvin elements connected in series (see Fig.1). The Kelvin element is build of a spring and a dashpot connected in parallel. The

generalized Maxwell model is built of the spring and a set of the m Maxwell elements connected in parallel (see Fig.2). The Maxwell element is the classical Maxwell rheological model, i.e., the spring and dashpot connected in series. As shown in [18], the frequency dependence of the properties of VE dampers can be accurately taken into account using the generalized rheological models.

Figure 1: A schematic of the generalized Kelvin model

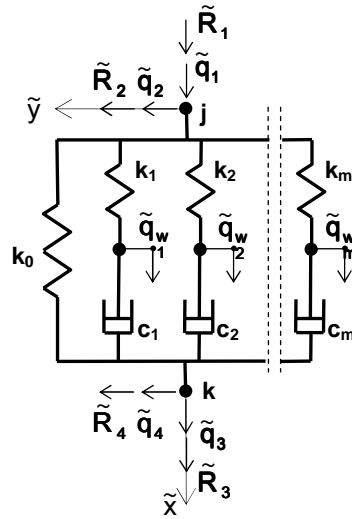

Figure 2: A schematic of the generalized Maxwell model

The concept of superelement and the concept of so-called internal variables have been used in describing both models. The dynamic behavior of the Kelvin damper can be described by means of the following equations:

$$u_0(t) = k_0 (\tilde{q}_{w,1}(t) - \tilde{q}_1(t)) , \quad (1)$$

$$u_i(t) = k_i (\tilde{q}_{w,i+1}(t) - \tilde{q}_{w,i}(t)) + c_i (\dot{\tilde{q}}_{w,i+1}(t) - \dot{\tilde{q}}_{w,i}(t)) , \quad (2)$$

$$u_m(t) = k_m (\tilde{q}_3(t) - \tilde{q}_{w,m}(t)) + c_m (\dot{\tilde{q}}_3(t) - \dot{\tilde{q}}_{w,m}(t)) , \quad (3)$$

where $u_i(t)$ is the force in the i -th element of the model ($i = 0, 1, \dots, m$), k_i and c_i are the spring stiffness and the damping factor of the dashpot of the i -th element of the model, respectively, and symbols $\tilde{q}_1(t)$ and $\tilde{q}_3(t)$ denote the external nodes displacements given in the local coordinate system (compare Fig.1). Moreover, the dot denotes differentiation with respect to time t and the symbol $\tilde{q}_{w,i}(t)$ denotes the internal variable ($i = 1, \dots, m$).

After introducing the vector of external reactions $\tilde{\mathbf{R}}_z(t) = \text{col}(\tilde{R}_1(t), \tilde{R}_2(t), \tilde{R}_3(t), \tilde{R}_4(t))$ (see Figure 1) and utilizing the equilibrium conditions of the external nodes: $\tilde{R}_1(t) = -u_0(t)$, $\tilde{R}_2(t) = 0$, $\tilde{R}_3(t) = u_m(t)$ and $\tilde{R}_4(t) = 0$ we can write the following matrix equation:

$$\tilde{\mathbf{R}}_z(t) = \tilde{\mathbf{K}}_{zz} \tilde{\mathbf{q}}_z(t) + \tilde{\mathbf{K}}_{zw} \tilde{\mathbf{q}}_w(t) + \tilde{\mathbf{C}}_{zz} \dot{\tilde{\mathbf{q}}}_z(t) + \tilde{\mathbf{C}}_{zw} \dot{\tilde{\mathbf{q}}}_w(t) , \quad (4)$$

where $\tilde{\mathbf{q}}_z(t) = \text{col}(\tilde{q}_1(t), \tilde{q}_2(t), \tilde{q}_3(t), \tilde{q}_4(t))$, $\tilde{\mathbf{q}}_w(t) = \text{col}(\tilde{q}_{w,1}(t), \dots, \tilde{q}_{w,m}(t))$. The matrices $\tilde{\mathbf{K}}_{zz}$, $\tilde{\mathbf{K}}_{zw}$, $\tilde{\mathbf{C}}_{zz}$ and $\tilde{\mathbf{C}}_{zw}$ are defined in Appendix A.

Moreover, the equilibrium conditions of the internal nodes, i.e., $u_{i-1}(t) - u_i(t) = 0$ for $i = 1, \dots, m$ lead to the following matrix equation:

$$\tilde{\mathbf{K}}_{wz} \tilde{\mathbf{q}}_z(t) + \tilde{\mathbf{K}}_{ww} \tilde{\mathbf{q}}_w(t) + \tilde{\mathbf{C}}_{wz} \dot{\tilde{\mathbf{q}}}_z(t) + \tilde{\mathbf{C}}_{ww} \dot{\tilde{\mathbf{q}}}_w(t) = \mathbf{0} , \quad (5)$$

where $\tilde{\mathbf{K}}_{wz} = \tilde{\mathbf{K}}_{zw}^T$, $\tilde{\mathbf{C}}_{wz} = \tilde{\mathbf{C}}_{zw}^T$ and the matrices $\tilde{\mathbf{K}}_{ww}$, $\tilde{\mathbf{C}}_{ww}$ are defined in Appendix A.

The equation of motion of the Kelvin model of a VE damper written in the local coordinate system can be finally presented in the form:

$$\tilde{\mathbf{R}}_d(t) = \tilde{\mathbf{K}}_d \tilde{\mathbf{q}}_d(t) + \tilde{\mathbf{C}}_d \dot{\tilde{\mathbf{q}}}_d(t) , \quad (6)$$

where $\tilde{\mathbf{R}}_d(t) = \text{col}(\tilde{\mathbf{R}}_z(t), \mathbf{0})$, $\tilde{\mathbf{q}}_d(t) = \text{col}(\tilde{\mathbf{q}}_z(t), \tilde{\mathbf{q}}_w(t))$,

$$\tilde{\mathbf{K}}_d = \begin{bmatrix} \tilde{\mathbf{K}}_{zz} & \tilde{\mathbf{K}}_{zw} \\ \tilde{\mathbf{K}}_{wz} & \tilde{\mathbf{K}}_{ww} \end{bmatrix} , \quad \tilde{\mathbf{C}}_d = \begin{bmatrix} \tilde{\mathbf{C}}_{zz} & \tilde{\mathbf{C}}_{zw} \\ \tilde{\mathbf{C}}_{wz} & \tilde{\mathbf{C}}_{ww} \end{bmatrix} . \quad (7)$$

Transforming nodal parameters to the global coordinate system, the usual transformation of displacements of the external nodes of the damper is used while the internal variables of the damper are still defined in the local coordinate system. This means that the transformation matrix is:

$$\mathbf{T}_d = \begin{bmatrix} \tilde{\mathbf{T}}_d & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} , \quad (8)$$

where

$$\tilde{\mathbf{T}}_d = \begin{bmatrix} \tilde{\mathbf{T}} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{T}} \end{bmatrix} , \quad \tilde{\mathbf{T}} = \begin{bmatrix} c & s \\ -s & c \end{bmatrix} , \quad (9)$$

$c = \cos \alpha$, $s = \sin \alpha$, α is the angle between the global and local coordinate systems and \mathbf{I} is the $(m \times m)$ identity matrix.

In the global coordinate system the generalized Kelvin model equation has the form:

$$\mathbf{R}_d(t) = \mathbf{K}_d \mathbf{q}_d(t) + \mathbf{C}_d \dot{\mathbf{q}}_d(t) , \quad (10)$$

where

$$\begin{aligned} \mathbf{R}_d(t) &= \text{col}(\mathbf{R}_z(t), \mathbf{0}) = \mathbf{T}_d^T \tilde{\mathbf{R}}_d \mathbf{T}_d , & \mathbf{R}_z(t) &= \text{col}(R_1(t), R_2(t), R_3(t), R_4(t)) , \\ \mathbf{q}_d(t) &= \text{col}(\mathbf{q}_z(t), \mathbf{q}_w(t) = \tilde{\mathbf{q}}_w(t)) = \mathbf{T}_d^T \tilde{\mathbf{q}}_d \mathbf{T}_d , & \mathbf{q}_z(t) &= \text{col}(q_1(t), q_2(t), q_3(t), q_4(t)) , \end{aligned} \quad (11)$$

are the vector of nodal reactions and the vector of nodal parameters, respectively, in the global coordinate system. The explicit forms of matrices \mathbf{K}_d and \mathbf{C}_d are given in Appendix A.

The dynamic behavior of the Maxwell damper could be described in a similar way. Using the internal variables defined in Fig. 2, the following equations can be written:

$$u_0(t) = k_0(\tilde{q}_3(t) - \tilde{q}_1(t)) , \quad (12)$$

$$u_{is}(t) = k_i(\tilde{q}_{w,i}(t) - \tilde{q}_1(t)) , \quad (13)$$

$$u_{id}(t) = c_i(\dot{\tilde{q}}_3(t) - \dot{\tilde{q}}_{w,i}(t)) , \quad (14)$$

for the spring element and for the i -th Maxwell element ($i = 1, \dots, m$), respectively. The symbols $u_0(t)$, $u_{is}(t)$ and $u_{id}(t)$ in the above relationships denote the force in the spring element, the force in the spring of the i -th Maxwell element, and the force in the dashpot of the i -th Maxwell element, respectively.

The nodal reactions in the local coordinate system are:

$$\tilde{R}_1(t) = -u_0(t) - \sum_{i=1}^m u_{is}(t) , \quad \tilde{R}_2(t) = 0 , \quad \tilde{R}_3(t) = u_0(t) + \sum_{i=1}^m u_{id}(t) , \quad \tilde{R}_4(t) = 0 . \quad (15)$$

After introducing relationships (12) – (14) into Eqns (15) we obtain again Eqn (4) though its matrices are defined in Appendix B. Moreover, in the global coordinate system, Eqn (10) is also valid with the matrices \mathbf{K}_d and \mathbf{C}_d given in Appendix B.

Many particular rheological models described in the literature can be obtained by varying the number of elements in the generalized models mentioned above.

However, the simple Kelvin and Maxwell models, which contain only one Kelvin or Maxwell element, respectively, are not particular instances of the generalized models being discussed because the spring element with stiffness k_0 is not present. For the reader's convenience, a brief description of the above-mentioned simple models is also presented. In the matrix notation the equation of both models could be written in the form of Eqns (6) and (10). The matrices and vectors appearing in these equations are defined in Appendix C.

3 EQUATION OF MOTION AND DYNAMIC CHARACTERISTICS OF STRUCTURES WITH VE DAMPERS

Planar frame structures with VE dampers are modeled using the finite element method. A typical two-node bar element with six nodal parameters is used to describe the structure treated as the elastic system. The mass and stiffness matrices together with the vector of nodal forces of the element can be found in many books. The equation of motion of the structure with VE dampers modeled using the generalized rheological models can be written in the following form:

$$\mathbf{M}_{ss} \ddot{\mathbf{q}}_s(t) + \mathbf{C}_{ss} \dot{\mathbf{q}}_s(t) + \mathbf{C}_{sd} \dot{\mathbf{q}}_d(t) + \mathbf{K}_{ss} \mathbf{q}_s(t) + \mathbf{K}_{sd} \mathbf{q}_d(t) = \mathbf{p}_s(t) , \quad (16)$$

$$\mathbf{C}_{ds} \dot{\mathbf{q}}_s(t) + \mathbf{C}_{dd} \dot{\mathbf{q}}_d(t) + \mathbf{K}_{ds} \mathbf{q}_s(t) + \mathbf{K}_{dd} \mathbf{q}_d(t) = \mathbf{0} , \quad (17)$$

where the symbols \mathbf{M}_{ss} , \mathbf{C}_{ss} , $\mathbf{C}_{sd} = \mathbf{C}_{ds}^T$, \mathbf{C}_{dd} , \mathbf{K}_{ss} , $\mathbf{K}_{sd} = \mathbf{K}_{ds}^T$ and \mathbf{K}_{dd} denote the mass, damping, and stiffness matrices of the system (i.e., structure with dampers), respectively, written in the global coordinate system. The dimension of matrices \mathbf{M}_{ss} , $\mathbf{C}_{ss} = \mathbf{C}_{ss}^{(s)} + \mathbf{C}_{ss}^{(d)}$

and $\mathbf{K}_{ss} = \mathbf{K}_{ss}^{(s)} + \mathbf{K}_{ss}^{(d)}$ is $(n \times n)$. The matrices \mathbf{M}_{ss} , $\mathbf{C}_{ss}^{(s)}$ and $\mathbf{K}_{ss}^{(s)}$ describe the inertia, damping, and elastic properties of the structure without dampers, while the matrices $\mathbf{C}_{ss}^{(d)}$, $\mathbf{K}_{ss}^{(d)}$ and the $(n \times r)$ matrices $\mathbf{C}_{sd} = \mathbf{C}_{ds}^T$, $\mathbf{K}_{sd} = \mathbf{K}_{ds}^T$ represent the effect of the coupling of dampers with the structure. The $(r \times r)$ matrices \mathbf{C}_{dd} and \mathbf{K}_{dd} describe the damping and stiffness properties of dampers with braces, respectively. Moreover, $\mathbf{q}_s(t)$, $\mathbf{q}_d(t)$ and $\mathbf{p}_s(t)$ are the global vectors of nodal generalized displacements, internal variables and nodal excitation forces, respectively. The concept of proportional damping is used to model the damping properties of the structure, i.e.: $\mathbf{C}_{ss}^{(s)} = \alpha \mathbf{M}_{ss} + \kappa \mathbf{K}_{ss}^{(s)}$ where α and κ are proportionality factors.

The equation of motion written in terms of state variables will also be useful. After introducing the following state vector $\mathbf{x}(t) = \text{col}(\mathbf{q}_s(t), \dot{\mathbf{q}}_s(t), \mathbf{q}_d(t))$ and adding the equation:

$$\mathbf{M}_{ss} \dot{\mathbf{q}}_s(t) - \mathbf{M}_{ss} \dot{\mathbf{q}}_s(t) = \mathbf{0}, \quad (18)$$

to the system of Eqns (16) and (17) the following state equation could be written

$$\mathbf{A} \dot{\mathbf{x}}(t) + \mathbf{B} \mathbf{x}(t) = \mathbf{s}(t), \quad (19)$$

where

$$\mathbf{A} = \begin{bmatrix} \mathbf{C}_{ss} & \mathbf{M}_{ss} & \mathbf{C}_{sd} \\ \mathbf{M}_{ss} & \mathbf{0} & \mathbf{0} \\ \mathbf{C}_{ds} & \mathbf{0} & \mathbf{C}_{dd} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{K}_{ss} & \mathbf{0} & \mathbf{K}_{sd} \\ \mathbf{0} & -\mathbf{M}_{ss} & \mathbf{0} \\ \mathbf{K}_{ds} & \mathbf{0} & \mathbf{K}_{dd} \end{bmatrix}, \quad \mathbf{s}(t) = \begin{bmatrix} \mathbf{p}(t) \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix}. \quad (20)$$

Please note that the matrices \mathbf{A} and \mathbf{B} are symmetrical and the matrix \mathbf{B} is non-singular.

The solution to the homogenous state equation, i.e., when $\mathbf{s}(t) = \mathbf{0}$, is assumed in the form:

$$\mathbf{x}(t) = \mathbf{a} \exp(st). \quad (21)$$

Introducing (21) into the state equation (19) we obtain the following eigenvalue problem:

$$(s\mathbf{A} + \mathbf{B}) \mathbf{a} = \mathbf{0}. \quad (22)$$

The linear eigenvalue problem (22) must be solved to determine the $(2n + r)$ eigenvalues s_i and eigenvectors \mathbf{a}_i . In the case of an undercritically damped structure the $2n$ eigenvalues (eigenvectors) are complex and conjugate numbers (vectors) while the remaining r eigenvalues (eigenvectors) are real numbers (vectors).

The dynamic behavior of a frame with VE dampers is characterized by the natural frequencies ω_i and the non-dimensional damping parameters γ_i . The above-mentioned quantities are defined as:

$$\omega_i^2 = \mu_i^2 + \eta_i^2, \quad \gamma_i = -\mu_i / \omega_i, \quad (23)$$

where $\mu_i = \text{Re}(s_i)$, $\eta_i = \text{Im}(s_i)$. The formulae (23) refer to complex eigenvalues only.

The third dynamic characteristic of the considered system are the frequency response functions. Before determination of these functions it is useful to rewrite equations of motion (16) and (17) in the form of the following one matrix equation:

$$\mathbf{M} \ddot{\mathbf{q}}(t) + \mathbf{C} \dot{\mathbf{q}}(t) + \mathbf{K} \mathbf{q}(t) = \bar{\mathbf{p}}(t), \quad (24)$$

where

$$\mathbf{M} = \begin{bmatrix} \mathbf{M}_{ss} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} \mathbf{C}_{ss} & \mathbf{C}_{sd} \\ \mathbf{C}_{ds} & \mathbf{C}_{dd} \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} \mathbf{K}_{ss} & \mathbf{K}_{sd} \\ \mathbf{K}_{ds} & \mathbf{K}_{dd} \end{bmatrix}, \quad \mathbf{q}(t) = \begin{Bmatrix} \mathbf{q}_s(t) \\ \mathbf{q}_d(t) \end{Bmatrix}, \quad \bar{\mathbf{p}}(t) = \begin{Bmatrix} \mathbf{p}(t) \\ \mathbf{0} \end{Bmatrix}. \quad (25)$$

To determine the frequency response functions the steady state harmonic responses of the system are considered. If the excitation forces vary harmonically in time, i.e., when

$$\bar{\mathbf{p}}(t) = \bar{\mathbf{P}} \exp(i\lambda t), \quad (26)$$

then the steady state response of the system under consideration can be described by:

$$\mathbf{q}(t) = \mathbf{Q} \exp(i\lambda t), \quad (27)$$

where $i = \sqrt{-1}$ is an imaginary unit.

After substituting Eqns (26) and (26) into Eqn (24) the following standard formula describes the matrix of the frequency response functions:

$$\mathbf{H}(\lambda) = (-\lambda^2 \mathbf{M} + i\lambda \mathbf{C} + \mathbf{K})^{-1}. \quad (28)$$

If the structure with dampers modeled by the simple Maxwell model is considered, then all of the relationships presented above in this section are valid provided that the matrices given in Appendix C are used to generate the global matrices appearing in Eqns (16) and (17).

The vector of internal variables $\mathbf{q}_d(t)$ does not exist in the case of a structure with dampers modeled by the simple Kelvin model, and the motion equation (16) takes the form:

$$\mathbf{M}_{ss} \ddot{\mathbf{q}}_s(t) + (\mathbf{C}_{ss} + \mathbf{C}_{dd}) \dot{\mathbf{q}}_s(t) + (\mathbf{K}_{ss} + \mathbf{K}_{dd}) \mathbf{q}_s(t) = \mathbf{p}_s(t). \quad (29)$$

The matrices \mathbf{C}_{dd} and \mathbf{K}_{dd} appearing in (29) are built from the matrices \mathbf{C}_d and \mathbf{K}_d , respectively, given by formulae (C.4).

The state equation has the form of Equation (19) where, now

$$\mathbf{x}(t) = \begin{Bmatrix} \mathbf{q}_s(t) \\ \dot{\mathbf{q}}_s(t) \end{Bmatrix}, \quad \mathbf{A} = \begin{bmatrix} \mathbf{C}_{ss} + \mathbf{C}_{dd} & \mathbf{M}_{ss} \\ \mathbf{M}_{ss} & \mathbf{0} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{K}_{ss} + \mathbf{K}_{dd} & \mathbf{0} \\ \mathbf{0} & -\mathbf{M}_{ss} \end{bmatrix}, \quad \mathbf{s}(t) = \begin{Bmatrix} \mathbf{p}(t) \\ \mathbf{0} \end{Bmatrix}. \quad (30)$$

Moreover, the matrix of frequency response functions must be defined as

$$\mathbf{H}(\lambda) = \left[-\lambda^2 \mathbf{M}_{ss} + i\lambda(\mathbf{C}_{ss} + \mathbf{C}_{dd}) + \mathbf{K}_{ss} + \mathbf{K}_{dd} \right]^{-1}. \quad (31)$$

4 RESULTS OF TYPICAL CALCULATIONS

4.1 Description of a representative structure and VE dampers

An eight-storey RC frame with three-bays is selected to determine the dynamic characteristics of a structure with dampers. The frame is designed according to the EC8 Part 1 for class B soils. The height of the columns is 3.0 m, the span of the beams is 5.0 m and Young's modulus for concrete is 31.0 GPa. The dimensions of the cross-section of the structural elements are presented in Table 1 while the unit masses of the frame elements are given in Table 2.

Table 3 shows the natural frequencies of vibration of the frame without dampers. The dynamic properties of the structure are obtained by way of a two-dimensional analysis of the frame. Any axial deformations and internal damping of the structure are neglected.

The dampers are attached in the middle bay on all floors of the structure. The dampers are modeled using the following rheological models: i) the simple Kelvin model; ii) the simple

Maxwell model; iii) the generalized Kelvin model with seven parameters, and iv) the generalized Maxwell model also with seven parameters.

Storey level	Lateral column [cm]	Central column [cm]	Beams [cm]
7, 8	35×35	40×40	30×40
5, 6	40×40	45×45	30×45
3, 4	45×45	53×53	30×50
1, 2	50×50	60×60	30×50

Table 1: Dimensions of eight-storey frame elements

Storey level	Unit lateral column mass [kg/m]	Unit central column mass [kg/m]	Unit beam mass [kg/m]
7, 8	306.2	400.0	15000.0
5, 6	400.0	506.2	15000.0
3, 4	506.2	702.2	15000.0
1, 2	625.0	900.0	15000.0

Table 2: Unit mass of eight-storey frame elements

Natural frequencies [rad/sec]			
3.1311	8.6582	15.4268	23.7804
31.2647	40.1148	42.1251	51.1550
52.3598	57.6067	65.6532	69.9862

Table 3: Natural frequencies of frame without dampers

Data from the real experiment are not adopted in this paper. Instead, the storage and loss modulus of dampers are calculated from the formulae:

$$K'(\lambda) = k + c\lambda^\alpha \cos(\alpha\pi/2), \quad K''(\lambda) = c\lambda^\alpha \sin(\alpha\pi/2), \quad (32)$$

which are the analytical formulae of the fractional-derivative Kelvin model of dampers. The chosen parameters of the fractional-derivative Kelvin model are: $\alpha = 0.63$, $k = 0.4 \times 10^6 \text{ N/m}$ and $c = 3.6 \times 10^6 \text{ N sec}^\alpha/\text{m}$. The value of the parameter α is similar to the one used in papers [1, 4], but the original values of k and c are divided by 2.0.

In paper [1] the parameters of generalized models are obtained by minimizing the mean square norm of the differences between the targeted modules and the analytical modules of the considered model. The parameters of the generalized Kelvin model and the generalized Maxwell model, both with seven parameters and used in this paper, are given in Table 4.

Stiffness ($\times 10^6$) [N/m]			Damping factor ($\times 10^6$) [N sec/m]		
	Kelvin model	Maxwell model		Kelvin model	Maxwell model
k_0	57.650	0.1065		–	–
k_1	18.350	33.385	c_1	2.729	1.478
k_2	6.160	3.310	c_2	6.190	1.732
k_3	0.5545	1.443	c_3	8.675	8.305

Table 4: Parameters of generalized Kelvin and Maxwell models

The energy dissipated by the damper was calculated assuming that the amplitude of a harmonically varying vibration of the damper is equal to 0.01 m in all of the considered cases. From this calculation, it can be concluded that the loss modulus and dissipation energy of the fractional-derivative Kelvin model and both generalized models are approximately equal in the range $0 - 15.0 \text{ rad/sec}$ of excitation frequency. This range of frequency covers the range of the first three natural frequencies of vibration of the structure considered.

The values of the parameters of the simple Kelvin model are: $k = 0.74637 \times 10^7 \text{ N/m}$, $c = 0.134420 \times 10^7 \text{ N sec/m}$ and the values of the parameters of the simple Maxwell model are: $k = 1.90392 \times 10^7 \text{ N/m}$ and $c = 0.338669 \times 10^7 \text{ N sec/m}$. These parameters are calculated by minimizing the mean square norm of difference between the target modules, given by (32), and the analytical modules of the respective model. However, the dissipation energy of simple models and the dissipation energy of the fractional-derivative model are not equal and, as expected, the differences are significant, especially for the simple Maxwell model.

Chevron braces are used to connect the dampers with the structure. The braces are made of HEB 200 stainless steel profiles of which the parameters are: $EA = 1.60105 \times 10^9 \text{ N}$ and $EJ = 1.1685 \times 10^7 \text{ Nm}^2$.

4.2 Comparison of dynamic characteristics of considered frame

Results of the solution to the eigenvalue problems are presented in Tables 5 – 10. The real and the complex conjugate numbers are obtained as eigenvalues. In Table 5 the values of the

first three complex conjugate eigenvalues are given for all of the considered models (the two parameter model denotes the simple Kelvin or Maxwell model).

Table 6: Real eigenvalues of frame with dampers

Given in Tables 6 and 7 are all real eigenvalues obtained for all of the models considered. The real eigenvalues for both of the generalized models could be divided into three groups, each with eight elements. The values of elements in one group are of the same order as the

eigenvalues of the eigenproblem obtained for one separate damper. For the generalized Kelvin model of damper with seven parameters the above-mentioned problem has the following form:

$$\left(\begin{bmatrix} k_0 + k_1 & -k_1 & 0 \\ -k_1 & k_1 + k_2 & -k_2 \\ 0 & -k_2 & k_2 + k_3 \end{bmatrix} + s \begin{bmatrix} c_1 & -c_1 & 0 \\ -c_1 & c_1 + c_2 & -c_2 \\ 0 & -c_2 & c_2 + c_3 \end{bmatrix} \right) \begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix}, \quad (33)$$

from which we obtain: $s_1 = -0.3975 \text{ sec}^{-1}$, $s_2 = -3.0518 \text{ sec}^{-1}$ and $s_3 = -41.418 \text{ sec}^{-1}$. In the case of the generalized Maxwell model the equations of the above-mentioned eigenproblem are uncoupled and the real eigenvalues are approximately equal to the inverse of the relaxation time of the Maxwell element (with a minus sign), i.e., in the case under consideration, $s_1 = -k_1 / c_1 = -22.588 \text{ sec}^{-1}$, $s_2 = -1.911 \text{ sec}^{-1}$ and $s_3 = -0.1738 \text{ sec}^{-1}$. A similar remark is true for the real eigenvalues of the frame with dampers modeled using the simple Kelvin model and presented in Table 7.

The reason why real eigenvalues exist for the frame with dampers modeled by the simple Kelvin model, given in Table 8, is completely different. The loss factor of the simple Kelvin model is a linear function of excitation frequency. This means that higher modes of vibration are more strongly damped, compared with lower ones, and could be overdamped, which happens in the case under consideration where eight modes of vibration are overcritically damped. In other cases, all modes are undercritically damped. It is a qualitative difference, compared with other damper models.

Table 8: Real eigenvalues for frame with dampers modeled by the simple Kelvin model

The first three natural frequencies of the frame with dampers modeled using different models are presented in Table 9. As is easily verified, the damper model does not significantly change the first three natural frequencies of the frame. The maximal difference is 6.1%. However, as is obvious from Table 10, the influence of the damper model on the non-dimensional damping ratios is substantial because the maximal difference is of the order of 80%.

Natural frequency	Kelvin model of damper with		Maxwell model of damper with

Table 10: Non-dimensional damping ratios of frame with dampers

A comparison of the first and second modes of vibration is shown in Figures 3. The dashed lines represent the shape of vibration of frame without dampers while the real and imaginary parts of eigenvector for the frame with dampers are shown by the solid line and the solid line with crosses, respectively. Moreover, the imaginary part of eigenvectors is multiplied by 10 in order to show this quantity in detail. The calculation is done for dampers modeled using the Kelvin model with seven parameters. It is easy to observe that the real part of both eigenvectors is very similar to the respective mode of vibration of the frame without dampers.

The frequency response functions are also calculated and one example is shown in Figures 4 where the frequency response function corresponding to the horizontal displacement of the eighth storey is shown. The frequency response curve for the frame with dampers modeled using the generalized Kelvin model (the solid line) and the simple Kelvin model (the dashed line) is shown.

Figure 3: A comparison of modes of vibration for a frame without dampers (the dashed lines) with the real part of eigenvector for frame with dampers modeled by the generalized Kelvin model (the solid line). The imaginary part of the eigenvector is multiplied by 10 and shown by the solid line with crosses

Figure 4: Frequency response function of frame with dampers modeled by the generalized Kelvin model (the solid line) and by the simple Kelvin model (the dashed line)

5 CONCLUSIONS

Several models of dampers are used in this paper to describe the dynamic behaviour of frame structures with VE dampers. A family of generalized rheological models, including the very often used simple Kelvin and Maxwell models, are compared in detail. The comparison is made in the frequency domain for a carefully selected frame structure with VE dampers. The finite element method is used to derive equations of motion.

Several conclusions can be formulated on the basis of the results of numerical analysis presented above. The most important ones are listed below.

- Different models are able to correctly describe the dynamic behaviour of VE dampers. The seven-parameter Kelvin model and the seven-parameter Maxwell model provide almost identical results. This conclusion is in agreement with the results presented by Singh and Chang [4] where the generalized Kelvin and Maxwell models are used as models of VE dampers.
- The simple Kelvin and the simple Maxwell models are not able to correctly describe, in the frequency domain, the dynamic behavior of frames with VE dampers. In particular, relative differences concerning the non-dimensional damping ratios are large.
- The linear eigenvalue problems must be solved in order to determine the dynamic characteristics of the frame with VE dampers. The solution procedure for this problem is much simpler than the solution procedure for the nonlinear eigenvalue problem obtained when the fractional-derivative Kelvin model or the complex modulus model are used as the VE damper model.
- There are some qualitative differences between the results obtained. For the frame with a fixed number of VE dampers the total number of eigenvalues and eigenvectors depends on the selected model of dampers and the number of parameters of the models. Both the real and complex eigenvalues are obtained. The number of real eigenvalues depends on dampers model.

THE ROCKING RESPONSE OF SEISMICALLY ISOLATED, FREE-STANDING RIGID BLOCKS.

Abstract. This paper examines the rocking response and stability of rigid blocks standing free on an isolated base supported on linear viscoelastic bearings and bearings that exhibit bilinear behavior. The investigation concludes that seismic isolation is beneficial only for small blocks. This happens because while seismic isolation increases the “static” value of the minimum overturning acceleration, this acceleration value remains nearly constant as we move towards larger blocks or higher frequency pulses; therefore seismic isolation removes drastically from the dynamics of rocking blocks the beneficial property of increasing stability as their size increases or as the excitation pulse period decreases. This remarkable result suggests that freestanding ancient classical columns exhibit superior stability as they are built (standing free on a rigid foundation) rather than if they were seismically isolated even with isolation systems with very long isolation periods. The study further confirms this finding by examining the seismic response of the columns from the peristyle of two ancient Greek temples when subjected to historic records.

1 INTRODUCTION

Under base shaking slender objects and tall rigid structures may enter into rocking motion that occasionally results in overturning. Early studies on the rocking response of a rigid block supported on a base undergoing horizontal accelerated motion were presented by Housner (1963) [1]. His pioneering work uncovered a size-frequency scale effect which explained why: (a) the larger of two geometrically similar blocks can survive the excitation that will topple the smaller block; and (b) out of two same acceleration-amplitude pulses the one with the longer duration is more capable to induce overturning.

As the size of the block increases, the duration of the coherent pulse of the base motion plays a dominant role in inducing overturning. For instance, Figure 1, plots the rocking response of a rigid block that is 2.0m tall and 0.5m wide when subjected to an intense ($a_p=0.5g$) but short duration ($T_p=0.5s$) one-sine acceleration pulse (left–no overturning) and a less intense ($a_p=0.29g$), yet longer duration pulse ($T_p=2s$) one sine acceleration pulse (right – overturning). Interestingly, this 2.0m×0.5m rigid block survives the intense, short duration pulse; yet overturns when subjected to the lower acceleration amplitude, long-duration pulse. The above example shows that reducing the base acceleration while lengthening the period of the excitation (what seismic isolation does) is not a beneficial approach for all combinations of block size and frequency content of the base excitation.

The rocking response of slender rigid objects standing free on a seismically isolated base is a subject that has received attention during the last two decades mainly from the need to protect slender art objects within museums (Augusti et al. 1992 [2], Vestroni and Di Cinto 2000 [3], Calio and Marletta 2003 [4], Roussis et al. 2008 [5], Contento and Egidio 2009 [6]

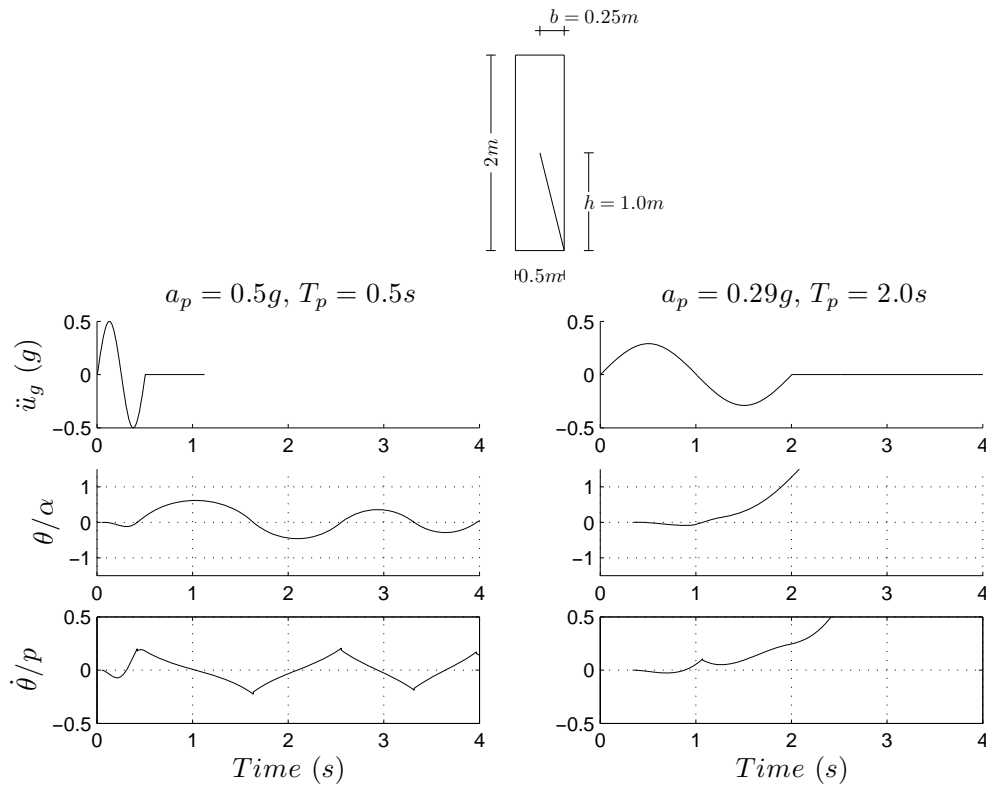

Figure 1. Horizontal ground acceleration, block rotation and angular velocity time histories of the block shown above ($p=2.67\text{rad/s}$, $\tan(\alpha)=0.25$) subjected to a one-sine pulse. Left: $a_p=0.50g$, $T_p=0.5s$ – no overturning, Right $a_p=0.29g<0.5g$ and $T_p=2.0s>0.5s$ – overturning.

among others). These studies primarily focused on the seismic protection of relative small size blocks such as art objects up to human-size statues and they invariably concluded that seismic isolation suppresses the rocking response and protects such objects from overturning. Given, however, the results of Figure 1, this paper investigates in depth up to what size of free standing objects the application of seismic isolation is beneficial and concludes that larger free-standing structures like ancient columns of temples have superior stability as they stand free atop their massive foundations compare to if they were seismic isolated. Furthermore, this study settles the matter of conservation of linear momentum of the entire system (the rocking – translating block and the translating isolated base) during the impact of the rocking block – a matter that has been overlooked by other investigators.

2 REVIEW OF THE ROCKING RESPONSE OF A RIGID BLOCK.

With reference to Figure 2 and assuming that the coefficient of friction is large enough so that there is no sliding, the equation of motion of a rocking block with size $R = \sqrt{h^2 + b^2}$ and slenderness $\alpha = \tan(b/h)$ for rotation around O and O' respectively is (Yim et al. 1980 [7], Makris and Roussos 2000 [8], Zhang and Makris 2001 [9] among others)

$$I_o \ddot{\theta}(t) + mgR \sin[-\alpha - \theta(t)] = -m\ddot{u}_g(t) R \cos[-\alpha - \theta(t)], \quad \theta(t) < 0 \quad (1)$$

$$I_o \ddot{\theta}(t) + mgR \sin[\alpha - \theta(t)] = -m\ddot{u}_g(t) R \cos[\alpha - \theta(t)], \quad \theta(t) > 0. \quad (2)$$

For rectangular blocks, $I_o = (4/3)mR^2$ and the above equations can be expressed in the compact form

$$\ddot{\theta}(t) = -p^2 \left\{ \sin[\alpha \operatorname{sgn}(\theta(t)) - \theta(t)] + \frac{\ddot{u}_g}{g} \cos[\alpha \operatorname{sgn}(\theta(t)) - \theta(t)] \right\}. \quad (3)$$

The oscillation frequency of a rigid block under free vibration is not constant, because it strongly depends on the vibration amplitude (Housner 1963 [1]). Nevertheless, the quantity

Figure 2. Geometric characteristics of the model considered. Left: Rigid block subjected to ground shaking. Right: Rigid block on isolated base.

$p = \sqrt{\frac{3g}{4R}}$ is a measure of the dynamic characteristics of the block. For the 2.0m×0.5m block shown in Figure 1 (say an modern refrigerator), $p = 2.67 \text{ rad/s}$, and for a household brick, $p \approx 8 \text{ rad/s}$.

Figure 3 shows the moment-rotation relationship during the rocking motion of a free-standing block. The system has infinite stiffness until the magnitude of the applied moment reaches the value $mgR\sin\alpha$, and once the block is rocking, its restoring force decreases monotonically, reaching zero when $\theta = \alpha$. During the oscillatory rocking motion, the moment-rotation curve follows this curve without enclosing any area. Energy is lost only during impact, when the angle of rotation reverses. When the angle of rotation reverses, it is assumed that the rotation continues smoothly from points O to O' and that the impact force is concentrated at the new pivot point, O' . With this idealization, the impact force applies no moment around O' , hence the angular momentum around O' is conserved. Conservation of angular momentum about point O' just before the impact and right after the impact gives

$$I_o \dot{\theta}_1 - m\dot{\theta}_1 2bR \sin(\alpha) = I_o \dot{\theta}_2 \quad (4)$$

where $\dot{\theta}_1$ = angular velocity just prior to the impact; and $\dot{\theta}_2$ = angular velocity right after the impact. The ratio of kinetic energy after and before the impact is

$$r = \frac{\dot{\theta}_2^2}{\dot{\theta}_1^2} \quad (5)$$

which means that the angular velocity after the impact is only \sqrt{r} times the velocity before the impact. Substitution of (4) into (5) gives

$$r = [1 - \frac{3}{2} \sin^2 \alpha]^2 \quad (6)$$

The value of the coefficient of restitution given by (6) is the maximum value of r under which a block with slenderness α will undergo rocking motion. Consequently, to observe rocking motion, the impact has to be inelastic. The less slender a block (larger α), the more plastic is the impact, and for the value of $\alpha = \sin^{-1} \sqrt{2/3} = 54.73^\circ$, the impact is perfectly plastic.

Figure 3. Moment rotation diagram of a rocking object

During rocking motion of slender blocks, if additional energy is lost due to the inelastic behavior at the instant of impact, the value of the true coefficient of restitution r will be less than the one computed from equation (6).

3 TIME SCALE AND LENGTH SCALE OF PULSE-LIKE GROUND MOTIONS

The relative simple form, yet destructive potential of near source ground motions has motivated the development of various closed form expressions which approximate their leading kinematic characteristics. The early work of Veletsos et al. [10] was followed by the papers of Hall et al. [11], Heaton et al. [12], Makris [13], Makris and Chang [14], Alavi and Krawinkler [15] and more recently by the paper of Mavroeidis and Papageorgiou [16]. Some of the proposed pulses are physically realizable motions with zero final ground velocity and finite accelerations whereas some other idealizations violate one or both of the above requirements. Physically realizable pulses can adequately describe the impulsive character of near-fault ground motions both qualitatively and quantitatively. The input parameters of the model have an unambiguous physical meaning. The minimum number of parameters is two, which are either the acceleration amplitude, a_p , and duration, T_p , or the velocity amplitude, v_p , and duration, T_p (Makris 1997[13], Makris and Chang 2000[14]). The more sophisticated model of Mavroeidis and Papageorgiou [16] involves 4 parameters, which are the pulse period, the pulse amplitude as well as the phase and number of half cycles, and was found to describe a large set of velocity pulses generated due to forward directivity or permanent translation effect. The pulse period, T_p , of the most energetic pulse of strong ground motions is strongly correlated with the moment magnitude, M_w , of the event. For a given moment magnitude, the duration of pulses produced by strike-slip faults is on average larger than the duration of pulses generated by reverse faults. Assuming that the time scale T_p is independent of the source–station distance, for stations located within ~10km from the causative fault, the pulse period and moment magnitude are related through the following empirical relationship which also satisfies a self-similarity condition [16, 17, 18]:

$$\ln T_p = -2.9 + 0.5M_w \quad (7)$$

Furthermore, seismological data indicate that the amplitude of the velocity pulses recorded within a distance of 7 km from the causative fault varies from 60 to 120 cm/s. This observation is in good agreement with the typical slip velocity value of 90 cm/s frequently considered by seismologists (Brune 1970 [19], Aki 1983[20]).

The current established methodologies for estimating the pulse characteristics of a wide class of records are of unique value since the product, $a_p T_p^2 = L_p$, is a characteristic length scale of the ground excitation and is a measure of the persistence of the most energetic pulse to generate inelastic deformations (Makris and Black 2004 [21]). It is emphasized that the persistence of the pulse is a different characteristic than the strength of the pulse which is measured with the peak pulse acceleration. The reader should recall that among two pulses with different acceleration amplitude (say $a_{p1} > a_{p2}$) and different pulse duration (say $T_{p1} < T_{p2}$), the inelastic deformation does not scale with the peak pulse acceleration (most intense pulse) but with the stronger length scale (larger $a_p T_p^2$ = most persistent pulse), Makris and Black 2004a,b [21],[22], Karavassilis et al. 2010 [23].

The heavy line in Figure 4 (top) which approximates the long-period acceleration pulse of the NS component of the 1992 Erzinkan, Turkey, record is a scaled expression of the second derivative of the Gaussian distribution, $e^{-\frac{t^2}{2}}$, known in the seismology literature as the

symmetric Ricker wavelet (Ricker 1943[24], 1944[25]) and widely referred as the “Mexican Hat” wavelet, Addison 2002[26])

$$\ddot{u}_g(t) = a_p \left(1 - \frac{2\pi^2 t^2}{T_p^2}\right) e^{-\frac{1}{2} \frac{2\pi^2 t^2}{T_p^2}} \quad (8)$$

The value of $T_p = \frac{2\pi}{\omega_p}$, is the period that maximizes the Fourier spectrum of the symmetric Ricker wavelet.

Similarly, the heavy line in Figure 4 (center) which approximates the long-period acceleration pulse of the Pacoima Dam motion recorded during the February 9, 1971 San Fernando, California earthquake is a scaled expression of the third derivative of the Gaussian

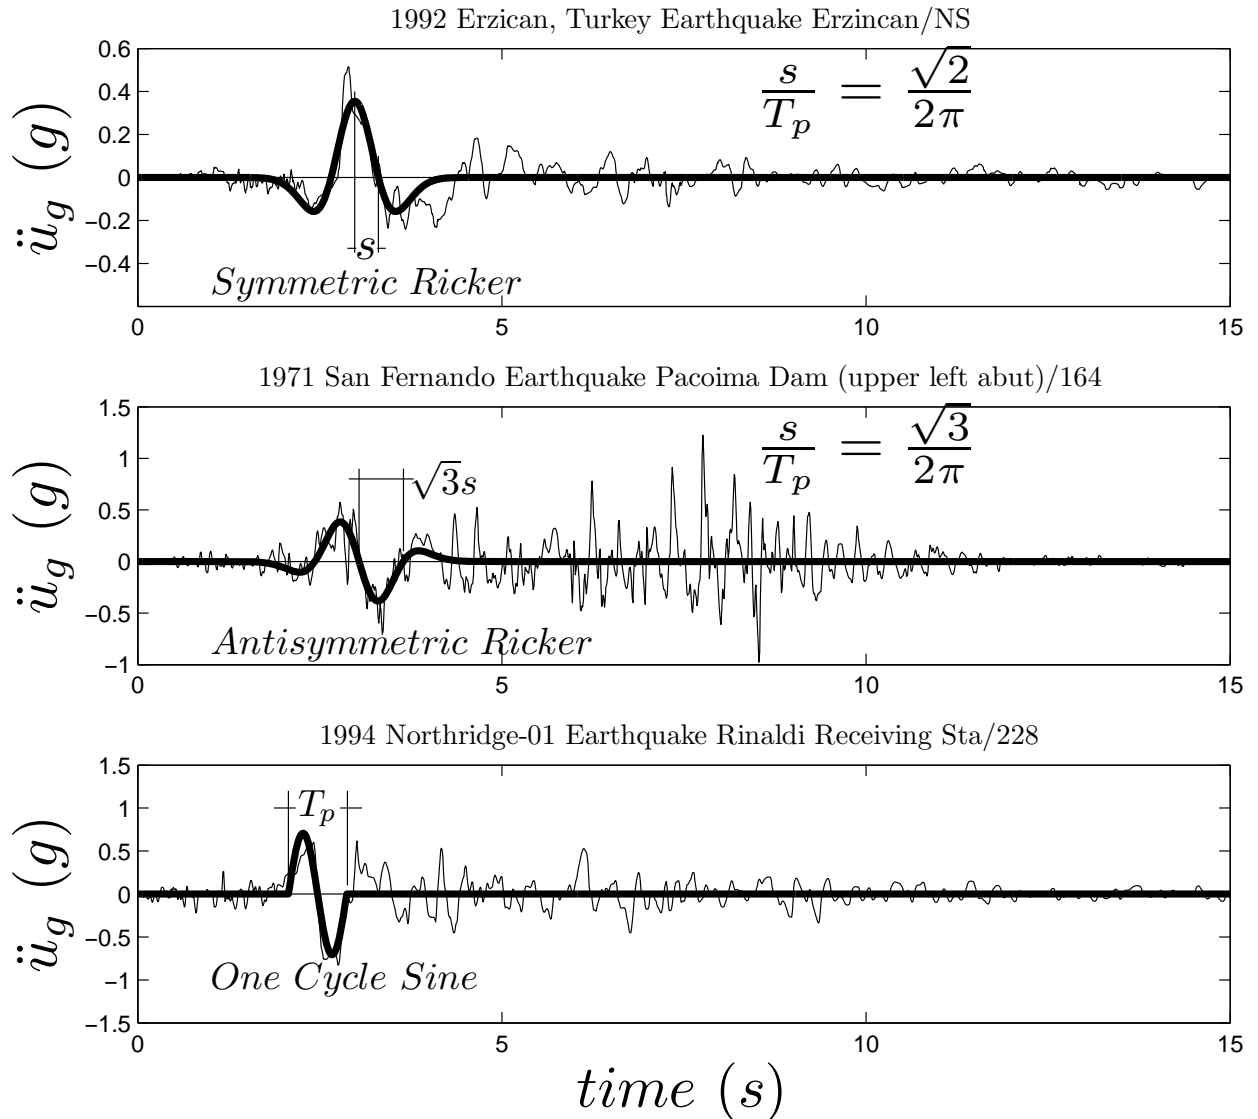

Figure 4. Acceleration time histories recorded during the: (Top) 1992 Erzincan, Turkey earthquake together with a symmetric Ricker wavelet; (Center) 1971 San Fernando earthquake – fault normal component of the Pacoima Dam record together with an antisymmetric Ricker wavelet; and (bottom) 1994 Northridge earthquake – 228 Rinaldi station together with a one cycle sine pulse.

distribution $e^{-\frac{t^2}{2}}$. Again, in equation (18) the value of $T_p = \frac{2\pi}{\omega_p}$ is the period that maximizes the Fourier spectrum of the antisymmetric Ricker wavelet.

$$\ddot{u}_g(t) = \frac{a_p}{\beta} \left(\frac{4\pi^2 t^2}{3T_p^2} - 3 \right) \frac{2\pi t}{\sqrt{3}T_p} e^{-\frac{1}{2} \frac{4\pi^2 t^2}{3T_p^2}} \quad (9)$$

in which β is a factor equal to 1.38 that enforces the above function to have a maximum $-a_p$.

The choice of the specific functional expression to approximate the main pulse of pulse-type ground motions has limited significance in this work. In the past simple trigonometric pulses have been used by the senior author (Makris 1997[13], Makris and Chang 2000[14], Makris and Black 2004[21],[22]) to extract the time scale and length scale of pulse-type ground motions. For instance the heavy line in Figure 4 (bottom) which approximates the strong coherent acceleration pulse of the 228 component at the Rinaldi receiving station of the 1994 Northridge earthquake is a one-sine acceleration pulse

$$\ddot{u}_g(t) = a_p \sin(\omega_p t), \quad 0 < t < T_p \quad (10)$$

A mathematically rigorous and easily reproducible methodology based on wavelet analysis to construct the best matching wavelet on a given record (signal) has been recently proposed by Vassiliou and Makris (2009)[27,28].

5 OVERTURNING SPECTRA – SELF-SIMILAR RESPONSE

Consider a free standing rigid block subjected to an acceleration pulse (like those shown in Figure 4) with acceleration amplitude a_p and pulse duration $T_p = \frac{2\pi}{\omega_p}$. From equation (3) it results that the response of a rocking block subjected to an acceleration pulse is a function of five variables

$$\theta(t) = f(p, \alpha, g, a_p, \omega_p) \quad (11)$$

The six (6) variables appearing in Equation (11), $\theta \doteq []$, $a_p \doteq [L][T]^{-2}$, $\omega_p \doteq [T]^{-1}$, $p \doteq [T]^{-1}$, $\alpha \doteq []$, $g \doteq [L][T]^{-2}$ involve only two reference dimensions; that of length [L] and time [T]. According to Buckingham's Π -theorem the number of dimensionless products with which the problem can be completely described is equal to [number of variables in Eq. (11) = 6] – [number of reference dimensions = 2]. Herein we select as repeating variables the characteristics of the pulse excitation, a_p and ω_p . The four independent Π -terms are

$$\Pi_\theta = \theta \quad (12)$$

$$\Pi_\omega = \frac{\omega_p}{p} \quad (13)$$

$$\Pi_\alpha = \tan(\alpha) \quad (14)$$

$$\Pi_g = \frac{a_p}{g} \quad (15)$$

With the four dimensionless Π -Terms established equation (11) reduces to

$$\theta(t) = \varphi\left(\frac{\omega_p}{p}, \tan \alpha, \frac{a_p}{g}\right) \quad (16)$$

The rocking response of a rigid block when subjected to a horizontal base acceleration, $\ddot{u}_g(t)$, is computed by solving equation (3) in association with the minimum energy loss expressions given by equation (6) which takes place at every impact. The solution of the nonlinear differential equation given by (3) is computed numerically by means of a state-space formulation. The state vector of the system shown in Figure 2 (left) is merely

$$\mathbf{y}(t) = \begin{bmatrix} \theta(t) \\ \dot{\theta}(t) \end{bmatrix} \quad (17)$$

and the time-derivative vector $\mathbf{f}(t) = \dot{\mathbf{y}}(t)$ is

$$\dot{\mathbf{y}}(t) = \begin{bmatrix} \dot{\theta}(t) \\ -p^2[\sin[\alpha \operatorname{sgn}[\theta(t)] - \theta(t)] + \frac{\ddot{u}_g(t)}{g} \cos[\alpha \operatorname{sgn}[\theta(t)] - \theta(t)] \end{bmatrix} \quad (18)$$

The numerical integration of (18) is performed with standard Ordinary Differential Equations (ODE) solvers available in MATLAB (The Mathworks, 1992) [29].

Figure 5 shows the overturning acceleration spectrum of a rigid block with slenderness $\alpha = 14^\circ$ due to a one sine acceleration pulse (left), a symmetric Ricker wavelet (center) and an antisymmetric Ricker wavelet (right). Figure 5 indicates that as $\Pi_\omega = \frac{\omega_p}{p}$ increases the acceleration needed to overturn the object becomes appreciably larger than the one needed to uplift it.

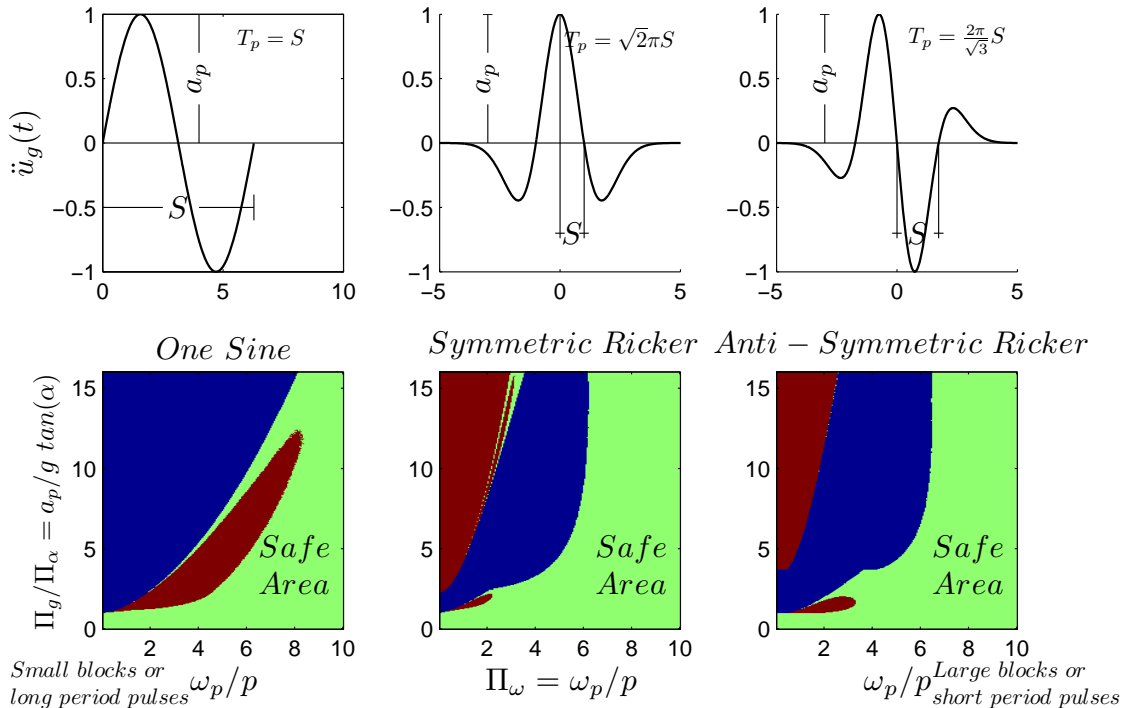

Figure 5 Overturning acceleration spectra of a free standing block with slenderness $\alpha=14^\circ$ subjected to a one-sine acceleration pulse (left); a symmetric Ricker wavelet (center) and an antisymmetric Ricker wavelet (right)

The light grey (green in the colored version) area in all three bottom plots corresponds to stability (no overturning). Note that all three plots show that there are safe areas above the minimum overturning acceleration – a behavior that results from the strong nonlinear nature of the problem. Most importantly is that as the ratio $\Pi_\omega = \omega_p/p$ increases (shorter duration pulses or larger blocks) the minimum overturning acceleration needed to overturn the block increases appreciably.

6 ROCKING RESPONSE OF A RIGID BLOCK STANDING FREE ON A SEISMICALLY ISOLATED BASE

6.1 Linear Viscoelastic Isolation System

We consider a rigid block with mass, m , slenderness α , and frequency parameter p , standing free on a seismically isolated base with mass m_b , horizontal linear stiffness k_b and viscous damping c_b , as shown in Figure 2 (right). The equation of motion can be derived from equation (3) by substituting \ddot{u}_g with $\ddot{u}_g + \ddot{u}$ where u is the displacement of the isolated base relative to the ground. Then equation (3) becomes

$$\ddot{\theta}(t) = -p^2 \left\{ \sin[\alpha \operatorname{sgn}(\theta(t)) - \theta(t)] + \frac{\ddot{u}_g(t) + \ddot{u}(t)}{g} \cos[\alpha \operatorname{sgn}(\theta(t)) - \theta(t)] \right\} \quad (19)$$

Moreover, given that there is no sliding, horizontal force equilibrium of the isolated base below isolators gives

$$-k_b u - c_b \dot{u} = m_b (\ddot{u}_g + \ddot{u}) + m (\ddot{u}_g + \ddot{u} + \ddot{x}) \quad (20)$$

where x is the horizontal, relative to the base translation of the center of mass of the rigid block given by

$$x(t) = \operatorname{sgn}(\theta(t)) R \sin(\alpha) - R \sin(\operatorname{sgn}(\theta(t)) \alpha - \theta(t)) \quad (21)$$

Equations (19) and (20) are expressed in terms of \ddot{u} and $\ddot{\theta}$ which are explicit expressions of the four states of the system, $u(t), \dot{u}(t), \theta(t), \dot{\theta}(t)$ in order to solve the system of equations explicitly. Accordingly,

$$\ddot{u}(t) = \frac{-\omega_b^2 u(t) - 2\zeta \omega_n \dot{u}(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R p^2 \cos A(t) \sin A(t)}{1 - \frac{\gamma R p^2 \cos^2 A(t)}{g}} - \ddot{u}_g(t) \quad (22)$$

$$\ddot{\theta}(t) = -p^2 (\sin A(t) + \cos A(t) \left(\frac{-\omega_n^2 u(t) - 2\zeta \omega_n \dot{u}(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R p^2 \cos A(t) \sin A(t)}{g - \gamma R p^2 \cos^2 A(t)} \right)) \quad (23)$$

where the term $A(t) = \alpha \operatorname{sgn} \theta(t) - \theta(t)$ and $\gamma = \frac{m}{m_b + m}$ and $\omega_b = \sqrt{\frac{k_b}{m_b + m}}$

Again, in this case we assume that when the angle of rotation reverses, the rotation of the block continues smoothly from point O to O' and that the impact force is concentrated as a point force which applies on the new pivot point O'. The subtle difference between a rocking

block impacting a base with finite mass, m_b , and a rocking block impacting a rigid foundation with infinite mass, is that the translational velocity of the isolated base also experiences a finite jump during impact; whereas the translational velocity of the rigid foundation with infinite mass remains the same during impact.

With reference to Figure 6, conservation of angular momentum around point O' gives

$$\int_{block} \mathbf{r} \times (\dot{\mathbf{v}}_1 + \dot{\mathbf{u}}_1) dm = \int_{block} \mathbf{r} \times (\dot{\mathbf{v}}_2 + \dot{\mathbf{u}}_2) dm \quad (24)$$

where $\dot{\mathbf{v}}_1$ and $\dot{\mathbf{v}}_2$ are the velocities (with respect to the isolated base) of a point mass due to rotation before and after the impact and $\dot{\mathbf{u}}_1$ and $\dot{\mathbf{u}}_2$ are the translational velocities of the base (with respect to the ground) before and after the impact. Equation (24) gives

$$(I_o \dot{\theta}_1 - 2mRb \sin \alpha \dot{\theta}_1) \mathbf{e}_y + \int_{block} \mathbf{r} \times \dot{\mathbf{u}}_1 dm = I_o \dot{\theta}_2 \mathbf{e}_y + \int_{block} \mathbf{r} \times \dot{\mathbf{u}}_2 dm \quad (25)$$

or

$$I_o \dot{\theta}_1 - 2mRb \sin \alpha \dot{\theta}_1 + mhu_1 = I_o \dot{\theta}_2 + mhu_2. \quad (26)$$

For a rectangular block $I_o = \frac{4}{3}mR^2$ and the above expression reduces to

$$4R^2 \dot{\theta}_1 - 6Rb \sin \alpha \dot{\theta}_1 + 3h\dot{u}_1 = 4R^2 \dot{\theta}_2 + 3h\dot{u}_2 \quad (27)$$

Equation (27) indicates that because of the finite mass of the isolation base one has to determine the translational velocity of the base \dot{u}_2 after the impact. The extra equation that is needed to relate \dot{u}_1 and \dot{u}_2 is the conservation of the linear momentum of the entire system (the rocking – translating block together with the translating base) along the horizontal direction. Accordingly

Figure 6. Rigid block rocking on an isolated base before (left) and after (right) the impact.

$$(m + m_b)\dot{u}_1 + mh\dot{\theta}_1 = (m + m_b)\dot{u}_2 + mh\dot{\theta}_2 \quad (28)$$

or

$$(\gamma + 1)\dot{u}_1 + \gamma h\dot{\theta}_1 = (\gamma + 1)\dot{u}_2 + \gamma h\dot{\theta}_2 \quad (29)$$

From equations (27) and (29) one obtains

$$\dot{\theta}_2 = \frac{(\gamma + 4)\cot^2 \alpha - 2(\gamma + 1)}{(\gamma + 4)\cot^2 \alpha + 4(\gamma + 1)}\dot{\theta}_1 \quad (30)$$

and

$$\dot{u}_2 = \dot{u}_1 + \frac{6\gamma h}{(\gamma + 4)\cot^2 \alpha + 4(\gamma + 1)}\dot{\theta}_1 \quad (31)$$

Note that in the limiting case of a very heavy base ($m_b \rightarrow \infty$ or $\gamma \rightarrow 0$) equation (30) reduces to equation (6); while $\dot{u}_1 = \dot{u}_2$; therefore the situation of a block rocking on a rigid foundation is recovered. From equation (30) the maximum value of the coefficient of restitution that allows rocking motion of a block rocking on an isolated base is

$$r = \left(\frac{\dot{\theta}_2}{\dot{\theta}_1} \right)^2 = \left(\frac{(\gamma + 4)\cot^2 \alpha - 2(\gamma + 1)}{(\gamma + 4)\cot^2 \alpha + 4(\gamma + 1)} \right)^2. \quad (32)$$

The expression of the coefficient of restitution given by (32) is in agreement with an equivalent expression presented by Roussis et al. [5], which, to our knowledge is the only past publication that treats this problem correctly.

Figure 7 plots the expression given by equation (32) for three values of $\gamma = m/m_b = 0.01, 0.1$ and 1. Figure 7 indicates that when the mass of the base is finite, the rocking block loses additional energy during impact (compared to the same block rocking on a rigid foundation) due to the reason that the translational velocity of the isolated base experiences a finite jump at the instant of the impact.

Figure 7. Coefficient of restitution, r , vs slenderness, α , for different values of $\gamma = m/m_b$.

6.2 Overturning Spectra – Self-Similar Response

We consider again that the ground excitation of the system shown in Figure 2 is characterized by a coherent acceleration pulse with amplitude a_p and pulse duration ($T_p = \frac{2\pi}{\omega_p}$). From equations (22) and (23) it results that the response of a rocking block standing free on an isolated base subjected to an acceleration pulse is a function of eight (8) variables

$$u(t) = f(p, \alpha, g, \omega_b, \zeta, \gamma, \alpha_p, \omega_p) \quad (33)$$

$$\theta(t) = f(p, \alpha, g, \omega_b, \zeta, \gamma, \alpha_p, \omega_p) \quad (34)$$

Each of the coupled Equations (20) and (21) $\theta \doteq []$, $u \doteq [L]$, $a_p \doteq [L][T]^{-2}$, $T_p \doteq [T]$, $T_b \doteq [T]$, $\zeta \doteq []$, $p \doteq [T]^{-1}$, $\alpha \doteq []$, $g \doteq [L][T]^{-2}$, $\gamma \doteq []$ involves only two reference dimensions; that of length $[L]$ and time $[T]$. According to Buckingham's Π -theorem the number of dimensionless products (Π -Terms) = [number of variables in Eq. (20) and (21) = 10] – [number of reference dimensions = 2]; therefore for the 2 DOF system described above, there are $10-2 = 8$ Π -terms

$$\Pi_m = \frac{u_{\max} \omega_p^2}{a_p} \quad (35)$$

$$\Pi_\theta = \theta \quad (36)$$

$$\Pi_\omega = \frac{\omega_b}{\omega_p} \quad (37)$$

$$\Pi_\zeta = \zeta \quad (38)$$

$$\Pi_\gamma = \gamma \quad (39)$$

$$\Pi_p = \frac{\omega_p}{p} \quad (40)$$

$$\Pi_a = \tan(\alpha) \quad (41)$$

$$\Pi_g = \frac{a_p}{g} \quad (42)$$

The rocking response of a rigid block standing free on an isolated base subjected to a horizontal base acceleration is computed by solving equations (21) and (22) in association with the minimum energy loss expression given by equation (32) which takes place at every impact. In this case, the state vector of the system shown in Figure 2 (right) for linear viscoelastic bearings is

$$\mathbf{y}(t) = \begin{bmatrix} u(t) \\ \dot{u}(t) \\ \theta(t) \\ \dot{\theta}(t) \end{bmatrix} \quad (43)$$

and the time derivative vector $\mathbf{f}(t) = \dot{\mathbf{y}}(t)$ is

$$\dot{\mathbf{y}}(t) = \begin{bmatrix} \dot{u}(t) \\ \frac{-\omega_b^2 u(t) - 2\zeta \omega_b \dot{u}(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R \cos A(t) p^2 \sin A(t)}{1 - \gamma R p^2 \cos^2 A(t)} - \ddot{u}_g(t) \\ g \\ \ddot{\theta}(t) \\ -p^2 \left[\sin A(t) + \cos A(t) \left(\frac{-\omega_b^2 u(t) - 2\zeta \omega_b \dot{u}(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R \cos A(t) p^2 \sin A(t)}{g - \gamma R p^2 \cos A(t)} \right) \right] \end{bmatrix} \quad (44)$$

Figure 8 plots the overturning acceleration spectra for a rigid block with slenderness $\alpha=10^\circ$ (top) and $\alpha=20^\circ$ (bottom) when it is standing free on a rigid foundation (left), and when it is isolated (center and right) and subjected to a symmetric Ricker wavelet. The viscous damping ratio of the bearings is $\zeta=5\%$ and the mass ratio is $\gamma=0.01$ (heavy base). Figure 8 indicates that the presence of the isolation base increases the “static” overturning acceleration; however, for isolated rigid blocks this “static” value remains nearly constant as the ratio ω_p / p increases (moving to larger blocks or high frequency pulses). Consequently, the presence of an isolation base removes appreciably from the dynamics of rocking blocks the fundamental property of increasing stability as their size increases or as the excitation pulse-period decreases.

The findings of Figure 8 together with results due to an antisymmetric Ricker excitation are summarized in Figure 9 in terms of minimum acceleration overturning spectra. In all configurations the free-standing block on a rigid base (heavy dark line) beyond a certain value of ω_p/p exhibits superior stability than the same block when isolated. Note also that for both symmetric (left plots) and antisymmetric (right plots) Ricker wavelets, the minimum overturning acceleration of the free standing block on a rigid foundation exceeds the overturning acceleration of the isolated configuration at smaller values of ω_p/p as the slenderness of the block decreases (larger values of α).

The practical use of the results shown in Figure 9 is illustrated by considering the dominant pulses that capture the coherent component of the two earthquake records shown in Figure 10 – that of the fault parallel component of the OTE record from the 1995 Aigio, Greece earthquake (top) and that of the Gilroy – Array #6 record from the 1979 Coyote Lake, USA earthquake (bottom). For the FP OTE record shown in Figure 10 (top), $T_p=0.6s$ while for the Coyote Lake record (bottom), $T_p=0.9s$. The corresponding values of the semidiagonal, R , beyond which non-isolated free standing blocks exhibit more stability than when seismic isolated are offered in Table 1 for two values of slenderness $\alpha=10^\circ$ and $\alpha=20^\circ$ and three values of T_b/T_p 2, 3 and 4.

Table 1 indicates that free-standing objects appreciably smaller than ancient classical columns $R \approx (3.5m - 5.0m)$ are more stable when they stand free on a rigid foundation while seismic isolation would have been detrimental.

The influence of the mass ratio $\gamma = \frac{m}{m + m_b}$ (m = mass of the rocking block, m_b = mass of the isolated base) is shown in Figure 11 for a block with slenderness $\alpha=12^\circ$, two values of $T_b/T_p=2$ and 3 and five values of γ . Figure 11 indicates that for values of $\omega_p/p < 6$ (the range when it makes sense to isolate rocking blocks) all response curves for $\gamma \leq 0.1$ tend to the finite

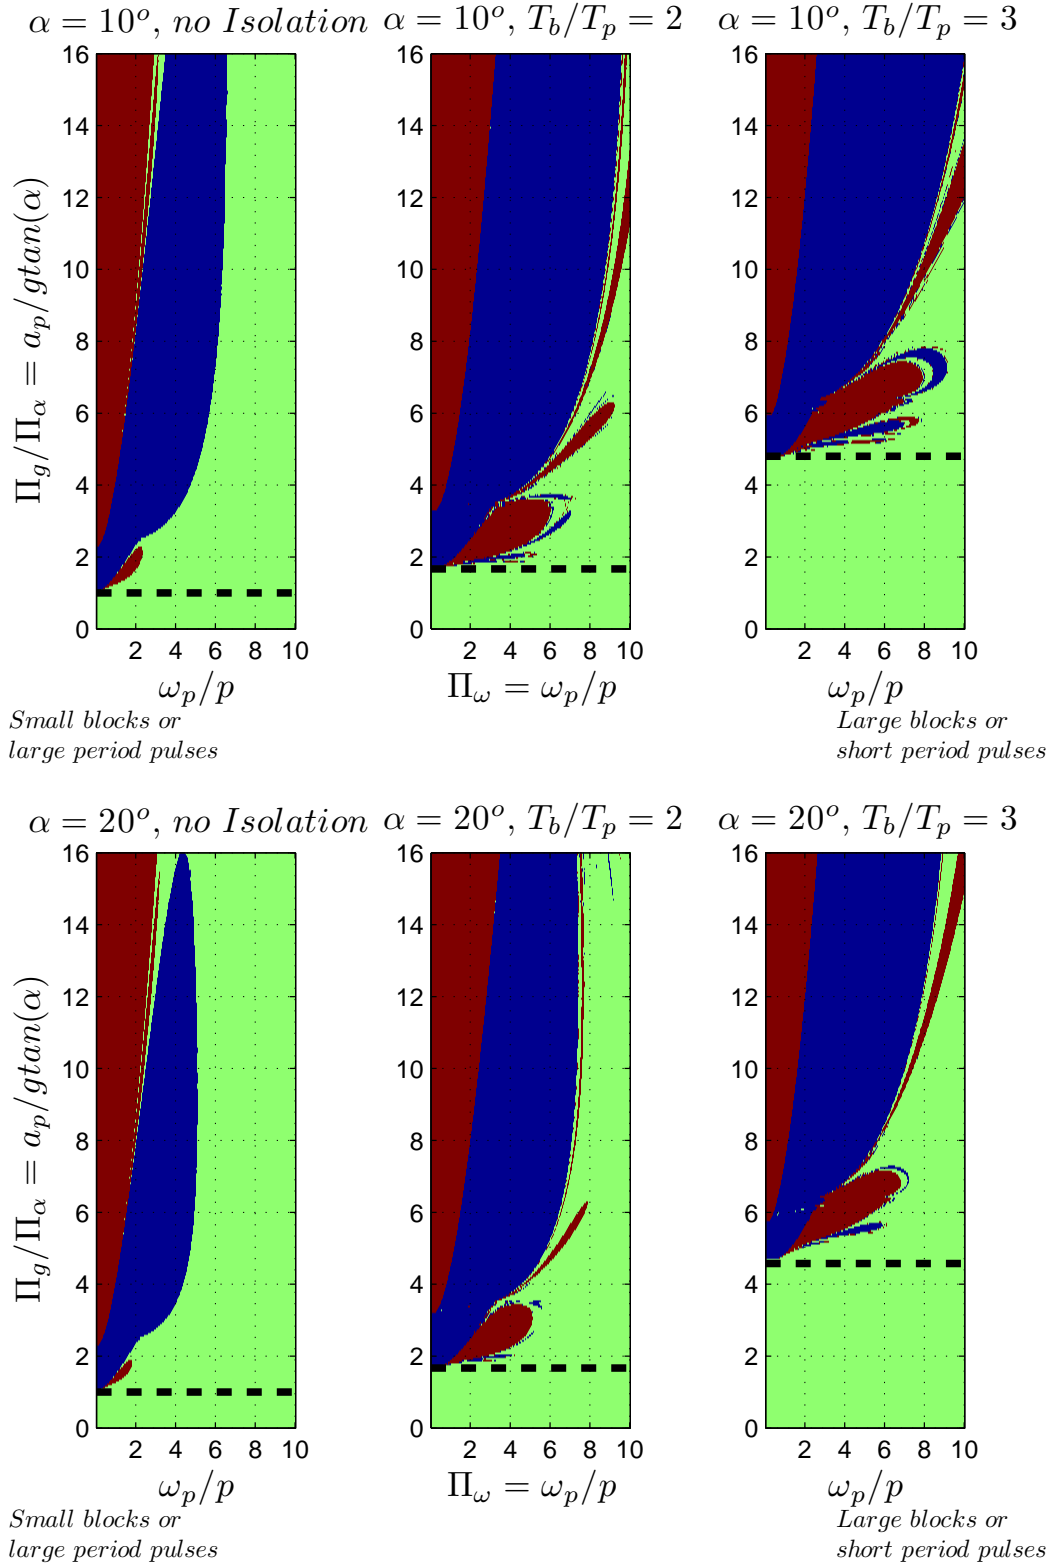

Figure 8. Overturning spectra for rigid block without isolation (left), and with linear isolation with $T_b/T_p=2$ (center) and $T_b/T_p=3$ for slenderness $\alpha=10^\circ$ (top) and $\alpha=20^\circ$ (bottom) for a symmetric Ricker excitation.

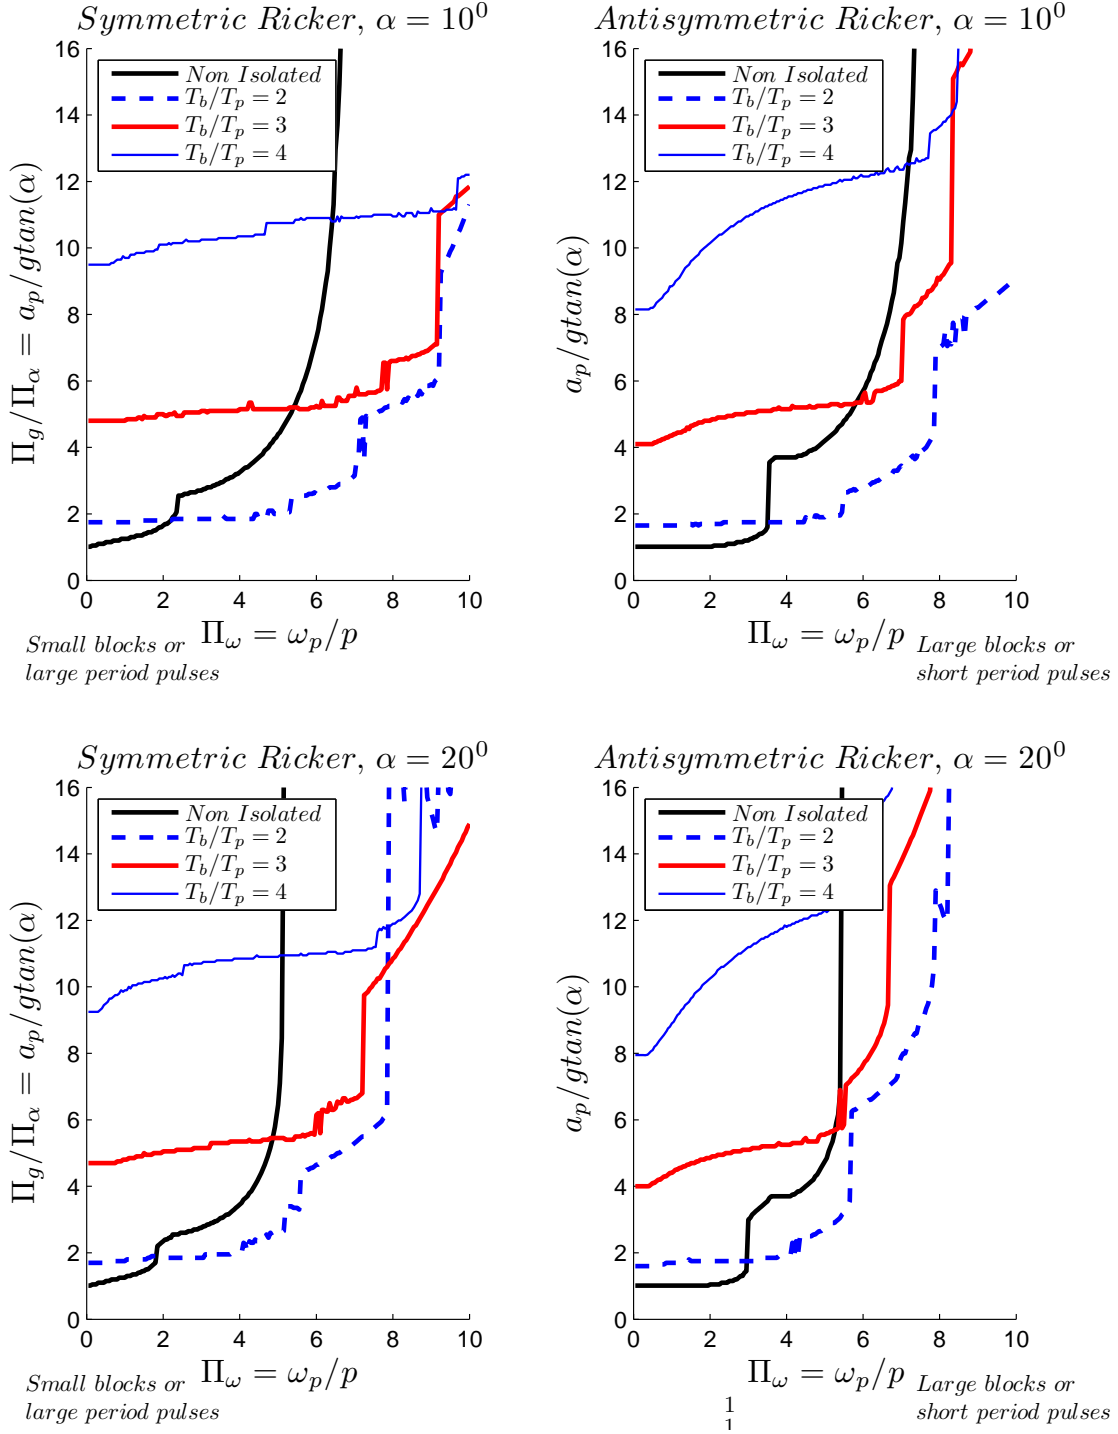

Figure 10. Comparison of the minimum acceleration needed to overturn a rigid block of slenderness $\alpha=10^\circ$ (top) and $\alpha=20^\circ$ (bottom) resting on rigid ground and on an isolated bases with various isolation frequencies when excited by a symmetric Ricker pulse (left) or an antisymmetric Ricker pulse (right).

Table 1. Length of the semidiagonal, R , of rigid blocks beyond which they exhibit superior stability when they stand free on a rigid base (no isolation).

limit where the response of the heavy base is not influenced by the response of the light rocking block (decoupled system). Consequently for the case where $\gamma \leq 0.1$ the mass ratio γ drops out of consideration ($\gamma=0$) and it can be eliminated from equations (33) and (34) – a conclusion that shows that the rocking response of a rigid block standing free on an isolated

base exhibits a “complete similarity” in terms of the mass ratio $\gamma = \frac{m}{m + m_b}$.

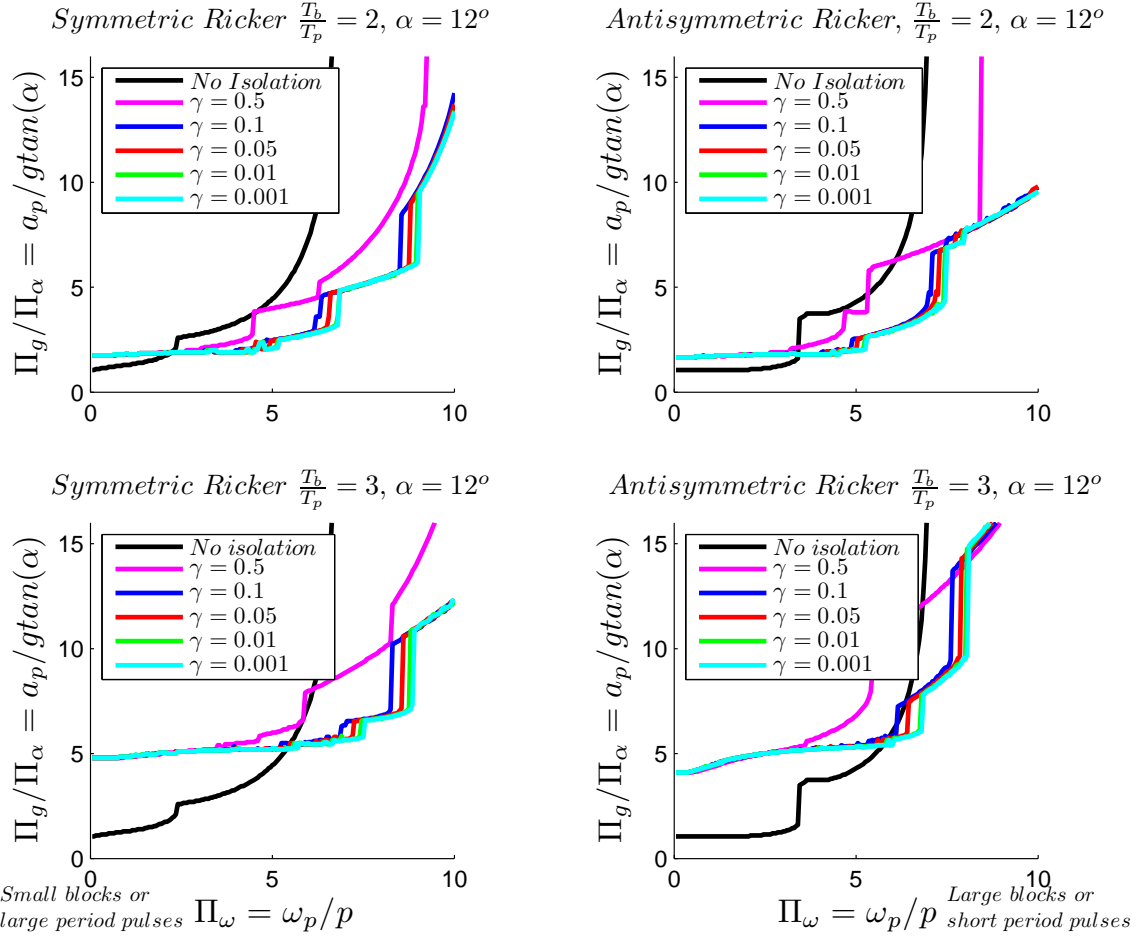

Figure 12 Comparison of the minimum acceleration needed to overturn a rigid block of slenderness $\alpha=12^\circ$ resting on a linear viscoelastic isolated base subjected to a symmetric Ricker wavelet (left) and an antisymmetric

Ricker wavelet (right). Results for five values of mass ratio $\gamma = \frac{m}{m + m_b}$ are used showing that for values of

$\gamma < 0.1$ the overturning acceleration does not depend on the mass ratio $\gamma = \frac{m}{m + m_b}$

6.3 Bilinear isolation system

When the behavior of the isolation system is bilinear – a very good idealization for the behavior of spherical sliding bearings and lead rubber bearings, the equation of the rocking block is again given by equation (19) whereas, horizontal equilibrium of the isolated base below isolators gives

$$-k_b u(t) - Q \cdot z(t) = m_b (\ddot{u}_g(t) + \ddot{u}(t)) + m (\ddot{u}_g(t) + \ddot{u}(t) + \ddot{x}(t)) \quad (45)$$

where k_b is the second slope of the bilinear idealization, Q is the strength of the system (force at zero displacement), $x(t)$ is the horizontal relative to the base translation of the center of mass of the rigid block and $z(t)$ is a dimensionless parameter of the Bouc-Wen model given by

$$\dot{z}(t) = \frac{1}{u_y} \left(\dot{u}(t) - \gamma |\dot{u}(t)| z(t) |z(t)|^{n-1} - \beta \dot{u}(t) |z(t)|^n \right), \quad (46)$$

where u_y is the yield displacement of the bilinear behavior.

In this paper our study concentrates in the case where u_y is very small ($u_y \approx 0.25\text{mm}$). In this case the bilinear model is the mathematical description of the spherical sliding bearing with coefficient of friction μ , in which case the strength $Q = \mu(m + m_b)g$. Recent studies (Makris and Chang [14], Makris and Vassiliou [30]), have demonstrated that the response of isolated structures is merely indifferent to the exact value of the yield displacement, therefore the results obtained in this paper are also valid for isolation systems that use lead rubber bearings (larger values of u_y) as long as they experience the same second slope and the same strength. Given equations (45) and (46), together with equation (19) the state vector of the system shown in Figure 2 (right) with spherical sliding bearings is:

$$\mathbf{y}(t) = \begin{bmatrix} u(t) \\ \dot{u}(t) \\ z(t) \\ \theta(t) \\ \dot{\theta}(t) \end{bmatrix} \quad (47)$$

$$\dot{\mathbf{y}}(t) = \begin{bmatrix} \dot{u}(t) \\ \frac{-\omega_b^2 u(t) - \mu g z(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R \cos A(t) p^2 \sin A(t)}{1 - \frac{\gamma R p^2 \cos^2 A(t)}{g}} - \ddot{u}_g(t) \\ \frac{1}{u_y} \left(\dot{u}(t) - \gamma |\dot{u}(t)| |z(t)|^{n-1} - \beta \dot{u}(t) |z(t)|^n \right) \\ \dot{\theta}(t) \\ -p^2 \left(\sin A(t) + \cos A(t) \left(\frac{-\omega_b^2 u(t) - \mu g z(t) - \gamma R (\dot{\theta}(t))^2 \sin A(t) + \gamma R \cos A(t) p^2 \sin A(t)}{g - \gamma R p^2 \cos A(t)} \right) \right) \end{bmatrix} \quad (48)$$

In the case where the base is isolated on lead rubber bearings exhibiting a strength Q , the term μg in the 1st and 5th component of the $\dot{\mathbf{y}}(t)$ vector is replaced with $\frac{Q}{m + m_b}$.

Figure 12 plots overturning spectra of a rigid block with slenderness $\alpha = 16^\circ$ standing free on a base that is isolated on single concave spherical sliding bearings with coefficient of friction $\mu = 5\%$ when subjected to a symmetric Ricker wavelet next to the overturning acceleration spectra when the base is isolated on linear viscoelastic bearings with coefficient $\zeta = 5\%$. The response between the two isolation configurations is very similar. For completeness, Figure 12 (bottom) shows the minimum overturning acceleration associated with the two isolation configurations together with the corresponding spectrum of a rigid block rocking on a rigid foundation (heavy dark line). The near-vertical growth of the heavy dark line indicates that regardless how flexible the isolation system is, for values of $\omega_p/p > 6$, the rigid block rocking on a rigid foundation has superior stability. The seismic response of a rigid block standing free on a base that is isolated on double concave spherical sliding bearings is presented in the paper by Vassiliou and Makris [32].

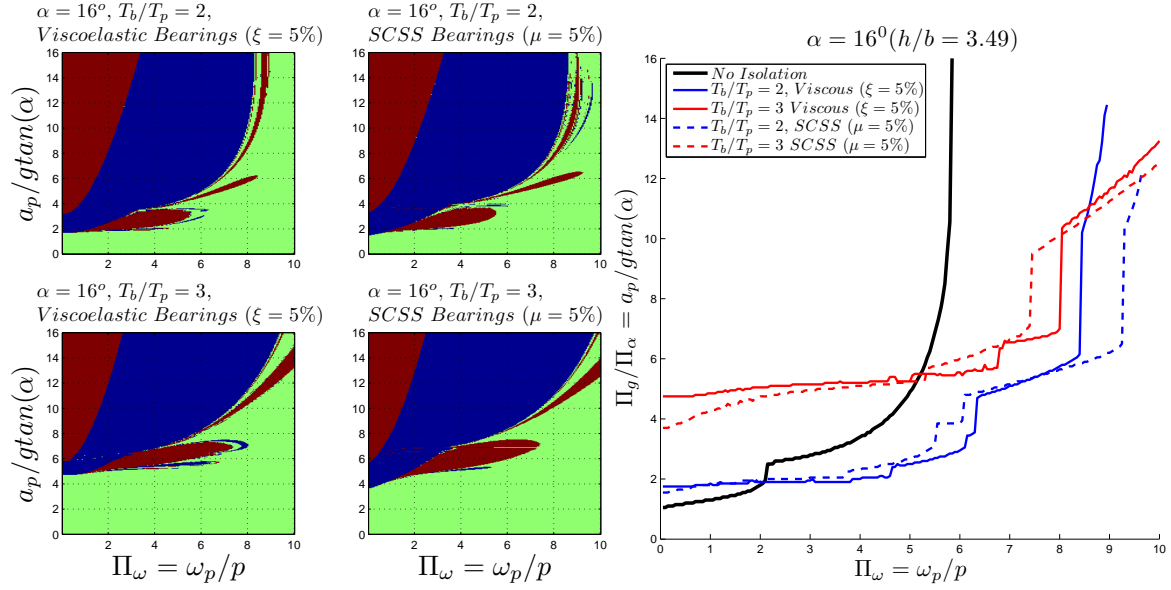

Figure 13. Comparison of overturning spectra (top) and minimum acceleration overturning spectra (bottom) of a rigid body with slenderness $\alpha=16^\circ$ when the supporting base is isolated on viscoelastic bearings with damping ratio $\xi=5\%$ (left) and single concave spherical sliding bearings with coefficient of friction 5% (right). The excitation is a symmetric ricker wavelet and the mass ratio $\gamma=0.01$

7 THE EFFECT OF SEISMIC ISOLATION ON ANCIENT CLASSICAL COLUMNS

The seismic response analysis of rocking blocks standing free on an isolated base has been studied in this paper by using as ground excitation, acceleration pulses described either by the symmetric or the antisymmetric Ricker wavelets. The acceleration amplitude, a_p , and duration T_p of any distinct acceleration pulse allow the use of the dimensional analysis presented in this work and the derivation of the associated Π -products which improve appreciably the understanding of the physics that governs the problem together with the organization and presentation of the response quantities in a most meaningful way. Nevertheless, in order to stress the main finding of this study – that for large blocks (say $\omega_p/p > 6$) the use of seismic isolation reduces the seismic stability of free-standing rocking structures – we examine the seismic response of two free standing slender blocks which have the dimensions of the columns of the peristyle of the Temple of Appolo at Bassae and the Temple of Zeus at Nemea, both located in Peloponese, Greece.

The Temple of Apollo at Bassae is a fifth Century BC doric style structure. The columns of the temple are 5.95m high, the diameter of the base drum is 1.11m (resulting in slenderness $\alpha=0.1844$ and in size $R=3.03\text{m}$). The number of drums in each column is not constant for all the columns and is controlled by the size of the sound rock that was available in the ancient limestone quarry. The temple is still standing but has suffered from erosion of the building material caused by the adverse climatic conditions at the site (1000m altitude a.s.l.) and from the tilting of some columns due to differential settlement of the foundations [32].

The Temple of Zeus at Nemea was built in the late fourth century BC. The columns of this temple are much taller and more slender than the ones of the temple at Bassae, reaching a height of 10.33 m. All columns consist of 13 drums and the base drum diameter is 1.52 m. The resulting slenderness is $\alpha=0.1461$ and $R=5.22\text{m}$. This slenderness ratio is the smallest among the ancient Greek temples of continental Greece. Only one column of the peristyle and two columns of the pronaos of the Temple of Zeus remain standing from the ancient times.

While the columns from the two abovementioned Temples are multidrum, this investigation proceeds by considering that they are monolithic free standing blocks. Past studies led by the senior author (Konstantinidis and Makris, 2005 [33]) have shown that multidrum columns exhibit slightly more controlled response than the equal size monolithic configuration.

Our investigation proceeds by examining the response of the two abovementioned columns when subjected to the 11 historic records shown in Table 2. The columns are considered to stand free on a rigid foundation, or standing free on a seismic isolated base with isolation periods $T_b=2s, 2.5s$ and $3s$ and linear viscous damping $\xi_b=0.1$.

Table 3 summarizes the results from the nonlinear time history analysis. The column from the Temple of Apollo at Bassae ($R=3.03m$ $\alpha=0.1844$) when standing free on a rigid foundation survives all the induced records, while when isolated on bearings that offer an isolation period, $T_b=2.0s$, it topples in all but one records. As the period of the isolation system increases the column survives additional records. Similarly, the column for the Temple of Zeus at Nemea ($R=5.22m$, $\alpha=0.1461$) when standing free on a rigid foundation survives 9 out of the 11 records, while when isolated on bearings that offer an isolation period

$T_b=2.0s$ it topples in all records

Again, as the isolation period increases the column survives additional records; however, even when the isolation period is $T_b=3.0s$ the column from the Temple of Zeus at Nemea survives only 3 out of the 11 records. The reason that seismic isolation is so detrimental to the stability of tall slender blocks is because the presence of the isolation system lengthens the duration of the pulses while at the same time increases the number of the significant induced cycles.

As an example, Figure 13 plots the response of a rigid block with the dimensions of a column of a column from the peristyle of the Temple of Zeus at Nemea subjected to the 022 component of the Jensen Filter Plant record from the 1994 Northridge earthquake when is standing free on a rigid foundation (left) and when standing free on an isolated base with $T_b=3.0s$ (right).

Figure 14. Comparison of the response of a rigid block with the dimensions of a column from the peristyle of the Temple of Zeus at Nemea subjected to the 022 component of the Jensen Filter Plant record from the 1994 Northridge earthquake when is standing free on a rigid foundation (left) and when standing free on an isolated base with $T_b=3.0s$ (right).

8 CONCLUSIONS

In this paper the seismic response analysis and stability of slender rigid blocks standing free on a seismically isolated base is investigated in depth. The paper examines the rocking response when the isolated base is supported: (a) on linear viscoelastic bearings, (b) on single concave and (c) on double concave spherical sliding bearings. Our study revisits the equations of motion and settles the matter of conservation of linear momentum of the entire moving system that is the rocking – translating block together with the translating isolated base. This analysis leads to a closed form expression (eq. (32)) for the maximum value of the coefficient of restitution during impact that allows rocking motion of a block rocking on an isolated base and is concluded that this value is always smaller (more energy is dissipated) than the

maximum value, $r = \left(1 - \frac{3}{2} \sin^2 \alpha\right)^2$ which is associated with a rigid block rocking on a rigid (non-isolated) foundation. Our extended parametric analysis concludes that seismic isolation is beneficial for small blocks. This happens because seismic isolation increases the “static” overturning acceleration; however for isolated rigid blocks this “static” value remains nearly constant as the ratio ω_p/p increases (moving to longer blocks or higher frequency pulses). Consequently, while the presence of an isolation base increases the “static” overturning acceleration it removes appreciably from the dynamics of rocking blocks the fundamental property of increasing stability as their size increases or the excitation pulse period decreases. This behavior prevails regardless whether the rocking block is supported on an isolated base with linear viscoelastic or spherical sliding bearings with single or double curvature. The longer the isolation period of the supporting base is, the more stability is offered to the rocking blocks; however large blocks subjected to moderate period pulses (say $\omega_p/p > 6$) exhibit superior stability when they stand free on a rigid base (non-isolated) rather than when they are isolated even on isolation systems with very long periods. This remarkable result suggests that free standing ancient classical columns exhibit superior stability as they are built (standing free on a rigid foundation) rather than if they were seismic isolated. Consequently, seismic isolation is not recommended as a technology to improve the seismic stability of ancient Greek or Roman temples.

Abstract. *This paper presents a methodology for the optimal design of multiple Tuned Mass Dampers (TMDs) in 3D irregular buildings. The objective function minimizes the total mass of all added TMDs. Constraints are added to limit the total accelerations experienced at the edges of the floors in the direction parallel to each edge. The formulation of the design methodology relies on optimality criteria conjectured herein, hence, a two stage iterative analysis/redesign procedure that is based on analysis tools only is resulted. This allows the application of the methodology in a practical design process.*

1 INTRODUCTION

Seismic protection of structures is an important issue in structural design due to its threatening consequences. Often, it is required that the design of a structure provide even more than life safety, promising a certain level of serviceability following a severe earthquake, while allowing for a defined level of damage, i.e. performance-based design. Damage to structural components is often linked to inter-story drifts, when considering damage due to maximal responses, and to energy dissipation when considering damage due to cumulative actions. When considering damage to acceleration sensitive non-structural elements, total accelerations (which are accelerations in respect to an inertial frame of reference, also referred to as absolute accelerations) produced during the ground-motion are of most interest. Total acceleration levels are also very important when considering the comfort level of human occupancy. In addition, total accelerations have an effect on base-shear and overturning moments [1].

There is ample literature on the control of these responses through control devices that reduce the energy dissipation demand of the structure. Several passive damping devices are available, including viscous and visco-elastic dampers, and metallic and friction hysteretic dampers [1, 2]. Another device to be used herein is the Tuned-Mass-Damper (TMD). Details about TMDs and their applications may be found in the fine works [1, 3, 4, 5, 6], only to name a few.

The use of TMDs for the reduction of responses of tall buildings due to wind loadings became widespread [7, 8, 9]. With efficient seismic design strategies, those devices may be attractive for multi-hazard mitigation of both winds and earthquakes. While wind-induced vibrations are usually dominated by a single mode, using TMDs for seismic structural protection is more complicated. In seismic vibrations, no single distinct frequency dominates the behavior, but rather many frequencies, including the ones of higher modes. Many researchers are therefore hesitant in using TMDs for seismic structural applications [10, 11, 12, 13, 14]. It should be noted that most of those works use only a single TMD tuned to a fundamental frequency. In addition, a TMD relies on tuning the device's natural frequency as to suppress the vibration of the structure, based on the structure's natural frequencies. However, if detuning occurs, the device loses much of its efficiency.

One solution to these drawbacks may be found in active or semi-active TMDs (ATMDs or SATMDs), whose frequencies may be altered at each moment [15, 16, 17, 18]. Active control, however, requires an external power source to be activated, which may be costly and may force a reliability issue during an actual earthquake. Another possible solution may be achieved using multiple TMDs (MTMDs), each tuned to a different frequency. This may lead to a solution that controls various frequencies for various modes of the structure. Those TMDs could also be distributed along the structure and located at locations which will optimize the control of the structure. In addition, each TMD that is aimed at controlling a certain mode of the structure could be split to several TMDs, each tuned to a slightly different frequency within a bandwidth close to the natural frequency of the main system, thus reducing the detuning effect and allowing design robustness (for example [19]). The idea of using MTMDs tuned to various natural frequencies of the structure and distributed along its height is not new. Clark [20] indicated that a single TMD can not significantly reduce the motion created due to seismic excitations, while MTMDs can substantially reduce motion. Moon [21, 22] shows a practical application of vertically-distributed MTMDs in tall buildings for reducing wind-induced vibrations, and offers a method of distributing them by mode shape. In his work, dampers are located at the perimeter in the space between the inner and outer façade layers in double skin façade systems, as their vibrations are in the direction perpendicular to the edge of the floor. In the methodology presented herein a somewhat different approach is

taken, as the dampers' vibrations are in parallel to the floor edge. This allows a better control of torsional response as well as larger strokes for the dampers.

Several methodologies for the optimal design of a single passive TMD for MDOF structures exist, each using a different objective function [8, 23, 24, 25]. Hadi and Arfiadi [26] use an H_2 performance index to retrieve the optimal parameter of a TMD added to a MDOF structure. H_2 and H_∞ optimization criteria are also widely used in ATMD problems (for example [27]). The H_2 approach minimizes a weighted average of the weighted sum of responses at various locations, and the control energy input. In the case of passive control, however, the control energy input is not a relevant cost measure. The H_∞ approach, on the other hand, minimizes the worst case energy attenuation of the controlled output with respect to an excitation of a given energy. Here, however, the characteristics of the input motion expected at the site where the structure is located are not considered. It should be emphasized that both approaches make use of smeared measures of the controlled responses rather than limiting each local response separately. In buildings in general, however, (see for example [28, 29]), and in the case of irregular buildings in particular, it is highly important to limit each local response separately. In addition, both approaches do not target an allowable response limit. In the context of the last two highly important issues, Bounded State Control (BSC) seems more appropriate since local states are each bounded to allowable limits [28, 29].

Bounded State Control algorithms can be roughly categorized into two groups. The first relies on a train of high energy pulses of control forces (e.g. [29, 30] and references therein) while the second makes use of a continuous control law (e.g. [31, 32, 33]). While may be attractive in the application of an active control system, the pulse control strategies are not likely to be implemented by passive means. The methods that make use of continuous control laws, on the other hand, usually require formal optimization.

There are not many methodologies available for the design of MTMDs of various frequencies and locations in seismic application. In their pioneering work, Chen and Wu [34] use a frequency based transfer function as a response measure of the multi-modal vibration problem of structures. Rather than solving a formal optimization problem, they use a sequential search technique in order to allocate multi-modal MTMDs. A pre-assumed number of TMDs is sequentially added at locations where the location index (which, for example, can be the location of maximal root-mean-square (RMS) acceleration prior to placement of each damper) is optimal in each sequence. Luo et al. [35] also dealt with the multi-modal vibration problem of structures using MTMDs. In their work, a dynamic magnification factor (DMF) of the first mode obtained based on the transfer function of the structure's response in frequency domain is minimized. Constraints on the DMFs of other modes are also considered. Lin et al. [36] proposed a two-stage frequency-domain based optimal design of MTMDs taking into consideration both the structural response and the TMD stroke, and found that there is a good balance between limiting the TMD stroke and not substantially compromising on structural response. Fu and Johnson [37] suggest using passive MTMDs with a vertical distribution of mass, where each story is assigned with one TMD of which its' parameters (mass, stiffness and inherent damping) are optimized as to minimize the sum of inter-story drifts. The optimization problem is solved using a pattern-search, and a local minimum is obtained. While the above methodologies present a huge step forward, there is still no methodology that leads to a desired performance under a realistic representation of the ground motion hazard, in small computational efforts while using analysis tools only.

This paper presents a simple frequency-domain performance-based methodology for solving the allocation and sizing problem of multi-modal MTMDs in structures undergoing seismic excitations. The objective function minimizes the total mass of all added TMDs. Constraints are added to limit the total accelerations experienced at the edges of the floors in

the direction parallel to each edge. The methodology is based on a simple iterative analysis/redesign procedure where first, an analysis is performed for a given design and then redesign of the TMDs is performed according to recurrence relations. The redesign first determines the mass of all dampers at a given location based on RMS acceleration (peak acceleration could be indirectly used). Then this mass is distributed between dampers tuned to various frequencies. The methodology is based on the simple optimal design parameters of TMDs presented by Den-Hartog [3] and Warburton [4] to successfully reduce the acceleration demands within the structure. The advantages of the proposed methodology is its simplicity, relaying on analyses tools only, it is performance-based - catered to serve any desirable performance, and its fast convergence.

2 PROBLEM FORMULATION

2.1 Equations of motion

Following Soong [29], the equations of motion of a MDOF system can be represented in state-space notation as:

$$\begin{aligned}\dot{\hat{\mathbf{x}}}(t) &= \mathbf{A} \cdot \hat{\mathbf{x}}(t) + \mathbf{B} \cdot a_g(t) \\ \mathbf{y}(t) &= \mathbf{CC} \cdot \hat{\mathbf{x}}(t)\end{aligned}\tag{1}$$

where $\hat{\mathbf{x}}^T = [\mathbf{x}^T \quad \dot{\mathbf{x}}^T]$; $\mathbf{x} \in R^N$, $\hat{\mathbf{x}} \in R^{2N}$ is the state variable vector, $\mathbf{x}(t)$ is the displacement vector between the DOFs and the ground, $a_g(t)$ is the ground-motion's acceleration, a dot represents the derivative with respect to time, and $\mathbf{y}(t)$ is the output vector of the system, whose entries are responses of interest. Those responses are a linear combination of the state variables and the input forces (in our case $\mathbf{y}(t) = \mathbf{x}(t)$). The matrices \mathbf{A} , \mathbf{B} and \mathbf{CC} are defined as following:

$$\mathbf{A} = \begin{bmatrix} \mathbf{0}_{N \times N} & \mathbf{I}_{N \times N} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} \mathbf{0}_{N \times 1} \\ -\mathbf{e} \end{bmatrix} \quad \mathbf{CC} = [\mathbf{I}_{N \times N} \quad \mathbf{0}_{N \times N}] \tag{2}$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, inherent damping and stiffness matrices of the structure according to the chosen N degrees-of-freedom (DOFs), respectively, \mathbf{e} is the excitation direction vector with values of zero and one, \mathbf{I} is the identity matrix and $\mathbf{0}$ is a zero matrix of appropriate dimensions, as noted.

It should be noted that for the sake of presentation, Eq. (1) and the following methodology are presented using a single input (component of the ground motion). An extension to the case of multiple inputs simultaneously, or multiple components of the ground motion in different directions, is straightforward.

2.2 Performance measures

Sensitivity of equipment within the structure, as well as human discomfort is found to be most dependent on total accelerations produced within the structure during an earthquake [1, 34]. The acceleration serviceability limit of structures is thus a suitable performance criterion for design. Reducing the drift levels within the structure is also a goal that should be reckoned with, as drifts are the main source of structural damage. This criterion is not directly taken into consideration in the present work; however, as will be seen in the example, using the proposed methodology leads to a considerable reduction of peak drifts as well. Moreover, some structures are expected to lead to acceptable, or close to acceptable, drifts even without

retrofitting, but to be sensitive to total accelerations. One example for that is buildings for which wind loads dictate the design for lateral loads. Here, earthquakes may still lead to high total accelerations. Hence, total accelerations serve in this paper as the performance measure of the structure.

Added TMDs help control the responses of the structure, and the measure of cost of this controlling system is by the amount of added mass. As more mass is added to the structure, the retrofit is said to be more expensive and thus less cost-effective.

2.3 Problem formulation

The problem at hand is formulated as an optimization problem for which the objective function minimizes the total amount of added masses in the TMDs under constraints of maximal performance measures. The total accelerations at all peripheral locations of all floors are taken as the performance measures, as they are the largest accelerations expected within story limits. Those locations are shown in Fig. 1 as: $(\mathbf{x}_{pyl})_n$, $(\mathbf{x}_{pyr})_n$, $(\mathbf{x}_{pxt})_n$ and $(\mathbf{x}_{pxb})_n$, and are the peripheral coordinates in the "y", "y", "x" and "x" directions, at the left, right, top and bottom edges of floor n , respectively. The remaining variables will be explained subsequently. That is, the constraints are on the total accelerations at the edges of all floors in the directions parallel to each edge. The optimization problem is thus formulated as:

$$\begin{aligned} \min J &= \sum_l^{\text{all locations}} \sum_f^{\text{all frequencies}} (\mathbf{m}_{\text{TMD}})_{l,f} \\ \text{s.t.} \quad & \frac{\max_{eq} \left(\max_t \left(\left(\ddot{\mathbf{x}}_p^t(t) \right)_l \right) \right)}{a_{\text{all}}^t} \leq 1.0 \quad \forall l = 1, 2, \dots, N_{\text{locations}} \end{aligned} \quad (3)$$

where $(\mathbf{m}_{\text{TMD}})_{l,f}$ is the mass of the TMD located at peripheral location l tuned to frequency f , $\max_{eq} \left(\max_t \left(\left(\ddot{\mathbf{x}}_p^t(t) \right)_l \right) \right)$ is the envelope of peak total acceleration in time at each location, l , under all considered earthquakes, a_{all}^t is the allowable total acceleration, and $N_{\text{locations}}$ is the number of locations to be constrained ($=4N_{\text{floors}}$ where N_{floors} is the number of floors). The peripheral locations, l , are ordered such that the vector of peripheral coordinates is $\mathbf{x}_p = [\mathbf{x}_{pyl}^T \ \mathbf{x}_{pyr}^T \ \mathbf{x}_{pxt}^T \ \mathbf{x}_{pxb}^T]^T$ (see also Fig. 1). It should be noted that with a slight modification, the methodology to follow could also constrain the total accelerations of the floors' corners in any direction, if desired.

Rather than directly solving the time-domain representation of the problem (Eq. (3)), the proposed methodology uses an equivalent frequency-domain representation, introducing peripheral RMS total accelerations rather than peripheral peak total accelerations. The allowed values for the RMS total accelerations are properly scaled so as to lead to the desired allowable peak accelerations in time of Eq. (3). In frequency-domain, Eq. (3) is transformed into:

$$\begin{aligned} \min J &= \sum_l^{\text{all locations}} \sum_f^{\text{all frequencies}} (\mathbf{m}_{\text{TMD}})_{l,f} \\ \text{s.t.} \quad & \frac{RMS \left(\left(\ddot{\mathbf{x}}_p^t \right)_l \right)}{a_{\text{all}}^{\text{RMS}}} \leq 1.0 \quad \forall l = 1, 2, \dots, N_{\text{locations}} \end{aligned} \quad (4)$$

where $a_{\text{all}}^{\text{RMS}}$ is the allowable RMS total acceleration and $\text{RMS}(\ddot{\mathbf{x}}_p^t)_l$ is the root mean square of the total acceleration at location l (the l^{th} term of $\text{RMS}(\ddot{\mathbf{x}}_p^t)$). Such reference to a component of a vector or a matrix, i.e. $(\cdot)_l$, will be used throughout the paper.

Figure 1: Definition of dynamic DOFs and peripheral coordinates of the n^{th} floor.

3 PROPOSED SOLUTION SCHEME

3.1 Fully-stressed design (FSD)

Designs that are based on fully stressed characteristics go back to the classical design of trusses under static loads, whereby the weight is minimized for a given allowable stress. For that problem, it had been widely accepted that the optimal design yields a: statically determinate fully stressed design, with members out of the design having strains smaller than the allowable. This result appeared in the literature as early as 1900 as: "A statically determined framework of included figure is the most economic form of a framework of given indeterminate figure for the support of a given loading" [38]. It was later shown that this design is a Karush-Kuhn-Tucker point and therefore, an optimal design [39].

Recently, it was shown that some dynamic optimal designs also possess "fully stressed" characteristics. Levy and Lavan [40] considered the minimization of total added viscous damping to frame structures subjected to ground accelerations, while constraining various inter-story responses. Their optimal solutions attained by formal optimization indicated that: "At the optimum, damping is assigned to stories for which the local performance index has reached the allowable value. Stories with no assigned damping attain a local performance index which is lower or equal to the allowable." That is, the optimal solutions attained "fully stressed" characteristics.

Based on past experience of the authors in similar problems, it is conjectured here that the optimal solution to MTMD allocation and sizing in structures (the solution of Eq. (4)) possesses FSD characteristics, i.e.:

At the optimum, TMDs are assigned to peripheral locations for which the RMS total acceleration has reached the allowable value under the considered input acceleration PSD. In addition, at each location to which TMDs are added, TMDs of a given frequency are assigned only to frequencies for which the output spectral density is maximal.

Potential locations for TMDs are located at the edges of the floors, as their lines of action are in direction parallel to the edges (Fig. 2). Those are actually the same locations where total accelerations are to be limited. The coordinates "z" in Fig. 2 will be explained subsequently.

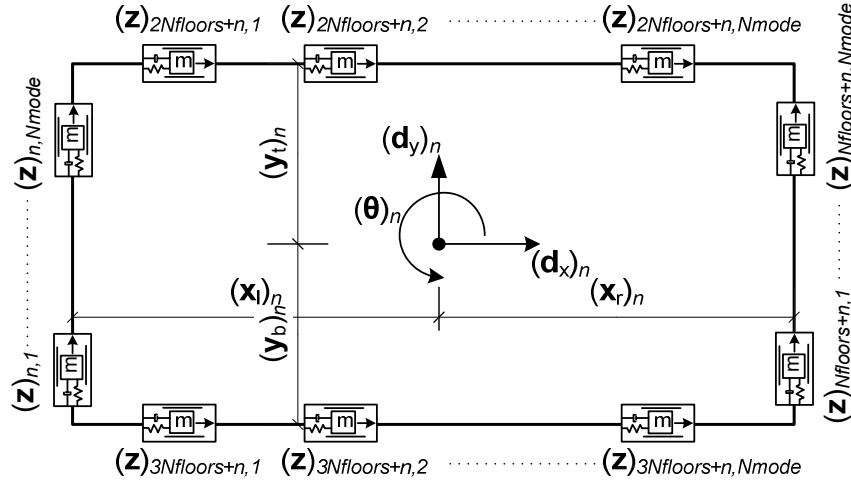

Figure 2: Locations of TMDs at the floor n and their associated z DOFs.

Stage one of the conjecture, imposes that for all peripheral locations with masses within the design, the total acceleration equals the allowable one, while all peripheral locations with zero masses (outside the design) have an acceleration equal to or less than the allowable. This is illustrated on the left-hand side of Fig. 3, which presents the concept on a selected peripheral frame. Here, the 5th floor is the only one to be dampened ($\sum_f (\mathbf{m}_{\text{TMD}})_{5,f} \neq 0$), as it is the

only floor to reach the allowable RMS acceleration. The second stage of the conjecture imposes that for all dampers at a peripheral location where the acceleration equals the allowable one, and are within the design, the output spectral densities are maximal (with respect to ω) and equal. As for masses outside of the design at this DOF, the output spectral density is less than maximal. This is illustrated on the right-hand side of Fig. 3 where $(\mathbf{R}_{\mathbf{x}_p^t}(\omega))_l$ is the output spectral density for the total acceleration at the location l ($=5$ in Fig. 3). As can be seen, $(\mathbf{m}_{\text{TMD}})_{5,1}$ and $(\mathbf{m}_{\text{TMD}})_{5,2}$ are the only ones with a mass larger than zero as their output spectral densities, $(\mathbf{R}_{\mathbf{x}_p^t}(\omega))_5$, are largest. It should be noted that if the desired constraints are on the corners' total accelerations in any direction, dampers would be added to the direction that contributes more to the acceleration (between x and y).

The above conjecture suggests that the tuning frequency of each TMD is searched for amongst all possible frequencies. However, for practical reasons, it is reasonable to assume that these frequencies are in the vicinity of the bare structure's frequencies, and thus the tuning of TMDs could be in relation to the bare structure's natural frequency.

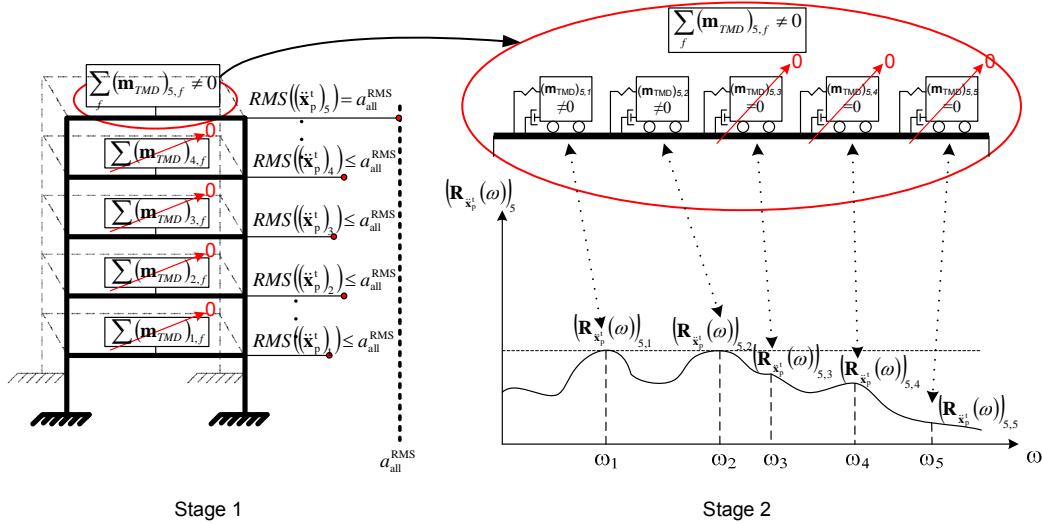

Figure 3: Illustrations of the first part of the conjecture (left) and the second part of the conjecture (right).

3.2 Analysis/Redesign algorithm

Solutions to optimization problems, which possess fully stressed characteristics, are efficiently achieved iteratively using a two step algorithm in each iteration cycle. In the first step, an analysis is performed for a given preliminary design, whereas in the second step the design is changed using a recurrence relationship that targets fully stressedness. The recurrence relation can be generally written as:

$$x_l^{(n+1)} = x_l^{(n)} \cdot \left(\frac{pi_l^{(n)}}{pi_{allowable}} \right)^P \quad (5)$$

where x_l is the value of the design variable associated with the location l , pi_l is the performance measure of interest for the location l , $pi_{allowable}$ is the allowable value for the performance measure, n - the iteration number and P - a convergence parameter. Fully stressedness is obtained from using Eq. (5) since upon convergence one of the following must take place. Either $x_l^{(n+1)} = x_l^{(n)}$ giving $pi_l^{(n)} = pi_{allowable}$, or $x_l^{(n+1)} = x_l^{(n)} = 0$ giving $pi_l^{(n)} \leq pi_{allowable}$.

In the optimal design of trusses, for example, the engineer would assume initial values for the cross sections as design variables (x_l 's in Eq. (5)) and run an analysis. Then, based on the attained stresses as the performance measures (pi_l 's in Eq. (5)), and their allowable values, the cross section of each bar could be redesigned using Eq. (5). The process could be repeated until convergence. The advantages of the analysis/redesign algorithm include its simplicity, the need to use analysis tools only, and the fairly small computational effort that lies in the small number of analyses required for convergence. Such analysis/redesign procedure will be utilized here to attain fully stressed designs where the mass, frequency and locations of MTMDs within framed structures is to be determined.

4 DESIGN METHODOLOGY

The proposed design methodology relies on the analysis/redesign procedure which leads to the FSD criteria presented above. The proposed methodology is summarized in the following flowchart. Following the flowchart is an extensive elaboration of each step, including the equations referred to within the flowchart.

4.1 Stepwise flowchart

Initial actions

1. Determine the mass, stiffness and inherent damping matrices of the structure. Decide on allowable RMS accelerations, which should represent the desired peak total acceleration.
2. Determine the natural frequencies and mode shapes of the structure.
3. Decide on an input PSD, which should represent an ensemble of chosen ground-motions (see example). For each DOF, evaluate the total acceleration transfer function in frequency domain using Eq. (8), transform this transfer function into peripheral coordinates using Eq. (10) and determine the peripheral output spectral density using Eq. (11). The peripheral RMS acceleration is derived from Eq. (12).
4. Add N_{mode} (N_{mode} being the number of modes potentially damped) TMDs at each peripheral coordinate, each tuned to one frequency of the structure, with the initial properties described in Eqs. (14), (17) and (19).

Iterative action

5. Update the mass, stiffness and damping matrices of the structure with the added damping system, using Eqs. (20) - (25).
6. Re-evaluate the RMS accelerations excited within the structure using Eqs. (8) - (12). Notice that for Eq. (8) the expressions $\mathbf{M}^{-1}\mathbf{K}$ and $\mathbf{M}^{-1}\mathbf{C}$ are taken from Eqs. (26) and (27), to avoid singularity.
7. Redesign the mass of each TMD according to the recurrence formulas given in Eqs. (28) and (29). Accordingly, reevaluate the stiffness and damping coefficient of each TMD using Eqs. (15) - (19).
8. Repeat steps 5 to 7 until convergence of the mass is reached.
9. Validate the results using time-history analysis and the selected set of ground-motions.
10. If desired, the allowable RMS acceleration may be scaled according to the reduction of envelope peak acceleration determined in step 9 and the allowable peak acceleration in time domain, using Eq. (30), followed by repeating steps 5-9 until fully satisfied.

Step 1: A desired maximal RMS acceleration (representing the desired peak total acceleration) is chosen. The mass, damping and stiffness matrices of the structure are assembled according to the relevant dynamic DOFs, which in the case of the simplest n^{th} floor of a 3D structure are two perpendicular displacements of a chosen coordinate and the floor's rotation, as noted in Fig. 1 by " $(\mathbf{d}_x)_n$ ", " $(\mathbf{d}_y)_n$ " and " $(\boldsymbol{\theta})_n$ ". As it is desired to control peripheral responses (which include the largest responses within floor limits in the "x" and "y" directions), a coordinate transformation from floor DOFs to peripheral coordinates is performed as follows:

$$\mathbf{x}_p = \mathbf{T} \cdot \mathbf{x} \quad (6)$$

where $\mathbf{x} = [\mathbf{d}_x^T \quad \mathbf{d}_y^T \quad \boldsymbol{\theta}^T]^T$ and the transformation matrix \mathbf{T} is:

$$\mathbf{T}_{(4 \cdot N_{floors} \times 3 \cdot N_{floors})} = \begin{bmatrix} \mathbf{0}_{(N_{floors} \times N_{floors})} & \mathbf{I}_{(N_{floors} \times N_{floors})} & \text{diag}(\mathbf{x}_l)_{(N_{floors} \times N_{floors})} \\ \mathbf{0}_{(N_{floors} \times N_{floors})} & \mathbf{I}_{(N_{floors} \times N_{floors})} & \text{diag}(\mathbf{x}_r)_{(N_{floors} \times N_{floors})} \\ \mathbf{I}_{(N_{floors} \times N_{floors})} & \mathbf{0}_{(N_{floors} \times N_{floors})} & -\text{diag}(\mathbf{y}_t)_{(N_{floors} \times N_{floors})} \\ \mathbf{I}_{(N_{floors} \times N_{floors})} & \mathbf{0}_{(N_{floors} \times N_{floors})} & -\text{diag}(\mathbf{y}_b)_{(N_{floors} \times N_{floors})} \end{bmatrix} \quad (7)$$

where N_{floors} is the number of floors, N is the number of DOFs and \mathbf{x}_l , \mathbf{x}_r , \mathbf{y}_t , and \mathbf{y}_b are the distances from the DOFs' coordinate system's origin to the left, right, top and bottom edges, ordered from first to top floor, as shown for the story n in Fig. 1.

Step 2: Solution of the eigenvalue problem determines the structure's natural frequencies and mode shapes.

Step 3: A power spectral density (PSD) for the input acceleration is chosen. Examples of such input spectrums are stationary white-noise, which gives a constant PSD, and the Kanai-Tajimi PSD [41]. Additional PSDs for ground-motional modeling can be found in Nagara-jiah and Narasimhan [42] and in Agrawal et al. [43]. The PSD is fitted to represent real ground-motions. This is done by fitting its parameters to a frequency-based spectrum, representing the decomposition of earthquakes into frequency components (for example, a FFT spectrum). For each DOF, the transfer function of total acceleration of the bare frame is evaluated using Eq. (8). This transfer function represents the ratio between the sinusoidal output amplitude to a sinusoidal input amplitude with frequency ω .

For total accelerations it can be shown that the appropriate transfer vector, $\mathbf{H}_{\mathbf{x}^t}(j\omega)$, is:

$$\mathbf{H}_{\mathbf{x}^t}(j\omega) = -\mathbf{M}^{-1} \cdot (j\omega\mathbf{C} + \mathbf{K}) \cdot \mathbf{H}_{\mathbf{x}}(j\omega) \quad (8)$$

where $j = \sqrt{-1}$ and $\mathbf{H}_{\mathbf{x}}(j\omega)$ is the displacement transfer vector [44], given by:

$$\mathbf{H}_{\mathbf{x}}(j\omega) = \mathbf{C}\mathbf{C} \cdot (j\omega\mathbf{I} - \mathbf{A})^{-1} \cdot \mathbf{B} \quad (9)$$

This transfer function is transformed to peripheral coordinates using:

$$\mathbf{H}_{\mathbf{x}^t_p}(j\omega) = \mathbf{T} \cdot \mathbf{H}_{\mathbf{x}^t}(j\omega) \quad (10)$$

where $\mathbf{H}_{\mathbf{x}^t_p}(j\omega)$ is the structure's transfer function of total accelerations in peripheral coordinates. The output spectral densities of the peripheral accelerations, $(\mathbf{R}_{\mathbf{x}^t_p}(\omega))_l$, are evaluated using:

$$(\mathbf{R}_{\mathbf{x}^t_p}(\omega))_l = \left| (\mathbf{H}_{\mathbf{x}^t_p}(j\omega))_l \right|^2 \cdot S(\omega) \quad (11)$$

where $S(\omega)$ is the input PSD, $\left| (\mathbf{H}_{\mathbf{x}^t_p}(j\omega))_l \right|^2 = (\mathbf{H}_{\mathbf{x}^t_p}(j\omega))_l \cdot (\mathbf{H}_{\mathbf{x}^t_p}^*(j\omega))_l$ where $(\mathbf{H}_{\mathbf{x}^t_p}(j\omega))_l$ is the l^{th} term of $\mathbf{H}_{\mathbf{x}^t_p}(j\omega)$, $(\mathbf{H}_{\mathbf{x}^t_p}^*(j\omega))_l$ is its complex conjugate.

The area under the output spectral density curve equals the mean-square response [45], and thus, the root-mean-square (RMS) of total accelerations at peripheral coordinate l , $RMS(\ddot{\mathbf{x}}_p)_l$, taking into consideration the contribution of all frequencies to the total response, is derived using:

$$RMS(\ddot{\mathbf{x}}_p)_l = \sqrt{2 \cdot \int_0^\infty \left(\mathbf{R}_{\ddot{\mathbf{x}}_p}(\omega) \right)_l d\omega} \quad (12)$$

Step 4: If for any peripheral coordinate, l , the RMS acceleration obtained is larger than the allowable RMS acceleration, MTMDs are added to suppress the acceleration produced. Each TMD of mass $(\mathbf{m}_{TMD})_{l,f}$ is assigned with a DOF for its displacement relative to the ground, $(\mathbf{z})_{l,f}$. Here, the subscript l stands for its location while the subscript f stands for its frequency. The location, l , is corresponding to the peripheral coordinate $(\mathbf{x}_p)_l$ the TMD is attached to. At each location, N_{mode} TMDs are added, to suppress N_{mode} original frequencies of the structure, where N_{mode} is the number of modes to potentially be controlled. Thus, generally a total of $N_{mode} \cdot N_{locations}$ dampers are potentially added (Fig. 2). Note that the order of DOFs in the damped structure is:

$$\tilde{\mathbf{x}} = [\mathbf{d}_x^T \quad \mathbf{d}_y^T \quad \boldsymbol{\theta}^T \quad (\mathbf{z})_{1,1} \quad (\mathbf{z})_{2,1} \quad \cdots \quad (\mathbf{z})_{N_{locations},1} \quad \cdots \quad (\mathbf{z})_{1,N_{mode}} \quad (\mathbf{z})_{2,N_{mode}} \quad \cdots \quad (\mathbf{z})_{N_{locations},N_{mode}}]^T \quad (13)$$

Note the difference between the coordinates $(\mathbf{x}_p)_l$ to the coordinates $(\mathbf{z})_{l,f}$. While the coordinates $(\mathbf{x}_p)_l$ relate to peripheral displacements of the floors themselves, $(\mathbf{z})_{l,f}$ relate to displacements of the masses of TMDs relative to the ground. Note also that those two vectors are organized such that the component l of \mathbf{z} relates to the displacement of a TMD that is attached to the floor at the location of the component l of \mathbf{x}_p , i.e. the locations l are corresponding in those two vectors.

The initial properties of each such damper are obtained based on a SDOF system representing the damped mode. In this work, Den-Hartog's properties [3] were chosen. These properties were derived for the optimal reduction of mass displacement of a SDOF system under external sinusoidal loading. They were later shown to also reduce the maximum total acceleration response of the mass of a SDOF system undergoing a harmonic base excitation [4]. It should be noted that any different set of chosen properties (mass, stiffness and inherent damping of each TMD) can be easily used with the proposed scheme instead of Den-Hartog. In the case of optimal Den-Hartog properties:

1. For each peripheral coordinate, the initial mass of all TMDs located at that coordinate is taken as certain predetermined percentage of the structure's mass (say 1%). It is divided equally between the dampers situated at the same location:

$$(\mathbf{m}_{TMD})_{l,f} = \frac{0.01}{N_{mode}} \cdot M_{structure} \quad (14)$$

where l represents the damper's location, f represents the mode dampened and $M_{structure}$ is the structure's total mass. The mass ratio $(\mu_{TMD})_f$ of all TMDs tuned to frequency f equals the ratio between the effective TMD mass of all TMDs tuned to frequency f and the f^{th} modal mass of the structure. This mass ratio is defined as:

$$(\mu_{TMD})_f = \frac{\phi_f^T \cdot \mathbf{T}^T \cdot \mathcal{D}((\mathbf{m}_{TMD})_f) \cdot \mathbf{T} \cdot \phi_f}{\phi_f^T \cdot \mathbf{M}_{original} \cdot \phi_f} \quad (15)$$

where ϕ_f is the f^{th} mode-shape of the bare structure, $[\mathbf{M}_{\text{original}}]$ is the bare frame's mass matrix, \mathbf{T} is the transformation matrix of Eq. (7), and $\mathcal{D}((\mathbf{m}_{\text{TMD}})_f)$ is a diagonal matrix with the terms $(\mathbf{m}_{\text{TMD}})_{1:N_{\text{locations}},f}$ sitting on the diagonal in the order of TMD DOFs, as in Eq. (13).

2. Each TMD's stiffness is determined according to the frequency of the mode which is dampened by the TMD. The frequency is tuned to:

$$(\omega_{\text{TMD}})_f = \frac{(\omega_n)_f}{1 + (\mu_{\text{TMD}})_f} \quad (16)$$

where $(\omega_n)_f$ is the frequency f to be dampened. The compatible stiffness is:

$$(\mathbf{k}_{\text{TMD}})_{l,f} = (\mathbf{m}_{\text{TMD}})_{l,f} \cdot ((\omega_{\text{TMD}})_f)^2 \quad (17)$$

3. Each TMD's modal damping ratio is determined according to:

$$(\xi_{\text{TMD}})_f = \sqrt{\frac{3 \cdot (\mu_{\text{TMD}})_f}{8 \cdot (1 + (\mu_{\text{TMD}})_f)^3}} \quad (18)$$

and the matching damping coefficient:

$$(\mathbf{c}_{\text{TMD}})_{l,f} = 2 \cdot (\mathbf{m}_{\text{TMD}})_{l,f} \cdot (\xi_{\text{TMD}})_f \cdot (\omega_n)_f \quad (19)$$

Step 5: The mass, damping and stiffness matrices of the damped frame are formulated, using the following. The new mass matrix is:

$$\mathbf{M} = \begin{bmatrix} [\mathbf{M}_{\text{original}} + \mathbf{B}_{\text{dm}}^T \mathbf{m}_{\text{TMD}} \mathbf{B}_{\text{dm}}] & \mathbf{0} \\ \mathbf{0} & [\mathbf{m}_{\text{TMD}}] \end{bmatrix} \quad (20)$$

where $[\mathbf{M}_{\text{original}}]$ is the bare frame's mass matrix and $[\mathbf{m}_{\text{TMD}}]$ is a diagonal matrix with the terms $(\mathbf{m}_{\text{TMD}})_{l,f}$ sitting on the diagonal in the order of TMD DOFs, as in Eq. (13). The matrix

\mathbf{B}_{dm} is a transfer matrix, used to add the mass of TMDs to the mass of the structure perpendicular to their original DOF (i.e. if a certain damper is used to reduce vibration in the "y" direction, and thus its DOF is in the "y" direction, the mass of that TMD is added to the mass of the structure in the "x" direction of the story where it is situated). It is given by:

$$\mathbf{B}_{\text{dm}}^T = \begin{bmatrix} 1 & . & . & . & . & . & N_m \\ \mathbf{T}_m^T & . & . & . & . & . & \mathbf{T}_{\text{an}}^{\sigma T} \end{bmatrix} \quad (21)$$

where:

$$\mathbf{T}_m = \begin{bmatrix} \mathbf{I}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} \\ \mathbf{I}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} \\ \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{I}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} \\ \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{I}_{(N_{\text{floors}} \times N_{\text{floors}})} & \mathbf{0}_{(N_{\text{floors}} \times N_{\text{floors}})} \end{bmatrix} \quad (22)$$

The damping matrix of the damped frame is constructed as:

$$\mathbf{C} = \begin{bmatrix} [\mathbf{C}_{\text{original}} + \mathbf{B}_d^T \mathbf{c}_{\text{TMD}} \mathbf{B}_d] & [-\mathbf{B}_d^T \mathbf{c}_{\text{TMD}}] \\ [-\mathbf{c}_{\text{TMD}} \mathbf{B}_d] & [\mathbf{c}_{\text{TMD}}] \end{bmatrix} \quad (23)$$

where $[\mathbf{C}_{\text{original}}]$ is the bare frame's inherent damping matrix and $[\mathbf{c}_{\text{TMD}}]$ is a diagonal matrix with the terms $(\mathbf{c}_{\text{TMD}})_{l,f}$ sitting on the diagonal in the order of DOFs as in Eq. (13). The matrix \mathbf{B}_d is a transfer matrix, used to assign the TMDs within the structure.

$$\mathbf{B}_d^T = \begin{bmatrix} 1 & . & . & . & . & . & N_m \\ \mathbf{T}^T & . & . & . & . & . & \mathbf{T}_g^T \end{bmatrix} \quad (24)$$

The stiffness matrix of the damped frame is constructed similarly as:

$$\mathbf{K} = \begin{bmatrix} [\mathbf{K}_{\text{original}} + \mathbf{B}_d^T \mathbf{k}_{\text{TMD}} \mathbf{B}_d] & [-\mathbf{B}_d^T \mathbf{k}_{\text{TMD}}] \\ [-\mathbf{k}_{\text{TMD}} \mathbf{B}_d] & [\mathbf{k}_{\text{TMD}}] \end{bmatrix} \quad (25)$$

where $[\mathbf{K}_{\text{original}}]$ is the bare frame's stiffness matrix and $[\mathbf{k}_{\text{TMD}}]$ is a diagonal matrix with the terms $(\mathbf{k}_{\text{TMD}})_{l,f}$ sitting on the diagonal in the order of DOFs as in Eq. (13).

Step 6: The peripheral RMS accelerations of the damped frame at all coordinates are evaluated using frequency-domain analysis based on Eqs. (8) - (12), using the newly-updated matrices (note that in Eq. (12) it is needed to take only the first N components of the extended vector $\mathbf{H}_{\tilde{\mathbf{x}}_t}(j\omega)$ as now DOFs of TMDs are included in this vector). As earlier mentioned, this requires the evaluation of each DOF's transfer function. As the computation of the transfer function involves inversion of the mass matrix, and some TMD masses may get very small during the design process, singularity issues may occur. To avoid those, the expressions $\mathbf{M}^{-1}\mathbf{K}$ and $\mathbf{M}^{-1}\mathbf{C}$ used in Eq. (2) are evaluated as follows:

$$\mathbf{M}^{-1}\mathbf{K} = \begin{bmatrix} (\mathbf{M}_{\text{original}} + \mathbf{B}_{\text{dm}}^T \mathbf{m}_{\text{TMD}} \mathbf{B}_{\text{dm}})^{-1} \cdot (\mathbf{K}_{\text{original}} + \mathbf{B}_d^T \mathbf{k}_{\text{TMD}} \mathbf{B}_d) & -(\mathbf{M}_{\text{original}} + \mathbf{B}_{\text{dm}}^T \mathbf{m}_{\text{TMD}} \mathbf{B}_{\text{dm}})^{-1} \mathbf{B}_d^T \mathbf{k}_{\text{TMD}} \\ -\Omega_{\text{TMD}}^2 \mathbf{B}_d & \Omega_{\text{TMD}}^2 \end{bmatrix} \quad (26)$$

where Ω_{TMD}^2 is a diagonal matrix with the terms $((\omega_{\text{TMD}})_{l,f})^2$ sitting on the diagonal in the order of DOFs given in Eq. (13), and:

$$\mathbf{M}^{-1}\mathbf{C} = \begin{bmatrix} (\mathbf{M}_{\text{original}} + \mathbf{B}_{\text{dm}}^T \mathbf{m}_{\text{TMD}} \mathbf{B}_{\text{dm}})^{-1} \cdot (\mathbf{C}_{\text{original}} + \mathbf{B}_d^T \mathbf{c}_{\text{TMD}} \mathbf{B}_d) & -(\mathbf{M}_{\text{original}} + \mathbf{B}_{\text{dm}}^T \mathbf{m}_{\text{TMD}} \mathbf{B}_{\text{dm}})^{-1} \mathbf{B}_d^T \mathbf{c}_{\text{TMD}} \\ -\Omega \xi_{\text{TMD}} \mathbf{B}_d & \Omega \xi_{\text{TMD}} \end{bmatrix} \quad (27)$$

where $\Omega \xi_{\text{TMD}}$ is a diagonal matrix with the terms $2 \cdot (\xi_{\text{TMD}})_{l,f} \cdot (\omega_{\text{TMD}})_{l,f}$ sitting on the diagonal in the order of DOFs given in Eq. (13).

Step 7: The TMD's mass is re-determined using two stages; the total mass of all dampers located at a given location is determined, followed by the distribution of that mass between all

TMDs at that location, having various tuning frequencies. This is done according to the recurrence relationships described below. Following the change in mass, the stiffness and modal damping ratio of each TMD are also updated while keeping the Den-Hartog principles intact, using Eqs. (15) - (19). The two-stage analysis/redesign procedure is carried out iteratively, in the following way.

Stage 1: The first stage of redesign includes the evaluation of the total mass of all TMDs at a certain location, which promises the existence of the first part of the conjecture. This is formulated using:

$$\left(\mathbf{m}_{\text{TMD,total}}^{(n+1)}\right)_l = \sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n+1)}\right)_{l,f} = \sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n)}\right)_{l,f} \cdot \left(\frac{RMS\left(\left(\ddot{\mathbf{x}}_p^{(n)}\right)_l\right)}{a_{\text{all}}^{\text{RMS}}} \right)^P \quad (28)$$

where $(\cdot)^{(n)}$ is the value at iteration n , $\left(\mathbf{m}_{\text{TMD,total}}^{(n+1)}\right)_l$ is the total mass of all dampers at location l , and P is a constant which influences the convergence and convergence rate. A large P will result in a faster but less stable convergence of the above equation. Based on the authors' experience, a P in the range of 0.1-2.0 should be satisfying in terms of stability, convergence and fair amount of iterations.

Stage 2: In the second stage of redesign, the total mass obtained at each location is distributed between N_{mode} dampers (dampening modes $(\omega_n)_f$) at that same location l , promising the existence of the second part of the conjecture, using the following:

$$\left(\mathbf{m}_{\text{TMD}}^{(n+1)}\right)_{l,f} = \left(\mathbf{m}_{\text{TMD}}^{(n)}\right)_{l,f} \left(\frac{\sqrt{\left(\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}\left((\omega_n)_f\right)\right)_l}}{\max_f \left(\sqrt{\left(\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}\left((\omega_n)_f\right)\right)_l} \right)} \right)^P \cdot \frac{\left(\mathbf{m}_{\text{TMD,total}}^{(n+1)}\right)_l}{\sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n)}\right)_{l,f} \left(\frac{\sqrt{\left(\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}\left((\omega_n)_f\right)\right)_l}}{\max_f \left(\sqrt{\left(\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}\left((\omega_n)_f\right)\right)_l} \right)} \right)^P} \quad (29)$$

where $\left(\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}\left((\omega_n)_f\right)\right)_l$ is the component of $\mathbf{R}_{\ddot{\mathbf{x}}_p^{(n)}}(\omega)$ at the location l evaluated at $\omega = (\omega_n)_f$.

The analysis/redesign procedure is continued until convergence. It shall be noted that each iteration cycle may result in either a bigger or smaller mass.

Rational: Upon convergence, i.e when values at the iteration $n+1$ are equal to the corresponding values at the iteration n , Eq. (28) is satisfied under one of two conditions. That is,

either $\sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n+1)}\right)_{l,f} = \sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n)}\right)_{l,f} \neq 0$ and thus $RMS\left(\left(\ddot{\mathbf{x}}_p^{(n+1)}\right)_l\right) = RMS\left(\left(\ddot{\mathbf{x}}_p^{(n)}\right)_l\right) = a_{\text{all}}^{\text{RMS}}$, or

$RMS\left(\left(\ddot{\mathbf{x}}_p^{(n+1)}\right)_l\right) = RMS\left(\left(\ddot{\mathbf{x}}_p^{(n)}\right)_l\right) \leq a_{\text{all}}^{\text{RMS}}$ and then $\sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n+1)}\right)_{l,f} = \sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n)}\right)_{l,f} = 0$. This por-

trays fully-stressedness in total accelerations, i.e. the first part of the conjecture. Eq. (29), on the other hand, portrays fully-stressedness in frequency response. Here, taking the sum of each side of the equation with respect to f implies that the sum of masses of TMDs at the location l and iteration $n+1$ equals the desired total mass from the first stage, $\left(\mathbf{m}_{\text{TMD,total}}^{(n+1)}\right)_l$, or

$\sum_{f=1}^{\text{all frequencies}} \left(\mathbf{m}_{\text{TMD}}^{(n+1)}\right)_{l,f} = \left(\mathbf{m}_{\text{TMD,total}}^{(n+1)}\right)_l$. This is actually attained using the fraction on the right-hand side

of Eq. (29), which is constant for all f 's. The remaining part of Eq. (29) has a similar structure to that of Eq. (28). That is, upon convergence, either $(\mathbf{m}_{\text{TMD}}^{(n+1)})_{l,f} = (\mathbf{m}_{\text{TMD}}^{(n)})_{l,f} \neq 0$ and thus $\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l} = \max_f \left(\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l} \right)$, or $\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l} \leq \max_f \left(\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l} \right)$ and then $(\mathbf{m}_{\text{TMD}}^{(n+1)})_{l,f} = (\mathbf{m}_{\text{TMD}}^{(n)})_{l,f} = 0$. This portrays fully-stressedness in frequency response, i.e. the second part of the conjecture. It should be noted that the normalization of $\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l}$ with respect to $\max_f \left(\sqrt{(\mathbf{R}_{\mathbf{x}_p}^{(n)}((\omega_n)_f))_l} \right)$ has no effect on the results of this equation and is done here only for clarification of the rational behind Eq. (29).

Step 8: Repeat steps 5 to 7 until convergence of the mass is reached.

Step 9: After the process converges, the retrofitted frame's response is validated using time history analysis for all ground-motions within the chosen ensemble.

Step 10: The percent of reduction in RMS acceleration and the percent of reduction of envelope peak accelerations in time domain may not be entirely compatible. Thus, a modification of the allowable RMS acceleration may be performed as to scale these two frequency/time domain measures, using the following:

$$a_{\text{all},l}^{\text{RMS}} = a_{\text{all}}^t \cdot \frac{\text{RMS}(\ddot{\mathbf{x}}_p^t)}{\max_{eq} \left(\max_t (\ddot{\mathbf{x}}_p^t(t))_l \right)} \quad \forall l = 1, 2, \dots, N_{\text{locations}} \quad (30)$$

where: $a_{\text{all},l}^{\text{RMS}}$ is the modified allowable RMS acceleration to be used in the frequency-domain analysis.

Once the allowable RMS acceleration is re-scaled, steps 5-9 are repeated until the reduction in peak acceleration is as desired in the performance-based design.

5 EXAMPLE

The following 8-story asymmetric RC frame structure (Fig. 4) introduced by Tso and Yao [46] is retrofitted using MTMDs for an excitation in the "y" direction. A uniform distributed mass of 0.75 ton/m^2 is taken. The column dimensions are 0.5m by 0.5m for frames 1 and 2 and 0.7m by 0.7m for frames 3 and 4. The beams are 0.4m wide and 0.6m tall. 5% Rayleigh damping for the first and second modes is used. A 40% reduction of the peripheral peak total acceleration obtained in the bare structure is desired. Hence, initially, an allowable peripheral RMS acceleration of 60% of the maximal peripheral RMS acceleration of the bare structure is adopted. The response is analyzed under a Kanai-Tajimi PSD with parameters fitted to the average FFT values of a chosen ensemble of ground-motions (SE 10 in 50). The design variables are the locations and properties of the individual tuned mass dampers. The dampers are to potentially be located in the peripheral frames, where they are most effective, and as the excitation is in the "y" direction only, dampers will be assigned only to peripheral frames 1 and 4, to dampen frequencies of modes which involve "y" and "θ". The 'stepwise flowchart' described above is closely followed to optimally design the MTMDs.

Figure 4: eight-story asymmetric structure.

Step 1: The mass, inherent damping and stiffness matrices of the frame in the dynamic DOFs shown in Fig. 1 were constructed.

Step 2: The natural frequencies, of the structure were determined. The first 10 frequencies are presented in Table 1.

Mode no.	Angular frequency (rad/sec)	Mode direction	Mode no.	Angular frequency (rad/sec)	Mode direction
1	5.135	x	6	22.407	y, θ
2	5.463	y, θ	7	29.649	x
3	7.087	y, θ	8	29.876	y, θ
4	16.240	x	9	40.918	y, θ
5	16.938	y, θ	10	44.770	y, θ

Table 1: Frequencies of the structure.

Step 3: The RMS accelerations of the undamped building at the peripheral frames in the "y" direction are presented in Fig. 5. Those were obtained using the Kanai-Tajimi PSD with parameters: $\omega_g = 13 \text{ rad/sec}$, $\xi_g = 0.98$ and $S_0 = 1$. Those parameters were determined by fitting the parameters ω_g and ξ_g to a spectrum of mean FFT values of the SE 10 in 50 ground-motion ensemble, scaled to $S_0=1.0$ (see Fig. 6). The actual value of S_0 has no effect since the allowable RMS acceleration is determined by the percentage of reduction desired. The allowable RMS acceleration for all peripheral accelerations was earlier adopted as 60% of the maximum peripheral RMS acceleration of the bare frame, giving: $a_{\text{all}}^{\text{RMS}} = 15.95$. It is assumed, as a first guess, that a similar reduction would be achieved in the envelope peak acceleration in time domain.

Figure 5: Peripheral RMS accelerations of bare structure (continuous) and allowable values (dashed).

Figure 6: chosen input power-spectral-density.

Step 4: 160 TMDs were added, as a first guess, with initial properties as given in Table 2. Those are comprised of 10 dampers each tuned to a different mode frequency (of modes related to "y" and "θ") at each of the 16 peripheral locations of frames 1 and 4.

No. TMD	mode to dampen	Initial mass (ton)	Initial natural frequency (rad/sec)	Initial damping ratio
1-16	2	2.592	5.37	0.0788
17-32	3	2.592	6.89	0.1004
33-48	5	2.592	16.64	0.0795
49-64	6	2.592	21.78	0.0998
65-80	8	2.592	29.34	0.0805
81-96	9	2.592	39.79	0.0989
97-112	11	2.592	43.94	0.0816
113-128	12	2.592	60.28	0.0822
129-144	13	2.592	62.30	0.0983
145-160	15	2.592	77.55	0.0826

Table 2: Initial properties of TMDs.

Step 5: The mass, stiffness and damping matrices were updated using Eqs. (20) - (25).

Step 6: With the newly-updated matrices and the same PSD input, new peripheral RMS accelerations, shown in Fig. 7 (for frames 1 and 4), were evaluated using Eq. (8) – (12). Peripheral accelerations smaller than the allowable, were attained for all floors of frames 5 and 8 (see Fig. 4 for frame numbering).

Figure 7: Peripheral RMS accelerations of structure with initial TMDs (continuous) and allowable values (dashed).

Step 7: The problem has not converged, and thus the TMDs' properties were altered, using the recurrence relations of Eqs. (28) and (29), while using $P=2$ as the convergence parameter, giving updated total masses at each DOF. For example, the newly updated mass of all TMDs

at floor 1 of peripheral frame 1 is: $m_{TMD,1}^{(i)} = 2.592 \cdot \left(\frac{9.41}{15.92} \right)^2 = 0.906$ for a RMS total acceleration of 9.41 at that location (frame 1, 1st floor) after adding initial TMDs (Fig. 7). The total mass of each peripheral coordinate was then distributed between the 10 dampers at the same location using Eq. (29).

Step 8: Iterative analysis/redesign as described in Eqs. (28) and (29) while altering the mass of the damper is carried out until convergence to allowable levels. Upon convergence the dampers' total mass at each location are shown in Table 3.

TMDs with non-zero properties were located at frames number 1 and 4 at, both at the 8th floor, which is the top floor of each peripheral frame. The final properties of each added TMD are shown in Table 4. For frame number 1, the TMDs are set to dampen mode 2, while for frame number 4, the TMDs are set to dampen modes 2 and 3.

floor	Total mass frame 1	Total mass frame 4
1-7	0	0
8	112.69	6.25

Table 3: Total mass of TMDs upon convergence

frame	floor	mode to dampen	Final mass (ton)	Final stiffness (kN/m)	Final damping ratio
1	8	2	112.69	2472.15	0.1983
4	8	2	5.69	124.89	0.1983
4	8	3	0.55	27.72	0.0209

Table 4: Final properties of added TMDs

Finally, an analysis of the retrofitted structure yields the peripheral RMS accelerations shown in Fig. 8.

Figure 8: Peripheral RMS accelerations of structure with final TMDs (continuous) and allowable values (dashed).

All 4 assigned TMDs add up to 4.59% of the original structure's mass. As can be seen, only floors who had reached the maximum allowable RMS total acceleration (Fig. 8) were assigned with added absorbers (Table 4), making the solution obtained a FSD.

Fig. 9 presents the convergence of the design variables (masses) and the performance measure (acceleration). As can be seen in Fig. 9, although the initial guess was very far from optimum, convergence is practically reached within less than 40 iterations.

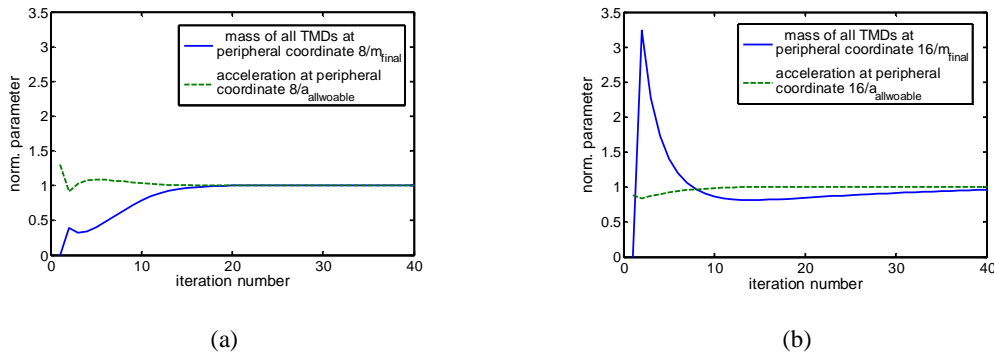

Figure 9: Convergence of sum of masses and RMS acceleration at (a) 8th floor of peripheral frame number 1 and (b) 8th floor of peripheral frame number 4.

Step 9: The retrofitted structure was examined using time-history analysis under the SE 10 in 50 ensemble of real recorded earthquakes, scaled by a factor of 0.8, to check the validity of the solution obtained. The results of the envelope peak peripheral total accelerations and inter-story drifts of frames 1 and 4 obtained using time-history analysis are shown in Fig. 10. Smaller accelerations were attained in frames 5 and 8.

The results reveal that for this ensemble, the envelope maximum total acceleration of all locations of the bare structure was at the 8th floor of frame number 1, equaling 1.34g, while the envelope maximum total acceleration of all locations of the damped structure was 1.11g

(8th floor of frame 4). This represents a 17% reduction in acceleration response, not so close to the desired reduction of 40% in maximum response.

Although reducing the drifts was not part of the design process, it can be seen that these too were appreciably reduced. The maximum peripheral drift of all locations was reduced from 1.95% in the bare structure to 1.30% in the damped structure.

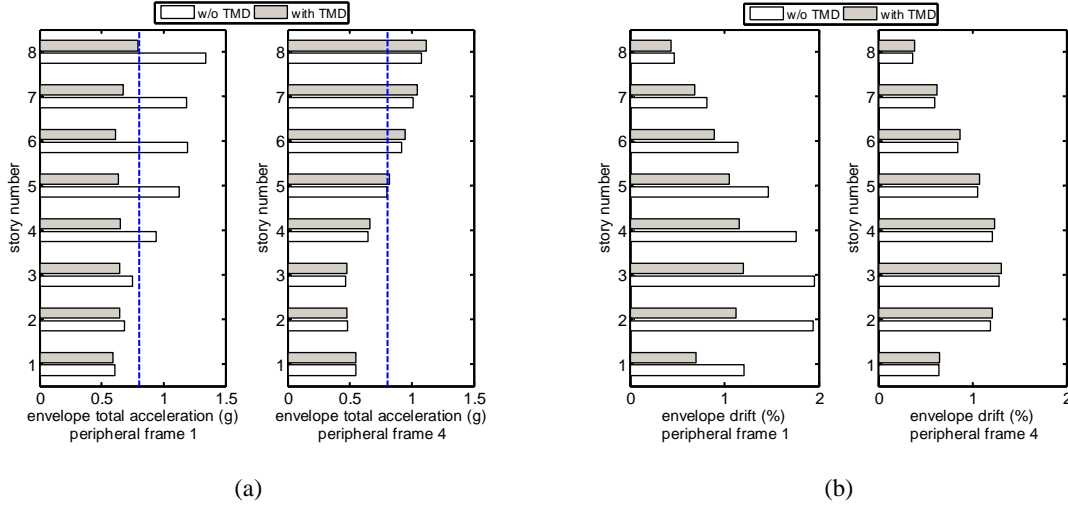

Figure 10: Peripheral envelope (a) accelerations and allowable values (dashed) and (b) drifts of the bare and damped structure under the SE 10 in 50 ground motion ensemble.

Step 10: For a more accurate design, the allowable RMS total acceleration of each story is modified to better reflect the allowable peak acceleration, using Eq. (30).

In this case, a 40% reduction in envelope peak acceleration is desired, thus $a_{all}^t = 0.6 \cdot \max_i \left(\max_{eq} \left(\max_t \left(\ddot{\mathbf{x}}_p^t(t)_{frame-1}^{bare} \right) \right) \right) = 0.6 \cdot 1.34 = 0.804 g$. For example, for location 8

(frame 1, 8th floor): $a_{all,8}^{RMS} = 0.804 \cdot \frac{15.952}{0.795} = 16.15$. Using this modification, the analy-

sis/redesign process (steps 5-9) is repeated until convergence is once again reached. After convergence, the total mass was increased to 8.36% of the structure's mass. The modified retrofitted structure was again examined using time-history analysis under the SE 10 in 50 ensemble scaled by a factor of 0.8. The reduction between maximal envelope acceleration of all floors of the bare and damped structure was increased to 34.8%. The results can be modified yet again using step 10. After the third modification, the added mass of all TMDs increased to 8.87% (see Table 5), while the envelope peak total acceleration equaled 0.82g, representing a 39.0% reduction in response, which is very close to the desired reduction of 40%. The results of the envelope peak peripheral total accelerations and inter-story drifts of frames 1 and 4 obtained using time-history analysis are shown in Fig. 11.

frame	floor	mode to dampen	Final mass (ton)	Final stiffness (kN/m)	Final damping ratio
1	8	2	114.18	2397.4	0.2062
4	8	2	115.81	2431.7	0.2062

Table 5: Final properties of added TMDs after 3rd modification

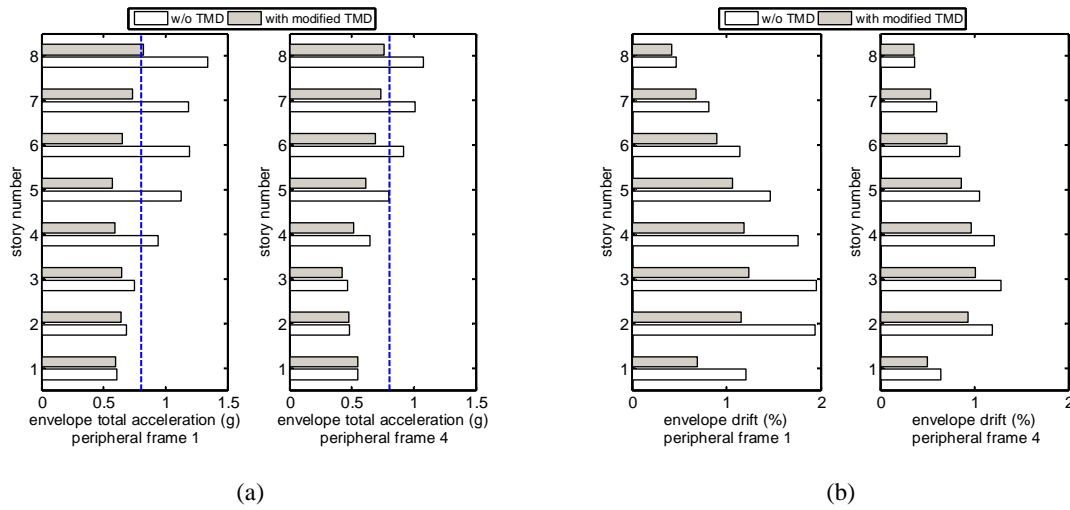

Figure 11: Peripheral envelope (a) accelerations and allowable values (dashed) and (b) drifts of the bare and 3rd-time modified damped structure under the SE 10 in 50 ground motion ensemble.

6 CONCLUSIONS

An analysis/redesign frequency-domain-based methodology for optimally allocating and sizing MTMDs in 3D irregular structures was presented. The proposed methodology considers the possible dampening of all modes of the structure, at all peripheral frames, thus eliminating the decision of what modes to dampen and where the TMDs should be allocated. As shown, using MTMDs tuned to various frequencies can efficiently reduce total accelerations within the structure and bring them to a desired level, allowing for performance based design. The advantages of this methodology are its simplicity of use and relying solely on analysis tools to solve the allocation and sizing problem, with no assumptions or pre-selection of any design variable. These advantages make the proposed methodology very attractive and efficient for practical use.

The methodology is based on the following conjecture: *At the optimum, TMDs are assigned to peripheral locations for which the RMS total acceleration has reached the allowable value under the considered input acceleration PSD. In addition, at each location to which TMDs are added, TMDs of a given frequency are assigned only to frequencies for which the output spectral density is maximal.* And the designs are attained using a very simple analysis/redesign based methodology suggested.

As previously mentioned, detuning of the TMDs may cause major deterioration to the passive control system. Depending on the level of detuning expected, a TMD located at location l tuned to dampen mode f can be split into several smaller TMDs, each with a slightly different frequency within a bandwidth close to the natural frequency f of the main system. Thus reduction of the detuning effect and design robustness could be achieved. This could be done a-priori and taken into account in the design methodology. In cases where the damped structure is not brought to behave linearly, and damage to the structural system is apparent, the natural frequencies of the structure may change considerably. In those cases, a design according to the proposed scheme, combined with the use of semi-active TMDs (for example, [15, 16, 17]) which allow the simple change of the TMD's tuning, while still keeping the control system's low-cost, could be beneficial.

Keywords: Vibration ball absorber, Dynamic stability, Nonlinear vibration.

Abstract. *Wind excited vibrations of slender structures such as towers, masts or certain types of bridges can be reduced using passive or active vibration absorbers. If there is available only a limited vertical space to install such a device, a ball type of absorber can be recommended. In general, it is a semi-spherical horizontal dish in which a ball of a smaller diameter is rolling. Ratio of both diameters, mass of the rolling ball, quality of contact surfaces and other parameters should correspond with characteristics of the structure. The ball absorber is modeled as a holonomous system. Using Lagrange equations of the second type, governing non-linear differential system is derived. The solution procedure combines analytical and numerical processes. As the main tool for dynamic stability investigation the 2nd Lyapunov method is used. The function and effectiveness of the absorber identical with those installed at the existing TV towers was examined in the laboratory of the Institute of Theoretical and Applied Mechanics. The response spectrum demonstrates a strongly non-linear character of the absorber. The response amplitudes at the top of a TV tower with ball absorber were reduced to 15 ÷ 40% of their original values.*

1 INTRODUCTION

Passive vibration absorbers of various types are very widely used in civil engineering, especially when wind induced vibration should be suppressed. TV towers, masts and other slender structures exposed to wind excitation are usually equipped by such devices. Conventional passive absorbers are of the pendulum type. Although they are very effective and reliable, they have several disadvantages limiting their application. First of all, they have certain requirements to space, particularly in a vertical direction. These requirements cannot be satisfied any time when an absorber should be installed as a supplementary equipment. Also horizontal construction, like foot bridges, cannot accept any absorber of the pendulum type. Another disadvantage represents a need of a regular maintenance.

Both above shortcomings can be avoided using the absorber of ball type. The basic principle comes out of a rolling movement of a metallic ball of a radius r inside of a metallic rubber coated dish of a radius $R > r$. This system is closed in an airtight case. Such a device is practically maintenance free. Its vertical dimension is relatively very small and can be used also in such cases where a pendulum absorber is inapplicable due to lack of vertical space or difficult maintenance. First papers dealing with the theory and practical aspects of ball absorbers have been published during the last decade, see [1] and [2].

Dynamics of the ball absorber is more complicated in comparison with the pendulum one. Its movement can be hardly described in a linear state although for the first view its behavior is similar to the pendulum absorber type. A number of problems are still open being related with movement stability, bifurcations, auto-parametric resonances and at least but not last with dish and ball surface imperfections. This paper presents basic mathematical model in 2D together with its numerical evaluation and practical application as far as to the state of the realization including some results of long-term measurements.

2 MATHEMATICAL MODEL IN TWO DIMENSIONS

The dish is fixed to a vibrating structure. Their dynamic character is represented by a linear SDOF system represented by a mass M . Inside of a dish an internal ball m in a vertical plane is moving, i.e. 2DOF system should be investigated, as it is outlined in the Fig. 1. It follows from geometric relations:

$$R \cdot \varphi = r(\psi + \varphi) \Rightarrow r\psi = \varrho\varphi \quad (1)$$

where $\varrho = R - r$. It holds for vertical, or horizontal components of a displacement and velocity of the internal ball centre:

$$\left. \begin{array}{l} \text{horiz.:} \quad u + \varrho \cdot \sin \varphi \Rightarrow \dot{u} + \varrho \dot{\varphi} \cos \varphi \\ \text{vert.:} \quad \varrho \cdot \cos \varphi \Rightarrow -\varrho \dot{\varphi} \sin \varphi \end{array} \right\} \quad (2)$$

Kinetic energy of a moving system of balls m, M can be written in a form:

$$T = \frac{1}{2}m[(\dot{u} + \varrho \dot{\varphi} \cos \varphi)^2 + \varrho^2 \dot{\varphi}^2 \sin^2 \varphi] + \frac{1}{2}J\dot{\psi}^2 + \frac{1}{2}M\dot{u}^2 = \frac{1}{2}(m+M)\dot{u}^2 + m\varrho\dot{u}\dot{\varphi} \cos \varphi + \frac{m}{2\kappa}\varrho^2 \dot{\varphi}^2 \quad (3)$$

Figure 1: Basic scheme of a system

$m/\kappa = m + J/r^2 \Rightarrow \kappa = 5/7$, while the potential energy is given by an expression:

$$V = mg\rho(1 - \cos \varphi) + \frac{1}{2}Cu^2 \quad (4)$$

The damping should be introduced in a form of a simple Rayleigh function:

$$B = \frac{1}{2}(Mb_u\dot{u}^2 + mb_\varphi\dot{\varphi}^2) \quad (5)$$

- m – mass of the ball m ;
- J – inertia moment of the ball m ;
- b_u, b_φ – damping coefficients (logarithmic decrements);

Expressions (3), (4), (5) should be put into the Lagrange equations of the second type, see e.g. [3]:

$$\sum_{r=1}^n \left\{ \frac{d}{dt} \left(\frac{\partial T}{\partial \dot{q}_r} \right) - \frac{\partial T}{\partial q_r} + \frac{\partial V}{\partial q_r} + \frac{\partial B}{\partial \dot{q}_r} \right\} \delta q_r = P_r(t) \quad (6)$$

$$q_1 = u = \zeta \cdot \rho; \quad q_2 = \varphi; \quad P_u(t) = p(t) \cdot M\rho; \quad P_\varphi(t) = 0$$

which give the governing equations of the system:

$$\ddot{\varphi} + \kappa b_\varphi \dot{\varphi} + \kappa \omega_m^2 \sin \varphi + \kappa \ddot{\zeta} \cdot \cos \varphi = 0 \quad (a)$$

$$\mu \ddot{\varphi} \cos \varphi - \mu \dot{\varphi}^2 \sin \varphi + (1 + \mu) \ddot{\zeta} + b_u \dot{\zeta} + \omega_M^2 \zeta = p(t) \quad (b) \quad (7)$$

$$\mu = m/M; \quad \omega_M^2 = C/M; \quad \omega_m^2 = g/\rho \quad (c)$$

Eq. (7) describes 2D movement of a ball absorber under excitation by the force $P(t)$ at any arbitrary deviation amplitudes including incidental transition through a limit cycle towards an open regime.

3 THEORETICAL ANALYSIS OF THE ABSORBER

Theoretical efficiency of the absorber will be assessed using its frequency characteristics for excitation of the mass M by harmonic force $p(t) = p_0 \cdot \sin \omega t$ simulating influence of external loading or for kinematic excitation of the same mass M . In the later case the movement of the ball m rolling inside of the dish is fully described by Eq. (7a). Should we solve the deviation $\varphi(t)$, Eq. (7b) can serve us subsequently for an evaluation of the force $p(t)$, which is necessary when the deviation $u(t) = \rho \cdot \zeta(t)$ should be achieved. To obtain frequency characteristics the harmonic excitation $\zeta(t) = \zeta_o \cos(\omega t)$ should be introduced into Eq. (7), which yields:

$$\ddot{\varphi} + \kappa b_\varphi \dot{\varphi} + \kappa \omega_m^2 \sin \varphi - \kappa \omega^2 \cos \varphi \cdot \zeta_o \cos \omega t = 0 \quad (a) \quad (8)$$

$$\mu \ddot{\varphi} \cos \varphi - \mu \dot{\varphi}^2 \sin \varphi + (-(1 + \mu)\omega^2 + \omega_M^2) \zeta_o \cos \omega t - b_u \omega \cdot \zeta_o \sin \omega t = p(t) \quad (b)$$

Eq. (8a). corresponds to the equation of a mathematical pendulum excited in a point of suspension. Its effective mass is increased due to a moment of inertia of the ball m by the factor $1/\kappa = 7/5$. Even in practice the movement amplitudes of this ball do not admit to linearize the Eq. (8a). At least a simple Duffing non-linear form should be retained:

$$\ddot{\varphi} + \kappa b_\varphi \dot{\varphi} + \kappa \omega_m^2 \left(\varphi - \frac{1}{6} \varphi^3 \right) - \kappa \omega^2 \left(1 - \frac{1}{2} \varphi^2 \right) \cdot \zeta_o \cos \omega t = 0 \quad (9)$$

Let us concentrate in this paper to the prior case when the excitation of a harmonic force is taken into account. As the resulting system is auto-parametric, the corresponding methods can be applied, see e.g. [4]. Expecting a single mode response, following approximate expressions for excitation and response can be written (c.f. e.g. [5]):

$$\begin{aligned} p(t) &= p_0 \sin(t\omega) \\ \varphi(t) &= \alpha \sin(t\omega) + \beta \cos(t\omega) \\ \zeta(t) &= \gamma \sin(t\omega) + \delta \cos(t\omega) \end{aligned} \quad (10)$$

Having four new variables $\alpha = \alpha(t), \beta = \beta(t), \gamma = \gamma(t), \delta = \delta(t)$ instead of two original unknowns $\varphi(t), \zeta(t)$, two additional conditions can be freely chosen:

$$\dot{\alpha} \sin(t\omega) + \dot{\beta} \cos(t\omega) = 0, \quad \dot{\gamma} \sin(t\omega) + \dot{\delta} \cos(t\omega) = 0 \quad (11)$$

After substitution (10) and (11) into (7) and substituting the sin and cos functions by two terms of Taylor expansion, the harmonic balance procedure gives differential system for unknown amplitudes $\mathbf{X} = (\alpha, \beta, \gamma, \delta)^T$, see e.g. [6] or [7].

$$\mathbf{M}(\mathbf{X})\dot{\mathbf{X}} = \mathbf{F}(\mathbf{X}) \quad (12)$$

The system (12) for amplitudes $\mathbf{X}(t)$ is meaningful if they are functions of a "slow time", in other words if their changes within one period $2\pi/\omega$ are small or vanishing and individual steps of the harmonic balance operation are acceptable. The matrix \mathbf{M} and right hand side vector \mathbf{F} have the following form

$$\mathbf{M} = \begin{pmatrix} 0 & -\omega & -\frac{1}{4}\alpha\beta\kappa\omega & \frac{1}{8}\kappa\omega A_\alpha \\ \omega & 0 & -\frac{1}{8}\kappa\omega A_\beta & \frac{1}{4}\alpha\beta\kappa\omega \\ -\frac{1}{8}\mu\omega A_\beta & \frac{1}{4}\alpha\beta\mu\omega & (\mu+1)\omega & 0 \\ -\frac{1}{4}\alpha\beta\mu\omega & \frac{1}{8}\mu\omega A_\alpha & 0 & -(\mu+1)\omega \end{pmatrix} \quad (13)$$

$$\mathbf{F} = \frac{1}{48} \begin{pmatrix} 6A_0\kappa(3\gamma\omega^2 - \alpha\omega_m^2) + 12\omega^2(\kappa(\alpha\beta\delta + (8 - \beta^2)\gamma) - 4\alpha) - 48\beta\kappa\omega b_\varphi \\ 6A_0\kappa(\delta\omega^2 - \beta\omega_m^2) + 12\omega^2(\alpha\gamma\kappa + \beta\delta\kappa - 4)\beta + 48\alpha\kappa\omega b_\varphi \\ \omega^2(A_0(A_0 + 22)\beta\mu - 16(3\delta(\mu+1) - 4\beta\mu)) + 48(\gamma\omega b_u + \delta\omega_M^2) \\ \omega^2(A_0(A_0 + 22)\alpha\mu - 16(3\gamma(\mu+1) - 4\alpha\mu)) - 48(\delta\omega b_u - \gamma\omega_M^2 + p_0) \end{pmatrix} \quad (14)$$

where

$$A_0 = \alpha^2 + \beta^2 - 8, \quad A_\alpha = 3\alpha^2 + \beta^2 - 8, \quad A_\beta = \alpha^2 + 3\beta^2 - 8$$

Determinant of the system matrix \mathbf{M} can be easily evaluated:

$$\det(\mathbf{M}) = -\frac{\omega^4}{4096} (64(\kappa-1)\mu + \kappa\mu\Delta_1 R^2 - 64) (64(\kappa-1)\mu + \kappa\mu\Delta_3 R^2 - 64) \quad (15)$$

$$\Delta_1 = (R^2 - 16), \quad \Delta_3 = 3(3R^2 - 16)$$

where $R^2 = R^2(t) = \alpha^2 + \beta^2$ is the amplitude of φ . Polynomial (15) has four roots R_1^2, \dots, R_4^2 :

$$3R_1^2 = R_2^2 = 8 \left(1 - \frac{\mu+1}{\sqrt{\kappa\mu(\mu+1)}} \right), \quad 3R_3^2 = R_4^2 = 8 \left(1 + \frac{\mu+1}{\sqrt{\kappa\mu(\mu+1)}} \right) \quad (16)$$

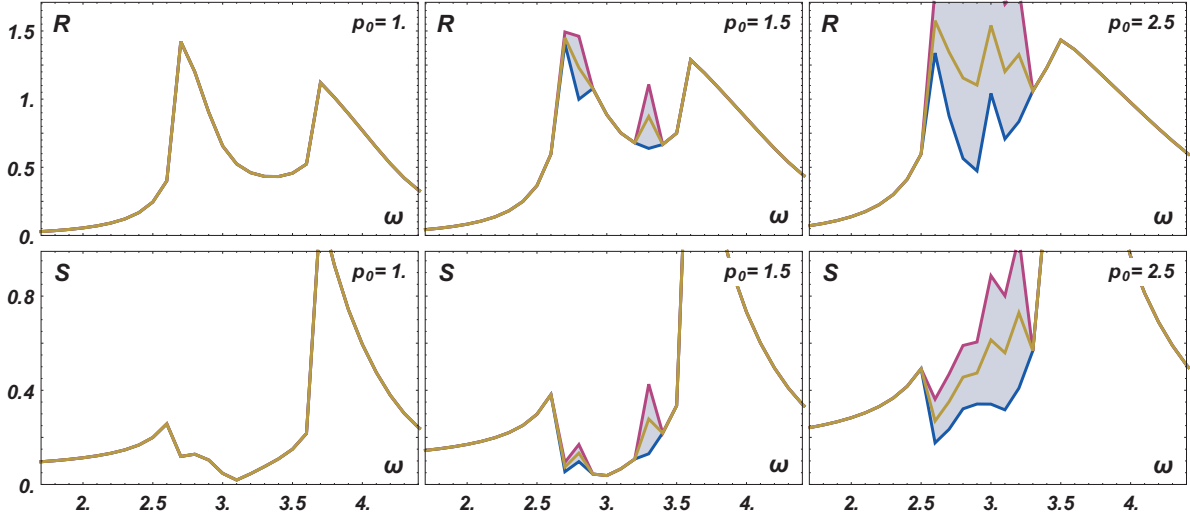

Figure 2: Stabilized numerical solution Eq. (12). Values of the amplitude $R = \sqrt{\alpha^2 + \beta^2}$ (variable φ , first row) and $S = \sqrt{\gamma^2 + \delta^2}$ (variable ζ , second row) are shown for three selected excitation amplitudes $p_0 = 1, 1.5, 2.5$. The excitation frequency ω is on the horizontal axis. Greyed areas correspond to the frequency region of non-stationary response.

For positive μ and $0 < \kappa < 1$ are the first two roots negative, the last two roots are positive. The negative roots have not any physical meaning, whereas the positive roots form strictly decreasing functions of parameter μ . For $\kappa = 5/7$ (see (3)) it holds:

$$\lim_{\mu \rightarrow \infty} R_3^2 = \frac{8}{15} (5 + \sqrt{35}) \approx 5.82191, \quad \lim_{\mu \rightarrow \infty} R_4^2 = 8 \left(1 + \sqrt{\frac{7}{5}} \right) \approx 17.4657 \quad (17)$$

With respect to the meaning of variable φ , even the lower value should not be reached in any real case.

Knowing the exact form and regularity properties of the system matrix \mathbf{M} , its inverse could be easily derived and then the normal form of the differential equation (12) can be established. However, as long as the matrix \mathbf{M} is regular, the original right hand side \mathbf{F} can be studied equivalently.

Let us consider stationary response of the system. In this case, the derivatives $d\mathbf{X}/dt$ vanish and the right hand side \mathbf{M} has to vanish too. Eq. (12) degenerates to the form of:

$$\mathbf{F}(\mathbf{X}) = 0 \quad (18)$$

Thus, to identify the stationary solutions, the zero solution points of \mathbf{F} , depending on the excitation frequency and amplitude, should be traced. In the same time, the signum and the zero points of the Jacobian $\det(\mathbf{JF})$ have to be checked. Negative value of the Jacobian for a particular point indicates that the corresponding solution is stable, whereas when Jacobian vanishes a bifurcation could occur.

The curve $\mathbf{F}(\alpha, \beta, \gamma, \delta, \omega) = 0$, projected into the planes (ω, R) or (ω, S) (for $S^2 = \gamma^2 + \delta^2$), forms the resonance curves known from the analysis of linear oscillators. However, correspondence of this curve to the original equation (7) is limited to the case of stationary response. It is necessary to remind, that limits of stationarity of the response cannot be determined from properties of Eq. (18) itself. The complete Eq. (12) has to be taken into account for this purpose.

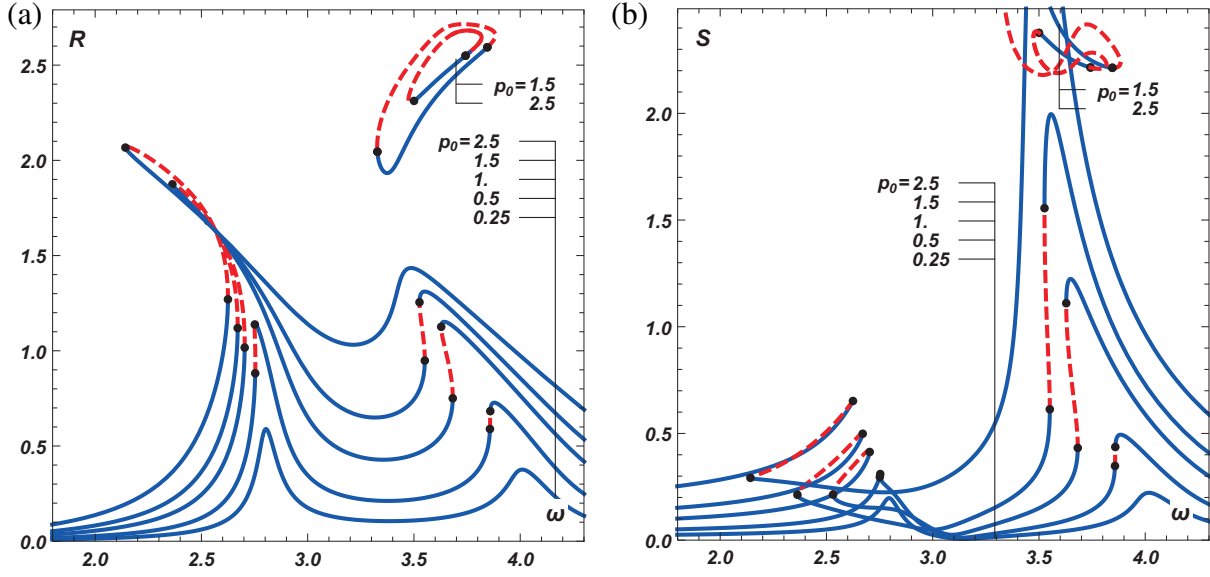

Figure 3: Non-linear resonance curves describing the stationary response of the system computed as zero solutions of Eq. (18) for excitation amplitudes $p_0 = 0.25, 0.5, 1, 1.5, 2.5$. Stable branches are shown as solid blue curves, unstable parts are indicated as the red dashed curves. Amplitudes $R = \sqrt{\alpha^2 + \beta^2}$ are shown in the left part of the figure, amplitudes $S = \sqrt{\gamma^2 + \delta^2}$ are on the right.

4 NUMERICAL ANALYSIS

The aim of this study is a basic engineering approach demonstrating the problem as a whole from the theoretical background until realization in practice. Thus, the numerical analysis has been selected as it leads the most quickly to a basic overview about dynamic properties of a ball absorber.

With respect to actual experiences regarding passive vibration absorbers and some interesting properties of the system (7), following reference input data have been introduced:

$$M = 10.0 ; m = 2.0 ; \varrho = 0.71 ; b_\varphi = 0.1 ; b_u = 0.2 ; C = 140 ; p_o = 0.5 \div 2.5 \quad (19)$$

Several analysis procedures have been performed:

- (a) Numerical integration of Eq. (7) shows the response characteristics of the system.
- (b) Numerical solution of Eq. (12) can help to decide if the response is stable or unstable.
- (c) Analysis of the term $F(X)$ given by Eq. (18) gives the resonance curve including the unstable branches.

Frequency response characteristics of the Eq. (12) for the particular data is shown in the Fig. 2. This non-linear equation has to be solved numerically. Starting from non-trivial initial conditions solution $\alpha(t), \beta(t), \gamma(t), \delta(t)$ stabilizes after certain time. Mean value and standard deviation of the stabilized amplitudes $R = \sqrt{\alpha^2 + \beta^2}$ (variable φ , first row) and $S = \sqrt{\gamma^2 + \delta^2}$ (variable ζ , second row) depending on the excitation frequency ω are shown in Fig. 2. The variance of the amplitudes is shown as greyed area around the mean curve. Thus, the greyed areas indicate regions where a non-stationary solution should be expected (amplitudes R and S are not constant). It should be emphasized here, that validity of the Eq. (12) in non-stationary case is limited, as it was derived with an assumption of slow time change of the amplitudes.

Utilizing the Eqs. (18) and (14), the non-linear resonance curves describing the stationary response of the system (7) can be obtained. A set of such curves for excitation amplitudes $p_0 = 0.25, 0.5, 1, 1.5, 2.5$ is shown in the Fig. 3. It is obvious for the first view the non-linear

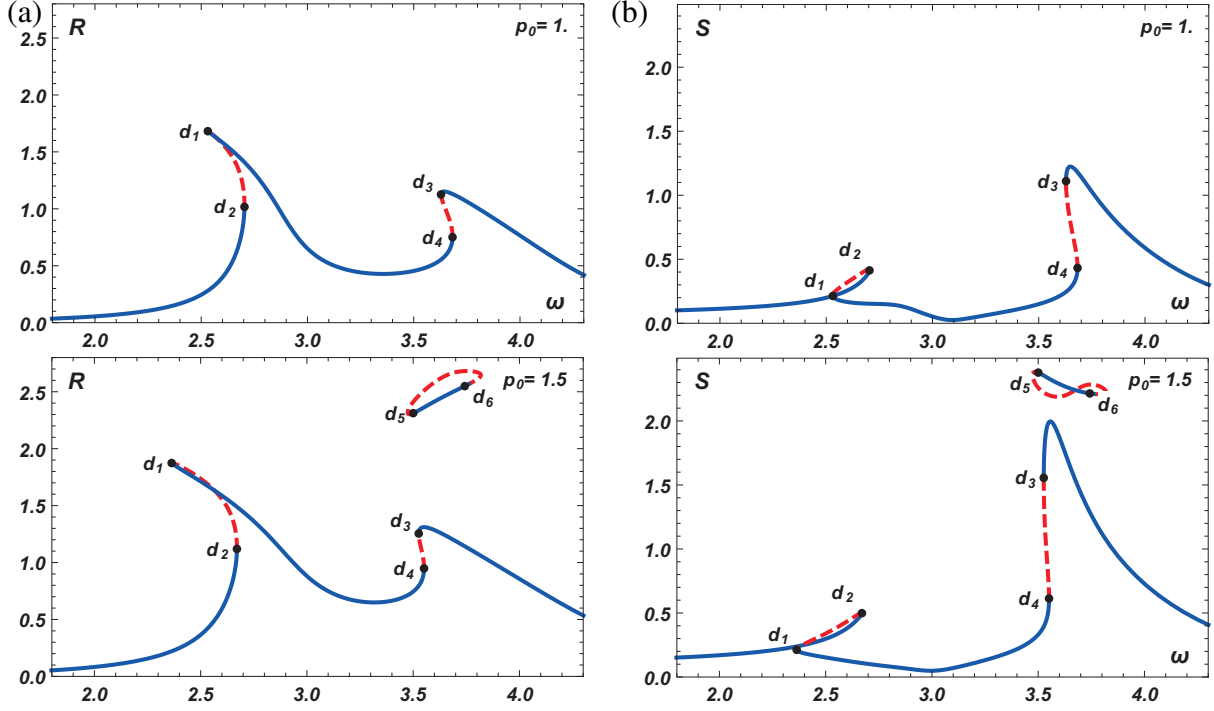

Figure 4: Selected non-linear resonance curve for $p_0 = 1$ and $p_0 = 1.5$. (a) The case for $R = \sqrt{\alpha^2 + \beta^2}$ is on the left, (b) case for $S = \sqrt{\gamma^2 + \delta^2}$ is in the right part of the figure. Points d_1, \dots, d_6 correspond to zero points of Jacobian \mathbf{JF} and indicate change of stability properties of the curve.

character manifesting oneself by a dependence of a position of extreme points on an amplitude of excitation force. This effect is visible predominantly in a neighbourhood of a conventional "linear" natural frequency of the absorber although also the second natural frequency corresponding to the original natural frequency of the structure is affected. The resonance curves are typical for a system with "softening" non-linearities. It turns out that the non-linear element represented by a ball absorber can be more effective when broad band random response should be reduced. Even better results can be expected in case of non-stationary excitation when amplitude spectrum is significantly variable in time. In such a case no doubt non-linear absorber should be preferred, while the linear one works better in cases of strong narrow band excitation mostly of deterministic character.

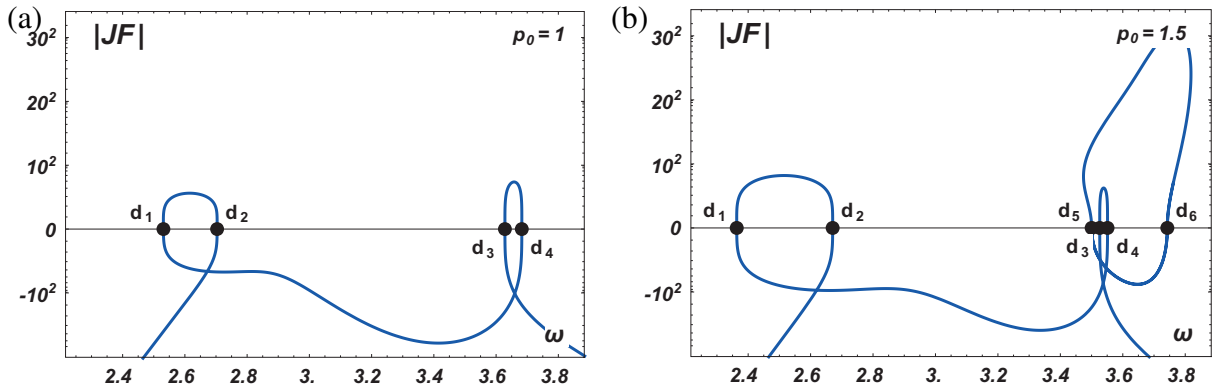

Figure 5: Values of Jacobi determinant $\det(\mathbf{JF})$ corresponding to the stationary resonance curve for $p_0 = 1$ (a) and $p_0 = 1.5$ (b). Negative values indicate stable branches of the resonance curve and vice versa. Closed curve in the right part of fig. (b) correspond to the isolated part of the resonance curve, c.f. second row of Fig. 4.

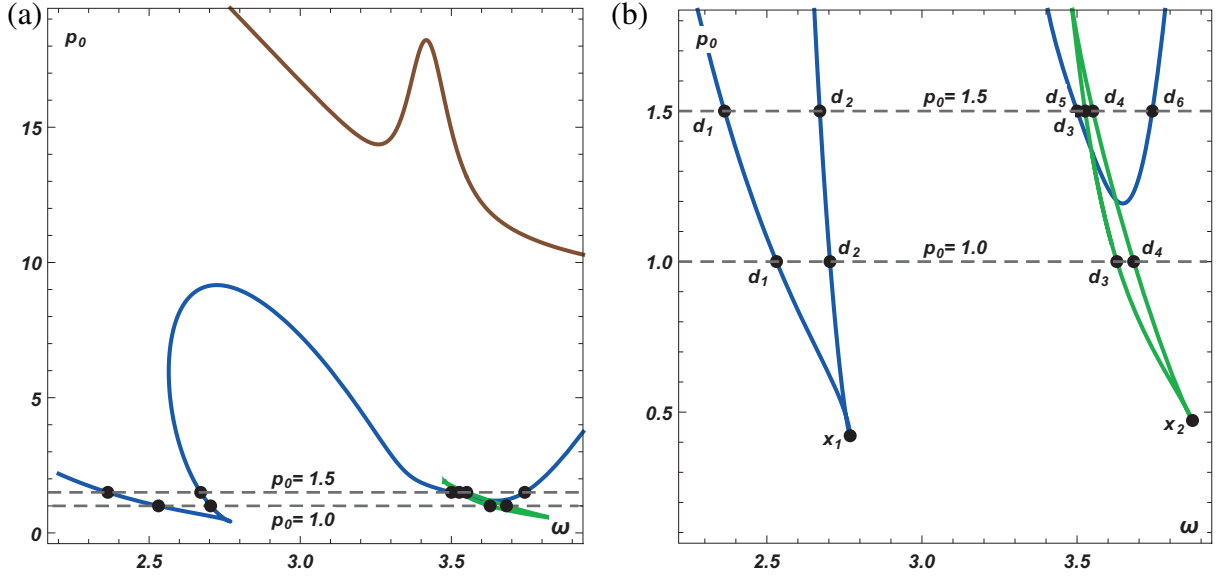

Figure 6: (a) Position of zeroes of the Jacobian in the (ω, p_0) plane. (b) Zoomed view of the interesting area for $p_0 \in (0, 2)$ of the figure (a). Points d_1, \dots, d_6 are indicated on the level of $p_0 = 1$ and $p_0 = b$, c.f. figures 4 and 5. Points x_1 and x_2 show the critical values of p_0 computed using Eq. (20-21).

Let us comment the isolated curves indicating high amplitudes of response for $p_0 = 2$ and 3. Limit value for R , as it results from the roots of the $\det(\mathbf{M})$ (Eq. (15)) is for data (19) $R < 3.22$. This limit is for the high curves in Fig. 3 still not violated. However, these curves have not any physical meaning in this case: (i) such high amplitudes of R are unrealistic, (ii) Eq. (12) was derived utilizing two terms of Taylor expansions for \sin and \cos functions and thus assuming only "small" amplitudes.

Let us study in more detail the stability of one particular curve from Fig. 3, the one for $p_0 = 1$. The both R and S (or φ and ζ respectively) resonance dependencies are shown in the first row of Fig. 4. The solid parts of the curves correspond to the stable solution, whereas the red dashed sections correspond to the unstable solution of Eq. (18). Second row of Fig. 4 shows similar curves for higher excitation amplitude $p_0 = 1$. The isolated part of the response curve is present in this case.

Response of a real system cannot be expected to reach values of a unstable part of resonance curve. The stability of the individual sections of the curves follows from the sign of the Jacobian. Course of this value, corresponding to the curves in Fig. 4 is shown in Fig. 5a for $p_0 = 1$ and in Fig. 5b for $p_0 = 1.5$. Here the points d_1, \dots, d_4 or d_1, \dots, d_6 correspond to zero points of Jacobian \mathbf{JF} and indicate change of stability properties of the curve, c.f. all parts of Fig. 4. Closed curve in the right part of Fig. 5b correspond to the isolated part of the resonance curve.

Existence of the unstable branches could serve as a characteristic of the system from the engineering point of view. It can be stated, that until the system properties (structural parameters) and the expected excitation amplitude are such that no unstable part of the resonance curve occurs, almost linear and stationary behaviour of the system can be expected. Positions of the dangerous values of the excitation amplitude p_0 depending on the excitation frequency are shown in Fig. 6. The overall situation for the system defined by values (19) is shown in the left part of the figure (a), whereas the part of realistic expected amplitudes is shown in the part (b). Positions of points d_1, \dots, d_4 corresponding to the excitation amplitude $p_0 = 1$ and d_1, \dots, d_6 for $p_0 = 1.5$ are shown in the both parts of the Fig. 6.

The curves from the Fig. 6 can be relatively easily computed from the algebraic system

$$\begin{aligned} \det(\mathbf{JF}(\mathbf{X}, \omega)) &= 0 \\ \mathbf{F}(\mathbf{X}, \omega, p_0) &= 0 \end{aligned} \quad (20)$$

Having a solution of (20) for any particular value of ω and p_0 the curves can be considered as parameter dependent $\omega(s)$ and $p_0(s)$ and traced e.g. using the arc-length method. The extremal values are then such points $(\omega(s), p_0(s))$ that

$$\partial_s \omega(s_0) = \partial_s p_0(s_0) = 0 \quad (21)$$

To cover all the extremes, the relation (21) has to be used for all interesting solutions obtained from the system (20). For data defined by (19) are the critical values of the amplitude p_0 shown in the Fig. 6 as points x_1 and x_2 . Corresponding critical values of p_0 are $p_{0,x_1} = 0.421$ and $p_{0,x_2} = 0.472$ for $\omega_{x_1} = 2.77$ and $\omega_{x_2} = 3.87$.

For sake of comparison, the non-linear resonance curve for $p_0 = 1$ is shown together with result of the frequency response relation, which has been obtained using numerical integration of the original system (7) for excitation amplitude $p_0 = 1$. As it can be seen from the Fig. 7, the agreement is rather good. Relatively low non-stationarity can be seen as the greyed areas of the curve for ω just above points d_2 and d_4 . For other excitation amplitudes the graphs resemble the Fig. 3 and thus are not shown here.

It appears, that increasing the excitation amplitude over a certain limit a domain of unstable chaotic response to deterministic excitation emerges. It does not reveal that this domain increases significantly when random instead of deterministic excitation is applied. Nevertheless a presence of chaotic response domain is for the sake of the structure, as the effective response amplitudes are decreasing under these circumstances due to the rapid increase of the entropy of the response probability density.

On the other hand it is necessary to remain realistic. During testing in laboratory many effects corresponding to various critical and post-critical effects have been observed which are not yet described and quantified theoretically.

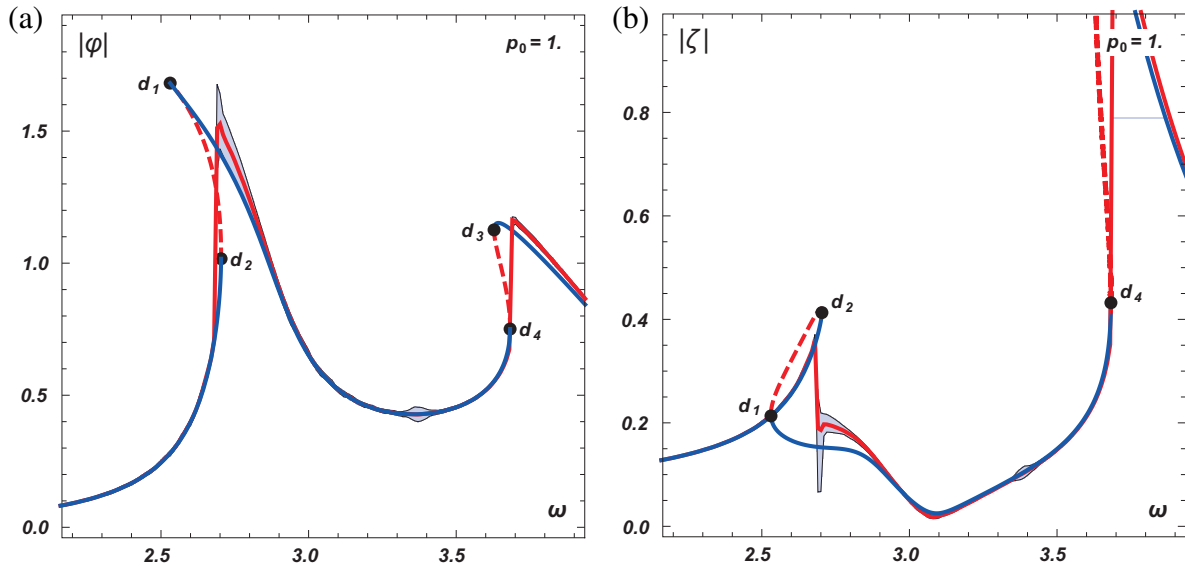

Figure 7: Example of correspondence between stationary resonance curves computed using (14) (blue curves) and response characteristics obtained via numerical integration of Eq. (7) (show in red). Absolute values of the maximum, minimum and mean peak responses of φ are shown on the left and for ζ on the right. Greyed area between minima and maxima curves shows the regions of non-stationary response.

5 APPLICATION OF BASIC THEORY AND EXPERIMENT

First of all two practical knowledge resulting from laboratory experiments and in situ measurements should be mentioned.

As regards the damping, the use of the logarithmic decrement as the measure of damping does not correspond very well to the non-linear nature of the phenomenon. However, a comparison of the behaviour of different physical models which were examined is very useful. Fig. 8 shows the value of the logarithmic decrement b_φ of the model plotted against the absorber - mass ratio μ , see Eq. (7c). The model was put into vibration by initial deflection from its equilibrium position. In this figure diagrams for several values of initial displacement have been plotted. It can be seen that the model without ball ($\mu = 0$) has the damping nearly 0.02 (the point on the horizontal axis $\mu = 0$), while adding ball the damping reaches 0.17-0.25 (the points on the horizontal axis $\mu = 0.2$, curves valid for simple motion) i.e. nearly 8 times more. Similar effect appears also on conventional pendulum absorbers. For details, see [1].

The influence of inclination was also tested on the model, involving the case when the dish of the absorber exercises the rotation about the horizontal axis, coupled with its horizontal translation. The most unfavourable case was tested, i.e. when the frequency of dish inclination approaches the natural frequency of the ball rolling inside the dish (ω_m). No unfavourable increase of the amplitudes of the ball was observed.

The function and effectiveness of vibration ball absorber was described in detail in [2]. Now we shall describe the experiments made in the laboratory. The dish was fastened to a table supported by nine steel balls enabling the excitation of its movement by one, possibly two mutually perpendicular forces. The forces were supplied by one (uniaxial excitation) or two (biaxial excitation) MTS cylinders (jacks) via arms. The "position control" regime was selected in which the excited movement displacement was constant within a frequency range $\omega \in (4.40 \div 9.40 s^{-1})$. Excitation force amplitude was variable being a function of excitation frequency. Two series of experiments have been done. The first one with the internal side of the dish with rubber covering layer and the second one without this covering.

During the excitation by one harmonic force, the excitation frequency was varied within the range $\omega \in (4.40 \div 9.40 s^{-1})$ in steps of $\Delta\omega = 0.5$, and in the resonance domain in steps of

Figure 8: Logarithmic decrement b_φ plotted against the mass-ratio μ for different initial amplitudes

 Figure 9: Experimental resonance curves of exciting force and of ball m response

$\Delta\omega = 0.25$. The duration of one step was 30 seconds, the transition from one step to another 15 seconds. Seven amplitudes of table displacements ranging from 1 mm to 7 mm were applied. As an example (table displacement amplitude $u_o = 4\text{ mm}$), Fig. 9 shows the resonance curves of the ball m and dish movement depending on frequency of the excitation force, when the dish is without rubber coating (another plot applies for the state with coating). Fig. 9 shows also the phase shift of the ball and the dish displacement in the excitation direction, once again for the increasing as well as decreasing excitation frequency, see the bottom part in the Fig. 9. Two jumps of phase shift (increase or decrease) within the range $(0 - 2\pi)$ can be observed in a neighborhood of the frequency corresponding with the biggest excitation force values.

The ball, although subjected to uniaxial excitation, performed a movement which comprised also a component deviating from the direction of excitation. This complex 3D ball movement appeared in the dish without rubber lining. The response spectrum contains peaks different from excitation frequency, particularly outside the resonance domain and corresponding rather with multiples of the natural frequency of the linearized system. It is another evidence of significant non-linear character of the system, which manifests this time by super-harmonics of the response.

Relation of logarithmic decrement of the damping and the amplitude $\varphi_o \cdot \varrho$ of the dish is presented in the Fig.10a,b, while the relationship of the natural frequency of the ball (moving on steel and on rubber coating respectively) on the amplitude $\varphi_o \cdot \varrho$ has been outlined in the Fig. 10c.

Figure 10: (a) and (b): Relation of logarithmic decrement b_φ and amplitude $\varphi_o \cdot \varrho$ of the ball m ,
(c) Relation of natural frequency ω_φ and amplitude $\varphi_o \cdot \varrho$ of the ball m

6 PRACTICAL REALIZATION

The ball absorber was used recently on two TV towers in the Czech Republic to suppress wind excited vibration (Figs 11a, 11b). Both towers under observation showed two dominant natural frequencies before absorber has been installed $\omega_{(1)} = 7.98s^{-1}$, $\omega_{(2)} = 10.68s^{-1}$ (nearly identical for both towers). Corresponding natural modes and the amplitude of vibration in wind of mean velocity $8 - 15m/s$ are plotted in the Fig. 11c. The response amplitude at the top of the tower is $10.65mm$, while that at the RC platform level $0.273mm$. Four legs of the steel lattice part were recently strengthened.

The ball absorber before the mounting on the top of the tower presents the photo at the Fig. 12. The most important numerical results demonstrating the absorber efficiency in dimensionless values are outlined in the Tab. 1. The efficiency has been evaluated for the most important

Figure 11: TV towers, their two lowest natural modes and amplitudes of wind induced vibrations

Table 1: Ball absorber efficiency

Frequency [Hz/s^{-1}]	without absorber		with absorber		ratio with/without absorber	
	X	Y	X	Y	X	Y
0.90/5.65	0	0.0948	0	0.2031	-	2.14
1.27/7.98	19.064	3.279	0.271	0	0.0142	-
1.70/10.68	0	7.382	0	0.466	-	0.0632

$$X = f \cdot G_x(f)/\sigma_x^2; \quad Y = f \cdot G_y(f)/\sigma_y^2$$

frequencies using records of the long term measurements. For evaluation of absorber efficiency the following parameters has been introduced:

$$\varepsilon_x = \frac{f \cdot G_x(f)}{\sigma_x^2}; \quad \varepsilon_y = \frac{f \cdot G_y(f)}{\sigma_y^2} \quad (f = \omega/2\pi)$$

$G_x(f)$, or $G_y(f)$ – power spectral density of the tower top displacement in directions x , or y ;

σ_x^2 , or σ_y^2 – RMS of the tower top displacement in respective directions x , or y ;

The scale of the response is presented in a form of a comparison of the values $\varepsilon_x, \varepsilon_y$ valid for the state without absorber (columns 2 and 3) and with absorber (columns 4 and 5), while columns 6 and 7 represent ratio of with/without absorber for respective directions. In particular, both columns 6 and 7 demonstrate high efficiency of the installed vibration absorber of ball type.

7 CONCLUSIONS

The vibration absorber of a ball type has been introduced. The basic Lagrangian analytical theory of non-linear behaviour has been done. Very wide numerical investigation reveals that the non-linear character of this device is an important factor influencing significantly its dynamic properties and practical efficiency. It turns out, that the non-linear character making the form of resonance curves dependent on the excitation amplitude leads to better efficiency in comparison with linear mechanism. For the same reason also chaotic component of the response can occur in certain frequency domains which increases significantly the efficiency of this device due to

higher energy loss. Laboratory tests of a ball vibration absorber with the dish without and with rubber coating have demonstrated several aspects of real operation of the damper. They have also proved the effectiveness of the damper and the influence of the rubber coating. With respect to laboratory tests and long-term in situ measurements can be concluded that the ball vibration absorber is a simple nearly maintenance free low cost device with very small vertical dimensions. For these properties it is very convenient for application especially in cases when broad band excitation of random character prevails and when very limited space is available.

The same experiments gave many results demonstrating various processes of stability loss and transition into various post-critical states under certain conditions. These phenomena remained without adequate theoretical explanation and without any assessment of influence onto damping properties. Therefore an intensive theoretical investigation should be provided. Detailed stability analysis is necessary to enable a reliable description of post-critical regimes, bifurcation points and corresponding transition effects involving the damping process. Also random parametric excitation and stochastic imperfection influence should be carefully studied.

ACKNOWLEDGEMENT

The kind support of the Czech Science Foundation project No. 103/09/0094, Grant Agency of the ASCR (projects No. IAA200710902, No. IAA200710805) and of the research plan AV OZ720710524 are gratefully acknowledged.

Keywords: Magneto-Rheological (MR) damper, Structural Dynamics, Real-Time Hybrid Simulation, Dynamics of Electromagnetism

Abstract. *Magneto-rheological (MR) dampers are a promising device for seismic hazard mitigation of structural systems due to their ability to adaptively vary their damping characteristics using an appropriate control law. A majority of past research has involved small-scale MR dampers. In order to investigate the dynamic behavior of large-scale MR dampers, characterization tests have been conducted on large-scale MR dampers at the Lehigh NEES equipment site. A new MR damper model, called the Maxwell Nonlinear Slider Model (MNS), was developed using the data from these tests. The new MR damper model can independently describe the pre-yield and post-yield behavior of an MR damper, making it easier to identify the model parameters. The new damper model utilizes the Hershel-Bulkley visco-plasticity formulation to describe the post-yield behavior of the damper, and possesses the characteristics of a non-Newtonian fluid, i.e., shear thinning and thickening behavior of MR fluid. The effects of the dynamics of an MR damper associated with variable current input from a semi-active control law is integrated into the model by a nonlinear differential equation describing the eddy current effect and the magnetization behavior of damper materials. The accuracy of the new MR damper model is compared with other existing models, such as the Bouc-Wen and hyperbolic tangent models. Experimental studies are performed involving real-time hybrid simulations of complete structural systems, where MR dampers in the structure are subjected to realistic demands associated with the design basis and maximum considered earthquakes. Comparisons of the measured hysteretic response of the large-scale dampers in the tests with the predicted behavior by the MNS damper model show that the new model is able to achieve a high degree of accuracy compared to existing MR damper models under earthquake loading conditions. The MNS model enables accurate nonlinear time history analysis for the response prediction of structural systems with MR dampers to be performed.*

1 INTRODUCTION

Magneto-rheological (MR) dampers are devices which can have their characteristics vary by changing the input current to the damper. The MR damper force depends on the yield stress of the MR fluid inside the damper, which is a function of the input current to the damper. When an MR fluid is subjected to a magnetic field, the iron particles in the fluid are aligned and form linear chains parallel to the field, changing the state of the fluid to a semi-solid, which in turn increases the fluid viscosity and restricts the fluid movement through the orifices in an MR damper. This results in changing the yield stress of the MR fluid. MR dampers can be used for seismic hazard mitigation by incorporating these devices into structures. Dyke et al. [1] studied the feasibility of an MR damper as a means of suppressing vibrations in a structure using a clipped optimal controller algorithm. Thereafter, numerous researchers have studied the behavior of structures with passively or semi-actively controlled MR dampers [2-4]. Most of those studies involved small-scale MR dampers.

Large-scale MR dampers have been experimentally investigated by numerous researchers [5-8]. Numerous damper models have been developed to predict the behavior of MR dampers [9-11]. Among these models, the Bouc-Wen model [9] and hyperbolic tangent model [11] are popular, and have been used by Yang et al. [12] and Bass and Christenson [8] to model large-scale MR dampers. Both the Bouc-Wen model and the hyperbolic tangent model can accurately predict the frequency dependent behavior and roll-off phenomenon that occurs at low velocities in MR dampers. However, due to the complexity of these nonlinear models the estimation of the model parameters can be difficult. Moreover, it is difficult for these models to accurately describe the shear thinning or thickening behavior that occurs in the MR fluid [6] during the post yield response when high velocities can develop in the damper. In both the Bouc-Wen and hyperbolic tangent models the post-yield behavior is predominantly described by a linear dashpot; hence, the post-yield behavior of these models is a Newtonian fluid motion where the damper force is proportional to velocity. This can result in an inaccurate prediction of damper force at large amplitudes and high velocities, where under these conditions a non-Newtonian fluid behavior is experimentally observed to occur in the MR fluid.

This paper describes called the newly developed *Maxwell Nonlinear Slider* (MNS) model for modeling large-scale MR dampers. Characterization tests are conducted on a large-scale damper to identify the parameters for the MNS model. Comparisons are subsequently made between the behavior predicted by the MNS model and that measured while subjecting large-scale dampers to varying displacement and current histories. The results are shown to have better accuracy than existing models when applied toward the modeling of large-scale MR dampers.

2 MAXWELL NONLINEAR SLIDER MR DAMPER MODEL

The components of the MNS model are shown in Figure 1. The model has two modes: pre-yield and post-yield. In Figure 1, x is the degree of freedom of the model that is associated with the deformation of the damper, while y and z are variables associated with the pre-yield mode of the model. x and \dot{x} are referred to as the *damper displacement* and the *damper velocity*, respectively, for simplicity. The variables x and y are related through the velocities \dot{x} and \dot{y} as well as the force f in the damper. The variables y and z are related through equilibrium with the damper force f applied to the model. One of the advantages of the MNS model is that the pre- and post-yield modes of response can be separated from each other, enabling the model parameters that describe these two modes of behavior to be independently identified. This makes it easier to identify the parameters for the model compared to other existing MR damper models.

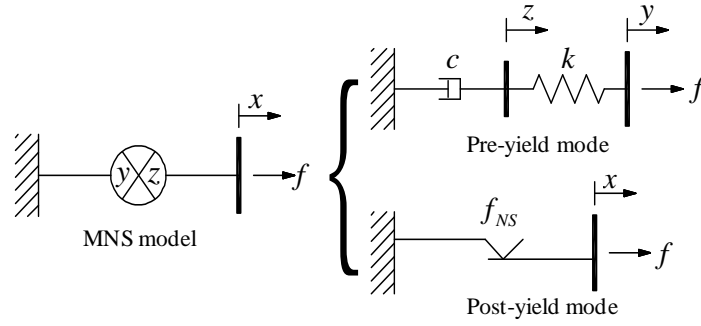

Figure 1. Proposed phenomenological MR damper model: Maxwell Nonlinear Slider (MNS) MR damper model

2.1 Pre-Yield Mode

During the pre-yield mode, the behavior of the damper is described by a Maxwell element, hence, the damper force f is determined by solving the following differential equation

$$f = k(y - z) = c\dot{z} \quad (1)$$

When the damper is in pre-yield mode, \dot{y} is equal to the damper velocity \dot{x} . The initial value of y is set to be equal to x ; thus Eq. 1 can be solved in terms of z for a given x and the damper force is then determined. The values of c and k for the Maxwell element are obtained from the force-velocity relationship observed in damper characterization tests, selecting two appropriate points on the hysteretic response curve and then applying visco-elasticity theory. Assuming the Maxwell element is subjected to a harmonic motion with an amplitude of u_0 and circular excitation frequency of ω , the coefficients c and k are calculated as follows:

$$c = \frac{1}{u_0\omega} \frac{f_0^2 + f_m^2}{f_m}, \quad k = \frac{1}{u_0} \frac{f_0^2 + f_m^2}{f_0} \quad (2)$$

where f_0 and f_m are the damper force when the damper velocity is zero and a maximum value, respectively.

2.2 Post-Yield Mode

The post-yield behavior of the MNS model is described by the nonlinear slider which a frictional force defined by a set of post-yield curves that are pre-defined trajectories of the damper force on the force-velocity plane. In the post-yield mode the force is based on considering the damper velocity, i.e., \dot{x} . Figure 2 shows the post-yield curves for the MNS model, where a curve is defined for both a positive and negative force and referred to as the *positive* and *negative force post-yield curves*, respectively. Each post-yield curve is based on the Herschel-Bulkley model [13] and a linear line that is tangential to this curve at the velocity of \dot{x}_t^+ or \dot{x}_t^- , as shown in Figure 2. Since the Herschel-Bulkley model is incorporated into the MNS model, the property of a non-Newtonian fluid can be easily described by the MNS model. The mathematical representation of the positive force post-yield curve for the MNS model is given by

$$f_{py}^+(\dot{x}) = \begin{cases} a + b|\dot{x}|^n & \text{if } \dot{x} \geq \dot{x}_t^+ \\ a_t(\dot{x} - \dot{x}_t^+) + f_t^+ & \text{if } \dot{x} < \dot{x}_t^+ \end{cases} \quad (3)$$

where a , b , n , and \dot{x}_t^+ are parameters to be identified from damper characterization tests; and $a_t = bn|\dot{x}_t^+|^{n-1}$ and $f_t^+ = a + b|\dot{x}_t^+|^n$. The negative force post-yield curve, $f_{py}^-(\dot{x})$, can be defined in a similar manner as $f_{py}^+(\dot{x})$ using the appropriate values for the negative force post-yield curve parameters. The simplicity of the Herschel-Bulkley model enables values for the model parameters to be readily obtained from characterization tests since the post-yield behavior is independent of the identification of the Maxwell element parameters c and k that describe the pre-yield mode of the MNS model.

Figure 2. Pre-defined post-yield curves for MNS model

The post-yield curve is composed of two phases in the MNS model, namely, an *increasing phase* and *decreasing phase*. If the magnitude of the damper force is increasing during the post-yield mode, the damper is in the increasing phase. On the contrary, the damper is in the decreasing phase if the magnitude of the damper force is decreasing. Experimental data from the characterization tests show the trajectory of damper forces can be slightly different during the increasing and decreasing phase [14]. To account for this behavior, an inertial term is added to the post-yield damper force for the MNS model, whereby the force f in the damper is:

$$f = \begin{cases} f_{py}^+(\dot{x}) & \ddot{x} \geq 0; \text{ increasing phase} \\ f_{py}^+(\dot{x}) + m_0\ddot{x} & \ddot{x} < 0; \text{ decreasing phase} \end{cases} \quad (4)$$

where m_0 is a mass to account for the force discrepancy. When the damper force is on the negative force post-yield curve, the damper force is

$$f = \begin{cases} f_{py}^-(\dot{x}) & \ddot{x} < 0; \text{ increasing phase} \\ f_{py}^-(\dot{x}) + m_0\ddot{x} & \ddot{x} \geq 0; \text{ decreasing phase} \end{cases} \quad (5)$$

The value for the parameter m_0 can be obtained by equating the product of the measured acceleration and m_0 to the discrepancy between the post-yield mode measured damper force and the predicted force by the MNS model without the inertia term, where the measured quantities are from damper characterization tests.

2.3 Criteria for Mode Change

When the damper force f from the Maxwell element reaches the post-yield curve, the non-linear slider is activated and the mode changes from the pre-yield to the post-yield state. Mathematically, this condition is expressed as

$$|f| = |f_{py}(\dot{x})| \quad (6)$$

Equation 6 implies that the generated damper force is always bounded by the positive and negative force post-yield curves in the MNS model. The transition from the post-yield mode to the pre-yield mode occurs when the following velocity equation is satisfied during the post-yield mode

$$\dot{x} = \dot{y} \quad (7)$$

where, \dot{y} is calculated from

$$\dot{y} = \frac{\dot{f}}{k} + \frac{f}{c} \quad (8)$$

Equation (8) is obtained by solving for y from Eq. (1) and then taking the time derivative of y . The value for \dot{y} is then calculated by substituting the damper force f and the time derivative of the damper force, \dot{f} , from the post-yield mode into Eq. (8). To obtain a smooth transition from the post-yield mode to the pre-yield mode, during the post-yield mode the pre-yield mode variables y and z of the model are continuously updated by solving Eq. (1) for z and y using the force f developed in the damper during the post-yield mode.

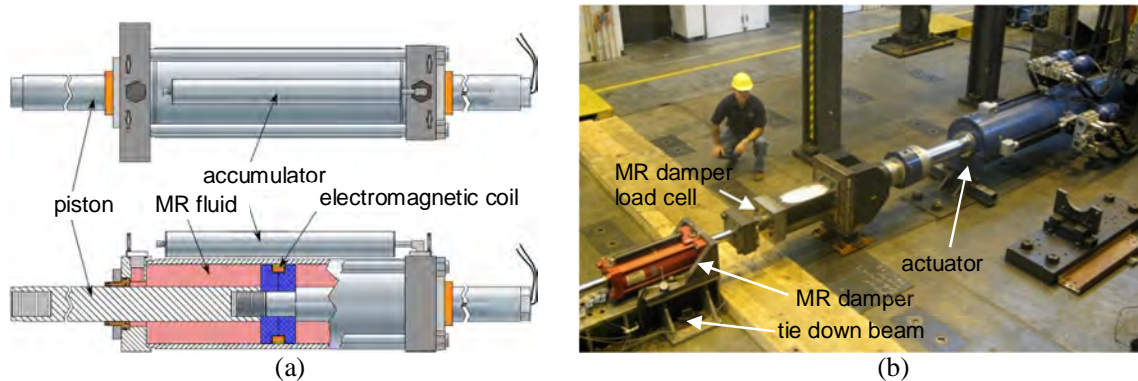

Figure 3. (a) Schematic of a large-scale MR damper by Lord Corporation (after Bass and Christenson 2007); (b) experimental setup for the characterization test of MR damper

3 DAMPER CHARACTERIZATION TESTS

Characterization tests were performed at the Lehigh NEES equipment site on a large-scale MR damper. The damper is manufactured by Lord Corporation and is similar to the MR dampers used by Bass and Christenson [8] in their research. The damper is shown schematically in Figure 3(a). The length and available stroke of the damper are 1.5m and ± 279 mm, respectively. The electromagnetic coil consists of 368 turns of 18 AWG magnet wire with an annular gap of 1.0 mm between the piston head and the inside diameter of the cylinder. The damper is filled with approximately 19 liters of MRF-132DG type MR fluid manufactured by Lord Corporation.

The experimental setup for the characterization test consists of primary two parts: i) a hydraulic actuator to control the movement of the MR damper; and ii) electrical hardware to supply an appropriate current to the damper for the control of the damper force. Figure 3(b) shows the test setup for the characterization test of the MR damper. The MR damper is connected to the hydraulic actuator through a stiff horizontal steel section. This is done in order to extend the arm of the actuator piston to accommodate the spacing of anchor locations for threaded rods that secure the damper and actuator to the laboratory strong floor. The maximum force capacity of the actuator is 1,700kN; with the actuator having the ability to generate approximately 500kN of force at a piston velocity of 1.0m/sec. A 534kN load cell is installed between the horizontal steel section and the damper piston to directly measure the force developed in the damper.

The current going into the damper is controlled by a pulse width modulation (PWM) type current driver manufactured by Advanced Motion Controls (30A8). The PWM servo-amplifier can supply the current to the electrical circuit up to 30A by driving the DC motor at a high rate of switching frequency (22kHz). To reduce the noise from the electrical power source, a Schaffner line filter is deployed in front of the DC power supply that provides 72 DC voltage to the PWM servo-amplifier. The command current is transferred to the PWM servo-amplifier through voltage signals from -10V to +10V to produce the desired current utilizing pulse width modulation. The current going into the MR damper is monitored by a current probe (CR Magnetics current transformer).

Table 1. Identified parameters for MNS damper model

Current, I (Amps)	c (kN s/m)	k (kN/m)	Positive force post-yield curve				Negative force post-yield curve				m_0 (kN s ² /m)

The parameters for the MNS damper model are identified in such a manner that a minimal error is achieved between the damper force predicted by the model and that measured during the characterization tests. In this paper the particle swarm optimization (PSO) algorithm by Kennedy and Eberhart [15] is used for the identification of the damper model parameters. The normalized root mean square (RMS) error by Gavin [11] is used as the objective function that is minimized to establish the values of the model parameters. The parameters are obtained for a range of selected currents from various characterization tests involving sinusoidal displace-

ment histories. For each current level, four different sinusoidal tests with the amplitude of 25.4mm and frequencies of 0.5Hz, 1.0Hz, 2.0Hz, and 3.0Hz were conducted for the identification of the model parameters. Table 1 shows the identified parameters of the MNS model for the various current levels. To compare the performance of the MNS model with the Bouc-Wen and hyperbolic tangent models the parameters for these other models are also identified using the PSO applied to the same experimental data set.

4 EXPERIMENTAL EVALUATION OF MNS MODEL UNDER CONSTANT CURRENT

The MNS model was evaluated by comparing the damper response predicted by the model with that recorded in tests where the displacement history was based on selected Gaussian white noise (see Figure 4(a) and Table 2). The comparisons are shown in Figure 4(b), (c) and (d), where the damper force time history, damper force-displacement, and damper force-velocity are given, respectively. The current input, I , for the damper is constant and equal to 2.5A for the results shown in Figure 4. Good agreement between the MNS model and the test results is evident in Figure 4.

Figure 4. Comparison of predicted damper force by MNS model with experimental data ($I=2.5A$): (a) time history of input displacement; (b) time history of damper force; (c) force-displacement relationship; (d) force-velocity relationship.

Table 2. Comparison of normalized RMS error of MR damper models with band-limited Gaussian white noise

Damper Current I (Amps)	Gaussian white noise (displacement input)			Normalized RMS error		
	Max. disp. (m)	Max. velocity (m/s)	Bandwidth (Hz)	Bouc-Wen model	Hyperbolic tangent model	MNS model
0.0	0.050	0.452	2.0	0.1291	0.0992	0.0688
2.5	0.030	0.445	4.0	0.0420	0.0409	0.0370

Table 2 presents a comparison of the normalized RMS error [11] for the MNS, Bouc-Wen, and hyperbolic-tangent damper models for two cases involving a constant current input of $I=0.0\text{A}$ and 2.5A . For the cases with $I=0.0\text{A}$ and 2.5A the displacement history is based on Gaussian white noise with a bandwidth of 2Hz and 4Hz , respectively. As can be seen in Table 2, the MNS model shows better agreement with the test data than with the Bouc-Wen and hyperbolic-tangent models.

5 DYNAMICS OF MR DAMPER ASSOCIATED WITH VARIABLE CURRENT

5.1 Dynamics of Current Driver (PWM Servo-Amplifier)

Due to the inductance of the electro-magnetic coil that generates the magnetic field in the damper, the current within the electro-magnetic circuit changes slowly if a voltage driven power supply is used [12]. To overcome this problem, a PWM servo-amplifier with a PI controller is often used. Yang presented a governing differential equation for the electro-magnetic circuit based on the duty cycle of a PWM servo-amplifier and PI controller [6]. In this paper the same governing equation is used, from which a transfer function $G(s)$ between the current output to the damper and current command signal for the current driver is derived:

$$G(s) = \frac{235s + 44522}{s^2 + 302s + 44522} \quad (9)$$

5.2 Dynamics of Electromagnetism

As noted previously, numerous semi-active control algorithms have been developed for MR dampers. These control laws involve supplying a variable current command to the damper. To understand the dynamics of an MR damper, it is necessary to investigate the dynamic behavior of the magnetic field in the damper associated with variable current. When the current changes inside the electromagnetic coil, a magnetic flux that is proportional to the current in the coil is generated. The magnetic flux induces eddy currents in the material around the coil (e.g., the piston head, cylinder housing), which opposes the magnetic flux generated by the coil according to Lenz's law. This results in the development of a time delay in the MR damper force under a variable current input [16]. The hysteresis of the magnetization of the MR damper fluid makes it difficult to predict the damper force, for the piston head and cylinder housing around the coil can develop a residual magnetic field after the applied magnetic field has been removed. This nonlinear hysteretic behavior not only can affect the induction of eddy currents, but it can also disturb the formation of the total magnetic field and the damper force. Therefore, the use of a first order filter [9] for the description of the dynamics of a MR damper may not be sufficient to explain the complex behavior of an MR damper under a variable current input. To obtain a better prediction of the damper force under variable current, this paper proposes a model based on the following nonlinear differential equation to relate the coil current to an equivalent static current:

$$\dot{I}_{eq} = \alpha(\dot{I}_r)(I - I_{eq}) \quad (10)$$

The function $\alpha()$ is determined from the Eqs. (11) and (12):

$$\alpha(\dot{I}_r) = \begin{cases} a^+ \dot{I}_r + \alpha_1 & \text{if } \dot{I}_r \geq 0 \\ a^- \dot{I}_r + \alpha_1 & \text{if } \dot{I}_r < 0 \end{cases} \quad (11)$$

$$\dot{I}_r = \alpha_0(I - I_r) \quad (12)$$

where, α_0 , α_1 , a^+ and a^- are constants which are obtained by utilizing nonlinear optimization theory to minimize the error between the predicted and experimental response of the damper force. I is the current in the coil, which is generated by the current driver. I_{eq} is an equivalent static current that can generate the same magnetic flux as the resultant magnetic flux at time t created by I , the eddy currents, residual magnetic fields, and other phenomena that affect the formation of the magnetic flux.

The MNS model with the Eqs. (9) and (10) to account for the effect of variable current input is referred to as the *variable current MNS model*. Figure 5 shows the block diagram for the variable current MNS model. With I_{eq} obtained from the solution to Eq. (10), the parameter sets in Table 1 can be interpolated or directly used under variable current inputs to specify the damper parameters for the model which enables the damper force to be calculated using the MNS model.

Figure 5. Block diagram for MR damper model under variable current

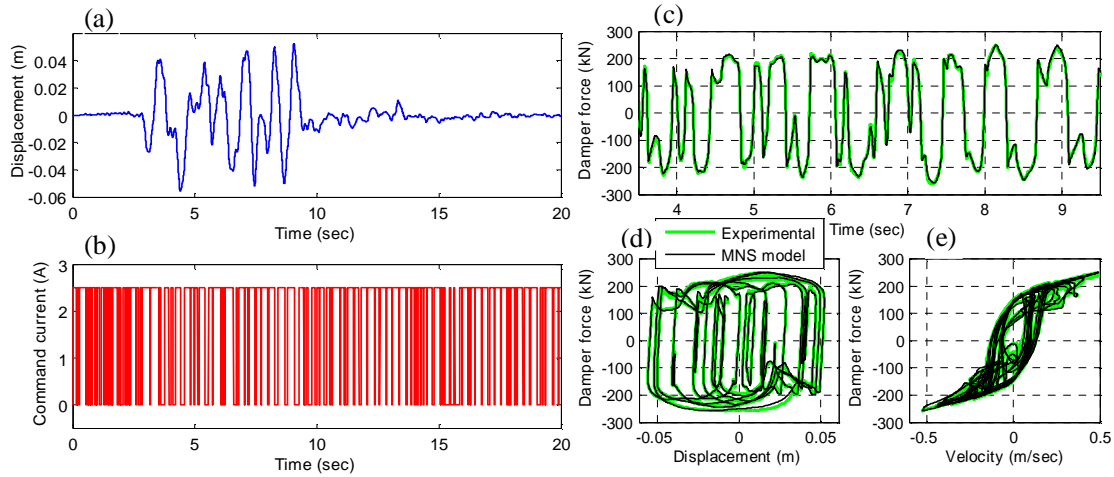

Figure 6. Response of large-scale MR damper under variable current: (a) time history of input displacement; (b) time history of input current; (c) time history of damper force; (d) force-displacement relationship; (e) force-velocity relationship.

To assess the model, tests with variable displacement and current were performed, where the variation in current simulated that from the clipped optimal controller algorithm with a maximum current of 2.5A. Figure 6 (a) and (b) show the pre-defined displacement and current time histories for the MR damper. The experimental response and MNS model prediction of the MR damper are shown in Fig. 6 (c) through (e). The values for the parameters for Eqs. 10, 11, and 12 are: $\alpha_0 = 24.96$, $\alpha_1 = 3.57$, $a^+ = 0.31$, $a^- = -0.30$. As can be observed in Figure 6, the MNS model can accurately predict the response of the MR damper under variable current.

In order to further validate the variable current MNS model, a real-time hybrid simulation of a 3-story building with the large-scale MR damper was conducted [17]. The experimental response of the damper was compared with the results from a numerical simulation involving the variable current MNS model. The building was subjected to the 1989 Loma Prieta earthquake ground motion scaled to the design basis earthquake (DBE) having about a 475 year return period [18]. The sliding mode control (SMC) [19] was used for the semi-active control of the MR damper. As can be observed in Figure 7, the damper force predicted by the variable current MNS model in the numerical simulation (denoted as *Numerical* in Figure 7) matches well with the measured experimental damper force obtained from the real-time hybrid simulation (denoted as *RTHS* in Figure 7); the command current from the numerical simulation also shows good agreement with that from the real-time hybrid simulation. The results shown in Figure 6 and 7 demonstrate the robustness and accuracy of the variable current MNS MR damper model.

6 CONCLUSIONS

A newly developed formulation called the variable current Maxwell Nonlinear Slider model was presented for the prediction of the dynamic behavior of large-scale MR dampers under variable current. In the Maxwell Nonlinear Slider model, the pre-yield and post-yield behaviors of an MR damper are independently described. This simplifies the identification of the model parameters from characterization tests. The Maxwell Nonlinear Slider model utilizes the Hershel-Bulkley model to describe the post-yield behavior, thereby enabling the property of a non-Newtonian fluid to be readily included in the Maxwell Nonlinear Slider model and the effects of shear thinning and thickening behavior of the MR fluid to be accounted for. The solution to a nonlinear differential equation is used to account for the time lag response of the MR damper force that occurs under with a variable current input. Predictions made by the Maxwell Nonlinear Slider model under constant and variable current inputs show good

agreement with experimental results. Further studies of the dynamics of MR dampers needs to be conducted in order to evaluate and calibrate the formulation over a wider range of variable current inputs, as well as frequencies and amplitudes in the displacement history than those presented in this paper.

Abstract. *Base Isolation System (BIS) is a very effective strategy for reducing the effects of earthquakes on building structures. The classical Response Spectrum Method (RSM) continues to be the most common approach for the design of base-isolated buildings. This paper offers a new strategy of seismic analysis and design for such structures in conjunction with the RSM. The main advantages of the proposed approach are: first, reduced computational effort with respect to an exact complex-valued modal analysis, which is obtained through a two-stage transformation of coordinates, both involving real-valued eigenproblems; second, accurate representation of the damping, which is pursued by consistently defining different viscous damping ratios for the modes of vibration of the coupled dynamic system made of superstructure and BIS; third, ease of use, since a convenient reinterpretation of the combination coefficients leads to a novel Damping-Adjusted Combination (DAC) rule, in which just a single response spectrum is required for the reference value of the viscous damping ratio.*

Keywords: BIS (Base Isolation System); CQC (Complete Quadratic Combination) rule; DCF (Damping Correction Factor); random vibration theory; RSM (Response Spectrum Method).

1 INTRODUCTION

Different types of Base Isolation System (BIS) have been developed over the years in the attempt of mitigating seismic effects on building structures, lowering structural and non-structural damages and reducing the risk for the occupants [1,2].

The main result of a BIS is to increase the fundamental period of vibration of the isolated structure, which is permitted by large deformations at the isolation level. This effect is contrasted either by providing isolators with high inherent damping, or by coupling them with additional fluid and/or metallic dampers. This combination of large period of vibration and high damping capabilities tremendously reduces the earthquake-induced forces in the superstructure, which in turn can be designed to remain in the elastic range, even in the case of strong ground motions. As a consequence, less energy is dissipated in the superstructure. It follows that, from a mathematical point of view, a seismically isolated structure is a non-classically damped system [3-6], with most of the energy being dissipated at the isolators' level, although this point is often overlooked in practice [7-10].

The classical Response Spectrum Method (RSM) continues to be the most common approach for the design of base-isolated buildings. This technique requires the following steps: (i) solve an eigenproblem for the undamped structure, i.e. frequencies, participation factors and deformed shapes for the first modes of vibration; (ii) select the appropriate viscous damping ratio for each mode; (iii) take from the pertinent design spectrum the maximum value for each modal response; (iv) combine the modal maxima to get the sought design response of the structure.

The last two steps introduce the main sources of inaccuracy in the practical application of the RSM. Indeed, most seismic codes furnish the response spectrum just for a reference value of the viscous damping ratio, which is typically $\zeta_0 = 0.05$, and thus quite different from the usual values assumed for BIS and superstructure. This circumstance motivates the use of a Damping Correction Factor (DCF), for which various expressions have been proposed [11-13]. It has been recently shown that such expressions can be quite different from each other [14], and they are not effective for seismically isolated structure [15,16].

In parallel, the combination rules available in the literature are not fully adequate. The so-called CQC (Complete Quadratic Combination) rule [17] is generally adopted by practitioners. This formula combines the ordinates of the given response spectrum by using the cross-correlation coefficients of the modal oscillators [18,19]. It has been recognized that the conventional expressions of CQC are unsuitable for analyzing non-classically damped structures, and hence alternative techniques have been proposed [20-22]. Unfortunately, the additional computational burden associated with the solution of complex-valued eigenproblems continues to limit the practical applications of these methods.

It follows that a new combination rule would be required for the analysis and design of base-isolated structures. To be effective in practice, and overcome the main shortcomings of existing techniques, an improved RSM should embed the following features: first, reduced computational effort; second, accurate representation of the damping; third, ease of use, requiring a single response spectrum for the reference value of the viscous damping ratio. These practical needs constitute the motivation of the present study.

The proposed DAC rule, which is alternative to the classical CQC rule and incorporates the features highlighted above, can be viewed as a special variant of the method originally developed by Falsone and Muscolino [23,24] for non-classically damped structures, and recently improved by Muscolino and Palmeri [25] for the seismic analysis of primary structures with light secondary appendages. The numerical results included in this contribution demonstrate the accuracy of the proposed method of analysis.

Figure 1. 3D sketch of a base-isolated building subjected to ground acceleration $\ddot{u}_g(t)$ with angle of attack α_g .

2 EQUATIONS OF MOTION OF COUPLED BIS-SUPERSTRUCTURE

Let us consider the n -floor base-isolated building depicted in Figure 1, subjected to the horizontal ground acceleration $\ddot{u}_g(t)$ in the generic line of action defined by the angle α_g . Assuming diaphragmatic constraint for slabs and masses lumped at the storey's level, the building possesses $3(n+1)$ Degrees of Freedom (DoFs). The isolation level has three DoFs, listed in the array $\mathbf{u}_b(t) = \{u_x^{(b)}(t) \ u_y^{(b)}(t) \ u_\phi^{(b)}(t)\}^T$, the superscript T denoting the transpose operator; these DoFs can be respectively defined as horizontal displacements along x and y directions of the origin O and rotation of the base about the vertical axis z , all taken with respect to the ground. The superstructure has $3n$ DoFs, listed in the n -dimensional block array $\mathbf{u}_s^T(t) = \{\mathbf{u}_1^T(t) \ | \ \mathbf{u}_2^T(t) \ | \ \dots \ | \ \mathbf{u}_n^T(t)\}^T$, where the i -th three-dimensional array $\mathbf{u}_i(t) = \{u_x^{(i)}(t) \ u_y^{(i)}(t) \ u_\phi^{(i)}(t)\}^T$ collects origin's displacements and storey's rotation for the i -th level, with $i=1, \dots, n$, all taken with respect to the isolation level. Since BIS (Base Isolation System) and superstructure are characterised by a high contrast of mechanical properties, the substructure approach is resorted to. Accordingly, BIS and superstructure are handled as two interconnected substructures, and the equations ruling the seismic motion of the coupled dynamic system can be posed in the form:

$$\hat{\mathbf{M}} \cdot \ddot{\mathbf{u}}(t) + \hat{\mathbf{C}} \cdot \dot{\mathbf{u}}(t) + \hat{\mathbf{K}} \cdot \mathbf{u}(t) = \hat{\mathbf{G}} \cdot \tau_b(\alpha_g) \ddot{u}_g(t), \quad (1)$$

where the dot symbol (\cdot) means matrix product; $\mathbf{u}(t) = \{\mathbf{u}_s^T(t) \ | \ \mathbf{u}_b^T(t)\}^T$ is the super-array of the DoFs of the base-isolated building; $\tau_b(\alpha_g) = \{\cos(\alpha_g) \ \sin(\alpha_g) \ 0\}^T$ is the three-dimensional array listing the influence coefficients of the ground shaking; the matrices of mass $\hat{\mathbf{M}}$, viscous damping $\hat{\mathbf{C}}$ and elastic stiffness $\hat{\mathbf{K}}$ are those of the whole structure, and can be assembled from the corresponding matrices of superstructure and isolation level:

$$\hat{\mathbf{M}} = \left[\begin{array}{c|c} \mathbf{M}_s & \mathbf{M}_s \cdot \mathbf{R}_{sb} \\ \hline \mathbf{R}_{sb}^T \cdot \mathbf{M}_s & \mathbf{m}_r \end{array} \right]; \quad \hat{\mathbf{C}} = \left[\begin{array}{c|c} \mathbf{C}_s & \mathbf{O}_{3n,3} \\ \hline \mathbf{O}_{3,3n} & \mathbf{c}_b \end{array} \right]; \quad \hat{\mathbf{K}} = \left[\begin{array}{c|c} \mathbf{K}_s & \mathbf{O}_{3n,3} \\ \hline \mathbf{O}_{3,3n} & \mathbf{k}_b \end{array} \right]; \quad \hat{\mathbf{G}} = - \left[\begin{array}{c|c} \mathbf{M}_s \mathbf{R}_{sb} \\ \hline \mathbf{m}_r \end{array} \right], \quad (2)$$

in which the symbol $\mathbf{O}_{p,q}$ stands for a zero matrix having p rows and q columns, while $\mathbf{R}_{sb} = [\mathbf{I}_3 \mid \mathbf{I}_3 \mid \cdots \mid \mathbf{I}_3]^T$ is a Boolean matrix of dimensions $3n \times 3$, the symbol \mathbf{I}_p being the identity matrix of size p ; \mathbf{M}_s , \mathbf{C}_s and \mathbf{K}_s in Eqs. (2) are the $(3n)$ -dimensional symmetric matrices of mass, damping and stiffness of the superstructure, assumed to be fixed to its own base; \mathbf{c}_b and \mathbf{k}_b in Eqs. (2) are the three-dimensional symmetric matrices collecting the effective values of viscous damping and elastic stiffness for the BIS, respectively; finally, \mathbf{m}_r is the three-dimensional symmetric mass matrix of the whole structure assumed as a rigid body moving on top of the seismic isolators:

$$\mathbf{m}_r = \mathbf{m}_b + \mathbf{R}_{sb}^T \cdot \mathbf{M}_s \cdot \mathbf{R}_{sb}, \quad (3)$$

in which \mathbf{m}_b is the three-dimensional mass matrix of the isolated base. One can easily verify that even though the mass, damping and stiffness matrices of two substructures separately taken satisfy the well-known condition due to Caughey-O'Kelly [26] the coupled BIS-superstructure assembly is in general a non-classically damped dynamic system.

3 TWO-STAGE TRANSFORMATION OF COORDINATES FOR THE MODAL EQUATIONS OF MOTION

The main difficulty in the direct use of Eq. (1) lies in the non classical nature of the energy dissipation for the whole structural system, which does not allow diagonalising together the matrices of mass, damping and stiffness in the real space. To overcome this drawback, a convenient two-stage transformation of coordinates is introduced in this section.

3.1 Stage 1

Two independent transformations of coordinates are initially operated on the base-isolated buildings, i.e. on superstructure and BIS, which can be written in compact form:

$$\left\{ \begin{array}{c} \mathbf{u}_s(t) \\ \mathbf{u}_b(t) \end{array} \right\} = \left[\begin{array}{c|c} \Phi_s & \mathbf{O}_{3n,3} \\ \hline \mathbf{O}_{3,m} & \Phi_b \end{array} \right] \cdot \left\{ \begin{array}{c} \mathbf{q}_s(t) \\ \mathbf{q}_b(t) \end{array} \right\}, \quad (4)$$

where the arrays $\mathbf{q}_s(t) = \{q_{s,1}(t) \cdots q_{s,m}(t)\}^T$ and $\mathbf{q}_b(t) = \{q_{b,1}(t) \ q_{b,2}(t) \ q_{b,3}(t)\}^T$ list the first $m \leq 3n$ modal coordinates of the base-fixed superstructure and the three modal coordinates of the BIS, respectively; and where the $3n \times m$ tall matrix Φ_s and the 3×3 square matrix Φ_b are the associated real-valued modal matrices of the two subsystems, which can be evaluated along with the corresponding spectral matrices $\Omega_s = \text{diag}\{\omega_{s,1}, \dots, \omega_{s,m}\}$ and $\Omega_b = \text{diag}\{\omega_{b,1}, \omega_{b,2}, \omega_{b,3}\}$ as solution of two decoupled real-valued eigenproblems:

$$\mathbf{K}_s^{-1} \cdot \mathbf{M}_s \cdot \Phi_s = \Phi_s \cdot \Omega_s^{-2}; \quad \mathbf{k}_b^{-1} \cdot \mathbf{m}_r \cdot \Phi_b = \Phi_b \cdot \Omega_b^{-2}, \quad (5)$$

with the respective ortho-normalization conditions

$$\Phi_s^T \cdot \mathbf{M}_s \cdot \Phi_s = \mathbf{I}_m; \quad \Phi_b^T \cdot \mathbf{m}_r \cdot \Phi_b = \mathbf{I}_3. \quad (6)$$

Upon substitution of Eqs. (4) into Eq.(1), after some simple algebra, the equations of motion take the form:

$$\bar{\mathbf{m}} \cdot \ddot{\mathbf{q}}(t) + \bar{\mathbf{c}} \cdot \dot{\mathbf{q}}(t) + \bar{\mathbf{k}} \cdot \mathbf{q}(t) = \bar{\mathbf{g}}(\alpha_g) \ddot{u}_g(t), \quad (7)$$

in which $\mathbf{q}(t) = \left\{ \mathbf{q}_s^T(t) \mid \mathbf{q}_b^T(t) \right\}^T$ is $(m+3)$ -dimensional array collecting the modal coordinates of both superstructure and BIS. The other quantities appearing in Eq. (7) are so defined:

$$\bar{\mathbf{m}} = \begin{bmatrix} \mathbf{I}_m & \Phi_s^T \cdot \mathbf{M}_s \cdot \mathbf{R}_{sb} \cdot \Phi_b \\ \Phi_b^T \cdot \mathbf{R}_{sb}^T \cdot \mathbf{M}_s \cdot \Phi_s & \mathbf{I}_3 \end{bmatrix}; \quad (8)$$

$$\bar{\mathbf{c}} = \begin{bmatrix} 2\zeta_s \Omega_s & \mathbf{O}_{m,3} \\ \mathbf{O}_{3,m} & 2\zeta_b \Omega_b \end{bmatrix}; \quad \bar{\mathbf{k}} = \begin{bmatrix} \Omega_s^2 & \mathbf{O}_{m,3} \\ \mathbf{O}_{3,m} & \Omega_b^2 \end{bmatrix}; \quad \bar{\mathbf{g}}(\alpha_g) = - \begin{bmatrix} \Phi_s^T \mathbf{M}_s \mathbf{R}_{sb} \\ \Phi_b^T \mathbf{m}_r \end{bmatrix} \cdot \boldsymbol{\tau}_b(\alpha_g).$$

3.2 Stage 2

The reduced matrices $\bar{\mathbf{m}}$, $\bar{\mathbf{c}}$ and $\bar{\mathbf{k}}$ specified in Eq.(8), as the corresponding matrices of Eqs.(1), do not satisfy the Caughey-O'Kelly condition [26]. Hence, the practical difficulty persists that the conventional formulation of the RSM is not applicable. This drawback can be overcome by using a further transformation of coordinates:

$$\mathbf{q}(t) = \tilde{\Phi} \cdot \tilde{\gamma}(\alpha_g) \cdot \tilde{\theta}(t), \quad (9)$$

where $\tilde{\theta}(t) = \left\{ \tilde{\theta}_1(t) \cdots \tilde{\theta}_{m+3}(t) \right\}^T$ is the $(m+3)$ -dimensional array of the modal coordinates obtained by combining superstructure and BIS; the square transformation matrix $\tilde{\Phi}$, along with the diagonal spectral matrix $\tilde{\Omega} = \text{diag}\{\tilde{\omega}_1, \dots, \tilde{\omega}_{m+3}\}$, can be obtained as solution of the new real-valued eigenproblem:

$$\bar{\mathbf{k}}^{-1} \cdot \bar{\mathbf{m}} \cdot \tilde{\Phi} = \tilde{\Phi} \cdot \tilde{\Omega}^{-2}, \quad (10)$$

with the ortho-normalization condition $\tilde{\Phi}^T \cdot \bar{\mathbf{m}} \cdot \tilde{\Phi} = \mathbf{I}_{m+3}$; $\tilde{\gamma}(\alpha_g) = \text{diag}\{\tilde{\gamma}_1(\alpha_g), \dots, \tilde{\gamma}_{m+3}(\alpha_g)\}$ is the diagonal matrix collecting the $(m+3)$ modal participation coefficients $\tilde{\gamma}_i(\alpha_g) = \left\{ \tilde{\Phi} \right\}_i^T \cdot \bar{\mathbf{g}}(\alpha_g)$, $\left\{ \tilde{\Phi} \right\}_i$ being the i -th column of the matrix $\tilde{\Phi}$; and where the over-tilde denotes all the quantities associated with the proposed stage-2 transformation of coordinates. In doing so, the reduced equations of motion in the modal space take the alternative form:

$$\ddot{\tilde{\theta}}(t) + \tilde{\Xi} \cdot \dot{\tilde{\theta}}(t) + \tilde{\Omega}^2 \cdot \tilde{\theta}(t) = \mathbf{1}_{m+3} \ddot{u}_g(t), \quad (11)$$

in which the symbol $\mathbf{1}_s$ stands for a unit array of size s , while $\tilde{\Xi} = \tilde{\Phi}^T \cdot \bar{\mathbf{c}} \cdot \tilde{\Phi}$ is the matrix of viscous damping in the transformed modal space. Given the non-classical nature of the energy dissipation in base-isolated buildings, this matrix is generally sparse, but with off-diagonal terms much less than the diagonal ones. Hence, from an engineering point of view, the modal coupling in terms of damping forces can be neglected, so that the time evolution of i -th modal coordinate $\tilde{\theta}_i(t)$ is ruled by:

$$\ddot{\tilde{\theta}}_i(t) + 2\tilde{\zeta}_i \tilde{\omega}_i \dot{\tilde{\theta}}_i(t) + \tilde{\omega}_i^2 \tilde{\theta}_i(t) = \ddot{u}_g(t). \quad (12)$$

where $\tilde{\zeta}_i = \tilde{\Xi}_{ii}/2\tilde{\omega}_i$. In this equation $\tilde{\Xi}_{ii}$ and $\tilde{\omega}_i = \tilde{\Omega}_{ii}$ are the elements on principal diagonal of the matrices $\tilde{\Xi}$ and $\tilde{\Omega}$, respectively. It is worth emphasizing that the additional computational burden required by the proposed two-stage transformation of coordinates is very low. Indeed, in real applications the size of the second eigenproblem (Eq. (10)) is much less than the size of the eigenproblem required for a conventional modal analysis, being very often $m+3 \ll 3(n+1)$.

Remarkably, only two approximations have been introduced so far, namely:

- i) modal truncation for the superstructure, since only the first m modes of vibration are retained for the base-fixed superstructure;
- ii) modal decoupling, since the off-diagonal terms in modal matrix of viscous damping are neglected.

Both approximations are acceptable in the vast majority of practical design situations.

4 CONVENTIONAL RESPONSE SPECTRUM METHOD

Before proceeding with the formulation of the proposed Response Spectrum Method (RSM), let us summarize the conventional implementation of the RSM as formulated in EC8 [27], for base-isolated buildings, which requires the following steps:

1. Select the number \hat{m} of vibrational modes to be retained for the superstructure-BIS coupled dynamic system (in practice, $\hat{m} \ll 3(n+1)$);
2. Compute modal matrix $\hat{\Phi}$, whose columns are the real-valued modal shapes of the superstructure-BIS combined system, and the associated spectral matrix $\hat{\Omega} = \text{diag}\{\hat{\omega}_1, \dots, \hat{\omega}_{\hat{m}}\}$, which are solution of the real-valued eigenproblem:

$$\hat{\mathbf{K}}^{-1} \cdot \hat{\mathbf{M}} \cdot \hat{\Phi} = \hat{\Phi} \cdot \hat{\Omega}^{-2}, \quad (13)$$

with the normalization condition $\hat{\Phi}^T \cdot \hat{\mathbf{M}} \cdot \hat{\Phi} = \mathbf{I}_{\hat{m}}$, where $\hat{\mathbf{M}}$ and $\hat{\mathbf{K}}$ are the block matrices of mass and stiffness introduced in Eq. (2).

3. Define the equivalent viscous damping ratio ζ_b for the BIS and ζ_s for the superstructure.
4. For the generic structural response of interest, $y(t)$, define the set of influence coefficients \hat{e}_i of the \hat{m} modal coordinates $\hat{q}_i(t)$, with $i = 1, \dots, \hat{m}$, so that:

$$y(t) \equiv \hat{y}(t) = \sum_{i=1}^{\hat{m}} \hat{e}_i \hat{q}_i(t), \quad (14)$$

where the hat means the use of conventional approach. Notice that in the influence coefficients \hat{e}_i .

5. Evaluate the design value of $\hat{y}(t)$ according to the Complete Quadratic Combination (CQC) rule (Wilson et al. 1981):

$$\hat{Y} = \sqrt{\sum_{i=1}^{\hat{m}} \sum_{k=1}^{\hat{m}} \hat{\rho}(i, k) \hat{e}_i \hat{g}_i(\alpha_g) \hat{e}_k \hat{g}_k(\alpha_g) \frac{A_e(\hat{T}_i, \hat{\zeta}_i)}{\hat{\omega}_i^2} \frac{A_e(\hat{T}_k, \hat{\zeta}_k)}{\hat{\omega}_k^2}}, \quad (15)$$

where $\hat{g}_i(\alpha_g) = \{\hat{\Phi}\}_i^T \cdot \hat{\mathbf{G}} \cdot \mathbf{r}_b(\alpha_g)$ is the i -th participation factor; $\hat{\rho}(i, k)$ is the correlation coefficient between i -th and k -th modes of vibration, usually computed under the assumption that the seismic acceleration is a zero-mean stationary Gaussian white noise [17-19]; and $A_e(\hat{T}_i, \hat{\zeta}_i)$ is the i -th ordinate of the elastic response spectrum in terms of pseudo-acceleration. This quantity depends in turn on periods of vibration $\hat{T}_i = 2\pi/\hat{\omega}_i$ and viscous damping ratios $\hat{\zeta}_i$ of the \hat{m} modes of vibration. It is generally assumed that the modal viscous damping ratios for the BIS-superstructure combined system take the values $\hat{\zeta}_i = \zeta_b$ for $i \leq 3$ and $\hat{\zeta}_i = \zeta_s$ for $i \geq 4$. Indeed, the first three modes of vibrations are those associated with large deformations of the seismic isolators, and hence the energy dissipation of the

BIS dictates the damping, while higher modes of vibration mainly involves the deformation of the superstructure, which dissipates less energy.

It may be useful to remember that Eq. (15) is consistent with the random vibration theory, so that the sought design value \hat{Y} is defined as the expected extreme value of the structural response $\hat{y}(t)$ during the seismic motion, that is:

$$\hat{Y} = E \langle \max |\hat{y}(t)| \rangle = PF \langle \hat{y}(t) \rangle SD \langle \hat{y}(t) \rangle, \quad (16)$$

where the symbols $E \langle \cdot \rangle$, $PF \langle \cdot \rangle$ and $SD \langle \cdot \rangle$ denote Expectation (E) operator, dimensionless Peak Factor (PF) and Standard Deviation (SD), respectively; and where the notation $|x|$ stands for the modulus of the scalar x . In the conventional CQC rule it is also made the additional simplifying assumption that PFs of structural response $\hat{y}(t)$ and modal coordinates $\hat{q}_i(t)$ are approximately equal.

5 PROPOSED DAMPING-ADJUSTED COMBINATION RULE

Aim of this section is to then formulate a Damping-Adjusted Combination (DAC) rule in which a new set of combination and correction coefficients, consistently based on the random vibration theory, enables one to make use of a single response spectrum in combining the modal maxima. The particularization of the proposed DAC rule in the case of white noise excitation, leading to handy closed-form expressions, is presented in the next section. The equivalence of dimensionless PF for structural response and PFs for the contributing modal responses (i.e. one of the main assumptions of CQC rule) is also removed.

Let $y(t)$ be the time history of a generic structural quantity of interest for the purposes of designing a base-isolated building. Without loss of generality, this structural response can be expressed as linear combination of the DoFs of the system:

$$y(t) = \mathbf{d}_s^T \cdot \mathbf{u}_s(t) + \mathbf{d}_b^T \cdot \mathbf{u}_b(t), \quad (17)$$

where the arrays $\mathbf{d}_s = \{d_{s,1} \ \cdots \ d_{s,3n}\}^T$ and $\mathbf{d}_b = \{d_{b,1} \ d_{b,2} \ d_{b,3}\}^T$ collect the influence coefficients of superstructure and isolation level, respectively. Once the suggested two-stage transformation of coordinates is adopted, the generic structural response $y(t)$ can be expressed by a linear combination of the modal responses:

$$y(t) \cong \tilde{y}(t) = \tilde{\mathbf{e}}^T \tilde{\boldsymbol{\theta}}(t) = \sum_{i=1}^{m+3} \tilde{\varepsilon}_i \tilde{\gamma}_i(\alpha_g) \tilde{\theta}_i(t), \quad (18)$$

in which $\tilde{\mathbf{e}} = \{\tilde{\varepsilon}_1 \ \cdots \ \tilde{\varepsilon}_{m+3}\}^T$ is the array listing the influence coefficients of the $m+3$ modal coordinates for structural response under consideration, and can be assembled as:

$$\tilde{\mathbf{e}} = \tilde{\boldsymbol{\Phi}}^T \cdot \begin{Bmatrix} \boldsymbol{\Phi}_s^T \cdot \mathbf{d}_s \\ \boldsymbol{\Phi}_b^T \cdot \mathbf{d}_b \end{Bmatrix}^T. \quad (19)$$

By assuming that structural response $\tilde{y}(t)$ and modal responses $\tilde{\theta}_i(t)$, with $i = 1, \dots, (m+3)$, are zero-mean Gaussian random processes, the standard deviation $SD \langle \tilde{y}(t) \rangle$ can be expressed in the form:

$$\text{SD}\langle \tilde{y}(t) \rangle = \sqrt{\sum_{i=1}^{m+3} \sum_{k=1}^{m+3} \tilde{\rho}(i, k) \tilde{\varepsilon}_i \tilde{\gamma}_i(\alpha_g) \tilde{\sigma}_i \tilde{\varepsilon}_k \tilde{\gamma}_k(\alpha_g) \tilde{\sigma}_k}, \quad (20)$$

where $\tilde{\rho}(i, k)$ is the following correlation coefficient:

$$\tilde{\rho}(i, k) = \tilde{\sigma}_{i,k} / (\tilde{\sigma}_i \tilde{\sigma}_k), \quad (21)$$

in which $\tilde{\sigma}_i$ and $\tilde{\sigma}_{i,k}$ stand for Standard Deviation (SD) of the i -th stationary modal response $\tilde{\theta}_i(t)$ and steady-state covariance between $\tilde{\theta}_i(t)$ and $\tilde{\theta}_k(t)$, respectively:

$$\tilde{\sigma}_i = \text{SD}\langle \tilde{\theta}_i(t) \rangle = \sqrt{\text{E}\langle \tilde{\theta}_i(t)^2 \rangle}; \quad (22)$$

$$\tilde{\sigma}_{i,k} = \text{E}\langle \tilde{\theta}_i(t) \tilde{\theta}_k(t) \rangle. \quad (23)$$

Following now the same strategy recently proposed by Muscolino and Palmeri [25] for the seismic analysis of light secondary substructures, let us rewrite the modal correlation coefficient in the equivalent form:

$$\tilde{\rho}(i, k) = \frac{\tilde{\sigma}_{i,k}}{\tilde{\sigma}_i \tilde{\sigma}_k} = \tilde{r}(i, k) \frac{\tilde{\sigma}_i^{(0)} \tilde{\sigma}_k^{(0)}}{\tilde{\sigma}_i \tilde{\sigma}_k}, \quad (24)$$

in which the novel combination coefficient $\tilde{r}(i, k)$ is so defined:

$$\tilde{r}(i, k) = \frac{\text{E}\langle \tilde{\theta}_i(t) \tilde{\theta}_k(t) \rangle}{\tilde{\sigma}_i^{(0)} \tilde{\sigma}_k^{(0)}}, \quad (25)$$

where the denominator $\tilde{\sigma}_i^{(0)} = \text{SD}\langle \tilde{\theta}_i^{(0)}(t) \rangle$ denotes the standard deviation of the stationary seismic response of a dummy SDoF oscillator associated with the i -th mode of vibration of the base-isolated building. This dummy oscillator has unit mass, a reference value of the viscous damping ratio, ζ_0 , for which the elastic response spectrum is known, and undamped period of vibration $\tilde{T}_i = 2\pi/\tilde{\omega}_i$. Therefore, the dynamic response of this dummy oscillator is ruled by:

$$\ddot{\tilde{\theta}}_i^{(0)}(t) + 2\zeta_0 \tilde{\omega}_i \dot{\tilde{\theta}}_i^{(0)}(t) + \tilde{\omega}_i^2 \tilde{\theta}_i^{(0)}(t) = \ddot{u}_g(t). \quad (26)$$

Interestingly, Eq. (26) can be simply derived from Eq. (12) by substituting the viscous damping ratio (i.e., the reference value ζ_0 instead of the actual modal value $\tilde{\zeta}_i$).

Once the new set of combination coefficients has been introduced, substitution of Eq. (24) into Eq. (20), and the result into Eq. (16), gives:

$$\tilde{Y} = \text{PF}\langle \tilde{y}(t) \rangle \sqrt{\sum_{i=1}^{m+3} \sum_{k=1}^{m+3} \tilde{r}(i, k) \tilde{\varepsilon}_i \tilde{\gamma}_i(\alpha_g) \tilde{\varepsilon}_k \tilde{\gamma}_k(\alpha_g) \tilde{\sigma}_i^{(0)} \tilde{\sigma}_k^{(0)}}. \quad (27)$$

This formula can be further manipulated by multiplying and dividing each term in the double summation by the PF of the corresponding dummy oscillator, and by introducing the dimensionless correction coefficient $\tilde{\chi}_i^{(0)}$ so defined:

$$\tilde{\chi}_i^{(0)} = \text{PF}\langle \tilde{y}(t) \rangle / \text{PF}\langle \tilde{\theta}_i^{(0)}(t) \rangle. \quad (28)$$

Indeed, according to Eq. (16) and to the conventional CQC rule, the expected extreme value of the dynamic response of a dummy oscillator can be assumed to be equal to the maximum displacement given by the pertinent elastic response spectrum:

$$\left\{ \text{PF} \left\langle \tilde{\theta}_i^{(0)}(t) \right\rangle \tilde{\sigma}_i^{(0)} \right\} = \text{E} \left\langle \max \left| \tilde{\theta}_i^{(0)}(t) \right| \right\rangle = \frac{A_e(\tilde{T}_i, \zeta_0)}{\tilde{\omega}_i^2}. \quad (29)$$

Therefore, Eq. (27) gives:

$$\tilde{Y} = \sqrt{\sum_{i=1}^{m+3} \sum_{k=1}^{m+3} \tilde{r}(i, k) \frac{\tilde{\varepsilon}_i \tilde{\gamma}_i(\alpha_g) \tilde{\chi}_i^{(0)}}{\tilde{\omega}_i^2} \frac{\tilde{\varepsilon}_k \tilde{\gamma}_k(\alpha_g) \tilde{\chi}_k^{(0)}}{\tilde{\omega}_k^2} A_e(\tilde{T}_i, \zeta_0) A_e(\tilde{T}_k, \zeta_0)}, \quad (30)$$

which is formally similar to the CQC rule of Eq. (15). However, there are three fundamental novelties in the proposed formula:

1. The combination coefficient $\tilde{r}(i, k)$, defined by Eq.(25), is no more the correlation coefficient between i -th and k -th modal oscillators of the base-isolated building, and requires the evaluation in the frequency domain of the following quantities:

$$\tilde{\sigma}_i^{(0)} = 2 \int_0^{+\infty} \left| \tilde{H}_i^{(0)}(\omega) \right|^2 S_g(\omega) d\omega; \quad (31)$$

$$\text{E} \left\langle \tilde{\theta}_i(t), \tilde{\theta}_k(t) \right\rangle = 2 \int_0^{+\infty} \tilde{H}_i^*(\omega) \tilde{H}_k(\omega) S_g(\omega) d\omega. \quad (32)$$

in which $S_g(\omega)$ is the Power Spectral Density (PSD) function simulating the energy distribution of the design ground shaking and:

$$\tilde{H}_i^{(0)}(\omega) = \left[\left(\tilde{\omega}_i^2 - \omega^2 \right) + j \left(2 \zeta_0 \tilde{\omega}_i \omega \right) \right]^{-1}; \quad (33)$$

$$\tilde{H}_i(\omega) = \left[\left(\tilde{\omega}_i^2 - \omega^2 \right) + j \left(2 \tilde{\zeta}_i \tilde{\omega}_i \omega \right) \right]^{-1}. \quad (34)$$

2. The correction coefficient $\tilde{\chi}_i^{(0)}$ is introduced with respect to the i -th dummy oscillator (Eq.(28)), so that the hypothesis of equivalence between dimensionless PFs for structural response and contributing modal responses is removed;
3. Most importantly, only the elastic response spectrum for the reference value ζ_0 of the viscous damping ratio is required. It follows that the use of a semi-empirical DCF is avoided, and the effects of different viscous damping ratios in the actual modal oscillators are consistently taken into account by the novel combination (\tilde{r}) and correction ($\tilde{\chi}^{(0)}$) coefficients introduced in the double summation of Eq.(30). For this reason the formula has been termed Damping-Adjusted Combination (DAC) rule.

It is worth mentioning that all the quantities appearing in the proposed DAC rule of Eq. (30) can be easily evaluated in practice, so that the computational effort is just slightly higher with respect to the traditional CQC rule. Indeed, the modal parameters ($\tilde{\varepsilon}_i$, $\tilde{\gamma}_i$, $\tilde{\omega}_i$ and \tilde{T}_i) simply require the application of the two-stage transformations of coordinates presented in the third section, while the novel coefficients \tilde{r} and $\tilde{\chi}_i^{(0)}$ introduced for the DAC rule just depend on the first spectral moments of both actual modal oscillators and dummy oscillators, which in turn can be easily computed by using traditional techniques of the random vibration theory.

6 CLOSED FORM EXPRESSION UNDER WHITE NOISE ASSUMPTION

The traditional CQC rule is usually applied under the simplified assumption that the ground acceleration is a stationary white noise, i.e. with energy uniformly distributed over the frequencies. The same assumption is considered in this section with the purpose of deriving simple closed-form expressions for the new coefficients introduced in the proposed Damping-Adjusted Combination (DAC) rule, in so reducing the computational burden. Indeed, when the Power Spectral Density (PSD) function of the input is constant, it is possible to evaluate the exact solution of the following integrals appearing in previous expressions. In particular by assuming that $S_g(\omega) = 1$ the new combination coefficients of Eq. (25) becomes:

$$\tilde{r}(i, k) = \frac{\zeta_0}{\sqrt{\tilde{\zeta}_i \tilde{\zeta}_k}} \tilde{\rho}(i, k), \quad (35)$$

where $\tilde{\rho}(i, k)$ is the correlation coefficient between i -th and k -th modes of vibration evaluated assuming the seismic excitation as a white noise process [18,19]:

$$\tilde{\rho}(i, k) = \frac{8}{\tilde{C}_{i,k}} \sqrt{\tilde{\zeta}_i \tilde{\zeta}_k} \tilde{\omega}_i \tilde{\omega}_k \sqrt{\tilde{\omega}_i \tilde{\omega}_k} (\tilde{\zeta}_i \tilde{\omega}_i + \tilde{\zeta}_k \tilde{\omega}_k), \quad (36)$$

and

$$\tilde{C}_{i,k} = \tilde{B}_{i,k}^2 + 4 \tilde{A}_{i,k} \tilde{\zeta}_i \tilde{\zeta}_k \tilde{\omega}_i \tilde{\omega}_k + 4 (\tilde{\zeta}_i^2 + \tilde{\zeta}_k^2) \tilde{\omega}_i^2 \tilde{\omega}_k^2, \quad (37)$$

$$\tilde{A}_{i,k} = \tilde{\omega}_i^2 + \tilde{\omega}_k^2; \quad \tilde{B}_{i,k} = \tilde{\omega}_i^2 - \tilde{\omega}_k^2. \quad (38)$$

Under the white noise approximation, an additional simplification arises in the computation of the coefficient $\tilde{\chi}_i^{(0)}$ defined in Eq. (28) by introducing the Vanmarcke's PF [28,29], for the structural response of interest $\text{PF}\langle \tilde{y}(t) \rangle$ and for the dummy responses $\text{PF}\langle \tilde{\theta}_i^{(0)}(t) \rangle$:

$$\text{PF}\langle \tilde{y}(t) \rangle = \sqrt{2 \ln \left\{ 2.89 N^+ \langle \tilde{y}(t) \rangle \left[1 - \exp \left(-1.77 q \langle \tilde{y}(t) \rangle^{1.20} \sqrt{\ln (2.89 N^+ \langle x(t) \rangle)} \right) \right] \right\}}; \quad (39)$$

$$\text{PF}\langle \tilde{\theta}_i^{(0)}(t) \rangle = \sqrt{2 \ln \left\{ 0.4601 \tilde{\omega}_i T_g \left[1 - \exp \left(-0.3283 \sqrt{\ln (0.4601 \tilde{\omega}_i T_g)} \right) \right] \right\}}. \quad (40)$$

Importantly, $\text{PF}\langle \tilde{\theta}_i^{(0)}(t) \rangle$ depends only on the dimensionless quantity $\tilde{\omega}_i T_g$, T_g being the duration of the strong-phase of the ground motion, while $\text{PF}\langle \tilde{y}(t) \rangle$ depends on the expected number of upcrossings of the time axis, $N^+ \langle \tilde{y}(t) \rangle$, and on the bandwidth parameter $q \langle \tilde{y}(t) \rangle$. These quantities can be evaluated as:

$$N^+ \langle \tilde{y}(t) \rangle = \frac{1}{2\pi} \sqrt{\frac{\lambda_2 \langle \tilde{y}(t) \rangle}{\lambda_0 \langle \tilde{y}(t) \rangle}} T_g; \quad (41)$$

$$q \langle \tilde{y}(t) \rangle = \sqrt{1 - \frac{\lambda_1 \langle \tilde{y}(t) \rangle^2}{\lambda_0 \langle \tilde{y}(t) \rangle \lambda_2 \langle \tilde{y}(t) \rangle}}. \quad (42)$$

The symbol $\lambda_\ell \langle \tilde{y}(t) \rangle$ in Eqs. (41) and (42) is the spectral moments of order $\ell = 0, 1, 2$ of the structural response $\tilde{y}(t)$, which under the white noise approximation can be evaluate in closed form as:

Figure 2. Bottom (left) and top (right) plan layouts of the base-isolated building considered in the numerical applications; circle (o) and cross (x) identify centre of mass (C_M) and centre of rigidity (C_R), respectively.

$$\lambda_0 \langle \tilde{y}(t) \rangle = \sum_{i=1}^{m+3} \sum_{k=i+1}^{m+3} \frac{4\pi \tilde{\varepsilon}_i \tilde{\varepsilon}_k}{\tilde{C}_{i,k}} \tilde{\gamma}_i \tilde{\gamma}_k (\tilde{\zeta}_i \tilde{\omega}_i + \tilde{\zeta}_k \tilde{\omega}_k); \quad (43)$$

$$\lambda_1 \langle \tilde{y}(t) \rangle = \sum_{i=1}^{m+3} \sum_{k=i+1}^{m+3} \frac{2\tilde{\varepsilon}_i \tilde{\varepsilon}_k}{\tilde{C}_{i,k}} \tilde{\gamma}_i \tilde{\gamma}_k [(\tilde{\zeta}_i \tilde{A}_{i,k} + 2\tilde{\zeta}_k \tilde{\omega}_i \tilde{\omega}_k) \tilde{D}_i + (\tilde{\zeta}_k \tilde{A}_{i,k} + 2\tilde{\zeta}_i \tilde{\omega}_i \tilde{\omega}_k) \tilde{D}_k - \tilde{B}_{i,k} \ln(\tilde{\omega}_i / \tilde{\omega}_k)]; \quad (44)$$

$$\lambda_2 \langle \tilde{y}(t) \rangle = \sum_{i=1}^{m+3} \sum_{k=i+1}^{m+3} \frac{4\pi \tilde{\varepsilon}_i \tilde{\varepsilon}_k}{\tilde{C}_{i,k}} \tilde{\gamma}_i \tilde{\gamma}_k \tilde{\omega}_i \tilde{\omega}_k (\tilde{\zeta}_i \tilde{\omega}_k + \tilde{\zeta}_k \tilde{\omega}_i), \quad (45)$$

in which:

$$\tilde{D}_i = \frac{1}{\sqrt{1 - \tilde{\zeta}_i^2}} \arctan \left(\frac{\sqrt{1 - \tilde{\zeta}_i^2}}{\tilde{\zeta}_i} \right). \quad (46)$$

7 NUMERICAL APPLICATIONS

7.1 Objective structure

Aimed at validating the proposed method of analysis and design, the seismic response of a representative 5-storey base-isolated building ($n = 5$) has been investigated. A superstructure with irregular distributions of mass and stiffness in plan and elevation has been chosen (see Figure 1). The first three storeys have dimensions of 25 m by 10 m, which reduce to 13 m by 10 m for the last two storeys. The floor layouts are sketched in Figure 2, where the position of centres

Table I. Exact (\hat{T}_i) and approximate (\tilde{T}_i) periods of vibration for the base-isolated building.

Mode i	\hat{T}_i (s)	\tilde{T}_i (s)	Inaccuracy (%)	Mode i	\hat{T}_i (s)	\tilde{T}_i (s)	Inaccuracy (%)

Case	Ground type	Duration of stationary part	Damping ratios		superstruc- ture's modes
		T_g (s)	superstructure ζ_s	BIS ζ_b	m
(1)	A	15	0.02	0.12	8
(2)	A	30	0.02	0.012	8
(3)	C	30	0.02	0.012	8
(4)	C	30	0.01	0.18	8
(5)	C	30	0.01	0.18	13

of mass C_M (o) and rigidity C_R (x) is also shown. Their relative distance is 2.31 m for the first three storeys and 1.82 m for the last two storeys. The total mass of the base-isolated building is $M_{\text{tot}} = 1,106$ Mg and the lateral stiffness of the BIS is $K_{\text{lat}}^{(b)} = 10,370$ kN/m, so that the nominal value of the isolation period is $T_{\text{iso}} = 2\pi \sqrt{M_{\text{tot}}/K_{\text{lat}}^{(b)}} = 2.05$ s.

7.2 Modal analysis

Aimed at investigating the accuracy of the proposed two-stage transformation of coordinates against the conventional modal analysis, exact ($\hat{T}_i = 2\pi/\hat{\omega}_i$) and approximate ($\tilde{T}_i = 2\pi/\tilde{\omega}_i$) periods of vibration for the first 8 modes of the undamped structure have been evaluated by using the full eigenproblem of Eq. (13) and the reduced one of Eq. (10), respectively. As shown in Table I, exact and approximate values are in excellent agreement, in so confirming the validity of the novel two-stage modal analysis for base-isolated buildings, which in turn is adopted for the proposed DAC rule.

7.3 Seismic analyses

Five methods of analysis have been applied and compared, namely: i) Response Spectrum Method (RSM), as formulated in EC8 [27]; ii) Monte Carlo Simulation (MCS), with 400 samples of artificially generated time histories of ground acceleration consistent with the response spectrum; iii) direct application of the random vibration theory with a consistent PSD function of the accelerograms; iv) proposed Damping-Adjusted Combination (DAC) rule; v) simplified version of the DAC rule under White Noise input (DAC-WN), as presented in Section 6. For each analysis, the angle of attack $\alpha_g = 90^\circ$ has been used.

In order to test the performances of the proposed approach in different design situations, five cases have been analysed, which differ in seismic input and/or damping properties and/or number of retained modes. As summarized in Table II, two different soil conditions have been considered, i.e. ground types A (rocks) and C (deep deposits of dense sands or stiff clay) as defined in EC8 [27], along with two durations of the stationary part of the accelerogram, i.e. $T_g = 15$ s and 30 s; two sets of viscous damping ratios have been used for superstructure and BIS, i.e. $\{\zeta_s = 0.02, \zeta_b = 0.12\}$ and $\{\zeta_s = 0.01, \zeta_b = 0.18\}$; either $m = 8$ or 13 modes of vibration have been retained for the superstructure.

Figure 3 depicts the profiles of inter-storey drifts along the epicentral direction of the ground shaking for the five design situations summarized in Table IV and for angle of attack $\alpha_g = 90^\circ$, which is the weakest direction of the 3D frame. In the pictures, the mean value of the MCS with 400 samples is shown with a solid black line, and the corresponding interval of confidence (mean value \pm standard deviation) is delimited by a pair of dashed thin lines; the prediction of the random vibration theory is shown with a dashed gray line, while the values consistent with

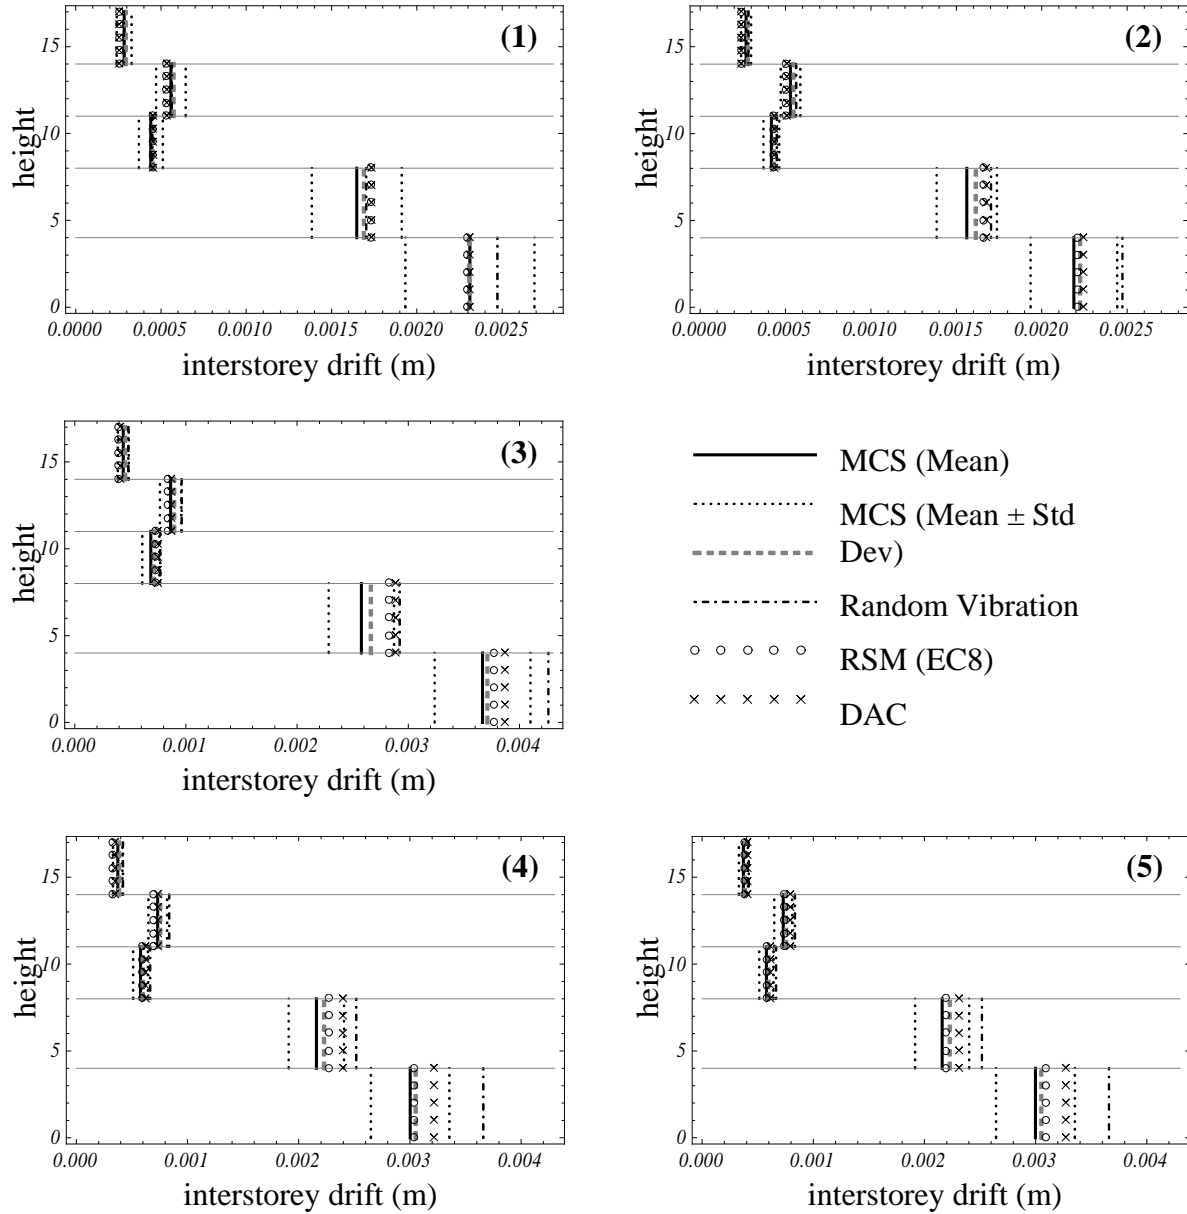

Figure 3. Profiles of superstructure's interstorey drifts for the five cases of Table IV when the angle of attack of the ground motion is $\alpha_g = 90^\circ$ (weakest superstructure's direction).

RSM as formulated in EC8 are those with dot-dashed thin lines; DAC and DAC-WN results are reported with circles and crosses, respectively.

The inspection of these graphs reveals that:

- The proposed DAC and DAC-WN rules are always in good agreement with the results of MCS and random vibration theory.
- The results of the RSM (EC8) very often show large inaccuracies, falling most of the times outside the interval of confidence of the MCS.
- The larger is the stationary duration of the accelerogram, the smaller is the interval of confidence of the MCS (comparison of cases (1) and (2)), i.e. the more deterministic is the mean value of the generated response spectra.

- The predictions of the RSM (EC8) are less accurate when the viscous damping ratios ζ_s and ζ_b become smaller for superstructure and larger for BIS, respectively (comparison of cases (3) and (4)), i.e. when the discrepancy increases with respect to the reference value $\zeta_0 = 0.05$ (3)).
- The results' trend is not significantly affected by soil type (comparison of cases (2) and (3)) and number of modes retained in the analysis (comparison of cases (4) and (5)).

8 CONCLUSIONS

The two main sources of inaccuracy of the classical Response Spectrum Method (RSM) in the practical analysis and design of base-isolated buildings have been pointed out. First, the use of elastic response spectra for different values of the viscous damping ratio, although the seismic action is defined for just a single reference value; second, the use of combination rules not fully adequate for non-conventional structures. This is confirmed by the numerical results included in this paper, where the inaccuracy of the conventional RSM with DCF (Damping Correction Factor) and CQC (Complete Quadratic Combination) rule can be as large as 27% , which is unacceptable from an engineering point of view.

Aimed at overcoming these shortcomings, an improved RSM has been presented and validated. The proposed technique consists of a two-stage transformation of coordinates in parallel with a novel Damping-Adjusted Combination (DAC) rule. The following features have been embedded in the formulation: first, light computational effort, since the calculation of the exact complex-valued eigenproperties of base-isolated buildings is avoided; second, accurate representation of the damping for both superstructure and Base Isolation System (BIS); third, ease of use, requiring a single response spectrum for the reference value of the viscous damping ratio, i.e. the only spectrum which defines the seismic action. Numerical investigations for a realistic structure confirm the improved accuracy of the proposed method, leading toward more economical and/or dependable design of base-isolated buildings. The closed-form expressions derived under the white noise assumption for the ground acceleration allow reducing the computation burden in the proposed DAC rule, and hence they are particularly suitable for practical applications.

Abstract. Supplemental damping systems are known to improve the performance of structures under the design basis earthquake (DBE) and maximum considered earthquake (MCE). In this paper, the seismic collapse potential of a 3-story building with large-scale MR dampers is investigated for extreme levels of ground motion beyond the MCE, where the MR dampers are controlled by various control algorithms. The control algorithms include: i) passive control; ii) linear quadratic regulator (LQR) semi-active control; iii) sliding model control (SMC) semi-active control; iv) decentralized bang-bang (DBB) semi-active control; and v) phase angle control (PAC) semi-active control. The collapse fragility curves of the building with these structural control strategies are obtained using the incremental dynamic analysis (IDA) procedure with an ensemble of ground motions recommended by FEMA P695. The nonlinear time history analysis for the IDA is conducted using OpenSees, where a phenomenological based model to account for strength deterioration in beam plastic hinge regions subject to cyclic loading is incorporated into OpenSees. The collapse fragility curves for various structural control strategies are compared and discussed to assess the performance of the building structure with MR dampers in mitigating structural collapse under extreme earthquake ground motions.

1 INTRODUCTION

In earthquake engineering, collapse implies that a structural system, or a part of it, is incapable of maintaining gravity load carrying capacity in the presence of seismic effects [1]. When a building is subjected to large story drifts, it is vulnerable to dynamic instability due to P- Δ effects and deterioration in strength and stiffness of its structural components that can lead to collapse of the system. Collapse prevention has always been a major concern in the design of structures. The recently developed FEMA P695 [2] document provides a methodology for seismic collapse assessment of structures.

While several studies have been conducted to assess the performance of supplemental damping systems and their effectiveness in mitigating the seismic hazard of structures under the design basis earthquake (DBE) and maximum considered earthquake (MCE), the collapse resistance of buildings with Magneto-Rheological (MR) dampers has not been investigated. The seismic collapse potential of structures with passive supplemental damping systems has been investigated by a few researchers using the incremental dynamic analysis (IDA) method [4-6]. In this paper, the collapse resistance capacity of a 3-story building with moment resisting frames (MRFs) and braced frames with MR dampers designed to achieve specified performance levels under the DBE and MCE is assessed for seismic collapse using the procedure given in FEMA P695. The nonlinear time history analyses used in the IDA method are conducted using OpenSees [6]. A phenomenological-based model developed by Ibarra and Krawinkler [1] and modified by Lignos [7] for modeling deterioration in beam plastic hinge regions in MRFs is incorporated into OpenSees. IDA are performed on the building for cases involving five different controllers [8]: i) passive control; ii) linear quadratic regulator (LQR); iii) sliding mode control (SMC); iv) decentralized bang-bang control (DBB); and v) phase angle control (PAC). Collapse fragility curves are obtained using the ensemble of 22 recorded far-field ground motion pairs (i.e., 44 far-field ground motions) recommended by FEMA P695. The collapse fragility curves for the various control strategies are compared in order to assess the performance of the MR damper control strategies in mitigating structural collapse under extreme earthquake ground motions.

2 BEAM PLASTIC HINGE DETERIORATION MODEL

The P- Δ effect and the strength and stiffness deterioration of structural components are considered to be the major contributors to the collapse of a structural system under seismic loading. The P- Δ effect is well-understood and mathematical models have been formulated for use in linear and nonlinear structural analysis, while the modeling of strength and stiffness deterioration under seismic loading is an on-going research topic. For the accurate evaluation of the collapse of a structure, it is necessary to construct a model that is capable of capturing the strength and stiffness deterioration of structural components under seismic loading. In this section, recently developed deterioration models for plastic hinges in steel beams of MRFs are introduced. The models are used for the IDA presented later in this paper.

Ibarra and Krawinkler developed a hysteretic inelastic deterioration model to describe the moment-rotation behavior in the plastic hinge region of a steel or concrete beam [1]. The model is based on a backbone curve that defines a reference skeleton behavior of a non-deteriorated system. A set of rules are used to define the basic characteristics of the hysteretic behavior between the bounds defined by the backbone curve as well as deterioration in strength and stiffness with respect to the backbone curve.

Lignos modified the Ibarra-Krawinkler model based on observations from data from several hundred tests that had been conducted on steel and reinforced concrete beams [7]. Lignos modified the backbone curve and the cyclic deterioration formulation in the original Ibarra-

Krawinkler model, where the new backbone curve proposed by Lignos is shown in Figure 1. In Figure 1, δ_c is the cap deformation (deformation associated with capacity F_c for monotonic loading); F_y is the effective yield strength; δ_y is the effective yield deformation ($=F_y/K_e$); K_e is the effective elastic stiffness; F_r is the residual strength capacity; δ_r is the deformation at the residual strength; δ_u is the ultimate deformation capacity; δ_p is the plastic deformation capacity associated with monotonic loading; δ_{pc} is the post-capping deformation capacity associated with monotonic loading; and κ is the residual strength ratio ($=F_r/F_y$). The capacity F_c mentioned above is the strength cap associated with the maximum strength incorporating average strain hardening. The strain hardening ratio α_s and the post-capping stiffness ratio α_c are defined as $\alpha_s = K_s/K_e = [(F_c/F_y)/\delta_p]/K_e$ and $\alpha_c = K_{pc}/K_e = (F_c/\delta_{pc})/K_e$, respectively. The reference energy dissipation capacity E_t , which is used to describe the cyclic deterioration, is defined as $E_t = \Lambda\delta_p$, where Λ denotes the reference cumulative deformation capacity.

Figure 1 Modified backbone curve of Ibarra-Krawinkler model

3 MODELING OF 3-STORY BUILDING

The 3-story building shown in plan and elevation in Figures 2 and 3, respectively, was used for the study. The building has two perimeter MRFs along each of its sides and braced internal bays with MR dampers (called *damped brace frames* (DBFs)) at the 2nd and 3rd floors. The structure was designed using the simplified design procedure developed by Chae et al. [8] to achieve a performance objective of 1.5% story drift and 2.6% story drift under the DBE and MCE, respectively. The 3-story building was scaled down using a scale factor of 0.6 for the study since a reduced scale model of the building will be constructed and tested in the laboratory in future research studies. The members of the MRF are proportioned using a weak beam-strong column design. Yielding is expected to occur predominately at the ends of the MRF beams and at the base of the columns in the first story of the MRF and DBF under the DBE. The beams and diagonal bracing members in the DBF have pin-ended connections. The beams are axially restrained in the DBF by the floor diaphragm (which is assumed to be rigid in-plane) at each floor level. The inertial force due to the floor mass is transferred to the MRF and DBF through the rigid floor diaphragm connected to the lean-on column depicted in Figure 4. The diagonal bracing is expected to remain elastic up to 135% story drift [9].

Figure 2 Floor plan of prototype building

Figure 3 Exterior elevation of prototype building

Table 1 Member sizes for MRFs and gravity frames

Story (or Floor Level)	MRFs		Gravity Frames	
	Column	Beam	Column	Beam
1	W8X67	W18X46	W8X48	W10X30
2	W8X67	W14X38	W8X48	W10X30
3	W8X67	W10X17	W8X48	W10X30

Table 2 Member sizes for DBFs

Story (or Floor level)	Column	Beam	Diagonal bracing
1	W10X33	W10X30	-
2	W10X33	W10X30	W6X20
3	W10X33	W10X30	W6X20

Tables 1 and 2 summarize the member sizes for the 0.6-scale building. The OpenSees model for the scaled building is shown in Figure 4. Symmetry in the floor plan and ground motions along only one principal axis of the building were considered in the analysis. Hence, only one-quarter of the building was modeled consisting of one MRF, one DBF, and the gravity frames that are within the tributary area of the MRF and DBF.

Figure 4 OpenSees model of the 3-story structure for the incremental dynamic analysis

Each beam of the MRF in the model consists of three elements: two inelastic deterioration elements with zero length at the column faces based on the modified Ibarra-Krawinkler model; and one linear elastic element between the deterioration elements. The parameters for the deterioration element are summarized in Table 3, where M_y , θ_p and θ_{pc} denote the yield moment, plastic rotation capacity and the post-capping rotation capacity, respectively. The values of these parameters are based on Lignos and Krawinkler [10] for the beam sections used in the MRF.

Table 3 Parameters for deterioration element for MRF beams

Beam size	Deterioration element parameters						
	K_e (kN-m/m)	M_y (kN-m)	α_s	θ_p (rad)	θ_{pc} (rad)	Λ	κ
W10X17	103531	116	0.002	0.062	0.207	1.244	0.01
W14X38	462520	383	0.002	0.043	0.171	1.084	0.01
W18X46	855748	564	0.002	0.033	0.186	1.104	0.01

The columns of the MRF and DBF are modeled using a nonlinear distributed plasticity force-based beam-column element. Each fiber is modeled with a bilinear stress-strain relationship with a post-yielding stiffness that is 0.01 times the elastic stiffness. The columns extend below the ground level in the model to the base, where they are pinned. The beam-to-column joints in the MRF are modeled using a nonlinear panel zone element, where shear and symmetric column bending deformation modes are considered [11]. Doubler plates in the panel zones of the MRF are included in the model. The beams and braces of the DBF are

modeled using linear elastic truss elements. The gravity frames are idealized using the concept of a lean-on column, where an elastic beam-column element with geometric stiffness is used to model the lean-on column. The section properties of the lean-on column are obtained by taking the sum of the section properties of each column of the gravity frames within the tributary area (i.e., one quarter of the floor plan) of the MRF and the DBF.

The structural model in Figure 4 has two major structural components that can lead to dynamic instability under extreme earthquake ground motions: (1) negative stiffness induced by the gravity loads acting on the lean-on column (the P- Δ effect); and (2) strength deterioration in the inelastic deterioration elements in the beams of the MRF. The columns of the MRF and DBF are assumed to have sufficient strength and compactness of their cross-sections such that no deterioration in strength or stiffness of the columns is expected to occur.

To model a rigid floor diaphragm at each floor level the top node of each panel zone element in the MRF and the beam-column joint in the DBF are horizontally constrained together with the node of the lean-on column, while the vertical and rotational DOFs are released. The MR damper is assumed to be located between the top of the diagonal bracing and beam-to-column joint of the DBF. The variable current MNS model developed by Chae [9] is used to model the MR dampers for the nonlinear time history analysis.

Large-scale MR dampers were used for the study which can generate a 200kN damper force at a velocity of 0.1m/sec. [12]. The damper has a stroke limit of ± 279 mm. The story height of the 3-story building is 2.286m, implying that the dampers will reach their stroke limit at 12.2% story drift. Since large story drifts can be expected in a collapse simulation, the MR damper may bottom out with respect to the damper stroke limit under extreme earthquake ground motions. In this case, a gap or the hook element should be included in the model to account for the dynamic behavior associated with reaching the stroke limit, as suggested by Miyamoto et al. [5]. The MR dampers in this study are assumed to have sufficient stroke limit to accommodate the large story drifts during a collapse simulation since no experimental data exists that can be used to model the effect of bottoming out of the dampers.

4 GROUND MOTIONS

As noted previously, the far-field ground motion record set recommended by FEMA P695 (ATC 2009) was selected as ground motions for the IDA. These ground motions were selected to permit evaluation of the record-to-record (RTR) variability of the structural response and calculation of the median of the intensity of spectral acceleration at which collapse occurs. Among the 22 earthquakes, 14 occurred in the United States and 7 in other countries. Event magnitudes range from M6.5 to M7.6, with an average magnitude of M7.0. Each earthquake has two horizontal components so that a total of 44 ground motions are used for the IDA.

FEMA P695 recommends the use of spectral acceleration at the fundamental period of a structure, S_{aT_1} , as the intensity measure (IM). The ground motions are scaled up (or down) based on the spectral acceleration at the fundamental period of the structure. The MR damper stiffness depends on its displacement amplitude [9]. Hence, the effective fundamental period of the structure is dependent on the amplitude of the damper displacements, which is a function of the intensity of ground motion. In this paper, the fundamental period of the structure without MR dampers is used to determine the spectral acceleration corresponding to the IM, rather than using the effective fundamental period of the structure with the dampers. The fundamental period without the MR dampers is 0.94 sec [9], and the scaling of ground motions is performed based on the spectral acceleration at this period.

5 CONTROLLERS

As noted previously, five different control strategies for MR dampers are used in this study, namely: i) passive control; ii) linear quadratic regulator (LQR); iii) sliding mode control (SMC); iv) decentralized bang-bang control (DBB); and v) phase angle control (PAC). More details on these controllers can be found in Chae [9]. A constant current with $I=2.5A$ is supplied to the MR dampers for passive control, while for the semi-active controllers the current switched from $I=0.0A$ to $2.5A$ based on the semi-active control law.

6 INCREMENTAL DYNAMIC ANALYSIS

The incremental dynamic analysis (IDA) curves are a set of plots that correlate a damage measure (DM) with the IM that characterizes the applied scaled accelerograms [13]. The roof drift ratio of the building, θ_{roof} , is selected as the DM for this study. A ground motion is scaled up until dynamic instability occurs, where an IDA curve becomes a flat line, i.e., at collapse. Each selected ground motion is gradually scaled up until θ_{roof} reaches 17% or collapse occurs. For the 44 ground motions in the ensemble, the IDA curves all became flat indicating collapse before θ_{roof} reached 17%. The median roof drift when the IDA curves become flat is approximately 14%.

Figures 5 through 10 show the IDA curves for the structure with various control strategies. These results are for the 44 ground motions. The collapse margin ratio (CMR) was determined for each case, where the CMR is defined by FEMA P695 as the ratio of the median value for the collapse spectral acceleration, \hat{S}_{CT} , to the spectral acceleration of the MCE, S_{MT} , at the fundamental period of the structural system:

$$CMR = \frac{\hat{S}_{CT}}{S_{MT}} \quad (1)$$

\hat{S}_{CT} for each control case is calculated from the IDA curves and marked in Figures 5 through 10 along with the S_{MT} . Table 4 shows the CMR values for each control strategy. Since the purpose is to evaluate the collapse capacity of a structure with MR dampers with various control strategies, the further adjustment of the CMR values based on the spectral shape factor (SSF) [2] is not considered in this study. The results in Table 4 show that when passive control is used that the CMR value increases by about 26% compared to the no damper case, demonstrating the benefit of using MR dampers. The overall performance of each semi-active controller is similar to that of the passive control case, except for the LQR controller. The LQR controller shows the highest CMR value, where the improvement over passive control is about 7%.

7 COLLAPSE FRAGILITY CURVES

A collapse fragility curve is the cumulative distribution function (CDF) which relates the intensity of ground motion to the probability of collapse, and is constructed utilizing the results of the IDAs. For a prescribed level of spectral acceleration S_{aT_1} , the number of cases, N_{SaT_1} , where collapse occurs for a spectral acceleration equal to or less than this value of S_{aT_1} among the IDA curves for the various ground motions is counted. The probability of collapse associated with this value of S_{aT_1} is N_{SaT_1}/N_{tot} , where N_{tot} is the total number of IDA curves (i.e., ground motions).

Figure 5 IDA curves: no damper case

Figure 6 IDA curves: passive control

Figure 7 IDA curves: LQR control

Figure 8 IDA curves: SMC

Figure 9 IDA curves: DBB control

Figure 10 IDA curves: PAC

The probability of collapse typically follows a lognormal distribution. A set of collapse data points can thus be fitted using the lognormal distribution to construct the collapse fragility curve. The fitted lognormal distribution is defined by two parameters, namely, the median collapse spectral acceleration (\hat{S}_{CT}), and the standard deviation of the natural logarithm of the collapse spectral accelerations (ζ). The CDF with a lognormal distribution, $F(x)$, is mathematically expressed as

$$F(x) = \int_0^x \frac{1}{s\zeta\sqrt{2\pi}} \exp\left[-\frac{(\ln s - \lambda)^2}{2\zeta^2}\right] ds = \Phi\left(\frac{\ln x - \lambda}{\zeta}\right) \quad (2)$$

where, Φ is the cumulative distribution function of the standard normal distribution and $\lambda = \ln \hat{S}_{CT}$. Figure 11 compares the collapse fragility curves for passive control with the no damper case. The fragility curve for passive control is located to the right of the fragility curve for the no damper case, which means the collapse potential of the structure with passive control is lower than that for the structure with no dampers. This result is also illustrated in Table 4 by a comparison of the CMR values, where passive control has a higher CMR value. The collapse fragility curve for various semi-active control strategies are compared to the collapse fragility curve for passive control in Figures 12 through 15. The collapse fragility curves for the semi-active control strategies are shown to be similar to passive control, except for the LQR controller. The collapse fragility curve for the building with the LQR controller is more notably to the right of that for the passive control case (Figure 12) than for the other comparisons, indicating a lower probability of collapse compared to passive control, and consistent with having a higher CMR value in Table 4.

Figure 11 Collapse fragility curves where no damper case is compared with passive control

Table 4 Collapse margin ratio (CMR) for 3-story building with various control strategies

	No damper	Passive	LQR	SMC	DBB	PAC
CMR	2.39	3.02	3.23	3.03	3.02	3.05

8 COLLAPSE MODE

The collapse mode of the building studied is characterized by the formation of plastic hinges in the beams and columns leading to a collapse mechanism. A soft story mechanism, where both ends of all columns at a particular story level develop plastic hinges, did not occur in any of the cases. The design methodology based on a strong column-weak beam design appears to enable a soft story collapse mechanism to be avoided.

Figure 16 shows the deformed shape of the building with passively controlled MR dampers at the time of maximum drift under the 1994 Northridge earthquake (Canyon country, 000 component), where the ground motion was scaled to a spectral acceleration of $S_{aT_1} = 2.25g$. Collapse for this ground motion occurs when $S_{aT_1} = 2.27g$. Both ends of each beam in the 1st through 3rd floors in the MRF and the ground level of the 1st story columns for both the MRF and DBF form plastic hinges during the earthquake.

9 CONCLUSIONS

In this paper, the collapse potential of a 3-story steel frame building with MR dampers controlled by various control strategies was investigated. A model of the structure was developed using OpenSees that included strength and stiffness deterioration along with the $P-\Delta$ effect. Incremental dynamic analyses based on nonlinear time history earthquake simulations were performed to obtain the statistical response and collapse margin ratios (CMRs) for the structure. Five different control strategies for the MR dampers were used, and the collapse potential for each case was compared. The passive control of MR dampers with a 2.5A constant current input improved the CMR value by about 26% compared to the structure without MR dampers. The collapse fragility curves for sliding mode control, decentralized bang-bang control, and phase angle control resulted in almost the same collapse potential as passive control, while the LQR controller provided a reduction in the collapse potential. The CMR is about 7% greater for the structure with an LQR controller compared to passive control.

The LQR and SMC controllers require control gains to be specified. To reach more general conclusions about the seismic collapse potential of buildings with semi-active controlled MR dampers it is recommended that the effect of the control gains on the collapse potential be further investigated. In addition, other semi-active controllers and various structural geometries (e.g. the height of the building) should be included. The effect of a damper bottoming out on the collapse potential of structures with MR dampers also needs to be investigated.

Abstract. *This paper deals with the incorporation of model uncertainties and the usage of robust control techniques in active vibration suppression of smart structures. The used advanced control techniques are based on the H_∞ criterion and m -analysis. Both techniques allow us to take into account the worst case scenario of uncertain disturbances and noise of the system. The presented results demonstrate remarkable efficiency of the proposed techniques.*

1 INTRODUCTION

The field of smart structures has been an emerging area of research for the last few decades [2, 3, 4, 5, 9]. Smart structures are equipped with sensors, actuators and control units, and are able to respond in a smart way to external stimuli. The importance of this field is supported by developments in the field of materials science and technology and in the fields of control and electronics. In materials science, new smart materials are developed that can be used for sensing and actuation in an efficient and controlled manner. These smart materials can be integrated into structures so they can be employed as actuators and sensors for the resulting smart composite structure. On the other hand the applicability of a smart structure strongly depends on the efficient design and implementation of the control systems. Critical issues, like deviation of the structure or the environment from their nominal values or time-delay, must be addressed. In this paper we focus our attention on the existence of uncertainties in smart structures. A finite element based model of a smart beam equipped with uncertainties is used. Based on this model an H_∞ and a μ -controller are designed which effectively suppress the vibrations of the smart beam under stochastic wind-type loading. The advantage of the H_∞ criterion is its ability to take into account the worst influence of uncertain disturbances or noise in the system. By using this technique it is possible to synthesize a H_∞ controller which will be robust with respect to a prespecified number of errors in the model.

Uncertainties in a structural model may arise from non-linearities which are not taken into account in a linear model, from inaccurate knowledge of certain parameters (for example, damping), from unmodelled dynamics in higher frequencies, as well as from their variations over the life of the structure. On the structural model with uncertainties a robust μ -controller is analyzed and synthesized, using the $D - K$ iterative method. The results are compared and commented upon using the various controllers. The results are very good: the oscillations were suppressed even for a real aeolian load, with the required voltages of the piezoelectric components taking values within their endurance limits.

Figure 1: Beam with piezoelectric sensors/actuators.

2 MATHEMATICAL MODELLING

A cantilever slender beam with rectangular cross-section is considered. Four pairs of piezoelectric patches are embedded symmetrically at the top and the bottom surfaces of the beam,

as shown in Fig. 1. The beam is made from graphite- epoxy *T300 – 976* and the piezoelectric patches are *PZTG1195N*. The top patches act like sensors and the bottom like actuators. The resulting composite beam is modelled by means of the classical laminated technical theory of bending. Furthermore, we assume that the mechanical properties of both the piezoelectric material and the host beam are independent in time. The thermal effects are considered to be negligible as well [9].

The beam has length L , width b and thickness h . The sensors and the actuators have width b_S and b_A and thickness h_S and h_A , respectively. The electromechanical parameters of the beam used for the application of the method in this paper are given in the table.

Parameters	Values
Beam length, L	$0.3m$
Beam width, W	$0.04m$
Beam thickness, h	$0.0096m$
Beam density, ρ	$1600kg/m$
Youngs modulus of the beam, E	$1.5 \times 10^{11}N/m^2$
Piezoelectric constant, d_{31}	$254 \times 10^{-12}m/V$
Electric constant, ξ_{33}	$11.5 \times 10^{-3}Vm/N$
Young's modulus of the piezoelectric element	$1.5 \times 10^{11}N/m^2$
Width of the piezoelectric element	$b_S = b_a = 0.04m$
Thickness of the piezoelectric element	$h_S = h_a = 0.0002m$

Table 1: Parameters of the composite beam.

2.1 Piezoelectric equations

In order to derive the basic equations for piezoelectric sensors and actuators (S/As), we assume that:

- The piezoelectric S/A are bonded perfectly on the host beam;
- The piezoelectric layers are much thinner then the host beam;
- The piezoelectric material is homogeneous, transversely isotropic and linearly elastic;
- The piezoelectric S/A are transversely polarized (in the z -direction)[9].

Under these assumptions the three-dimensional linear constitutive equations are given by [8],

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{xz} \end{Bmatrix} = \begin{bmatrix} Q_{11} & 0 \\ 0 & Q_{55} \end{bmatrix} \left(\begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{xz} \end{Bmatrix} - \begin{bmatrix} d_{31} \\ 0 \end{bmatrix} E_z \right) \quad (1)$$

$$D_z = Q_{11}d_{31}\varepsilon_{xx} + \xi_{xx}E_z \quad (2)$$

where σ_{xx} , σ_{xz} denote the axial and shear stress components, D_z , denotes the transverse electrical displacement; ε_{xx} and ε_{xz} are axial and shear strain components; Q_{11} , and Q_{55} , denote

elastic constants; d_{31} , and ξ_{33} , denote piezoelectric and dielectric constants, respectively. Equation 1 describes the inverse piezoelectric effect and equation 2 describes the direct piezoelectric effect. E_z , is the transverse component of the electric field that is assumed to be constant for the piezoelectric layers and its components in the xy -plane are supposed to vanish. If no electric field is applied in the sensor layer, the direct piezoelectric equation 2 is formed like this,

$$D_z = Q_{11}d_{31}\varepsilon_{xx} \quad (3)$$

and it is used to calculate the output charge created by the strains in the beam.[7]

2.2 Equations of motion

We assume that:

- The beam centroidal and elastic axis coincides with the x -coordinate axis so that no bending-torsion coupling is considered;
- The axial vibration of the host beam is considered negligible;
- The displacement field $\{u\} = (u_1, u_2, u_3)$ is obtained based on the usual Timoshenko assumptions [1],

$$\begin{aligned} u_1(x, y, z) &\approx z\phi(x, t) \\ u_2(x, y, z) &\approx 0 \\ u_3(x, y, x) &\approx w(x, t) \end{aligned} \quad (4)$$

where ϕ is the rotation of the beam's cross-section about the positive y -axis and w is the transverse displacement of a point of the centroidal axis ($y = z = 0$).

The strain displacement relations can be applied to equation 4 to give,

$$\varepsilon_{xx} = z \frac{\partial \phi}{\partial x} \quad \varepsilon_{xz} = \phi + \frac{\partial w}{\partial x} \quad (5)$$

We suppose that the transverse shear deformation ε_{xx} is equal to zero[2].

In order to derive the equations of the motion of the beam we use Hamilton's principle,[11]

$$\int_{t_2}^{t_1} (\delta T - \delta U + \delta W) dt = 0, \quad (6)$$

where T is the total kinetic energy of the system, U is the potential (strain) energy and W is the virtual work done by the external mechanical and electrical loads and moments. The first variation of the kinetic energy is given by,

$$\begin{aligned} \delta T &= \frac{1}{2} \int_V \rho \left\{ \frac{\partial u}{\partial t} \right\}^r \left\{ \frac{\partial u}{\partial t} \right\} dV \\ &= \frac{b}{2} \int_0^L \int_{-\frac{h}{2}-h_a}^{\frac{h}{2}+h_s} \rho \left(z \frac{\partial \phi}{\partial t} \delta \frac{\partial \phi}{\partial t} + \frac{\partial w}{\partial t} \delta \frac{\partial w}{\partial t} \right) dz dx \end{aligned} \quad (7)$$

The first variation of the kinetic energy is given by,

$$\begin{aligned}\delta U &= \frac{1}{2} \int_V \delta \{\epsilon\}^T \{\sigma\} dV \\ &= \frac{b}{2} \int_0^L \int_{-\frac{h}{2}-h_a}^{\frac{h}{2}+h_s} \left[Q_{11} \left(z \frac{\partial w}{\partial x} \delta \right) \left(z \frac{\partial w}{\partial x} \right) \right] dz dx\end{aligned}\quad (8)$$

If the load consists only of moments induced by piezoelectric actuators and since the structure has no bending twisting couple then the first variation of the work has the form [11],

$$\delta W = b \int_0^L M^a \delta \left(\frac{\partial \phi}{\partial x} \right) dx \quad (9)$$

where M^a is the moment per unit length induced by the actuator layer and is given by,

$$\begin{aligned}M^a &= \int_{-\frac{h}{2}-h_a}^{-\frac{h}{2}} z \sigma_{xx}^a dz = \int_{-\frac{h}{2}-h_a}^{-\frac{h}{2}} z Q_{11} d_{31} E_z^a dz \\ &\quad \left(E_z^a = \frac{V_a}{h_a} \right)\end{aligned}\quad (10)$$

2.3 Finite element formulation

We consider a beam element of length L_e , which has two mechanical degrees of freedom at each node: one translational ω_1 (respectively ω_2) in direction y and one rotational ψ_1 (respectively ψ_2), as it is shown in Fig. 2. The vector of nodal displacements and rotations q_e is defined

Figure 2: Beam finite element.

as [8],

$$q_e = [\omega_1, \psi_1, \omega_2, \psi_2] \quad (11)$$

The transverse deflection $\omega(x, t)$ and rotation $\psi(x, t)$ along the beam are continuous and they are interpolated by Hermitian linear shape functions H_i^ω and H_i^ψ as follows[5],

$$\begin{aligned}\omega(x, t) &= \sum_{i=1}^4 H_i^\omega(x) q_i(t) \\ \psi(x, t) &= \sum_{i=1}^4 H_i^\psi(x) q_i(t)\end{aligned}\quad (12)$$

This classical finite element procedure leads to the approximate (discretized) problem. For a finite element the discrete differential equations are obtained by substituting the discretized expressions 13 into equations 8 and 9 to evaluate the kinetic and strain energies. Integrating over spatial domains and using the Hamilton's principle 6 the equation of motion for a beam element are expressed in terms of nodal variable q as follows [2, 6, 8],

$$M\ddot{q}(t) + D\dot{q}(t) + Kq(t) = f_m(t) + f_e(t) \quad (13)$$

where M is the mass matrix, D is the viscous damping matrix, K is the stiffness matrix, f_m is the external loading vector and f_e is the generalized control force vector produced by electromechanical coupling effects. The independent variable vector $q(t)$ is composed of transversal deflections ω_i and rotations ψ_i , i.e.,[4]

$$q(t) = \begin{bmatrix} \omega_1 \\ \psi_1 \\ \vdots \\ \omega_n \\ \psi_n \end{bmatrix} \quad (14)$$

where n is the number of nodes used in the analysis. Vectors w and f_m are positive upwards. For the state-space control transformation, we are presented with,

$$\dot{x}(t) = \begin{bmatrix} q(t) \\ \dot{q}(t) \end{bmatrix} \quad (15)$$

Furthermore to express $f_e(t)$ in the form of $Bu(t)$ we write it as the product f_e^*u , where f_e^* is the piezoelectric force for a unit applied on the corresponding actuator, and u represents the voltages on the actuators. Finally, $d(t) = f_m(t)$ is the disturbance vector[3]. Then,

$$\dot{x}(t) = \begin{bmatrix} 0_{2n \times 2n} & I_{2n \times 2n} \\ -M^{-1}K & -M^{-1}D \end{bmatrix} x(t) + \begin{bmatrix} 0_{2n \times n} \\ M^{-1}f_e^* \end{bmatrix} u(t) + \begin{bmatrix} 0_{2n \times 2n} \\ M^{-1} \end{bmatrix} \quad (16)$$

$$= Ax(t) + Bu(t) + Gd(t) = Ax(t) + \begin{bmatrix} B & G \end{bmatrix} \begin{bmatrix} u(t) \\ d(t) \end{bmatrix} = Ax(t) + \tilde{B}\tilde{u}(t) \quad (17)$$

The previous description of the dynamical system will be augmented with the output equation (*displacements only measured*)[5],

$$y(t) = [x_1(t) \quad x_3(t) \quad \dots \quad x_{n-1}(t)]^T = Cx(t) \quad (18)$$

In this formulation u is $n \times 1$ (at most, but can be smaller), while d is $2n \times 1$. The units used are compatible for instance m, rad, sec and N. [6, 8]

3 DESIGN OBJECTIVES AND SYSTEM SPECIFICATIONS

The structured singular value of the transfer function to what matrix is defined as,

$$\mu(M) = \begin{cases} \frac{1}{\min_{k_m} \{ \det(I - k_m M \Delta) = 0, \bar{\sigma}(\Delta) \leq 1 \}} \\ 0, \Delta \det(I - M \Delta) = 0 \end{cases} \quad (19)$$

This quantity defines the smallest structured $\mu(M)$ (measured in terms of $\bar{\sigma}(\Delta)$) which makes $\det(I - M\Delta) = 0$: then $\mu(M) = \frac{1}{\bar{\sigma}(\Delta)}$. It follows that values of μ smaller than 1 are desired [12, 13]

The design objectives fall into two categories:

1. Stability of closed loop system (plant+controller).
 - (a) Disturbance attenuation with satisfactory transient characteristics (overshoot, settling time).
 - (b) Small control effort.
2. Robust performance

Stability of closed loop system (plant+controller) should be satisfied in the face of modelling errors. [10]

In order to obtain the required system specifications with respect to the above objectives we need to represent our system in the so-called Δ structure. Let us start with the simple typical diagram of Fig. 3. [14, 15]

Figure 3: Classical control block diagram (P : plant dynamical system, C : controller)

In this diagram there are two inputs, d and n , and two outputs, u and x . In what follows it is assumed that,

$$\left\| \begin{bmatrix} d \\ n \end{bmatrix} \right\|_2 \leq 1, \quad \left\| \begin{bmatrix} x \\ u \end{bmatrix} \right\|_2 \leq 1 \quad (20)$$

If this is not the case, appropriate frequency-dependent weights can transform original signals so that the transformed signals have this property. The details of the system are given in Fig.4:

In this description,

$$z = \begin{bmatrix} u \\ x \end{bmatrix}, \quad w = \begin{bmatrix} d \\ n \end{bmatrix} \quad (21)$$

where z are the output variables to be controlled, and w the exogenous inputs.

Given that P has two inputs and two outputs it is, as usual, naturally partitioned as,

$$\begin{bmatrix} z(s) \\ y(s) \end{bmatrix} = \begin{bmatrix} P_{zw}(s) & P_{zu}(s) \\ P_{yw}(s) & P_{yu}(s) \end{bmatrix} \begin{bmatrix} w(s) \\ u(s) \end{bmatrix} = P(s) \begin{bmatrix} w(s) \\ u(s) \end{bmatrix} \quad (22)$$

 Figure 4: Detailed two-port diagram (with a linear feedback control K)

Figure 5: Two-port diagram

In addition the controller is written,

$$u(s) = K(s)y(s) \quad (23)$$

Substituting (22) in (23) gives the closed loop transfer function $N_{zw}(s)$,

$$N_{zw}(s) = P_{zw}(s) + P_{zu}(s)K(s)(I - P_{yu}(s)K(s))^{-1}P_{yw}(s) \quad (24)$$

To deduce robustness specifications one more diagram is needed, namely that of Figure 6: where N is defined by (24) and the uncertainty modelled in Δ satisfies $\|\Delta\|_\infty \leq 1$ (details are given later on in this paper). Here,

$$z = \mathcal{F}_u(N, \Delta)w = [N_{22} + N_{21}\Delta(I - N_{11}\Delta)^{-1}N_{12}]w = Fw \quad (25)$$

Figure 6: Two port diagram with uncertainty

Given this structure we can state the following definitions:

$$\begin{aligned}
 &\text{Nominal stability (NS)} \Leftrightarrow N \text{ internally stable} \\
 &\text{Nominal performance (NP)} \Leftrightarrow \|N_{22}(j\omega)\|_\infty \leq 1 \quad \forall \omega \text{ and } NS \\
 &\text{Robust stability (RS)} \Leftrightarrow F = \mathcal{F}_u(N, \Delta) \text{ stable } \forall \Delta, \|\Delta\|_\infty < 1 \text{ and } NS \\
 &\text{Robust performance (RP)} \Leftrightarrow \|F\|_\infty < 1, \quad \forall \Delta, \|\Delta\|_\infty < 1 \text{ and } S
 \end{aligned} \tag{26}$$

It has been proved that the following conditions hold in the case of block-diagonal real or complex perturbations Δ :

1. The system is nominally stable if M is internally stable.
2. The system exhibits nominal performance if $\bar{\sigma}(N_{22}(j\omega)) < 1$
3. The system (M, Δ) is robustly stable if and only if,

$$\sup_{\omega \in \mathbb{R}} \mu_\Delta(N_{11}(j\omega)) < 1 \tag{27}$$

where μ_Δ is the structured singular value of N given the structured uncertainty set Δ . This condition is known as the generalized small gain theorem.

4. The system (N, Δ) exhibits robust performance if and only if,

$$\sup_{\omega \in \mathbb{R}} \mu_{\Delta_a}(N(j\omega)) < 1 \tag{28}$$

where,

$$\Delta_a = \begin{bmatrix} \Delta_p & 0 \\ 0 & \Delta \end{bmatrix} \tag{29}$$

and Δ_p is full complex, has the same structure as Δ and dimensions corresponding to w, z . [15]

Unfortunately, only bounds on μ can be estimated.

3.1 Controller synthesis

All the above results support the analysis problem and provide tools to judge the performance of any controller or to compare different controllers. However it is possible to approximately synthesize a controller that achieves given performance in terms of the structured singular value μ .

In this procedure, which is called $(D, G - K)$ iteration [20] the problem of finding an μ -optimal controller K such that $\mu(\mathcal{F}_u(F(j\omega)), K(j\omega)) \leq \beta, \forall \omega$ is transformed into the problem of finding transfer function matrices $D(\omega) \in \mathcal{D}$ and $G(\omega) \in \mathcal{G}$, such that,

$$\sup_{\omega} \bar{\sigma} \left[\left(\frac{D(\omega) \mathcal{F}_u(F(j\omega), K(j\omega)) D^{-1}(\omega)}{\gamma} - jG(\omega) \right) (I + G^2(\omega))^{-\frac{1}{2}} \right] \leq 1, \quad \forall \omega \quad (30)$$

Unfortunately this method does not guarantee even finding local maxima. However for complex perturbations a method known as $D - K$ iteration is available (implemented in MATLAB). [20] It combines H_{∞} synthesis and μ -analysis and often yields good results. The starting point is an upper bound on μ in terms of the scaled singular value,

$$\mu(N) \leq \min_{D \in \mathcal{D}} \bar{\sigma}(DND^{-1}) \quad (31)$$

The idea is to find the controller that minimizes the peak over the frequency range namely,

$$\min_K \left(\min_{D \in \mathcal{D}} \|DN(K)D^{-1}\|_{\infty} \right) \quad (32)$$

by alternating between minimizing $\|DN(K)D^{-1}\|_{\infty}$ with respect to either K or D (while holding the other fixed).

1. **K-step.** Synthesize an \mathcal{H}_{∞} controller for the scaled problem $\min_K \|DN(K)D^{-1}\|_{\infty}$ with fixed $D(s)$.
2. **D-step.** Find $D(j\omega)$ to minimize at each frequency $\bar{\sigma}(DND^{-1}(j\omega))$ with fixed N .
3. Fit the magnitude of each element of $D(j\omega)$ to a stable and minimum phase transfer function $D(s)$ and got to Step 1. [20]

3.2 System uncertainty

Let us assume uncertainty in the mass M and K matrices of the form,

$$\begin{aligned} K &= K_0(I + k_p I_{2n \times 2n} \delta_K) \\ M &= M_0(I + m_p I_{2n \times 2n} \delta_M) \end{aligned} \quad (33)$$

Alternatively, since in general the Reyleigh damping assumption is,

$$D = aK + \beta M \quad (34)$$

D could be expressed similarly to K , M , as,

$$D = D_0(I + d_p I_{2n \times 2n} \delta_D) \quad (35)$$

In this way we introduce uncertainty in the form of percentage variation in the relevant matrices. More detailed correlation of uncertainty with certain properties of the structures (e.g., material constants, flexibility of joints, cracks or delaminations) is possible and will be investigated in the future.

Here it will be assumed,

$$\|\Delta\|_\infty \stackrel{\text{def}}{=} \left\| \begin{bmatrix} I_{n \times n} \delta_K & 0_{n \times n} \\ 0_{n \times n} & I_{n \times n} \delta_M \end{bmatrix} \right\|_\infty < 1 \quad (36)$$

hence m_p , k_p are used to scale the percentage value and the zero subscript denotes nominal values (it is reminded here that the norm for a matrix $A_{n \times n}$ is calculated through $\|A\|_\infty = \max_{1 \leq j \leq n} \sum_{i=1}^n |a_{ij}|$)

With these definitions Eq. 13 becomes,

$$\begin{aligned} & M_0(I + m_p I_{2n \times 2n} \delta_M) \ddot{w}(t) + K_0(I + k_p I_{2n \times 2n} \delta_K) w(t) \\ & + [D_0 + 0.0005[K_0 k_p I_{2n \times 2n} \delta_K + M_0 m_p I_{2n \times 2n} \delta_M]] \dot{w}(t) = f_m(t) + f_e(t) \\ & \Rightarrow M_0 \ddot{w}(t) + D_0 \dot{w}(t) + K_0 w(t) = \\ & -[M_0 m_p I_{2n \times 2n} \delta_M \ddot{w}(t) + 0.0005[K_0 k_p I_{2n \times 2n} \delta_K + M_0 m_p I_{2n \times 2n} \delta_M] \dot{w}(t) + \\ & \quad K_0 k_p I_{2n \times 2n} \delta_K w(t)] \\ & = f_m(t) + f_e(t) \\ & \Rightarrow M_0 \ddot{w}(t) + D_0 \dot{w}(t) + K_0 w(t) = \tilde{D} q_u(t) + f_m(t) + f_e(t) \end{aligned} \quad (37)$$

where,

$$q_u(t) = \begin{bmatrix} \ddot{w}(t) \\ \dot{w}(t) \\ w(t) \end{bmatrix} \quad (38)$$

$$\begin{aligned} \tilde{D} &= -[M_0 m_p \quad K_0 k_p] \begin{bmatrix} I_{2n \times 2n} \delta_M & 0_{2n \times 2n} \\ 0_{2n \times 2n} & I_{2n \times 2n} \delta_K \end{bmatrix} \begin{bmatrix} I_{2n \times 2n} & 0.0005 I_{2n \times 2n} & 0_{2n \times 2n} \\ 0_{2n \times 2n} & 0.0005 I_{2n \times 2n} & I_{2n \times 2n} \end{bmatrix} \\ &= G_1 \cdot \Delta \cdot G_2 \end{aligned} \quad (39)$$

Writing (37) in state space form, gives,

$$\begin{aligned} \dot{x}(t) &= \begin{bmatrix} 0_{2n \times 2n} & I_{2n \times 2n} \\ -M^{-1}K & -M^{-1}D \end{bmatrix} x(t) + \begin{bmatrix} 0_{2n \times 2n} \\ M^{-1}f_e^* \end{bmatrix} u(t) + \begin{bmatrix} 0_{2n \times 2n} \\ M^{-1} \end{bmatrix} d(t) + \begin{bmatrix} 0_{2n \times 6n} \\ M^{-1}F_1 \cdot \Delta \cdot G_2 \end{bmatrix} q_u(t) \\ &= Ax(t) + Bu(t) + Gd(t) + G_u G_2 q_u(t) \end{aligned} \quad (40)$$

In this way we treat uncertainty in the original matrices as an extra uncertainty term. To express our system in the form of Fig. 6, consider Fig. 7.

The matrices E_1 , E_2 are used to extract,

$$q_u(t) \stackrel{\text{def}}{=} \begin{bmatrix} \ddot{w}(t) \\ \dot{w}(t) \\ w(t) \end{bmatrix} \quad (41)$$

Since,

$$\gamma = \begin{bmatrix} \dot{w}(t) \\ \ddot{w}(t) \end{bmatrix} \quad \beta = \int \begin{bmatrix} \dot{w}(t) \\ \ddot{w}(t) \end{bmatrix} dt = \begin{bmatrix} w(t) \\ \dot{w}(t) \end{bmatrix} \quad (42)$$

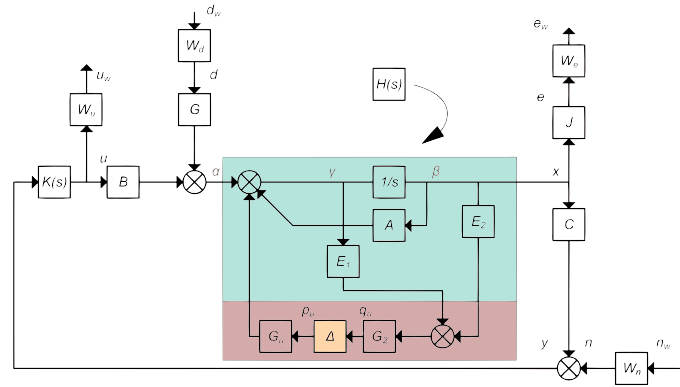

Figure 7: Uncertainty block diagram.

appropriate choices for E_1 , E_2 are,

$$E_1 = \begin{bmatrix} 0_{2n \times 2n} & \vdots & I_{2n \times 2n} \\ \dots & \vdots & \dots \\ I_{2n \times 2n} & \vdots & 0_{2n \times 2n} \\ \dots & \vdots & \dots \\ 0_{2n \times 2n} & \vdots & 0_{2n \times 2n} \end{bmatrix}, \quad E_2 = \begin{bmatrix} 0_{2n \times 2n} & \vdots & 0_{2n \times 2n} \\ \dots & \vdots & \dots \\ 0_{2n \times 2n} & \vdots & 0_{2n \times 2n} \\ \dots & \vdots & \dots \\ I_{2n \times 2n} & \vdots & 0_{2n \times 2n} \end{bmatrix} \quad (43)$$

The idea is to find an N such that,

$$\begin{bmatrix} q_u \\ \dots \\ e_w \\ u_w \end{bmatrix} = N \begin{bmatrix} p_u \\ \dots \\ d_w \\ n_w \end{bmatrix}, \quad N = \begin{bmatrix} N_{p_u q_u} & \vdots & N_{d_w q_u} & N_{n_w q_u} \\ \dots & \vdots & \dots & \dots \\ N_{p_u e_w} & \vdots & N_{d_w e_w} & N_{n_w e_w} \\ N_{p_u u_w} & \vdots & N_{d_w u_w} & N_{n_w u_w} \end{bmatrix} = \begin{bmatrix} N_{11} & N_{12} \\ N_{21} & N_{22} \end{bmatrix} \quad (44)$$

or in the notation of Fig. 6

$$\begin{bmatrix} q_u \\ w \end{bmatrix} = N \begin{bmatrix} p_u \\ z \end{bmatrix} \quad (45)$$

Now $N_{d_w e_w}$, $N_{n_w e_w}$, $N_{n_w u_w}$ are known. For the rest we will use a methodology known as “pulling out the Δ ’s”. To this end, break the loop at points p_u , q_u (which will be used as additional inputs/outputs respectively) and use the auxiliary signals a , β , γ . To get the transfer function $N_{d_w q_u}$ (from d_w to q_u):

$$q_u = G_2(E_2\beta + E_1\gamma) = G_2(E_2\frac{1}{s} + E_1)\gamma \quad (46)$$

$$\gamma = GW_d d_w + Bu + A\frac{1}{s}\gamma = GW_d d_w + BKC\frac{1}{s}\gamma + A\frac{1}{s}\gamma \quad (47)$$

$$\Rightarrow \gamma = (I - BKC\frac{1}{s} - A\frac{1}{s})^{-1}GW_d d_w \quad (48)$$

Hence,

$$N_{d_w q_u} = G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} G W_d \quad (49)$$

Now, $N_{p_u q_u}$, $N_{p_u e_w}$, $N_{p_u u_w}$, are similar to $N_{d_w q_u}$, $N_{d_w e_w}$, $N_{d_w u_w}$, with $G W_d$ replaced by G_u , i.e.,

$$\begin{aligned} N_{p_u q_u} &= G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} G_u \\ N_{p_u e_w} &= W_y JH[I + B[K(I - CHBK)^{-1} CH]]G_u \\ M_{p_u u_w} &= W_u K(I - CHBK)^{-1} CHG_u \end{aligned} \quad (50)$$

Finally to find $N_{n_w q_u}$,

$$q_u = G_2(E_2 \beta + E_1 \gamma) = G_2(E_2 \frac{1}{s} + E_1) \gamma \quad (51)$$

$$\gamma = Bu + A \frac{1}{s} \gamma = BK(W_n n_w + y) + A \frac{1}{s} \gamma = BKW_n n_w + BKC \frac{1}{s} \gamma + A \frac{1}{s} \gamma \quad (52)$$

$$\Rightarrow \gamma = (I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} BKW_n n_w \quad (53)$$

Hence,

$$N_{n_w q_u} = G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} BKW_n \quad (54)$$

Collecting all the above yields N :

$$N = \begin{bmatrix} G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} G_u & G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} G W_d & G_2(E_2 \frac{1}{s} + E_1)(I - BKC \frac{1}{s} - A \frac{1}{s})^{-1} B K W_u \\ W_e JH[I + BK(I - CHBK)^{-1} CF]G_u & W_e J(I - HBKC)^{-1} H G W_d & W_e J(I - HBKC)^{-1} H B K W_u \\ W_u K(I - CHBK)^{-1} C F G_u & W_u (I - KCHB)^{-1} KCHG W_d & W_u (I - KCHB)^{-1} K W \end{bmatrix} \quad (55)$$

Having obtained N for the beam problem, all proposed controllers $K(s)$ can be compared using the structured singular value relations. [18, 19, 21]

4 ROBUSTNESS ISSUES

The superiority of H_∞ control lies in its ability to take explicitly into account the worst effect of unknown disturbances and noise in the system. Furthermore, at least in theory, it is possible to synthesize an H_∞ controller that is robust to a prescribed amount of modeling errors. Unfortunately, this last possibility is not implementable in some cases, as it will be subsequently illustrated.[16, 17]

In what follows, the robustness to modeling errors of the designed H_∞ controller will be analyzed. Furthermore an attempt to synthesize a μ -controller will be presented, and comparisons between the two will be made.

In all simulations, routines from Matlab's Robust Control Toolbox will be used. In particular:

1. For uncertain elements,

2. To calculate bounds on the structured singular value,
3. To calculate a μ -controller,

Numerical models used in all simulations, are implemented in three ways:

1. Through Eq. 56

$$\begin{aligned} K &= K_0(I + k_p I_{2n \times 2n} \delta_K) \\ M &= M_0(I + m_p I_{2n \times 2n} \delta_M) \\ D &= D_0 + 0,0005[K_0 k_p I_{2n \times 2n} \delta_K + M_0 m_p I_{2n \times 2n} \delta_M] \end{aligned} \quad (56)$$

and subsequent evaluation of matrix N for specific values of k_p , m_p .

2. By use of Matlab's "uncertain element object". As explained, this form is needed in the D - K robust synthesis algorithm.
3. By Simulink implementation of Fig. 8.

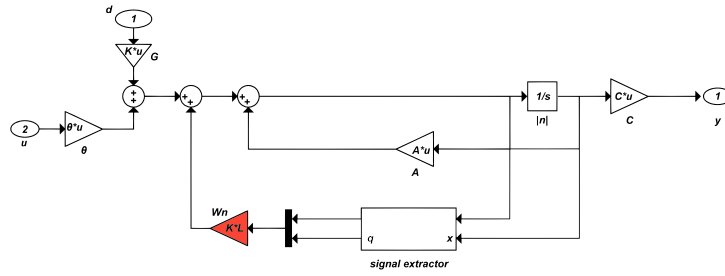

Figure 8: Simulink diagram of uncertain plant

4.1 Robust analysis - Results

Robust analysis is carried out through the relations:

$$\sup_{\omega \in \mathbb{R}} \mu_{\Delta}(N_{11}(j\omega)) < 1 \quad (57)$$

for robust stability, and,

$$\sup_{\omega \in \mathbb{R}} \mu_{\Delta_a}(N(j\omega)) < 1 \quad (58)$$

for robust performance.

In all the simulations that follow the disturbance is the mechanical load, i.e. $10N$ at the free end. For the H_{∞} found, robust analysis was performed for the following values of m_p , k_p .

1. $m_p = 0$, $k_p = 0.9$. This corresponds to a $\pm 90\%$ variation from the nominal value of the stiffness matrix K .

In Fig. 9 the displacement responses for this controller for the mechanical input are shown. In Fig. 10 are shown the bounds on the μ values. As seen the system remains

 Figure 9: Displacement response loading equal to 10N at free end, μ -controller for $m_p = 0$, $k_p = 0.9$

 Figure 10: μ -bounds of the H_∞ controller for $m_p = 0$, $k_p = 0.9$

 Figure 11: Displacement and control at free end for the H_∞ controller with $m_p = 0$, $k_p = 0.9$ (extreme values)

stable and exhibits robust performance, since the upper bounds of both values remain below 1 for all frequencies of interest. This result is validated in Fig. 11, where the displacement of the free end and the voltage applied are shown at the extreme uncertainty. Comparison with the open loop response for the same plant shows the good performance of the nominal controller.

2. $m_p = 0.9, k_p = 0$. This corresponds to a $\pm 90\%$ variation from the nominal value of the mass matrix M .

In Fig. 12 are shown the bounds on the μ values. As seen the system remains stable and exhibits robust performance, since the upper bounds of both values remain below 1 for all frequencies of interest. This result is validated in Fig. 13, where the displacement of the free end and the voltage applied are shown. Comparison with the open loop response for the same plant shows the good performance of the nominal controller.

Figure 12: μ -bounds of the H_∞ controller for $m_p = 0.9, k_p = 0$

Figure 13: Displacement and control at free end for the H_∞ controller with $m_p = 0.9, k_p = 0$ (extreme values)

3. $m_p = 0.9, k_p = 0.9$. This corresponds to a $\pm 90\%$ variation from the nominal values of both the mass and stiffness matrices M, K .

In Fig. 14 are shown the bounds on the μ values. As seen the system remains stable and exhibits robust performance, since the upper bounds of both values remain below 1 for all frequencies of interest. This result is validated in Fig. 15, where the displacement of the free end and the voltage applied are shown. Comparison with the open loop response for the same plant shows the good performance of the nominal controller.

5 CONCLUSIONS

In this paper advanced control techniques, like criterion H_∞ and m-analysis, have been applied for the suppression vibrations of smart structures. Under the assumption of an uncertainty introduced at the level of matrices in the structural analysis of the system the robust characteristics of the H_∞ controller and m-analysis were checked. There was a complete suppression of the oscillation and rigidity of the beam up to and including 90% variation from the nominal values.

An effort was made to find a robust μ -controller, using the recurring method $D - K$. In this case the resulting order of the controller as well as the required calculation requirements was very large. The performance of the robust μ -controller was not the one expected, something that most likely is due to the numerical properties of the system tables. Contrary to the H_∞ controller, the results are quite satisfactory and prove that the H_∞ control can suppress the oscillation of the smart beam taking into account the modelling uncertainties, external disturbances and the noise of the measurements.

In summary, the scientific fields which this paper has contributed to are:

- Application of the control in suppressing the oscillation of structural models.
- Introduction of the uncertainties in the mathematic model of structural elements.
- Suppression of oscillation and rejection of disturbances, by taking into account the modelling error, using the criterion of the robust H_∞ control.

- Reduction of the calculation requirements of the control using optimisation algorithms.
- Finding of a robust μ -controller

Experimental verification of the very good results that were found in this work as well as further detailed correlation of uncertainties with the real parameters of the mechanical system (material parameters, joints, cracks and delaminations etc) remain open for future investigations.

Keywords: Vibration control, Semi-active tuned mass damper, Variable stiffness, Wavelet Transform

Abstract. *An innovative design for a semi-active tuned mass damper (SATMD) with variable stiffness has been proposed for structural vibration control. The stiffness of the device can be continuously varied within a certain range using the variations of moment of inertia of an area. This adaptive tuned mass damper (TMD) is capable of real-time retuning and operates effectively in broad band frequency excitations. Employing the numerical simulations, the responses of a SDOF model coupled with the SATMD subjected to a seismic record are obtained. Wavelet transform is used to detect the instantaneous frequency of the excitation. The control effectiveness of the proposed SATMD is evaluated by comparing the results with those of the system coupled with a TMD. It is found that, the vibration suppression by the proposed SATMD is significantly superior to that of a conventional passive TMD.*

1 INTRODUCTION

Semi-active tuned mass damper (SATMD) is a semi-active vibration control device which basically originates from a passive tuned mass damper (TMD). TMD is a simple, inexpensive and reliable device to attenuate the undesired vibrations of systems. The principal drawback of TMDs, however, is that they are only effective over a narrow frequency band and their performance can be highly degraded due to changes in excitation frequency.

In an effort to improve the effectiveness of TMDs, active tuned mass dampers (ATMDs) have been introduced [1]. Although the ATMDs demonstrate better performance than the TMDs, the active system is more costly, more complex and needs careful maintenance. Besides, injection of energy into the controlled system by active control mechanisms enhances the potential for system destabilization.

Considering the advantages and limitations of the active system, the concept of a semi-active vibration control has been introduced. SATMD is the semi-active counterpart of TMD which has been subsequently modified to allow for the adjustment of damping [2, 3] and/or stiffness properties [4-8]. Compared to ATMDs, a smaller amount of active energy is required to modulate the damping or stiffness of such devices.

Most of the variable stiffness devices which have been proposed, involve several moving parts and mechanical and electrical components, which may put limits on the usage of these devices. Moreover, they may do not allow for the quick adjustment of stiffness, and their complicated design may cause manufacturing and maintenance difficulties.

In present study, in an effort to overcome the disadvantages of the above-mentioned variable stiffness devices, an innovative semi-active variable stiffness (SAVS) has been proposed. This beam-like device is capable of altering its stiffness in a smooth manner between minimum and maximum levels using the variations of the moment of inertia of an area as it rotates about a normal axis passing through its centroid. Theoretical expressions for the change of device stiffness as a function of rotation angle are developed underlying the concept of unsymmetrical bending of beams. A semi-active tuned mass damper (SATMD) is developed based on the proposed SAVS device. This adaptive vibration absorber is capable of real-time retuning and operates effectively in broad band frequency excitations. The excitation is assumed to be an earthquake record. Wavelet transform is employed to detect the instantaneous frequency of excitation and online tuning of the SATMD. The control effectiveness of the proposed SATMD is evaluated by comparing the results with those of the system coupled with a TMD.

2 THE INNOVATIVE SAVS DEVICE

The innovative variable stiffness device proposed in this paper is based on the variation of moment of inertia as an area rotates about a normal axis passing through its centroid. The formulations are developed using the well-known theory of skew bending or unsymmetrical bending of beams. The details are discussed in the following sub-sections.

2.1 Theory: Unsymmetrical bending of beams

Consider a cantilever prismatic elastic beam loaded at the end of the span with a concentrated force P as shown in Figure 1(a). The cross-sectional area of the beam is assumed to be rectangular with height h and width b , as shown in Figure 1(b). In this figure z and y are the principal axes passing through the centroid of the cross-sectional area. The downward deflection at the end of the beam is [9]

Figure 1: (a) Fixed-end beam loaded with a concentrated force at the end of the span and its deflected curve; (b) Cross-sectional area; (c) Rotated cross-section.

$$v_B = \frac{PL^3}{3EI_z} \quad (1)$$

where L , E and I_z are the length of the beam, modulus of elasticity of the beam material and moment of inertia of the cross-sectional area about principal axis z . It can be said that the effective stiffness at the end of the beam in y -direction is

$$k_{yB} = \frac{3EI_z}{L^3} \quad (2)$$

Now consider the case in which the beam is rotated clockwise about x -axis through an angle θ as shown in Figure 1(c). The new horizontal and vertical axes are denoted as z' and y' . The deflection at the end of the beam in y' and z' -directions can be expressed, respectively, as [10]

$$\bar{v}_B = \frac{PL^3 I_{y'}}{3E(I_{z'} I_{y'} - I_{z'y'}^2)} \quad (3a)$$

$$\bar{w}_B = \frac{PL^3 I_{z'y'}}{3E(I_{z'} I_{y'} - I_{z'y'}^2)} \quad (3b)$$

where I_y is the moment of inertia of the cross section about principal axis y and $I_{z'y'}$ is the product of inertia of the cross section in the new $z'y'$ -coordinates. \bar{v}_B is downward; and \bar{w}_B is rightward for $0 < \theta < \pi/2$ and leftward for $\pi/2 < \theta < \pi$. It can be concluded that the equivalent stiffness at the end of the beam in y' -direction is

$$k_{y'B} = \frac{3E(I_{z'} I_{y'} - I_{z'y'}^2)}{L^3 I_{y'}} \quad (4)$$

Using the well-known equations which relate $I_{z'}$, $I_{y'}$ and $I_{z'y'}$ to I_z and I_y [11], gives

$$k_{y'B} = \frac{6EI_z I_y}{L^3 [(I_z + I_y) - (I_z - I_y) \cos 2\theta]} \quad (5)$$

which shows the variation of the stiffness at the end of the rotated beam in vertical directions as a function of θ .

2.2 The proposed SAVS device

The proposed device is composed of a mass which is connected to the main structure by the use of two co-axial cantilever beams, located in two opposite sides of the mass as shown in Figure 2. The beams are hinged together at their free ends (point B) and their other ends are clamped to the main structure (points A and C). The rotational degrees of freedom at the clamped ends are released, so it is possible for the beams to be rotated about their neutral axes. The mass is perpendicularly connected to the hinge point through a rigid truss element. The beams are rotated through the same angle but in the opposite directions, Figure 2(b), as the result, point B and hence the mass will move just in horizontal direction. (the external excitation is assumed to be applied to the main structure horizontally). By rotating the beams, the effective stiffness of point B in horizontal direction will smoothly vary from its minimum value, Figure 2(a) to its maximum value, Figure 2(c). Electric motors mounted at two ends of the beams may rotate the beams about their neutral axes to the desired angle according to a signal which is supplied through control algorithm.

Figure 2: Variable stiffness device (a) $\theta = 0$; (b) $0 < \theta < 90^\circ$; (c) $\theta = 90^\circ$.

Since the beams behave like parallel springs, the effective stiffness at point B equals the sum of each beam's stiffness at their end points. Employing the same procedure as [7], it can be shown that

$$\bar{k}_{y'B} = \frac{6EI_{z'}}{L^3} \quad (6)$$

or

$$\bar{k}_{y'B} = \frac{3E}{L^3} [(I_z + I_y) + (I_z - I_y) \cos 2\theta] \quad (7)$$

It should be noted that due to opposite rotation of the beams through the same angle, their vertical deflections will cancel out.

3 VIBRATION CONTROL OF A SDOF SYSTEM BY THE PROPOSED SATMD

As a case study, the efficacy of the proposed SATMD for suppression of vibrations of a SDOF system under earthquake excitation is investigated.

3.1 Analysis of the model

Consider a SDOF system equipped with a SATMD. This integrated system can be modeled as a 2DOF system, as schematically shown in Figure 3. The governing equations of motion of the system are

$$\begin{aligned} m_1 \ddot{x}_1(t) + (c_1 + c_2) \dot{x}_1(t) - c_2 \dot{x}_2(t) + (k_1 + k_2(t))x_1(t) - k_2(t)x_2(t) &= -m_1 \ddot{x}_g \\ m_2 \ddot{x}_2(t) - c_2 \dot{x}_1(t) + c_2 \dot{x}_2(t) - k_2(t)x_1(t) + k_2(t)x_2(t) &= -m_2 \ddot{x}_g \end{aligned} \quad (8)$$

where m_1 , c_1 and k_1 are the mass, damping capacity and stiffness of the primary system, respectively; m_2 , c_2 and $k_2(t)$ are the mass, damping capacity and adjustable stiffness of the mass damper, respectively; $x_1(t)$ and $x_2(t)$ represent, respectively, primary and mass damper displacement relative to the ground; and \ddot{x}_g is the ground acceleration.

Figure 3: SDOF system equipped with a SATMD.

3.2 Tuning algorithm

In order to attenuate undesirable vibrations during earthquake, the stiffness of the mass damper is varied to tune the damper to the excitation frequency. However, in practice the semi-active stiffness coefficient is limited by both an upper bound, k_{max} , and lower bound, k_{min} . The instantaneous frequency of the excitation is detected using complex morlet wavelet transform and the stiffness of SATMD is altered to keep it tuned to the excitation in real time.

When the calculated tuning stiffness for the mass damper, $m_2 \omega^2(t)$, lies within the range specified by the lower and upper limit parameters, the damper stiffness is set to this value. When the calculated stiffness is outside these bounds, the damper stiffness is clipped to the upper or lower bound. The stiffness is then related to an angle θ according to Equation (7).

3.3 Developed model and parameter values used

In the system considered, the damper's stiffness varies nonlinearly with time. Therefore, the system response is to be obtained through numerical integration of equations of motion, in

which the damper's stiffness is to be calculated at each step. For this purpose a SIMULINK model is developed. The assumed parameters of the primary system and SATMD are summarized in Table 1. In present study, the variable spring is assumed to be massless and there is thus no kinetic energy associated with its motion.

The results are obtained and compared to those of the system equipped with a conventional TMD. For this case, the mass and damping coefficient of the TMD are the same as SATMD and the stiffness has a constant value such that the natural frequency of the TMD equals the steady-state excitation frequency.

Table 1: Primary system and SATMD parameters.

Primary system		SATMD	
Parameter	Value	Parameter	Value
m_1	10000 kg	b	4 mm
f_1	1 Hz	h	22 mm
ξ_1	0.02	L	48 cm
		E	2×10^{11} Pa
		ξ_2	0.01
		m_2	100 kg

3.4 Numerical results

In this study, 1968 Hachinohe earthquake signal is used as the excitation (Fig 4). Fig. 5 shows the instantaneous frequency of the earthquake which is detected by wavelet transform. The system's response is obtained numerically using the SIMULINK model. To evaluate the control system performance, maximum displacement, velocity and acceleration of the primary system for the system controlled by TMD (passive control) and by SATMD (semi-active control) are calculated. Since the performance of the controlled system may not be provided solely by the peak responses, normed system responses (RMS) are obtained as well. The norm, denoted $\|\cdot\|$, is defined as

$$\|\cdot\| = \sqrt{\frac{1}{t_f} \int_0^{t_f} [\cdot]^2 dt} \quad (9)$$

where t_f is the simulation time.

Figure 4: Hachinohe earthquake signal.

Figure 5: Instantaneous frequency of the excitation.

The primary system and mass damper's response for both TMD and SATMD cases are shown in Figures 6 to 8. The peak and RMS values of the primary system are summarized in Table 2. It can be observed that the maximum displacement response reduction in the case of SATMD compared to the TMD case is about 15%. This reduction for the maximum velocity and acceleration responses are about 13% and 4%, respectively. Furthermore, the reduction in RMS of displacement, velocity and acceleration responses is, respectively, about 39%, 39% and 36%.

Figure 6: Displacement response of (a) primary system; (b) vibration absorber.

Figure 7: Velocity response of (a) primary system; (b) vibration absorber.

Figure 8: Acceleration response of (a) primary system; (b) vibration absorber.

Table 2: max and RMS values of the primary system response.

Control System	$\max(x_1(t))$ (m)	$\max(\dot{x}_1(t))$ (m/s)	$\max(\ddot{x}_1(t))$ (m/s ²)	$\text{RMS}(x_1(t))$ (m)	$\text{RMS}(\dot{x}_1(t))$ (m/s)	$\text{RMS}(\ddot{x}_1(t))$ (m/s ²)
TMD	0.11	0.69	4.54	0.04	0.25	1.61
SATMD	0.10	0.60	4.35	0.02	0.15	1.02

According to the cross-sectional dimensions of the beam given in Table 1, the minimum and maximum values of the moment of inertia are 117.33 mm^4 and 3549.3 mm^4 , respectively. Therefore, the stiffness of SAVS device can vary between certain minimum and maximum values of 1273.1 N/m and 38513 N/m . Figure 9 shows the variation of SATMD's stiffness as a function of time. Figure 10 shows the angle of rotation of the each beams from the principal axis about which the moment of inertia is a maximum. The figure demonstrates that the angle varies between 79.94° to 23.11° to provide the required stiffness.

Figure 9: Variations of SATMD's stiffness versus time.

Figure 10: Angle of rotation of SAVS.

4 CONCLUSIONS

The design and formulations of a novel SAVS device is presented. The main advantages of this device can be enumerated as: simple structure, low power requirement, ease of design and manufacturing, quick adjustment of stiffness from minimum to maximum, low moving parts. A new SATMD is developed based on the SAVS device which is capable of adjusting its frequency in real-time. The effectiveness of the SATMD for suppression of a SDOF system under earthquake excitation is investigated. Wavelet transform is used to detect instantaneous frequency of the excitation and online tuning of SATMD. It was shown that the SATMD reduces the maximum and RMS displacement response of the primary system about 15% and 39%, respectively, compared to the passive TMD tuned to the operating frequency. A reduction of 13%, 4%, 39% and 36% is also observed for the maximum velocity, maximum acceleration and RMS of velocity and acceleration of the system, respectively.

Keywords: Response control, Clipped optimal control, MR dampers, Semi-active control.

Abstract. *The present work describes part of the R&D on using a semi-active structural control technique in a civil engineering experimental model frame equipped with a MR damper, developed within COVICOCEPAD project approved in the framework of Eurocores program S3T. Some results are provided associated with the calibration of a magneto-rheological (MR) damper at FEUP (Faculdade de Engenharia da Universidade do Porto) as well as on the experimental modal identification of the dynamic properties of a small-scale metallic frame, with and without the inclusion of a specific MR device. Some numerical results of the controlled frame under simulated earthquakes are given, to be later compared with the experimental results of such frame installed in a Quanser shaking table.*

1 INTRODUCTION

In the last two decades R&D of structural vibration control devices for buildings and bridges has been intensified in order to answer the construction market needs that demand more effective systems to reduce the damage caused on structures by seismic and wind loadings. Although the main purpose of a seismic design is to protect the population from the consequences of a severe earthquake, the protection of the building stock may also be regarded as an important option during the conception and design process.

Seismic isolation and passive energy dissipation are two well-established techniques validated by a huge amount of real applications [1, 2]. Magneto-rheological fluid based devices have the appropriate features justifying their relevance for possible civil engineering applications and therefore the attention of researchers to study its potential as vibration control hardware [3, 4]. The control strategy for these devices is based on semi-active control that may be more reliable and stable than active control.

In this paper is addressed some on-going R&D on the vibration control of a three degree-of-freedom (3-DOF) scaled metallic frame with a MR damper [5].

An equivalent device was tested in the laboratory to obtain the main rheological characteristics in order to develop a numerical model to simulate its behavior. Then a 3-DOF scaled frame was assembled and system identification techniques using an impact hammer procedure were performed to obtain the experimental dynamic properties of this structural system. Based on these results a numerical model was created to initiate the semi-active control research process in order to investigate and calibrate the frame behavior with the MR damper.

2 SEMI-ACTIVE CONTROL OF MR DAMPERS

MR fluids have become an extensively studied “smart” fluid and some experimental research has been done in the last years to produce a “smart” control device. The MR damper performance is often characterized by using the force versus velocity relationship. MR dampers have the possibility to change the damping characteristics based on a force versus velocity envelope, which can be described as an area rather than a line in the force-velocity plane.

Many authors have developed modeling techniques for the MR dampers. The Bouc-Wen model shown in Fig. 1 allows modeling nonlinear hysteretic systems and is frequently used to model MR dampers [3].

Figure 1: Bouc-Wen model for a MR damper.

The MR force of the device can be computed by

$$F_{MR} = c_0 + k_0(x - x_0) + \alpha z \quad (1)$$

In this equation F_{MR} is the predicted damping force, k_0 is the accumulator stiffness, c_0 is the viscous damping and z is the evolutionary variable of the first order nonlinear differential equation

$$\dot{z} = -\gamma |\dot{x}| z |z|^{n-1} - \beta \dot{x} |z|^n + A \dot{x} \quad (2)$$

The parameters β , γ and A allow controlling the linearity in the unloading and the smoothness of the transition from the pre-yield to the post-yield region. The equation of motion that describes the behavior of a controlled building under an earthquake load [6] is given by:

$$M\ddot{x} + C\dot{x} + Kx = -\Gamma f - M\lambda\ddot{x}_g \quad (3)$$

where M is the mass matrix, C is the damping matrix, K is the stiffness matrix, x is the vector of floors displacements, \dot{x} and \ddot{x} are the floor velocity and acceleration vectors respectively, f is the measured control force, λ is a vector of ones and Γ is a vector that accounts for the position of the MR damper in the structure. This equation can be rewritten in the state-space form as

$$\begin{cases} \dot{z} = Az + Bf + E\ddot{x}_g \\ y = Cz + Df + v \end{cases} \quad (4)$$

where z is the state vector, y is the vector of measured outputs and v is the measurement noise vector. The other matrix quantities are defined by

$$\begin{aligned} A &= \begin{bmatrix} 0 & I \\ -M^{-1}K & -M^{-1}C \end{bmatrix} & B &= \begin{bmatrix} 0 \\ M^{-1}\Gamma \end{bmatrix} & E &= -\begin{bmatrix} 0 \\ \lambda \end{bmatrix} \\ C &= \begin{bmatrix} -M^{-1}K & -M^{-1}C \\ I & 0 \end{bmatrix} & D &= \begin{bmatrix} M^{-1}\Gamma \\ 0 \end{bmatrix} \end{aligned} \quad (5)$$

To perform the numerical analysis a single bay three-storey frame (three degree of freedom in shear frame configuration) was designed. The columns at the corners, having the same stiffness, are made of aluminum with an average cross section of 1.5mm by 50mm and the diaphragm floors are made of polycarbonate plates monolithically attached to the columns. The frame mass is around 19 kg and each floor has an average mass of 3.65 kg. The stiffness of the experimental frame was designed to keep the fundamental frequency near to 2 Hz. Assuming a three storey shear frame, the frame mass (M) and the stiffness matrix (K) are obtained as:

$$M = \begin{bmatrix} 3.65 & 0 & 0 \\ 0 & 3.65 & 0 \\ 0 & 0 & 3.65 \end{bmatrix} (kg) \quad (6)$$

$$K = \begin{bmatrix} 5820 & -2910 & 0 \\ -2910 & 5820 & -2910 \\ 0 & -2910 & 2910 \end{bmatrix} (N/m) \quad (7)$$

The three natural frequencies obtained with the above mass and stiffness matrices are: 2.00Hz, 5.60Hz and 8.09Hz. A damping of 0.5% along with the above mass and stiffness matrices formed the initial parameters for the modal analysis.

The frame was then assembled (Fig. 2) to perform experimental research and calibration of the numerical model.

Figure 2: Metallic scaled frame at the shaking table.

After calibrating the MR damper numerical model it is necessary to select a proper control algorithm to efficiently use this device in reducing the dynamic response of structural systems. The fundamental condition to operate the MR damper is based on a generated damping force that is related with the input voltage; the control strategy is selected so that the damping force can track a desired command damping force.

In the last few years several approaches have been proposed for better selection of the input voltage that must be applied to the MR damper to achieve the maximum performance [7-9]. In the present numerical study a Clipped Optimal control will be used as shown in Fig. 3.

Figure 3: Clipped Optimal controller.

This strategy consists of a Bang-Bang (on-off) controller that causes the damper to generate a desirable control force that is determined by an “ideal” active controller (in state feedback form). A force feedback is used to produce the desired control force f_d , which is determined by a linear optimal controller $K_{k(s)}$, based on the measured structural responses y and the measured damper force f_c .

Only applied voltage v_a can be commanded (and not the damper force) that is selected by $v_a = v_{max} H(f_d - f_c) f_c$ in which v_{max} is the voltage level associated with the saturation of the magnetic field in the MR damper and $H(.)$ is the Heaviside step operator.

The following voltage selection algorithm is applied: When the actual force being generated by the damper f_c equals the desirable force f_d , the voltage applied remains the same. When the magnitude of the force f_c is smaller than the magnitude of f_d and both forces have the same sign, then the voltage applied is set to its maximum level to increase the damper force. Otherwise, voltage is set to zero.

The selected optimal controller is based on a Linear Quadratic Optimal Control. In this numerical study the linear controller is obtained with a Linear Quadratic Regulator (LQR) strategy that will be used in a state feedback control.

The main objective to design the optimal controller is to obtain an optimal control vector $f_c(t)$ that minimizes a performance index J . In this case a quadratic performance index in $z(t)$ and $f_c(t)$ is used and represented by:

$$J = \int_0^t \left[z^T(t) \cdot Q \cdot z(t) + f^T(t) \cdot R \cdot f(t) \right] dt \quad (8)$$

In eq. 8 Q and R are weighting matrices associated with the state variables and with the input variables respectively. The magnitudes of these matrices are defined according to the importance that is given to the state variables and the control forces on the minimization process. Increasing the values of Q matrix elements implies the prioritization of the response reduction over the control forces. On other hand, increasing the values of the elements of R implies the prioritization of the control forces over the response reduction.

The solution of the LQR problem is based on the analysis of the algebraic Riccati equation

$$PA + A^T P - PBR^{-1}B^T P + Q = 0 \quad (9)$$

and the LQR problem can be solved using a linear state feedback with a constant gain G according to

$$u(t) = -G \cdot x(t) = \left[R^{-1}B^T P \right] \cdot x(t) \quad (10)$$

To select the appropriate values for Q and R the following procedure was used in this study: it was assumed that R matrix has the following form

$$R = r \cdot I \quad (11)$$

where I is the identity matrix and r is a multiplier, and that Q matrix assumes the following form

$$Q = \begin{bmatrix} K & 0 \\ 0 & 0 \end{bmatrix} \quad (12)$$

A parametric study was carried out by changing the value of the multiplier (10^{-1} , 10^{-3} , 10^{-5} , 10^{-7} , 10^{-9} , 10^{-11} , 10^{-13} and 10^{-15}) and then verifying the efficiency of (reduction of floor displacements, accelerations and also the control force on the actuator). It was verified that decreasing this value implies a more marked reduction of the response.

In this case a significant reduction (up to 90% of the floor displacements and accelerations) was obtained with $r=10^{-9}$.

3 EXPERIMENTAL SETUP

According to the scheduled research program [10], the next stage was related to the study of the experimental dynamic behavior of a 3DOF scaled metallic load frame equipped with a semi-active device. The experimental frame located at FEUP-Covicocepad Lab, can be forced dynamically using the Quanser shaking table II as the dynamic loading actuator.

To study the semi-active control strategy a small MR damper was placed at the first floor level attached to the frame and rigidly attached to the shaking table as shown in Fig 4. To measure the damping force values generated during the experimental tests a load cell was placed in the MR damper support system.

Figure 4: a) MR damper attached to the experimental metallic frame; b) RD-1097-01 MR Damper.

The parameters of the MR damper shown in Fig. 5 are: minimum force in passive-off mode < 9 N (for current 0.0A at piston velocity 200 mm/s), maximum force 100 N (for current 1.0A and piston velocity 51 mm/s), stroke ± 25 and response time < 25 ms (time required to reach 90% of the steady-state value of force under a step change of the current from 0.0 to 1.0A, for 51 mm/s).

3.1 Experimental MR Damper Behavior

To study the behavior of a MR damper some experiments were carried out on a MTS universal testing machine (Mechanical Engineering Laboratory at FEUP) with two MR dampers: RD-1005-03 and RD-1097-01 supplied by LORD Corporation.

After assemblage the MR dampers were forced with a sinusoidal signal at a fixed frequency, amplitude and current supply. To obtain the response under several combinations of frequencies, amplitudes and current supplies a series of tests were carried out. Therefore, a set of frequencies (0.5, 1.0, 1.5 and 2.0 Hz), amplitudes (2, 4, 6, 8 and 10 mm) and current supplies (0.0, 0.1, 0.2, 0.25, 0.5, 0.75, 1.0 and 1.5 A) were used to complete the test program [6].

The variable current tests demonstrate that increasing the input current implies an increase in the force required to yield the MR fluid and a plastic-like behavior is observed in the hysteretic loop. In the frequency dependent test, it was observed that the maximum damping force increases with the frequency due to large plastic viscous force at higher speeds.

The same procedure was used to obtain the rheological behaviour of the RD-1097-01 MR damper. This was the selected device to be used in this analysis due to the small range of forces involved in the scaled frame dynamic analysis. In order to use the Bouc-Wen model, the following current (I) dependent parameters were used:

$$\begin{cases} \alpha(I) = 72.80/I^3 - 42.88/I^2 + 14.83/I + 0.29 \\ c_d(I) = -9.37/I^4 + 10.22/I^3 - 4.33/I^2 + 0.89/I + 0.02 \end{cases} \quad (13)$$

And the current independent parameters are: $k_0 = 0.0$, $\beta = -7.078$, $\gamma = 10.614$, $A = 36.21$ and $n = 1.0$. These are approximate values that proved to capture very well the hysteretic behaviour of the MR damper [11].

3.2 System Identification

An impulse hammer test was carried out in order to obtain the modal parameters of the structure. The structural response was measured with a piezoelectric accelerometer (Brüel & Kjær type 4393 with measuring amplifier type 2525) placed at the first floor and a portable

real-time analyzer (OROS 35 real-time multi-analyzer) that was used to perform the necessary mathematical rationing on input and response signals to produce the desired transfer function.

The desired frequency response functions (magnitude) for each input/output measurements are shown in Figs. 6-8.

Figure 6: Frequency Response Function of H1_1.

Figure 7: Frequency Response Function of H1_2.

Figure 8: Frequency Response Function of H1_3.

The parameters of the scaled frame were then obtained based on the data provided by these functions and are tabulated in Table 1.

Frequency	Damping	Modal Participation
1,913986 (1st mode)	0.03157	34.43248
5,627778 (2nd mode)	0.01198	35.25975
8,086245 (3rd mode)	0.00899	30.30777

Table 1: Parameters of the scaled frame.

4 RESULTS

To study the response of the structure with the semi-active controller, a few characteristic earthquake records were considered; those will be also input in the Quanser shaking table of FEUP-Covicocepad laboratorial facilities, in order to experimentally calibrate and numerically compare different control strategies. The results considered herein are just for the El Centro earthquake record selected as input.

The three horizontal floor displacements were selected as the parameters (output) to verify the efficiency of the control law. Some results of this numerical analysis are plotted in Figs. 11-14 for uncontrolled and semi-active controlled scenarios.

Figure 9: Uncontrolled response without MR damper.

Figure 10: Uncontrolled response with MR damper @ 0.00A.

The structure response plot shown in Fig. 9 was obtained without any device connected to the scaled frame (non-controlled response). Then, the MR damper was attached to the 1st floor in a passive configuration (without current applied) and a new displacement response plot was obtained as shown in Fig. 10. It is clear that a significant displacement reduction is obtained even with the MR damper in passive mode.

Figure 11: Uncontrolled response with MR damper @ 0.25A.

Figure 12: Semi-active control response.

A new analysis was carried out with the MR damper acting as a passive device but with a constant current of 0.25A. As it can be verified in Fig. 11, the three floor displacements were considerably reduced (from 0.008 to 0.006 m) due to the increase of damping and stiffness at this level. This means that the MR damper introduces a partial constraint and as consequence the frame behaves like a 2 DOF system above the first floor level. Finally, the semi-active controller was activated and the horizontal floor displacements were again plotted as shown in Fig. 12.

As expected, the semi-active control based on the Clipped Optimal algorithm was successfully applied. The lateral displacements of the building floors were reduced significantly during the earthquake duration, as visible by the maximum displacement of the top floor reaching a value of about 0.003 m. This value corresponds to 20% of what was reached initially without control; and to 40% of what was reached with passive control.

Although the main objective of this analysis is to validate the efficiency of the Clipped Optimal algorithm, it is clear that further numerical and experimental research must be carried out. Since this is an ongoing research program, the next step will be the implementation of new control strategies.

5 CONCLUSIONS

This paper addresses the vibration control of a 3-DOF experimental metallic frame with a MR damper. The MR damper was tested to find the dynamic properties and a numerical model was developed to simulate its behaviour. System identification allowed obtaining the dynamic response of this structural system. In a numerical example the three-story structure was

controlled using a MR damper on the first floor. The simulated results show that the Clipped Control algorithm resulted in an improvement over the uncontrolled system.

6 ACKNOWLEDGMENTS

This work is integrated in the thematic and activities of the international collaborative research project COVICOCEPAD approved by the European Science Foundation (ESF) within the Smart Structural Systems Technologies (S3T) Program. It was sponsored in Portugal until last December 2010 by FCT (Fundação para a Ciência e a Tecnologia) project PPPCDT-05-S3T-FP054-COVICOCEPAD, fact that is herein acknowledged.

Abstract. *This document demonstrates the usefulness, operation and design of Tuned Mass Dampers (TMDs) in the structural control of seismic response. This vibration control system, which main asset is the introduction of additional damping on structural system, can improve the structural behavior particularly in terms of forces and displacements, in case of seismic loads. This paper describes some practical situations using TMDs and the theoretical approach of their operation. Then, design graphics are presented as a result of the research work developed at FEUP and the effectiveness of this type of solution is demonstrated by an illustrative example.*

1 INTRODUCTION

Tuned Mass Dampers have been widely used to control the dynamic response of structures in Civil Engineering. These devices consist of an additional mass connected to the structure by a spring and a damper, and demonstrate effectiveness in the mitigation of harmonic vibrations. In this kind of vibrations, a well-tuned device behaves in a correct phase opposition to the response of the controlled system, reducing its vibrations [1]. Usually in these cases, the TMD mass represents 1 or 2% of the modal mass associated at the vibration mode in analysis, which results in a small control system, easily integrated architecturally or even hidden.

However, if the structure contains a non-harmonic response, as usually happens in Earthquake Engineering, the mechanism used by TMDs to reduce movement of the main system is no longer based on phase compensation to the movement. Thus, the main advantage is based on the effect of adding supplementary damping to the structure (Paredes, Barros and Cunha [2]). In these cases, the mobilization of considerable damping values which increase significantly the structural damping ratios and hence reduce the dynamic response of the system, is only possible through the use of additional heavy masses.

In this context, this paper aims to expose the research work that has been developed at FEUP about the possibility of using TMDs with heavy mass in structures, using as an additional mass a part of the own structure to control the remaining. This idea was inspired by some real applications in buildings such as the case “Applause Tower” located in Osaka, Japan. In this building, the mass associated with a helipad on the roof was used to act as control system of the remaining structure, using hydraulic actuators, which cause inertial forces between platform and building (Figure 1).

In the case of the control system proposed in this paper, the idea is to use a passive system mobilizing a heavier mass. To realize a practical system of this kind will be necessary to use a portion of the structure less commonly used, such as roof and technical floor. Thus, it is possible to materialize the high amount of mass required for the passive system to become efficient. Figure 2 presents some possible solutions (Barros [3]).

Figure 1 – a) Overview of the “Applause Tower”; b) Support equipment of the platform; c) Hydraulic actuators

Figure 2 – Examples of use of part of the structure to function as the control system (Barros [3])

2 ANALYSIS OF THE TMD'S OPERATION

2.1 Application to structures with low damping under harmonic solicitations

The structural model usually used to the analyses of the TMD's operation in structures under harmonic solicitations is indicated in Figure 3, where m_1 , k_1 and c_1 are the variables that define respectively the characteristics of mass, stiffness and damping of the initial structure, and m_2 , k_2 and c_2 define the same characteristics in TMD. When this device is optimally designed, the Frequency Response Function (FRF) presents two peaks corresponding to the natural frequencies of the system of two degrees of system. The FRF curve should be determined so that the two peaks are flat and have de lowest possible value of the amplification of the initial system (Figure 4). In these circumstances it is said that the TMD is tuned optimally.

Figure 3 – One degree of freedom model with a TMD

Figure 4 – FRF curves for three different TMDs in the same system ($q_{opt} = 0,87$)

In the particular case where the structural damping is null ($c_1 = 0$), the TMD's design may be done by the following expressions proposed by Den Hartog [1]:

$$q_{opt} = \frac{1}{1 + \mu} \quad (1)$$

$$\xi_{2opt} = \sqrt{\frac{3\mu}{8(1 + \mu)^3}} \quad (2)$$

where

$$\mu = \frac{m_2}{m_1} ; \quad q = \frac{\omega_2}{\omega_1} ; \quad \omega_1 = \sqrt{\frac{k_1}{m_1}} ; \quad \omega_2 = \sqrt{\frac{k_2}{m_2}} ; \quad \xi_2 = \frac{c_2}{2m_2\omega_2}$$

In this situation, the design process begins through the quantification of μ which corresponds to the maximum dynamic amplification (D) imposed to the main system, and this parameter can be obtained by the following expression.

$$D = \sqrt{\frac{2 + \mu}{\mu}} \quad (3)$$

After calculating the TMD's mass, using the parameter μ , the optimal frequency and damping of the device are given by the expressions (1) and (2).

The previous expressions can still be used on TMD's design in structures with low structural damping, typically less than 1% (Bachmann and Weber [4]). However, in structures with a higher level of damping, the assumptions used in obtaining such expressions are no longer valid, requiring a different methodology for the determination of the ideal characteristics of these devices. In this case, one should resort to numerical methods to obtain design graphics where to find the values of q_{opt} and ξ_{2opt} (or ξ_{TMD}) corresponding to a particular value of μ , which can minimize the dynamic amplification of the main structure.

2.2 Methodology used in the case of seismic actions

The implementation of a properly tuned TMD to a structure has as a result the introduction of a certain level of additional damping to the system. According to Villaverde [5], for one degree of freedom system with a damping ratio ξ_1 which is installed a small TMD optimally designed with damping ratio ξ_2 , the final damping ratio of the system with TMD is approximately

$$\xi_{Final} \cong \frac{\xi_1 + \xi_2}{2} \quad (4)$$

This expression clearly indicates that the inclusion of a TMD in a structure may increase the final damping to a defined level required for the system, which TMD damping is given by the previous equation. This approach is clearly appropriate to the context of seismic design of structures, since effect of structural damping in the response is quantified in the regulations. So, if you need the structural behavior remains within certain limits, which is associated with a given damping required to achieve it, this level of damping can be achieved with the installation of a Tuned Mass Damper.

However, the design procedure of these devices is different in these cases. Indeed, the classical definition based on the mass of the TMD that corresponds to a certain level of reduction of structural response and subsequent determination of the stiffness and damping is no longer valid. In seismic design, to obtain a certain final damping in the structure, first it's need to fix the value of TMD's damping and then his mass and stiffness.

An important aspect in determining the optimal parameters of a TMD is that you can only mobilize high levels of damping in the use of additional high mass values. Due to this fact arises the need for TMDs with heavy mass. Notice for example the FRF curves shown in Figure 5 (Paredes [6] , Barros [3]) which correspond to a structure with an initial damping ratio of 5% associated with a TMD which mass represents 5% of the mass of the initial system. The continuous curve corresponds to the situation where the device is optimally tuned (lower maximum possible dynamic amplification) resulting in a device with a damping of 14%. The attempt to increase the TMD's damping without changing its mass results in the loss of efficiency of the device. Nevertheless, until a certain amount of increased damping it is possible to keep the peaks with the same ordinate. For increasing damping ratio values, the TMD begins to behave like it is “clinging” to the structure and the set begins to converge to a system without TMD.

Figure 5 – FRF curves for three different TMDs in the same system ($\xi_{2opt} = 14\%$)

3 DESIGN GRAPHICS

3.1 Process for obtaining the TMD design graphs

In order to obtain the parameters of a TMD which can introduce a certain level of damping to the system, can be used a structural model similar to that shown in Figure 3. In this case, the values of m_1 , k_1 and c_1 as well as m_2 , k_2 and c_2 have the same physical meaning presented above. The m_2 parameter has to take several values fixed in corresponding to several values of ξ , and the system was studied so that the initial damping ratio takes value of 1%, 3% and 5%, thus resulting in three curves in each graph. Then, for various values of r_1 up to 0,50 was determinate the value of q_{opt} that flat the two peaks of the FRF curves for various damping values installed on TMD. The damping installed on the control system that corresponds to a lower dynamic amplification, is the optimum damping of the TMD (ξ_{2opt}).

After the addition of Tuned Mass Damper, the two resulting vibration modes have almost the same modal damping, so their average is presented in a third graphic, depending on the value of μ . This reasoning is repeated for each one of the three initial structural damping considered (Barros [3]).

3.2 Design graphics for determination of the TMD's parameters

Following the procedure presented above, it is possible to compile all the values of optimal parameters for the design of TMDs, for the three initial structural damping of 1%, 3% and 5%. Thus, the values of q_{opt} and ξ_{2opt} for a given value of the μ , can be obtained from the graphs presented in the following Figures 6 and 7.

Figure 6 – q_{opt} for values of μ up to 0,50 , (Barros [3])

Figure 7 – ξ_{2opt} for values of μ up to 0,50 , (Barros [3])

As already mentioned, have been made a third graphic that reflects the average value of the two final modal damping achieved, and this has an additional utility as the input of the query graph can be given by any one of its axes. In other words, you can set up the final damping achieved for a given μ , or otherwise, can determine the value of μ and thus the mass of the TMD necessary to achieve a given final damping desired, from an initial damping significantly lower. This second way of using this graphic is particularly interesting for the cases of structural control under seismic actions. This third graph is represented in Figure 8.

Figure 8 – Final structural damping for values of μ up to 0,50 , (Barros [3])

Comparing the final damping achieved with the inclusion of a Tuned Mass Damper in a system with an initial damping of, for example, 5% with the final damping proposed by Villaverde [5] (that would be approximately the average of both dampings in question), it appears that this formula is a good approximation for values of μ up to about 0,04. For higher values of μ , this match begins to lose its accuracy, thus corroborating the idea in the Villaverde's method that this approximation is valid for low values of μ and damping of TMD. The following Figure 9 represents the two curves referring to both final damping concerned and identifies the similarity to a range of μ up to 0,04 as well as the evolution of loss of accuracy of the approach suggested by Villaverde [5] for higher values of μ .

Figure 9 – Comparison between the real final damping achieved and the average of Villaverde's method [5]

4 EXAMPLE OF APPLICATION

4.1 Description of the problem

The application example presented consists in a fifteen storey reinforced concrete frame located in Portimão, Algarve. This case's study aims to compare the behavior of the structure in terms of displacements and applied forces resulting from seismic activity present in the regulatory response spectra of Eurocode 8 (EC8) [6], when the structure has or has not control system through a TMD. Also, when there is no TMD, the structure was studied as having two distinct behavior factors of 1,5 and 2,5, enabling the comparison of the effectiveness of the application of TMD into structures more or less ductile (Barros [3]).

This study was performed through a modal analysis by response spectrum which consists in a linear elastic analysis. This procedure is a simplified analysis by which, according to regulation FEMA 356 [7], when the structure is under control must behave elastically to the seismic action considered, although the EC8 does not refer such approach.

To realizing the TMD, was considered the two top floors of the frame structure as a mass to be used by the control system. The choice of the number of floors to behave as a mass of TMD was based on the final damping achieved in each scenario.

So, consider the structural scheme shown in Figure 10, which represents the frame structure treated, regular in height and plant and set on a ground classified as type C.

Figure 10 – Schematic structure of the frame in study (Barros [3])

Neglecting the contribution of the pillar's mass when compared with the floor's mass, it is assumed that in the almost permanent combination of actions the mass of each degree of freedom is worth 10 tones. With regard to the stiffness of the structure, the slabs are considered infinitely rigid in bending when compared with the pillars. It is also assumed that the section of the columns is constant in all the framed structures, with approximate dimensions of 0,30 x 0,40 square meters (C25/30 concrete), resulting in a fundamental frequency of vibration in the order of 1 Hertz.

4.2 Main results

In order to control the first vibration mode of the main structure (thirteen storeys), a TMD was installed consisting of two floors which should behave as a single mass, which is why the structure now has fourteen degrees of freedom. The TMD's characteristics were obtained from the design graphics presented and are shown in Table 1. The structural damping ratio of the frame structure increases from 5% to about 19%, consisting in a significant amplification of this parameter.

μ	q_{opt}	ζ_{TMD} (%)	ζ_{Final} (%)
0,295	0,741	30	19

Table 1 – TMD's characteristics and final damping achieved

As noted above, the structure without TMD is studied with two distinct behavior factors. The natural frequencies of vibration given below correspond to the frame structure without TMD (regardless of the behavior factor) and with TMD.

Vibration Mode	Natural frequency without TMD (rad/s)	Natural frequency with TMD (rad/s)
1	6,73	5,19
2	20,11	8,43
3	33,29	23,20
4	46,12	38,16
5	58,48	52,64
6	70,25	66,42
7	81,29	79,31
8	91,49	91,13
9	100,76	101,73
10	109,00	110,95
11	116,11	118,67
12	122,04	124,79
13	126,71	129,22
14	130,08	131,90
15	132,12	-

Table 2 – Natural frequencies of the structure with and without TMD

Regarding the effect of seismic accelerations in the structure are only shown the parameters for the type 1 earthquake, since the type 2 is not so onerous, being of course the type 1 that affects the design of the structure. Thus, Table 3 outlines the structure's displacements for the three cases of study, for each degree of freedom.

As can be seen by consulting Table 3, all degrees of freedom have strong reductions in their displacements after the installation of the control system. The exception is the two top floors, because they are associated with TMD have their movements increased, as expected. Another aspect that can be seen from the analysis of this table is that the final displacements of the structure without TMD are practically the same for both cases of different behavior factors.

Degree of freedom	Displacements for behavior factor of 2,5 (m)	Displacements for behavior factor of 1,5 (m)	Displacements for the structure with TMD (m)
1°	0,01506	0,01505	0,00566
2°	0,02993	0,02991	0,01114
3°	0,04444	0,04440	0,01633
4°	0,05842	0,05836	0,02113
5°	0,07172	0,07165	0,02553
6°	0,08424	0,08416	0,02953
7°	0,09586	0,09577	0,03315
8°	0,10651	0,10641	0,03639
9°	0,11610	0,11599	0,03924
10°	0,12455	0,12443	0,04171
11°	0,13177	0,13164	0,04374
12°	0,13768	0,13755	0,04530
13°	0,14220	0,14207	0,04635
14°	0,14526	0,14512	0,16487
15°	0,14681	0,14667	

Table 3 – Structure's displacements for the three studied cases

Likewise the seismic forces associated with each degree of freedom, for the two structural behavioral factors of 1.5 and 2.5, are tabulated in Table 4.

Degree of freedom	Applied forces for behavior factor of 2,5 (kN)	Applied forces for behavior factor of 1,5 (kN)	Applied forces for the structure with TMD (kN)
1°	4,90	8,17	14,59
2°	9,47	15,79	26,24
3°	13,43	22,38	33,15
4°	16,57	27,61	35,31
5°	18,79	31,31	34,57
6°	20,14	33,56	33,35
7°	20,84	34,71	32,59
8°	21,21	35,33	31,51
9°	21,68	36,11	29,99
10°	22,58	37,60	30,27
11°	24,00	39,97	34,41
12°	25,77	42,92	40,41
13°	27,56	45,89	39,02
14°	28,98	48,28	94,63
15°	29,77	49,59	

Table 4 – Applied forces to the structure for the three studied cases

In examining Table 4 it appears that when compared with the initial structure provided with a behavior factor of 2,5, the installation of a TMD does increase the seismic forces in the structure markedly. Moreover, when compared the seismic forces after docking the TMD with the forces arising from the same phenomenon in the structure with the behavior factor of 1,5, it appears that the addition of forces is much less significant, as there are a few degrees of freedom whose forces diminish its value.

5 CONCLUSIONS

The numerical study conducted on this issue has enabled the development of design graphs for TMDs with a heavy mass, which allow an easy practical and quick way to obtain the optimal parameters of such passive system of vibration control, which can be of important use for both buildings and bridges (Paredes and Barros [9]).

As can be understood through the analysis of Table 3, the displacements checked in the structure due to seismic accelerations are practically equal in both cases of different ductility characteristics. Thus it appears that the displacements do not depend on the behavior factors of the structure. Because of this, the effectiveness of the use of TMDs in displacements values is similar in both cases so that these parameters are a little more than a third of what they were initially. This proves that this control system is quite effective in terms of displacements under seismic actions.

With regard to seismic forces that arise in the structure (Table 4), and not forgetting the obligatoriness of the structure remains in elastic regime when it has control system (imposed by FEMA 356), the influence of the installation of TMD has strongly depends on the characteristics of ductility concerned. Indeed, when the structure is characterized by a behavior factor of 2,5, there is a significant increase of forces, there are even a few degrees of freedom increased to more than double its initial value, resulting in an increase of almost 60% in foundation's bending moments. When the structure is less ductile, having a behavior factor of 1,5, the seismic forces installed in most of the degrees of freedom reduce its value. In the remaining degrees of freedom, the increase is much less significant when compared with the situation of more ductile structure, leading to a reduction in the bending moments at the foundations of around 4%. Due to this scenario, the use of TMDs to control the seismic response of structures is more interesting in more rigid structures, and in the more ductile the extra efforts may undermine the feasibility of using this damping system.

ACKNOWLEDGEMENTS

This work is integrated in the thematic and activities of the international collaborative research project COVICOCEPAD approved by the European Science Foundation (ESF) within the Smart Structural Systems Technologies (S3T) Program. It was sponsored in Portugal until last December 2010 by FCT (Fundação para a Ciência e a Tecnologia) project PPPCDT-05-S3T-FP054-COVICOCEPAD, fact that is herein acknowledged.

Abstract. *This work addresses basic concepts regarding the wind effects on tall buildings and their subsequent wind responses. The methodology proposed in Eurocode 1 for quantification of the wind actions, is compared with the methodology still in force in the Portuguese legislation, to assess the pros and cons of each towards a more realistic building design. Using commercial software for the structural calculations, a specific study of a given tall building is performed by the actions associated with the two regulations, with the intention of comparing stress resultants and generalized displacements. A simplified method for quantifying the dynamic action on these structures is adopted, with the purpose of studying techniques for vibration control of the along-wind response in terms of displacements and accelerations. For the tall building case under study, a realistic comparison is made between the building's response under dynamic wind action with and without a TMD.*

1 INTRODUCTION

The wind action on towers (Almeida and Barros [1]) and masts (Barros [5]) and on a tall building (Ferreira [11], Taranath [21]) is of paramount importance to their design, which can influence the structural system to be adopted or even lead to the needed implementation of control systems to reduce vibrations caused by wind dynamic phenomena.

After a comparative analysis between the Portuguese Regulation on Safety and Actions for Building Structures and Bridges (RSAEEP) [18] and Eurocode 1 (EC1) [10] it can be concluded that there are differences in these methods here considered to quantify the wind actions, with an improvement for design inherent to the European regulation.

Using the World Trade Center (WTC) as reference tall building type, a parametric study was performed on the variation of shear forces and bending moments as a function of height, as evaluated by the RSAEEP and by EC1. An equivalent frame structure to the reference World Trade Center was modeled, based upon matching fundamental mode contribution, leading to a structural behavior very close to the three-dimensional modeled behavior found in available references.

For modeling the dynamic wind action reference is made to a method of generating sets of synthetic wind, called the method of Shinozuka. The dynamic response of the reference building, in the longitudinal along-the-wind direction, permits to assess occupants comfort level with regards to accelerations. A theoretical implementation of TMD will be studied and proven to be effective for this tall building under harmonic or under wind loads. The reductions of the responses were found to be more effective on accelerations than on displacements.

2 WIND ACTIONS UNDER TWO DESIGN CODES

For better understanding of the case of study that will be analyzed, some considerations and synthesis of the methodologies are given concerning the two used regulations, in this paper, for wind effects: Portuguese Regulation on Safety and Actions for Building Structures and Bridges (RSAEEP) [18] (still in use) and Eurocode 1 (EC1) [10] (in view of its implementation at European level).

2.1 Wind actions according to Portuguese Regulation RSAEEP

2.1.1 Zoning of territory

RSAEEP [18] admits the differentiation of Portuguese territory in two zones (A and B) based on the analyses of existing meteorological records that, for the same occurrence probability of occurrence, attributes wind intensities sufficiently differentiated.

	Zoning of territory
Zone A	Practically all Portugal except regions belonging to zone B
Zone B	Azores and Madeira; Coastal strip 5 km width; Places of altitude above 600 m; Places on zone A but subjected to particularly unfavorable wind conditions

Table 1 Zoning of Portuguese territory

2.1.2 Aerodynamic roughness of the terrain profile

RSAEEP [18] proposes the differentiation of the terrain profile roughness in two types: type I and type II. The variation of the wind speed with height depends strongly on the dimensions and distribution of existing obstacles in the terrain that affect the air flow in the neighborhood. Notice that the consideration of just two roughness types is a bit schematic and it results from the difficulty of characterizing objectively the multiplicity of the wind situations.

	Aerodynamic roughness of the terrain profile
Type I	Places inside urban zones where medium and tall buildings prevail
Type II	Remaining places: rural zones and periphery of urban zones

Table 2 Distinction between the two types of roughness at RSAEEP

Since roughness of type I is greater, to it will correspond lower wind speed and therefore lower dynamic wind pressures.

2.1.3 Quantification of wind speeds

The wind action on structures depends on the greatness and distribution of the wind speed and of its characteristics; therefore, it is necessary to define the characteristic values and the reduced values of the wind speed in function of the height above the soil.

The average wind speed is defined in function of the height above the soil and is referred to time intervals of 10 minutes. The variation with height h of the characteristic value of the mean wind velocity v (m/s) is given by equation (1). In this formula, h_0 is the height above the soil for which the roughness of the soil is no longer felt; v_0 is the average wind speed at the height h_0 ; and α is a parameter that depends on the soil roughness. For terrain roughness of type I, v_0 is equal to 18 m/s and $1/\alpha$ takes the value 0,28 ; for terrain roughness of type II, v_0 is equal to 25 m/s and $1/\alpha$ takes the value 0,20.

$$v = v_0 \left(\frac{h}{h_0} \right)^{1/\alpha} \quad (1)$$

Given the imprecision of the definition of the wind speeds in the immediate neighborhood of the terrain, it is advisable to admit a constant value of the wind speed: (i) of 20 m/s up to a height of 15 m, for terrain roughness of type I; (ii) of 25 m/s up to a height of 10 m, for terrain roughness of type II.

For the case of structures identically loaded by the wind in any direction (as is the case of structures with symmetry of revolution), the values of the wind speed to consider should be multiplied by $\sqrt{3}$.

To take into account the fluctuations of wind velocity resulting from the flow turbulence, RSAEEP [18] contemplates a constant value of 14 m/s to be added to equation (1) regardless of the terrain roughness type. RSAEEP [18] also contemplates that the characteristic value of the average wind velocity for zone B, are 10% higher than those of zone A. Table 3 synthesizes all the previous considerations. Additionally RSAEEP [18] contemplates situations on how to consider the height of ground in inclined terrains.

		Zone A		Zone B	
		Roughness Type I	Roughness Type II	Roughness Type I	Roughness Type II
Height (m)	≤ 10	$v_A = 20+14$	$v_A = 25+14$	$v_B=1.1 \ v_A$	$v_B=1.1 \ v_A$
	$10 \leq h \leq 15$	$v_A = 20+14$	$v_A = 25\left(\frac{h}{10}\right)^{0.20} + 14$		
	>15	$v_A = 18\left(\frac{h}{10}\right)^{0.28} + 14$			

Table 3 Characteristic values of wind velocity (m/s)

2.1.4 Determination of Wind Actions on Buildings

For determining the wind actions on buildings, RSAEEP [18] is based on a simplified method that consists on the application of a static pressure on the surface of the structure. The static pressure p is obtained multiplying the dynamic wind pressure w_k (dependent on the wind speed and therefore also on height or elevation along the structure) by shape coefficients δ that are characteristic of the aerodynamic shape of the structure, as given by equation (2).

$$p = w_k \delta \quad (2)$$

It should be enhanced that this process does not lead to correct results for flexible structures, since they are dynamically excited by the flow and therefore generating a fluid-structure interaction (FSI) difficult to quantify. Nevertheless, on this section, wind actions are evaluated according to RSAEEP [18] methodology, for comparison with the results that will be obtained through the EC1. Although the latter also calculates the actions based in equivalent static loads, it presents however a structural factor contemplating dynamic effects.

The dynamic wind pressure w_k (N/m² or Pa), corresponding to a specific or volumetric air mass density of 1,225 kg/m³, is given by equation (3) with the wind speed v in m/s.

$$w_k = 0.613 v^2 \quad (3)$$

For determining the characteristic values of the wind dynamic pressure along height above ground, RSAEEP [18] presents a graph for zone A (Figure 1) coherent with Table 3.

Figure 1 Characteristic values of the dynamic pressure w_k (kN/m²) for zone A

The values corresponding to zone B are obtained multiplying by 1.2 the values indicated for zone A (since wind speed for zone B is 10% higher than that of zone A, and in the equation for dynamic pressure the speed is raised to the power exponent 2). According to regulation RSAEEP [18], the reduced values of the wind dynamic pressures should be obtained through the following coefficients: $\Psi_0 = 0.4$, $\Psi_1 = 0.4$ and $\Psi_2 = 0.4$. Also, depending on the building typology, Ψ_0 can reach the value of 0.6.

The shape coefficients can be: (exterior and interior) pressure coefficients and force coefficients. The pressure coefficients permit to determine the wind pressure perpendicularly to the building surfaces, in agreement with equation (2). The acting force on a surface will be given by the product of the pressure by the respective area. The resulting force of the wind action is obtained through the summation of the (interior and exterior) forces applied to each considered surface. Figure 2, taken literally from RSAEEP [18], gives the exterior pressure coefficients for building facades.

Figure 2 Values of the external pressure coefficients for the facades of buildings

The force coefficients allow to determine directly the resulting force F of the wind pressures on a certain structure (or on part of it) according to the equation (4), where A is the area of the surface (or portion) of the structure and d_f is the force coefficient.

$$F = w_k d_f A \quad (4)$$

2.2 Wind actions according to Eurocode EC1

The Eurocode 1 Part 1-4 (EC1) [10] gives characteristic values of wind actions for the global structure, and for parts of it (for example, walls and roofs) or for elements linked to the structure (for example, chimneys).

The calculation is based in a model using a peak factor. The basic idea of this model is that the maximum wind action in a static analysis or the dynamic response of the structure, can be described by the sum of an average component (constant part of the action) with a turbulent component (not constant). The development of this calculation model and its promotion is attributed to Davenport [8].

The wind action calculated according to the EC1 [10] gives characteristic values, that are obtained from base values of wind speed and wind pressure, corresponding to a probability of annual exceedence of 2% (ie, 0.02) that is equivalent to a return period of 50 years. The return period (R) for a set of generic value of a random variable (U) is the reciprocal or inverse of the probability of exceedence, and it corresponds to the number of samples that it is necessary to consider, on the average, so that a sample is registered with a value higher than U.

The effect of the wind in the structure depends on the size, shape and dynamic properties of the structure. The response of the structure should be calculated from the peak velocity pressure q_p at a reference height and in the undisturbed wind field. Also the coefficients of pressure and/or of force should be considered, as well as the contribution of a structural factor $c_s c_d$. Peak velocity pressure depends on the wind climate, the terrain roughness and orography, and the reference height; such pressure is equal to the mean velocity pressure plus a contribution from short-term pressure fluctuations.

2.2.1 Zoning of territory by categories

EC1 characterizes and distinguishes between five categories of terrain roughness according to Table 4, which also gives terrain parameters (roughness length z_0 and minimum height z_{\min}).

Terrain category		z_0 (m)	z_{\min} (m)
0	Sea or coastal area exposed to the open sea	0,003	1
I	Lakes or flat and horizontal area with negligible vegetation and without obstacles	0,01	1
II	Area with low vegetation such as grass and isolated obstacles (trees, buildings) with separations of at least 20 obstacle heights	0,05	2
III	Area with regular cover of vegetation or buildings or with isolated obstacles with separations of maximum 20 obstacle heights (such as villages, suburban terrain, permanent forest)	0,3	5
IV	Area in which at least 15 % of the surface is covered with buildings and their average height exceeds 15 m	1	10

Table 4 Terrain categories and terrain parameters

2.2.2 Basic values

The fundamental value of the basic wind velocity $v_{b,0}$ is the characteristic 10 minutes mean wind velocity, irrespective of wind direction and time of year, at 10 m above ground level in open country terrain with low vegetation such as grass and isolated obstacles with separations of at least 20 obstacle heights (terrain category II).

The basic wind velocity v_b (defined as a function of wind direction and time of year at 10m above ground of terrain category II) shall be calculated from the following equation

$$v_b = c_{dir} c_{season} v_{b,0} \quad (5)$$

where c_{dir} is the directional factor, c_{season} is a season factor and $v_{b,0}$ is the fundamental value of the basic wind velocity. In some situations it is advantageous to consider a fundamental velocity with a probability of annual exceedence (p) different from 0,02 (or 2%). The method used by EC1 is based in the statistical treatment of European wind pressure data. The basic velocity is then obtained multiplying the previous equation (5) by a probably factor c_{prob} (given below) and dependent of the desired or intended probability (p).

$$c_{prob} = \left(\frac{1 - K \ln(-\ln(1-p))}{1 - K \ln(-\ln(0.98))} \right)^n \quad (6)$$

The shape parameter K , depending on the coefficient of variation of the extreme-value distribution, and the exponent n , are parameters that should be quantified in the respective national annexes and whose recommended values are 0,2 and 0,5, respectively.

2.2.3 Mean wind

The mean wind velocity varies with height and is defined as the average value of wind speed for a 10 minutes period at an appropriate height above ground. The variation of the mean wind velocity $v_m(z)$ at a height z above the terrain depends on the terrain roughness (Houghton and Carruthers [13]) and orography and on the basic wind velocity v_b and should be determined according to:

$$v_m(z) = c_r(z) c_o(z) v_b \quad (7)$$

where $c_r(z)$ is the roughness factor and $c_o(z)$ is the orography factor (usually taken as 1). The roughness factor accounts for the influence of the ground roughness of terrain (upwind of the structure in the wind direction considered) in the vertical distribution of the mean wind velocity at the site (profile along the height above ground level). It is given by:

$$c_r(z) = \begin{cases} k_r \ln\left(\frac{z}{z_0}\right), & \text{for } z_{\min} \leq z \leq z_{\max} \\ c_r(z_{\min}), & \text{for } z \leq z_{\min} \end{cases} \quad (8)$$

where the roughness length z_0 and the minimum height z_{\min} depend on the terrain categories and assume the recommended values given in Table 4. The terrain factor k_r depends on the roughness length z_0 and is calculated using

$$k_r = 0.19 \left(\frac{z_0}{z_{0,II}} \right)^{0.07} \quad (9)$$

where $z_{0,II} = 0.05$ m (terrain category II), z_{\min} is the minimum height (Table 4, according to terrain categories) and z_{\max} is to be taken as 200 m.

The category of roughness which should be used for a given wind direction depends on the distance at which the roughness is constant, called the reference distance (small areas presenting different roughness of the terrain can be ignored), and within a sector angle of 15 degrees to each side of the fixed wind direction. The reference distance must be specified in the National Annex and in case of choice between two or more terrain categories it should be chosen the area corresponding to the lower roughness. The orographic factor takes into account the existence of mountains, hills or cliffs, where their existence results in an increase in wind speed by more than 5%. The regulation indicates that the procedure for determining this factor should be given in the national annex of each country.

Nevertheless, the effects of orography can be overlooked when the theoretical slope (average slope of terrain) upstream is less than 3. Although this is not usually a problem for tall buildings, it should be noted that for considering the wind effects on lower building structures, it must be taken into account that these may be affected by strong winds led to the near-ground due to the existence of higher neighboring structures. Annex A.4 of the Eurocode EC1 proposes a methodology for taking into account these effects on structures.

2.2.4 Wind turbulence

According to Cook [7], because the standard deviation of the turbulence near the ground is relatively constant with height, EC 1 [10] adopts a simplified model where the turbulence intensity decreases with height in inverse proportion to the growth of average wind speed between heights z_{\min} and z_{\max} , and taking a constant value for heights below z_{\min} .

The turbulence intensity $I_v(z)$ at height z is defined as the standard deviation of the turbulence σ_v divided by the mean wind velocity, as given in equation (10).

$$\begin{cases} I_v(z) = \frac{\sigma_v}{v_m(z)} = \frac{k_t}{c_0(z) \ln\left(\frac{z}{z_0}\right)} & \text{for } z_{\min} \leq z \leq z_{\max} \\ I_v(z) = I_v(z_{\min}) & \text{for } z \leq z_{\min} \end{cases} \quad (10)$$

The turbulent component of wind velocity has a mean value of 0 and a standard deviation σ_v determined - in terms of the terrain factor k_r , basic wind velocity v_b and for the turbulence factor k_t - by:

$$\sigma_v = k_r v_b k_t \quad (11)$$

The value of the turbulence factor k_t may be given in the National Annex of each country. The recommended value for k_t is 1. Cook [7] proposes a better balance of turbulence factor values, as given in Figure 3 where k_t values are also a function of the height. Figure 4 shows the evolution of turbulence intensity as a function of height for different terrain categories, using the values recommended by the Eurocode EC1 EC 1 [10] for k_t and c_0 .

Figure 3 Alternative values for turbulence factor k_t

Figure 4 Profiles of turbulence intensities according to EC1

2.2.5 Wind dynamic pressure for peak velocity

The calculation of wind dynamic pressure by EC1 is based on the method of the “gust loading factor”, assuming that the response of the structure can be obtained through the sum of an average (constant) component with a fluctuating (dynamic) component; the latter component is expressed through a peak gust factor $g(t)$ (Kappos [15], Almeida and Barros [1], Cook [7]). In this situation the peak velocity can be given by

$$\hat{v} = v_m(z) + g(t) \sigma_v(z) = v_m(z) [1 + g(t) I_v(z)] \quad (12)$$

As the dynamic wind pressure is $\frac{1}{2} \rho v(z)^2$, the peak pressure is given by:

$$q_p(z) = \frac{1}{2} \rho (\hat{v}(z))^2 = \frac{1}{2} \rho (v_m(z))^2 \left[1 + 2 g(t) I_v(z) + (g(t))^2 (I_v(z))^2 \right] \quad (13)$$

As last term in the previous equation is negligible with comparison with the others, EC1 suggests the following equation for determining the wind dynamic pressure for peak velocity:

$$q_p(z) = \frac{1}{2} \rho (\hat{v}(z))^2 \approx [1 + 7 I_v(z)] \frac{1}{2} \rho (v_m(z))^2 = c_e(z) q_b \quad (14)$$

where ρ is the specific mass air density varying with height, temperature and barometric pressure (recommended value is 1.25 kg/m^3), q_b is the basic velocity pressure given by $\frac{1}{2} \rho v_b^2$ and $c_e(z)$ is the exposure factor interpreted as the ratio

$$c_e(z) = q_p(z) / q_b = 1 + 7 I_v(z) \quad (15)$$

The value 7 in the previous equation corresponds to a gust peak factor of 3.5 for an average period of 10 minutes.

2.2.6 Actions due to wind

The wind pressures on external surfaces w_e are obtained by multiplying a pressure coefficient of external pressure c_{pe} by the dynamic pressure for peak velocity $q_p(z_e)$ evaluated at a certain reference height for the external pressure z_e (section 7 of EC1), according to the equation:

$$w_e = q_p(z_e) \cdot c_{pe} \quad (17)$$

Similarly, the wind pressures on internal surfaces w_i are obtained by multiplying a pressure coefficient of external pressure c_{pi} by the dynamic pressure for peak velocity $q_p(z_i)$ evaluated at a certain reference height for the external pressure z_i , according to a similar equation. The actuating pressure on a given area will be given by the difference pressure between the exterior and interior, taking into account the signs. The reference heights to adopt as well as the coefficients of external and internal pressure for different structures are recommended in Section 7 of EC1.

According to EC1 and with respect to buildings, the pressure coefficient of external pressure depends on the size of the area where wind action is applied. The coefficient of external pressure for loaded areas smaller than 1 m^2 ($c_{pe,1}$) and greater than 10 m^2 ($c_{pe,10}$) are provided in tables for appropriate settings of buildings. Table V presents the recommended values for pressure coefficients of external pressure on the windward and leeward sides of the vertical walls of buildings rectangular in plan. Figure illustrates the reference height z_e to consider for the same type of structures on the windward side.

Zona	D		E	
	h/d	$c_{pe,10}$	$c_{pe,1}$	$c_{pe,10}$
5		+0,8	+1,0	-0,7
1		+0,8	+1,0	-0,5
$\leq 0,25$		+0,7	+1,0	-0,3

Table 5 Coefficients of external pressure on the windward and leeward sides of the vertical walls of buildings rectangular in plan

Figure 5 Reference height for the external pressure and corresponding pressure profile in the windward side

According with EC1, the wind forces acting in the entire structure (or on a structural component) can be determined directly through the: (i) appropriate force coefficients applied to the whole structure or on the structural component; (ii) vectorial sum of the components of pressure (external and internal forces in structural members evaluated from surface external and internal pressures) and frictional stresses acting on the structure resulting from the friction of the wind parallel to the external surfaces.

When using force coefficients, the wind force F_w acting on a structure or a structural component may be determined directly by

$$F_w = c_s c_d c_f q_p(z_e) A_{ref} \quad (18)$$

or by vectorial summation over the individual structural elements using the expression

$$F_w = c_s c_d \sum_{elements} c_f q_p(z_e) A_{ref} \quad (19)$$

where the product $c_s c_d$ is the structural factor, c_f is the force coefficient for the structure or structural element (Section 7 of EC1), $q_p(z_e)$ is the peak velocity pressure evaluated at the reference height z_e , and A_{ref} is the reference area of the structure or structural element (Section 7 of EC1).

Wind forces obtained by the sum of the components of external and internal pressure and frictional forces are given by:

$$F_w = c_s c_d \sum_{surfaces} w_e A_{ref} + \sum_{surfaces} w_i A_{ref} + c_{fr} q_p(z_e) A_{fr} \quad (20)$$

where w_e is the external pressure on the individual surface at height z_e , w_i is the internal pressure on the individual surface at height z_i , c_{fr} is the friction coefficient and A_{fr} is the area of external surface parallel to the wind.

The frictional forces act only on the surfaces parallel to the wind and are small when compared with the forces of pressure, so that only become significant when the area of surfaces parallel to the flow is considerable. The EC 1 [10] states that the effects of friction surfaces may be waived when the area of all surfaces parallel to the wind flow (or that do the least angle with this) is equal to or less than four times the area of all exterior surfaces perpendicular to the flow.

It is important to also emphasize that the dynamic effects and the effects related to the size of the structure, due to the structural factor $c_s c_d$, are restricted to the external components because the code standard assumes that the internal pressures and the frictional forces are static values that are fully distributed along the surfaces.

According to Cook [7] this assumption is correct with respect to the internal pressures, which depend on the volume inside, but it is not quite correct with respect to the friction forces. If in fact the structural factor takes into account fluctuations of pressure normal to the surfaces (due to wind gusts not acting simultaneously along a large surface), then the friction effects caused by these blasts also do not act simultaneously.

2.2.7 Structural factor

The structural factor $c_s c_d$ takes into account the combined effect of: (i) No simultaneous occurrence of the peak pressure of wind on the facades of the structure, often called the size effect (size factor c_s); (ii) Vibration of the structure in its fundamental mode due to the turbulence action, commonly called dynamic response (dynamic factor c_d).

The Eurocode defines a number of situations for which the value of the structural factor can be used as 1, avoiding the detailed process of calculation. These situations correspond to small structures or structural elements, for which the effect of size and the dynamic effect are both small. In the case of structures which are not suitable for the direct consideration of this factor as a unit value, this can be obtained using two different procedures specified in the code standard. In Annex D, EC1 provides indicative figures of the structural factor for different types of structures and their characteristics. Figure shows the values of the structural factors (taken from Annex D), with respect to reinforced concrete buildings.

Figure 6 Structural factor for multistory concrete buildings

For the case of vertical structures such as buildings, or horizontal structures such as bar members or beams or point-like structures as signboards, and for the case where the vibration of the structure in wind direction occurs only in its fundamental mode of vibration, the structural factor is given by equation (21):

$$c_s c_d = \frac{1 + 2 K_p I_v(z_s) \sqrt{B^2 + R^2}}{1 + 7 I_v(z_s)} \quad (21)$$

where z_s is the reference height, K_p is the peak factor defined as the ratio of the maximum value of the fluctuating part of the response to its standard deviation, $I_v(z_s)$ is the turbulence intensity, B^2 is the background factor allowing for the lack of full correlation of the pressure on the structure surface, R^2 is the resonance response factor allowing for turbulence in resonance with the vibration mode.

This procedure then estimates the dynamic response of the structure as the square root of the sum of one resonance component and another background component. According to EC1 the evaluation of component parcels (K_p, B^2, R^2) can be made according to two procedures suggested in separate annexes B and C of the code standard. Both annexes indicate that it is conservative to take $B^2 = 1$. As an indication it is suggested that the values obtained by these two procedures should not differ by more than 5%.

In the following paragraph a comparative study of these procedures will be presented, here labeled *Procedure 1* and *Procedure 2* and evaluated respectively in agreement with Annexes B and C of EC1. A synthetic description of these is given in Table 6, outlining the calculation the main parameters.

Procedure 1 – Annex B (EC1)	Procedure 2 – Annex C (EC1)
$B^2 = \frac{1}{1 + 0,9 \left(\frac{b+h}{L(z_s)} \right)^{0,63}}$	$B^2 = \frac{1}{1 + \frac{3}{2} \cdot \sqrt{\left(\frac{b}{L(z_s)} \right)^2 + \left(\frac{h}{L(z_s)} \right)^2 + \left(\frac{b}{L(z_s)} \cdot \frac{h}{L(z_s)} \right)^2}}$
$R^2 = \frac{\pi^2}{2 \cdot \delta} \cdot S_L(z_s, n_{1,x}) \cdot R_h(\eta_h) \cdot R_b(\eta_b)$	$R^2 = \frac{\pi^2}{2 \cdot \delta} \cdot S_L(z_s, n_{1,x}) \cdot K_s(n_{1,x})$
$K_p = \sqrt{2 \cdot \ln(v \cdot T)} + \frac{0,6}{\sqrt{2 \cdot \ln(v \cdot T)}}$	$K_p = \sqrt{2 \cdot \ln(v \cdot T)} + \frac{0,6}{\sqrt{2 \cdot \ln(v \cdot T)}}$
$\sigma_{a,x}(z) = \frac{c_f \cdot \rho \cdot b \cdot I_v(z_s) \cdot v_m^2(z_s)}{m_{1,x}} \cdot R \cdot K_x \cdot \phi_{1,x}(z)$	$\sigma_{a,x}(z) = c_f \cdot \rho \cdot I_v(z_s) \cdot v_m^2(z_s) \cdot R \cdot \frac{K_y \cdot K_z \cdot \phi(y, z)}{\mu_g \cdot \phi_{max}}$

Table 6 Two procedures for calculating parameters of the structural factor

In both procedures the turbulence length scale $L(z)$, representing the average gust size for natural winds, is given by equation (22); the non-dimensional power spectral density function $S_L(z, n)$ given by equation (23) is illustrated in Figure 7.

$$\begin{cases} L(z) = L_t \left(\frac{z}{z_t} \right)^\alpha, & \text{for } z \geq z_{\min} \\ L(z) = L(z_{\min}) & \text{for } z \leq z_{\min} \end{cases} \quad (22)$$

$$S_L(z, n) = \frac{6,8 f_L(z, n)}{(1 + 10,2 f_L(z, n))^{5/3}} \quad \text{with} \quad f_L(z, n) = \frac{n L(z)}{v_m(z)} \quad (23)$$

In these equations the reference height $z_t = 200$ m, the reference length scale $L_t = 300$ m, the exponent $\alpha = 0,67 + 0,05 \ln(z_0)$, where the roughness length z_0 (m) and the minimum height z_{\min} (m) are given in Table IV.

Also the non-dimensional frequency f_L is determined by the natural fundamental frequency n of the structure (in Hz) by the mean velocity $v_m(z)$ and by the turbulence length scale $L(z)$, as detailed in equation (23) above.

Figure 7 Power spectral density function $S_L(f_L)$

Annex F of EC1 presents the considerations for calculating the dynamic characteristics of some structures and for the case of buildings, with height h above 50 m, the fundamental frequency can be approximately calculated according to equation (24):

(24)

$$n = \frac{46}{h} \quad (\text{Hz, with height in m})$$

For the use of Table VI: b and h are the width and height of the building, respectively; δ is the logarithmic decrement of the damping, given by the sum of the structural logarithmic decrement δ_s with the aerodynamic logarithmic decrement δ_a and the logarithmic decrement due to the existence of special damping systems (tuned mass dampers TMD, sloshing tanks TLD, etc) δ_d ; the calculation of δ is specified in Annex F of the code standard EC1; the variables $R_h(\eta_h)$ and $R_b(\eta_b)$ are aerodynamic admittance functions and $K_s(n_{1,x})$ is a size reduction function (expressed in terms of the natural frequency of the structure $n_{1,x}$, which may be determined using Annex F), given in Annexes B and C of EC1; T is the averaging time for the mean wind velocity ($T = 600$ seconds); the up-crossing frequency ν should be obtained from equation (25); $\sigma_{a,x}(z)$ is the standard deviation of the characteristic along-wind acceleration of the structural point at height z (Annex B of EC1); $\Phi_{1,x}(z)$ is the fundamental along wind modal shape (first approximation expressions are given in Annex F); $m_{1,x}$ is the along wind fundamental equivalent mass; K_x , K_y and K_z are coefficients defined in Annexes B and C.

(25)

$$\nu = n_{1,x} \sqrt{\frac{R^2}{B^2 + R^2}} \quad (\nu \geq 0,08 \text{ Hz})$$

3 COMPARATIVE ANALYSIS BETWEEN RSAEEP AND EC1

As summarized in previous chapters, it can be seen that although both code regulations RSAEEP [18] and EC 1 [10] detail calculation methods for the actions of wind on buildings through consideration of equivalent static loads, these two regulations are quite distinct.

In short, EC 1 [10] departs from a basic wind velocity from which the mean wind velocity is calculated, and thereafter the turbulence intensity. The dynamic pressure for peak velocity is obtained from the turbulence intensity and from the mean wind velocity. The wind pressure exerted on the surfaces is then calculated by multiplying the pressure peak velocity by their pressure coefficients, specific to each zone. The forces are finally obtained multiplying the wind pressure by the reference area, introducing corrections taken into account by the structural factor.

In RSAEEP [18] the quantification of the wind forces results from the multiplication of the dynamic pressures (function of the gust velocity, at the height of the floor in analysis) by the coefficient of external pressure (depending on wind direction and dimensions of the building) and by the area of influence corresponding to the application of force on each floor.

In order to understand and compare the procedures adopted by both code regulations for evaluating the shear forces and the bending moments at the base of a building due to wind actions, the results obtained for these generalized actions on a reference tall building are given herein; the considered reference building has a square cross section of 20 m x 20 m and a variable height ranging from 3 m to 200 m. It is also intended with this analysis to have an idea of the variation of wind forces along the height of the reference buildings, as evaluated by these two independent design code regulations.

The EC1 refers to the national annex defining the reference point for calculating the pressures at the leeward side. Since RSAEEP allows the distribution of pressure on this face equal to the face of windward, it is adopted here this same assumption; in this way taking the coefficients of internal pressure the same value, the corresponding forces in opposite directions due to internal pressure shall be cancelled. The wind was considered acting solely in one direction, the topography of the terrain is considered flat and horizontal and were not considered the effects of the possible interferences in the wind flow due to existing structures in the vicinity of the building under review.

The building was considered as being situated in zone A and all the types of terrain roughness available in each design code were considered (as a way to interpret its influence in the results).

To analyze this problem under RSAEEP, equation (1) was used to calculate the mean wind velocity with the appropriate parameters for terrain roughness of type I or type II.

To calculate the mean wind velocity according to EC1 equation (5) was used with $V_{b,0}$ equal to 28 m/s, since up to now there is no recommendation for this value in the national annex. The choice of this basic value is in accordance with the established for the zone A in an earlier version of EC1.

The velocity profiles for the two types of roughness considered in RSAEEP and for the five different categories of terrain considered in EC1 are represented in Figure 8.

Figure 8 Profiles of mean wind velocities for two design codes and different types of terrain roughness

From the analysis of Figure 8 it is seen that the growth of wind velocity with height is more enhanced when calculated by RSAEEP than when it is calculated according to EC1: the gradient or slope of the curve is bigger. This can be justified and understood because the law used to calculate the wind velocity by the Portuguese code RSAEEP is a power law, while the one of EC1 is a logarithmic law. It was referred by Cook [7] that the logarithmic law, in the EC1 design code, for a height near the ground reveals to be a good approximation while for bigger heights it becomes non-conservative compared with the power law used by older design code regulations (such as RSAEEP). It should be noted however that considering a larger number of terrain categories (as in EC1) leads to a better differentiation of the ground types reflected in the velocity profile. According to the same Figure 8, it appears that as the terrain category evolves from the category 0 to the category IV (EC1) or from type II to type I (RSAEEP), the velocity values decrease for a given height. This would be expected since the terrain category IV or the terrain profile type I corresponds to a bigger terrain roughness, therefore lower wind speed.

Based on the calculation method proposed in the design code RSAEEP previously outlined, the variations with the height of the buildings of the shear forces and bending moments at the base of the buildings were determined for the two terrain profile types (Figures 9 and 10, for RSAEEP).

Figure 9 Total shear force at the base of buildings according to RSAEEP

Figure 10 Total bending moment at the base of buildings according to RSAEEP

As shown in Figures 9 and 10 (RSAEEP), a terrain profile corresponding to roughness of type II leads to higher shear forces and bending moments at the base. This situation can be understood because a profile of type II is associated with a roughness smaller than that of a terrain profile of Type I; therefore, type II corresponds to higher mean wind velocity and consequently higher dynamic pressure and greater generalized forces at the base of the buildings.

For a building 200 m height and with the square cross section considered earlier, the shear forces and the bending moments at the base are about 13% higher when calculated for a terrain profile with roughness of type II than when calculated for a terrain profile with roughness of the type I.

Now by using the calculation method proposed in EC1, the wind forces on a structure can be determined by the sum of forces acting on each one of the facades multiplied by a structural factor $c_s c_d$ that can be calculated by two procedures (Procedure 1 and Procedure 2, in Table 6), for the five different categories of terrain roughness.

The left part of Figures 11 and 12 detail the variations with the height of the buildings of the shear forces and bending moments at the base of the buildings determined for the categories of terrain roughness, using EC1 – Procedure 1. Seemingly, the right part of Figures 11 and 12 detail the variations of the shear forces and bending moments at the base of the buildings determined for the categories of terrain roughness, using EC1 – Procedure 2.

Figure 11 Base shear force as a function of height and terrain category, for structural factor calculated by Procedure 1 (left) and Procedure 2 (right)

Figure 12 Base bending moment as a function of height and terrain category, for structural factor calculated by Procedure 1 (left) and Procedure 2 (right)

Figures 11-12 show that for the considered basic velocity (28 m/s) the values obtained by the calculation Procedures (1 and 2) described in EC1 are generally higher than those obtained by applying the current Portuguese design code RSAEEP. The difference in the results is due to the pressure coefficients adopted by each design code for the leeward facade of the building. While for the conditions analyzed Portuguese design code allows for the coefficient of external pressure a value of -0.25 (Figure 2), the EC1 admits this coefficient varies as a function of building height and may take values of -0.7 for $h/d > 5$ (Table 5).

By this study and for the building situations examined, it is understood that EC1 is based in the method of the Gust Loading Factor, to quantify the wind actions. Also EC1 considers the non-simultaneity of occurrence of pressures over the building as well as possible dynamic phenomena that may occur.

As regards to this aspect it is seen that the values obtained by each of the proposed procedures (Procedure 1 and Procedure 2) do not differ considerably; also, for lower building heights it seems conservative to use this factor with the unit value.

With EC1 it is possible to estimate the acceleration of the building along the wind longitudinal direction (Table 6), while the Portuguese design code RSAEEP has no indication to that effect. It is also noted that EC1 considers coefficients that take into account the wind direction, season of the year, presence of structures in the vicinity of the building, which constitute factors that are not properly contemplated in RSAEEP. The use and definition in EC1 of a higher number of terrain categories, also allows quantification of more realistic wind actions.

Therefore it seems to exist a considerable evolution in the way of handling the wind actions on buildings by the Eurocode EC1, as compared with RSAEEP especially when dealing with larger tall buildings.

4 NUMERICAL MODELING OF A REAL STRUCTURE UNDER WIND ACTION

This chapter begins by describing the structure of the tall building chosen for case study and how it was modeled computationally. The building chosen was tower-1 of World Trade Center (WTC) and the program used for structural calculations was the “ROBOT MILLENNIUM v16.5” available at FEUP. [It was so chosen WTC because of its significant structural importance, but also majorly *as of public homage to all the innocent victims of the ignominious attack and consequent destruction of this structural icon*].

For use of this program a frame was modeled with specific characteristics that reproduce the structural behavior of the chosen building. The wind loads were calculated according to RSAEEP and to EC1, and its application in the equivalent frame permitted to compare generalized displacements and stresses.

It is also addressed the way the dynamic wind action was modeled to obtain the structural response of the building. Mathematical modeling of turbulent flow is complex and the possibility of interaction between the flow and the tall building structure (FSI) may lead to changes in dynamic pressure and in the response of the building along time. This chapter also addresses the simplifications used to consider this dynamic action.

4.1 Structural description of the building case-study (Tower 1 of WTC)

Each of the twin towers of WTC had 110 floor level above ground zero plaza and 7 underground sub-caves. With a 417 m height and a 64 m x 64 m base, tower-1 owned then the title of tallest building in the world.

The building weighed an average of about 420 ton/m [39] but despite the huge gravitational weight the wind action was the most significant action affecting its structural system (Eagar and Musco [9]). Rigidly connected to each other, the walls of the facades that formed the structure consisted of 240 tubular square hollow columns (tubular pillars) spaced about 1 meter apart (Figure 13) and with varying thickness every 22 floors (Santos [19]). With square section 36 cm x 36 cm, the pillars played a key role in the building structural strength to resist the wind action. The adjacent pillars were connected by a deep beam 1.3 m high (Figure 13).

The wall acted by the incident wind behaved as the tensile flange of the tube, and the opposite wall behaved as the compression flange. The side walls behaved like the web of the tube, and transferred the wind actions between the windward and the leeward walls.

The stiffness of the deep beams, created by the combined effect of reduced span and significant beam height, created a structural system that was rigid laterally and vertically.

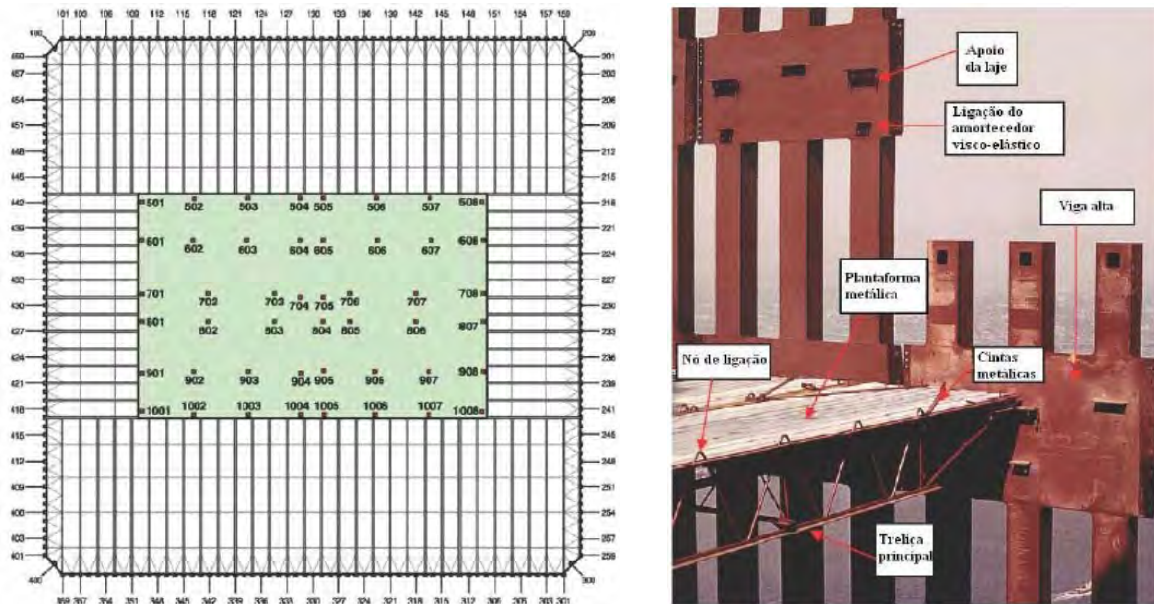

Figure 13 Structural plan of WTC tower-1 and detail of facade pillars with deep beam and metallic truss

The construction of the exterior walls was achieved using prefabricated modules, each consisting of three pillars with a height of three floors, connected by deep beams, and welding all the elements. At the base of the building each set of three adjacent pillars were gathered to form a bigger pillar in a formation like that in a “fork”. According to Eagar and Musco [9] this building was designed to withstand a wind lateral pressure of about 2 kPa.

In the center of the building there was a core that supported most of the building weight. Some of the constitutive pillars were very thick, with sections of 356 mm by 915 mm, converting themselves at the upper floors into large laminated profiles. The building slabs had the behavior of a mixed composite structure, consisting of 10 cm lightweight concrete slabs (13 cm in the core zone) and a metal lattice platform (Wilkinson [24]). Outside the core the platform floor was supported by a series of trusses which were placed between the outer wall and core (Figure 14) and which gave great torsional stiffness to the building.

Figure 14 Metallic truss supporting the floor slabs (detail of connection floor-outer facade column)

Between floors 106 and 110 there were a series of diagonal bars in the frames of the building. These diagonals, together with the columns and slabs, formed a space truss extending between the exterior walls and passing through the core of the building. This system reinforced the framework for wind resistance, mobilizing some of the weight supported by the core itself to ensure stability against overturning.

The proximity of the two towers caused that the wind action in each one was conditioned by change in flow caused by such proximity. The quantification of wind action was made through a wind tunnel test, developed at the University of Colorado using a scale model of 1:500 [39]. About 10000 visco-elastic dampers were used, placed between the bottom of the main truss of the slab and the columns of the outer wall, from the 7th to the 107th floor. These dampers, designed by Mahmoodi (Santos [19]), were first applied in skyscrapers with the purpose of reducing building movement induced by wind and earthquakes. Figure 14 also details their location and connection with the outer columns.

4.2 Modeling a frame equivalent to WTC

In the software ROBOT MILLENNIUM v.16.5 was computationally modeled a frame that would reproduce the behavior of the structural system of the WTC tower-1, having stiffness and mass that would approximately describe the behavior of the building under the horizontal wind action. Each of the side columns of the equivalent frame has inertia equivalent to the total inertia of the columns on a plane façade perpendicular to the wind direction. The central column of the frame has an inertia equivalent to the sum of inertias of the two plane facades along lateral wind direction added with the inertia due to the core contribution. A schematic illustration is given in Figure 15.

Figure 15 Schematic equivalent frame to WTC

According to Santos [19], the contribution of inertia of the facades along with core is given approximately by the values in Table 7, taking into account the variation in thickness of the columns every 22 floors. The average building mass is 420 ton/m, and the considered steel elasticity modulus and damping ratio were 200 GPa and 2% respectively.

Adopting a rectangular section 1 m wide, the dimensions of the central column were calculated so that the equivalent inertia of inertia would correspond to the inertia of each group. The equivalent sections adopted are presented in Table 5.2. The contribution of the side columns in terms of inertia is small as compared with that the central column.

Structural Group	WTC structural data				Modeled equivalent frame	
	M (ton/m)	I _{FAC} (m ⁴)	(%) Core	I _{Total} (m ⁴)	Lateral Columns	Central Column
Until 22 nd floor	454,16	2831,57	34	3794,30	1 m x 1 m	1 m x 36 m
Until 44 nd floor	436,32	2165,73	30	2815,44	1 m x 1 m	1 m x 33 m
Until 66 nd floor	413,52	1666,18	27	2116,04	1 m x 1 m	1 m x 30 m
Until 88 nd floor	392,19	1333,08	21	1613,02	1 m x 1 m	1 m x 27 m

Table 7 Structural data of WTC tower-1 and of the modeled equivalent frame

Regarding to the simulation of the floors, an equivalent beam was simulated equivalent to the metallic lattice truss that supports the slab of lightweight concrete. The center of gravity of the truss and the inertia of the metallic truss bars to that center were determined, corresponding to a value of $3.86 \times 10^{-2} \text{ m}^4$ for such total inertia of floor. Choosing a beam of rectangular area with an area approximately equal to the area of the main members of the truss, and with the calculated inertia given above, it was found an equivalent beam size with dimensions $b=0.55 \text{ m}$ and $h=0.95 \text{ m}$.

Table 8 shows the values of the natural frequencies and natural periods found for the first six modes of vibration of the equivalent structure. Figure 16 depicts the first two modes of vibration of the structure modeled by the equivalent frame to WTC tower-1.

Figure 16 First two modes of vibration of the equivalent frame modeled

The vibration frequency of the first mode was evaluated as $f_1=0.132 \text{ Hz}$, quite close to the fundamental frequency given by Santos [19] and relative to a three-dimensional modeling of the building in the program SAP2000. It is seen that the structure had two modes whose frequencies of vibration were less than 1 Hz , but the first mode clearly displays a lower frequency corresponding to a very flexible structure.

Mode	Mode 1	Mode 2	Mode 3	Mode 4	Mode 5	Mode 6
Frequency (Hz)	0,132	0,692	1,831	3,496	5,550	8,104
Period (s)	7,577	1,446	0,546	0,286	0,180	0,123

Table 8 Natural frequencies and natural periods of the first six vibration modes of the equivalent frame

4.3 Modeling wind dynamic action

Although it is recognized the great complexity in modeling turbulent flow around buildings, even with scaled physical models in wind tunnels, some simplifications will be considered herein with regards to the quantification of dynamic pressures and generalized forces due to wind action in a tall building along the time. For that, the FSI is considered negligible and the correlations of the velocity fluctuations in height are considered in a simplified manner. Firstly it is addressed the methodology for generating time series of wind to be used latter in the calculation of the instantaneous dynamic pressures and therefore in the quantification of the generalized wind forces acting at every floor level of the equivalent frame.

The methodology used to generate synthetic time series is commonly referred as the Method of Shinozuka, which bases the generation of time series in the calculation of the inverse function of the Fourier Transform of the amplitude of the random process (given by a spectral density function of the energy of a process). Such generation of synthetic series of wind occurs in the range of wavelengths corresponding to fluctuations of wind velocity with an approximately Gaussian distribution of the atmospheric wind flow (Saraiva and Silva [20]).

The purpose of the method is to obtain a realization of a stochastic process (for example: a time series of the fluctuations of the longitudinal component of wind velocity) from the spectral density function that characterizes the process.

The method uses this function to perform a weighted sum of sinusoidal functions (in this case of cosines). The contribution of each of the N waves is given by the amplitude of the spectrum ($S_L(z, n)$, real function) for each corresponding natural frequency (n). The phases are obtained (for the case of one-dimensional spectrum of simple non-correlated series) by pseudo-random number generation in the interval $[0, 2\pi]$.

According to the Method of Shinozuka, in the simplest case of one-dimensional univariate stochastic processes, a realization of the random process may be obtained (Barbat and Canet [4], Saraiva and Silva [20]) by equation (26).

$$u(t) = \sqrt{2} \sum_{k=1}^n A_k \cos(\omega_k t + \phi_k) \quad \text{with } A_k = \sqrt{S(\omega_k) \Delta\omega} \quad \text{and} \quad \Delta\omega = \frac{\omega_{\max} - \omega_{\min}}{N} \quad (26)$$

In the previous expression N is the number of frequencies of the discretization of the spectrum, and $\omega = 2\pi n$ is the angular frequency. To generate the synthetic time series of wind velocity it is necessary to define a spectral density function of the fluctuations of longitudinal velocity of the wind; the spectral density function given in EC1 is used herein in the dimensionless form of equation (23) and the description of Figure 7.

For the generation of the synthetic series to be considered an ergodic process, according to [40] the number N of frequencies for discretization of the spectrum should be sufficiently high. However, not having an indication of the number of discrete frequencies to use, a study of the generation of wind series was made discretizing the spectrum into a different number of frequency ranges. Herein five processes for five frequency intervals were studied, corresponding to the division of the spectral density function in 50, 100, 500, 1000 and 5000 intervals respectively; for each case, fluctuations of longitudinal wind velocity were obtained according with the process described.

These fluctuations were calculated for an elevation $H=100$ m, and considering that the WTC was located on a terrain of class IV according to EC1 to which corresponds a roughness length $z_0=1$ m. The basic velocity assumed for a return period of 50 years was 30 m/s (based on the recorded data in 3 meteorological stations close to New York city) and in these conditions, according to EC1, standard deviation of the turbulent component of wind velocity was $\sigma_v = 7.03$ (Santos [19]). Figure 17 represents the time series of the fluctuations of wind velocity, evaluated with the previous data, for the four higher discretizations.

As the spectral density function has high values for low frequencies but reduces rapidly with increasing frequency (Figure 7), from the analysis of previous figures it is noted that when choosing a lower number of frequencies of discretization (lower N) for generation of the synthetic time series of wind, these are clearly more affected by low frequency components (where the spectrum has more energy) resulting in a value numerically higher.

Herein was adopted a reference number of discretization frequencies of around 500, for which it is no longer noticeable the influence of low frequency components; also, although for discretizations with 1000 and 5000 intervals the greater number of sinusoids would induce a better defined process, there seems not to exist large differences between the time series associated with these divisions of the wind spectrum.

Figure 17 Time series of fluctuations of wind velocity for wind spectrum with 100-500-1000-5000 intervals

For the instantaneous wind velocity $U(t)$ at any height given by the sum of a constant mean component \bar{U} with a dynamic fluctuation component $u(t)$, the instantaneous wind force $F(t)$ on any surface A is given by:

$$F(t) = \frac{1}{2} \rho c_f A [\bar{U} + u(t)]^2 = \frac{1}{2} \rho c_f A \bar{U}^2 + \rho c_f A \bar{U} u(t) + \frac{1}{2} \rho c_f A (u(t))^2 \quad (27)$$

where c_f is the force coefficient for the structure or structural element.

The fluctuations of wind velocity along time also have a spatial variability, which for a first approximation is herein neglected. For the case of tall buildings whereas the response is majorly due to the contribution of the first mode of vibration (which is also a condition imposed for the calculation of the structural factor $c_s c_d$ by EC1), modeled as a structural system with one degree of freedom, the passage or conversion of the power spectrum of the wind velocity fluctuations into structural response spectrum is given by:

$$S_x(n) = \frac{4 \bar{X}}{\bar{U}^2} |H(n)|^2 (\chi(n))^2 S_u(n) \quad (28)$$

where $|H(n)|^2$ represents the mechanical admittance function given by equation (29) and $(\chi(n))^2$ represents an aerodynamic admittance function (Vickery and Kao [22]) given approximately by equation (30).

According to Holmes [12], in a frequency domain analysis for tall large structures, it is this latter function that takes into account the non-simultaneous occurrence of the fluctuations of wind velocity. It is explicitly stated that: “For larger structures, the velocity fluctuations do not occur simultaneously over the windward face and their correlation over the whole area must be considered. To allow for this effect, an aerodynamic admittance $(\chi(n))^2$ is introduced”.

$$|H(n)|^2 = \frac{1}{\left(1 - \left(\frac{n}{n_1}\right)^2\right)^2 + \left(2\xi \frac{n}{n_1}\right)^2} \quad (29)$$

$$\chi(n) = \frac{1}{1 + \left(\frac{2n\sqrt{A}}{U}\right)^{4/3}} \quad (30)$$

According to EC1 for tall structures with the shape and conditions equivalent to the case-study under consideration, the parameters of the spectral density function for calculating the structural factor should be determined for a reference height of approximately 0.6 times the height of the building. Given this indication, for generating sets of time series, the height chosen was 250 meters that is about 60% of the height of tower-1 of the World Trade Center.

So, for the dynamic analysis of this case-study, ten random sets of fluctuation velocities were generated. The applied wind generated forces were obtained according to equation (27) taking account the acting dynamic pressures and the influence area for each floor, considering the mean wind velocity depending on the height (given by the expression of EC1) and the fluctuation velocities given by the random series generated.

As an example, Figure 18 (left) presents one series (called Series 1) for the fluctuations of wind velocity generated in these conditions at a height of 250m and using wind power spectrum of EC1. Figure 18 (right) shows the same series, that is adopting the same phase angles for the harmonics, but generated from the wind power spectrum multiplied by the previously mentioned aerodynamic admittance function $\chi^2(n)$.

Figure 18 Fluctuation velocity time series for: height of 250 m, basic velocity 30 m/s, terrain roughness of category IV, using EC1 wind power spectrum (at left, not multiplied by the aerodynamic admittance function; at right, already multiplied by aerodynamic admittance function)

4.4 Modeling a TMD for passive control of vibrations

The tuned mass dampers (TMD) can be used to control one or more vibration modes of structures excited by external actions. However, in many cases, control of the first mode is sufficient to reduce significantly the level of vibrations recorded. Except for cases in which it is intended to simultaneously monitor the contribution of more than one mode of vibration, the use of a single TMD may be satisfactory. Examples of application of this system in tall buildings are listed in the literature, namely: John Hancock Tower Building (with 60 floors) in Boston (USA) and the building Chiba Port Tower (with 125 m) in Japan, where large-scale measurements were performed to evaluate the efficiency these systems (Holmes [12]).

The building tower Taipei 101 (with 508 m) in Taiwan, has the largest (so far) TMD mass (about 730 ton mass) placed on top of the building to control excessive vibrations due to wind and earthquakes; according to [14], the accelerations would be reduced by about 40% to 45%.

The behavior of TMD in tall buildings under wind action was studied by Kwok and Samali [17]. The design of a TMD for application to structures without damping is based on two parameters – mass ratio μ and frequency ratio q – as detailed in Kelly [16]. The optimum frequency ratio q_{opt} (corresponding to the fixed points at the same level or with the same displacement amplitude), the maximum amplitude of the controlled principal system, and the inherent optimal damping $\xi_{2,opt}$ of the TMD, are given in the set of equations (31).

$$q_{opt} = \frac{1}{1+\mu}, \quad \frac{X_1}{X_{1,static}} = \sqrt{\frac{2+\mu}{\mu}}, \quad \text{and} \quad \xi_{2,opt} = \sqrt{\frac{3\mu}{8(1+\mu)^3}} \quad (31)$$

For the design of a TMD tuned for application to structures with damping, it is still possible to use these equations provided the damping is less or equal to 1%. For higher damping, the use of such equations will lead to a non optimized tuning of the TMD. For such cases, the design of the TMD can be done with design graphs associated with the numerical solution of the expression of maximum amplitude of the controlled principal system (Barros, Moutinho and Barros [6]).

The considerations made previously focused its application to a structure with a single degree of freedom which was associated with a second mass, thus resulting in a system of two degrees of freedom. However, in the case of real structures with various degrees of freedom, it becomes essential to consider a system of one degree of freedom that translates roughly the dynamic behavior of the structure under analysis.

The reduction of structural vibrations using the vibration control theory can be addressed either through modal control or through optimal control (Yao [25]). In the former, a pre-determined structural mode of vibration is controlled; in the case of long slender metallic towers under wind actions, tuned mass dampers (TMDs) are frequently the choice but tuned liquid dampers (TLDs) or tuned liquid column dampers (TLCDs) can also be used with equivalent efficiency. In the latter, structural performance criteria are controlled such as the minimization of the structural deflections (top tip displacement and/or top section rotation).

Kwok and Samali [17] studied the behavior of TMD's in tall buildings subjected to the action of wind and, according to the authors, the considerations presented here about the effectiveness of a TMD in response of a system of one degree of freedom can be extended to solid structures such as in the case of tall buildings, leading to a modal analysis. Kwok and Samali [17] indicated that while there were large decreases in response for the modes controlled by the TMD's installed, the higher order modes were not affected. For such higher modes to be less contributive to the structural response would require implementing new TMD's tuned according to their frequency.

Thus, using modal analysis, for each vibration mode whose contribution to the overall response of the structure is important, and that one wishes control, it is necessary to determine the corresponding values of stiffness, of mass and of modal damping. According to Villaverde [23], for the determination of the dynamic characteristics of the equivalent system, should be adopted a mode normalization criteria based on attributing a unit value to the mode component associated to the degree of freedom where TMD would be applied.

Since the fundamental frequency of the WTC tower-1 is very low (0.132 Hz) and because the wind action has a spectral density function with strong content for low frequencies, it is possible that the response is conditioned by the harmonic of the fundamental frequency. It is therefore assumed herein, for control of vibrations purposes, that the response is only dependent on the first vibration mode, with which the TMD solutions were designed with the expressions available for harmonic vibration with frequency equal to the first vibration frequency of the overall structure.

Accordingly, the value of the modal mass corresponding to the first mode of vibration was determined (with the structural software used: Robot Millennium) as 41378.414 ton and the corresponding modal stiffness of 28463kN/m, values quite close to the ones found in a three-dimensional modeling of the building (Santos [19]). For the case-study structure with the deployment of TMD's, two different mass ratios of $\mu=0.01$ and $\mu=0.005$ were used, for which with design charts (Barros, Moutinho and Barros [6]) it was possible to determine the optimal parameters to be adopted for each TMD situation. In Table 9 the values adopted are systematized.

TMD mass ratio	q_{opt}	$\xi_{TMD, opt}$	m_{TMD} (ton)	ω_{TMD} (rad/s)	k_{TMD} (kN/m)	Size (cm) of square section steel bar E=210 GPa , L=2 m
$\mu = 0.01$	0,987	0,046	413,78	0,81860	277,2764	8,1 x 8,1
$\mu = 0.005$	0,993	0,036	206,89	0,82357	140,3284	6,8 x 6,8

Table 9 Optimal parameters of TMD in WTC tower-1 case-study, for two mass ratios μ

Since the structural software used does not have an intrinsic function that allows the direct introduction of dampers, herein for the simulation of the TMD's were determined the dimensions of a square section bar with a lateral stiffness equivalent to that required for the damper placed on top. Acting as a vibrating bar (built in end – free end) with a concentrated mass that would give the frequency obtained for the sizing of the TMD with the damping introduced in the material parameters constitutive of the bar.

Assuming a bar length $L=2$ m, made of steel with elasticity module $E=210$ GPa, from the bar stiffness $3EI/L^3$ is obtained the equivalent inertia I of the square section bar. Table 10 also indicates the dimensions required for such bar, for the two mass ratios considered in the design of the TMD. Table 10 shows the first six natural frequencies of the vibration modes of the case-study structure (WTC tower-1) incorporating the two TMD solutions; some changes occur as compared with Table 8 of the structure without any TMD.

Mode	Mode 1	Mode 2	Mode 3	Mode 4	Mode 5	Mode 6
Frequency (Hz) for WTC using TMD with $\mu=0.01$	0,125	0,138	0,692	1,831	3,496	5,550
Frequency (Hz) for WTC using TMD with $\mu=0.005$	0,127	0,136	0,692	1,831	3,496	5,550

Table 10 Natural frequencies of first six vibration modes of the equivalent frame with TMD vibrating bar

5 ANALYSIS OF RESULTS BY DESIGN CODES

This chapter begins by comparing the results obtained for the forces acting on each floor due to wind action, obtained by applying each of the two regulations addressed in this case-study of the WTC tower-1. The corresponding displacements were also evaluated and compared with the computer software used herein, applied to the computational structural model addressed earlier.

The wind was considered actuating perpendicular to the facade of the building and for the implementation of RSAEEP, the building was considered as implanted in Zone B with terrain roughness of type 1 corresponding to an urban area.

For application of EC1 the building was considered on a terrain category of type IV, with a basic velocity of 30 m/s, with unit orography factor and with frictional forces neglected (since the total area of the facades of the building parallel to the wind direction is less than 4 times the area of the facades perpendicular to the wind direction). Since the ratio between the height of building h and its width d is greater than 5, the EC1 indicates that the forces due to wind on buildings should be based on force coefficients. For the building under study, the value obtained for the force coefficient was 1.428. The structural factor calculated according to EC1, by the two procedures (Procedure 1 and Procedure 2) contemplated in that design code as outlined in the previous paragraph (2.2.7), was 0.95 (Procedure 1) or 0.97 (Procedure 2).

Table 11 compares the results for the wind forces, along the height of the case-study building, evaluated by the two design codes. Figure 19 compares the results for the shear forces and bending moment due to wind pressures, along the height of the case-study building, evaluated by the two design codes.

Figure 19 Shear forces (top graph) and bending moments (bottom graph) at every floor of WTC, evaluated by the two design codes: RSAEEP and EC1

Floor	RSAEEP	EC1(Pr.1)	EC1(Pr.2)	Floor	RSAEEP	EC1(Pr.1)	EC1(Pr.2)

Table 11 Forces on every floor due to wind, under the two design codes RSAEEP and EC1

For both generalized forces, the two EC1 procedures gave higher values than the one's obtained by RSAEEP. In fact the basal bending moment by RSAEEP was evaluated as 15231856 kNm while by the procedures in EC1 was 16612740 kNm and 16962482 kNm.

Applying the previous wind design forces on every floor in the computational model of the case-study WTC, the following lateral displacements were obtained (Figure 20) leading to top floor lateral displacements of 0.99 m (with RSAEEP forces) and 1,05 m and 1,07 m (with the two procedures of EC1 for the determination of the structural factor). These lateral displacements, obtained with the simplified equivalent computational model proposed, slightly overpass the recommended maximum value of top displacement given by the building height/500 (0.85 m, for this WTC tower with a height of 417 m) as suggested by the *Subcommittee on Wind Bracing* of ASCE [2].

Figure 20 Lateral displacements in every floor by the application of the design forces on the considered computational model

As regards to the determination of the maximum acceleration on the top of this building, according to the two procedures in EC1 described earlier (paragraph 2.2.7) for multiplying the standard deviation of the acceleration by the peak factor, the values obtained were 0.27 m/s² (Procedure 1) and 0.32 m/s² (Procedure 2). Comparing these acceleration values due to wind action with the limits of human perception, it was clear that the lateral top acceleration lies between the threshold of perception and discomfort (Bachmann [3]); therefore no problems are expected to the level of human comfort due to the wind horizontal direction analyzed.

It should be noted that if the aerodynamic damping would not have been considered, the acceleration values would be ranging from 0.38 m/s² to 0.45 m/s² and that would lead to discomfort for human occupants. This shows once more that, in the longitudinal along the wind direction, the aerodynamic damping plays an important role in vibration control, and therefore its correct evaluation is really important for a good design.

6 ANALYSIS OF RESULTS EVALUATED COMPUTATIONALLY

Based on the methodology adopted for consideration of the dynamic wind action (using a set of 10 time series, for frequencies in the wind spectral density function evaluated with 500 frequency intervals), the results in terms of displacements and accelerations were evaluated and compared for the computational structural model, without and with installed TMD vibrating bar (with an hypothetical vibrating mass with appropriate stiffness and damping properties).

Using the mentioned structural software with modal superposition, a damping ratio of 2% and an integration time step of $\Delta t=0.25$ sec, ten series of wind dynamic loads were applied and their average results obtained in terms of displacements and accelerations. As an example Figure 21 shows the time variations of displacement and acceleration on the top of WTC, for the wind loads evaluated using equation (27), with velocity fluctuations corresponding to wind series 1.

Figure 21 Displacement and acceleration on the top of WTC, for the wind loads corresponding to wind series 1

Table 12 presents a summary of maximum values of displacements and accelerations on top of the building, for each of the time series. It also presents the maximum values of the same variables but which are calculated (Holmes [12]) by multiplying the standard deviation of the responses by the peak factor of 3.16 (evaluated conservatively for the natural frequency of the structure of 0.11 Hz and for a time interval of 600 seconds, during which the maximum value is evaluated (Davenport [8])).

Table 14 Maximum displacements and accelerations on top of WTC, for each of the wind time series (using TMD with mass ratio of $\mu=0,01$)

The efficiency on the use of the modeled TMD on top of building can be interpreted by the results of Table 15, here associated with mass ratio of 1%: reduction of maximum displacements and accelerations on the order of 10% and 20%, respectively. Quite similar conclusions, with less efficiency, were obtained for the TMD with mass ratio of 0,5%.

	Building w/o TMD	Building w/ TMD ($\mu=0,01$)	Reduction relative to building w/o TMD
Average max displacement evaluated from response	1,17 m	1,07 m	9%
Average max acceleration evaluated from response	0,33 m/s^2	0,25 m/s^2	24%

7 CONCLUSIONS

After a comparative analysis between the Portuguese Regulation on Safety and Actions for Building Structures and Bridges (RSAEEP) [18] and Eurocode 1 (EC1) [10], it can be concluded that there are differences in these methods here considered to quantify the wind actions with an improvement of the European regulation. Eurocode 1 is based on the method of “Gust Loading Factor” for the quantification of wind action and that takes into account a structural factor that considers the non-simultaneity of the occurrence of the pressures along the facade of the building where potential dynamic phenomena may occur.

Comparing the two procedures suggested by EC1 to quantify this structural factor, it can be concluded that the difference in values obtained by each of them is less than 5%; since it is dependent on the frequency of vibration of the structure, a decrease of same frequency leads to an increase in the value of the structural factor. With a variation of vibration frequency of the structure of 25% over the value obtained by the expression recommended for buildings by EC1, the difference in the value of the structural factor as calculated by the two procedures continues to be no more than 5%, thus leading both of the procedures adopted to very similar results.

A parametric study on the variation of the design wind shear forces and design wind bending moments as a function of height, as evaluated by the RSAEEP and by EC1, was performed using the World Trade Center (WTC) as the reference tall building type.

It can be concluded that for the considered base velocity (28m/s), the values obtained for these generalized forces by EC1 are generally higher than those obtained by RSAEEP, a fact that is related to differences in the coefficient of external pressure evaluated by each code standard adopted for the along the wind façade. Also the definition of a greater number of terrain categories inherent to EC1, allows a more realistic quantification of the wind actions as compared with RSAEEP.

Regarding the modeling of an equivalent frame structure equivalent to the reference World Trade Center, it can be concluded that the value of the structural parameters found for the frequency, mass and stiffness corresponding to the first mode of vibration led to a structural behavior very close to the three-dimensional modeling performed earlier by Santos [19].

For modeling the dynamic wind action reference is made to a method of generating sets of synthetic wind – called the method of Shinozuka – and for which the number of discretization intervals to adopt is discussed; the greater the number of intervals to adopt, the better the process, but with divisions over 1000 intervals results are already quite acceptable.

The simplified methodology adopted for the evaluation of the effects of the dynamic wind action, consisted of varying forces over time at each floor, following the same law of variation. This law is obtained, from each generated time series based on the power spectrum previously multiplied by the aerodynamic admittance function.

Through the generation of ten different series, it was concluded that the dynamic results obtained in terms of average values of maximum displacements, were about 10% higher than those results obtained by applying EC1. Also, the dynamic response of the structure is greatly influenced by the wind series of load considered.

The dynamic response of the building, in the longitudinal along-the-wind direction, indicates that the dynamic phenomena for the case study are not significant with regards to the occupants comfort level since the accelerations obtained are within the limits considered acceptable. It should be emphasized that for this situation the aerodynamic damping, added to the structural damping, appears to contribute significantly in controlling the response under service conditions in this direction.

Regarding the implementation of TMD, it was concluded that these are proving very effective in terms of displacements and in terms of acceleration when the structure is subjected to a harmonic action with frequency equal to the fundamental frequency of vibration of the building. The application of these devices for vibration control can therefore be very effective for control resonances in the transverse direction to the flow caused by the formation of vortices.

However, the attenuation found for the structure equipped with a modeled top floor TMD, when subjected to the wind action modeled as representative, depends greatly on the wind series generated; it is not as effective as before, under perfect harmonic action at resonance.

For the TMD modeled with the parameters calculated, it was concluded that in terms of maximum accelerations reductions of the order of 24% can be achieved for a TMD with 1% mass ratio, and reductions of the order of 18% can be achieved for a TMD with a 0.5% mass ratio. With regard to maximum displacements it was concluded that the structural reference system has proved less effective, achieving reductions of only 9% for a TMD with 1% mass ratio, and of the order of 7% for a TMD with 0,5% mass ratio.

ACKNOWLEDGEMENTS

This work is integrated in the thematic and activities of the international collaborative research project COVICOCEPAD approved by the European Science Foundation (ESF) within the Smart Structural Systems Technologies (S3T) Program. It was sponsored in Portugal until last December 2010 by FCT (Fundação para a Ciência e a Tecnologia) project PPPCDT-05-S3T-FP054-COVICOCEPAD, fact that is herein acknowledged.

Keywords: Magnetorheological damper, neural network, semi-active control.

Abstract. *This paper presents a neural network based semi-active control method for a rotary type magnetorheological (MR) damper. The characteristics of the MR damper are described by the classic Bouc-Wen model, and the performance of the proposed control method is evaluated in terms of a base excited shear frame structure. As demonstrated in the literature effective damping of flexible structures is obtained by a suitable combination of pure friction and negative damper stiffness. This damper model is rate-independent and fully described by the desired shape of the hysteresis loops or force-displacement trajectories. The proposed neural network controller is therefore trained based on data derived from these desired force-displacement curves, where the optimal relation between friction force level and response amplitude is determined explicitly by simply maximizing the damping ratio of the targeted vibration mode of the structure. The neural network control is then developed to reproduce the desired force based on damper displacement and velocity as network input, and it is therefore referred to as an amplitude dependent model reference control method. An inverse model of the MR damper is needed to determine the damper current based on the derived optimal damper force. For that reason an inverse MR damper model is also designed based on the neural network identification of the particular rotary MR damper. The performance of the proposed controller is compared to that of an optimal pure viscous damper. The top floor displacement and acceleration of the base excited shear frame structure are selected as the performance parameters of this comparison. It is found by the simulations that the proposed control design yields a reduction in the structural response compared to the viscous case.*

1 INTRODUCTION

As large scale structures become increasingly slender and flexible the magnitude of dynamic response due to loading from wind, traffic and even earthquakes may increase beyond the acceptable level. Thus, the need for additional external damping is pronounced, where in particular the concept of semi-active control has received a great amount of attraction during the most recent decades. The Magnetorheological (MR) damper is one of the most popular types of semi-active devices. It is inherently dissipative and thereby stable, and it behaves roughly as a friction damper, where the friction force level can be altered real-time by simply changing the applied damper current. Thus, the MR damper is a cost effective device that combines some of the adaptability of active control with the low power requirements and reliability of pure passive dampers.

The main challenges arising in connection with the use of most semi active damping devices lies in the development of effective control laws, and in the subsequent digital and real-time implementation. Most control strategies for semi-active structural control fall into two main categories. The first one consists of control strategies that require accurate mathematical formulation for the plant model. Examples in this category are the H2/LQG, H_∞ and the sliding mode control, where any active parts are simple clipped. Conversely, the second category contains control strategies that do not require an accurate mathematical model of the plant. Neural network and fuzzy control fall into this category. Several neural network based control strategies [1-3], neuro-fuzzy network based strategies [4,5] or neuro-predictive control methods [6] have been developed for different control aspects of MR dampers. The advantage of neural network based methods is that they mainly excel in the handling of uncertainties in nonlinear applications, which makes them suitable for both modeling and control of the inherently nonlinear MR damper.

It has been demonstrated in [7,8] that for semi-active control of flexible structures the combination of pure friction and a negative stiffness component yields very effective damping of structural vibrations. Therefore, this paper considers the development of a model reference neural network, which will track the desired hysteresis behavior of an ideal friction damper with negative stiffness. The proposed controller performance is compared with performance of an optimal viscous damper, and for the response of a simple shear frame structure subjected to harmonic base excitation the good performance of the proposed method is verified.

2 STRUCTURAL MODEL AND MR DAMPER PROPERTIES

The performance of the semi-active control strategies for the MR damper is in this paper assessed by the harmonic response of a base excited five-storey shear frame structure. The MR damper is collocated at the first floor of the shear frame, where the measuring data is collected. To apply the semi-active control strategy on the MR damper, an inverse model of the damper is needed to predict the damper current associated with the desired MR damper force. The equation of motion of the shear frame structure with MR damper and inverse MR damper model are discussed in the following sub-sections.

2.1 Equation of motion

In dynamic analysis of flexible structures the structural model is typically modeled by finite elements or determined by experimental modal analysis, whereby the equation of motion can be written in the form

$$\mathbf{M}_c \ddot{\mathbf{x}} + \mathbf{C}_c \dot{\mathbf{x}} + \mathbf{K}_c \mathbf{x} = -\lambda \mathbf{f} + \mathbf{M}_c \mathbf{I}(-\ddot{x}_g) \quad (1)$$

where \mathbf{M}_c , \mathbf{C}_c and \mathbf{K}_c are the mass, damping and stiffness matrices in Cartesian coordinates, \mathbf{x} is the displacement vector containing the displacements of the five concentrated masses, the dot represents the time derivative, f is the force of the external MR damper, $\lambda = [1, 0, 0, 0, 0]^T$ is the connectivity vector that applies the semi-active force f to the first mass, $\mathbf{I} = [1, 1, 1, 1, 1]^T$ is the unity vector and \ddot{x}_g is the ground acceleration. The schematic illustration of the shear frame structure with rotational MR damper is shown in Fig. 1.

Figure 1: Shear Frame Structure with MR damper

2.2 MR damper model

The rotational MR damper is modeled using the classical Bouc-Wen hysteresis model. The parameters of the model have been calibrated by experiments, where the damper has been driven harmonically in a testing machine at various frequency-amplitude combinations. The modified Bouc-Wen model by Spencer et al. [9] was formulated for the cylindrical type MR damper. In the present case this model is slightly simplified, mainly because the cylindrical damper concept has no need for an accumulator chamber, which for the many cylindrical type dampers introduce an additional stiffness component. Figure 2 shows the close up of the rotary type damper at the Swiss Federal Laboratory of Material Science and Research (EMPA) and the schematic diagram of the classical Bouc-Wen model. For more information on the characteristics and modeling of the rotary MR damper please see Boston et al. [10].

Figure 2: Rotational MR Damper and Bouc-Wen damper model

The governing equations for the damper force f predicted by the classical Bouc-Wen model can be written as follows:

$$f = (\alpha z + c_0 \dot{x}) \quad (2)$$

where the hysteresis effect follows from the evolutionary variable z controlled by the Bouc-Wen equation

$$\dot{z} = -\gamma |\dot{x}| z |z|^{n-1} - \beta(\dot{x}) |z|^n + A(\dot{x}) \quad (3)$$

The gain parameters on the hysteresis effect and the viscous effect are in the present case described by cubic and linear functions of the applied current, respectively:

$$\alpha = \alpha_a + \alpha_b u + \alpha_c u^2 + \alpha_d u^3, \quad c_0 = c_{0a} + c_{0b} u \quad (4)$$

The applied current u is described with a time delay relative to the desired current I by the following first order filter:

$$\dot{u} = -\eta(u - i) \quad (5)$$

The estimated parameters of the simplified Bouc-Wen model for the rotational MR damper are given in Table. 1.

MR Damper Parameters			
α_a	4.038	η	100
α_b	1.984	γ	410
α_c	7.901	β	410
α_d	-0.704	A	1000
c_{0a}	10	c_{0b}	100

Table 1: Parameters for Bouc-Wen Model

Typical force-displacement and force-velocity hysteresis loops for the rotational MR damper are shown in Fig. 3. It is seen that the MR damper behaves approximately as a friction damper, where the friction force level can be altered by changing the applied damper current. The opening of the force-velocity loops indicates some form of stiffness or inertia effects.

Figure 3: Force Displacement /Velocity hysteresis loops.

2.3 Inverse MR damper

The inverse model modeling for rotary MR damper is a quite complicated task due to high nonlinearity in MR damper dynamics. This work can be done by using parametric [10] such as Evolutionary Algorithm and also non-parametric system identification methods such as neural network identification approach [11, 12]. The inverse MR damper behavior is modeled to solve the force tracking task by MR damper in closed loop cycle. The training and validation data are generated by dynamic tests of the MR damper mounted on a hydraulic testing machine. The inverse modeling training data are absolute velocity and absolute force and the current is the target. This approach has been chosen because current is always positive and thereby leads to a small modeling error independently of the sign of velocity. The inverse model of the MR damper is verified with totally independent set of input-output data. The model validation is thoroughly described in Bhowmik et al [14].

The inverse MR damper behaviour, i.e. the input states at time instant k are the damper velocity $\dot{x}_1(k)$ and desired control force $f_{des}(k)$ and the output state is current $I(k)$, is modelled by a neural network with the following architecture

$$I(k) = NN \begin{bmatrix} |\dot{x}_1(k)| & |\dot{x}_1(k-1)| & |\dot{x}_1(k-2)| & |\dot{x}_1(k-3)| \\ |f_{des}(k)| & |f_{des}(k-1)| & |f_{des}(k-2)| & |f_{des}(k-3)| \end{bmatrix} \quad (6)$$

The neural network based inverse MR damper model is used to solve the force tracking task.

3 CONTROL STRATEGIES

The present paper describes a neural network based model reference control strategy for the prediction of the desired force to control structural vibrations. To evaluate the performance of the proposed model reference controller, the optimal pure viscous damper force is also applied to the structure.

For linear damper models the characteristics of the damper are conveniently formulated in the frequency domain as

$$f(\omega) = gH(\omega)x \quad (7)$$

where g is the control gain and $H(\omega)$ is the associated frequency dependent transfer function.

The effective damping of the structure is evaluated in terms of its modal damping ratio, where the presence of the external damper generates a non-proportional damping with corresponding complex valued natural frequencies and mode shapes. The analysis of the damper modal vibrations is described by the two-component system reduction technique introduced by Main and Krenk [13]. In that formulation the response of the structure is represented by a linear combination of the two limiting mode shapes for the structure without damper \mathbf{u}_0 and for the structure with the damper fully locked \mathbf{u}_∞ , respectively. The linear combination can then be written as:

$$\mathbf{x} = \mathbf{u}_0 \mathbf{r}_0 + \mathbf{u}_\infty \mathbf{r}_\infty \quad (8)$$

The first term represents the classical undamped case, while the second term introduces the local effect of the damper described in terms of its ability to lock the structure at its location. The undamped mode shape is governed by the classical generalized eigenvalue problem

$$(\mathbf{K} - \omega_0^2 \mathbf{M}) \mathbf{u}_0 = \mathbf{0} \quad (9)$$

A similar eigenvalue problem exists for the case where the damper link is fully locked, defining ω_∞ and \mathbf{u}_∞ . The locked mode shape \mathbf{u}_∞ is by construction orthogonal to the connectivity vector which yields the identity $\lambda^T \mathbf{u}_\infty = 0$.

The two-component representation reduces the full dimensional problem to a two-dimensional problem, where the associated characteristic equation can be solved explicitly, providing expressions for the complex valued natural frequency and the corresponding modal damping ratio. Optimal calibration of the damper model is based on the maximization of the damping ratio. For the general damper format in (7) it is demonstrated in [14] that the optimal gain can be determined by the expression:

$$g_{opt} = \frac{1}{|H|} \frac{(\omega_\infty^2 - \omega_0^2)}{u_0^2} \quad (10)$$

where u_0 is the amplitude of the undamped mode shape at damper location. This expression is in the following used to calibrate the control strategies.

3.1 Viscous damping strategy

The prototype damper model is the pure viscous model. For this model the damper force is directly proportional to the collocated velocity of the damper motion,

$$f = c\dot{x} \quad (11)$$

where c is the viscous parameter. When compared with the linear frequency representation of the damper force in Eq. 7, the damper transfer function for the viscous damper is

$$H(\omega) = i\omega \approx i\omega_0 \quad (12)$$

while the gain value is

$$g = c \quad (13)$$

Substitution of (12) and (13) into (10) gives the following expression for the optimal viscous parameter:

$$c_{opt} \approx \frac{2(\omega_\infty - \omega_0)}{u_0^2} \quad (14)$$

where $\omega_\infty + \omega_0 \approx 2\omega_0$

The optimal viscous damper is without stiffness and is therefore a suitable benchmark example for damper models with negative stiffness.

3.2 Proposed Neural network based model reference control strategy

The proposed controller is developed based on a neural network model identification technique, where the neural network model is trained by a reference damper model. In this paper, the characteristics of the damper model are described by the desired shape of the hysteresis loop, which combines an amplitude dependent friction damper with a negative stiffness component. The optimal shape of this hysteresis loop has originally been identified and verified by Boston et al. [7]. The hysteresis loop is based on the assumption of pure harmonic displacement and velocity, which is used as the input to the proposed neural model, while the damper force based on the desired hysteresis loop is used as the output of the neural controller. The optimal shape of the force-displacement trajectory is shown in fig. 4.

Figure 4: Force-Displacement Hysteresis model for Friction Damper with negative stiffness

The hysteresis model is inherently nonlinear, whereas the calibration formulation in (10) requires a linear damper model. Thus, an equivalent linear model is assumed to contain a viscous and a stiffness component,

$$f = c\dot{x} + kx \quad (15)$$

If x is a sinusoidal signal, the parameters of the linear equivalent model in (15) can be determined by equivalence over a full vibration period, see [14]. This yields the following equivalent linear model for the hysteresis loop in Fig. 4:

$$f = \frac{2f_m}{\pi\omega A} \dot{x} - \frac{f_m}{2A} x \quad (16)$$

where A is the amplitude of the damper displacement, k is negative stiffness and f_m is maximum force of the hysteresis loop. In frequency domain the model is expressed as

$$f = \frac{f_m}{A} \left(-\frac{1}{2} + i \frac{2}{\pi} \right) x \quad (17)$$

Comparison with the frequency representation in Eq. 7 gives the following expression for the transfer function of the linear equivalent hysteretic damper model:

$$H(\omega) = \left(-\frac{1}{2} + i \frac{2}{\pi} \right) \quad (18)$$

and the corresponding gain value:

$$g = \frac{f_m}{A} \quad (19)$$

From Eq.10 the optimal value of g is determined as

$$g_{opt} = 1.24 \frac{(\omega_\infty^2 - \omega_0^2)}{u_0^2} \quad (20)$$

The optimal value f_m is determined as

$$f_m = g_{opt} A \quad (21)$$

where A is the amplitude of the displacement.

In this paper, a four-layer feed forward neural network is adopted which consists of one input, two hidden layers and a single output layer. The displacement and velocity with current state and five preceding values are taken as input and force at current state is output in the proposed neural network. The neural network controller is trained with training data generated at different amplitudes and at different frequencies of both the displacement response and the corresponding force data from the optimal friction model. The trained model is verified with independent data set and subsequently used in a closed loop implementation. The training algorithm used in the feed forward back propagation neural network is the Levenberg-Marquardt (LM) algorithm based on a least-square curve fitting.

4 NUMERICAL EXAMPLES

To evaluate the effectiveness of the proposed control strategy for the structural vibration mitigation with rotary MR damper, two numerical examples are considered. The first one is based on pure viscous damping strategy and the second one is our proposed neural network based model reference control (NN-MRC). Both the examples are discussed below

4.1 Viscous Damper

The viscous damping strategy using MR damper in closed loop is simulated for five storied shear frame structure with harmonic base excitation. The force-velocity and force-displacement hysteresis plots of the damper force and desired force from control law are compared for optimal viscous damping strategy and the result is quite satisfactory. The force tracking task by MR damper is quite well. From fig. 3, it is visible that MR damper has a force limit at zero current. For that reason it is not possible for MR damper to follow the desired force below the force limit at zero current. Here for this damper, force limit is 24 N.

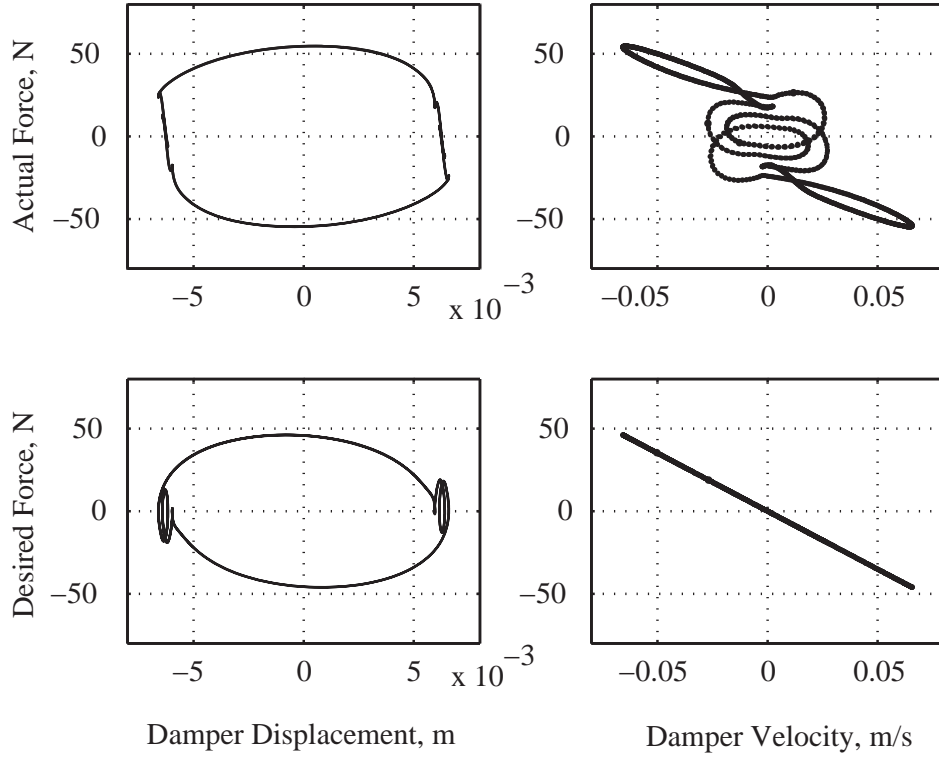

Figure 5: Force-Displacement and Force Velocity hysteresis diagram for viscous damper

The top floor displacement and damper displacement are shown in fig. 6.

Figure 6: Time history of damper and top floor displacement for viscous damper

The viscous damping strategy is also applied directly on structure without MR damper and compared the change in performance.

4.2 Model Reference Neural Controller

The proposed neural control strategy is applied for structural vibration reduction based on harmonic base excitation using MR damper in closed loop simulation. The Time history of damper displacement and top floor displacement are shown below.

Figure 7: Force-Displacement and Force Velocity hysteresis diagram for neural controller

The hysteresis plots for force-displacement and force-velocity trajectories are shown in fig.8.

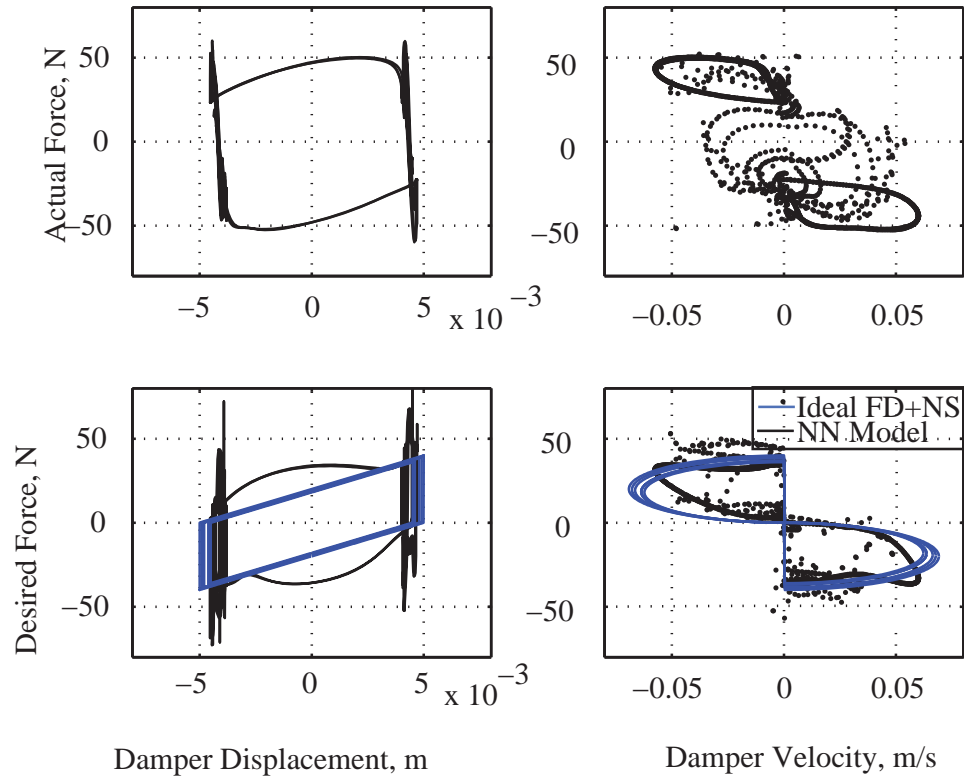

Figure 8: Time history of damper and top floor displacement for neural controller

The schematic diagram for the closed loop simulation is shown below

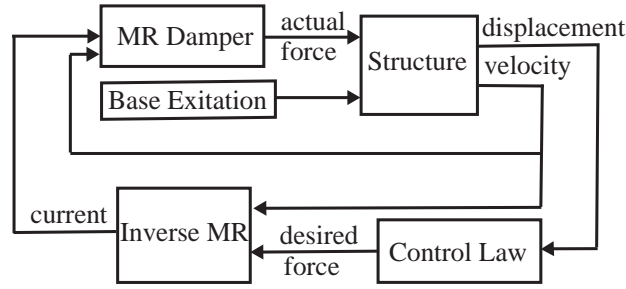

Figure 9: Schematic diagram for closed loop simulation

Force from an optimal friction damper with negative stiffness are calculated by analytical method and compared with the desired force prediction from neural network. Desired force from neural controller and the analytical force have some deviation because the slope of the desired force is not linear due to change in the motion of the damper. The damper displacement is slightly changed from pure sinusoidal due to some spiky effect in current output from inverse MR damper model. The current from inverse MR damper model is shown in fig. 10

Figure 10: Time history of current from inverse MR model

The force-displacement and force-velocity diagram are shown in Fig. 8. The diagrams are quite satisfactory with compared with identical one. There is some deviation in the force prediction due to non-sinusoidal behaviour of the structural response. This is mainly due to some spiky current prediction by inverse MR model but overall the force tracking is quite satisfactory.

	Passive Viscous	Viscous with MR damper	NN-MRC
$\text{RMS}(x_1^{\max})$	0.0091 m	0.0066 mm	0.0044 mm
$\text{RMS}(x_5^{\max})$	0.036 m	0.030 m	0.024 m
$\text{RMS}(a_1^{\max})$	0.64 m/s ²	0.81 m/s ²	0.80 m/s ²
$\text{RMS}(a_5^{\max})$	2.02 m/s ²	1.81 m/s ²	1.76m/s ²

Table 1: Performance Parameters

5 CONCLUSIONS

In the closed loop simulation, two neural network models are used. One is for force tracking which is an inverse MR damper model and another is used for tracking reference damper model which is following hysteresis force-displacement behaviour for optimal friction damper with negative stiffness. RMS of the peak displacement and peak acceleration of each cycle for top floor and damper location are taken as performance parameters. From the performance parameters chart, it is clearly visible that proposed control method can reduce around 35% in damper displacement and 30% in top floor displacement. The damper displacement for viscous damping strategy with and without MR damper has deviation due to limitation MR damper force realization at zero current when MR damper is attached. The response of the top floor using semi active neural controller gives is quite satisfactory with compared to pure viscous damping. There is also significant improvement in acceleration term and but the acceleration contains some noise. The major advantage of the proposed controller is it is inherently modeled with amplitude dependency and the inherent time-delay problem which is an important drawback of model based control can be solved in neural based control. In general, a neural network is trained under certain condition which can be used in a slightly modified but similar nature of the training state. The important feature of neural network is that it can handle nonlinearity so well that it can apply to nonlinear structural control also based on linearly trained neural model. This is the reason why neural network is used in this paper for structural control. The numerical study revealed that proposed neural based model reference controller can track the desired hysteresis behaviour of optimal friction damper with negative stiffness satisfactorily and the performance is better than optimal viscous damper.

Keywords: Resonance in Railway Bridges, Passive Control of Structures, Double-beam System, Moving Loads, Dynamics of Bridges, Fluid-viscous Dampers.

Abstract. *In this contribution the application of Passive Control techniques is applied to reduce the severe transverse vibrations that railway bridges of moderate lengths may experiment under resonance conditions. The proposed solution consists on connecting the slab to a series of auxiliary beams with partially restrained rotational end conditions through a set of fluid-viscous dampers. A particular configuration minimizing the space occupied under the bridge deck by the devices and the auxiliary beams is proposed for slabs and girder bridges, typical typologies in the aforementioned range of lengths. First, the dynamic response of the double-beam system at resonance is obtained in closed-form under harmonic excitation in order to detect the main governing parameters of the bridge response. Then conditions for the optimal dampers constants and minimum beam sizes that minimize the bridge dynamic amplification at resonance are obtained using a planar analytical model. Finally the effectiveness of the solution and the adequacy of the expressions derived from the harmonic case are proven under railway traffic excitation. Special attention is given to the beneficial effect of partially restraining the auxiliary beam supports throughout the study.*

1 INTRODUCTION

The extensive construction of new High-Speed railway lines and the use of conventional lines for higher operating train velocities require the continuous upgrading of railway infrastructure and, in particular, of bridge structures. Even though modern trains' axle loads are not higher than old-time vehicles transmitted forces, higher design velocities may lead to the appearance of resonance phenomena. Resonance, in a railway bridge, takes place when the exciting frequency of the train's periodic loading becomes close to the natural frequency of the bridge. If this is the case, the loads enter the bridge in phase with the natural oscillations of the structure leading to a progressive increase of the deck transverse oscillations. If structural damping is low, as it usually is the case in railway bridges [1], and the number of axles is sufficient severe transverse vibrations at the platform area could build up causing the failure of the Serviceability Limit State of vertical acceleration [2]. Specially critical structures in this regard are short-to-medium-span bridges (12 to 25 m) where the main structural elements are simply-supported (S-S) beams or plates. In these structures resonance phenomena may cause not only impact or fatigue related damage but also failure of ballast-beds due to relaxation and scattering of ballasts. This can compromise the running safety of the trains, the ride comfort of passengers, and ultimately increase the bridge maintenance costs [1, 3, 4].

In existing bridges that experiment this kind of behavior, due to either an increase in the Maximum Line Speed at the site or to structural degradation with time, classical solutions could be applied such as increasing the mass of the deck and therefore reducing its acceleration or augmenting its stiffness and consequently raising its natural frequencies and critical velocities. Nevertheless in many circumstances it is not possible to preserve the original structure and the deck needs to be demolished and replaced with the subsequent interruption of the line services. Alternatively, in this contribution the reduction of the bridge dynamic response by artificially increasing the overall damping of the structure applying Passive Control techniques and, in particular, retrofitting the bridge deck with Fluid Viscous Dampers (FVDs) is proposed and evaluated.

Despite the fact that vibration control systems have been applied to reduce the dynamic response of structures since the 1960s, only a few authors have addressed the practical application of these technologies to bridges under the action of moving vehicles. The application of Tuned Mass Dampers (TMDs) to the train-induced vibration problem has been addressed by Kwon et al. [5], Wang et al. [6], Yau et al. [7, 8, 9] and Li et al. [10]. These authors investigate the dynamic performance of bridges using planar models retrofitted with single or multiple TMDs. TMDs are tuned to a single frequency of the superstructure (usually the fundamental one) or several frequencies which contributions need to be reduced. From these works it can be inferred that the vehicle passage time on the bridge is, in many circumstances, too short to build up the needed TMD vibrating regime that effectively mitigates the bridge excessive vibrations; besides, detuning problems may arise if the devices are tuned to the bridge natural frequency, due to the variability of this magnitude over time associated to vehicle-bridge interaction effects, changing environmental parameters (e.g. temperature), or to the decay of the TMD stiffness with time. Nevertheless this second drawback may be partially overcome with multiple TMDs tuned in a frequency interval [8, 10] or with the string-type TMD presented in [9]. Recently Samani [11] has compared the vibration reduction capability of nonlinear TMDs when compared to linear elements connected to simply-supported beams under moving loads concluding that the vibration reduction achieved levels are very similar.

Minsili et al. [12] suggest the installation of supplemental diagonal elements in truss bridges connected to the original braces through Slotted Friction Connections, in order to mitigate traffic and earthquake induced vibrations. The authors point out that with this alterna-

tive structural displacements can be reduced to a great extent, but vertical accelerations may exceed their initial values due to the nature of the new forces introduced in the bridge deck. The appearance of residual displacements in the structure after the devices activation is an additional inconvenient of the proposed system.

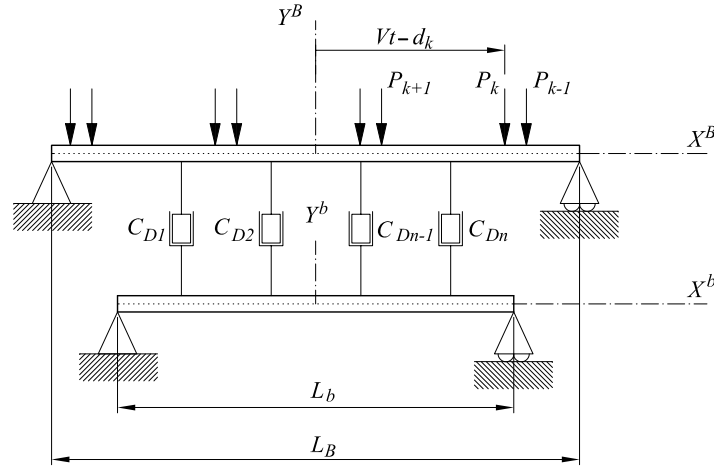

Figure 1: Simply-supported double beam system connected through FVDs and (b) simply-supported-partially-clamped double beam system connected through FVDs.

The use of viscoelastic (VE) materials to improve the dynamic performance of railway bridges has been addressed by a number of researchers. Choo et al. [13] propose the introduction of acrylic rubber patches connected to S-S beams deforming in shear when the main elements bend. The authors carry out an experimental program and adjust a numerical constitutive model for this material. They finally conclude that the proposed design could reduce to permitted levels the structural response of long span bridges which experience inadmissible vertical accelerations. A few authors have investigated the applicability of Continuous Dynamic Vibration Absorbers (CDVAs) combined with viscoelastic materials, to the vibration control of beams under harmonic and moving loads. Vu et al. [14] and Abu-Hilal [15] study the possibility of reducing the dynamic response of a Bernoulli-Euler (B-E) beam by connecting it to an identical element through a continuous layer of VE material. On-sizczuk analyses the dynamic behaviour of double-beam [16, 17] and double plate systems [18, 19] linked through continuous Winkler media focusing on the relative properties of the three elements that control the oscillations of the main element. Recently, Moliner et al. [20, 21] have investigated the dynamic performance of the double-beam system connected by discrete Kelvin elements and have evaluated its applicability in reducing the resonant response of short S-S railway bridges. A few authors have addressed the use of pure viscous dampers to reduce the amplification in beams traversed by moving vehicles. Oliveto et al. [22] and Greco et al. [23] solve the dynamic problem of a continuous beam with two end rotational viscous dampers under the circulation of a single load, by using an extension of the complex mode superposition method. Nevertheless, to the authors' knowledge, this type of damper has never been previously applied in the context of High-Speed railway traffic.

FVDs have been selected, as compared to other Passive Control devices for this application, because they dissipate energy at a wide scope of frequency ranges, and not only at narrow ranges like TMDs. As a consequence, they do not present relevant tuning and detuning drawbacks. A further advantage is the fact that dissipative devices based on friction or yielding increase replacement operations and maintenance costs. In contrast, some FVDs are equipped with labyrinth seals which eliminate mechanical friction [24], allowing them to undergo an enormous number of cycles before they have to be replaced. Moreover, since in FVDs the

maximum force and maximum displacement are out of phase, additional forces introduced in the structure are small when compared to other techniques.

The authors of this contribution have investigated in the past the dynamic behaviour of a double-beam system as the one shown in Fig. 1 linked through a distribution of pure FVDs under the circulation of moving loads [25, 26].

It consists of a *main beam*, which represents the bridge, and an *auxiliary beam* with simply-supported end conditions connected to the bridge by means of FVDs. Closed-form expressions for the optimal dampers minimising the bridge response have been provided, and a methodology for the auxiliary beam design has been developed based on the overall damping needs. This study has been completed accounting for the contribution of three-dimensional modes of the bridge, which cannot be neglected in multi-track decks or when the deck has a skew geometry. To this end the dynamic performance of orthotropic plates connected to auxiliary beams distributed along the deck width with, again, simply-supported end conditions through FVDs has been analysed in detail [25, 27, 28].

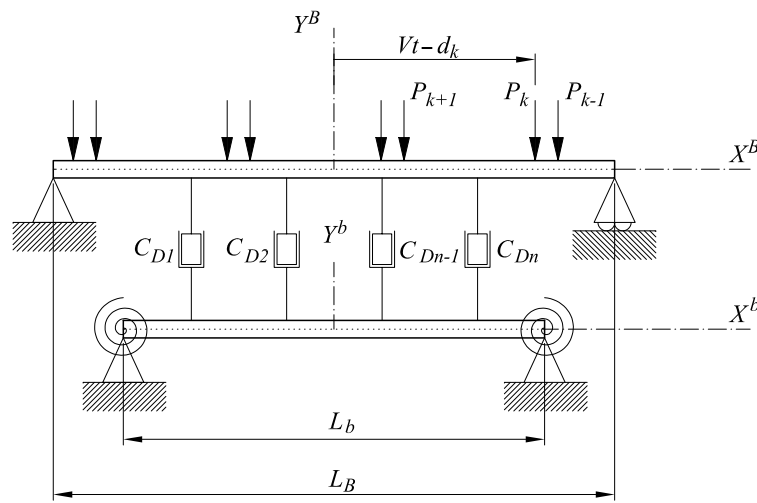

Figure 2: Simply-supported-partially-clamped double beam system connected through FVDs.

One of the main conclusions derived from the previous works by the authors is that in order for the FVDs to effectively reduce the deck vibratory response, the fundamental frequency of the auxiliary beam (lower beam in Fig. 1) needs to exceed the bridge or main beam highest frequency which contribution is to be controlled. Moreover, as the auxiliary beam frequency increases, the dissipative capacity of the system raises. Due to this condition the secondary beam needs always to be oversized when compared to the minimum beam that would accomplish resistance requirements under the dampers forces. As the proposed configuration, that is presented in section 2, consists on installing the retrofitting system below the slab the needed auxiliary beams may occupy an excessive portion of the free space under the deck. Furthermore, as current design standards [2, 29] prescribe to account for frequency contents up to 30 Hz in the computation of the deck transverse acceleration, modes close to 30 Hz are almost impossible to control with the proposed system because beams with fundamental frequencies exceeding 30 Hz require enormous section heights for spans in the neighborhood of 20-25 m. To overcome this problem a variation on the configuration of the retrofitting system already studied by the authors is proposed which consists on transforming the original simply-supported boundary conditions of the auxiliary beam restraining the extreme sections rotation. In an ideal case if the beam could be perfectly clamped at the ends the natural frequency of the fundamental mode would increase approximately 2.27 times with respect to simply-supported end conditions. As perfect clamping is not possible the system shown in Fig. 2 is

analyzed. This way the efficiency of the solution can be investigated in terms of the partial rotational restriction of the beam supports.

The objectives of the present study are (i) to propose a methodology to select the minimum size of the auxiliary beam and optimum FVDs constants minimizing the dynamic response of the main simply-supported beam at resonance; (ii) to prove that with the proposed solution severe levels of vertical acceleration may be drastically reduced without exceeding the devices maximum bearing capacity, the maximum admissible stress in the beams nor the punching force in the slab, and (iii) to evaluate the beneficial effect of partially clamping the auxiliary beam supports when compared to the previously analyzed simply-supported case.

2 CONFIGURATION OF THE DAMPING SYSTEM

The dissipative system to be installed on the beam supporting the passage of the loads consists of two main elements. The first element is an auxiliary, partially clamped beam which in typical applications is generally located underneath the main one.

The second element is a set of FVDs linking the vertical motion of certain sections of the main beam and the auxiliary one. Our attention here is focused on mitigating the flexural vibrations of the main beam when the train of moving loads induces a resonance situation. For this reason, the planar model shown in Fig. 2 is used to analyse the performance of the proposed retrofit alternative. For the sake of simplicity two Cartesian coordinate systems are introduced with origins located at both beams mid-span sections.

The loads acting on the structure are assumed to be constant-valued, i.e. vehicle–bridge interaction effects are neglected. Also, the main beam is assumed to rest directly on the abutments without any intermediate elastic bearing.

The torsional oscillations experienced by beams subjected to eccentric moving loads are not accounted for in the analytical formulation and optimisation of this study. Consequently, the results presented in sections 2 and 3 are not applicable to either multi-track or single-track skewed railway bridges. However, it should be emphasised that single-track non-skewed bridges, and in particular, medium to short-span ones are some of the most unfavourable cases found in practice. As a consequence of their low total mass, this type of structures may undergo severe resonant oscillations under the passage of fast trains, thus generating highly demanding situations for any dissipative system.

Figure 3: Retrofit configuration for a concrete girders bridge deck.

Fig. 3 shows a possible configuration of the auxiliary beam and dampers installed in a sin-

gle-track railway bridge. The dampers link the lower side of the slab and the upper flange of an auxiliary beam with hollow rectangular cross-section. The auxiliary beam is clamped on the abutments at the outermost sections of the bridge. Other suitable configurations could be adopted for different auxiliary beams geometries and deck typologies with an essential dynamic behaviour as that represented in Fig. 2.

3 GOVERNING PARAMETERS AND INFLUENCE ON THE RESPONSE

3.1 Equations of motion of a simple beam under moving loads

The partial differential equation governing the flexural behaviour of a simply supported beam (main beam of the system) subjected to a train of concentrated loads can be found in the works of several authors such as Frýba [30, 31], Olsson [32], Yang et al. [33] and Museros and Alarcón [34]. Neglecting the effects of shear deformation and rotary inertia, and considering that the loads are aligned with the axis of symmetry of the cross-section (Y axis), the governing equation can be written as

$$m \frac{\partial^2 y}{\partial t^2} + \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 y}{\partial x^2} \right) = q(x, t). \quad (1)$$

In Eq. (1) the following notation is used: m is the mass per unit length, $y = y(x, t)$ the transverse displacement of any beam section at time t , x refers to the longitudinal coordinate, E is the Modulus of Elasticity, I the second moment of area of the cross-section and $q(x, t)$ stands for the distributed load per unit length acting at time t (positive if directed upwards).

The deformed shape is expressed as a linear combination of a family of sines and cosines $\phi_j(x)$ as in Eq. (2), where N_{mod} stands for the number of modes considered, $\xi_j(t)$ is the amplitude of the j th mode, and L is the length of the beam.

$$y(x, t) = \sum_{j=1}^{N_{mod}} \xi_j(t) \cdot \phi_j(x) \quad \text{where} \quad \phi_j(x) = \begin{cases} \cos\left(\frac{j\pi x}{L}\right) & \text{if } j = \text{odd number} \\ \sin\left(\frac{j\pi x}{L}\right) & \text{if } j = \text{even number} \end{cases} \quad (2)$$

The loads are represented by means of Dirac delta functions acting at $x = Vt - d_k$, where V is the constant train speed, and d_k is the original distance from the k th load to the mid-span section of the beam. Thus, $q(x, t)$ may be expressed as follows:

$$q(x, t) = - \sum_{k=1}^{N_p} \left(H\left(t - \frac{d_k}{V}\right) - H\left(t - \frac{d_k + L}{V}\right) \right) P_k \delta(x - (Vt - d_k)), \quad (3)$$

where N_p is the total number of axle loads; P_k is the value of the k th load; and $H(t - t_0)$ is the Heaviside unit function acting at time t_0 . When Eqs. (2) and (3) are introduced in Eq. (1), and multiplication by the n th function $\phi_n(x)$ and integration along the span L are carried out, the n th modal equation of motion is obtained. To this end, the mass per unit length m and the flexural stiffness EI are assumed to be constant along the beam. Introducing a modal viscous damping ratio ζ_n , the modal equation of motion is expressed as

$$\ddot{\xi}_n(t) + 2\zeta_n \omega_n \dot{\xi}_n(t) + \omega_n^2 \xi_n(t) = \frac{-2}{mL} \sum_{k=1}^{N_p} \left(H\left(t - \frac{d_k}{V}\right) - H\left(t - \frac{d_k + L}{V}\right) \right) P_k \cos \frac{n\pi(Vt - d_k)}{L}, \quad (4)$$

where over-dots indicate differentiation with respect to time, and ω_n represents the n th circular frequency of the main beam in rad/s

$$\omega_n = \left(\frac{n\pi}{L} \right)^2 \sqrt{\frac{EI}{m}}. \quad (5)$$

3.2 Governing equations of the beam equipped with fluid viscous dampers and subjected to moving loads

In this section the equations of motion of the double-beam system are formulated as the auxiliary beam is connected to the main one through the dampers distribution.

The auxiliary beam is partially clamped, therefore, the boundary conditions of the secondary beam are considered to be simply supported with two identical rotational springs at both ends. The partial differential equation governing the flexural behaviour of the auxiliary beam has the same general expression than that of a simply supported element Eq. (1).

When the auxiliary beam is connected to the main one by means of the FVDs, the equations of motion must be suitably modified. In practical applications, resonance induced by constant moving loads is a problem of bridges subjected to the passage of fast trains. Museros and Alarcón [34] show that resonance of the second bending mode can take place in certain cases but, in single-track bridges it is most likely that resonance will be related to oscillations of the first bending mode. This is a consequence of the maximum speed attainable by modern high-speed trains. Under such circumstances, the influence of modes other than the one undergoing resonance can be disregarded for the computation of the main beam response.

The oscillations of the first mode of the main beam at resonance tend to create a symmetric distribution of dampers forces with respect to the mid-span section. These forces excite the movement of the auxiliary beam which, consequently, can be initially analysed only taking into account the contribution of its first bending mode as well. The viability of disregarding the second and higher modes of the beams in the calculation of the optimal parameters of the damping system is subsequently verified in section 5.

If the deformed shape of the auxiliary beam is expressed as the product of a modal amplitude times its first modal shape:

$$y(x, t) = \xi_1(t) \cdot \phi_1(x) = \xi_1(t) \cdot \left(\frac{\cosh\left(\frac{\beta \cdot L}{2}\right) \cdot \cos(\beta \cdot x) - \cos\left(\frac{\beta \cdot L}{2}\right) \cdot \cosh(\beta \cdot x)}{\cosh\left(\frac{\beta \cdot L}{2}\right) - \cos\left(\frac{\beta \cdot L}{2}\right)} - \frac{\cosh\left(\frac{\beta \cdot L}{2}\right) \cdot \cosh(\beta \cdot x)}{\cosh\left(\frac{\beta \cdot L}{2}\right) - \cos\left(\frac{\beta \cdot L}{2}\right)} \right) \quad (6)$$

where β is:

$$\beta = \sqrt[4]{\frac{\omega_1^2 \cdot m}{E \cdot I}}. \quad (7)$$

In expression (7) ω_1 represents the first circular frequency of a simply-supported beam with rotational springs, in rad/s, which can be computed from the lowest root of the frequency equation:

$$-\frac{(\beta L)^2}{4} \sinh(\beta L) \sin(\beta L) + \bar{K} \beta L \sinh(\beta L) \cos(\beta L) - \bar{K} \beta L \cosh(\beta L) \sin(\beta L) + 2\bar{K}^2 \cosh(\beta L) \cos(\beta L) - 2\bar{K}^2 = 0 \quad (8)$$

being \bar{K} a stiffness ratio between the rotational springs constants and the beam bending stiffness defined as

$$\bar{K} = \frac{KL}{4EI}. \quad (9)$$

Considering therefore only the contribution of the fundamental modes of both beams, the resulting equations of motion of the double-beam system linked by the distribution of the dampers in modal space are as follows:

$$\ddot{\tilde{m}}_B \xi_B(t) + 2\zeta_B \omega_B \dot{\tilde{m}}_B \xi_B(t) + C_D^{BB} \ddot{\xi}_B(t) - C_D^{Bb} \ddot{\xi}_b(t) + \tilde{K}_B \xi_B(t) = q(x, t) \quad (10a)$$

$$\ddot{\tilde{m}}_b \xi_b(t) + 2\zeta_b \omega_b \dot{\tilde{m}}_b \xi_b(t) + C_D^{bb} \ddot{\xi}_b(t) - C_D^{Bb} \ddot{\xi}_B(t) + \tilde{K}_b \xi_b(t) = 0 \quad (10b)$$

$$q(x, t) = -\sum_{k=1}^{N_p} \left(H\left(t - \frac{d_k}{V}\right) - H\left(t - \frac{d_k + L_B}{V}\right) \right) P_k \cos \frac{n\pi(Vt - d_k)}{L_B} \quad (10c)$$

The notation in Eq. (10) is analogous to previous equations but with superscripts and subscripts B and b , which are included to indicate magnitudes associated to the main and auxiliary beam, respectively. Moreover, in equation (10):

$$\tilde{m}_B = \frac{m_B L_B}{2} \quad \text{is the first modal mass for the main beam} \quad (11)$$

$$\tilde{K}_B = \frac{\omega_B^2 m_B L_B}{2} \quad \text{is the first modal stiffness for the main beam} \quad (12)$$

$$\tilde{m}_b = m_b \cdot c \quad \text{is the first modal mass for the auxiliary beam, where:} \quad (13)$$

$$c = \frac{L_b \cdot [2\gamma + \gamma \cos \gamma + \cosh \gamma (\gamma - \sin \gamma) - \sin \gamma - (1 + \cos \gamma) \sinh \gamma]}{4\gamma \left[\cos\left(\frac{\gamma}{2}\right) - \cosh\left(\frac{\gamma}{2}\right) \right]^2} \quad (14)$$

$$\gamma = \beta L_b \quad (15)$$

$$\tilde{K}_b = \left(\frac{\gamma}{L_b} \right)^4 \cdot c \cdot E_b \cdot I_b \quad (16)$$

$$C_D^{BB} = \sum_{i=1}^{N_D} C_{Di} \cdot \left(\cos\left(\frac{\pi x_{Di}^B}{L_B}\right) \right)^2 \quad (17)$$

$$C_D^{Bb} = \sum_{i=1}^{N_D} C_{Di} \cdot \cos\left(\frac{\pi x_{Di}^B}{L_B}\right) \cdot \left[A \cdot \cosh\left(\frac{\gamma \cdot x_{Di}^b}{L_b}\right) + B \cdot \cos\left(\frac{\gamma \cdot x_{Di}^b}{L_b}\right) \right] \quad (18)$$

$$C_D^{bb} = \sum_{i=1}^{N_D} C_{Di} \cdot \left[A \cdot \cosh\left(\frac{\gamma \cdot x_{Di}^b}{L_b}\right) + B \cdot \cos\left(\frac{\gamma \cdot x_{Di}^b}{L_b}\right) \right]^2 \quad (19)$$

Notice that parameter γ is a function of the quotient between the auxiliary partially clamped beam circular frequency and the same beam frequency with simply-supported end conditions:

$$\gamma = \beta L_b = \pi \sqrt{\frac{\omega_b}{\omega_{b,ss}}} \quad (20)$$

In expressions (17), (18) and (19), C_{Di} is the constant of the i th damper. The location of the i th damper is designated as x_{Di}^B along the X^B axis of the main beam, and as x_{Di}^b along the X^b axis of the auxiliary beam. The significance of parameters A and B is:

$$A = \frac{-\cos\left(\frac{\gamma}{2}\right)}{\cosh\left(\frac{\gamma}{2}\right) - \cos\left(\frac{\gamma}{2}\right)} \quad B = \frac{\cosh\left(\frac{\gamma}{2}\right)}{\cosh\left(\frac{\gamma}{2}\right) - \cos\left(\frac{\gamma}{2}\right)} \quad (21)$$

From Eqs. (10) it can be seen that, if the modal system of equations is written in matrix form, the load term associated to the forces exerted by the FVDs gives rise, in general, to a full damping matrix.

3.3 Nondimensional formulation of the system under harmonic excitation

This article focuses on the reduction of the resonant response of beams or bridges, and therefore the system shown in Fig. 2 will first be analysed under the action of a harmonically varying force applied at the mid-span section of the main beam (see Fig. 4a). This kind of excitation captures the essential features of the system response at resonance.

Figure 4: (a) Double-beam system under harmonic excitation applied at mid-span. (b) Equivalent 2dof system in modal space.

In what follows, it will be assumed that the lengths of both beams are equal, $L_B = L_b = L$ and the main and auxiliary beams are vertically aligned so that $x_{Di}^B = x_{Di}^b$, $i = 1, 2, \dots, N_D$. These hypotheses are the most relevant ones for real applications because it is most likely that in actual bridges, the auxiliary beam or beams are supported at the original abutments or close to them. If only the first mode of both beams is taken into account, any number of FVDs located at different sections is equivalent to a single equivalent FVD located at mid-span with equivalent damping constant:

$$C_D = \sum_{i=1}^{N_D} C_{Di} \cdot \left(\cos\left(\frac{\pi x_{Di}^B}{L_B}\right) \right)^2 \quad (22)$$

Under the aforementioned circumstances, the response in terms of modal amplitudes corresponds to that of the two-degree-of-freedom (2dof) system shown in Fig. 4b, where ξ_B and ξ_b , are the first modal amplitudes of the main and auxiliary beam, respectively.

The equations of motion of the system may be expressed as:

$$\begin{bmatrix} \tilde{m}_B & 0 \\ 0 & \tilde{m}_b \end{bmatrix} \cdot \begin{pmatrix} \ddot{\xi}_B \\ \ddot{\xi}_b \end{pmatrix} + \begin{bmatrix} 2\zeta_B \omega_B \tilde{m}_B + C_D^{BB} & -C_D^{Bb} \\ -C_D^{bB} & 2\zeta_b \omega_b \tilde{m}_b + C_D^{bb} \end{bmatrix} \cdot \begin{pmatrix} \dot{\xi}_B \\ \dot{\xi}_b \end{pmatrix} + \begin{bmatrix} \tilde{K}_B & 0 \\ 0 & \tilde{K}_b \end{bmatrix} \cdot \begin{pmatrix} \xi_B \\ \xi_b \end{pmatrix} = \begin{pmatrix} -P_0 \cos(\omega_f t) \\ 0 \end{pmatrix} \quad (23)$$

In Eq. (23) P_0 and ω_f are the amplitude and the forcing frequency of the excitation, respectively. In order to solve Eq. (23) the following dimensionless ratios are defined:

$$\text{Frequency ratio: } \eta = \omega_b / \omega_B \quad (24a)$$

$$\text{Excitation frequency ratio: } \Omega = \omega_f / \omega_B \quad (24b)$$

$$\text{Mass ratio: } \mu = m_b / m_B \quad (24c)$$

$$\text{Supplemental damping ratio: } \zeta_D = C_D / (m_B L \omega_B) \quad (24d)$$

Moreover, when there is only a single equivalent FVD located at mid-span, with $x_D^B = x_D^b = 0$ parameters C_D^{BB} , C_D^{Bb} and C_D^{bb} become equal:

$$C_D^{BB} = \sum_{i=1}^{N_D} C_{Di} \cdot \left(\cos \left(\frac{\pi x_{Di}^B}{L_B} \right) \right)^2 = C_D \quad (25)$$

$$C_D^{Bb} = \sum_{i=1}^{N_D} C_{Di} \cdot \cos \left(\frac{\pi x_{Di}^B}{L_B} \right) \cdot \left[A \cdot \cosh \left(\frac{\gamma \cdot x_{Di}^b}{L_b} \right) + B \cdot \cos \left(\frac{\gamma \cdot x_{Di}^b}{L_b} \right) \right] = C_D \cdot [A + B] = C_D \quad (26)$$

$$C_D^{bb} = \sum_{i=1}^{N_D} C_{Di} \cdot \left[A \cdot \cosh \left(\frac{\gamma \cdot x_{Di}^b}{L_b} \right) + B \cdot \cos \left(\frac{\gamma \cdot x_{Di}^b}{L_b} \right) \right]^2 = C_D \cdot [A + B]^2 = C_D \quad (27)$$

Rewriting Eq. (23) in terms of the dimensionless ratios defined in Eqs. (24) yields

$$\begin{bmatrix} 1 & 0 \\ 0 & \mu \end{bmatrix} \cdot \begin{pmatrix} \ddot{\xi}_B \\ \ddot{\xi}_b \end{pmatrix} + 2\omega_B \begin{bmatrix} \zeta_B + \zeta_D & -\zeta_D \\ -\zeta_D & \zeta_b \eta \mu + \zeta_D \end{bmatrix} \cdot \begin{pmatrix} \dot{\xi}_B \\ \dot{\xi}_b \end{pmatrix} + \omega_B^2 \begin{bmatrix} 1 & 0 \\ 0 & \eta^2 \mu \end{bmatrix} \cdot \begin{pmatrix} \xi_B \\ \xi_b \end{pmatrix} = \begin{pmatrix} \frac{-2P_0}{m_B L} \cos(\omega_f t) \\ 0 \end{pmatrix} \quad (28)$$

Equation (28) written in terms of the nondimensional parameters is equivalent to that of the double-beam system with simply-supported end conditions in both beams previously analysed by the authors in reference [26]. Assuming again that the maximum response of the main beam will take place at resonance the transient solution is neglected and the dynamic amplification of the response is obtained for both beams as:

$$\begin{pmatrix} \bar{\xi}_B \\ \bar{\xi}_b \end{pmatrix} = (-\omega_f^2 \mathbf{M} + i\omega_f \mathbf{C} + \mathbf{K})^{-1} \cdot \begin{pmatrix} \frac{-2P_0}{m_B L} \\ 0 \end{pmatrix} \quad (29)$$

where $\bar{\xi}_B$ and $\bar{\xi}_b$ are the complex amplitudes, \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness modal matrices from Eq. (28), and $i = \sqrt{-1}$. The moduli of $\bar{\xi}_B$ and $\bar{\xi}_b$ give the amplitudes of the response. In order to obtain a dimensionless representation of the beams response, two modal amplifications are defined as the modulus of $\bar{\xi}_B$ and $\bar{\xi}_b$ divided by the static deflection caused by the concentrated load P_0 acting on the main beam

$$A_B = \frac{|\bar{\xi}_B|}{2P_0 / (\omega_B^2 m_B L)} \quad (30a)$$

$$A_b = \frac{|\bar{\xi}_b|}{2P_0 / (\omega_B^2 m_B L)} \quad (30b)$$

After some algebraic manipulation, the modal amplifications are obtained

$$A_B = \sqrt{\frac{4\Omega^2 (\zeta_b \eta \mu + \zeta_D)^2 + \mu^2 (\eta^2 - \Omega^2)}{E^2 + 4\Omega^2 F^2}} \quad (31a)$$

$$A_b = \frac{2\Omega \zeta_D}{\sqrt{E^2 + 4\Omega^2 F^2}} \quad (31b)$$

being

$$E = \mu(1 - \Omega^2)(\eta^2 - \Omega^2) + 4\Omega^2 (\zeta_D^2 - (\zeta_B + \zeta_D)(\zeta_b \eta \mu + \zeta_D)) \quad (31c)$$

$$F = (1 - \Omega^2)(\zeta_b \eta \mu + \zeta_D) + \mu(\zeta_B + \zeta_D)(\eta^2 - \Omega^2) \quad (31d)$$

The main beam modal acceleration is also of great interest because of its relation with ballast stability, as mentioned in section 1. In the steady-state the amplitude of the acceleration a_B is

$$a_b = \left| \bar{\zeta}_B \right| \omega_f^2 = \frac{2P}{m_B L} \Omega^2 A_B \quad (32)$$

Eq. (31) shows that the amplification of the main beam response A_B , depends on the following six parameters: Ω , η , μ , ζ_D , ζ_b , ζ_B . Additionally, from Eq. (32) it can be seen that the modal acceleration of the main beam is inversely proportional to its total mass $m_B L$. The behaviour of the system in terms of these parameters is analysed in detail in the following section.

4 RETROFITTING SYSTEM OPTIMISATION

4.1 Optimal value of the supplemental damping ratio

The key variables of the problem that should be minimised are the main beam dynamic amplification and modal acceleration, A_B and a_B . In order to visualise how the governing parameters affect these magnitudes and determine what is the best selection of the auxiliary beam and damper for a particular bridge, a number of plots are included in Fig. 5.

Figure 5: Main beam amplification A_B versus Ω for different values of ζ_D , μ and η .

The plots illustrate the evolution of the main beam resonant amplification with μ , η , and ζ_D . In all the cases structural dampings of the main and secondary beams are 2% and 0.5%, respectively. In Fig. 5a μ and η are fixed and equal to 0.1 and 1.9, respectively. In this plot, for a particular bridge and auxiliary beam the resonant response of the former is analyzed as the damper constant increases. As it can be seen, there is an optimum value of the damper constant which, for a particular auxiliary beam, leads to the minimum response of the main element. In Fig. 5b it is shown how the main beam amplification at resonance monotonically

diminishes with the auxiliary beam mass for fixed values of this element natural frequency and damper constant. Finally, in Fig. 5c the evolution of A_B with the frequency ratio η of the two beams fundamental frequency is evaluated. From the analysis of this plot it can be concluded that in order for the retrofitting system to effectively reduce the dynamic response of the main beam, η has to be higher than one, that is, the secondary beam natural frequency must exceed the main beam frequency. The system hardly dissipates energy when $\eta=1$. For values of $\eta<1$ the secondary beam and damper behave in a certain way as a Tuned Mass Damper and the main beam resonant response partially reduces but this reduction can reach much higher levels for values of $\eta>1$. When η tends to infinity, A_B monotonically decreases as in this case the damper lower end tends to be attached to a fixed reference (the same occurs when $\mu\rightarrow\infty$). From this situation the clear advantage of partially clamping the auxiliary beam ends is evident as it leads to an increase of the secondary beam frequency and a reduction of the main beam resonant response.

In conclusion, as there are not optimal values of η and μ , or in other words, the dissipation capacity of the system increases with increasing values of any of these two parameters, the design strategy should be to select the smallest auxiliary beam such that with its associated optimal damper provides enough energy dissipation to achieve the desired target performance. In what follows, a closed form expression for the optimal supplemental damping ratio ζ_D is obtained.

Figure 6: Main beam amplification A_B versus Ω for different values of ζ_D neglecting structural damping.

From the works of the European Rail Research Institute [1] it can be concluded that damping ratios in modern railway bridges are usually small, of the order of 1% or 2%, or even smaller in composite or metallic bridges. Therefore, in most practical cases an approximate solution to the problem can be obtained by assuming that structural damping is negligible in comparison with the dissipation introduced by the external FVD. This hypothesis allows the computation of a closed form expression for the optimal value of ζ_D . The subsequent numerical examples will prove the soundness of this approach. Neglecting structural damping, that is $\zeta_B = \zeta_b = 0$, Eqs. (31a), (31c) and (31d) transform into

$$A_B = \sqrt{\frac{4\Omega^2\zeta_D^2 + \mu^2(\eta^2 - \Omega^2)^2}{(1 - \Omega^2)^2\mu^2(\eta^2 - \Omega^2)^2 + 4\Omega^2\zeta_D^2[1 - \Omega^2 + \mu(\eta^2 - \Omega^2)]^2}} \quad (33)$$

Comparing Figs. 5a and 6 the effect of structural damping on the response can be observed.

The maximum amplification for low and high values of ζ_D at resonance reaches a much higher level when structural damping is neglected as in Fig. 6, but two important facts must be highlighted. First, the difference between the maximum amplifications is much lower when ζ_D takes the optimal value. This fact reveals that, if structural damping is low and the optimal value of ζ_D is selected, the greater part of the energy at resonance is dissipated through the FVD. Secondly, if structural damping is neglected as in Fig. 6, A_B is independent of ζ_D at the value of Ω corresponding to the minimum maximum. This fact permits the computation of the excitation frequency ratio at the minimum maximum Ω_R^* :

$$\Omega_R^* = \frac{1}{2+\mu} \sqrt{(2+\mu)(2+\mu\eta^2)} \quad (34)$$

and the subsequent derivation of closed-form expressions for the optimal damping ratio ζ_D minimising the main beam amplification and acceleration responses:

$$\frac{\partial A_B}{\partial \Omega}(\Omega = \Omega_R^*, \zeta_D = \zeta_{D,A}^*) = 0 \quad \rightarrow \quad \zeta_{D,A}^* = \frac{(\eta^2 - 1)\mu}{\sqrt{4 + 6\mu + 2\mu^2 + 2\mu\eta^2 + 3\mu^2\eta^2 + \mu^3\eta^2}} \quad (35a)$$

$$\frac{\partial a_B}{\partial \Omega}(\Omega = \Omega_R^*, \zeta_D = \zeta_{D,a}^*) = 0 \quad \rightarrow \quad \zeta_{D,a}^* = \frac{(\eta^2 - 1)\mu}{\sqrt{4 + 2\mu + 6\mu\eta^2 + 3\mu^2\eta^2 + 2\mu^2\eta^4 + \mu^3\eta^4}} \quad (35b)$$

Substituting the damping ratios given by Eqs. (35) into Eq. (24d), the associated optimal damper constants are obtained when structural damping is neglected. These equations provide optimum *equivalent* dampers, which are related to a particular longitudinal distribution of FVDs as per (22). In reference [26] a comprehensive analysis proving the adequacy of expressions (35) when structural damping is not neglected has been performed under harmonic conditions. Finally, in the example of a bridge retrofitted with the system proposed herein that is included in section 5 it is proven that these expressions predict dampers constants real optima with a great degree of accuracy under railway traffic, accounting for modal contributions higher than the fundamental one and including the presence of structural damping.

4.2 Effect of partial rotational restriction at the auxiliary beam supports

In this section the effect of partially restraining the auxiliary beam ends is analysed in terms of the reduction of the main beam resonant response attained as that obtained with a simply-supported auxiliary element. In order to isolate the boundary conditions alteration effect from the secondary beam size, the frequency ratio η is expressed as:

$$\eta = \frac{\omega_{b,ss}}{\omega_B} \left(\frac{\gamma}{\pi} \right)^2 = \eta_{ss,B} \left(\frac{\gamma}{\pi} \right)^2 \quad (36)$$

where $\omega_{b,ss}$ is the auxiliary beam circular frequency with hypothetical simply-supported end conditions and γ varies from π in the simply-supported case to 4.73004074 in the clamped case. In Fig. 7a curves of A_B associated to optimal values of the damping ratio $\zeta_{D,A}^*$ versus Ω have been plotted for a particular pair of beams ($\mu=0.1$, $\eta_{ss,B}=1.2$, $\zeta_B=2\%$ and $\zeta_b=0.5\%$) for increasing levels of rotational restriction of the secondary beam.

In order to measure these levels, instead of using the frequency parameter γ , the increase experimented by the auxiliary beam fundamental frequency with respect to the simply-supported case is employed defining to this end the following ratio:

$$\eta_{b,ss} = \frac{\omega_b}{\omega_{b,ss}} = \left(\frac{\gamma}{\pi}\right)^2 \quad (37)$$

Values of $\eta_{b,ss}$ increase from unity when the beam is simply supported towards 2.267 in the ideal case of a perfectly clamped beam. In order to be conservative it is considered that with nowadays constructive technologies and materials the maximum increase in the secondary beam frequency that can be attained clamping it is 1.5 times. In Fig. 7a $A_B(\Omega)$ has been plotted in the unretrofitted case for comparison purposes. The remaining curves correspond to the minimum response of the main beam at resonance (for optimal damping values $\zeta_{D,A}^*$) for a particular pair of beams and increasing values of γ (and therefore $\eta_{b,ss}$). The amplification at resonance is reduced from 25 to 16.3 when the auxiliary beam is simply supported, which entails a 34.8% reduction with respect to the unretrofitted case. This reduction increases with the restriction of the beam end rotations achieving 73.4% for $\eta_{b,ss}=1.5$. In other words, the main beam response is reduced in more than twice when, due to the auxiliary beam rotational springs stiffening, the fundamental frequency of this element increases 50%. As we move towards the ideal case of a doubly clamped beam, this reduction tends to 88.6%. The interesting side of this alternative when compared to the simply-supported case previously analysed by the authors, is that the auxiliary beam size if partially clamped can be drastically reduced for the same main beam dynamic performance. If the beams are to be installed under the bridge deck in a practical application this is a crucial issue in order to minimise the free space occupied with the retrofit. Fig. 7b is similar to Fig. 7a but in this case the natural frequency of the secondary beam without restraining the ends rotations is higher ($\eta_{ss,B}=1.6$).

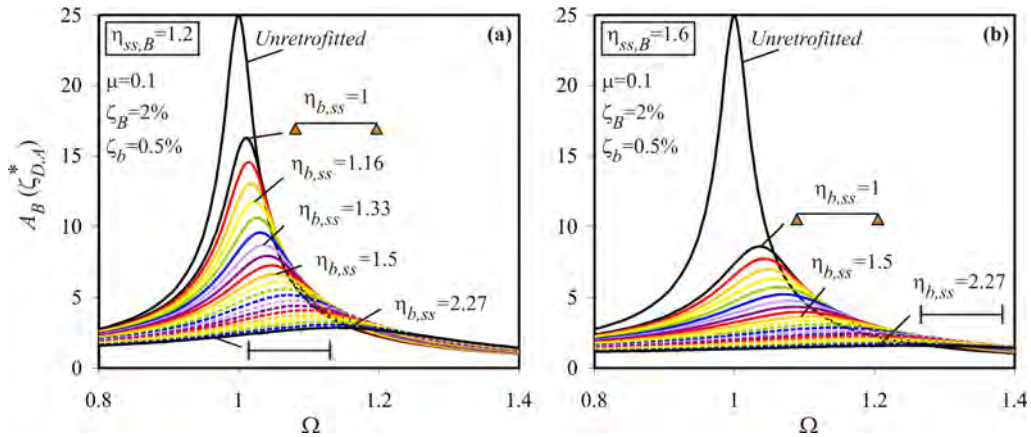

Figure 7: Main beam amplification A_B associated to the optimal damping ratio versus Ω for different clamping states of the auxiliary beam.

In order to visualize how the main beam response at resonance evolves with a particular auxiliary beam, always combined with the optimal equivalent damper, as the end rotational stiffness increases for different values of $\eta_{ss,B}$ the ratio R_{max} is defined measuring the reduction of the main beam maximum response achieved with the retrofit when compared to the unretrofitted case:

$$R_{max} (\%) = \frac{A_{B,unret}^{max} - A_B^{max}(\zeta_D = \zeta_{D,A}^*)}{A_{B,unret}^{max}} \cdot 100 \quad (38)$$

where $A_{B,unret}^{max}$ is the amplification of the main beam at resonance in the unretrofitted case and $A_B^{max}(\zeta_D = \zeta_{D,A}^*)$ is the amplification of the main beam retrofitted with a particular auxiliary

beam in the optimal case. In other words, $A_B^{\max}(\zeta_D = \zeta_{D,A}^*)$ is the minimum response of the main beam at resonance that can be obtained with a particular auxiliary beam. This variable is calculated fixing the value of $\eta_{ss,B}$, i.e. for a particular auxiliary beam with a particular natural frequency and lineal mass and recalculated as the rotational restriction at the beam ends increases towards the fully clamped case. Therefore only the degree of clamping of the auxiliary beam is modified. In Fig. 8, plots (a), (b), (c) and (d) correspond to values of $\eta_{ss,B}$ {1, 1.2, 1.4, 1.6} and in each graph each curve has been calculated with a different level of the main beam structural damping.

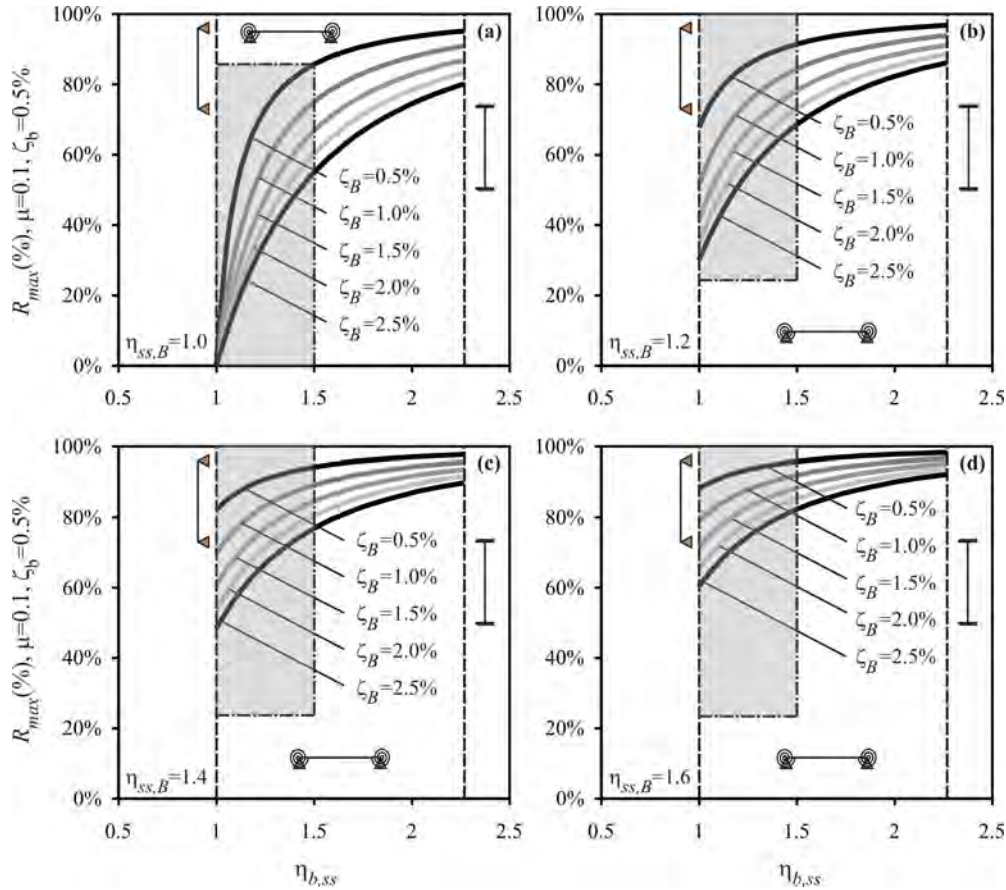

Figure 8: Maximum reduction with respect to the unretrofitted case vs. auxiliary beam frequency increase $\eta_{b,ss}$ due to supports rotational restriction.

In graph (a) $\eta_{ss,B}=1$, therefore prior to starting to clamp the secondary beam both beams have the same natural frequency. Due to this fact the retrofitting system efficiency is practically inexistent (see Fig. 5c) and the reduction of the main beam response is almost null. That is why for $\eta_{b,ss}=1$ (auxiliary beam simply-supported) all the curves tend to $R_{\max}=0$. As the rotational restriction at the ends increases and therefore $\eta_{b,ss}$ raises from 1 towards 2.267 (perfectly clamped case) the reduction of the main beam maximum response with respect to the unretrofitted situation drastically increases, especially for low levels of structural damping of the super-structure. In fact if $\zeta_B=0.5\%$ R_{\max} increases from zero reduction in the simply-supported case to approximately 87% for $\eta_{b,ss}=1.5$, that is, when the natural frequency of the auxiliary beam is increased 1.5 times its initial value thanks to restraining the end rotations. In the remaining three cases a similar tendency is observed although the results are less impressive as the retrofitting system effect on the main beam is already better in the simply-

supported case.

5 INTRODUCTION OF RAILWAY TRAFFIC EXCITATION

In the present section the effectiveness of the proposed solution and the adequacy of expressions (35) which provide the optimal dampers for a particular auxiliary beam are evaluated under railway traffic. To this end the dynamic performance of a single track bridge retrofitted with the partially clamped auxiliary beam system is investigated under the circulation of trains of moving loads which excite resonance situations in the superstructure.

In what follows the dynamic performance of a 15 m bridge is investigated using a planar FE model as the one shown in Fig. 2. The upper beam, which represents the deck, has a fundamental frequency $f_{B1}=8.92$ Hz and a linear mass $m_B=10000$ kg/m. The auxiliary beam is considered a steel element with a hollow rectangular cross-section, having $L_B=L_b=L$ and $E_b=2.1 \cdot 10^{11}$ N/m². The external dimensions of the auxiliary beam are $b \times h$ (width \times height) and its constant thickness is e . Thus, the second moment of area is $I=(bh^3-(b-2e)(h-2e)^3)/12$. The mass per unit length is $m_b=\rho_b(bh-(b-2e)(h-2e))$, where $\rho_b=7850$ kg/m³ is the mass density of steel. Respectively, linear and quadratic variations of b and e in terms of h are adopted

$$b(h) = a \times h \quad \text{for } a = 0.6 \quad (39)$$

$$e(h) = e_0 + e_1 \times h + e_2 \times h^2 \quad \text{for } e_0 = 2.14 \times 10^{-2} \text{ m}, e_1 = 7.86 \times 10^{-3}, e_2 = 1.07 \times 10^{-2} \text{ m}^{-1} \quad (40)$$

The dynamic response of the bridge retrofitted with a particular auxiliary beam with $h=0.80$ m is evaluated under the circulation of the eighth train of the High Speed Load Model –A (HSLM-A8) defined in Eurocode [35] using a moving load model. The degree of partial restriction of the auxiliary beam end section rotations is considered to be such that the fundamental frequency of the element is increased 1.5 times with respect to the simply-supported case. This corresponds to a rotational stiffness of $K=4.5 \cdot 10^8$ Nm leading to a fundamental frequency of the auxiliary beam $f_{b1}=15.87$ Hz. Three dampers are introduced linking the vertical motion of corresponding sections of the main and auxiliary beams. The response of the system is computed by Modal Superposition of the first three modes of the bridge and the first three modes of the auxiliary beam. Structural damping ratios of $\zeta_{Bi}=1.35\%$ and $\zeta_{bi}=0.5\%$ for $i=1,2,3$ are assumed for each element.

In first place the adequacy of the expressions derived in the harmonic case for the external optimal damping ratios (35) is evaluated. To this end the maximum vertical acceleration at the mid-span section of the bridge is calculated under the HSLM-A8 train for circulating velocities in the range [40, 125] m/s in steps of 0.5 m/s ([144, 450] km/h in steps of 1.8 km/h). The maximum response of the bridge retrofitted with the previously described beam is computed for several values of the dampers constants and plotted in terms of accelerations in Fig. 9. The bridge in the bare case ($\zeta_D=0\%$) experiments a second and a third resonance of its fundamental mode at the theoretical velocities

$$V_{m=1, n=2}^{RES} = \frac{d_k \cdot f_{B1}}{n} \cdot 3.6 = \frac{18 \cdot 8.92}{2} \cdot 3.6 = 401.4 \text{ km/h} \quad (41)$$

$$V_{m=1, n=3}^{RES} = \frac{d_k \cdot f_{B1}}{n} \cdot 3.6 = \frac{18 \cdot 8.92}{3} \cdot 3.6 = 267.6 \text{ km/h} \quad (42)$$

being $d_k=18$ m the characteristic distance (or distance causing resonance) of train HSLM-A8, m the mode number, n the resonance order (or number of oscillations completed by the upper beam between the passage of repetitive groups of axle loads separated d_k). The response of the bridge has been recalculated for increasing values of the external damping ratio and,

therefore, of the individual dampers constants. If the three dampers are located at $0.25L$, $0.5L$ and $0.75L$ the relation between the constants and ζ_D is given by

$$C_{Di} = \frac{1}{2} m_B L_B \omega_{B1} \zeta_D \quad \text{for } i = 1, 2, 3 \quad (43)$$

being ω_{B1} the circular frequency of the bridge fundamental mode. As ζ_D increases the bridge response decreases, especially at resonance, and the resonant or critical velocity slightly shifts towards higher values. This kind of behaviour was already detected in the harmonic case (see Fig. 5a). When ζ_D reaches certain value the amplification at resonance starts to increase again. The theoretical optimal external damping ratio associated to the minimum acceleration at resonance has been calculated applying equation (35b) for $\eta=1.779$ and $\mu=0.066$ (frequency and mass ratio for the particular case $h=0.80$ m and $K=4.5 \cdot 10^8$ Nm) providing a value of $\zeta_{D,a}^* = 6.1\%$. In Fig. 9 the maximum acceleration of the bridge has been represented for this particular retrofitting level in red trace.

Figure 9: Maximum acceleration at bridge mid-span vs. velocity of train HSLM-A8 for different values of ζ_D .

As it can be observed equation (35b) provides a good estimate of the dampers constants real optima under the circulation of moving loads, accounting for the contribution of three modes of each beam and considering structural damping. Regarding the difference between optimal damping ratios $\zeta_{D,A}^*$ and acceleration $\zeta_{D,a}^*$ provided by equations (35a) and (35b) respectively, the former provides better estimates for the optimal dampers minimising the bridge response in terms of displacements and the latter does the same in terms of accelerations. Nevertheless the difference between both values is very small. Finally, the real value of the optimal external damping, $\zeta_{D,a}^{*real}$, has been obtained numerically as the one minimising the acceleration at the second resonance of the bridge fundamental mode being as $\zeta_{D,a}^{*real} = 5.5\%$. The bridge acceleration at mid-span for the real optimal dampers has been represented as well in green trace in Fig. 9. Even though there is a difference of 0.6% between the real and the theoretical optimal damping the difference in the bridge response is practically negligible as it can be seen when comparing the red and green curves in Fig. 9. In particular the maximum response of the bridge at the second resonance when retrofitted with the theoretical optimal dampers $a_{B,max}(\zeta_{D,a}^* = 6.1\%) = 6.809 \text{ m/s}^2$ and when retrofitted with the real optimal dampers $a_{B,max}(\zeta_{D,a}^{*real} = 5.5\%) = 6.801 \text{ m/s}^2$.

Finally, the possibility of retrofitting the 15 m bridge so that the structure accomplishes the Serviceability Limit State of vertical acceleration (3.5 m/s^2 for ballasted tracks) is envisaged. To this end two possibilities are considered and compared: (i) connecting to the bridge deck to

a simply-supported auxiliary beam with its corresponding optimal dampers located at $0.25 L$, $0.5 L$ and $0.75 L$, and (ii) installing a partially clamped auxiliary beam with the same configuration of dampers. The aim of this analysis is to determine what would be the minimum size of the auxiliary beam needed to reduce the maximum acceleration of the bridge below 3.5 m/s^2 in each case. In the unretrofitted case the maximum acceleration of the bridge under the circulation of the HSLM-A8 train in the range of velocities $[144, 450] \text{ km/h}$ reaches 18.4 m/s^2 . The steel box section beam previously described is considered for the retrofit. Beam section heights starting from 1.0 m and increasing in 10 cm increments are first considered in the simply-supported case. For each beam, nondimensional parameters μ and η are calculated and the theoretical optimal damping ratio $\zeta_{D,a}^*$ is obtained as per Eq. (35b). From this value the dampers constants are determined and the bridge dynamic response after the retrofit is computed. In Table 1 a summary of the retrofitting system parameters along with the maximum response of the bridge that takes place for each particular retrofit has been included.

$h \text{ (m)}$	BC	$K \text{ (Nm)}$	$f_{b1} \text{ (Hz)}$	η	μ	$\zeta_{D,a}^* \text{ (\%)}$	$a_{B,max} \text{ (m/s}^2\text{)}$

Table 1: Retrofit parameters.

In Table 1 BC, SS and EC stand for *Boundary Conditions*, *Simply-Supported* and *Elastically-Clamped*, respectively.

In Fig. (10a) the maximum acceleration of the bridge at mid-span for a simply-supported auxiliary beam of section heights varying from 1.0 m to 1.3 m has been represented.

It is important to stress that each auxiliary beam is combined with the dampers that lead to the super-structure minimum response, that is, with the optimal dampers. As it is shown a minimum height of 1.3 m is needed for the maximum acceleration to reduce until the limit 3.5 m/s^2 if the beam is simply-supported. The same calculations are repeated considering that the beam is partially clamped. The rotational stiffness is supposed to be the same at both ends and such that the fundamental frequency of the auxiliary beam increases 1.5 times its corresponding value in the simply-supported case. In Fig. (10b) the maximum acceleration of the bridge is plotted for each particular beam size in the elastically-clamped case. The response of the bridge drastically reduces for a particular retrofit if the auxiliary beam ends rotations are restrained. It can be observed that if the beam is partially clamped a beam with a section height of 1 m would be sufficient for the bridge to accomplish the Serviceability State of vertical acceleration, while in the simply-supported case a 1.3 m beam was needed.

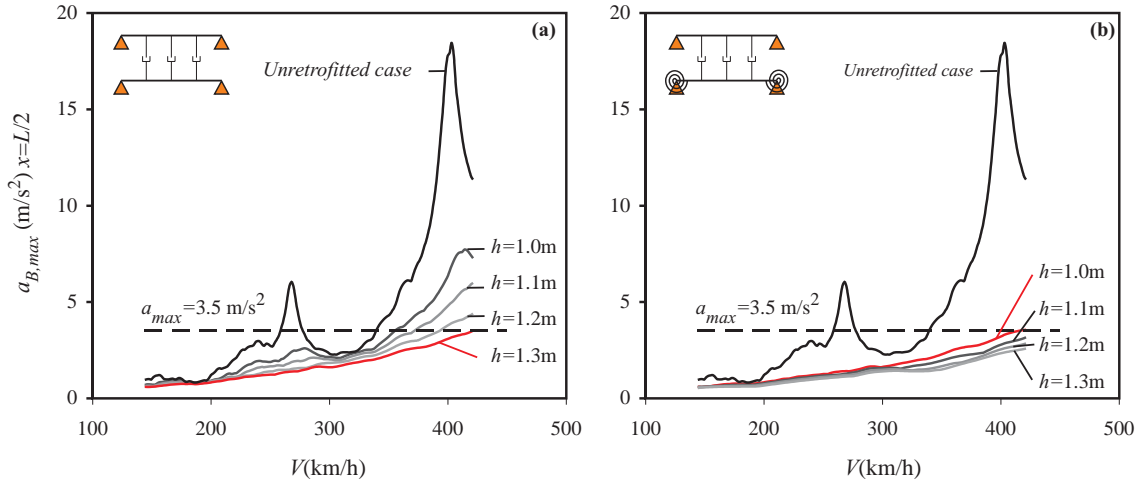

Figure 10: Maximum acceleration at bridge mid-span vs. velocity of train HSLM-A8 for different auxiliary beam sizes in the (a) simply-supported and (b) elastically clamped cases.

6 CONCLUSIONS

The dynamic performance of simply supported beams retrofitted with FVDs and subjected to moving loads has been evaluated. The main beam, which supports the passage of the loads, is connected to an auxiliary beam placed parallel to the former through a set of dampers linking the vertical motion of corresponding sections of the elements. The auxiliary beam is considered to be partially clamped at both ends. From the results obtained herein, the following conclusions can be derived:

- (i) The resonant vibrations that may appear in simply supported beams when subjected to moving loads can be drastically reduced with the damping system proposed herein.
- (ii) For a particular auxiliary beam, there exists an optimum value of the FVD constants that minimise the main beam response.
- (iii) The main beam response monotonically reduces with the auxiliary beam mass and natural frequency, but, in order for the dampers to effectively dissipate energy, the auxiliary beam fundamental frequency must exceed the main beam modal frequency which contribution is to be reduced.
- (iv) The design strategy should be to select the smallest auxiliary beam such that when associated with its corresponding optimal FVDs leads to the desired system performance.
- (v) Partially restraining the rotation of the auxiliary beam supports leads to an important reduction of the main beam response at resonance when compared to the simply-supported case. This permits to reduce the size of these elements which are to be installed underneath the deck in general applications.
- (vi) Analytical expressions for the optimal damper constants are provided which provide very accurate results as long as the maximum response of the main beam in the range of evaluated velocities occurs at resonance.

- (vii) With the system proposed in this article the FVDs need not interact with the upper side of the bridge. This allows existing railway bridges to be retrofitted while keeping the line in operation.
- (viii) The damping system and optimal damper expressions presented here may apply to other situations where simply supported beams vibrate at resonance due to different causes.

Keywords: Railway induced vibration, Empirical predictions; Dynamic soil–structure interaction

Abstract. *Ground borne vibration in buildings due to railway traffic is a major concern in densely built up areas. In practice, railway induced vibration is often predicted by means of empirical methods such as the Detailed Vibration Assessment developed by the U.S. Federal Railroad Administration (FRA). The vibration velocity level in a building is predicted based on a separate characterization of the source, the wave propagation and the receiver. They are characterized by a force density, a line transfer mobility and a coupling loss factor, respectively. While the line transfer mobility is determined directly with in situ measurements of transfer functions, the force density and the coupling loss factor are obtained indirectly. In this paper, a numerical model is used to simulate the experimental FRA procedure. The influence of the soil properties on the coupling loss factor is investigated by computing the coupling loss factor on three sites with different soil conditions. Each coupling loss factor is used to predict the vibration velocity level and the result is compared to a numerical prediction such that the accuracy of the procedure can be investigated. It turns out that the soil has a large influence on the coupling loss factor, as the reduction of the vibration velocity level between the free field and the foundation is affected by the relative stiffness of the building and the soil. Furthermore, the coupling loss factor strongly depends on the position of the point where it has been measured.*

1 Introduction

Ground borne vibration in buildings due to railway traffic is a major concern in densely built up areas. At low frequencies (1–80 Hz), vibration in buildings is perceived by the occupants as mechanical vibration, whereas at higher frequencies (16–250 Hz), it is perceived as re-radiated noise. An accurate prediction of this vibration is required so that effective mitigation measures can be taken.

The numerical modeling of vibration in building is a problem of dynamic soil–structure interaction. Generally, the coupling between the source and the receiver can be neglected such that a prediction in two steps is possible. First, the dynamic load is determined at the source and the vibration in the free field is computed. Second, the free field vibration is imposed as the incident wave field and the building response is computed. Several numerical models have been developed for the prediction of free field vibration due to railway traffic at grade [1, 2] at the source side and the building response at the receiver side. The validation of these models show that a good knowledge of all relevant input parameters is necessary to obtain reliable predictions. In practice, empirical predictions where these parameters are inherently taken into account are therefore often used. The Federal Railroad Administration (FRA) and the Federal Transit Administration (FTA) of the U.S. Department of Transportation have developed a set of empirical procedure to predict vibration levels due to railway traffic [3, 4]. Three different levels of assessment are described: the Screening procedure, the Generalized Vibration Assessment and the Detailed Vibration Assessment. The first two levels are used for general screening purposes. The third level is based on a prediction technique developed by Bovey [5] and Nelson and Saurenman [6] and presents a more elaborate method based on field measurements.

The Detailed Vibration Assessment predicts the vibration velocity level L_v [dB ref 10^{-8} m/s] (root mean square in one-third octave bands) with the following equation:

$$L_v = L_F + TM_L + C_{\text{build}} \quad (1)$$

The first term in equation (1) is the force density L_F [dB ref $1 \text{ N}/\sqrt{\text{m}}$] and is a measure for the power per unit length radiated by the source. The second term is the line transfer mobility TM_L [dB ref $10^{-8} \frac{\text{m/s}}{\text{N}/\sqrt{\text{m}}}$] and is a measure for the vibration energy that is transmitted through the soil relative to the power per unit length radiated by the source. The third term is the coupling loss factor C_{build} [dB] and is a measure for the modification of vibration spectrum due to the dynamic interaction between the foundation and the soil. Each term in equation (1) is determined experimentally.

The line transfer mobility TM_L is determined with an experimental measurement of transfer functions between the track and the free field (Figure 1). The point transfer mobility TM_{P_k} [dB ref $10^{-8} \frac{\text{m/s}}{\text{N}}$] is measured as the transfer function between the applied force in a single impact point k and the velocity in the free field. The line transfer mobility TM_L is obtained as the superposition of different point transfer mobilities, determined along the track alignment:

$$TM_L = 10 \log_{10} \left(L_a \sum_{k=1}^n 10^{\frac{TM_{P_k}}{10}} \right) \quad (2)$$

where L_a is the distance between the impact points and n is the total number of impact points.

The force density L_F is determined indirectly based on equation (1). The vibration velocity level during a train passage is measured in the free field (without the presence of a building). The line transfer mobility TM_L is determined experimentally and is subtracted from the free

Figure 1: The experimental setup for the determination of the line transfer mobility TM_L .

field vibration velocity level, resulting in a normalized force density L_F of the train passage. The force density is not only determined, however, by the dynamic characteristics of the train and the track, but also depends on the subsoil conditions.

The coupling loss factor C_{build} is determined indirectly as the relation between the vibration velocity level in the free field and the vibration velocity level at the foundation of a building. The coupling loss factor depends on the building and foundation type, but also on the subsoil conditions. In the FRA manual, a frequency dependent coupling loss factor is proposed for several building and foundation types.

In a prediction with the FRA procedure, each term in equation (1) is determined experimentally. When a new building is constructed in the neighborhood of an existing track, the vibration velocity level in the building is predicted as follows. The force density L_F and the line transfer mobility TM_L are measured on site. The advantage is that the source and the local transfer of vibration are correctly accounted for. The coupling loss factor C_{build} cannot be determined on site, however, as no building is present yet. It can be obtained from a database that contains previous measurements of the coupling loss factor of several building types. Examples of coupling loss factors are also given in de FRA manual [3]. The coupling loss factor is not only determined by the building or foundation type but also by the subsoil conditions, however. It is therefore important that the conditions of the soil are similar at the site where the coupling loss factor has been determined and at the site where it will be applied.

When a prediction is needed on a site with an existing building and a new track, the line transfer mobility TM_L and the coupling loss factor C_{build} are determined on site, whereas the force density L_F has to be determined at another site with similar conditions for the train, the track and the soil.

In the present paper, the influence of the soil characteristics on the coupling loss factor is investigated by numerical simulations to assess possible inaccuracies in the prediction due to a mismatch in the soil conditions. The influence of the soil conditions on the force density has been investigated previously [7]. In section 2, the numerical model is introduced. The vibration velocity level in the free field and in the building is computed numerically on three different soils in section 4 and section 5. In section 6, the coupling loss factor at each soil type is obtained from these results. Finally, in section 7, a prediction of the vibration velocity level in the building is made by combining the computed coupling loss factors for each soil type with the free field vibration velocity level at another site. The predictions are compared to the exact solution and the accuracy of the FRA procedure is evaluated.

2 Numerical model

A numerical model is used to compute the vibration velocity in a building due to a train passage on a railway track. The source and receiver are considered to be weakly coupled such that a prediction in two steps is possible. First, the vibration velocity in the free field due to moving loads is computed. Therefore, the axle loads of the moving train and the transfer functions from the track to the free field need to be determined. Second, the response of the building is computed based on the incident wavefield.

2.1 Source model

Figure 2 shows the coupled track–soil domain Ω of the source system, which is subdivided into the soil subdomain Ω_s and the track subdomain Ω_b , connected at the interface Σ_{bs} . Traction $\bar{\mathbf{t}}_b$ are imposed at the boundary $\Gamma_{b\sigma}$. In case of a train passage, these tractions represent the axle loads.

Figure 2: The geometry of the coupled track–soil system.

The vibration velocity $\mathbf{v}(\mathbf{x}', t)$ at a point \mathbf{x}' in the free field due to k moving axle loads $\mathbf{g}_k(t)$ is calculated with the following convolution integral [1, 8]:

$$\mathbf{v}(\mathbf{x}', t) = \sum_{k=1}^{n_a} \int_{-\infty}^t \mathbf{H}^T(\mathbf{x}_k(\tau), \mathbf{x}', t - \tau) \mathbf{g}_k(\tau) d\tau \quad (3)$$

Each element $h_{ij}(\mathbf{x}', \mathbf{x}, t)$ of the matrix $\mathbf{H}(\mathbf{x}', \mathbf{x}, t)$ represents the velocity at a point \mathbf{x} in the direction \mathbf{e}_j at time t due to an impulsive load at a point \mathbf{x}' in the direction \mathbf{e}_i at time $t = 0$. In equation (3), dynamic reciprocity is used to replace the matrix $\mathbf{H}(\mathbf{x}', \mathbf{x}, t)$ by $\mathbf{H}^T(\mathbf{x}, \mathbf{x}', t)$.

In the following, a longitudinal invariant track and a horizontally layered soil are assumed such that the geometry of the domain Ω is invariant in the longitudinal direction \mathbf{e}_y . In this case, the transfer function is unaffected by an arbitrary translation $l\mathbf{e}_y$ of the source and the receiver position. If l equals $y_{k0} + v\tau$, the source position $\mathbf{x}_k(\tau) - l\mathbf{e}_y = \{x_{k0}, 0, z_{k0}\}^T$ no longer depends on the time τ and can be omitted in the argument of the transfer function. Furthermore, the coordinates x' and z' of the receiver position $\mathbf{x}' = \{x', y', z'\}^T$ are assumed to

For any virtual displacement field $\hat{\mathbf{v}}_b$ imposed on the structure Ω_b , the sum of the virtual work of the internal and the inertial forces is equal to the virtual work of the external loads:

$$\begin{aligned} -\omega^2 \int_{\Omega_b} \hat{\mathbf{v}}_b \cdot \rho_b \hat{\mathbf{u}}_b d\Omega + \int_{\Omega_b} \hat{\mathbf{e}}_b(\hat{\mathbf{v}}_b) : \hat{\boldsymbol{\sigma}}_b(\hat{\mathbf{u}}_b) d\Omega \\ = \int_{\Omega_b} \hat{\mathbf{v}}_b \cdot \rho_b \hat{\mathbf{b}} d\Omega + \int_{\Gamma_{b\sigma}} \hat{\mathbf{v}}_b \cdot \hat{\mathbf{t}}_b^{\mathbf{n}_b} d\Gamma + \int_{\Sigma_{bs}} \hat{\mathbf{v}}_b \cdot \hat{\mathbf{t}}_b^{\mathbf{n}_b}(\hat{\mathbf{u}}_b) d\Gamma \end{aligned} \quad (6)$$

where $\hat{\mathbf{u}}_b$ is the displacement vector in the structure, $\rho_b \hat{\mathbf{b}}$ denotes the body force in the domain Ω_b , and $\hat{\mathbf{t}}_b^{\mathbf{n}_b} = \hat{\boldsymbol{\sigma}}_b \cdot \mathbf{n}_b$ is the traction vector on a boundary with unit outward normal vector \mathbf{n}_b . Tractions $\hat{\mathbf{t}}_b^{\mathbf{n}_b}$ are imposed on the boundary $\Gamma_{b\sigma}$.

When equation (6) is discretized by means of 3D finite elements and the equilibrium of stresses on the interface Σ_{bs} is accounted for, the following expression is obtained [9]:

$$\left(\mathbf{K}_{bb} - \omega^2 \mathbf{M}_{bb} + \hat{\mathbf{K}}_{bb}^s(\omega) \right) \hat{\mathbf{u}}_b = \hat{\mathbf{f}}_b(\omega) + \hat{\mathbf{f}}_b^s(\omega) \quad (7)$$

where \mathbf{K}_{bb} and \mathbf{M}_{bb} are the finite element stiffness and mass matrix, $\hat{\mathbf{K}}_{bb}^s(\omega)$ is the dynamic soil stiffness matrix, $\hat{\mathbf{f}}_b(\omega)$ is the external load vector and $\hat{\mathbf{f}}_b^s(\omega)$ is the force vector due to the incident wavefield. The dynamic soil stiffness matrix $\hat{\mathbf{K}}_{bb}^s(\omega)$ and the force vector $\hat{\mathbf{f}}_b^s(\omega)$ account for the interaction with the soil and for the incident wavefield, respectively, and are computed by means of the boundary element method.

3 Case

In the following sections, the vibration velocity level in the free field and in a building due to a train passage is computed by means of the numerical models introduced in section 2. The coupling loss factor can be determined numerically from these results. By considering different soil types, the influence of a mismatch in the soil conditions on the coupling loss factor and the resulting prediction is investigated. In this section, the characteristics of the train, track, soil and building are discussed.

In the present case, a classical ballasted track [1] is considered with UIC 60 rails supported every 0.60 m by rubber pads on monoblock concrete sleepers. The rails are continuously welded and are fixed with a Pandrol E2039 rail fastening system and supported by resilient studded rubber rail pads (type 5197) with a thickness of 11 mm. Each rail pad is preloaded with a clip toe load of about 20 kN per rail seat. The prestressed concrete monoblock sleepers have a length $l_{sl} = 2.50$ m, a width $b_{sl} = 0.235$ m, a height $h_{sl} = 0.205$ m and a mass $m_{sl} = 300$ kg. The track is supported by a porphyry ballast layer (calibre 25/50, thickness $d = 0.35$ m) and a limestone sub-ballast layer (thickness $d = 0.60$ m). The density of these ballast layers is 1700 kg/m^3 .

The track is modeled as a longitudinally invariant track [1] by means of the 2.5D finite element method, where the dynamics of the rail pads and the mass of the sleepers are uniformly distributed along the track. It has been shown that continuously and discretely supported tracks have similar dynamic behaviour up to about 500 Hz [10]. The rails are modeled as Euler–Bernoulli beams and the rail pads are modeled as continuous spring–damper connections. The sleepers are assumed to be rigid in the plane of the cross section and are modeled as a uniformly distributed mass along the track. The ballast bed is modeled as a set of distributed, independent linear springs and dampers. Figure 4 shows the cross section of the ballasted track model.

The track is supported by a homogeneous halfspace. In order to investigate the influence of the soil properties on the prediction of the vibration velocity level, three sites are considered

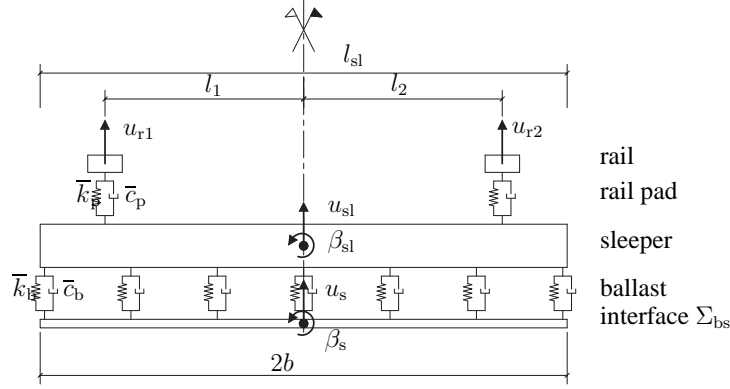

Figure 4: Cross section of a ballasted track model.

with different soil characteristics representing a soft, medium and stiff soil. The dynamic soil characteristics are summarized in Table 1.

Table 1: Dynamic soil characteristics.

Type	C_s [m/s]	C_p [m/s]	ν [-]	ρ [kg/m ³]	β [-]
Soft	100	200	0.33	1800	0.025
Medium	150	300	0.33	1800	0.025
Stiff	300	600	0.33	1800	0.025

The Thalys HST consists of two locomotives and eight carriages and has a total of 26 axles [8]. Each axle has an unsprung mass $M_u = 2027$ kg. The length l of the train equals 200.18 m. The train is modeled as a series of individual axles, as the coupling between different axles through the vehicle can be neglected. The mechanical model of the train therefore only takes into account the unsprung mass M_u of each axle.

At 30 m from the track, a masonry building with dimensions 12 m \times 6 m \times 6 m is assumed to be present (figure 5a) [11]. The structure has two stories, each subdivided into 4 rooms. The interior and exterior walls have a thickness $t_w = 0.10$ m, and consist of clay brick masonry. The floors are concrete slabs with a thickness $t_f = 0.20$ m. All floors are simply supported, corresponding to hinged joints at the slab edges. The structure is founded on a concrete strip foundation with a width $w_{fou} = 0.60$ m and a thickness $t_{fou} = 0.20$ m. Figure 5b shows the foundation of the building and indicates the location of points A, B, C and D where the response in the free field and in the building will be computed.

The building is modeled with the finite element method. The strip foundation, the walls and the floors are modeled by means of shell elements, using isotropic properties for the foundation and the floors and orthotropic properties for the masonry walls [11]. The lintels above the door and the windows are modeled by means of beam elements.

4 Vibration velocity level in the free field

In this section, the free field response due to the passage of the Thalys HST on the track at a speed of 150 km/h is computed with the source model described in section 2.1. Figure 6 shows the computed time history and the frequency content of the free field vibration velocity in point A due to the passage of the Thalys HST at a speed $v = 150$ km/h on a site with medium soil.

Figure 5: (a) Geometry and location of the building and (b) foundation of the building and location of the measurement points.

The duration of the passage is about 4.8 s which is approximately equal to the length l of the train divided by the train speed v . The time history can be divided in three parts: an increasing vibration level when the train approaches, a nearly stationary part when the train passes and a decreasing vibration level when the train moves away. The stationary part of the response is selected by means of the DIN selection procedure [12] based on the time T_2 and is indicated in black in Figure 6a. The vibration velocity level L_v is then defined as the one-third octave band RMS spectrum of the stationary part of the vibration velocity.

Figure 6: (a) Time history and (b) frequency content of the vertical velocity at 30 m from the track in the free field due to the passage of a Thalys HST at a speed of 150 km/h on a site with medium soil (stationary part of the time history is indicated in black).

Figure 7 shows the vibration velocity level L_v at the three different sites in the free field in the points corresponding to point A and point B (Figure 5b). In the response on the stiff soil, a peak around 63 Hz is found. This is due to the resonance of unsprung mass of the wheelsets on the track. In the low frequency range, the highest response is obtained for the soft soil. The response is increasingly attenuated, however, not only at larger distances from the track but also with increasing frequency. As this attenuation is stronger for softer soils, the peak at 63 Hz is

no longer observed in the response on the soft and the medium soil and the highest response in the high frequency range is obtained for the stiff soil.

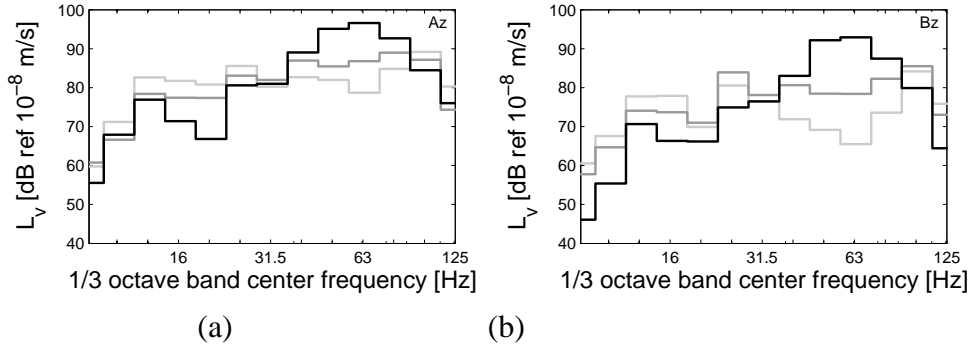

Figure 7: Free field vibration velocity level at (a) 30 m and (b) 42 m on a soft (light grey line), medium (dark grey line) and stiff (black line) soil.

5 Vibration velocity level in a building

In this section, the response of the building to the passage of the Thalys train on the track is computed with the receiver model described in section 2.2. In Figure 8, the vibration velocity levels at the foundation of the building determined on three different soils are compared. The response is shown at the front side (point A) and at the back side (point B) of the building (Figure 5b), corresponding to the points where the free field response is shown in Figure 7. At low frequencies the highest response is obtained for the soft and the medium soil, whereas at higher frequencies the highest response is obtained for the stiff soil, corresponding to the observation of the vibration velocity level in the same points in the free field. It can be observed, however, that the response at the foundation differs from the response in the free field due to the dynamic soil–structure interaction. This modification is described by the coupling loss factor, discussed in the next section.

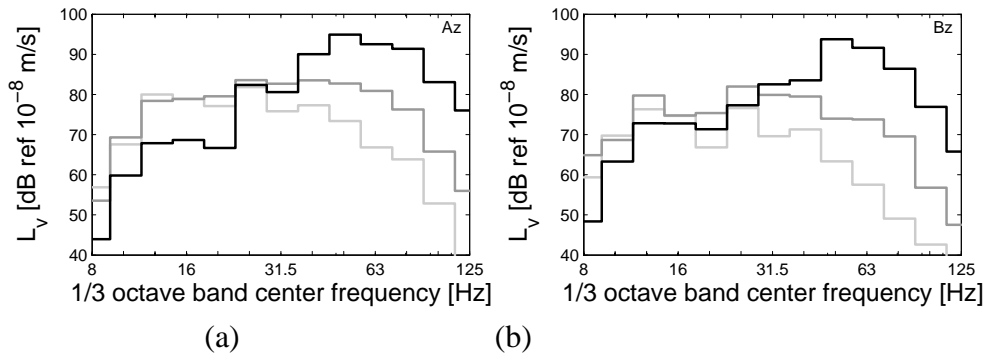

Figure 8: Vibration velocity level of the foundation in (a) point A and (b) point B on a soft (light grey line), medium (dark grey line) and stiff (black line) soil.

6 Coupling loss factor

The coupling loss factor C_{build} is determined by subtracting the vibration velocity level $L_F + \text{TM}_L$ in the free field from the vibration velocity level L_v at the foundation of the building:

$$C_{\text{build}} = L_v - (L_F + \text{TM}_L) \quad (8)$$

Figure 9 shows the coupling loss factors in point A and point B, determined at the three different soil types. These values are compared to coupling loss factor proposed in the FRA manual for a 2 to 4 story masonry building. A negative value of the coupling loss factor C_{build} implies a reduction of the vibration velocity level from the free field to the foundation, while a positive value means an increase of the vibration velocity level.

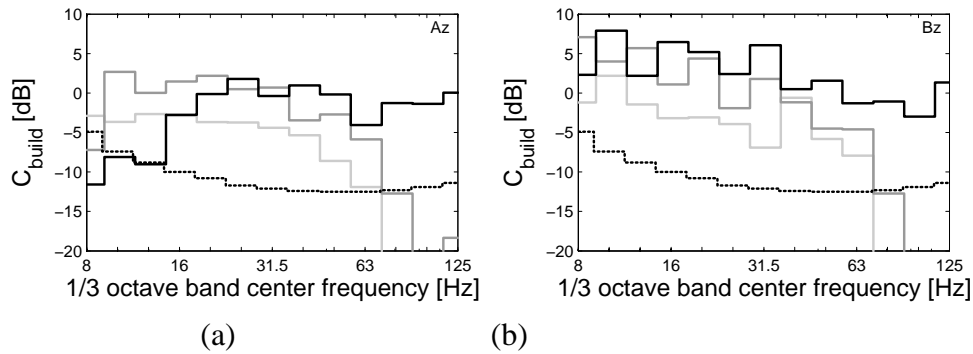

Figure 9: Coupling loss factor C_{build} in (a) point A and (b) point B on a soft (light grey line), medium (dark grey line) and stiff (black line) soil compared to the curve proposed in the FRA manual for a 2 to 4 story masonry building (dotted line).

In the high frequency range, a zero value is observed for the coupling loss factor for the stiff soil. Due to the high relative stiffness of the soil, the ground vibration is imposed to the building and is transmitted almost unaffectedly to the foundation. A large reduction is observed, however, for the coupling loss factor in the case of the soft and the medium soil. Due to the lower relative stiffness, the ground vibration is transmitted at a reduced level to the foundation. The interaction between the soil and the structure is determined by the characteristic wavelength of the vibration. As the wavelength decreases with increasing frequency and for softer soils, a higher reduction is obtained at high frequencies for the soft and the medium soil.

In the low frequency range, a difference up to 15 dB is observed between the coupling loss factor at the front side (point A) and the back side (point B) of the building. This can be due to the fact that the building response at low frequencies is an average response to the incident wavefield. As the incident wavefield itself is attenuated with increasing distance from the track, a reduction is found at the front side whereas an increase is found at the back side. This effect is more pronounced for the case of the stiff soil.

From the previous discussion it can be concluded that the soil conditions significantly affect the values obtained for the coupling loss factor. Furthermore, it is observed that the computed values for the coupling loss factor overestimate the values proposed by the FRA. The coupling loss factor is also strongly dependent, however, on the location of the measurement point. Figure 10 shows the coupling loss factor determined on the three soils in point C along the edge of the building and in point D in the centre of the building (Figure 5b). The reduction in point D is generally around 10 dB higher than the reduction in point C. The foundation response in a point is affected by the kinematics of the complete building as well as by the local geometry. When torsional and rotational modes of the building are excited, the response at the centre of the foundation is lower. As the incident wavefield is similar in point C and point D, the reduction is higher in point D.

Figure 11a shows the spatial variation over the foundation of the coupling loss factor at 63 Hz, confirming that a higher reduction is obtained in the centre of the building. Furthermore, it is observed that the reduction is generally higher at the front of the building (left side) than

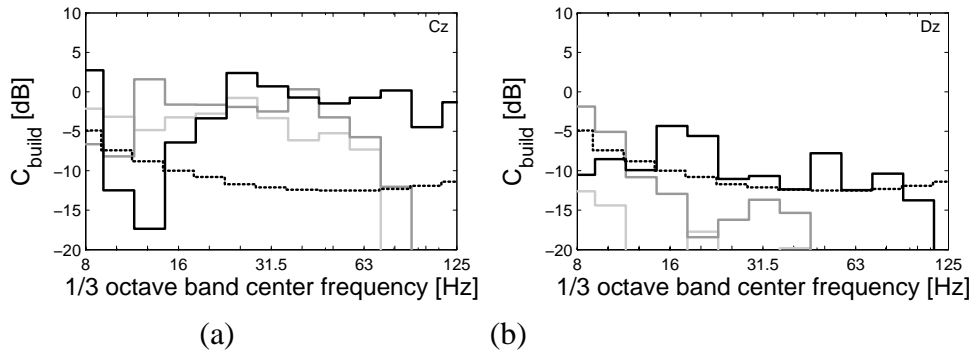

Figure 10: Coupling loss factor C_{build} in (a) point C and (b) point D on a soft (light grey line), medium (dark grey line) and stiff (black line) soil compared to the curve proposed in the FRA manual for a 2 to 4 story masonry building (dotted line).

at the back (right side). Figure 11b shows the average value of the coupling loss factor over all points in the foundation and the 90 % interval of the coupling loss factor values over the foundation. The coupling loss factor is strongly dependent on the location of the measurement point, as a large spread, up to 20 dB, can be observed. The conclusion still holds in case of the average coupling loss factor, however, that the reduction is stronger for softer soils, particularly at higher frequencies.

7 Prediction of the vibration velocity

In this section, a prediction is made for the vibration velocity level at the foundation of a building on a medium soil. In order to investigate the influence of the soil properties on the prediction accuracy, the free field vibration velocity level on a medium soil is therefore combined with the coupling loss factors obtained in section 6. As the coupling loss factor is affected by the position of the measurement point, the average value over the foundation is used. Figure 12 shows the prediction of the response in point A and point B (Figure 5b), compared to a 12 dB region around the exact solution for the medium soil. In case of a coupling loss factor determined on a medium soil, the prediction is generally within 6 dB of the exact solution. In case of a coupling loss factor determined on a soft or a stiff soil, however, the accuracy is significantly less good at higher frequencies. An overestimation of the response up to approximately 20 dB is obtained with the coupling loss factor of the stiff soil, whereas an underestimation up to approximately 15 dB is obtained with the coupling loss factor of the soft soil.

The prediction of the response in point A and B is relatively accurate with an average coupling loss factor determined on the same soil type. Due to the spatial variability, however, it can be expected that the accuracy of the prediction will be less good in other points of the building. Figure 13 shows the prediction of the response for point C and point D (Figure 5b) compared to a 12 dB region around the exact solution. The prediction of the response in point C, located at the edge of the foundation, is relatively accurate when the coupling loss factor of the medium soil is used. The prediction in point D, located in the centre of the foundation, however, is overestimating the response, even when the medium soil coupling loss factor is used.

From the previous analysis, it can be concluded that the coupling loss factor should be determined from data obtained at sites where the conditions for the building, the foundation and the subsoil are similar in order to obtain an accurate prediction. Furthermore, it can be concluded that the location of the measurement point strongly affects the coupling loss factor and

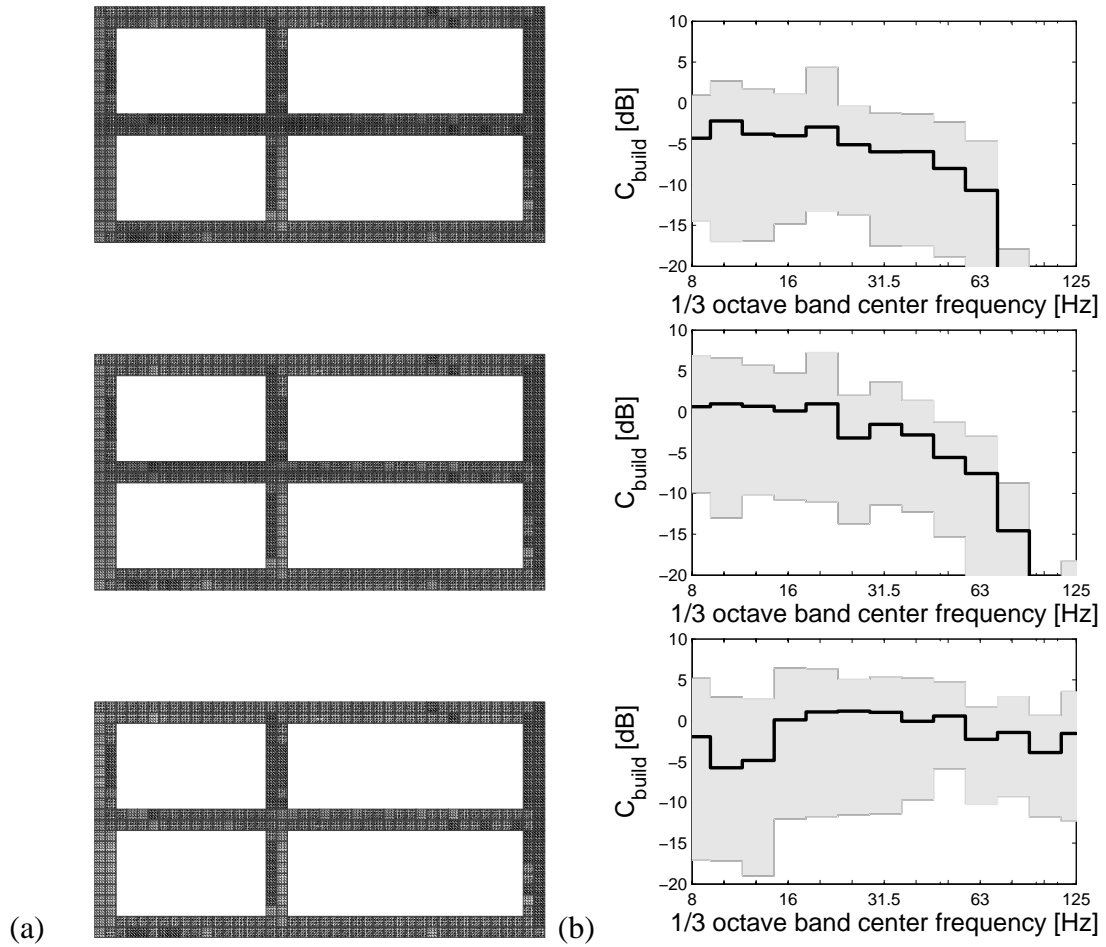

Figure 11: (a) Spatial variation at 63 Hz and (b) average value (black line) and 90 % interval (grey region) of the coupling loss factor C_{build} on a soft (top), medium (middle) and stiff (bottom) soil.

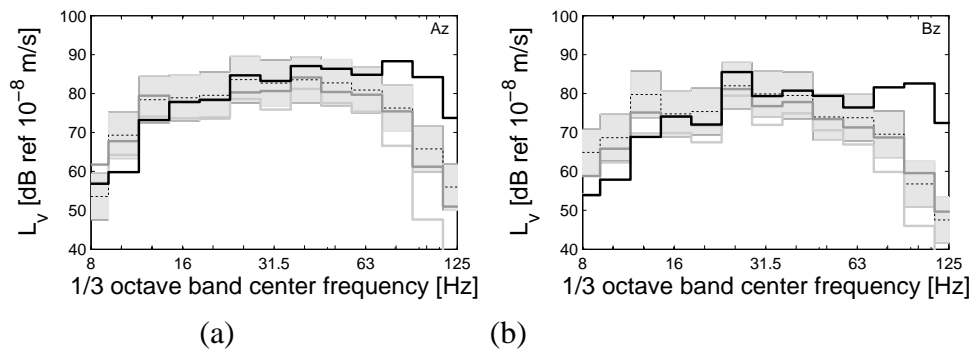

Figure 12: Predicted vibration velocity level in (a) point A and (b) point B using the average coupling loss factor determined on a soft (light grey line), medium (dark grey line) and stiff (black line) soil compared to a 12 dB region (grey region) around the exact solution (dotted black line).

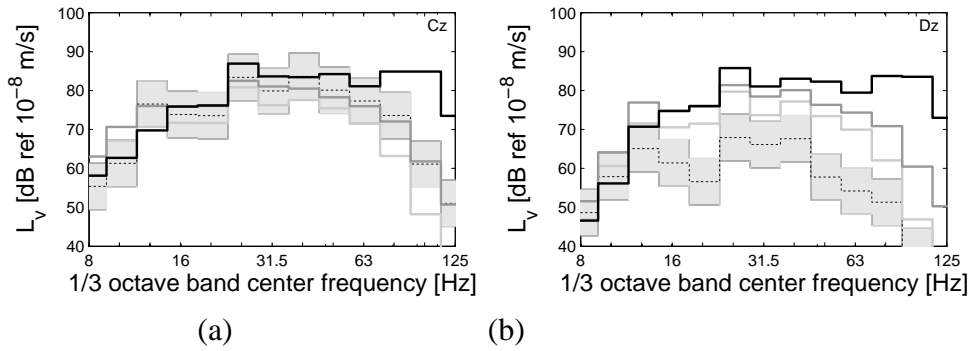

Figure 13: Predicted vibration velocity level in (a) point C and (b) point D using the average coupling loss factor determined on a soft (light grey line), medium (dark grey line) and stiff (black line) soil.

the resulting prediction of the vibration velocity level. In a prediction with the FRA procedure, an experimental value obtained from previous measurements of the coupling loss factor of a similar building type postis used. As the prediction is affected as well by parameters such as the subsoil conditions and the measurement point, however, an accurate experimental prediction is not possible in every situation. The accuracy of the prediction could be improved by providing predictions of the coupling loss factor by means of numerical simulation, as has been shown in this paper. The advantage of the numerical prediction of the coupling loss factor is the greater flexibility in dealing with different building and foundation configurations and soil properties, while the advantage of using experimental data of the source and the transfer of vibration is that the local conditions are correctly accounted for. A hybrid experimental–numerical prediction combines both advantages.

8 Conclusions

The FRA procedure is an empirical procedure for the prediction of railway induced vibration in buildings. The source, the wave propagation and the receiver are characterized experimentally by a force density, a line transfer mobility and a coupling loss factor, respectively. The line transfer mobility is determined directly based on wave propagation tests. The force density and the coupling loss factor are determined indirectly, however, and they are influenced by several parameters such as the subsoil conditions. Previously, the influence of the soil conditions and other parameters on the force density and the resulting prediction accuracy has been investigated [7]. In this paper, the influence of the soil conditions and the location of measurement points on the coupling loss factor of a specific building type has been investigated by means of a numerical simulation of the FRA procedure.

The coupling loss factor characterizes the modification of the vibration velocity level due to the dynamic soil–structure interaction at the receiver side. This effect, however, is dependent on the conditions of the subsoil. Generally, a higher reduction is obtained at a higher frequency and for softer soils. The dependency of the coupling loss factor on the soil conditions leads to an overestimation of the response in case of a coupling loss factor determined on a stiffer soil and an underestimation in case of a coupling loss factor determined on a softer soil. Furthermore, a large spatial variation is observed in the coupling loss factors determined at different points in the foundation of a building due to the kinematics of the building and local variations of the geometry.

As the coupling loss factor is influenced by several parameters such as the soil conditions and the location of the measurement point, it is important that experimental data of the coupling

loss factor is used on sites with similar conditions. An appropriate experimental coupling loss factor may not be available, making an accurate empirical prediction impossible. It has been shown in this paper that the coupling loss factor can also be predicted by means of numerical simulations and combined with an experimental prediction of the free field vibration velocity level. A hybrid experimental–numerical prediction method is then obtained that combines the advantages of both methods.

Abstract. *Different high-speed railway tracks have been analysed theoretically and experimentally, a ballasted track at a surface line, a slab track in a tunnel, and a ballasted track on a concrete bridge. Vehicle, track and ground vibration as well as their interaction are considered in a combined finite-element boundary-element (FEBEM) approach. The layered soil is calculated in frequency wavenumber domain and the solution for fixed or moving point or track loads follow as wavenumber integrals. The comparison of the dynamic compliances of the different tracks leads to an improved understanding of the different track elements. Certain maxima have been observed for certain train speeds and certain eigenmodes of the bridge. These maxima correlate with some maxima of the ground vibrations. The bridge and the ground vibrations are discussed with the axle-sequence of the train. The ground vibrations strongly depend on the regular and random inhomogeneity of the soil. The regular layering of the soil yields a cut-on and resonance phenomenon whereas the random inhomogeneity yields a scattering of the axle impulses which proved to be important for high-speed trains. All theoretical results are compared with measurements at a high-speed line.*

1 FINITE-ELEMENT BOUNDARY ELEMENT METHOD FOR THE DYNAMIC COMPLIANCE OF TRACKS ON LAYERED SOILS

A 3-dimensional track model is combined with the boundary element formulation of the soil. That means, that the Greens' functions of a homogeneous or layered soil are used to establish a fully coupling soil matrix which is added to the FEM matrix of the track.

1.1 Green's functions of the soil

The soil is a homogeneous or horizontally layered elastic half-space, which is excited at its surface by dynamic forces \mathbf{F} , and the displacements \mathbf{u} have to be calculated for surface points, too. The relation between the displacements \mathbf{u} and the force \mathbf{F} can be described in cylindrical (transversal, radial and vertical) components as

$$\begin{bmatrix} u_t \\ u_r \\ u_z \end{bmatrix} = \begin{bmatrix} f_{tt} & 0 & 0 \\ 0 & f_{rr} & f_{rz} \\ 0 & -f_{rz} & f_{zz} \end{bmatrix} \begin{bmatrix} F_t \\ F_r \\ F_z \end{bmatrix} \quad (1)$$

The four functions $f_{ij}(r, \omega)$ of distance and circular frequency can be calculated by integration in wavenumber domain [1], for example as

$$f_{zz} = \frac{1}{2\pi} \int_0^\infty H_{zz}(k) J_0(kr) k dk \quad (2)$$

for the simplest case of the vertical component. J_0 is the Bessel function of the first kind and the vertical compliance H_{zz} in wavenumber domain k can be given explicitly for the homogeneous half-space

$$H_{zz} = \frac{k_s^2 \sqrt{k_p^2 - k^2}}{iG \left[(k_s^2 - 2k^2)^2 + 4k^2 \sqrt{k_s^2 - k^2} \sqrt{k_p^2 - k^2} \right]} \quad (3)$$

with the abbreviations (v_s, v_p the shear and compressional wave velocities)

$$k_s = \omega / v_s \quad k_p = \omega / v_p \quad (4)$$

or calculated by matrix methods for a layered soil [1, 2]. Similar formulas hold for the other components and the complete set of Green's functions (1) is used in the present boundary element method of the soil.

1.2 The stiffness matrix of the discretized soil

First, the soil has to be defined by a set of m surface points with coordinates \mathbf{x}_α . A certain portion A_α of the surface area belongs to each surface point. A force \mathbf{F} at a point \mathbf{x}_α of the surface of the soil is considered. By using the Green's functions (of the preceding section), the displacements at all other points \mathbf{x}_β are calculated

$$\begin{bmatrix} u_x \\ u_y \\ u_z \end{bmatrix} = \begin{bmatrix} f_{rr}x_r^2 + f_{tt}y_r^2 & (f_{rr} - f_{tt})x_r y_r & f_{rz}x_r \\ (f_{rr} - f_{tt})x_r y_r & f_{rr}y_r^2 + f_{tt}x_r^2 & f_{rz}y_r \\ -f_{rz}x_r & -f_{rz}y_r & f_{zz} \end{bmatrix} \begin{bmatrix} F_x \\ F_y \\ F_z \end{bmatrix} \quad (5)$$

with

$$x_r = (x_\alpha - x_\beta) / r \quad y_r = (y_\alpha - y_\beta) / r$$

Equation (5) is the same as equation (1), but transformed into the cartesian coordinate system.

For the point of excitation \mathbf{x}_α itself, the Green's function cannot be evaluated because the solution is singular at this point. This difficulty can be overcome by calculating the mean value over the corresponding surface area. This leads to the mean values of the scalar functions $f_{ii}(r)$

$$\bar{f}_{ii} = \frac{2}{r_\alpha^2} \int_0^{r_\alpha} f_{ii}(r) r dr \quad (6)$$

where r_α is the radius of area A_α . So the compliance relation at the excited point of the soil is

$$\begin{bmatrix} u_x \\ u_y \\ u_z \end{bmatrix} = \begin{bmatrix} \frac{\bar{f}_{rr} + \bar{f}_{tt}}{2} & 0 & 0 \\ 0 & \frac{\bar{f}_{rr} + \bar{f}_{tt}}{2} & 0 \\ 0 & 0 & \bar{f}_{zz} \end{bmatrix} \begin{bmatrix} F_x \\ F_y \\ F_z \end{bmatrix} \quad (7)$$

The flexibility matrix of the soil is assembled of all these 3x3 matrices $\mathbf{f}_{\beta\alpha}$

$$\begin{bmatrix} \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_\beta \\ \vdots \\ \mathbf{u}_m \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{11} & \cdots & \mathbf{f}_{1\alpha} & \cdots & \mathbf{f}_{1m} \\ \vdots & & \vdots & & \vdots \\ \mathbf{f}_{\beta 1} & \cdots & \mathbf{f}_{\beta\alpha} & \cdots & \mathbf{f}_{\beta m} \\ \vdots & & \vdots & & \vdots \\ \mathbf{f}_{m1} & \cdots & \mathbf{f}_{m\alpha} & \cdots & \mathbf{f}_{mm} \end{bmatrix} \begin{bmatrix} \mathbf{F}_1 \\ \vdots \\ \mathbf{F}_\alpha \\ \vdots \\ \mathbf{F}_m \end{bmatrix} \quad (8)$$

with m the number of points, or in short form

$$\mathbf{u} = \mathbf{f} \mathbf{F} \quad (8')$$

The inversion of this equation

$$\mathbf{F} = \mathbf{f}^{-1} \mathbf{u} =: \mathbf{K}_S \mathbf{u} \quad (9)$$

gives the dynamic stiffness matrix $\mathbf{K}_S = \mathbf{f}^{-1}$ of the soil which is introduced in the finite element procedure for the structure [3].

1.3 Combined finite-element boundary-element method

Now the coupling of both sub-systems, track and soil, is done by introducing the soil into the finite element code as a new type of element. The points of the soil define one special element of which the dynamic stiffness matrix \mathbf{K}_S is calculated by the boundary element method. The track structure is described by the conventional finite element method. Local stiffness matrices as well as local mass matrices are assembled in a global stiffness matrix \mathbf{K}_0 and a global mass matrix \mathbf{M} respectively. Combining these matrices, the frequency-dependent dynamic stiffness matrix $\mathbf{K}_F(\omega)$ of the track structure

$$\mathbf{K}_F = \mathbf{K}_0 - \omega^2 \mathbf{M} \quad (10)$$

is obtained. Then the coupling of the boundary element and finite element part of the system can be expressed in terms of global representations of the matrices and

$$\mathbf{F} = (\mathbf{K}_F(\omega) + \mathbf{K}_S(\omega)) \mathbf{u} \quad (11)$$

is the equation of the whole track-soil system, that has to be solved for given external forces \mathbf{F} , for example the wheel-set forces.

2 CALCULATED COMPLIANCES OF BALLASTED AND SLAB TRACKS

Three different tracks, a ballasted surface track, a ballast track on a bridge and a slab track in a tunnel are considered (Fig. 1). All tracks have the same UIC60 rails with bending stiffness $EI_R = 6.4 \cdot 10^6 \text{ Nm}^2$ and mass per length $m' = 60 \text{ kg/m}$, and the same concrete sleepers with $EI_S = 5.2 \cdot 10^6 \text{ Nm}^2$ and $m = 338 \text{ kg}$. For each track, the stiffness of the material under the track (the ballast or the subsoil of the slab) is varied.

2.1 Ballasted track on a homogeneous soil

The surface track consists of a 0.35 m ballast layer. The sub-soil has a shear wave velocity of $v_S = 300 \text{ m/s}$. The rail pads are rather stiff with $k_P = 300 \text{ kN/m}$. The ballast is varied as

$$v_S = 100, 150, 200, 300 \text{ m/s}.$$

The dynamic compliances of the rails are given as amplitude and phase in Figure 2. Although the ballast stiffness is varied by a factor of 9, the static compliance of the rail is in the narrow range of $u/P = 1.8 \text{ to } 3.2 \cdot 10^{-9} \text{ m/N}$. That means 0.2 to 0.3 mm displacement under a 100 kN axle load. The stiff ballast yields an almost constant compliance and only a small phase delay of 20° . All softer ballast materials result in a stronger phase delay and a related amplitude reduction at a certain frequency which is lower for the softer ballast. The softest ballast has a strong phase and amplitude decay at about 60 Hz. The softest ballast with $v_S = 100 \text{ m/s}$ has the strongest contrast with the underlying soil $v_S = 300 \text{ m/s}$ and this results in moderate amplifications of the track amplitudes.

2.2 Ballasted track on a bridge (rigid base)

The ballasted track is the same on the bridge as for the surface line. The bottom of the ballast layer is fixed. The same variation of the ballast stiffness is analysed in Figure 2b. The rigid base reduces the static compliances of the ballasted tracks to values between $u/P = 1.4 \text{ to } 2.9 \cdot 10^{-9} \text{ m/N}$. No radiation damping of the soil is present and only small phase values due to the material damping can be observed. Clear resonances occur for the softer ballast materials at $f = 95$ and 135 Hz for $v_S = 100$ and 150 m/s . These resonance frequencies are lower than the layer frequencies $f = v_P/4d = 200/1.4 = 140$ or $300/1.4 = 210 \text{ Hz}$ due to the influence of the track mass. The phase decay at the resonance is stronger than for the surface line.

2.3 Slab track in a tunnel (on a layer over bedrock)

The slab track in the tunnel has a 0.6 m thick concrete plate which lies on a 1.5 m layer of softer soil material. The base is the tunnel floor which is assumed to be rigid. Medium soft rail pads of $k_P = 60 \text{ kN/m}$ are used to compensate the stiff track plate. The compliance of the rail is ruled by these soft rail pads and is constant if the stiffness of the sub-soil is varied between $v_S = 100$ and 300 m/s . Moreover it does not change its static value of $u/P = 3.7 \cdot 10^{-9} \text{ m/N}$ with increasing frequency (see Fig. 2d). The influence of the sub-soil can be clearly seen for the plate compliance under the axle load (Fig. 2c). The massive plate yields low resonance frequencies of $f = 20, 30, 40$ and 60 Hz with the compliances of the different sub-soils. These resonance frequencies are far below the layer resonances at $f = 33, 50, 66$ and 100 Hz . The amplitudes of the plate are much smaller than those of the rail. It is 20 or 10 % for the soft sub-soils and even less for the stiff sub-soils.

Figure 2d shows the rail compliances of the three tracks, surface track with soft ballast, bridge track with soft ballast, and tunnel track with a thick plate over a stiff sub-soil. The rail compliance of the tunnel is increasing at 150 Hz, the end of the frequency range. The resonance of the rail on the soft rail pads is expected at 205 Hz. While the ballasted tracks show a

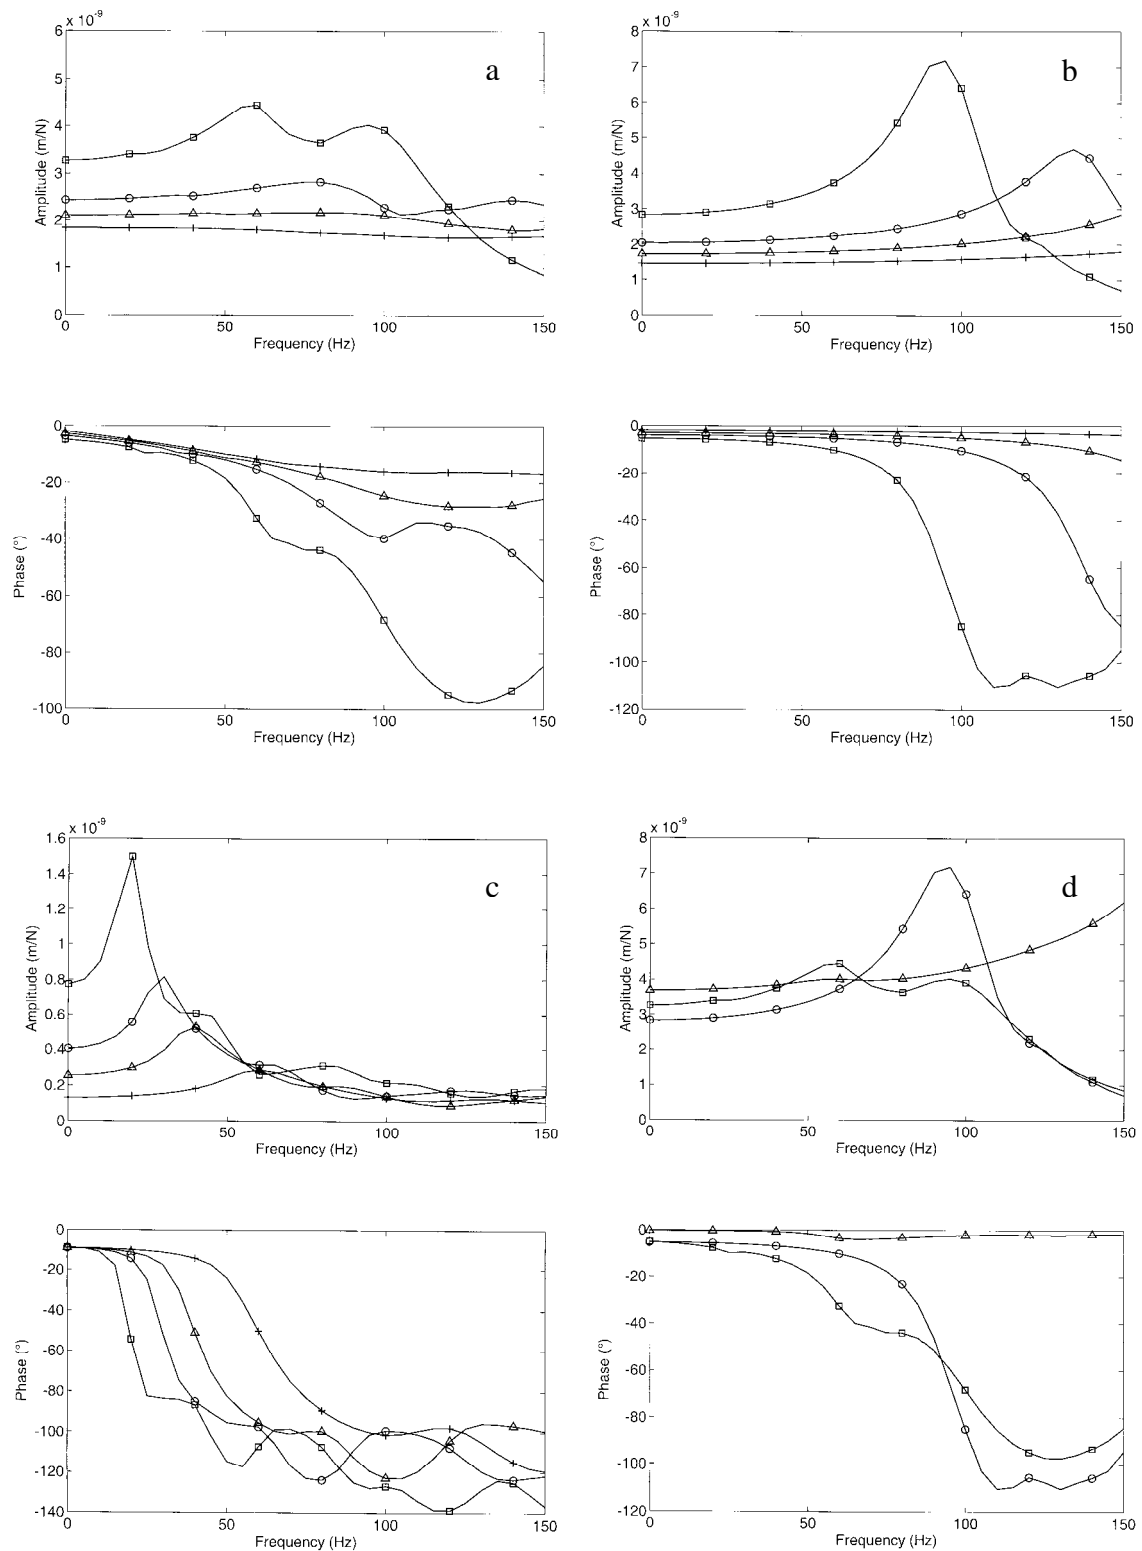

Figure 2: Compliances of different tracks, a) ballasted track on the soil, b) ballasted track on the bridge, c) slab track on a sub-soil layer (compliance of the plate) variation of the ballast or subsoil \square 100, \circ 150, \triangle 200 +300 m/s in a, b, c. Comparison of the rail compliances (d) for the ballasted track on the soil \square , the ballasted track on the bridge \circ , and the slab track \triangle .

phase drop below 100 Hz, the rail of the tunnel track shows almost no phase delay. Such strong differences between rail and sleeper displacements are only found for the tunnel track. The sleeper to rail displacement ratio of the ballasted tracks is at 33 to 67 % for the bridge track line and at 50 to 77 % for the surface line. The differences increase with a stiffer ballast material, but also with a softer rail pad.

3 TRAIN INDUCED GROUND VIBRATION

3.1 Calculation in wavenumber domain

An alternative method to the FEBEM is the calculation of an infinite track in frequency-wavenumber domain. This method yields the track behaviour and the ground vibration due to moving or fixed loads [4]. The dynamic stiffness of the soil under the track in frequency wavenumber domain is calculated as the wavenumber integral

$$\tilde{K}_S(k_y, \omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} H(k_x, k_y, \omega) p_1(k_x) dk_x = \frac{1}{K_S(k_y, \omega)} \quad (12)$$

The dynamic stiffness K_S of the soil is combined with the stiffness $K_T = EI k^4 - m' \omega^2$ of the track

$$H_{TS}(k_y, \omega) = \frac{1}{K_T + K_S} \quad T_{TS}(k_y, \omega) = \frac{K_S}{K_T + K_S} \quad (13)$$

and these track-soil transfer functions are used to calculate the displacements of the track and the soil

$$u_T(\omega) = \frac{F}{2\pi} \int_{-\infty}^{+\infty} H_{TS}(k_y, \omega - k_y v) dk_y \quad (14)$$

$$u_S(x, y^*, \omega) = \frac{F}{(2\pi)^2} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} H(k_x, k_y, \omega - k_y v) T_{TS}(k_y, \omega - k_y v) p_1(k_x) e^{i(k_x x + k_y y^*)} dk_x dk_y$$

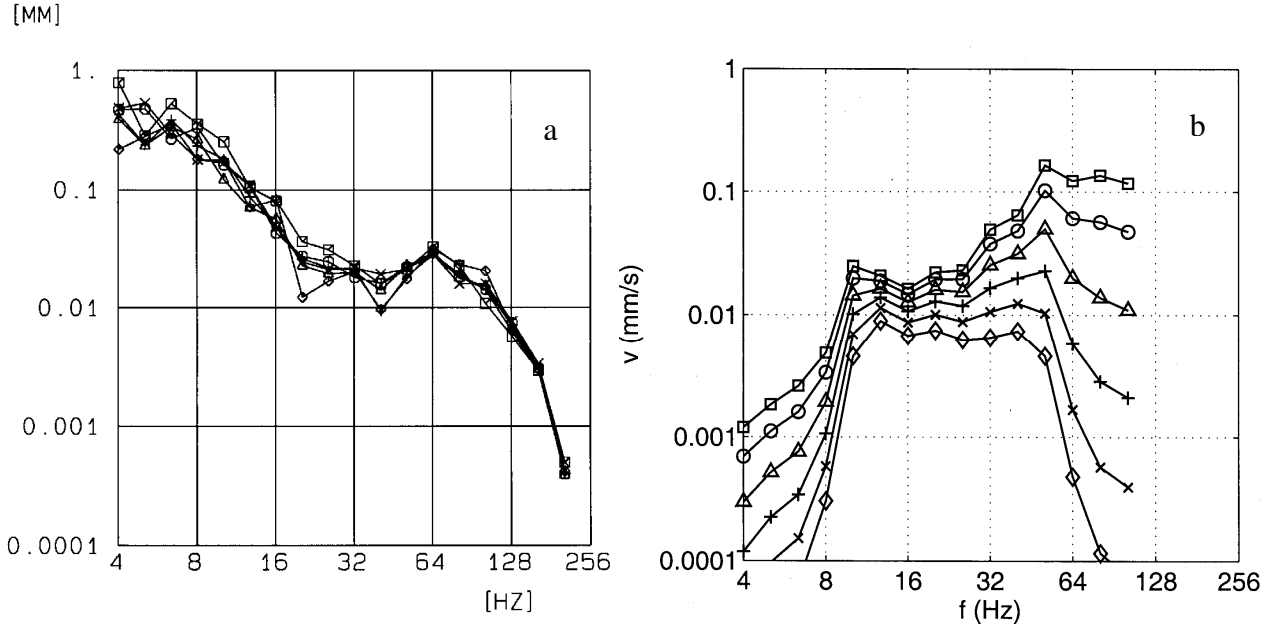

Figure 3: a) Third-of-octave spectra of the irregularities of the ballasted track at six different places of the 3 km long testing section; b) calculated ground vibration at the layered site; at □ 2.5, ○ 7.5, △ 12.5, + 20, × 30, ◇ 50 m distance from the track.

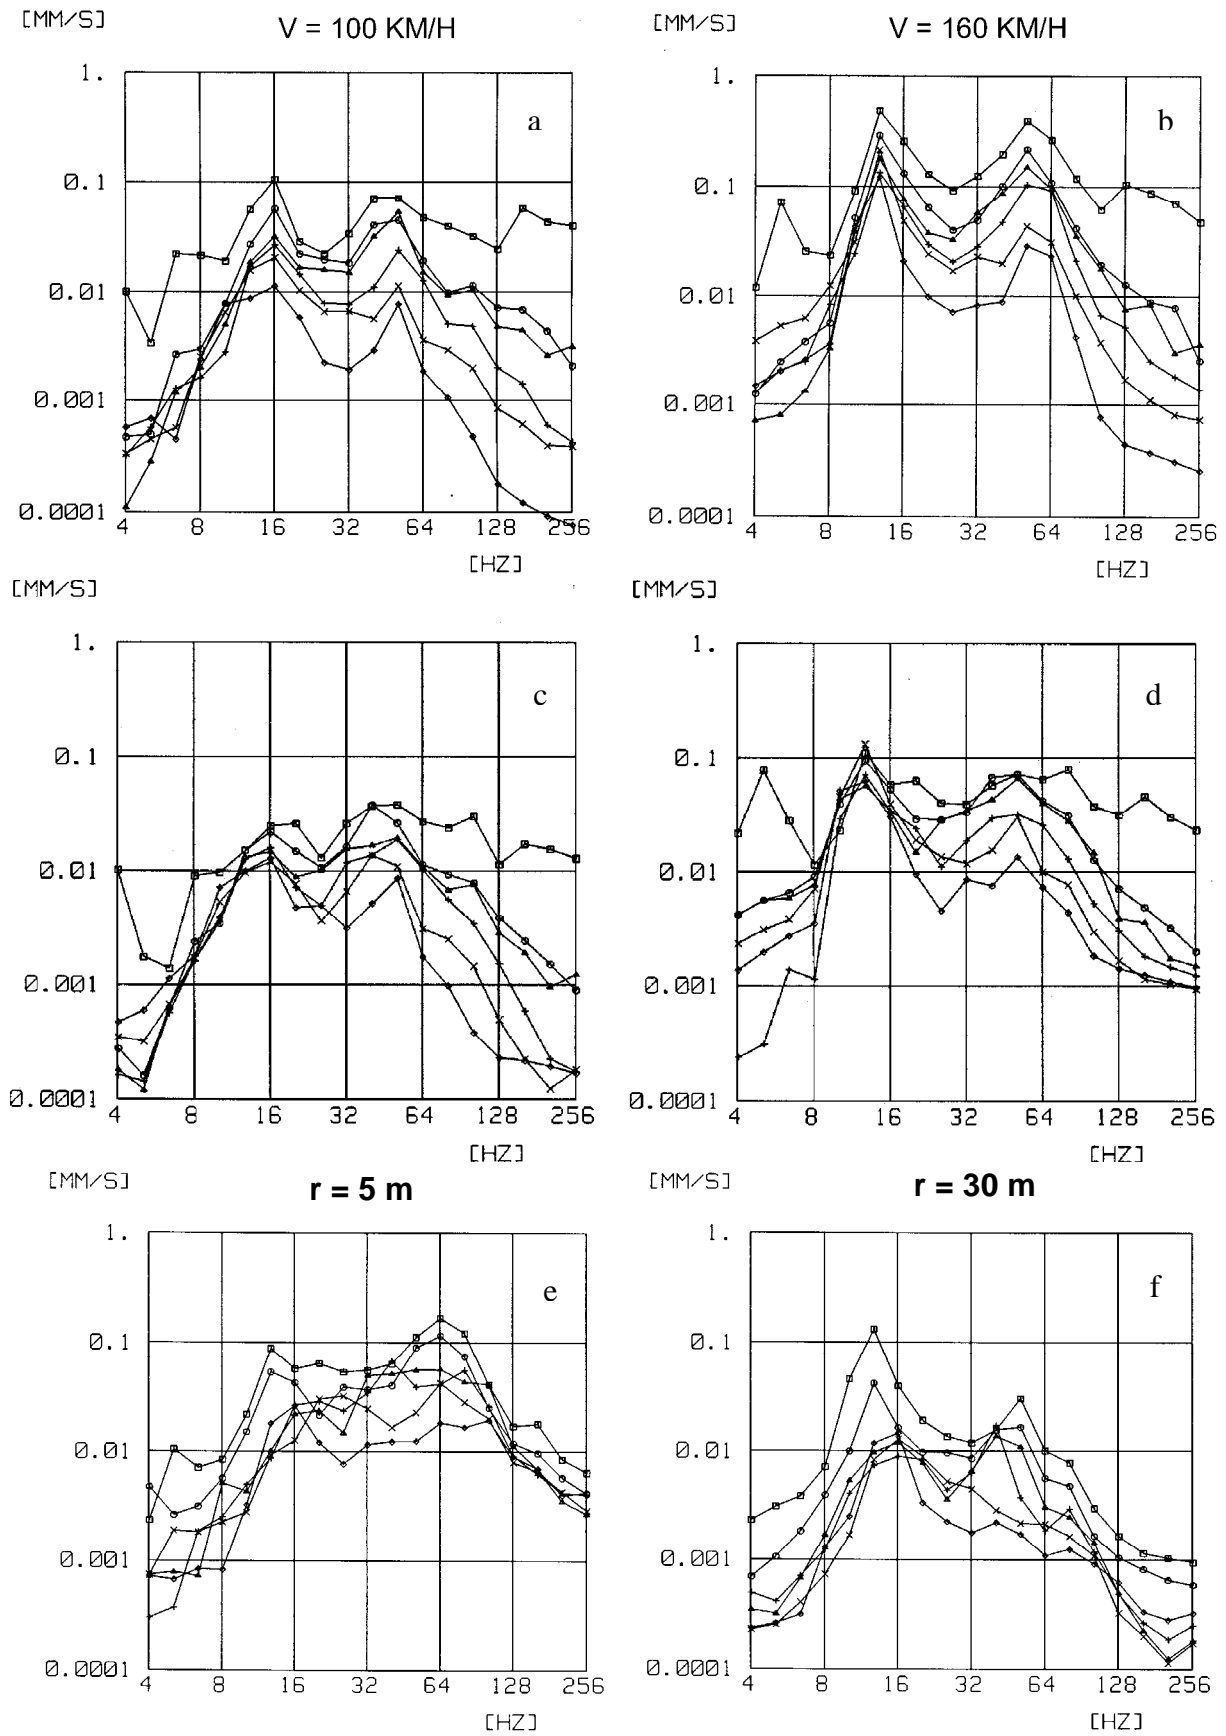

Figure 4: Train induced ground vibration, a), b) passage of a locomotive with $v_T = 100$ and 160 km/h , c), d) passage of a passenger car with $v_T = 100$ and 160 km/h , measured at $\square 2.5$, $\circ 7.5$, $\triangle 12.5$, $+ 20$, $\times 30$, $\diamond 50 \text{ m}$, e), f) results at $r = 5$ and 30 m with train speeds $v_T = \square 160$, $\circ 125$, $\triangle 100$, $+ 80$, $\times 63$, $\diamond 40 \text{ km/h}$.

The spectrum of vibration amplitudes $v(x, \omega)$ at a fixed point for an excitation frequency ω_E is calculated as [5]

$$v(x, \omega, \omega_E) = \frac{F}{2\pi v_T} T_{BS}\left(\frac{\omega_E - \omega}{v_T}, \omega\right) \int_{-\infty}^{+\infty} H(k_x, \frac{\omega_E - \omega}{v_T}, \omega) p_1(k_x) \exp(ik_x x) dk_x. \quad (15)$$

The excitation of the ground vibration is a force spectrum $F(\omega)$ which is due to the irregularities s of the track. The irregularity spectrum $s(\omega)$ of the ballasted track is shown in Figure 3a for different places of the 3 km long test section. The soil consists of a layer with $v_s = 250$ m/s and $h = 10$ m on a rock half-space of $v_s = 1000$ m/s. The material damping of the soil is increasing from $D = 1\%$ at 10 Hz to $D = 10\%$ at 100 Hz, see [6] for more details. The calculated response of the soil is shown in Figure 3b for distances between 2.5 to 50 m.

While the irregularities are decreasing with frequency, the resulting excitation forces are almost constant, and the ground vibration amplitudes are mainly increasing with frequency. There is a strong cut-off for the frequencies below 12.5 Hz, which is the resonance frequency of the soil layer. The increase of the amplitudes is very strong below the cut-off, and moderate above. Frequencies above 63 Hz are reduced considerably due to the strong material damping. The two cut-off phenomena yield a specific frequency range of the ground vibration between 10 and 63 Hz which is due to the soil and not to the train excitation. All these theoretical characteristics are in good agreement with the experimental results in Figure 4c.

3.2 Experimental observations

The measured ground vibrations of different distances, different train speeds and different trains are shown on Figure 4, [7] where the spectra due to the locomotive display stronger and clearer characteristics than those of the passenger cars. A sharp resonance is observed for the layer frequency at 12.5 Hz in case of a train speed of 160 km/h. The same excitation frequency would be at 8 Hz for the lower train speed of $v_T = 100$ km/h, but no resonance is observed. The frequency is in the cut-off region of the soil, and therefore only small amplifications can be seen in the near field which indicate some specific train excitation. The characteristics of the layered and strongly damped soil are so dominant that the spectra of the different train speeds (Fig. 4e and f) are very similar. At a near-field distance of 5 m, the characteristic frequency range from 10 to 63 Hz has an almost constant level whereas the low frequencies are more dominant in the far field at 30 m. An increase of the amplitudes with increasing train speed can be observed. Especially the increase for $v_T = 160$ km/h due to the resonance at $f = 12.5$ Hz is very strong in the far field.

4 TRAIN INDUCED BRIDGE VIBRATION

4.1 Experimental observations

Figure 5: 45 m long concrete bridge on elastic bearings

A 45 m long concrete bridge has been analysed and measured (Fig. 5), [7]. The cross section can be seen on Figure 1. The bridge is simply supported on elastic bearings. The first four modes and eigenfrequencies are shown on Figure 6. The first bending mode fits perfectly the mode shape of a simply supported bridge. The first torsional mode has a contribution of the elastic bearings. During the passage of the test train, a clear excitation of the 7 Hz resonance has been observed for a train speed of $v_T = 100$ km/h and of the 11 Hz resonance for $v_T = 160$ km/h (see Figure 11 in Appendix A), [7]. These frequencies are close to those observed on the soil.

Figure 6: The first four eigenmodes of the concrete railway bridge a) first bending mode, b) first torsional mode, c) second bending mode, d) second torsional mode.

4.2 Modal excitation of railway bridges by sequence of axle loads

To examine the effect of passing trains, first a single axle passage over the bridge is considered. (The moving load concept is used here which is conservative compared to the more detailed train-bridge interaction, see for example [8]).

The excitation of mode j with circular eigenfrequency ω_j and normalized eigenform $v_j(x)$ can be determined from the Fourier transformed differential equation of this mode

$$m_j(\omega_j^2 + 2Di\omega_j^2 - \omega^2)u_j = F_j(\omega) \quad (16)$$

where

$$F_j(\omega) = \text{FFT}\{F(t)v_j(x = v_T t)\} \quad (17)$$

is the transformed modal force component. The static load F_S yields

$$F_j(\omega) = F_S \text{FFT}\{v_j(x = v_T t)\} = F_S V_j(\omega) \quad (18)$$

and a harmonic dynamic load F_D of frequency ω_j yields

$$F_j(\omega_j) \approx F_D V_j(0). \quad (19)$$

Figure 8 shows the forces of the first and second mode as time histories and spectra. The low frequencies have always high amplitudes which are related to the slow impulse of the total passage of the static force. These frequencies are much lower than the resonance frequencies of the bridge. A resonance due to the bridge passage impulse is only possible for the high-speed passage over a short bridge.

The higher frequencies are due to the irregularities when the static load is entering and leaving the bridge. The simply supported bridge yields a sudden bend at the beginning of the bridge. If the bridge is on an elastic support, as in the present situation, there is an additional step. Both cases, the simply supported bridge on a rigid or elastic support are shown in Figure

8. The additional step of 15 % of the maximum displacement for the elastic support yields high-frequency amplitudes which are up to five times higher than for the bridge on rigid support. There is a strong variation with frequency due to the constructive or destructive superposition of the entering and leaving of the bridge. As the resonance curve has some bandwidth, a smoothed curve of the modal force $F_j(\omega)$ is better suited to discuss possible resonances.

Another excitation of the bridge is due to the irregularities s of the track. The measured irregularities of the ballasted track on the bridge are shown in Figure 7a. From the irregularities at the resonance frequencies 7 and 11 Hz, $s = 2$ and 1 mm, dynamic forces of approximately $F_7 = F_{11} = 1$ kN are deduced. Their effects on the modes of the bridge are shown in Figure 8c and d. The amplitudes of the modal forces are almost the same as the amplitudes due to the entering and leaving of the simply supported bridge (Fig. 8a and 8b).

Figure 7: a) Irregularities of the track □ on the soil, ○ on the bridge, △ in the tunnel (slab track),
b) vibration spectra of the bridge track during the passage of the passenger car with
 $v_T = \square 160, \circ 125, \triangle 100, + 80, \times 63$ km/h.

So far, no reason for the different excitation of different modes could be found. It should be due to the specific axle sequence of the train which is shown on Figure 9 for the two interesting train speeds and on Figure 7b in a third-of-octave version for all train speeds. A maximum is found at 7 Hz for 100 km/h and at 11 Hz for 160 km/h close to the excited eigenfrequencies. Each maximum is the highest peak in a wider frequency band with several peaks. At the same time there are minima and a range of reduced amplitudes around 7 Hz for the train speed of 160 km/h and around 11 Hz for 100 km/h. Moreover, these minima are also found for a single car or a single locomotive (Fig. 9c-d). So it is concluded, that the axle sequence is important for the excitation of the eigenfrequencies of the bridge. The axle sequence yields maxima and minima which are suitable to the experimental observation, and the cancellation due to the sequence of the axles seems to be more important [9]. Isolated peaks of the axle sequence spectrum are only found for specific, very regular trains [10].

The axle-sequence spectra discussed here are in relation to the signatures of trains in the UIC rules [11] which are expressed as the axle loads as a function of the wave length. But the axle sequence spectra also include higher frequencies which are important for the train-bridge situation discussed here.

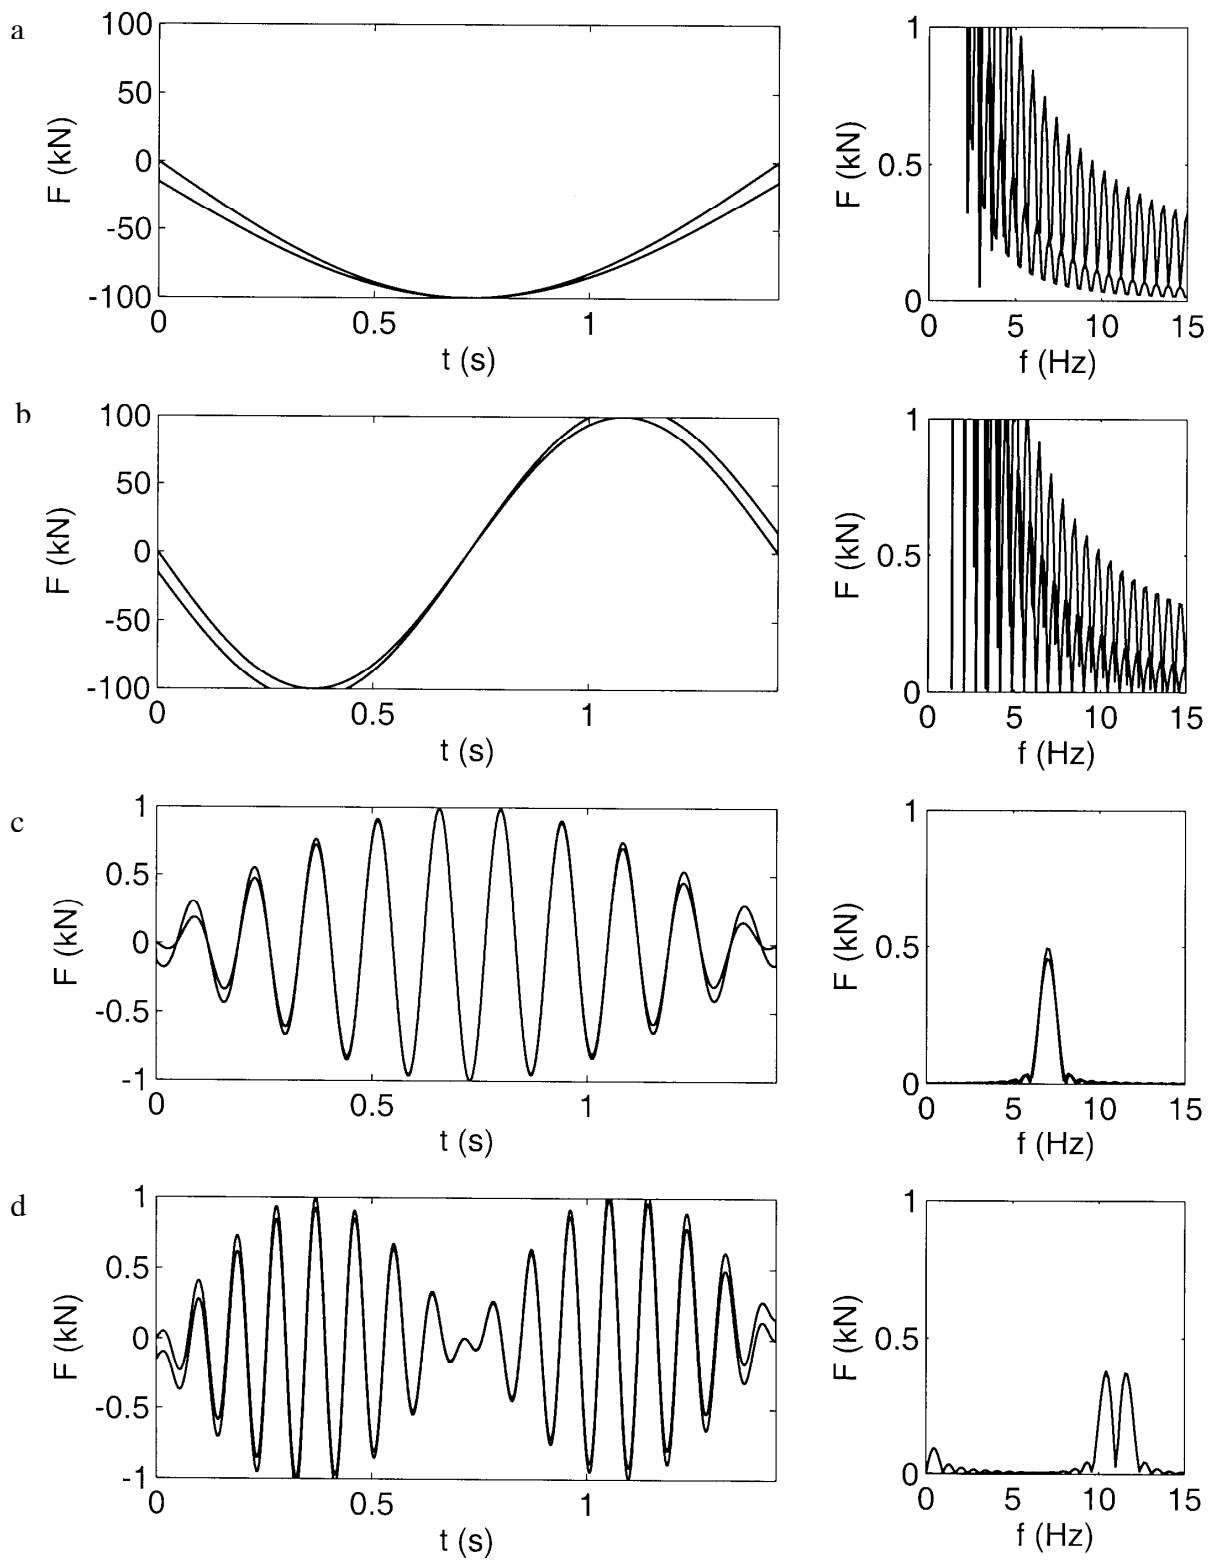

Figure 8: Modal forces as time history and spectra, due to the passage of a static load, a) first and b) second mode, and due to harmonic loads of $f =$ c) 7 Hz for the first mode and d) 11 Hz for the second mode, all results are given for rigid and elastic support.

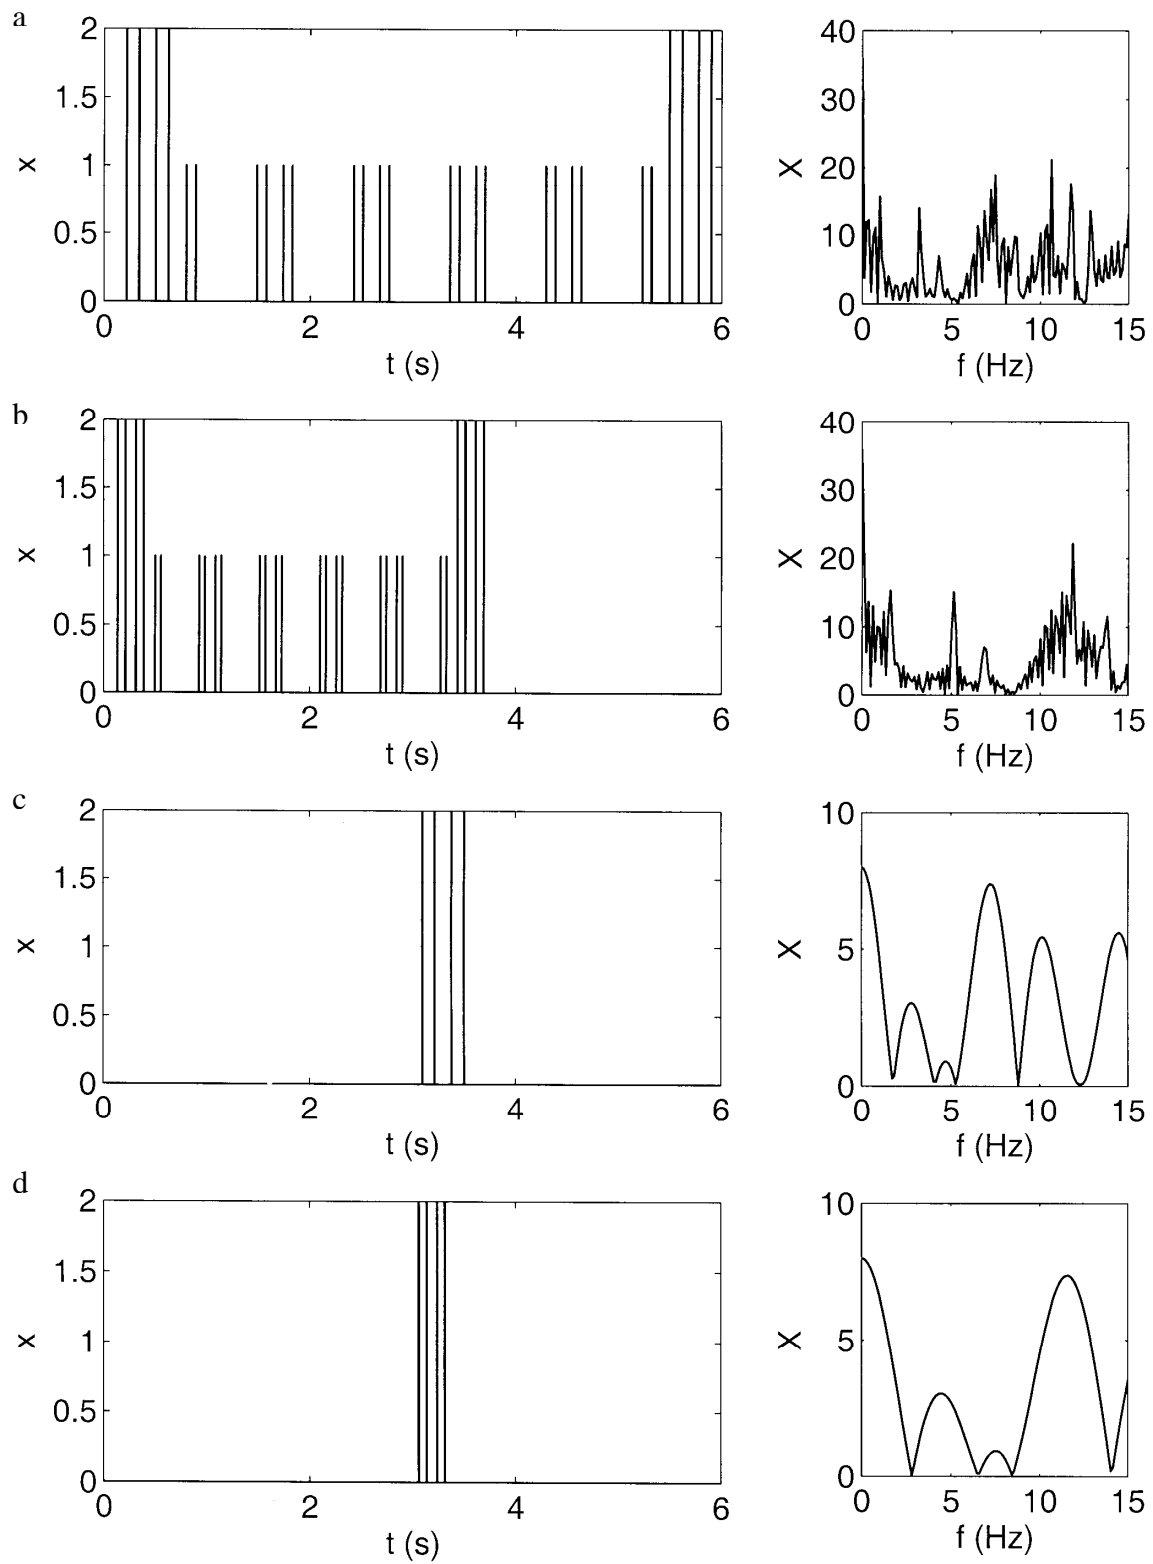

Figure 9: Axles sequence of the test train with $v_T =$ a) 100 and b) 160 km/h, time histories and spectra, c) and d) of the locomotive with 100 and 160 km/h respectively.

5 CONCLUSIONS

- The calculated compliances of different ballasted and slab tracks on layered soils show some typical characteristics, resonances, amplitude and phase delays, rail to sleeper amplitude ratios, which can also be found in the measurements.
- Dominant frequencies, which have been measured on the ground, are close to the resonance frequencies of the bridge that are excited by trains of the same speed.
- The excitation of the modes of the bridge can be due to the passing over the bridge, the entering and leaving of the bridge or the random irregularities of the track.
- All these excitations are modified by the axle sequence of the whole train. In the present case the axle sequence spectrum has a maximum at the excited eigenfrequency and a minimum at the other eigenfrequency of the bridge.
- The maximum of the axle sequence spectrum also excites the layer resonance of the soil for a train speed of 160 km/h whereas the same excitation is in the cut-off region of the soil for a train speed of 100 km/h.

APPENDIX A - MEASURED COMPLIANCES OF THE DIFFERENT TRACKS

The compliances of the different tracks of the surface, bridge and tunnel line have been measured by impulse tests and are shown on Figure 10 for a wide frequency range. The slab track in the tunnel has a high compliance up to 200 Hz (Fig. 10c) whereas the ballasted tracks drop down below 100 Hz (Figs. 10a and b). The bridge and tunnel track show a resonance, the ballasted track on the soil has no resonance amplification. The slab track in the tunnel has two resonances, the strongest at 205 Hz is due to the rail mass on the rail pad stiffness, and the minor resonance at about 100 Hz is due to the plate mass on the sub-soil stiffness. The displacements of the rail on the medium soft rail pad are ten times higher than those of the plate (Fig. 10c). The sleeper to rail amplitude ratios of the ballasted tracks are at about 70 %. All these details are in agreement with the theoretical results.

The experimental results can be used to choose the ballast and sub-soil parameters. The low-frequency decay of the ballasted tracks means a low stiffness of the ballast during the impulse tests. A higher stiffness of the ballast is expected under train loading. The sub-soil stiffness in the tunnel is stiff, but a thinner layer or a thinner plate could also explain the high plate-subsoil resonance frequency.

APPENDIX B – MEASURED TRAIN PASSAGE OVER THE DIFFERENT TRACKS

The behaviour of the different tracks under train passages is shown in Figure 11. The time histories on the left show the displacements of the rail and the sleeper which are calculated from the measured velocities [3]. The third of octave spectra on the right are for the original velocity measurements and compare several rail, sleeper and environmental measuring points. The displacements under a 100 kN axle load is about 0.3 mm for the ballasted track. The displacement of the slab track with softer rail pads are somewhat higher, but the displacements of the plate are considerably smaller as can be observed at the time histories and the spectra.

APPENDIX C – MEASURED TRAIN PASSAGE OVER THE BRIDGE

Figure 12 shows the time histories of two train passages over the bridge. One passage is with a train speed of $v_T = 100$ km/h, the other with $v_T = 160$ km/h. The time segment, when the middle of the train passes the bridge, is selected. A clear resonance is observed for both passages. For the lower train speed, all measuring points on the bridge are in phase, so it is a first symmetric mode of the bridge. For the higher train speed the north and south end of the bridge are in anti-phase and the middle of the bridge has the lowest amplitude. That means that a second antymmetric mode is excited by the train at 160 km/h. The eigenfrequencies which are clearly dominating for each train passage are also different, $f = 7$ Hz for $v_T = 100$ km/h and $f = 11$ Hz for $v_T = 160$ km/h.

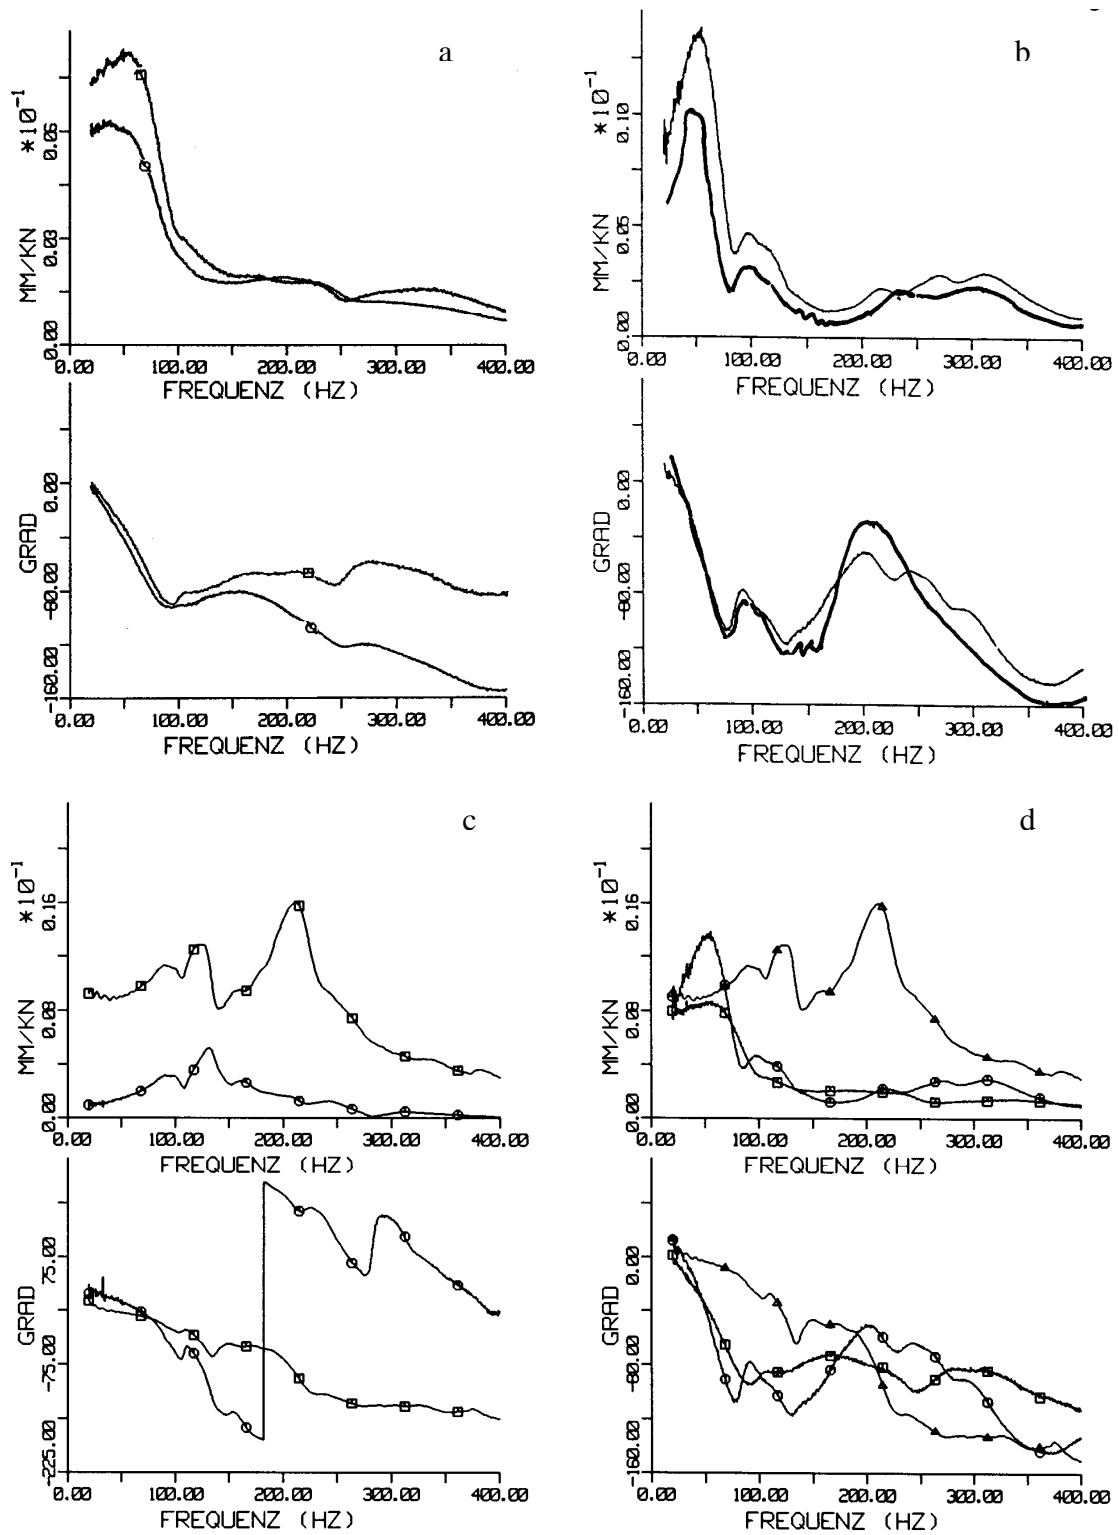

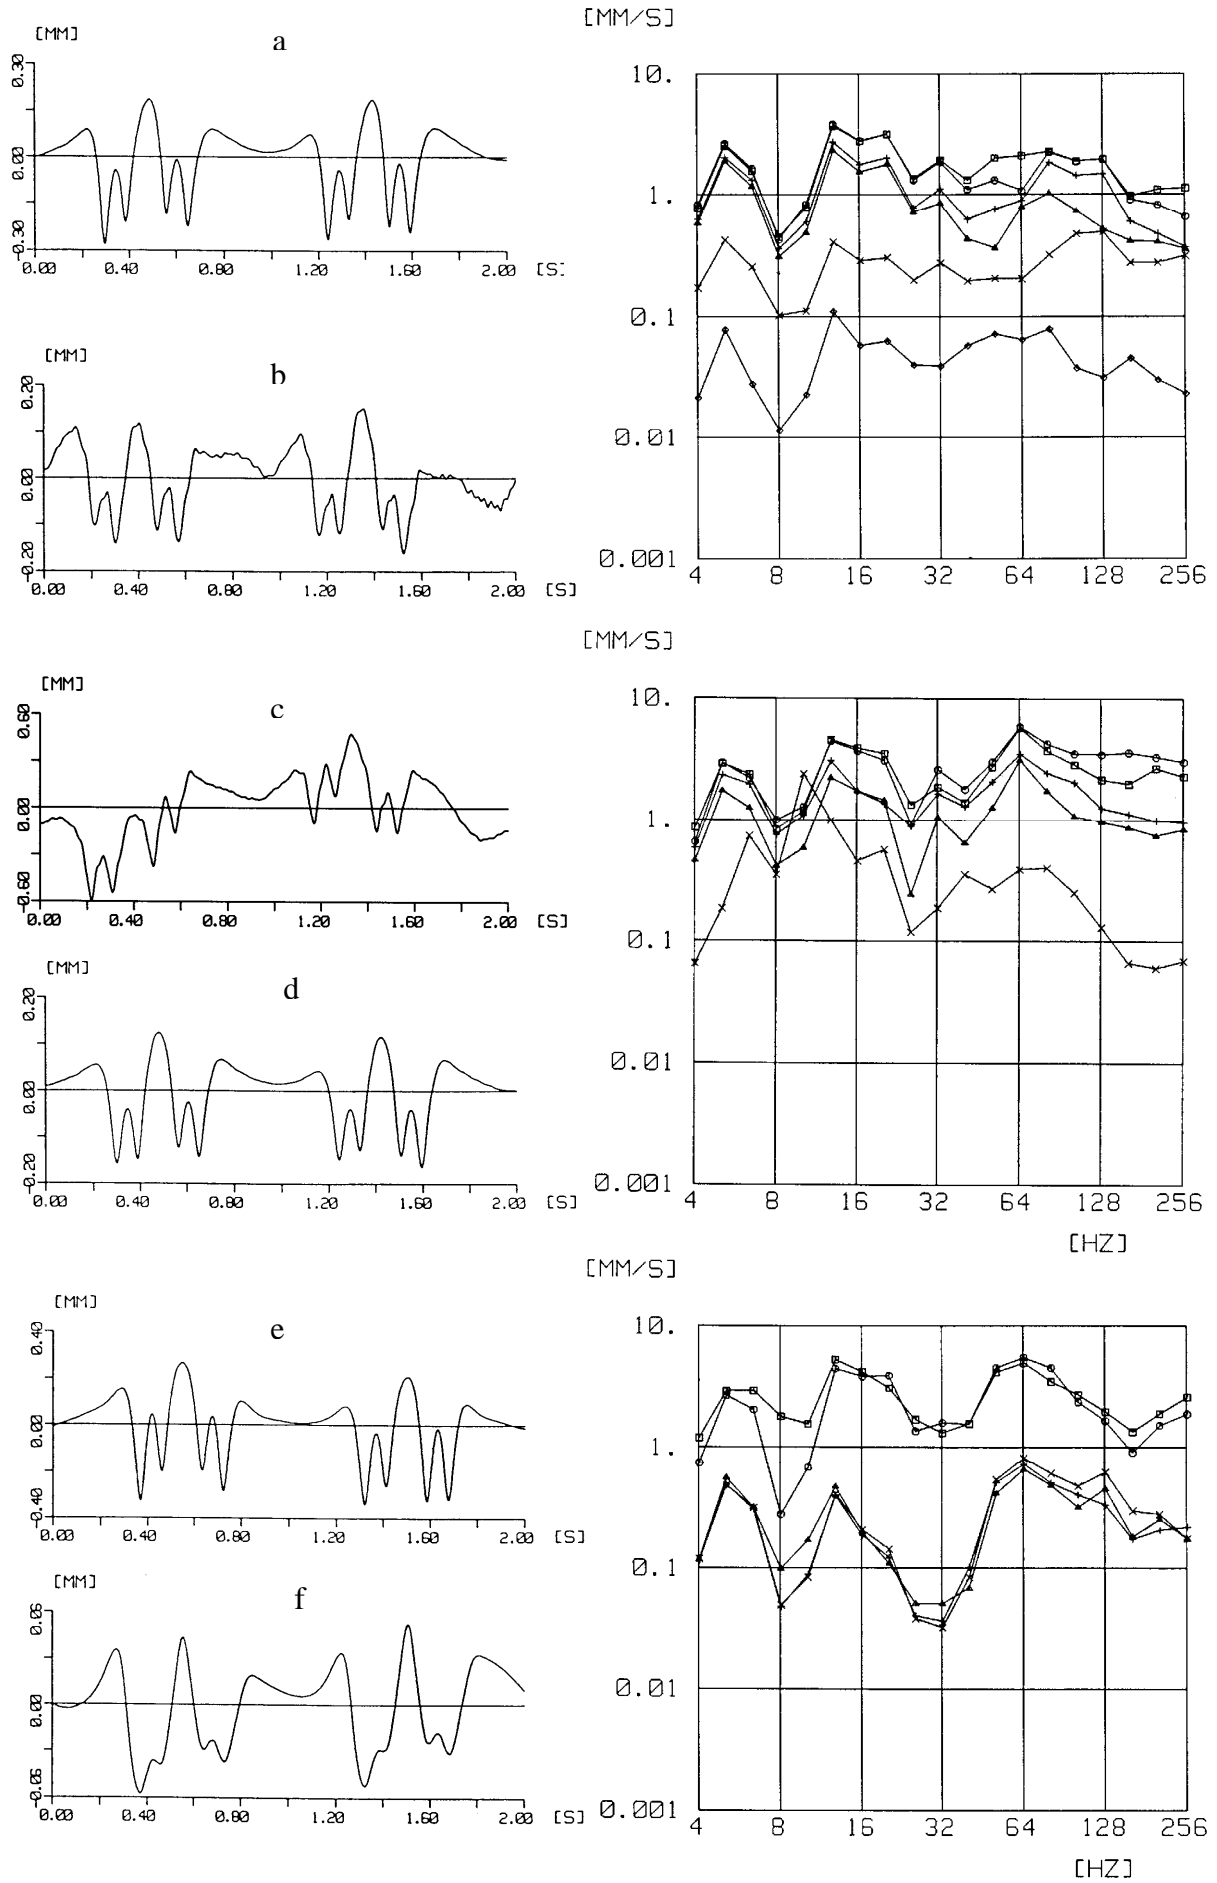

Figure 10: Compliances of the rail (□) and sleeper (○) of the different tracks, a) on the soil, b) on the bridge, c) in the tunnel, d) comparison of the rail compliance for the ballasted track □ on the soil, ○ on the bridge, and △ the slab track in the tunnel.

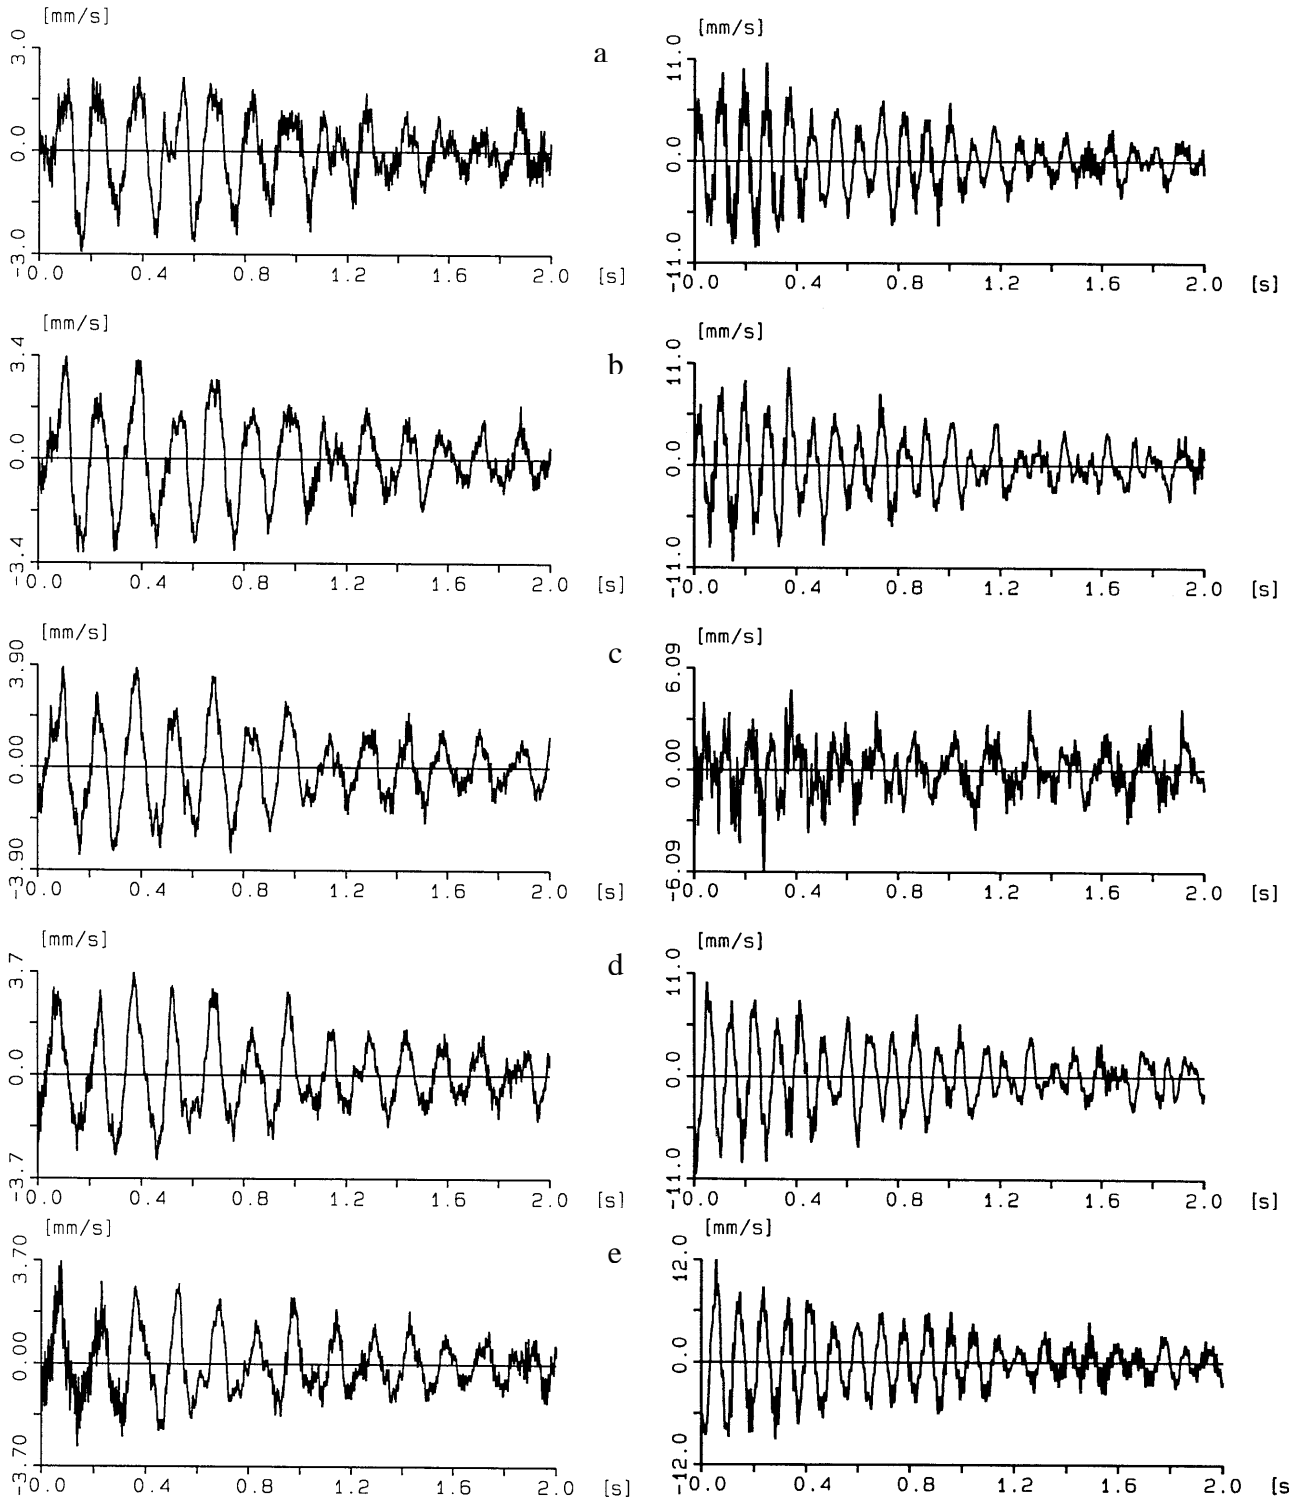

Figure 12: Time histories of the passage of the train with $v_T = 100$ km/h (left) and 160 km/h (right) at $x =$ a) 7.5, b) 15, c) 22.5, d) 30, e) 37.5 m

Figure 11 (previous page): Passage of the train over the different tracks surface line (top), bridge (middle) and tunnel (bottom), time histories of the displacements of the rail (a, c, e) and the sleeper (b, d, f), third-of octave spectra of the rail (\square , \circ), the sleeper (\triangle , $+$) and the soil, bridge or plate (\times).

DYNAMIC EFFECTS OF RAILWAY TRAFFIC DUE TO LATERAL MOTION IN LONG VIADUCTS WITH HIGH PIERS

Abstract. *The layout of new high-speed railway lines often requires long slender viaducts, including continuous decks with lengths of 1000 m or more, and high piers or arches with heights over 70 m. These structures generally exhibit a high lateral compliance. The fundamental mode of vibration usually corresponds to this lateral motion, with frequencies lower than 1 Hz and associated to long wavelengths. Current experience on lateral behavior of bridges under traffic includes research work carried out by ERRI D181 committee [1], which considered problems in European bridges for conventional rail with steel open decks, and of much shorter length and deformation wavelengths. According to the conclusions from ERRI minimum lateral vibration frequencies of spans are required to be higher than 1.2 Hz in the new design codes [2]. However, this case does not correspond to the high speed rail viaducts described above, for which there is so far not enough evidence on the behavior nor sufficient knowledge of the relevant mechanisms. In this work we present newly developed models for considering the coupled dynamic behavior of vehicles and structure in railway viaducts. The structure is discretised with finite elements of beam and shell type, and vehicles are considered with 3D multibody models, within ABAQUS [3]. A novel technique for considering contact between wheels and rails has been developed. This model includes both vertical and lateral contact, incorporating an implementation of Kalker's FASTSIM solution technique [4], providing adequate simulation of lateral nosing motion of railway vehicles.*

The models developed are applied to a representative case, the "Arroyo de Las Piedras" viaduct [5] with a total length of 1209 m and piers of 94m height. Several simulation scenarios are compared, considering track alignment irregularities or not as well as full interaction models or simpler moving load models.

1 INTRODUCTION

A considerable investment has been done in new high speed railway lines in Spain, having in operation as of today over 2000 km of new lines with UIC gauge. Due to the orography in the Iberian peninsula, often these lines have to cross deep valleys, necessitating tunnels and viaducts. Generally these viaducts must be supported on tall piers or arches, of the order of 100 m or more, and will consist of long continuous decks, of the order of 1000 m or more. As a consequence they will generally have very low lateral stiffness and associated low natural frequencies of vibration.

Figure 1: Viaducto “Arroyo las Piedras” in Córdoba–Málaga HS line: first mode of vibration 0.313 Hz

In some cases bridges with low lateral frequencies have been seen to develop considerable vibrations, causing concern for the safety of circulation of railway vehicles. Addressing this problem was the objective of the ERRI committee D181 [1], whose work included a number of European bridges. These bridges were generally steel structures with open decks and low lateral bending stiffness. Following the conclusions of this work several limitations for lateral deformability of decks and minimum natural frequencies have been introduced in the Eurocodes [2] and national codes [6].

In principle the types of bridges considered in the ERRI report are not of the same type here considered. Although the lateral compliance is high in both cases, the long and tall viaducts typical of high speed lines have a much longer wavelength of deformation and of vibration modes, of the order of several hundreds of meters or more, whereas the ERRI bridges had lateral deformation wavelengths of the order of tens of meters. It may be expected that with these latter wavelengths it is possible to produce some resonance or dynamic amplification of the vehicles lateral movement, whose kinematic wavelengths are also in this order of magnitude. On the other hand, for a long wavelength which will be generally longer than the complete train it may be more unlikely to obtain synchronous amplification in all vehicles, as well as with nosing motion.

However, there remain important uncertainties as the lateral dynamic coupled vibrations of vehicles and bridges have not been thoroughly studied and the possibilities of obtaining high amplifications or resonance may lead to tragic results for the safety of passengers. Furthermore, external actions such as high lateral winds or earthquake may make these matters worse.

In this work we present a description of a model to consider in a realistic manner vehicle-bridge interaction models, in order to apply to the type of long tall slender viaducts as described above. As will be described below, models for coupled lateral dynamics of railway vehicle-bridge interaction are considerable more complex in nature than those for vertical dynamic actions, due to the specific nature of the wheel-rail contact which admits some lateral relative movement.

The model for vehicle–bridge interaction consists of five main ingredients: 1) dynamic model for structure subsystem; 2) dynamic model for vehicle subsystem; 3) geometrical description of track including irregularities; 4) wheel–rail contact model and 5) a numerical solution algorithm for the equations.

Figure 2: The basic ingredients of vehicle-structure interaction: vehicles, bridge and the interaction forces

The structure is usually discretised with finite elements, either beam type as in [7], [8], [9] or shell type as in [10] or solid [11]. Vehicle models may be assembled from rigid bodies with joints and/or constraints as *multibody dynamic models*, including discrete springs or dampers. In railway vehicle–structure dynamics generally linear models are employed [7], [8], [12], [9], [13]. More complete models with nonlinear effects are used in [14] and [15].

A key point of the vehicle-bridge interaction for lateral dynamics is to establish the geometric and dynamic relationships between both subsystems (Figure 2). For establishing these relationships wheel-rail contact theories are used.

The simplest approach for modeling the wheel-rail contact is to consider a perfectly guided path, i.e. contact points between wheels and rails share positions and velocities, approach followed in [16], [10], [13]. This approach neglects nosing relative movement between wheelsets and rails. A relatively simple option to introduce this lateral movement is to prescribe a sinusoidal relative displacement between the wheelset and the track, as in [17], [16], [12]. This procedure permits consideration of a worst case of fully developed hunting motion, thus providing a hypothetical upper bound for these effects, but is a relatively simplistic solution and does not take into account the real dynamic coupling in lateral motion. This was also the approach followed in our previous work reported in [18].

In order to include the dynamic effects from lateral motion in the wheel-rail contact the relative displacements between wheels and rails must be considered, subject to the geometric constraints and dynamic contact laws. The first basic ingredient of any such procedure is a geometric model of wheel and rail profiles. Once the position is well determined it is necessary to introduce the normal and tangential forces. For normal contact, the well established nonlinear Hertz theory [19] is probably the best option, see [7], [20], [14] and [15]. Often a linearization of this theory is applied, as in [9]. The full solution of tangential contact, including precise local slip limits at each point within every contact area requires a high amount of computer resources. For this reason Kalker’s linear theory [21] is often applied in vehicle-bridge interaction models as in [7], [8], [9]. Other works more focused on the dynamic behaviour of vehicles [14], [15] introduce more realistic and complex tangential contact models, such as Kalker’s variational

theory [22] or the simplification of this in FASTSIM [4]. A practical alternative is the USETAB tables [23], is based on Kalker Variational Theory [22], which is the approach followed in this work.

In addition, it must be considered that tracks do not follow perfectly the ideal geometry. The alignment irregularities are an essential ingredient for excitation of lateral vibrations of vehicles. For considering a hypothetical upper bound scenario Irregularity profiles can be generated using power spectral density functions as defined in [24]. This approach is followed in [9], [18] and also in this work. Another option is of course to employ irregularity profiles measured directly from the track, as in [17], [8] and [16].

The last ingredient for the model is the strategy for numerical solution at each time-step. An option is to integrate separately both subsystems and establish at each time-step an iteration loop for achieving force and displacement compatibility at contact points, as in [17], [9], [25] and [26]. Another option is to form a global set of coupled equations including both subsystems can be solved directly, as in [8], [16], [12], [13] and [27]. In this work the approach followed is similar to this latter option, including both subsystems within the same dynamic model, with special emphasis on the contact interface.

In the remaining of this work firstly the details of the numerical model employed will be discussed. Following, this will be applied for the Las Piedras viaduct [5] in the spanish high-speed railway Cordoba–Malaga, which has piers of 94 m and length of 1209 m. The results obtained show that, for the scenarios considered, no adverse lateral vibration effects are foreseeable.

2 NUMERICAL MODEL

The vehicle-bridge interaction system is composed of the vehicle and bridge subsystems and the contact interface between them. The model is constructed within ABAQUS simulation system [3], employing multibody capabilities for the vehicles, finite elements for the bridge, and user-developed algorithms for the compatibility between both and the contact interface.

Common cartesian coordinates are used in both subsystems: x along the bridge's longitudinal direction, z pointing upwards and y laterally. The corresponding rotations around each of these axes will be called θ_x , θ_y and θ_z (Figure 3).

2.1 Vehicle model

The vehicle is considered as a multibody system. Car body, bogies and wheelsets are considered as rigid bodies. The primary and secondary suspensions are defined using linear springs and dampers (figure 4). Anti-yaw dampers are included in the model with appropriate definition of viscoelastic properties. For the vehicle model, the following assumptions are considered:

- (A1) Small displacements are considered here (except for the wheel-rail contact interface). However this is not a limitation of the model, there is no restriction for nonlinear multibody dynamics effects should they be necessary, as a full nonlinear solution is performed at each time-step.
- (A2) The train is supposed to cross the bridge at a constant speed v .
- (A3) The train is composed of independent cars: no connection between cars is considered.
- (A4) A constant velocity v along the x axis is considered for all the bodies of each car, therefore the degrees of freedom of car-bodies and bogies are y , z , θ_x , θ_y and θ_z . For wheelsets, θ_y is prescribed as $\dot{\theta}_y = v/r_0$, being r_0 the nominal rolling radius of wheels.

Figure 3: Vehicle schema and coordinates.

Figure 4: Multibody model showing vehicle box and bogies

- (A5) The coordinates used for each of the rigid bodies are absolute inertial coordinates, not relative coordinates with respect to the bridge.

The multibody capabilities within ABAQUS program [3] are employed in this work to obtain the vehicle multibody dynamic models.

2.2 Bridge model

The bridge is modeled with finite elements through the finite element library provided within ABAQUS [3]. In general, any type of finite elements can be employed (continuum, shell, beam or truss). In this case the model has been built using 3D beam elements for the deck and the piers of the viaduct. The assumptions that have been made are:

- (A6) Small displacements and linear elastic materials are considered in this case (except for the wheel-rail contact interface). However this is not a limitation of the model, there is no restriction for nonlinear effects should they be necessary, as a full nonlinear solution is performed at each time-step.

Figure 5: Schematic representation of bridge deck and 3D beam finite elements.

Figure 6: Kinematic constraints for wheelset position on bridge deck: schema and deformed view of rigid contact surfaces

- (A7) The rails are supposed to be rigidly attached to the deck section, with the appropriate offsets and eccentricities.
- (A8) Elastic effects for rail deformation are neglected.

The points on the rails corresponding to each wheelset are derived by interpolation and kinematical constraints with the beam degrees of freedom. For this purpose, special rigid contact surfaces are defined in the finite element model, linked kinematically to the structural beams (figure 6).

2.3 Track alignment irregularities

An essential ingredient for proper consideration of the vehicle dynamic effects are the track irregularities. For this work irregularities for horizontal alignment and vertical profile were considered as these will be the most important for lateral dynamics. In order to provide probabilistic upper bounds, irregularities were generated from a power spectral density spectrum adjusted to upper bounds of deviations to be expected in the wavelength between 3 and 25 m from maintenance operations (figure 7). The procedure used here is similar to that followed in [24]

Figure 7: Profile of generated alignment irregularities and check for fit to PSD spectrum

2.4 Vehicle-bridge interaction

The final ingredient are the forces for establishing the interaction between the vehicle and the structure. This is achieved through contact models, including geometric and dynamic components. The coupled system of equations may be represented as:

$$\begin{pmatrix} \mathbf{M}^V & \mathbf{0} \\ \mathbf{0} & \mathbf{M}^B \end{pmatrix} \begin{Bmatrix} \ddot{\mathbf{X}}^V \\ \ddot{\mathbf{X}}^B \end{Bmatrix} \begin{pmatrix} \mathbf{C}^V & \mathbf{0} \\ \mathbf{0} & \mathbf{C}^B \end{pmatrix} \begin{Bmatrix} \dot{\mathbf{X}}^V \\ \dot{\mathbf{X}}^B \end{Bmatrix} \begin{pmatrix} \mathbf{K}^V & \mathbf{0} \\ \mathbf{0} & \mathbf{K}^B \end{pmatrix} \begin{Bmatrix} \mathbf{X}^V \\ \mathbf{X}^B \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}^V + \mathbf{F}_c^V \\ \mathbf{F}^B + \mathbf{F}_c^B \end{Bmatrix}, \quad (1)$$

where superscripts $(\cdot)^V$ and $(\cdot)^B$ refer to the vehicle and bridge subsystems respectively. Additionally, \mathbf{F}_c^V is the vector of forces applied on the vehicle as a consequence of the interaction with the structure, and \mathbf{F}_c^B , on the structure, which will be computed from the vehicle and bridge displacements, velocities and time. The components of the contact forces are described in Section 2.5.

Equation (1) will be solved directly in time using the HHT Method [28], which is an implicit algorithm. The tangent matrices of contact forces are needed for the numerical solution:

$$\mathbf{K}_c = \frac{d\mathbf{F}_c}{d\mathbf{X}}, \quad \mathbf{C}_c = \frac{d\mathbf{F}_c}{d\dot{\mathbf{X}}}, \quad (2)$$

where $\mathbf{F}_c = (\mathbf{F}_c^V, \mathbf{F}_c^B)^T$. The expressions of the tangential forces applied in this work do not have analytical derivatives and hence the tangent matrices are computed using numerical jacobians.

2.5 Nonlinear contact forces

The wheel-rail contact forces are developed in this Section. Considering some assumptions, that are exposed below, this problem can be split in three main parts:

Geometric problem: it consists on computing the main geometric variables which depend on the relative displacements between wheel and rail.

Normal problem: considering the geometric variables obtained before, the contact ellipse dimensions and the normal stress distribution is calculated using the Hertz theory [19].

Tangential problem: the tangential forces, which depend on the contact geometry, normal stresses and relative velocities between wheel and rail, are computed.

According to [22], if the wheel and rail materials have the same mechanical properties, the three problems can be studied separately: geometric problem is solved firstly, normal problem secondly and tangential problem thirdly.

2.5.1 Geometric contact problem

For obtaining the main geometric variables of the contact problems several assumptions are made:

- (A9) Separations between wheel and rail are not allowed.
- (A10) The wheel-rail contact appears only in one area.
- (A11) Only rigid body movements perpendicular to x axis are considered for the wheelset and the track.

Considering that the distance between two wheelset of the same wheelset is $2d_W$, the geometric variables can be computed as a function of only variable: the lateral displacement of the wheelset relative to the track Δy_W . These geometric variables for wheels A and B (Figure 9) are (see Figure 8):

- r_A and r_B : the rolling radii of both wheels at the contact point.
- γ_A and γ_B : the angle between horizontal and contact plane (the plane where the contact ellipse is contained).
- k_A^a, k_A^b, k_B^a and k_B^b : ellipse dimension coefficients that depend on the curvatures of wheel and rail in the two main directions at the contact point (see [19]). a is the ellipse semiaxis along x_c , and b along y_c .
- $\Delta \hat{z}_W$ and $\Delta \hat{\theta}_{x,W}$: relative vertical displacement and rotation between the wheelset and the track, considering only geometric conditions.

Figure 8: Main variables of the contact geometry.

In this article, realistic wheel and rail profiles are considered (biconic profiles are avoided), due to that, when the relative lateral displacements of the wheelset respect to the track are small, the variation of the previous variables is linear. However, when the displacements become

larger, contact between the flange of the wheel and the rail occurs, and the variation becomes nonlinear.

The relative displacements of the wheelset of vehicle respect to the track are:

$$\Delta y_W = y_W - y_T^B(x), \quad (3a)$$

$$\Delta z_W = z_W - z_T^B(x), \quad (3b)$$

$$\Delta \theta_{x,W} = \theta_{x,W} - \theta_{x,T}^B(x), \quad (3c)$$

$$\Delta \theta_{z,W} = \theta_{z,W} - \theta_{z,T}^B(x), \quad (3d)$$

being y_W , z_W , $\theta_{x,W}$ and $\theta_{z,W}$ the absolute displacements and rotations of the wheelset.

2.5.2 Normal contact problem

The Hertz theory [19], for solving the shape and dimensions of the contact surface and the normal stress distribution, take into consideration the following assumptions:

- (A12) At contact point, contact surfaces are continuous and nonconformal.
- (A13) No plastic deformation is considered and strains are supposed to be small and elastic.
- (A14) Stresses are neglected far from contact point.
- (A15) Friction between surfaces does not affect to normal problem.
- (A16) Quadratic functions of two variables can be used to define the wheel and rail surfaces near to contact point.

With these assumptions, contact area is considered an ellipse and normal stress distribution an ellipsoid.

The ellipse semiaxes can be computed as:

$$a^k = k_k^a(\Delta y_W) \left(\frac{1-\nu}{G} N^k \right)^{1/3} \quad (4a)$$

$$b^k = k_k^b(\Delta y_W) \left(\frac{1-\nu}{G} N^k \right)^{1/3} \quad (4b)$$

where $k = \{A, B\}$, G is the shear stress modulus, ν the Poisson coefficient of wheels and rails and N^k the contact normal force in wheel-rail pair (it is explained below how to compute these normal forces). The coefficients k_k^a and k_k^b , which depend on Δy_W , are computed before the calculation and depend on the main curvatures of wheel and rail at contact point (see [4]).

2.5.3 Tangential contact problem

In this problem the tangential contact forces are computed. They appear as a consequence of a rolling and sliding motion between wheels and rails. In each point of the contact surface the shear stress value can not be greater than the normal stress times friction coefficient. Thus, in the contact ellipse adhesion and slip areas could appear.

The main variables of the tangential contact are the creepages, which are defined as the non dimensional relative velocities between wheel and rail. ζ_x^k , ζ_y^k and ζ_R^k are, respectively, longitudinal, lateral and rotational creepages of wheel-rail pair k and can be expressed as:

$$\zeta_x^k = 1 - \frac{r_k}{r_0} \pm \frac{\Delta \dot{\theta}_{z,W}}{v} d_W \quad (5a)$$

$$\zeta_y^k = \frac{1}{v} [(\Delta \dot{y}_W + \Delta \dot{\theta}_{x,W} r_k) \cos \gamma_k + (\Delta \dot{z}_W \pm \Delta \dot{\theta}_{x,W} d_W) \sin \gamma_k] \quad (5b)$$

$$\zeta_R^k = -\frac{\sin \gamma_k}{r_0} \quad (5c)$$

where the upper sign of \pm and \mp in the above equations corresponds to the wheel-rail pair A , and the lower, to B (see Figure 9).

Depending on the assumed hypothesis, different methods for solving tangential contact exist. The Kalker Variational Method [22] is a very accurate method for computing tangential forces, however, due to it is computationally very expensive, it can not be applied in an analysis like that. The USETAB approximation [23], proposed by Kalker, is used in this work. This method obtains the tangential forces in a pre-calculated table whose input variables are the contact normal force, the ellipse semiaxes, the friction coefficient and the creepages, and the output variables are the tangential forces in longitudinal T_x^k and lateral T_y^k local directions and moment around normal direction M_z^k . The values of this table have been computed using the Kalker Variational method for different values of the input variables.

2.5.4 Vehicle-structure interaction forces

As it has been seen above, vertical relative displacement Δz_W and relative rotation $\Delta \theta_{x,W}$ can be computed as geometric variables, without regard to dynamic aspects. Thus, the relative displacements computed as geometric variables and those obtained from the dynamic response of vehicle and structure must be equal:

$$\Delta z_W = \Delta \hat{z}_W(\Delta y_W), \quad (6a)$$

$$\Delta \theta_{x,W} = \Delta \hat{\theta}_{x,W}(\Delta y_W). \quad (6b)$$

For imposing these constraints, a penalty force and moment are introduced in wheelsets gravity centre:

$$F_c^z = k_z (\Delta \hat{z}_W(\Delta y_W) - \Delta z_W)^{3/2}, \quad (7a)$$

$$M_c^x = k_\theta (\Delta \hat{\theta}_{x,W}(\Delta y_W) - \Delta \theta_{x,W})^{3/2}. \quad (7b)$$

These nonlinear penalty expressions derive from the approach expression between two bodies of the Hertz theory. Stiffness coefficients k_z and k_θ depend on Δy_W and N_W^k , but in order to simplify the equations, they are computed considering only the train own weight in a static case and $\Delta y_W = 0$.

The forces applied on the wheelset gravity centre, shown in Figure 9, can be written as:

$$F_c^y = -N^A \sin \gamma_A + T_y^A \cos \gamma_A - N^B \sin \gamma_B + T_y^B \cos \gamma_B, \quad (8a)$$

$$F_c^z = N^A \cos \gamma_A + T_y^A \sin \gamma_A + N^B \cos \gamma_B + T_y^B \sin \gamma_B, \quad (8b)$$

$$M_c^x = \left(-N^A \cos \gamma_A - T_y^A \sin \gamma_A + N^B \cos \gamma_B + T_y^B \sin \gamma_B \right) d_W + \left(T_y^A \cos \gamma_A - N^A \sin \gamma_A \right) r_A + \left(-N^B \sin \gamma_B + T_y^B \cos \gamma_B \right) r_B, \quad (8c)$$

$$M_c^z = \left(T_x^A - T_x^B \right) d_W + M_z^A \cos \gamma_A + M_z^B \cos \gamma_B. \quad (8d)$$

Using equations (7), (8b) and (8c), normal forces N^A and N^B , which are needed to compute the tangential forces and moments, can be obtained and applied to compute the values of F_c^y and M_c^z . Thus, the equation set (8) is nonlinear and, in order to solve a linear system, as it is proposed in [14], the normal forces computed in the previous time step are used for computing the tangential forces in the current time step. Before obtaining F_c^y and M_c^z , the contact forces T_y^A , T_x^B , T_y^B and moments M_z^A and M_z^B must be computed using normal forces of the previous time step and the creepages of current step.

3 Application

3.1 Models for viaduct “Arroyo las Piedras”

The above numerical model has been applied to a bridge representative of the type discussed in this work, the “Arroyo las Piedras” viaduct, in operation in the Córdoba–Málaga high speed line. The viaduct is a double-track composite steel-concrete continuous deck beam, supported on concrete piers with pot-type bearings. The spans of the deck are of 65 m, and the section has upper and lower concrete slabs performing a so-called double composite action, with adequate torsional stiffness. The tallest piers are of 94 m height. The first natural frequency of this viaduct is 0.313 Hz and corresponds to a lateral deformation mode (figure 1). More complete details of the structure may be seen in [5].

As described above, the model for the viaduct is based on 3D beams with appropriate kinematic constraints. The Rayleigh method has been used for the damping matrix of the structure subsystem, with a 0.5% damping centered in the two first natural frequencies. The train that has been used in the calculations is an approximation of the Siemens ICE 3 composed of 8 cars, each of 24.775 m length. The ICE3 is a distributed power train, and, for that reason, all cars are supposed to have the same geometrical and mechanical properties.

Calculations have been carried out for train speeds of 250, 300 and 350 km/h, in several different models:

Figure 9: Wheelset equilibrium.

- (1) *Bridge only model with moving loads*, consisting only of the bridge dynamic subsystem, with the vehicle wheelsets simplified as moving loads of fixed magnitude. This amounts to neglecting the dynamic effects of vehicle vibration, and serves as a basic result with which to compare the influence of the vehicle vibration on the results. It also serves the purpose of obtaining a so-called *virtual path* for the wheelsets of the vehicles, which can be later applied to these in a decoupled approach to the vehicle-bridge dynamics: the bridge history of displacements is obtained in a first step, and these histories are then applied in a second step to the vehicle wheelsets to obtain the response of the train.
- (2) *Vehicle model*, consisting only of the vehicle subsystem, in two different scenarios:
 - (a) Vehicle on rigid platform (i.e. no bridge) with prescribed profiles of irregularities. This model will enable to compare the influence of the bridge deformation on the vibrations of the vehicle.
 - (b) Vehicle on *virtual path*, as described above, this path results from previous analysis of the bridge with moving loads. The geometric track irregularities are added to the *virtual path* in order to consider their effect on the vehicle.
- (3) *Bridge-Vehicle model*, performing the calculation for the global system with the wheel-rail contact interaction. In this case, two scenarios have been considered:
 - (a) Model with interaction but without track irregularities
 - (b) Model with interaction and with track irregularities

3.2 Results for bridge and vehicle response

Following we show only the results for train speed of $v = 350$ km/h, as they correspond to the greatest effects. Firstly we present results for the deformation of the bridge deck. The displacements and rotations at the center of span 11, corresponding to the tallest pier, are shown in figure 10. These correspond to the three different scenarios defined in section 3.1, the cases enumerated as 1, 3a and 3b. It may be clearly seen that the influence of the vehicle vibration and of the track irregularities on the bridge deformation is negligible. It is also seen that these deformations are small, with maximum lateral displacement of 9 mm, which for a viaduct of 1209 m length is very small.

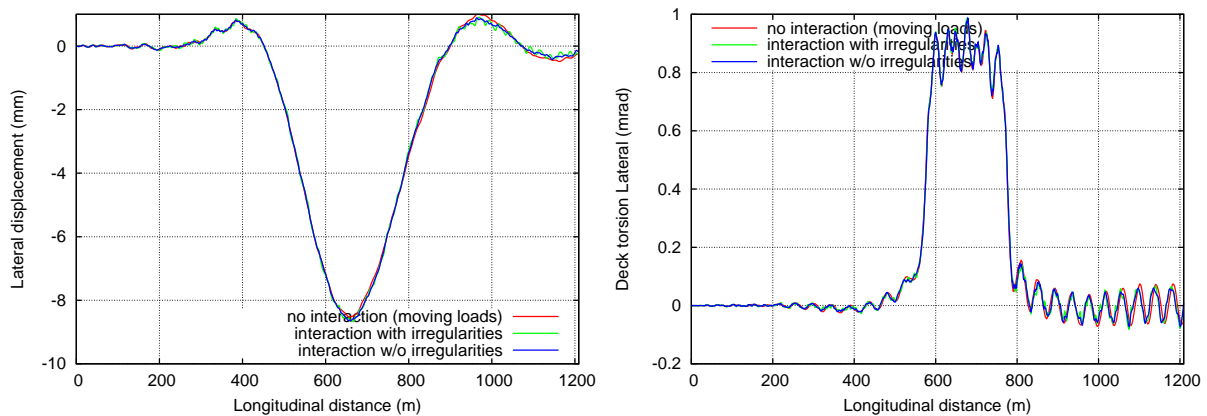

Figure 10: Displacements and torsional rotation of bridge deck at center of span 11, $v = 350$ km/h.

Regarding the response of the vehicle, the accelerations of vehicle body on coach 4 are shown in figure 11. Four scenarios are shown, as defined in section 3.1, the cases enumerated as 2a, 2b, 3a and 3b. Maximum accelerations experienced are in the order of $0.2 - 0.3 \text{ m/s}^2$. First we remark that very clearly irregularities are the main cause responsible for vehicle vibrations, as in the case 2a accelerations are negligible compared to other cases with irregularities. In other words, the vehicle body accelerations attributable to deformation of the bridge are of the order of 0.05 m/s^2 . In figure 12 the lateral loads exerted by one of the wheels of the vehicle on the rail are shown. These achieve maximum values of the order of 15 kN.

4 CONCLUSIONS

The following remarks are concluded from the above work:

- Lateral dynamic effects in tall and long railway viaducts are an important issue with high lateral compliance must be studied in order to consider adequately the safety of the traffic.
- In this paper a model considering the dynamics of the bridge, the vehicle and the geometric and dynamic aspects of wheel-rail contact has been developed and validated. This model includes multibody subsystems for the vehicles, a structural finite element subsystem for the viaduct, and a specially developed wheel-rail contact interface between them.
- The case of HS viaduct on “Arroyo las Piedras” [5] has been studied as a representative case. The loading considered includes only the vertical effects from the traffic, considering track alignment irregularities, but not other possible actions such as lateral wind or earthquake. For the cases studied it is shown that the lateral effects on the viaduct are small and do not compromise in any way its safety.
- The lateral vibration of the vehicle is originated mainly from the assumed irregularities of the track, with a small contribution from the bridge deformation and interaction. The level of acceleration obtained as well as the loads transmitted by vehicle wheels to the rails are small and well within acceptable limits.
- The above procedure could be applied to evaluate realistically the effect of high lateral winds on the vehicles as they traverse the viaduct, as well as the earthquake actions.

Keywords: Railway tracks, Dynamics, Precast slabs

Abstract. *As far as slab tracks are concerned, UIC [1] considers seven different families of structures, regarding the type of slab supporting (punctual or continuous), the construction method (in situ or precast), the number of resilient levels and also the type of the foundation material (plain concrete or bituminous material).*

This paper begins with a brief description of precast slab systems currently available for high-speed railway lines. A research work on the dynamic behavior of precast slab tracks is being undertaken in order to identify the dynamic effects of high-speed traffic in this type of systems. In this paper some of the results attained so far in the numerical calculations are presented and discussed. Calculations are performed in 2D with the finite element program Ansys, considering several vehicle speeds and also different types of vehicle models. The dynamic response of the track is evaluated in terms of track displacement, force at the fastening systems, bending moment on the slab and also on the support concrete layer. Also the influence of the track foundation and the track geometrical quality on its response is studied.

1 INTRODUCTION

According to the Technical Specification for Interoperability (TSI) relating to the infrastructure [2], there are three types of high speed railways: new lines for speed higher than 250 km/h; specially upgrade lines for speed higher around 200 km/h; new or upgrades lines with technical constraints.

In general, railway tracks can be categorized in ballasted systems and ballastless or slab systems. Nowadays, there are two currents of opinion on the track concept for high speed railway lines. The first one defends the ballasted track -the traditional permanent-way. The second current considers that slab tracks can meet the exigent demands of a modern railway track for high speed lines with reduced maintenance actions.

As far as slab tracks are concerned, UIC [1] considers seven different families of structures, regarding the type of slab supporting (punctual or continuous), the construction method (in situ or precast), the number of resilient levels and also the type of the foundation material (plain concrete or bituminous material), which are:

1. systems without punctual fixing of the rail;
2. systems with punctual fastening of the rail and independent stretches of rail;
3. systems with punctual fastening of the rail on sleepers incorporated in structure by infill concrete;
4. systems with punctual fastening of the rail on sleepers incorporated in structure by vibration;
5. systems with punctual fastening of the rail on sleepers laid and anchored on a supporting structure;
6. systems with punctual fastening of the rail on sleepers separated from supporting structure by a resilient level;
7. systems with punctual fastening of the rail on prefabricated slabs.

Currently commercial prefabricated slabs present a wide variety of dimensions, materials and configurations. These prefabricated slabs may be reinforced or prestressed into which fastening systems and rails are incorporated.

Figures 1 to 3 present the most known precast slabs used in high speed railways lines: the Bogl, the OBB-Porr and the Shinkansen systems.

Figure 1: Bogl system

Figure 2: OBB-Porr system

Figure 3: Shinkansen system

The Bogl system (Figure 1) consists in prestressed slabs in the transversal direction fixed with spindles on a stabilised layer in the earthworks case, on a tunnel base or on a bridge deck [3]. The OBB-Porr system (Figure 2) is a conventionally-reinforced precast concrete slab with two rectangular openings from where concrete is introduced during construction in the site. This concrete block ensures the transfer of forces in the horizontal direction. The joints between adjacent slabs are no filled. The Shinkansen system (Figure 3) is used by the Japanese National Railways and it has provided excellent performance by maintaining track geometry and reducing maintenance costs of the track. The geometrical configuration of this system is more complex than the two previous ones, because of the slab geometry and also because of the existence of stoppers between adjacent slabs. Complete descriptions of these precast systems and others (in situ) slab systems may be found in [1, 3, 4, 5].

2 VEHICLE TRACK INTERACTION MODEL

In general, the simulation of train-track interaction implies that the whole system is divided into two subsystems, the vehicle and the track, and between them a physical wheel-rail contact. Until recently the behavior of these dynamic subsystems were investigated separately but the increase of train speed demands a better understanding of the dynamic phenomena, considering the vehicle and the track together as an unique system. In the present study a time domain methodology is adopted to calculate the interaction forces between the wheel and the rail and the track vibrations, in the vertical direction.

2.1 Vehicle model

Assuming loading to be symmetrically distributed on the two rails, 2D models can be adopted to represent the vehicle, such as the models presented in Figures 4 to 6.

Figure 4: Quarter bogie model

Figure 5: Two independent quarter bogie model

Figure 6: Half bogie model

In all these models, the vehicle is characterized by the wheel and the bogie masses and by the primary suspension represented by a linear spring in parallel to a dashpot. The two independent quarter bogie model (Figure 5) and the half bogie model (Figure 6) allow to consider the superposition of the action of the two bogie axles in the track response. In the half bogie model, the two axles are connected by the bogie, which is more realistic than the two independent quarter bogie model.

2.2 Track model

A rail track is a complex structure and in the case of slab track it is composed by rails, pads, sleepers, slab, concrete support layer and foundation.

To represent the precast slab track in study the model indicated in Figure 7 may be used. The rail is modeled as a continuous beam discretely supported on sleepers. The fastening systems and the pads are represented by springs in parallel with dashpots; theirs masses are disregarded. The slab and the concrete support layer are modeled by plain stress finite elements. The foundation is modeled by distributed springs in parallel to dashpots with no interaction between them (Winker foundation with damping). The joint between adjacent slabs are filled with an elastic material with the same mechanical characteristics of the interface layer between the slab and the concrete support layer.

Figure 7: Track model

2.3 Contact model

The contact interaction force between the wheel and the rail is determined by the contact theory. For normal contact between two bodies with no tangential forces and at the contact area, the nonlinear Hertzian model is usually adopted. According to the Hertz model, the interaction

(contact) load is given by Equation (1):

$$F = \begin{cases} C_H(x - y - \bar{r})^{3/2} & \text{if } x - y - \bar{r} \geq 0 \\ 0 & \text{if } x - y - \bar{r} \leq 0 \end{cases} \quad (1)$$

where x is the wheel vertical displacement; y is the rail displacement; \bar{r} , the rail profile; C_H , the Hertzian stiffness.

However a linearized model can be adopted when the variation of the dynamic load is not considerable. In this situation, the linearized stiffness can be evaluated by Equation (2):

$$k_H = \frac{dF}{d\delta} = \frac{3}{2}C_H\delta^{1/2} = \frac{3}{2}C_H(F/C_H)^{1/3} = \frac{3}{2}C_H^{2/3}F^{1/3} \quad (2)$$

where: $\delta = x - y - \bar{r}$ is the relative displacement between the wheel and the rail; F is the load adopted for the linearization.

3 NUMERICAL ANALYSIS

In this section of the paper, the dynamic response of a precast tracks is evaluated in order to study:

- the influence of the vehicle model and the train speed;
- the influence of the mechanical characteristics of the interface layer between the slab and the concrete support layer;
- the influence of the track foundation;
- the influence of the slab dimension;
- the influence of the geometrical quality of the track.

The numerical assumptions considered for calculations are:

- 2D track model;
- track composed by 20 slabs;
- segment track in a straight alignment;
- ICE 2 train;
- train speed varying from 200 to 420 km/h in steps of 20 km/h.

In all calculations, except for the analysis of the influence of slab dimension on the track response, the total length of the model is $20 \times 5.15 \text{ m} = 104.0 \text{ m}$.

3.1 Track and train characteristics

In Table 1, the characteristics of the track are presented. Usually the foundation is characterized by the elastic modulus and the Poisson coefficient. To define the foundation stiffness and damping parameters to include in the track model the methodology proposed by Vale et al. [6] is used.

Component	Type of element	Parameter
Rail UIC 60	Euler Bernoulli beam	$E = 210 \text{ GPa}; I = 3055 \text{ cm}^4$; $\nu = 0.3; A_t = 76.84 \text{ cm}^2$; $\rho = 60.34 \text{ kg/m}$
Pad + fastening system	spring and dashpot in parallel	$k_p = 40 \text{ kN/mm}$; $c_p = 8 \text{ kNs/m}$
Prefabricated slab	plain stress finite elements	$E = 34 \text{ GPa}; \nu = 0.2$; $H_s = 0.24 \text{ m}; L_s = 5.15 \text{ m}$; $W_s = 2.8 \text{ m}; \rho = 2500 \text{ kg/m}^3$
Interface layer	plain stress finite elements	$E = 300 \text{ MPa}; \nu = 0.3$; $H_i = 0.06 \text{ m}; L_i = 104 \text{ m}$;
Joint	plain stress finite elements	$E = 300 \text{ MPa}; \nu = 0.3$; $w = 0.05 \text{ m}$;
Concrete support layer	plain stress finite elements	$E = 10 \text{ GPa}; \nu = 0.3$; $H_c = 0.30 \text{ m}; L_c = 104 \text{ m}$; $W_c = 3.4 \text{ m}; \rho = 2500 \text{ kg/m}^3$
Foundation	Winkler foundation	$k_f = 50 \text{ kN/mm}$; $c_f = 492 \text{ kNs/m}$

Table 1: Mechanical and geometrical properties of the track elements

In this Table, E is the elasticity modulus; I , the moment of inertia; ν , the Poisson coefficient; A_t , the area of the transversal section of the rail; ρ , the density; k_p , the stiffness of the pad; c_p , the damping of the pad; H_s , the thickness of the precast slab; L_s , the longitudinal length of the slab; W_s , the width of the slab; H_i , the thickness of the interface layer; L_i , the longitudinal length of the interface layer; w , the width of the joint; H_c , the thickness of the concrete support layer; L_c , the longitudinal length of the concrete support layer; W_c , the width of the concrete support layer; k_f , the stiffness of the foundation; c_f , the damping of the foundation.

The vehicle characteristics are indicated in Table 2.

Bogie	Mass - M_b [kg]	5600
Primary suspension	Stiffness - k_1 [N/m]	2.40×10^6
	Damping - c_1 [Ns/m]	5.4×10^4
Wheel	Mass - M_r [kg]	1001.5
	Axle load - P [N]	0.981×10^5

3.2 Results and discussion

3.2.1 Influence of the vehicle model and the train speed

For studying the influence of the vehicle model and the train speed, the response of a perfect track is evaluated for train speeds varying from 220 to 420 km/h in steps of 20 km/h and considering the three vehicle models indicated in Section 2.1.

In Figures 9 and 10, the maximum vertical displacement in the rail and in the slab are presented for the three models together with the results attained with the complete load model of the ICE2 train (Figure 8).

Figure 9: Maximum vertical displacement in the rail for different vehicle model and train speed

Figure 10: Maximum vertical displacement in the slab for different vehicle model and train speed

The maximum moments in the slab is presented in Figure 11, for the same scenarios.

Figure 11: Maximum moments in the slab for different vehicle model and the train speed

The results presented in Figures 9 to 11 show that the quarter bogie is insufficient to represent the correct response of the track due to the passage of the bogie, because the load of the quarter bogie model is 1/2 to the load of the half bogie model and also because the influence of the wheel spacing of the same bogie is relevant in this type of track models. Although the moving load model gives similar response to the ones attained with the two quarter bogie and the half bogie models, the moving load model is no suitable in the case of track with irregularities. In this analysis the results are similar for these three vehicle models, because the track has no irregularity.

Based on these results the following calculations are performed considering the half bogie model.

3.2.2 Influence of the interface characteristics between the slab and the concrete support layer

For the analysis of the influence of the characteristics of the interface layer between the slab and the concrete layer, elastic modulus varying from 0 to 10000 MPa with $\nu = 0.5$. The simulation of a sliding interface between the slab and the underlying concrete layer corresponds to an elastic modulus equal to zero with a Poisson coefficient equal to 0.5. In this study, a vehicle speed of 360 km/h is adopted. Although the value of the Poisson coefficient ($\nu = 0.5$) is different from $\nu = 0.3$, the value indicated in Table 1 and used for the other parametric analysis, this fact does not influence the system elasticity for the numerical application presented here, as Figures 12 and 13 show.

Figure 12: Rail displacement over the slab

Figure 13: Rail displacement over the joint

In Figures 14 and 15, the maximum dynamic loads at the front and at the rear vehicle axles are presented for different elastic modulus of the interface layer.

Figure 14: Maximum dynamic load at the front axle

Figure 15: Maximum dynamic load at the rear axle

These figures show that the maximum dynamic load is independent of the interface elastic modulus. However, the elastic properties of the interface layer between the slab and the concrete layer may influence the track dynamic behavior.

In Figures 16 to 21, the maximum track response in terms of vertical displacement in the rail, in the slab and in the concrete sub-base are presented for an increasing interface elastic modulus.

Figure 16: Maximum vertical displacement in the rail over the middle point of the slab

Figure 17: Maximum vertical displacement in the rail over the joint between slabs

Figure 18: Maximum vertical displacement in the middle point of the slab

Figure 19: Maximum vertical displacement in the edge of the slab

Figure 20: Maximum vertical displacement in the concrete support layer under the middle point of the slab

Figure 21: Maximum vertical displacement in the concrete support layer under the joint between slabs

The results evidence that the vertical displacement of the rail decreases with the increase of the elastic modulus of the interface layer. Varying this elastic modulus from zero to 10000 MPa, the decrease of the slab vertical displacement is around 33-37% and the vertical displacement of the concrete support layer is slightly lower, around 10-12% (Figures 18 to 21). For elastic modulus of the interface higher than 1000 MPa, the displacements of the track elements tend to a constant value.

Figure 22 shows that increasing the interface elastic modulus also the maximum dynamic force in the fastening increases with a decreasing rate.

Figure 22: Maximum dynamic force in the fastening systems

Figure 23 and 24 present the maximum bending moments in the rail and in the slab for different characteristics of the interface material.

Figure 23: Maximum moment in the rail

Figure 24: Maximum moment in the slab

The moments in the rail and in the slab decrease with the increase of the elastic modulus of the interface layer. In the rail the reduction is insignificant ($\approx 2\%$); in the slab the reduction of the moments is considerable (around 82%).

3.2.3 Influence of the track foundation

Figures 25 and 26 present, respectively, the maximum vertical displacements in the rail and in the slab, for a vehicle speed of 360 km/h and for four elastic modulus of foundation: 50, 80, 130 and 200 MPa.

Figure 25: Maximum vertical displacement in the rail

Figure 26: Maximum vertical displacement in the slab

The maximum moments in the rail and in the slab for the same traffic and foundation scenarios are shown in Figures 27 and 28.

From the Figures, the increase of the elastic modulus of the foundation causes a reduction of the maximum values of displacements and bending moments on both the rail and the slab. The influence of the foundation characteristics is more pronounced in the slab than in the rail.

Figure 27: Maximum moments in the rail

Figure 28: Maximum moments in the slab

In Figure 29, the percentage of the global displacement in each one of the track elements is presented for different elastic modulus of the foundation. As it can be seen, the displacement of the concrete support layer decreases with the increase of the elastic modulus of the foundation.

Figure 29: Percentage of displacement in the track elements for different elastic modulus foundation

3.2.4 Influence of the slab dimension

In this paper, the influence of the slab dimension is analyzed for a vehicle speed of 360 km/h. In calculations the width of the slab is considered to be constant (2.4 m). The length of the slab varies between 3.2 and 7.75 m in steps of 0.65 m.

Figures 30 and 31 illustrate that the length of the slab do not influence significantly the maximum vertical displacement of the rail and the slab.

Figure 30: Maximum vertical displacement in the rail

Figure 31: Maximum vertical displacement in the slab

From figure 32, increasing the length of the slab, the moments in this track element also increase, which shows that bigger slabs behave almost as continuous elements.

Figure 32: Maximum moments in the slab

3.2.5 Influence of the geometrical quality of the track

Although slab tracks may present a low level of irregularities, in this research the influence of the geometrical quality of the track on its response is also evaluated for train speeds from 220 to 420 km/h.

In Figure 33, the longitudinal level adopted in calculations is indicated. This track profile presents a standard deviation of 1.25 mm, which is near the alert limit for preventive maintenance according to the European Standard EN 13848-5 [8] for wavelengths between 3 and 25 m.

Figure 33: Longitudinal level of the track

The dynamic load for perfect and rough track is presented in Figure 34 together with the static load.

Figure 34: Static load and dynamic load for perfect and rough track

The results reveal that dynamic load in the track is higher in a rough track than in a perfect one and the ratio between these two dynamic loads increase with the increase of the train speed.

4 CONCLUSIONS

A numerical study on the dynamics of a precast track for high speed railways is presented in order to evaluate in the track response the influence of the vehicle model and the train speed, the influence of the interface characteristic between the slab and the concrete support layer, the influence of the track foundation elastic properties, the influence of the slab dimension and also the influence of the track geometrical quality. Calculations are performed in 2D, with Ansys software, in the time domain, considering no dynamic interaction between the wheel of the ICE 2 and the rail (load model) and dynamic interaction between these two elements. For second case, three vehicle models are used: the quarter bogie model, two independent quarter bogie model and half bogie model.

The results show that:

- the half bogie model is the most suitable simplified vehicle model to be used when assessing numerically in 2D the dynamic behavior of slab tracks composed by precast elements;
- the characteristics of the interface layer between the precast slab and the concrete support layer mainly influence the slab response;
- the rail displacements and bending moments are higher over the slab joint than in the middle point of this element;
- the vertical displacement of the concrete support layer decreases with the increase of the elastic properties of the foundation;
- the elastic properties of the foundation strongly influence the slab response in terms of displacements and bending moments;
- the influence of the slab length in the track response seems to be insignificant;
- the track irregularity induces higher dynamic loads on the track, that increase with the vehicle speed.

In the authors' opinion, more numerical and experimental research is needed on this topic for a better understanding of precast systems for high speed railway lines.

Abstract. *The dynamic vehicle-track-bridge-soil interaction is studied on high speed lines. The analysis is carried out using a general and fully three dimensional multi-body-finite element-boundary element model, formulated in the time domain to predict vibrations due to the train passage over the bridge. The vehicle is modelled as a multi-body system, the track and the bridge are modelled using finite elements and the soil is considered as a homogeneous half-space by the boundary element method. Usually, moving force model and moving mass model are employed to study the dynamic response of bridges. In this work, the multi-body system allows one to consider the quasi-static and dynamic excitation mechanisms. Soil-structure interaction is taken into account on the dynamic behaviour on simply-supported short span bridges. The influence of soil-structure interaction is analysed in both resonant and non-resonant regimes.*

1 INTRODUCTION

Resonance phenomenon on railway bridges occurs when the loading frequency is close to a multiple of a natural frequency of the structure. In short-span bridges, actual operation velocity could be higher than resonance velocities. In that case, high level vibrations reached on resonance regime can result in problems to the security, passenger comfort and track stability. Therefore, the dynamic behaviour of railway bridges becomes an important design issue. Bridge behaviour is influenced by many factors such as the axle load, successive load passage and track irregularities. These effects are evaluated by dynamic amplification factors on railway bridge standards, which represent the amplification in the dynamic response in relation with the static response for a single moving load [1]. However, the dynamic amplification factors do not account for the resonance effects and its use is limited to trains speed below 220 km/h. In other cases, it is required further analysis.

References about the dynamic response of railway bridges are quite extensive. Frýba [2] presented a theoretical model of a bridge using the integral transformation method. An estimation of the amplitude of the free vibration was given. Li et al. [3] investigated the influence of the vehicle-bridge interaction on resonant vibrations. They concluded that the maximum response in resonant regime is reached at the first resonance velocity. Ju et al. [4] suggested a three-dimensional finite element model to study resonant effects on multi-span bridges, concluding that loading frequencies and natural frequencies of bridges should be as different as possible to avoid resonance phenomenons. Xia et al. [5] investigated the resonance mechanisms and conditions of train-bridge system, analysing the resonant regimens according to their excitation mechanisms.

One of the first steps in the study of railway bridge vibrations is to develop an accurate model of the induced force by the train. Different vehicle-bridge interaction models have been used: moving load model, moving mass model and moving oscillators models. The moving force model is the simplest vehicle-bridge interaction model. The model can be used if the train speed is low enough to neglect its inertia. The model has been widely employed by the scientific community [6, 7, 8, 9]. Most sophisticated model is the moving mass model. This model takes into account the mass of the vehicle, but the model does not consider the effect of the suspension. Finally, comprehensive moving oscillator models have been used by several authors [3, 4, 5, 10, 11]. Pesterev et al. [10] examined the asymptotic behaviour of the moving oscillator for large and small values of the suspension. For infinite spring stiffness, the moving oscillator model is not equivalent to the moving mass model. Liu et al. [11] studied under which conditions dynamic train-bridge interaction must be considered for the dynamic analysis of railway bridges. They have concluded that the dynamic vehicle-bridge interaction is more important for large train-bridge mass ratio. Li and Su [3] established that the dynamic vehicle-bridge interaction leads a lower level dynamic response of the bridge than the moving force model.

The number of publications about the influence of soil-structure interaction (SSI) on railway bridges vibrations is reduced. Takemiya et al. [12, 13] studied the soil-foundation-bridge interaction under moving loads using a dynamic substructure method in the frequency domain. Recently, Ülker-Kaustell et. al [14] presented a qualitative analysis of dynamic the soil-structure interaction on a frame railway-bridge. That work is based on Takemiya's work.

In this work, a three dimensional numerical model is developed to study vehicle-track-structure-soil interaction (Fig. 1). The numerical model is based on the three dimensional finite element and boundary element formulation in the time domain. The articulated train con-

figuration is modelled as a multi-body system. Therefore, quasi-static and dynamic excitation mechanisms are considered.

Figure 1: Vehicle-track-structure-soil interaction.

The outline of this papers is as follows. First, the numerical model is presented, including a brief summary of finite element and boundary element time domain formulation, and the multi-body model used to represent the vehicle-track-structure-soil interaction. Second, the influence of soil-structure interaction on the dynamic properties of the bridge is analysed. Third, the contribution of the dynamic excitation mechanisms due to high speed train passage are studied. Finally, induced vibrations on a simply-supported short span bridge are computed for several train speeds. Resonant and non-resonant regimes are studied. The influence of soil-structure interaction in the vibrations of railway bridge is considered.

2 Soil-structure interaction model

The model is based on the three-dimensional finite element [15] and boundary element [16] time domain formulations.

The boundary element method system of equations can be solved step-by-step to obtain the time variation of the boundary unknowns; i.e. displacements and tractions. Piecewise constant time interpolation functions are used for tractions and piecewise linear functions for displacements. Nine node rectangular quadratic elements are used for spatial discretization. Explicit expressions of the fundamental solution of displacements and tractions corresponding to an impulse point load in a three dimensional elastic full-space can be seen in reference [17].

Once the spatial and temporal discretizations are carried out it is obtained the following equation for each time step:

$$\mathbf{H}^{nn} \mathbf{u}^n = \mathbf{G}^{nn} \mathbf{p}^n + \sum_{m=1}^{n-1} (\mathbf{G}^{nm} \mathbf{p}^m - \mathbf{H}^{nm} \mathbf{u}^m) \exp [-2\pi\alpha(n-m)\Delta t] \quad (1)$$

where, \mathbf{u}^n is the displacement vector and \mathbf{p}^n is the traction vector at the end of the time interval n , and \mathbf{H}^{nn} and \mathbf{G}^{nn} are the full unsymmetrical boundary element system matrices, in the time interval n , α is the soil attenuation coefficient and Δt is the time step. An approach based on the classical Barkan expression [18] is employed to account for the material damping in the soil; the right hand side term derived from previous steps is damped by an exponential coefficient α using a linearly increasing exponent with time.

The equation which results from the finite element method can be expressed symbolically as follows if an implicit time integration Newmark method is applied [19]:

$$\mathbf{D}^{nn} \mathbf{u}^n = \mathbf{f}^n + \mathbf{f}^{n-1} \quad (2)$$

where \mathbf{D}^{nn} is the dynamic stiffness matrix, \mathbf{u}^n the displacement vector and \mathbf{f}^n the equivalent force vector, in the time interval n .

In this paper, damping matrix \mathbf{C} is considered proportional to mass matrix \mathbf{M} and stiffness matrix \mathbf{K} :

$$\mathbf{C} = \alpha_0 \mathbf{M} + \alpha_1 \mathbf{K} \quad (3)$$

α_0 and α_1 are obtained from i^{th} and j^{th} modal damping ratios (ζ_i and ζ_j , respectively). The n^{th} modal damping ratio is [20]:

$$\zeta_n = \frac{\alpha_0}{2\omega_n} + \frac{\alpha_1 \omega_n}{2} \quad (4)$$

The i^{th} and j^{th} modes should be chosen to obtain the damping ratios for all modes that contribute at the response. If both modes have the same damping ratio ζ , it is obtained:

$$\alpha_0 = \zeta \frac{2\omega_i \omega_j}{\omega_i + \omega_j} \quad \alpha_1 = \zeta \frac{2}{\omega_i + \omega_j} \quad (5)$$

Coupling boundary element and finite element sub-regions entails satisfying equilibrium and compatibility conditions at the interface between both regions [21].

3 Vehicle model

The multi-body model used to represent the vehicle-structure-soil dynamic interaction is shown in figure 2.(a). Axles and car bodies are considered rigid parts. Primary and secondary suspensions are represented by spring and damper elements [22].

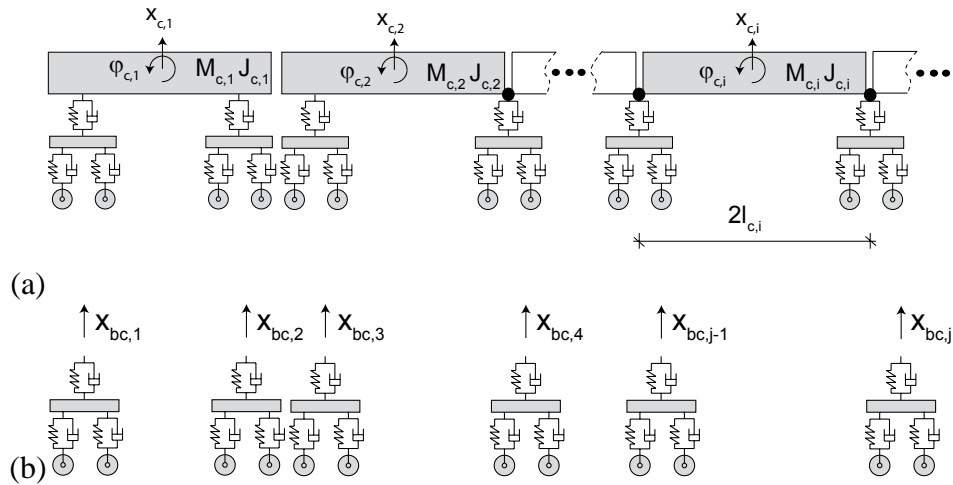

Figure 2: (a) The multi-body model for an articulated HST. (b) Uncoupled bogies.

The equations of motion for the uncoupled multi-body system shown in Fig. 2.(b) can be written as follows:

$$\tilde{\mathbf{M}}\ddot{\mathbf{x}} + \tilde{\mathbf{C}}\dot{\mathbf{x}} + \tilde{\mathbf{K}}\mathbf{x} = \tilde{\mathbf{F}} \quad (6)$$

where, $\tilde{\mathbf{M}}$, $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{K}}$ are the mass, damping and stiffness matrices, respectively. Vehicle response is described by the displacement x_c and rotation φ_c of the body, the displacement x_b and rotation φ_b of the bogies, and the displacement of the wheels x_{wr} and x_{wf} .

Figure 3: The multi-body model for a bogie.

The mass matrix of each bogie (Eq. 7) is composed of the bogie mass M_b , the bogie inertia moment J_b and wheel masses M_w :

$$\mathbf{M}_b = \text{diag} (0 \ M_b \ J_b \ M_w \ M_w) \quad (7)$$

The stiffness and damping matrices of a bogie can be written as:

$$\mathbf{K}_b = \begin{pmatrix} k_2 & -k_2 & 0 & 0 & 0 \\ -k_2 & 2k_1 + k_2 & 0 & -k_1 & -k_1 \\ 0 & 0 & 2k_1 l_w^2 & -k_1 l_w & k_1 l_w \\ 0 & -k_1 & -k_1 l_w & k_1 & 0 \\ 0 & -k_1 & k_1 l_w & 0 & k_1 \end{pmatrix} \quad (8)$$

$$\mathbf{C}_b = \begin{pmatrix} c_2 & -c_2 & 0 & 0 & 0 \\ -c_2 & 2c_1 + c_2 & 0 & -c_1 & -c_1 \\ 0 & 0 & 2c_1 l_w^2 & -c_1 l_w & c_1 l_w \\ 0 & -c_1 & -c_1 l_w & c_1 & 0 \\ 0 & -c_1 & c_1 l_w & 0 & c_1 \end{pmatrix} \quad (9)$$

where, k_1 and c_1 are the stiffness and damping of the primary suspension, k_2 and c_2 are the stiffness and damping of the secondary suspension, and $2l_w$ is the distance between axles of a bogie.

The equation of motion of the whole train can be obtained from displacement relationships between car bodies and bogies. The relationships to obtain the equation of motion of the front traction car [22] are:

$$\begin{aligned} x_{bc,1} &= x_{c,1} - \varphi_{c,1} l_c \\ x_{bc,2} &= x_{c,1} + \varphi_{c,1} l_c \end{aligned} \quad (10)$$

where, $x_{c,1}$ and $\varphi_{c,1}$ represent vertical displacement and rotation of the car body, respectively, and $2l_c$ the bogie distance in a vehicle. Similar expression can be drawn for the first passenger car (Fig. 2). The vertical displacement $x_{bc,n}$ for the m^{th} vehicle can be written as follows:

$$x_{bc,n} = 2 \sum_{i=3}^m ((-1)^{n+i} x_{c,i}) + (-1)^n (x_{c,2} + l_{c,2} \varphi_{c,2}) \quad (11)$$

The relationships for the whole train can be expressed as:

$$\mathbf{x}_{bc} = \mathbf{L} \mathbf{x}_c \quad (12)$$

Figure 4: (a) Deck cross-section. (b) Abutment geometry.

Introducing Eq. (12) into Eq. (6) lead to:

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F} \quad (13)$$

where, \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness matrices of the articulated HST (Fig. 2.(a)). The mass matrix is obtained by assembling car body mass matrix:

$$\mathbf{M}_c = \text{diag} (M_c J_c) \quad (14)$$

where M_c is the mass of the car body and J_c the inertia moment of the car body. The degree of freedom of rotation of the vehicle allows us to consider the pitch car inertia moment.

Finally, the equation of motion of the vehicle is introduced in the soil-structure interaction equation imposing equilibrium and compatibility conditions at each wheel-rail contact point. A Hertzian contact spring is considered between wheels and rails [22, 23]. As vehicle moves along the track according to its speed, contact points between wheels and rails change as time goes on. A moving node is created at each wheel-rail contact point in the rail to couple vehicles and track. So the track mesh including rail changes at each time step. Then, mass, damping and stiffness matrices vary at each time step and the obtained finite element system of equations becomes non-linear. Nevertheless, the time domain formulation allows one to solve the non-linear system of equations using, for example, the methodology presented in reference [24].

4 Dynamic behaviour of simply-supported short span bridge

In this section, the dynamic behaviour of a simply-supported short span bridge under HST passage is studied. First, the modal properties are obtained account for soil-structure interaction. Second, the quasi-static and the dynamic load contribution are studied. Finally, the dynamic response of the bridge due to HST passage is analysed taken into account soil-structure interaction.

4.1 Soil-structure dynamic interaction

In this paper a railway bridge with a single supported slab bay of 12 m is studied. The deck (Fig. 4.(a)) is composed of a 0.25 m thickness concrete slab. The slab resting over five pre-stressed concrete beams with a 0.75×0.3 m rectangular cross-section. A distance 1.39 m between beams is considered. The concrete has a density $\rho = 2500 \text{ kg/m}^3$, a Poisson ratio $\nu = 0.2$, and a Young's modulus $E = 31 \times 10^9 \text{ N/m}^2$.

The deck leans over two concrete abutments (Fig. 4.(b)) with density $\rho = 2500 \text{ kg/m}^3$, a Poisson ratio $\nu = 0.3$, and a Young's modulus $E = 20 \times 10^9 \text{ N/m}^2$. Beams resting on laminated rubber bearings. The bearings have a thickness of 20 mm and the stiffness and damping values are $k_b = 560 \times 10^6 \text{ N/m}$ and $c_{rp} = 50.4 \times 10^3 \text{ Ns/m}$.

A single ballast track is located over the deck. The track is composed of two UIC60 rails with a bending stiffness $EI = 6.45 \times 10^6 \text{ Nm}^2$ and a mass per unit length $m = 60.3 \text{ kg/m}$ for each rail. The rail-pads have a 10 mm thickness and their stiffness and damping values are $k_{rp} = 150 \times 10^6 \text{ N/m}$ and $c_{rp} = 13.5 \times 10^3 \text{ Ns/m}$, respectively. The prestressed concrete monoblock sleepers have a length $l = 2.50 \text{ m}$, a width $w = 0.235 \text{ m}$, a height $h = 0.205 \text{ m}$ (under the rail) and a mass $m = 300 \text{ kg}$. A distance $d = 0.6 \text{ m}$ between the sleepers is considered. The ballast has a density $\rho = 1800 \text{ kg/m}^3$, a Poisson ratio $\nu = 0.2$, and a Young's modulus equal to $E = 209 \times 10^6 \text{ N/m}^2$. The width of the ballast equals 2.92 m and the height $h = 0.7 \text{ m}$.

The structure is assumed to be located at the surface of a homogeneous half-space that represents a stiff soil, with a S-wave velocity $C_s = 400.0 \text{ m/s}$, a P-wave velocity $C_p = 799.4 \text{ m/s}$, and a Rayleigh wave velocity $C_R = 372.6 \text{ m/s}$.

Figure 5: Soil-structure discretization.

Fig. 6 shows the first four mode shapes, corresponding with the first bending (symmetric), the first torsional, the first bending of cross-section (symmetric) and the first antisymmetric bending deck mode shapes, respectively.

Fig. 7 shows the vertical displacement at the center of the mid-span deck due to an impulsive load $P(t) = -1 \text{ N} (H(t) - H(t - 0.045 \text{ s}))$ acting in both rails. The response is governed by the first bending (symmetric) deck mode. The same structural damping is considered for all modes that contribute significantly to the response of the structure $\zeta = 2 \%$. Damping matrix (Eq. 2) is obtained considering $\omega_i = \omega_1$ and $\omega_j = \omega_4$, being $\alpha_0 = 2.3$ and $\alpha_1 = 1.24 \times 10^{-4}$. Fig. 7 shows that the resonant frequency moves to $\tilde{f}_1 = 11.06 \text{ Hz}$ and an amplification in the response when SSI is considered. This effect is due to the additional level of flexibility between the abutments and the soil. The damping can be obtained from the free vibration response. Its value increases to $\tilde{\zeta} = 3.9 \%$ when SSI is considered.

4.2 Quasi-static and dynamic excitation mechanisms

Induced vibrations due to HST passage are generated by several excitation mechanisms: the quasi-static contribution, the parametric excitation due to the discrete support of the rails and the dynamic contribution due to wheel and rail unevenness. In this section, the different excitation mechanisms are studied.

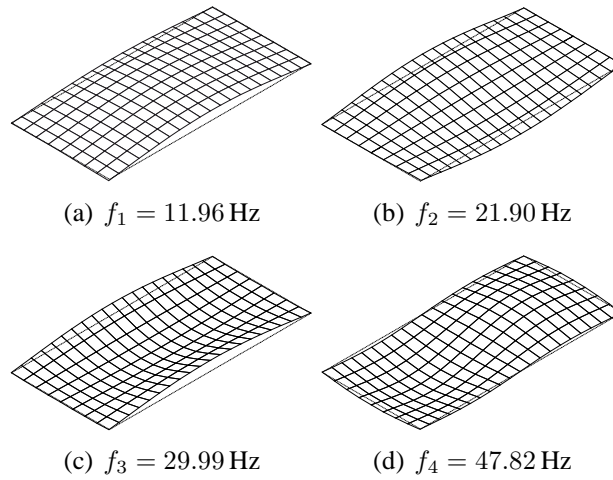

Figure 6: First four modes of vibrations of the structure.

Figure 7: Track-structure-soil and track-structure receptance

Usually, the quasi-static contribution is modelled as moving constant forces and inertia effects of the vehicle are neglected. In this paper, the proposed multi-body system allows one to consider the sprung masses and the vehicle's suspension. Fig. 8 shows the articulated HST studied in this work. The train system consists of one front traction car, eight passenger cars and one rear traction car. Passenger cars adjacent to traction cars share one bogie with the neighbouring passenger car, while central passenger cars share both bogies with the neighbouring cars. Bogie distances, l_b , and axle distances, l_a , are shown in Fig. 8. The mechanical properties of the HST are summarized in table 1.

Figure 8: HST configuration.

Description	Name	Unit	Traction cars	Passenger cars
Mass of car-body	M_c	kg	55790	24000
Mass of bogie	M_b	kg	2380	3040
Mass of wheel-axle	M_w	kg	2048	2003
Car-body inertia moment	J_c	$kg\ m^2$	1.15×10^3	1.48×10^3
Bogie inertia moment	J_b	$kg\ m^2$	1.48×10^6	2.68×10^3
Primary suspension stiffness	k_1	N/m	2.45×10^6	1.4×10^6
Secondary suspension stiffnessa	k_2	N/m	2.45×10^6	0.82×10^6
Primary suspension damping	c_1	Ns/m	20×10^3	10×10^3
Secondary suspension damping	c_2	Ns/m	40×10^3	48×10^3

Table 1: Mechanical properties of HST

The transmitted load by an axle can be computed as the elastic interaction force F_H at wheel-rail contact point as follows:

$$F_H = -2k_H(u_c - u_w) \quad (15)$$

where, u_c is the rail displacement at contact point, u_w represents the wheel displacement and $k_H = 1.4 \times 10^9$ N/m is a Hertzian contact spring between wheels and rail [23]. Fig. 9 shows the one-third octave band spectra of the transmitted load for train speed $v = 80$ m/s and $V_{1,2} = 110.14$ m/s. $V_{1,2}$ is resonant resonant speed of the bridge (see section 4.3). The computed results are compared with those obtained using a moving force model. Both models lead to the same results at the bogie passing frequency, $f_b = v/l_b$, and the axle passing frequency, $f_a = v/l_a$. However, the computed transmitted forces present differences at higher frequencies due to inertia effects are neglected in the moving force model.

Figure 9: Excitation force on the track computed with a moving force model (grey line) and the multi-body system (black line) for a HST travelling at (a) $v = 80$ m/s and (b) $V_{1,2} = 110.14$ m/s

Figure 10: One-third octave band spectra of the vertical displacement at the wheel (red line), bogie (blue line) and the car body (green line) due to the track unevenness (black line) for a HST travelling at $v = 80$ m/s.

The dynamic contribution account for track and wheel irregularities. The displacement vector u_c is equal to the sum of rail displacement u_r and rail unevenness $u_{w/r}$ perceived by an axle [25, 26]:

$$u_c = u_r + u_{w/r} \quad (16)$$

In this paper, random track unevenness $u_{w/r}(x)$ is modelled as a stationary Gaussian random process characterized by its one-sided PSD function $\tilde{S}_{u_{w/r}}(k_y)$. The spectral representation theorem is used to generate samples of track unevenness $u_{w/r}(x)$ as a superposition of harmonic functions with random phase angles [25, 26]:

$$u_{w/r}(x) = \sum_{m=1}^n \sqrt{2\tilde{S}_{u_{w/r}}(k_{ym})\Delta k_y} \cos(k_{ym}y - \theta_m) \quad (17)$$

where $k_{ym} = m\Delta k_y$ is the wavenumber sampling used only to compute the artificial profile, Δk_y the wavenumber step and θ_m are independent random phase angles uniformly distributed in the interval $[0, 2\pi]$. The artificial track profile is generated from PSD function according to ISO 8608 [27]:

$$\tilde{S}_{u_{w/r}}(k_y) = \tilde{S}_{u_{w/r}}(k_{y0}) \left(\frac{k_y}{k_{y0}} \right)^{-w} \quad (18)$$

An artificial profile is obtained from the PSD function with $k_{y0} = 1$ rad/m and $\tilde{S}_{u_{w/r}}(k_{y0}) = 2\pi \times 10^{-8} \text{ m}^3$. $w = 3.5$ is commonly assumed for wheel-rail unevenness in current high speed lines.

Fig. 10 shows the one-third octave band spectra of the vertical displacement at the wheel, bogie and body car due to the unevenness profile shown in the same figure. Primary and secondary suspensions system isolate body car and bogie at frequencies higher than 1.2 Hz y 5.5 Hz, respectively.

Figs. 11(a),(b) show the one-third octave band spectra of the vertical acceleration at the center of the mid-span deck for a train passage at $v = 80$ m/s and $V_{1,2} = 110.14$ m/s, respectively. The quasi-static contribution are represented in these figures. The deck response is governed by the quasi-static contribution.

4.3 Induced vibrations due to HST

In this section, SSI effect on induced vibrations due to HST passage is studied. Resonant and non resonant regimes are analysed. The geometry and the mechanical properties of the bridge have been described in previous sections.

Figure 11: The computed total response (black line) and the computed quasi-static (grey line) one-third octave band spectra of the vertical acceleration at the center of the mid-span deck for a HST travelling at (a) $v = 80$ m/s y (b) $V_{1,2} = 110$ m/s.

Figure 12: Maximum vertical acceleration at the mid-span center deck computed from SSI model (black line) and non-SSI model (grey line).

The resonant condition of a bridge excited by a row of moving forces can be expressed as follows [2, 5]:

$$V_{n,i} = \frac{f_n d}{i} \quad (n = 1, 2, \dots, i = 1, 2, \dots) \quad (19)$$

where, $V_{n,i}$ is the train speed, f_n is the n^{th} resonant frequency of the bridge and d is a characteristic distance of the moving loads.

Fig. 12 shows the maximum vertical acceleration at the center of mid-span deck in relation to the train speed passage. There is an increase of deck acceleration when the speed increases. Maximum levels are reached at resonant velocities of the first bending (symmetric) mode shape, considering the distance between bogies $d = 18.7$ m. Figure 12 shows the resonant velocities $V_{1,2} = 110.14$ m/s, $V_{1,5} = 44.06$ m/s and $V_{1,7} = 31.47$ m/s. The Spanish Standard [1] sets a limit state of vertical accelerations at $a_{max} = 3.5$ m/s², plotted in Fig. 12. The maximum acceleration at the center of the mid-span deck is below this limit in the range of operating speeds on current high speed lines. The response of the structure varies substantially when SSI is considered. Resonant velocities decrease due to variation of the dynamic behaviour of the structure. The maximum response occurs at $\tilde{V}_{1,2} = 103.41$ m/s. Moreover, it is observed that the maximum level of acceleration achieved in resonant regime is significantly lower when the soil-structure interaction is considered. The structural damping varies from $\zeta = 2\%$ to $\tilde{\zeta} = 3.9\%$.

Fig. 13 shows the time histories and frequency content of the vertical acceleration at the center of mid-span deck for three train speed passage: $v = 80$ m/s, $\tilde{V}_{1,2} = 103.41$ m/s and $V_{1,2} = 110.14$ m/s. In the first case, the response obtained with both models corresponds with a non-resonant regime. The time history shows similar levels in both cases and the differences

are not significant. The response is governed by the bogie passing frequency, for the first bending (symmetric) mode and the first bending mode of the cross-section. The SSI produces an amplification of the response at the bogie passing frequency. In addition, the frequency response associated with the natural frequencies of the structure decreases. In resonant regime, the response of the structure shows a gradually increase of the vibrations with the successive bogie passage at the resonant velocities $\tilde{V}_{1,2}$ and $V_{1,2}$ (Fig. 13.(c),(e), respectively). The predominant frequency in the response are associated with the first bending mode (Fig. 13.(d),(f)). The model without SSI does not estimate accurately the bridge response as can be seen in Fig. 13.(c),(d). Since the amplitude of the resonant vibration depend inversely on damping [2], the model without soil overestimates the response, as can be seen in Figs. 13.(e),(f).

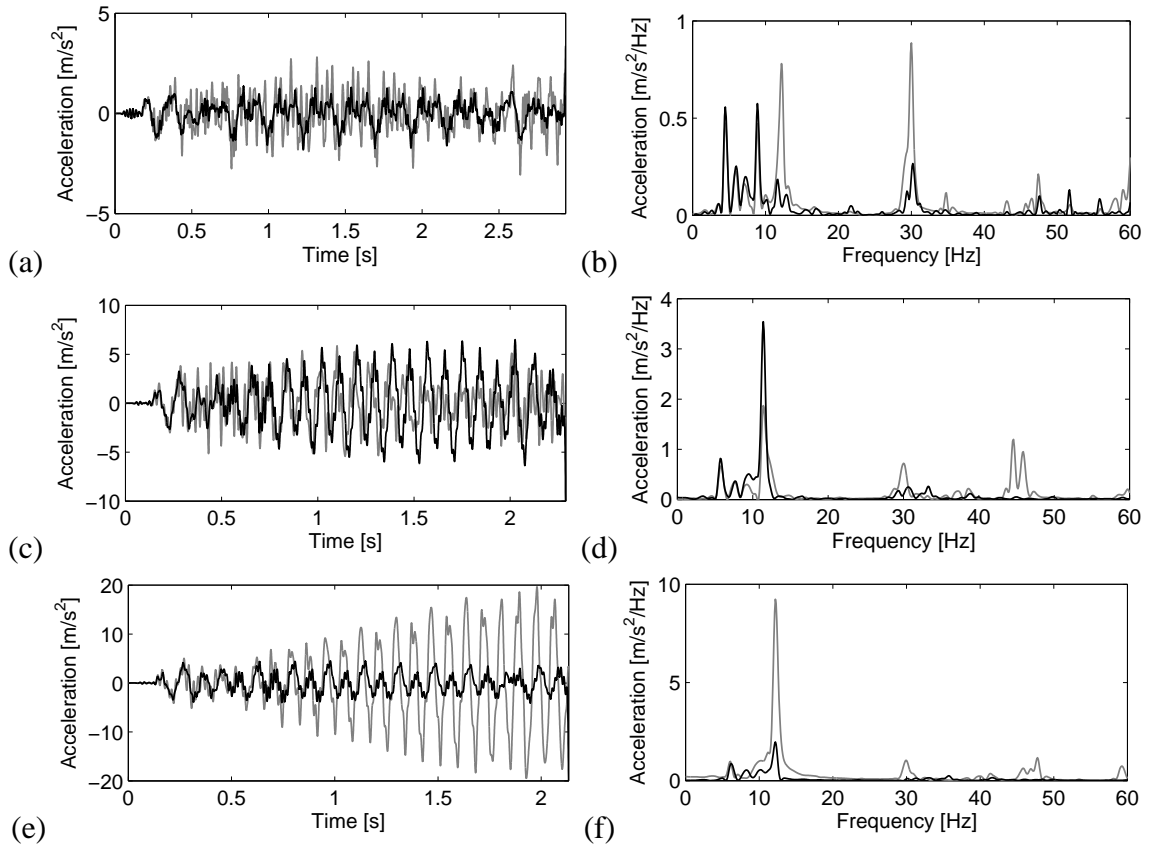

Figure 13: (a,c,e) Time histories and (b,d,f) frequency contents of the vertical acceleration at the mid-span center deck for a HST travelling at (a,b) $v = 80 \text{ m/s}$, (c,d) $\tilde{V}_{1,2} = 103.41 \text{ m/s}$ y (e,f) $V_{1,2} = 110.14 \text{ m/s}$, computed from the SSI model (black line) and the non-SSI model (grey line).

5 Conclusions

In this paper, a numerical model to predict vibrations on railway bridges has been presented. The numerical model is based on the three dimensional finite element and boundary element formulations in time domain. The articulated HST is modelled as a multi-body system. Therefore, the different excitation mechanisms can be considered accurately. The following conclusions can be drawn from the obtained results:

1. Transmitted force has a high frequency content that the moving force model does not

reproduce accurately due to vehicle's inertia effects are neglected.

2. Structure soil interaction produces a reduction in the natural frequencies and an increase of structural damping due to the additional flexibility level between the abutment and the soil.
3. Therefore, the resonant behaviour occurs at speeds lower than those predicted by the model without soil.
4. The amplitude of the resonant response regime depends on the structural damping ratio. So, it is necessary to take into account the influence of the SSI to estimate correctly the response.

Keywords: Track-ground vibrations induced by railway traffic; numerical modeling; experimental validation

Abstract. This paper presents two main parts, encompassing the experimental assessment and the numerical modelling of vibrations induced by railway traffic. Firstly, a global description of an experimental trial field developed in the Portuguese railway network is presented. In that trial field several tests were performed in order to obtain a reasonable mechanical characterization of the main elements involved in the process of generation and propagation of waves induced by traffic. So as to reach the proposed goal, a geotechnical characterization campaign was performed, including cross-hole tests and specific tests to estimate the ground damping properties. Concerning the track properties, receptance tests and a campaign of measurement of irregularities were conducted. After the global characterization of the site and of the track, vibrations induced by the railway traffic were then measured both in the railway track and in the free-field.

The results of the tests are used in the validation of a 2.5D FEM/BEM model developed by the authors. The model fully accounts for the dynamic interaction between the train, the track and the layered ground. The railway track and embankment, assumed to be invariant in the longitudinal direction, are modelled with 2.5D finite elements [1]. On the other hand, the layered ground below the embankment is simulated by a 2.5D boundary elements formulation. This formulation allows an efficient solution of the track-ground dynamic interaction problem in the frequency-wavenumber domain, as recently explained by François et al. [2]. Regarding the modelling of the rolling stock, a multi-body model is adopted, where the main masses and suspensions of the train are incorporated.

The study, involving experimental and numerical techniques, revealed to be very useful, allowing not only the experimental validation of the numerical model proposed by the authors, but also a deep understanding of the influence of several aspects who determine the problem's solution.

1 INTRODUCTION

The railway is one the most efficient transport systems. Nowadays, it is well known that for middle distances, i.e., lower than 500 km, the energetic efficiency and the comfort associated to the rail transportation turns this transportation system very competitive when compared with the air traffic or with the road transit [3]. However, the sustainable development of modern railway networks should take into account several aspects, few of them neglected in the past.

One particular and important concern is related with the environmental impact that the railway traffic can present on the facilities near to the track, mainly in urban environment, comprising the noise and vibration induced by the train passage. Apart from other issues, the railway traffic can cause discomfort to inhabitants or affect the regular use of sensitive equipments in surrounding buildings. Although structural damage in building is not commonly related to traffic, it is not so unusual the occurrence of some cosmetic damages, which are also unacceptable in the case of important and historical heritage. Therefore, the prediction and assessment of train induced ground vibration is becoming increasingly important, and much attention has been given to this challenge during the last decade, since proposals of empirical prediction models to advanced numerical models. As result, several numerical and semi-analytical models have been proposed. The semi-analytical approaches present a clear supremacy in terms of computation efficiency and capability to the understanding of the phenomena. Many research studies about this subject were carried out since the introduction of the pioneer concept of equivalent stiffness of the ground by Dieterman and Metrikine [3, 4]. An efficient and comprehensive three dimensional model that takes into account the fully interaction train-track-ground was presented by Sheng et al [5]. Despite of the effort dedicated by many researchers in order to improve the semi-analytical models for the incorporation of more complex geometries, the strictness generally found on these solutions does not allow the consideration of the complex geometries usually found in practical applications [6].

The above mentioned limitations, intrinsic to the semi-analytical approaches, combined with the development of computational capabilities, has leaded to the development of numerical approaches specially designed for the simulation of large domains subjected to moving loads. An efficient approach to the modeling of the dynamic track-ground response can be reached taking advantage of some properties commonly assumed, namely: the linearity and the invariability of the domain along the track direction [7]. These properties allow solving the 3D problem by an efficient computational scheme, usually called 2.5D, which only requires the cross section discretization since the spatial coordinate along the track development is subjected to a domain transformation by a Fourier transform. This procedure is becoming very popular, and several researchers have applied this concept to the formulation of models based on the finite elements approach, and more recently also to the boundary elements approach [1, 8-12]. Recently, François et al [2] presented an efficient and comprehensive approach for coupling between both methods, which was also applied in a study performed by Galvín et al. [13].

Apart from the matters related with the modeling of track-ground response, a lack of experimental validation of proposed models remains. In fact, the number of case studies reported in the bibliography remains very scarce, contributing to the difficulty generally found on the experimental validation of the numerical models.

The aim of this paper is twofold. The first objective is to present a numerical model for the assessment of track-ground vibrations induced by railway traffic. This model was developed by the authors and implemented on the numerical platform Matlab 2009, taking advantage of this platform for the use of parallel computation schemes.

The second objective is to present a set of experiments, developed on a site of the Portuguese railway network, which are used for the validation of this particular numerical model, but can also be used for the validation of further models proposed by other authors.

2 NUMERICAL MODEL

2.1 Generalities

The proposed numerical model is divided into two main modulus: the former includes the track-ground structure, modeled by a 2.5D approach where the tridimensionality of the domain is taken into account: the latter concerns to the simulation of the dynamic of the structural behavior of the train, which is simulated by a multi-body formulation taking into account the main masses and suspensions of the vehicles.

Both formulations are integrated by a compliance formulation in order to take into account the train-track interaction. In following sections the main aspects and assumptions of both methods are described.

2.2 Track-ground simulation by 2.5D FEM-BEM

The track-ground dynamic response induced by train passage is computed by a numerical procedure based on the coupling between finite elements and boundary elements methods, both formulated in the 2.5D domain. Since it is assumed that the dynamic problem is linear, the formulation can be developed in the wavenumber-frequency domain, employing Fourier expansions for space (only in the track development direction) and time. This procedure, called 2.5D, allows obtaining the 3D solutions without the need of numerical discretization along the development direction of the track. A similar model was recently presented by François et al. [2] and Galvín et al. [13].

Domain decomposition is used to solve the dynamic problem, being the track modeled by the 2.5D FEM and the layered ground simulated through 2.5D BEM, as shown in Figure 1.

The coupling between both domains is done by a finite elements formulation, comprising the transformation of the flexibility matrix that governs the dynamic behavior of the BEM domain into a dynamic stiffness matrix.

Following the inner formalism of the 2.5D FEM, the dynamic equilibrium equations of the medium can be reached by the formulation in the variation form. So, for a conservative system, the sum of the virtual work of the internal forces and of the inertial forces is equal to the virtual work of the external forces. After introducing the discretization of the cross-section into 2.5D finite elements and applying a Fourier transform regarding the x coordinate, the dynamic equilibrium can be described by the following system of equations:

$$(K_1^{\text{global}} + ik_1 K_2^{\text{global}} + k_1^2 K_3^{\text{global}} + k_1^4 K_4^{\text{global}} - \omega^2 M^{\text{global}} + K_5^{\text{global}}(k_1, \omega)) \tilde{u}_n(k_1, \omega) = \tilde{p}_n(k_1, \omega) \quad (1)$$

where K_1^{global} to K_4^{global} are stiffness matrices of the domain described by finite elements, M^{global} is the mass matrix, k_1 is the Fourier image of the coordinate x , ω is the frequency, u_n is the vector of the nodal displacements, p_n is the vector of the external forces, and, finally K_5^{global} is the matrix that collects the impedance terms of the layered ground.

Figure 1 - 2.5D FEM-BEM coupling.

The continuous medium, i.e., the embankment and the granular layers of the track are simulated by 8 nodes finite elements, with exception of the elements that establish the connection between the FEM domain with the BEM domain. In the latter, 7 nodes elements are adopted in order to have two nodes along the side of connection FEM-BEM. Regarding to particular elements of the track, as for instance the sleepers and the rails, a comprehensive description of the modeling strategy can be found on Alves Costa et al. [1]

Since the 2.5D FEM is well explained in several technical documents, including in one paper previously presented by the authors, the deduction of the above mentioned matrices is not presented here again; the reader is advised to consult the following references: [1, 2, 13]. In following, the attention is focalized on the coupling between 2.5 FEM-BEM, which is described by the matrix K_5 .

Several 2.5D boundary integral equations have been proposed during the recent years. Sheng et al. [14] have proposed a 2.5D boundary integral equation based on the reciprocity theorem. More recently, François et al. [2] proposed a new approach based on a regularized version of the boundary integral equation in order to avoid the analytical integration of singular terms. However, the version here presented is simpler, since it is assumed that the coupling between the FEM and BEM domains occurs along the ground surface, not being allowed the embedment of the finite element mesh in the BEM domain. In that case, taking into account the reciprocity theorem and the Somigliana identity, the boundary integral equation assumes the following aspect:

$$u_j(\mathbf{x}, \omega) = \int_{\Sigma} u_{ji}^G(\mathbf{x}, \mathbf{y}, \omega) p_i(\mathbf{y}, \omega) d\Sigma \quad (2)$$

where u_j corresponds to the displacement of the point with coordinates \mathbf{x} when a pressure, p_i , is applied along the surface Σ (belonging to the ground surface). On the other hand u_{ji}^G is the tensor of the Green's functions of the displacements.

For the computation of the displacement Green's function several methodologies can be followed. Since the objective is to find the BEM matrices in the 2.5D domain, it looks be natural and, apparently more efficient, the option by the 2.5D Green's function proposed by Tadeu and António [15] for a halfspace instead of other methodology. However, in order to avoid the discretization of the interface between distinct layers, in the present study 3D Green's functions are adopted, which are computed in the transformed domain by resource to a hybrid formulation of Thin-layer method, as proposed by Kausel [16].

The introduction of the ground surface discretization is anteceded by some simplifications that must be mentioned and clarified. In approach followed in the present work, only linear boundary elements are used, with one point of collocation (in the middle of the element) and its dimension is defined by the side length of the neighbor finite element. It should be remem-

bered that the neighbor finite element only presents two nodes along the side of connection FEM-BEM, which means that some error of approximation is allowed between the displacements computed by both methods along the connection surface.

In sum, considering the 2.5D discretization and the schematic representation presented in Figure 2, the BEM equilibrium equation can be described by:

$$u_n(k_1, y_1, 0, \omega) = [G(k_1, y_j - y_i, z_1, \omega)] p_n(k_1, \omega) \quad (3)$$

where u_n is the vector of that collects the displacements of the collocation points; p_n is the vector of the applied pressures along each boundary element and, finally the matrix G corresponds to the flexibility matrix of the domain.

Figure 2- 2.5D ground surface discretization.

The FEM-BEM coupling can be performed by several approaches. In the present study the coupling is done in FEM sense, being the flexibility matrix G transformed into the dynamic stiffness K_5 , through the following relationship:

$$K_5 = [T_q][G(k_1, \omega)]^{-1}[T] \quad (4)$$

where T is a matrix that relates nodal displacements with the homologous evaluated in the collocation points and, T_q is a matrix resulting from the integration of the shape functions (of the finite elements) along the coupling boundary.

Since the motion and equilibrium of the domain is formulated by a 2.5D approach, where Fourier transform are applied over the x coordinate and time, the simulation of moving loads is easy, and can be found in several paper related with this matter.

Solving the equations system presented in (1), the nodal displacements in the transformed domain are obtained, as well as the traction along the coupling boundary. Once these tractions and the Green's functions of the displacements are known, the computation of the free field response is trivial.

2.3 Track-Train interaction

The load applied by the train on the track can be divided into two components: i) the static load, resulting from the weight of the train; ii) the dynamic load, due to the dynamic interaction between the train and the track. As the first component is an input data and not an unknown variable, its consideration on a numerical model is trivial. Unfortunately, the same statement cannot be extended for the latter component, which demands for the solution of the dynamic train-track interaction problem. In the present study, this problem is solved by a compliance procedure formulated in a referential that moves with the train, as suggested by several authors [10, 11, 17, 18].

Assuming perfect contact between both structures, the following relationship must be adhered to at any temporal instant for all connection points between the train and the track:

$$u_{c,i} = u_r(x = ct + a_i) + \Delta u \left(t + \frac{a_i}{c} \right) \quad (5)$$

where u_c represents the vector of vertical displacements of the vehicle in the connection points, u_r is the vector of vertical displacements of the track at the same location; Δu is the rail unevenness; t is the time; a_i is the location of contact point i at $t=0$ s and c is the vehicle speed.

Since the wheelsets are simulated by rigid bodies, the displacement of any axle is equal to the sum of the displacement of the corresponding connection point with the deformation of the Hertzian spring introduced in order to take into account the contact deformation:

$$u_{c,i} = u_r(x = ct + a_i) + \Delta u \left(t + \frac{a_i}{c} \right) + \frac{P_i(t)}{k_H} \quad (6)$$

where k_H is the Hertzian stiffness and P_i is the dynamic interaction force developed at the connection point i .

Equation 5 can be written in matrix form in the frequency domain using the transformation of the unevenness for that domain. So, the train-track interaction force in the frequency domain is given by:

$$P(\Omega) = -([F] + [F]^H + [A])^{-1} \Delta u(\Omega) \quad (7)$$

where $[F]$ is the train compliance at the contact points with the track, $[F]^H$ is a diagonal matrix where the terms are equal to $1/k_H$ and $[A]$ is the compliance matrix of the track. All matrices are square with a dimension equivalent to the number of wheelsets and its deduction can be found in Alves Costa et al. [19]

Analyzing equation 7, one can conclude that the influence of the vehicle properties and of the modeling strategy used only affects matrix $[F]$. A simple but general vehicle model, which takes into account the main structural aspects of the train dynamics, was proposed by Zhai e Cai [20] (Figure 3).

Figure 3 - Complete 2D vehicle model.

However, the difficulty generally found in the determination of the mechanical properties of the vehicle, gave rise to proposals of simplified models where the motion of the car body and, sometimes, also the motion of the semi-sprung masses (bogies) are disregarded [10, 21]. A parametric study developed by the authors in order to discern the influence of the sprung and semi-sprung masses on the global dynamic response of the system, revealed that the vehicle model must comprise, at least, the dynamic behavior of the bogies and wheelsets [19].

3 EXPERIMENTAL ACTIVITIES

3.1 General description and objectives

In order to validate the numerical models developed by the authors, an experimental test site was selected and implemented in the Portuguese railway network (between Lisbon and Oporto), near to Carregado site.

Regarding the main aspects of the site, it must be referred that the track presents a straight alignment, corresponding to a renewed part of the railway connection between Porto and Lisbon. The line is composed by a double track on ballast, as illustrated in Figure 4, and distinct types of traffic are allowed in this line, ranging from freight trains up to passenger trains that circulate at speeds close to 220 km/h.

Figure 4 – General view of the site.

Two sets of experiments were performed: i) the first, to evaluate the dynamic properties of the track and of the ground; ii) the second, to measure the vibrations induced by the passage of the Alfa-Pendular train. Additionally, the track unevenness, key parameter for performing a dynamic train-track interaction analysis, was also measured.

The first set of experiments is used for the calibration of the numerical model and for a deeper understanding of the dynamic behavior of the track-ground system. On the other hand, the second set of experiments, comprising the response of the track-ground system during the passage of Alfa-Pendular train, is used for the experimental validation of the numerical model presented above.

3.2 Geodynamic characterization of the ground

Due to the uncertainty generally attributed to the ground properties, a detailed attention must be addressed to the geotechnical characterization of the ground. Following this logic three types of tests were performed in the site: i) one bore-hole with SPT tests spaced 1,50 m into depth; ii) two CPT tests; iii) two cross-hole tests.

Concerning the geotechnical scenario, the SPT and CPT tests allowed to find four main formations: i) up to 1.80 m to 2.00 m, the ground is mainly constituted by fine soil, overconsolidated; ii) between 1.80 m to 5.40 m, a relatively homogeneous formation is found, comprising clayey soils; iii) below 5.40 m and above 7.2 m, the ground is constituted by very soft organic layers intercalated with sand layers; iv) finally, for depths below 7.20 m, the ground is very homogeneous, corresponding to a thick layer of clays. Figure 5, shows the classification chart of the soil from the CPT tests, according the proposal of Robertson. The laboratorial tests confirmed this layering.

Figure 5 – Soil classification from the CPT test (red dots – $0 \text{ m} < z < 1.8 \text{ m}$; black dots – $1.8 \text{ m} < z < 5.4 \text{ m}$; blue dots – $5.4 \text{ m} < z < 7.2 \text{ m}$; green dots – $z > 7.2 \text{ m}$).

The device used to perform the cross-hole tests enables to generate polarized S waves, allowing the measurement of P and S wave velocities. Figure 4 shows the measured wave velocities profile as well as the values adopted in the numerical model.

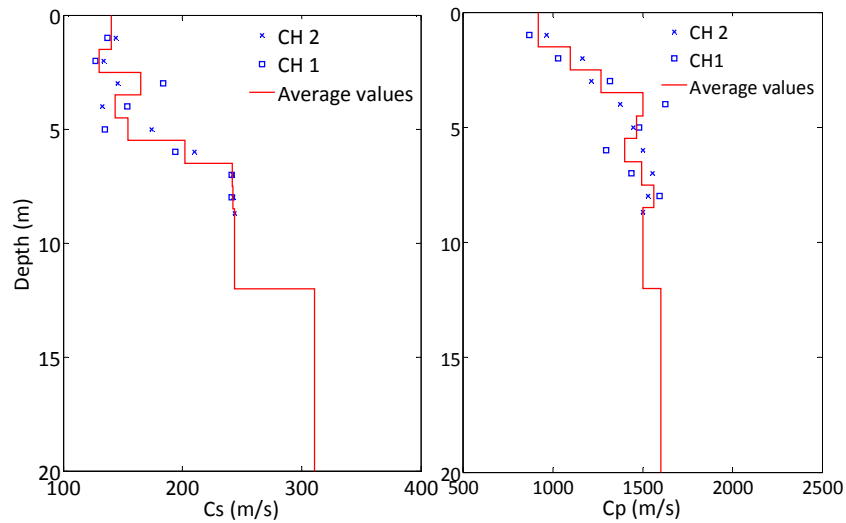

Figure 6 – Seismic wave velocities profile: a) Shear wave; b) Compressive wave.

A complete geodynamic characterization, for the purpose of the present study, should attend not only to the elastic properties of the ground but also to an estimation of the damping profile in depth.

In the present study, the damping profile was estimated from an inversion procedure based on the calibration of the numerical model in order to obtain a reasonable fit between measured and computed mobilities of the ground due to an excitation induced by a controlled source. The experimental setup adopted is shown on Figure 7.

Figure 7 – Damping evaluation tests. Experimental setup.

From the acquired data, the experimental mobility is computed for the set of measuring points. On the other hand, a theoretical model was developed, taking into account the ground layering and stiffness properties described in Figure 6, where the damping profile is adjusted in order to obtain a reasonable fit between the measured and computed mobilities. Therefore, the only unknown variable in the numerical model is the damping of the ground, which gives rise to a simple inversion procedure. Figure 8 shows the modulus of the mobility measured and computed, for the 4 points of analysis. It is well patent in the figures that a reasonable fit between measured and computed results is achieved when the damping profile illustrated in Figure 9 is adopted.

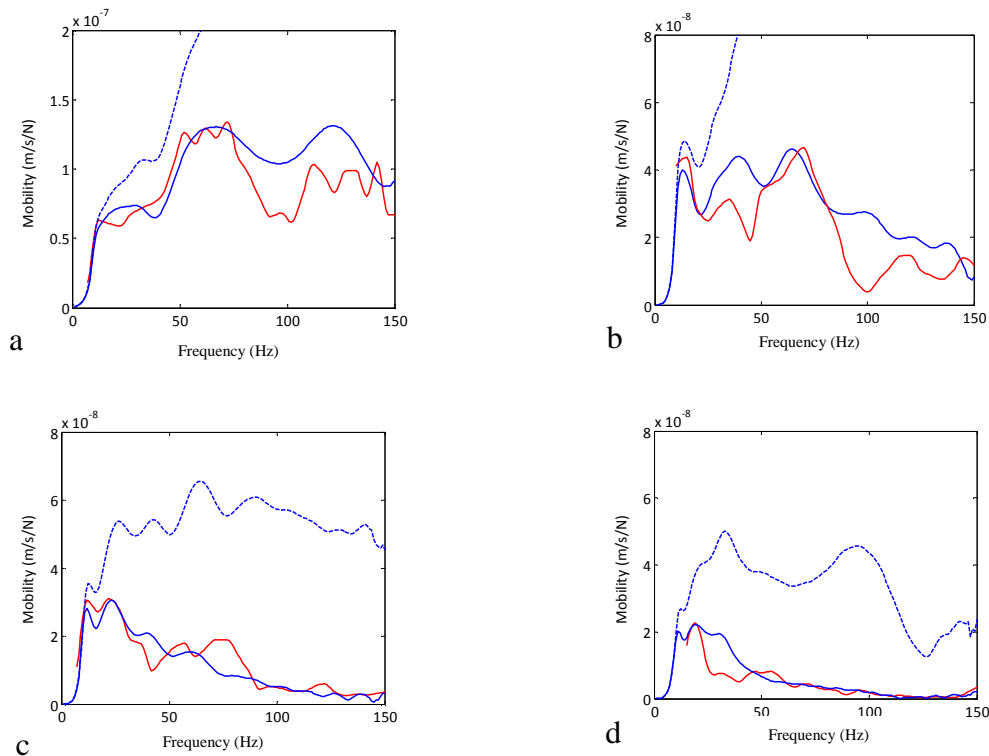

Figure 8 – Experimental and numerical mobility at different distances receiver-source:
a) 4.25 m; b) 8.00 m; c) 12.00 m; d) 16.00 m.

Figure 9 – Damping profile.

3.3 Assessment of the track mechanical properties

Another challenging usually found in the numerical analysis of railway tracks is due to the difficulty in the assessment of the properties of this complex structural system. If, by one hand, the properties of the rail and sleepers are well defined, the same statement cannot be extended to the other components such as the ballast or the railpads. In order to minimize the uncertainty related to properties of those elements, receptance tests were performed and the numerical model was calibrated, by an inversion procedure, in order to obtain a reasonable fit between the measured and computed receptances.

The adopted setup for the receptance tests is shown in Figure 10. As can be seen, the impact load (provided by an impulse hammer) is applied in the mid span of the sleeper and the response is measured by accelerometers installed on the sleeper extremities and on the rails.

Figure 10 – Receptance tests setup.

A preliminary examination of the receptance of the rails enabled to confirm that very stiff railpads are used in this railway track. Through a simplified analysis it was found that the resonance frequency of the rails over the sleepers is related to a railpad stiffness of 700 kN/m, which is in correspondence with the value previously pointed out by the railpad manufacturer. Despite of the mentioned above, several variables (properties of the track elements) remain unknown, namely: the stiffness, the damping and the mass of the ballast and of subballast.

These properties are determined by the solution of a nonlinear least squares optimization problem with a residual that is a function of the track characteristics.

Figure 11 shows the geometry adopted for the numerical model, as well as the properties adopted after the optimization solution (see Figure 12). It should be noticed that the rail and sleepers were simulated according to the above mentioned properties of the materials. The layered ground was simulated by the 2.5D BEM procedure taking into account the stiffness, mass and damping provided by the set of tests described in the latter section.

Figure 11 – Numerical model geometry and mechanical properties.

As is well patent is Figure 12, a reasonable agreement was found between measured and computed receptances, mainly for frequencies in the range between 70 Hz and 250 Hz.

Figure 12 – Numerical and experimental sleeper receptance.

3.4 Measurement of track unevenness

As shown by equation 4, the knowledge of the track unevenness is a key parameter for the analysis of the dynamic excitation mechanism. Unlike other case studies, where the track un-

evenness is artificially generated, in the present study it was measured. Distinct equipments were used in order to have a reliable unevenness profile comprising the frequency bandwidth relevant to the analyses of vibrations induced by traffic. The recording car used by the Portuguese Railway Company (REFER) enables to measure the unevenness for wavelengths between 1.0 m and 25.0 m (Figure 13a). Therefore, for moderate running velocities, it is also necessary to know the short wavelength unevenness (also called rail corrugation) in order to take into account excitation frequencies up to 150 Hz. So, it was used a device that enabled the measurement of the wavelengths range between 0.4m and 1.0m. Both equipments are illustrated in Figure 13.

Figure 13 – Equipments for measuring the track unevenness: a) recording car; b) device for measuring the rail corrugation.

Figure 14 shows the measured unevenness profile of the right rail for the range of wavelengths between 0.4m and 25m. At a train speed of 212 km/h this range of wavelengths corresponds to an excitation frequency range of the vehicles between 2.1 Hz and 147 Hz. The reference section, i.e., the cross-section of the track and of the ground that was instrumented during the train passage, is also indicated in Figure 14.

Figure 14 – Track unevenness profile.

3.5 Experimental assessment of vibrations induced by traffic

After the initial characterization experiments, focus was given to the measurement of track and free-field vibrations induced by traffic. Bearing this in mind, the setup illustrated in Figure 15 was implemented in order to experimentally evaluate the track-ground response due to traffic. As can be seen, the experimental setup comprised the measurement of vertical accelerations on the sleepers and on the ground surface, the latter at several distances from the track along a cross section. Complementarily, the displacement of the rail induced by the traffic was also measured by a laser device.

Although the huge amount of data acquired in this experimental test, subsequent to the passage of several distinct trains running at different speeds, in the following analysis only a fraction of the collected data was used, always regarding to the passage of the train Alfa-Pendular at a running speed of 212 km/h.

Figure 15 – Experimental setup.

4 EXPERIMENTAL VALIDATION

4.1 Model description

As emphasized before, the main objective of the study is the experimental validation of the numerical model presented in the initial sections of the paper. Thus, a numerical model comprising the train-track-ground dynamic interaction was constructed, in accordance to the formulation previously described.

The numerical model for the track-ground system is consistent with the information illustrated in Figure 11, reason why do not deserve more commentaries or justifications. Only a small remark must be done concerning to the difference between the real double-track geometry and the homologous adopted in the numerical modeling. In fact, as is well patent in Figure 11, the numerical model introduces a false plane of symmetry, crossing the mid span of the sleepers. An earlier sensibility study performed by the authors allowed concluding that this simplification is reasonable and doesn't give rise to an appreciable loss of accuracy in the prediction. Moreover, the numerical model was calibrated taking into account this "false" symmetry, reason why it is expected to obtain a good description of the physical reality through this model.

Concerning the rolling stock properties and the interaction mechanisms, in the following sections is considered the passage of train Alfa-Pendular at the speed of 212 km/h. The track

unevenness, in accordance to the results of the measurements presented in previous section, is included in the modeling procedure.

The Alfa-Pendular is the fastest train operating in Portugal. It is a conventional train composed by 6 vehicles, as indicated in Figure 16.

Figure 16 – Alfa Pendular geometry.

The main mechanical properties of the train were provided by the operator. In spite of this information, some identification modal tests for the structural characterization of the train were also developed and the properties adopted in the numerical model were adjusted in order to obtain a good fit between numerical and experimental natural frequencies. Table 1 summarizes the main properties of the train, in correspondence with the values adopted in the numerical analyses. The vehicles of the train are not exactly equal; Table 1 indicates the range of values found for the distinct vehicles of the train.

Table 1 – Train properties

Axles	Mw (kg)	1538-1884
Primary suspension	Kp (kN/m)	34200
	Cp (kNs/m)	36
Bogies	Mb (kg)	4712-4932
	Jb (kg/m ²)	5000-5150
Car body	Mc (kg)	32900-35710

A simplified structural model for the train was adopted. In that model, the motion of the sprung mass (car body) is discarded. However, this suffices for the purpose of the present study due to the fact that secondary suspension of the Alfa-Pendular train is soft enough to guarantee an efficient isolation of the car body for frequencies higher than few hertz.

4.2 The track dynamic response

Figure 17 compares the computed rail displacement with the measurement supplied by the laser device. In order to minimize the noise present in the measured signal, a low-pass filter with a cut-off frequency of 80 Hz was applied to both results.

Figure 17 – Time record of the rail displacement (blue line – measurement; red line – computation).

As can be seen a splendid fit between rail displacement prediction and measurement was achieved. In fact, excluding a little discrepancy found during the passage of the first vehicle, the ability showed by the numerical model in the reproduction of the rail displacement is notorious.

Concerning the sleeper response, Figure 18 compares experimental and numerical time histories of the vertical velocity of the sleeper induced by the passage of the train Alfa-Pendular at 212 km/h.

Figure 18 – Time record of the sleeper velocity (blue line – measurement; red line – computation).

Once again, a very good match between both results is emphasized by Figure 18. A clear distinction of the passage of each bogie is identified in the record, and a very good agreement between numerical and experimental results is found. Despite of the high quality of the results,

it must be noticed that slight differences between measurement and prediction are found for frequencies above 75 Hz.

4.3 The free-field dynamic response

Fulfilling the requirements of synthesis of this paper, only the results concerning the points of the ground closer to the track are here analyzed. The reader is invited to consult Alves Costa et al. [19] where complementary results are shown.

Figure 19 shows the time records of the vertical velocity of those points induced by the passage of train Alfa-Pendular at 212 km/h. The numerical prediction is overlapped to the experimental record.

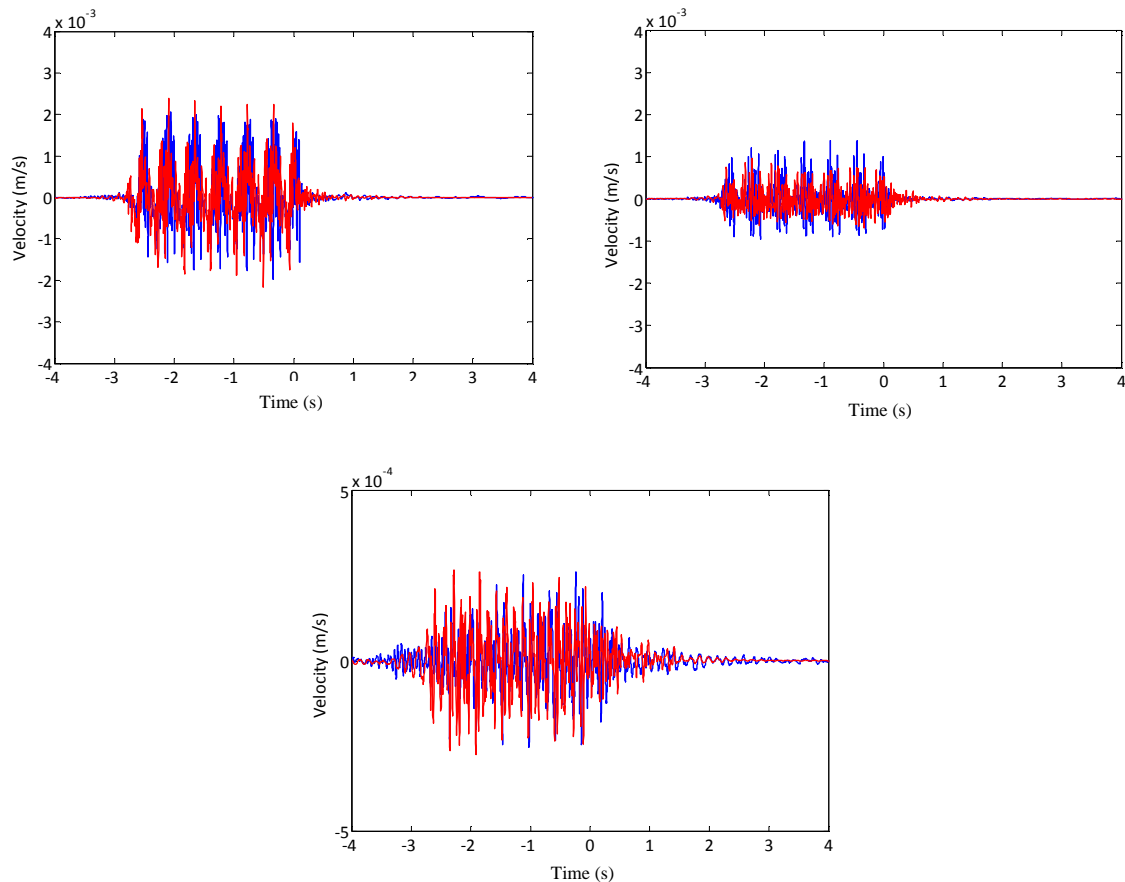

Figure 19 – Vertical velocity record at different distances from the track: a) 3.5 m; b) 7.0 m; c) 15.0 m (blue line – experimental; red line – computed).

Despite some differences between predicted and measured free-field vertical velocities, a reasonable agreement between simulation and physical reality was found. In fact, the numerical model was able to simulate the main aspects of the time record. However, a better discernment can be achieved by the analysis of the frequency content of the records, as illustrated in Figure 20.

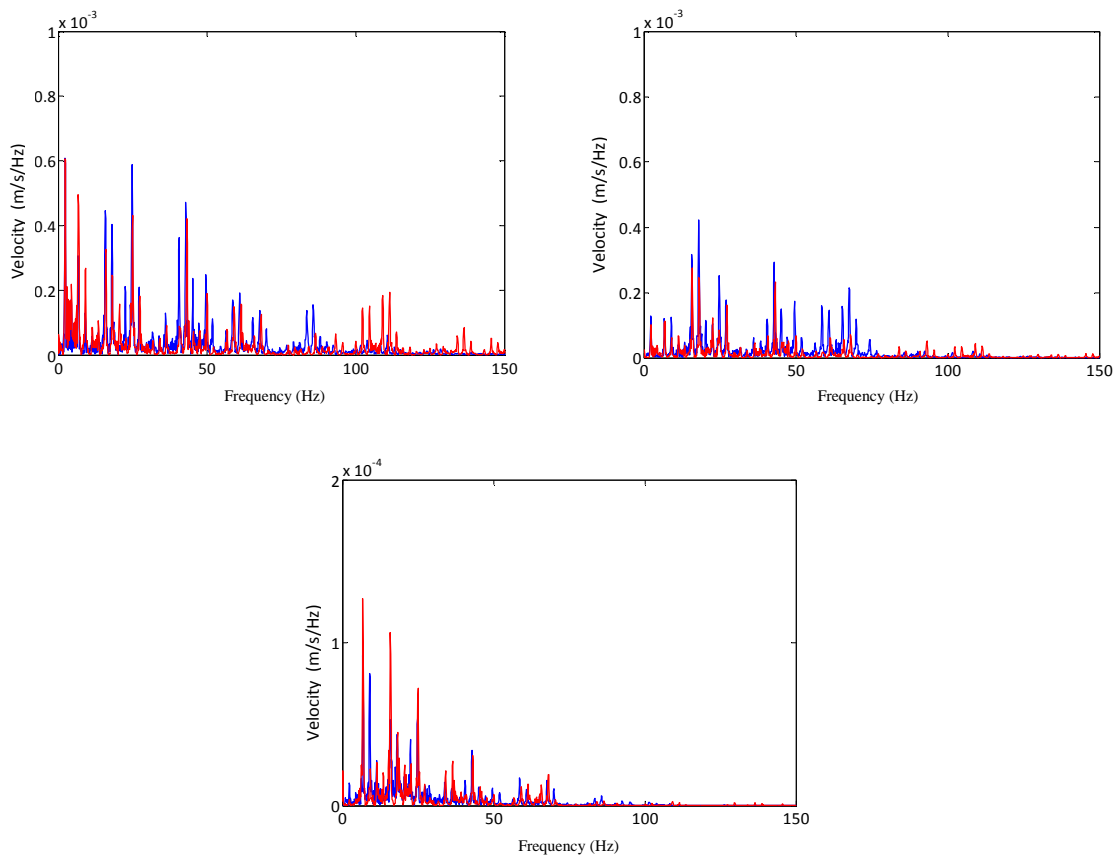

Figure 20 – Frequency content of the vertical velocity at different distances from the track: a) 3.5 m; b) 7.0 m; c) 15.0 m (blue line – experimental; red line – computed).

From the results exposed in Figure 20, one can conclude that the main characteristics of the frequency content were also well reproduced by the numerical model. Despite of this global good fit, for the point at a distance of 7.0 m, a more evident discrepancy between prediction and measurement is observed. Probably this difference is due to a local geotechnical condition of the ground that is distinct from the average scenario assumed in the simulation.

Despite of the successful obtained in the experimental validation of the model, it should be noticed that the discrepancy between prediction and measurement is much more evident when the analysis is focused on the dynamic response of the free-field than when the attention is dedicated to the track response. This fact shows well the complexity of the mechanisms of the wave propagation and the difficulty usually found in its numerical modeling.

5 CONCLUSIONS

In this paper, an experimental validation procedure of a 2.5D FEM-BEM model for the prediction of vibrations induced by railway traffic was shown.

The guidelines of the numerical model, implemented in Matlab 2009, were revealed, with special emphasis for the coupling procedure between the domains simulated by the 2.5 D FEM and the 2.5D BEM. Moreover, the model is able to perform train-track interaction analysis, aspect that was also described in the paper.

Bearing in mind the objective of the paper, an experimental test field, which was implemented in the Portuguese railway network, is described with emphasis to the experiments developed in order to calibrate the numerical model.

Finally, the vibrations measured during the passage of Alfa-Pendular train are compared with the prediction. The comparison between both results revealed a very good agreement for the track response and also for ground vibrations.

In the authors' opinion, the successful of this prediction is intrinsically related with a reliable characterization of the soil and of the track. Despite of the good fit reached between measurements and prediction, it should be noticed that the discrepancies between both results increases when the attention is focused on the prediction of free-field vibrations instead of track vibrations. This evidence is justified by the strong influence that local soil properties and inhomogenities of stiffness and damping can present on the waves propagation mechanisms.

ACKNOWLEDGMENTS

This paper reports research developed under the financial support of "FCT - Fundação para a Ciência e Tecnologia", Portugal, namely from the research project - PTDC/ECM/114505/2009. The first author wishes to thank FCT for the financial support provided by the grant SFRH / BD / 29747 / 2006.

The authors also wish to acknowledge the support of the project "Risk Assessment and Management for High-Speed Rail Systems" of the MIT – Portugal Program Transportation Systems Area.

The collaboration of REFER, CP and LNEC was also appreciated by the authors of the present work.

Keywords: Rheda 2000[®] ballastless track, ballasted track, high-speed railway bridge, dynamic analysis, moving loads, finite element numerical models.

Abstract. *This paper presents a study performed with the purpose of providing a comparison between the effects of the two types of railway track – ballasted and ballastless – in the dynamic behaviour of a bridge. This study also addresses the different methods to model the various types of track, as well as their consequences for the parameters defining the dynamic behaviour of the bridge structure.*

Initially, an overview of the different types of track systems is presented, comprising the more traditional solution of ballasted track, and, alternatively, the ballastless track solution, with an emphasis on the wide range of options currently available for both of these track systems.

At a later stage, the presented study is focused in how the dynamic behaviour of a bridge is affected by the type of track and what might be the consequences for the dynamic response parameters (vertical acceleration, displacement and internal stresses). This work is complemented by a comparative analysis of various numerical models, in which the different types of railway track systems are considered with varying degrees of refinement of the track mechanical models. This comparative analysis is carried out with the hypothetical case study of the São Martinho Viaduct, near Alcácer do Sal, in Portugal, a viaduct that was recently designed and built for conventional rail traffic (design speed of 220 km/h). A comparative

analysis of four types of finite element models of the bridge – solid, shell and frame (grid and single bar) elements – is also presented.

At the end, some conclusions based on parametric analysis of the case study are drawn, highlighting the different results concerning the modelling and the use of these two different railway track systems.

1 INTRODUCTION

The high-speed railway network has imposed stringent new demands on the structure of railway bridges. These demands are, in part, a reaction to the dynamic effects due to the passage of vehicles. As a consequence, the study of the dynamic behaviour of railway bridges subjected to moving vehicles gained a substantial importance in the design of such structures. It is crucial to question the assumptions under which all the study is based, which will largely determine its degree of reliability. It should be noted, for example, the degree of representation and detail desired for a possible numerical model of a bridge. A better representation of the railway track through finite elements may have influence on the dynamic response of the structure. And given this representation, it is interesting to see how some of the components of the track interfere in the dynamic behaviour. Finally, it is important to assess how the type of railway track, i.e. ballasted track or ballastless track, influences such dynamic behaviour.

2 TYPES OF RAILWAY TRACK

2.1 Ballasted track

2.1.1. Track characterization

The ballasted track, Figure 1, is a solution with more than two centuries of existence and has been used in a vast number of high speed tracks. In railway bridges, this typology is composed by the superstructure (rails, sleepers and fastening systems) and by the substructure (ballast).

Figure 1 - Ballasted track.

Besides the fact that this typology is the most commonly used nowadays, the definition of its geometry as well as the properties of the elements used has some variability.

Rails

The rails are the first elements in contact with the vehicle wheels and its main functions are the transmission and distribution of the vertical and horizontal forces by the sleepers and guidance of the vehicle wheels. The choice of the UIC60 rail is justified in high speed lines by technical and economical reasons as referred by Gil [1].

Fastening Systems

The choice of the type of fastening system depends essentially on the railway and sleeper type used and on the stiffness of the granular layers which support the sleepers. These elements should guarantee a good connection between the rail and the sleeper. The rail pads may also be used to limit the stiffness of the railway track in order to reduce the dynamic effects resulted by the circulation of the trains. Teixeira [2] states that, in high-speed railways, the stiffness of the rail pads varies between 30 and 500 kN/mm. In spite of these values being

generally attributed to a certain type of pad, these may not consider the pre-loading effect which has relevant influence in the dynamic properties of the rail pads.

Sleepers

The sleepers are elements of considerable stiffness and allow the distribution of stresses coming from the rail to the layer which supports them. The most common typology is the monoblock sleeper and those elements are generally placed at a distance which can vary between 50 and 70 cm.

Ballast layer

The ballast layer is designed in order to guarantee the capacity of spreading and conveniently transmitting the loads that are transmitted to the supporting structure. In the EN 1991-2 [3], it is referred that, to be assured a good distribution of this stresses without damaging the surface of a bridge or of an eventual ballast mats, a depth not inferior to 250 mm should be adopted. In general, a depth of 350 mm is adopted, which allows an efficient maintenance of the track.

2.1.2. Modelling of the ballasted track

The numeric or analytic modelling of the railway track has been used together with field experiments to study its behaviour as well as its element characterization, its properties and also the vehicle-track-bridge interaction.

Facing the desired goals, more or less detailed models can be used.

The Ballasted Track can be modelled as a simple dead load, distributed over the deck, or by means of intermediate complexity models, in which the physical properties of the track are defined. In this paper, 2D simplified models are presented, based on studies of previous authors, to represent the effect of the various elements of the track:

- **Non-vibrating ballast model:** Calçada [4] and De Man [5] used a model in their studies which considers the rails represented as a beam with an Euler-Bernoulli or Timoshenko behaviour and with such a length that the edge restrictions do not affect the structural behaviour. The sleepers are modelled as suspended masses connected to the beam, in the top, through parallel systems of spring-damper which represents the pads' properties, and to the subsoil/bridge, in the bottom, through parallel spring-damper systems which represent the ballast properties. In this model, the distance between elements is defined by the spacing between sleepers.
- **Vibrating ballast model:** The Specialists' Committee D214 of the ERRI [6] presents a similar model to the one presented beforehand, but which considers the ballast modelled as suspended masses. These masses are connected to the sleepers, in the top, and to the subsoil/bridge, in the bottom, through parallel spring-damper systems which respectively represent the pads' properties and the connection between the ballast and the bridge subsoil.

Figure 2 presents schematically this two simplified models:

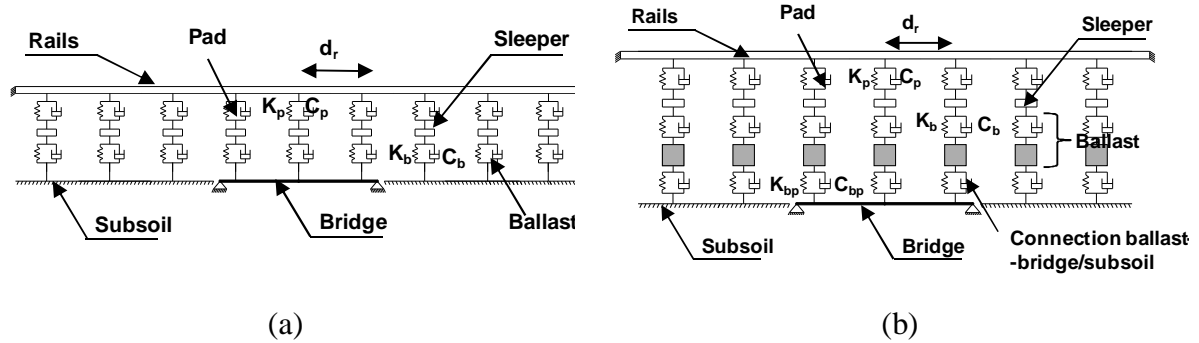

Figure 2 - 2D simplified models of ballasted track: considering the ballast without a vibrating mass (a) and considering the ballast as a vibrating mass (b).

Some properties that characterize elements such as rails, pads and sleepers, can be found in catalogues of suppliers. In this paper, the characterization of the ballast layer may be more ambiguous.

Zhai [7] presents various equations which allow the calculation of the vibrating mass and the vertical stiffness as a function of the geometry of the ballast layer and the distance between sleepers.

The computation of each vibrating mass that corresponds to the influence of a half-sleeper is related to the attenuation angle (α) as presented in Figure 3 and expressed by the following equation.

$$M_b = \rho_b h_b \left[l_e l_b + (l_e + l_b) h_b \tan \alpha + \frac{4}{3} h_b^2 \tan^2 \alpha \right] \quad (1)$$

In which ρ_b is the ballast density, h_b is the depth of ballast, l_e is the effective supporting length of half sleeper and l_b is the width of sleeper underside.

The vertical stiffness for each vibrating mass of the ballast is computed by:

$$K_b = \frac{2(l_e - l_b) \tan \alpha}{\ln(l_e / l_b) (l_b + 2h_b \tan \alpha) / (l_e + 2h_b \tan \alpha)} E_b \quad (2)$$

where E_b is the elastic modulus of the ballast. These equations assume that there is no overlapping over the adjacent cone regions of ballast.

Figure 3 – Model of the ballast under one rail support point.

2.2 Ballastless track

2.2.1. Track characterization

The ballastless track is already at the forefront of the Railway Engineering, presenting a wide range of advantages when compared to the conventional ballasted track. The high demands imposed by high speed railway traffic have provided conditions to invest in a new kind of track with increased performance levels.

Actually, it is especially at high speed that greater benefits can result from the resource to ballastless tracks. This innovative type of railway track stands out mainly for its performance, leading to substantial reductions in maintenance costs and also in maintenance work like tamping, ballast cleaning or track lining. Despite the high initial construction costs, these expenses may be offsetted over the service life of the track, creating a more economical and competitive solution when one assesses a broader dimension of time.

Additionally, the problem with drag forces at ballast due to the passage of high speed trains is no more a reason for concern. Indeed, this feature, together with others, has increasingly been providing the application of ballastless tracks on high speed railway lines.

The wide range of different solutions developed by different countries, such as Germany, Japan or even the Netherlands, may eventually hamper the selection process by the designer. In fact, there is a high technical, economical, or even functional ambiguity among the different solutions available.

Nevertheless the Rheda[®] system may be considered a benchmark for proving its performance and efficiency over the years, having already presented a wide range of applications since its origin.

The cross-section of Rheda 2000[®] ballastless track used on the Hollandsch Diep Bridge, in the Netherlands, on which this study was also based, is depicted in Figure 4.

Figure 4 – Cross-section of Rheda 2000 ballastless track used on the Hollandsch Diep Bridge (in millimetres). Adapted from [8].

The Rheda 2000[®] slab is anchored to the bridge structure in pre-designated free-drilling zones by means of high quality stainless steel dowels with a diameter of 40 mm [8]. An important feature of this connexion is its capacity to allow movements in the longitudinal direction. Thus, the overloading of dowels, as a result of expansion or shrinkage of deck or even track's concrete, can be avoided [9]. The ballastless track is composed by segmented slabs with a length of 3.50 to 6.40 m. The Rheda 2000[®] slab used concrete of C35/45 grade for its construction.

2.2.2. Modelling of the track

The ballastless track was considered according to two different approaches:

- consideration of the track by means of linear distributed forces;
- consideration of the track by means of a finite element model, which reproduces the characteristics of several components of the track.

The first procedure was very simple and easy to perform. The inclusion of the ballastless track in the grid model through its equivalent weight was the basis for this type of representation.

The second procedure, i.e. the numerical modelling, was inspired by the double beam model, a type of representation suggested by several authors [10], [5] and [11] and depicted in Figure 5:

Figure 5 – Schematic representation of the ballastless track model.

The UIC60 rails and the Rheda 2000 slab were modelled using frame elements, while the remainder components were modelled using finite elements that reflect the properties of a viscoelastic material characterized by stiffness and damping values. The longitudinal alignment of the frame elements of the Rheda 2000[®] slab is not continuous but segmented, with segments of 6.5 m length.

3 PRESENTATION OF THE CASE STUDY

3.1 Presentation of the bridge

The case study for the bridge was based on the São Martinho Viaduct, located in the Natural Reserve of the Sado river estuary, near Alcácer do Sal. This structure is designed to accommodate rail traffic on ballasted track, with a design speed of 220 km/h.

From the structural point of view, the Viaduct is composed of 8 continuous segments, 7 with 4 spans of 28.4 m length each, giving a total length of 113.6 m, and another segment with 56.8 m, consisting of 2 spans of 28.4 m. Only the structural portion of 113.6 m in length will be modelled to study its dynamic behaviour.

The Viaduct cross-section (Figure 6) consists of a prestressed concrete deck, composed of two main beams connected by the railway platform concrete slab. At supports there is a diaphragm with 0.60 m width.

The weight of the deck advocated for this viaduct, including the other permanent loads (except the weight of the railway track), corresponds to 248 kN/m.

Figure 6 – São Martinho Viaduct cross-section (in meters). Adapted from [12].

3.2 Numerical modelling of the bridge

São Martinho Viaduct was represented using 4 different numerical models based on finite elements. These 4 models have undergone a process of evaluation and comparison to identify which is the best suited for the present study. The models created were:

- A numerical model with solid finite elements;
- A grid numerical model with frame finite elements;
- A numerical model with shell finite elements;
- A bar numerical model with frame finite elements.

3.2.1. Model with solid elements

This model is composed by solid elements with 8 nodes each. Each node has 3 degrees of freedom of translation, providing a total of 24 degrees of freedom per element. The size of these finite elements was cleared to ensure a high degree of discretization. In total, 60 530 nodes and 37 540 solid finite elements were used.

This model was considered a reference for the calibration of the remaining models, given its high degree of reliability and given the impossibility of conducting an experimental campaign. For such calibration several static and modal analyses were performed.

This model was not selected to perform the planned dynamic analyses because of the unreasonable calculation times that would otherwise greatly extent the duration this task. This situation would persist even if a coarser discretization was used.

3.2.2. Grid model

Regarding the grid model, the Viaduct was modelled in a three-dimensional configuration with frame finite elements.

The two beams were modelled making use of two longitudinal alignments of frame elements with an appropriate cross-section identical to the beam. The frame elements representing the cantilevers and the top slab between beams were calibrated and transversely aligned, being replicated to a constant value of 0.65 m. Finally, the diaphragms were modelled resorting to the use of frame elements with 0.60 m thick. In total, 3002 nodes and 3243 frame finite elements were used.

Figure 7 represents graphically two fundamental mode shapes obtained from modal analysis:

Figure 7 – Graphical representation of the vertical fundamental mode shape ($f=4.0271$ Hz)(a) and of the torsional fundamental mode shape ($f=7.0443$ Hz)(b).

The grid model was selected to perform the desired dynamic study and subsequent dynamic analyses. With a performance very similar to the shell model, regarding the comparison criteria used, this model proved to be a strong option for the realization of dynamic analyses. In addition, the calculation times of this model were likely to be lower than those from the shell model, which did not show other significant advantages. The grid model is the most appropriate, among the four models, to conduct the remaining stages of the desired dynamic study.

3.2.3. Bar model and shell model

These models have interesting features and the results are similar to those obtained from the two models presented above.

Regarding the bar (frame) model, the deck was modelled making use of frame finite elements longitudinally aligned and with an average length of 0.3 m. In order to represent deck areas on piers and on half span, two different cross sections for frame finite elements were defined. In total, 400 nodes and 399 frame finite elements were used.

The bar model was not used to perform dynamic analyses because it is completely unable to effectively represent the torsional behaviour of the Viaduct and, therefore, its torsional mode shapes. This model is not appropriate for the concerned dynamic study since it is not possible to represent, in a reliable way, the effect of the eccentricity of rails.

Regarding the shell model, the beams are represented making use of two longitudinal alignments of shell finite elements classified as “thick” and with a non-constant thickness in order to consider the differences between the bottom and the top of the beam. The top slab between beams and the cantilevers were modelled in a similar way using shell finite elements classified as “thin” and with a non-constant thickness. The diaphragms are represented with shell elements classified as “thin” and with a constant thickness.

In total, this model contains 6825 nodes and 6554 shell finite elements.

The shell model could be a viable option, if the grid model did not exist, thanks to the high degree of reliability of its performance, very close to the model with solid elements. The criteria used for comparison showed few parameters with deviations exceeding 5%. Moreover there is a clear similarity between the first 9 mode shapes and those obtained from the reference model. This option was not used to perform the desired dynamic analyses since it could cause high calculation times. Indeed, as one may know, using shell elements could lead sometimes to a more complex model.

3.3 Railway track models

3.3.1. Ballasted track models

The dynamic analyses of the viaduct can be conducted considering the track as a uniformly distributed load along the deck or considering a simplified model.

Regarding a ballasted track, the EN1991-2 [3] refers that the dynamic analyses should be performed considering the minimum density of a clean ballast with a minimum depth and a maximum saturation density to a dirty ballast taking into account the probable increase on depth of ballast layer. The present study was performed considering a depth of ballast of 350 mm and two different ballast densities $\rho_{\text{ballast}} = 17 \text{ kN/m}^3$ and $\rho_{\text{ballast}} = 20 \text{ kN/m}^3$. Table 1 presents the weight of the ballasted track on the Viaduct.

Typology	Properties	Weight (kN/m)
Ballasted track (double track)	Model BT1 ($\rho_{\text{ballast}}=17 \text{ kN/m}^3$)	95
	Model BT2 ($\rho_{\text{ballast}}=20 \text{ kN/m}^3$)	112

Table 1 – Different typologies of ballasted track considered and its weight per linear meter on the Viaduct.

Regarding the models of ballasted track, Table 2 shows the parameters used on the study of the influence of the various elements of this type of track in the dynamic behaviour of the structure. The geometry of the ballasted track as well as the ballast properties are related to the properties of model BT2.

3.3.2. Ballastless track models

In similarity to the ballasted track, the dynamic analyses were also performed considering the ballastless track by means of linear distributed forces and by means of a simplified finite element model.

The Rheda 2000[®] ballastless track (double track) highlighted in this paper has a weight per linear meter of 35 kN/m [8].

With regard to the track model, the properties of the frame elements are shown in Table 2:

	Parameters of the railway track	Symbology	Value		
			Non-vibrating ballast	Vibrating ballast	Ballastless track
UIC60 Rail	Cross section	$S_r [\text{cm}^2]$	76,86	76,86	76,86
	Mass	$m_r [\text{kg/m}]$	60,34	60,34	60,34
	Elasticity modulus	$E_r [\text{GPa}]$	210,00	210,00	210,00
	Poisson's ratio	$\nu_r [-]$	0,30	0,30	0,30
	Vertical bending inertia	$I_{xx} [\text{cm}^4]$	3050	3050	3050
	Lateral bending inertia	$I_{yy} [\text{cm}^4]$	515,60	515,60	515,60
Pad	Dynamic stiffness	$K_p (\text{MN/m})$	65 [13]	65	Variable
	Damping	$C_p (\text{kNs/m})$	5,50 [13]	5,50	Variable
Sleeper	Mass	$M_s [\text{kg}]$	300	300	-
	Spacing	$l_s [\text{m}]$	0,60	0,60	0,65
Ballast	Vertical stiffness	$K_b [\text{N/m}]$	3,30E08	3,30E08	-
	Damping	$C_b [\text{Ns/m}]$	1,20E05 [6]	1,20E05	-
	Vibrating mass	$M_b [\text{kg}]$	-	770,94	-
Connexion	Vertical stiffness	$K_{bp} [\text{N/m}]$	-	1000E06 [6]	-

Parameters of the railway track		Symbology	Value		
			Non-vibrating ballast	Vibrating ballast	Ballastless track
ballast/deck	Damping	C_{bp} [Ns/m]	-	50E03 [6]	-
Rheda2000® slab	Specific weight	ρ_L [kN/m ³]	-	-	26,37
	Length x Height	L_{xh} [mxm]	-	-	2,60x0,24
	Elasticity modulus	E_L [GPa]	-	-	34,00
	Poisson's ratio	ν_L [-]	-	-	0,20

	Damping	C_{Gt} [GNs/m/m]	-	-	20

Table 2 – Parameters used in the ballasted and ballastless models.

4 DYNAMIC ANALYSES

4.1 General considerations

The dynamic analyses were performed according to the following assumptions:

- The method of modal superposition was applied, considering a number of frequencies and associated mode shapes on the analysis up to the greater of 30 HZ, as recommended in EN1990-A2 [14];
- The structural damping was simulated using the Rayleigh damping;
- The used time step was $\Delta t = 0.005$ s;
- The range of speeds used was 140 km/h to 420 km/h with a speed step of $\Delta v = 10$ km/h;
- Only the 4th span of the Viaduct was assessed.

4.2 Results of the ballasted track models

This subsection presents the results of the dynamic analyses performed, making use of the grid model with and without the ballasted track model. The load models were regarded as moving loads. The realized parametric study aims to assess the effect of the various components of the track in the dynamic behaviour of the support structure.

4.2.1. Grid model without the ballasted track model

The envelope of accelerations and displacements, depicted in Figure 8, were obtained for all the ten HSLM-A defined in EN1991-2 [3] and making use of the grid model without the track model (BT1).

Figure 8 – Envelope of accelerations (a) and envelope of displacements (b) for the passage of the HSLM-A

The following conclusions were drawn:

- a maximum vertical acceleration peak of $a_v = 4,38 \text{ m/s}^2$ occurs for the load model HSLM-A7;
- a maximum vertical displacement peak of $\delta_v = 0,0111 \text{ m}$ occurs for the load model HSLM-A10;
- the limit of $3,5 \text{ m/s}^2$ for the acceleration of ballasted tracks, defined in EN1990-A2 [14], was exceeded;
- the maximum limit of $\delta_{lim} = L/600$ for the vertical displacement, defined in EN1990-A2 [14], was never exceeded.

With regard to the model BT2 and in comparison with the results obtained for the model BT1, a maximum vertical acceleration is obtained with a lower value but occurring also for a lower resonance speed. On the contrary, the maximum vertical displacement is not influenced by the variation of the weight of the track.

4.2.2. Grid model with the ballasted track models

The results presented in Table 3 correspond to the values of the first 5 natural frequencies of the structure with and without consideration of the ballasted track models. There are minor variations of the values in each vibration mode shape and on the first mode shapes this variation is barely perceptible. Such results do not demonstrate a contribution of the ballasted track properties for the overall behaviour of the structure. Analyzing the Figure 9 it is of clear understanding that a superposition of the obtained results exists, not only for the maximum vertical accelerations but also for the maximum vertical displacements along the load path, to the considered speed range. It is concluded, though, that the consideration of the ballasted track models does not change the structural response when the dynamic analysis are limited to lower than 30 Hz mode shapes. To the viaduct modelled with a span length of $L=28.4\text{m}$ the distribution of the loads along various sleepers resulting from the track models, does not contribute to the acceleration reduction nor to the structures' displacements.

Mode shape of vibration	Vibration frequency[Hz]		
	BT2 Model	Vibrating ballast	Non- vibrating ballast
1	3,058	3,059	3,059
2	3,600	3,600	3,600
3	4,653	4,653	4,654
4	5,132	5,146	5,147
5	5,222	5,236	5,237

Table 3 - Comparison of the vibrating frequencies of the viaduct with and without the consideration of the ballasted track models.

Figure 9 – Envelope of accelerations (a) and envelope of displacements (b) for the HSLM-A8, considering three different possibilities for the inclusion of the ballasted track

In fact, calculating the vibration fundamental frequencies of the ballasted track and assuming a simplified SDOF model graphically represented in Figure 10, a fundamental frequency of vibration of 115Hz has been computed, thus largely exceeding the 30 Hz limit of vibration mode shapes to be considered in the dynamic analyses. Barbero [15] has reached similar conclusions and noticed that the railway vibrates jointly with the bridge when the vibration frequencies of the track are much higher than those of the bridge.

Dynamic analyses considering a more flexible ballasted track were also performed. Nevertheless, the obtained results did not show different variations.

Figure 10 – Model with three degrees of freedom representative of the behaviour of the ballasted track.

4.3 Results of the ballastless track model

This subsection presents a comparative study that aims at evaluating the dynamic behaviour of the Viaduct taking into account the type of representation chosen for the ballastless track

4.3.1. Grid model without the ballastless track model

The envelope of accelerations and displacements, depicted in the Figure below, were obtained for all the ten HSLM-A defined in EN1991-2 [3] and making use of the grid model without the track model:

Figure 11 – Envelope of accelerations (a) and envelope of displacements (b) for the passage of the HSLM-A.

As it can be observed:

- the maximum acceleration and displacement occur for the HSLM-A10, which induces dynamic responses with quite significant resonance peaks;
- a maximum acceleration of 4.613 m/s^2 and a maximum displacement of 0.01062 m were computed;
- the serviceability limit of 5 m/s^2 for the acceleration of ballastless tracks, defined in EN1990-A2 [14], was never exceeded;
- the maximum limit of $\delta_{\text{lim}} = L/600$ for the vertical displacement, defined in EN1990-A2 [14], was never exceeded.

4.3.2. Grid model with the ballastless track model

Regarding the grid model with the track model, a parametric study was performed considering the properties of the pads, such as the dynamic stiffness and damping, assigned with the values present in Table 4.

Grid model	Pads	
	Dynamic stiffness $k_{d,p}$ [kN/m]	Damping c_p [kNs/m]
With track model 1	100000	15
With track model 2	100000	75
With track model 3	100000	500
With track model 4	30000	15
With track model 5	30000	75
With track model 6	30000	500
With track model 7	∞	—

Table 4 – List of models tested with distinct properties for the pads.

Figure 12 shows the results obtained from the dynamic analyses performed for the HSLM-A10:

Figure 12 – Envelope of accelerations (a) and displacements (b) for the passage of the HSLM-A10, obtained from the grid model with track model 1-7 and from the grid model without the track model.

As it can be observed, and regarding the 7 models tested, the graphical representations of the envelopes are indistinguishable from each other. The variation of the properties of the pads between the different proposed values does not cause any substantial change in the response of the global structure.

Furthermore, the envelope of accelerations and displacements display deviations when compared to those obtained from the grid model without the track model. However, the configuration of these envelopes still exhibits an obvious similarity.

Similar conclusions were drawn after a parametric study assessing the influence of the geo-textile.

By comparing the dynamic responses of the grid model without the track model and the grid model with the track model it can be concluded that the main differences recorded are due to the frame elements used to represent the rails and the Rheda 2000[®] slab. In fact, these elements add an extra stiffness in the structure. Naturally, such stiffness is not taken into account in the grid model without the track model. This extra stiffness will appreciably change the dynamic response of the structure since these elements absorb some of the load of the vehicles.

Consequently, it is useful to assess the degree of stiffness of the ballastless track since such stiffness might influence the dynamic response of the structure.

4.4 Comparative assessment of the type of track

Aiming for a comparative analysis of the two types of track, it will be taken into account the influence of the weight of the tracks and the influence of the modelling of the tracks in the dynamic response of the structure.

To assess the influence of the weight of the tracks, two grid models without the ballasted track model (BT1 and BT2 with different weights) and the grid model without the ballastless track model (BLT), were considered.

Figure 13 shows the results obtained from the dynamic analyses performed for the HSLM-A10:

Figure 13 – Envelope of accelerations (a) and displacements (b) for the passage of the HSLM-A10, obtained from the grid model without ballastless track model (BLT) and from the grid models without ballasted track model (BT1 and BT2).

As it can be observed, the envelopes of accelerations and displacements are lagged, despite the obvious similarity in their configurations. Thus, the lighter the track is, the more to the right the resonance peaks will be shifted, which will correspond to higher speeds. Furthermore, the lighter the track is, the higher the accelerations peaks will be. In structures with a lighter track one might avoid resonance peaks recorded in structures with heavier tracks if such peaks occur outside the range of speeds analysed.

With Figure 9 and Figure 12 the influence of the modelling of the tracks may be assessed. As can be seen, and contrarily to what occurs in the case of the ballastless track, the ballasted track considered by means of a track model with vibrating ballast or non-vibrating ballast does not cause significant changes in the dynamic response obtained from the grid model without the track model.

This happens because the models with vibrating and non-vibrating ballast are prone to vibrate for frequencies above the limit of 30 Hz, imposed by the EN1990-A2 [14] to determine the dynamic response. Furthermore, it is not considered the shear stiffness of the ballast. Therefore, the ballasted track models added just a small extra stiffness in structure. Such stiffness is related to the rails. This small stiffness increment causes virtually no effect in the dynamic response of the structure.

The ballastless track models also tend to vibrate for high frequencies. However, the Rheda 2000[®] slab adds a significant stiffness in structure.

5 CONCLUSIONS

By assessing the influence of the type of railway track in the dynamic response of the bridge, some conclusions can be drawn:

- When a lighter track is used, the resonance peaks will occur at higher speeds. It is possible to avoid resonance peaks occurring in structures with heavier tracks if a lighter track is used and if such peaks occur outside the range of speeds analysed;
- The lighter the track is, the higher the resonance peaks will be;
- The modelling of the ballasted track does not significantly influence the dynamic response of the global structure when obtained from a grid model without a ballasted track model. On the contrary, such dynamic response may be affected if a ballastless track model is used;
- The increment of stiffness provided by the track is an important feature distinguishing the models of the two types of railway track;
- The railway track models presented tend to vibrate for frequencies above the limit of 30 Hz, advocated by the EN1990-A2 [14] to determine the dynamic response.

6 ACKNOWLEDGMENTS

This study was developed under the co-operation protocol celebrated between IST and Rave in May 2007 and renewed in April 2010. The purpose of this protocol is to support the Portuguese national high-speed railway project with a set of recommendations for the structural design, particularly in what concerns the railway track.

The authors would like to thank GRID, specially Professor Ant3rio Reis and Eng. Nuno Lopes, for supplying valuable data related to the case study. They would also like to send their appreciation to Eng Jo3o Francisco Henriques for his generosity in handing out his pre-process computation, which has proved to be very useful for the dynamic analysis. The opinion and relevant published work of Professor Rui Calçada are also gratefully acknowledged.

Abstract. *A series of finite element analyses have been conducted to assess the capability of an open source finite element code in dynamic analysis of a caisson quay wall with liquefiable backfill and foundation soils. A typical quay wall of Rokko island that suffered large displacements and rotations during the 1995 Earthquake in Kobe was considered as a case study. The nonlinear fully-coupled finite element analyses led to the following observations. Earthquake-induced excess pore water pressures have caused significant stiffness degradation in the backfill and foundation soil. This is a likely cause of large lateral displacements and settlements of the caisson wall and the backfill soil. Vertical displacements of the wall and the backfill soil were under-predicted by the finite element simulations. However the numerical simulations produced correct displacement modes, and the order of magnitude of lateral displacement was also correctly simulated.*

1 INTRODUCTION

In the past two decades, there has been considerable progress in development of advanced constitutive and numerical modeling techniques for seismic analysis of geotechnical structures containing liquefiable granular soils. An accurate estimation of earthquake-induced permanent deformations in these structures is an essential component of a performance-based design approach that is currently becoming the prevailing design concept in geotechnical earthquake engineering. In this paper, a caisson quay wall that suffered large displacements and rotations during the 1995 Earthquake in Kobe (Iganaki, et al., 1996) is considered as a case study (Figure 1). The wall is sitting on rubble material underlain by a medium dense sandy soil. The backfill soil is also a sandy soil underlain by an alluvial clay layer. Iganaki et al. (1996) have presented a detailed study of the engineering properties of the backfill and foundation soils.

Figure 1. A typical section of the caisson quay-wall in Rokko Island that sustained significant damage and permanent deformations during 1995 Kobe Earthquake (Iganaki, et al., 1996)

Iai et al. (1996) conducted detailed finite element simulations of this quay-wall structure by using a multi-mechanism strain-space plasticity model. The results presented by Iai et al. (1996) show good agreement with the observed response of the wall. In this paper, the results of a series of fully-coupled nonlinear finite element analyses are used to examine the capabilities and limitations of an advanced constitutive and numerical modeling platform (OpenSees, <http://opensees.berkeley.edu/index.php>) in seismic analysis of this quay wall system that contains liquefiable soils as backfill and foundation soils. An outline of the numerical simulations and the results obtained in these analyses is presented in this paper.

2 FINITE ELEMENT MODEL

A detailed finite element model of the wall, its foundation and the surrounding soil was developed, and the material models used for different parts of the model were calibrated based on the experimental data available for the site (Iganaki, et al., 1996). A typical finite element mesh used in the analyses is shown in Figure 2. In order to consider wall-water interaction, the body of water in front of the wall was also included in the finite element model (elements shown in red).

Figure 2. A Typical Finite Element Mesh used in the Analyses

Interfaces of the quay wall with the foundation and backfill soils were also modeled using appropriate interface elements. No-tension zero-length elements were used in the interface between the wall and foundation rubble, the wall and backfill rubble, and the wall and water. No friction was considered between the wall and backfill. Friction between the wall and foundation rubble was modeled using zero-length elements.

3 CONSTITUTIVE MODELS

The multi-surface plasticity models implemented in OpenSees platform (Elgamal et al., 2003) were used in the finite element simulations. The pressure dependent multi-surface plasticity model was used for sands and rubbles while the pressure-independent multi-surface plasticity model was used for the alluvial clay. The models were calibrated against the results of the triaxial tests conducted on the soil samples obtained from the site (Iganaki et al., 1996). Calibration efforts showed that it was difficult to match the observed response of the soil at all strain levels and for all shear stress ratios.

Figure 3 shows a typical comparison of the model predictions with the experimental data. In this Figure, the number of cycles to reach a double amplitude axial strain of 5% is plotted against shear stress ratio (i.e. deviatoric stress, τ_d , divided by initial vertical effective stress in the specimen). The calibration efforts showed that it is possible to match the experimental data for any specific level of shear stress ratio. However, when the applied stress ratio is changed to a different level, the predicted number of cycles using the same model constants (parameters) shows some discrepancies with the observed response in the experiments.

Figure 3. Comparison of the Number of Cycles Predicted by the Calibrated Constitutive Model against the Experimental Data Reported by Iganaki et al., (1996) for the Foundation Sand.

4 ANALYSIS STEPS

The finite element simulations were conducted in two steps. First, initial stresses and internal variables of the constitutive models were initialized by using an incremental gravity turn-on technique. Since the site consisted of both cohesionless and cohesive soils, a quasi-static fully-coupled effective stress analysis was conducted to ensure that both the initial pore water pressure and initial effective stresses were fully accounted for before the system was subjected to seismic loading.

Next, the complete soil-wall-water system was subjected to the horizontal and vertical ground motions recorded near the site during the 1995 earthquake (Iganaki, et al., 1996). Mesh sensitivity analyses were conducted to evaluate the accuracy of the numerical solutions. All the simulations were conducted by using the same parameters that were obtained from calibration of the constitutive models.

5 RESULTS

The numerical simulations showed that the earthquake caused significant pore water pressure generation in the backfill sand (Figure 3) and created a near liquefaction state in the foundation sand (Figure 4).

Figure 3. Excess Pore Pressure Ratios Computed at Different Elevations in the Backfill Soil

Figure 3 shows that very large negative excess pore pressure ratio is developed at a soil element located near ground surface in the backfill soil. This is mainly caused by the low confining stress in the soil which makes the soil highly dilative. Much less dilative response is seen in the mid height and bottom of the backfill sand (i.e., near the interface with the alluvial clay) where the higher initial confining stresses make the soil more contractive. It is also observed that the large excess pore pressure at the bottom of the backfill soil brings the

soil to a near liquefaction state. The excess pore pressure ratio remains at its high level even when the earthquake ceases.

Figure 4. Excess Pore Pressure Computed at Different Elevations in the Foundation Soil

Figure 4 shows that large positive excess pore pressure is generated at an element near the bottom of the foundation sand. This excess pore pressure significantly degrades the stiffness of the foundation soil and contributes to the rotation of the quay wall. A soil element near the top of the foundation soil (just below the foundation rubble), however, shows highly dilative response. This is likely due to the large shear stresses imposed by the movement of the wall on a soil element that is under a modest confining stress.

Figure 5. Vertical displacements in the backfill soil far away from the wall

Figure 5 shows the computed vertical displacements in a column of the backfill soil far away from the wall. The backfill soil has experienced significant settlements due to the large excess pore pressure generation caused by the earthquake.

The analysis results also indicate that despite the significant pore pressure generation in the foundation soil, the soil has amplified the base motion and the wall has experienced large horizontal accelerations at its crest. Figure 6 shows a comparison of the acceleration time histories computed at the ground surface and at the wall crest with the assumed base acceleration.

Figure 6. Comparison of the Acceleration Time Histories Computed at the Ground Surface in the Backfill (top) and at the Wall Crest (middle) with the Base Acceleration Time History (bottom).

The finite element simulations show a lateral displacement of about 2 meters for the wall and a settlement of 1 meter in the backfill soil. The wall tilted about 2.5° counter-clockwise.

The simulated displacements and deformation patterns are in general agreement with the observed response of the wall in the field. However both lateral and vertical displacements are under-predicted. Figure 7 shows the earthquake-induced displacements of the quay wall and its surrounding soils at the end of the earthquake loading.

Figure 7. Earthquake-induced Permanent Displacements in the Quay Wall and Surrounding Soils

6 CONCLUDING REMARKS

Based on the finite element simulations presented in this paper, the following observations are made:

- Relatively large excess pore water pressures were developed in the backfill and foundation soils. These excess pore pressures have likely led to significant stiffness degradation in these soils. This is a likely cause of large lateral and vertical displacements and in the caisson quay wall and the backfill soil.
- Vertical displacements of the wall and backfill were under-predicted by the finite element simulations. However, the numerical simulations produced correct displacement patterns, and the order of magnitude of lateral displacements was also correctly simulated.

A key factor contributing to the large rotation of the wall appears to be the local failure of the foundation soil. Given the inherent deficiency of classical continuum formulation in capturing the post-failure response of granular soils, it is difficult to model the local failure in the foundation soil by using the constitutive models that are based on classical continuum mechanics. An enhanced constitutive model with an internal length scale (e.g., Manzari, 2004) is necessary for proper modeling of the settlements and rotations caused by the local failure in the foundation soil.

7 ACKNOWLEDGMENT

The authors are grateful for the support provided by the National Science Foundation via Geomechanics and Geohazard programs directed by Dr. Richard Fragaszy. The first and fourth authors wish to acknowledge the REU supplemental funds for the participation of the fourth author during her undergraduate studies at the George Washington University. Profes-

Dr. Susumu Iai, Dr. Atsushi Nozu, Port and Airport Research Institute, and the Kobe City Government graciously provided the ground motion records used in the simulations.

Abstract. *The purpose of this paper is report on a recently developed methodology to decouple any linear dynamical system. The decoupling transformation is time-varying and reduces to the well known time-invariant modal transformation for linear systems that are undamped or classically damped.*

1 INTRODUCTION

It has long been recognized that coordinate coupling in damped linear systems is a considerable barrier to analysis and design. In the absence of damping, a linear system possesses classical normal modes, which constitute a linear time-invariant coordinate transformation that decouples the system. This process of decoupling the equation of motion of a dynamical system is a time-honored procedure termed modal analysis. A damped linear system cannot be decoupled by modal analysis unless it also possesses a full set of classical normal modes, in which case the system is said to be classically damped. Rayleigh [1] showed that a system is classically damped if its damping matrix is a linear combination of its inertia and stiffness matrices. Practically speaking, classical damping means that energy dissipation is almost uniformly distributed throughout the system. In general, there is no reason why this condition should be satisfied and thus damped linear systems cannot be decoupled by modal analysis [2-6]. In addition, it has been shown [7] that no time-invariant linear transformations in the configuration space can decouple all damped systems. Even partial decoupling, i.e. simultaneous transformation of the coefficient matrices of the equation of motion to upper triangular forms, cannot be ensured with time-invariant linear transformations [8].

It was shown in [9, 10] that a non-classically damped system in free vibration can be transformed into one with classical damping by synchronizing the phase angles in its non-classically damped modes. This process, termed phase synchronization, generates a real time-varying transformation that decouples the system in configuration space. Furthermore, the decoupling procedure reduces to modal analysis under classical damping. When additional time shifts induced by external forces are accounted for, the decoupling transformation for free vibration can be extended to decouple forced vibration [10]. The purpose of this paper is to summarize the decoupling of all linear systems concisely.

2 PROBLEM STATEMENT

The equation of motion of an n -degree-of-freedom viscously damped linear system can be written as

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \mathbf{f}(t) \quad (1)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are real symmetric and positive definite square matrices of order n . The generalized coordinate \mathbf{q} and the excitation $\mathbf{f}(t)$ are real n -dimensional vectors. Unless the three coefficient matrices are diagonal, Eq. (1) is coupled. Coupling is not an inherent property of a system but depends on the generalized coordinates used. The “classical decoupling problem” is concerned with the transformation of Eq. (1) into

$$\ddot{\mathbf{p}} + \mathbf{D}_1\dot{\mathbf{p}} + \mathbf{\Omega}_1\mathbf{p} = \mathbf{g}(t) \quad (2)$$

where \mathbf{D}_1 , $\mathbf{\Omega}_1$ are real diagonal matrices of order n , and \mathbf{p} and $\mathbf{g}(t)$ are also real. Over the years, various types of decoupling approximation were employed in the analysis of damped systems [11-20]. Different indices of coupling were also introduced to quantify coordinate coupling [21-29]. However, a solution to the “classical decoupling problem” has not been reported in the open literature.

2.1 The quadratic eigenvalue problem

Associated with system (1) is the quadratic eigenvalue problem [30-33]

$$(\mathbf{M}\lambda^2 + \mathbf{C}\lambda + \mathbf{K})\mathbf{v} = \mathbf{0} \quad (3)$$

There are $2n$ eigenvalues λ_j but there cannot be more than n linearly independent eigenvectors \mathbf{v}_j , where $j = 1, \dots, 2n$. Because the matrices \mathbf{M} , \mathbf{C} and \mathbf{K} are real, any complex eigen-

values must occur in complex conjugate pairs. The quadratic eigenvalue problem plays a key role in decoupling system (1). In fact, all required parameters for the decoupling transformation can be obtained from the solution of the quadratic eigenvalue problem (3).

2.2 Assumptions and possible relaxation

It will be assumed that the $2n$ eigenvalues λ_j of Eq. (3) are distinct. This assumption is made to streamline the introduction of new concepts and it can be readily relaxed. There will be little change to the exposition of decoupling under the less restrictive condition that eigenvectors associated with repeated eigenvalues are independent. When an eigenvalue is repeated m times and a full complement of m independent eigenvectors cannot be found, the eigenvalue problem (3) is said to be defective [30]. Decoupling of systems with defective eigenvalue problems is of a purely theoretical nature but is still relatively straightforward [see 9, 10 for more details].

2.3 Classical modal analysis

To set up the necessary terminology and notation, the decoupling of classically damped systems will be concisely surveyed. Since \mathbf{M} , \mathbf{K} are positive definite, solution of the symmetric eigenvalue problem

$$\mathbf{K}\mathbf{u} = \lambda\mathbf{M}\mathbf{u} \quad (5)$$

generates n positive eigenvalues λ_i and n real eigenvectors \mathbf{u}_i that are orthogonal with respect to either \mathbf{M} or \mathbf{K} . Upon mass normalization, the eigenvectors constitute the columns of a modal matrix $\mathbf{U} = [\mathbf{u}_1 | \mathbf{u}_2 | \cdots | \mathbf{u}_n]$. Define a modal transformation by

$$\mathbf{q} = \mathbf{U}\mathbf{p} \quad (6)$$

In terms of the principal coordinate \mathbf{p} , Eq. (1) takes the canonical form

$$\ddot{\mathbf{p}} + \mathbf{D}\dot{\mathbf{p}} + \mathbf{\Omega}\mathbf{p} = \mathbf{U}^T \mathbf{f}(t) \quad (7)$$

where $\mathbf{\Omega} = \text{diag}[\lambda_1, \lambda_2, \dots, \lambda_n]$ is the spectral matrix and $\mathbf{D} = \mathbf{U}^T \mathbf{C} \mathbf{U}$ is the modal damping matrix. A system is classically damped if it can be decoupled by classical modal analysis, whereby \mathbf{D} is diagonal. A necessary and sufficient condition [34] for classical damping is $\mathbf{C}\mathbf{M}^{-1}\mathbf{K} = \mathbf{K}\mathbf{M}^{-1}\mathbf{C}$. There is, of course, no particular reason why this condition should be satisfied. In general, a damped linear system cannot be decoupled by classical modal analysis.

Classical modal analysis utilizes real coordinate transformations and is amenable to physical interpretation. Foss and others [35-37] extended classical modal analysis to a process of complex modal analysis in the state space to treat non-classically damped systems. However, complex modal analysis still cannot decouple all damped linear systems. A condition of non-defective eigenvectors in the state space must be satisfied in order for complex modal analysis to achieve complete decoupling. Furthermore, upon state-space transformation it is generally not possible to classify the $2n$ state variables as displacements and velocities. Physical insight is thus greatly diminished. Perhaps it is even fair to say that decoupling in configuration space renders decoupling in state space unnecessary; the state of a system can always be obtained from displacements and their time derivatives.

3 THE DECOUPLING OF FREE VIBRATION

Suppose all eigenvalues of Eq. (3) are complex and distinct. The eigenvalues λ_j of Eq. (3) and the corresponding eigenvectors \mathbf{v}_j occur in n pairs of complex conjugates. Let

$$\lambda_j = \alpha_j + i\omega_j \quad (8)$$

$$\mathbf{v}_j = [r_{j1}e^{-i\varphi_{j1}} \quad r_{j2}e^{-i\varphi_{j2}} \quad \dots \quad r_{jn}e^{-i\varphi_{jn}}]^T \quad (9)$$

where α_j , ω_j , r_{jk} and φ_{jk} are real parameters for $j, k = 1, \dots, n$. The $2n$ complex conjugate eigensolutions $\mathbf{v}_j e^{\lambda_j t}$ are sometimes referred to as the complex modes in configuration space [30, 38, 39]. Two eigensolutions $\mathbf{v}_j e^{\lambda_j t}$ and $\bar{\mathbf{v}}_j e^{\bar{\lambda}_j t}$ combine to generate a non-classically damped mode of vibration [9]. A characteristic of a non-classically damped mode is a constant phase drift between system components in each mode. If suitable phase shifts are introduced into each mode, various components of the system vibrate in a synchronous manner, passing through their equilibrium positions at the same instant of time. In other words, the system is transformed into one with classical damping. A basic objective of a process termed phase synchronization is to do just that [9, 10]. Upon phase synchronization, the resulting classically damped system can be decoupled by modal analysis. When $\mathbf{f}(t) = \mathbf{0}$ and all eigenvalues λ_j of Eq. (3) are complex, Eq. (1) can always be converted into Eq. (2), for which

$$\mathbf{D}_1 = -\text{diag}[\lambda_j + \bar{\lambda}_j] = -\text{diag}[2\alpha_1, 2\alpha_2, \dots, 2\alpha_n] \quad (11)$$

$$\mathbf{\Omega}_1 = \text{diag}[\lambda_j \bar{\lambda}_j] = \text{diag}[\alpha_1^2 + \omega_1^2, \alpha_2^2 + \omega_2^2, \dots, \alpha_n^2 + \omega_n^2] \quad (12)$$

and $\mathbf{g}(t) = \mathbf{0}$. The free response $\mathbf{q}(t)$ of Eq. (1) can be recovered from the free response $\mathbf{p}(t)$ of Eq. (2) by

$$\mathbf{q}(t) = \sum_{j=1}^n \text{diag}[p_j(t - \varphi_{j1}/\omega_j), p_j(t - \varphi_{j2}/\omega_j), \dots, p_j(t - \varphi_{jn}/\omega_j)] \mathbf{z}_j \quad (13)$$

where

$$\mathbf{z}_j = [r_{j1}e^{\alpha_j \varphi_{j1}/\omega_j} \quad r_{j2}e^{\alpha_j \varphi_{j2}/\omega_j} \quad \dots \quad r_{jn}e^{\alpha_j \varphi_{jn}/\omega_j}]^T \quad (14)$$

If system (1) is non-oscillatory, both real and complex eigenvalues λ_j of Eq. (3) occur simultaneously. Free vibration with mixed eigenvalues can be decoupled by dividing its eigensolutions into two groups: one associated with the real eigenvalues and the other with complex eigenvalues. The complex eigensolutions are treated by complex conjugation and the real ones by real quadratic conjugation [10].

Specifically, let $2c$ eigenvalues be complex and $2r = 2(n - c)$ be real. Separate the distinct eigenvalues into two disjoint sets so that

$$\{\lambda\} = \{2c \text{ complex } \lambda\} \cup \{2r \text{ real } \lambda\} \quad (15)$$

The complex eigenvalues occur as c pairs of complex conjugates and the real eigenvalues can be classified into primary eigenvalues (the r smallest ones) and secondary eigenvalues (the r largest ones). Enumerate the eigenvalues in such a way that

$$\{2c \text{ complex } \lambda\} = \{\lambda_1, \dots, \lambda_c, \lambda_{n+1} = \bar{\lambda}_1, \dots, \lambda_{n+c} = \bar{\lambda}_c\} \quad (16)$$

$$\{2r \text{ real } \lambda\} = \{\lambda_{c+1} < \dots < \lambda_n < \lambda_{n+c+1} = \tilde{\lambda}_{c+1} < \dots < \lambda_{2n} = \tilde{\lambda}_n\} \quad (17)$$

The above indexing means that the first c eigenvalues are complex and the next $r = n - c$ are the real secondary eigenvalues. These are followed by c complex conjugates of the first set and finally by r real primary eigenvalues. Simultaneous phase synchronization of all damped modes [9, 10] produces a decoupled system (2) for which

$$\mathbf{D}_1 = -\text{diag}[\lambda_j + \bar{\lambda}_j, \lambda_k + \tilde{\lambda}_k] = -\text{diag}[\lambda_1 + \lambda_{n+1}, \lambda_2 + \lambda_{n+2}, \dots, \lambda_n + \lambda_{2n}] \quad (18)$$

$$\mathbf{\Omega}_1 = \text{diag}[\lambda_j \bar{\lambda}_j, \lambda_k \tilde{\lambda}_k] = \text{diag}[\lambda_1 \lambda_{n+1}, \lambda_2 \lambda_{n+2}, \dots, \lambda_n \lambda_{2n}] \quad (19)$$

The decoupling transformation is given by Eq. (13). See [10] for details on how to compute the parameters α_j , ω_j , r_{jk} and φ_{jk} using the concept of real quadratic conjugation.

4 DECOUPLING OF FORCED VIBRATION

It has been shown [9, 10] that a damped system in free vibration can be decoupled if suitable phase shifts are introduced into each damped mode of vibration so that all components are either in phase or out of phase. This process is termed phase synchronization, and its purpose is to compensate for the time drifts caused by viscous damping. The required phase drifts are constant; that is why the time-varying decoupling transformation for free vibration in Eq. (13) is merely time-shifting. In the presence of an external excitation $\mathbf{f}(t)$, the interplay between these time drifts and $\mathbf{f}(t)$ generates a genuinely time-varying decoupling transformation for forced vibration [10].

Postulate that system (1) is decoupled into the form (2), where the diagonal matrices \mathbf{D}_i , $\mathbf{\Omega}_i$ are still given by Eqs. (18) and (19). What is the relationship between $\mathbf{f}(t)$ and $\mathbf{g}(t)$? How is the decoupling transformation (13) generalized? While it is possible to investigate these issues in the configuration space, with the theoretical framework that has been set up it is more efficient to perform additional manipulations in state space.

Let $2c$ eigenvalues be complex, $2r = 2(n - c)$ be real and enumerate the eigenvalues as in Eqs. (16) – (17). Without loss of generality, normalize the eigenvectors according to

$$2\lambda_j \mathbf{v}_j^T \mathbf{M} \mathbf{v}_j + \mathbf{v}_j^T \mathbf{C} \mathbf{v}_j = \lambda_j - \lambda_{n+j} \quad (20)$$

$$2\lambda_{n+j} \mathbf{v}_{n+j}^T \mathbf{M} \mathbf{v}_{n+j} + \mathbf{v}_{n+j}^T \mathbf{C} \mathbf{v}_{n+j} = \lambda_{n+j} - \lambda_j \quad (21)$$

for $j = 1, \dots, n$. The above normalization reduces to mass normalization if system (1) is undamped or classically damped [6, 9, 10]. Cast Eq. (1) in state space in the symmetric form

$$\begin{bmatrix} \mathbf{C} & \mathbf{M} \\ \mathbf{M} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{q}} \\ \ddot{\mathbf{q}} \end{bmatrix} + \begin{bmatrix} \mathbf{K} & \mathbf{0} \\ \mathbf{0} & -\mathbf{M} \end{bmatrix} \begin{bmatrix} \mathbf{q} \\ \dot{\mathbf{q}} \end{bmatrix} = \begin{bmatrix} \mathbf{f}(t) \\ \mathbf{0} \end{bmatrix} \quad (22)$$

Define a state transformation by

$$\begin{bmatrix} \mathbf{q} \\ \dot{\mathbf{q}} \end{bmatrix} = \begin{bmatrix} (\mathbf{V}\bar{\Lambda} - \bar{\mathbf{V}}\Lambda)(\bar{\Lambda} - \Lambda)^{-1} & (\bar{\mathbf{V}} - \mathbf{V})(\bar{\Lambda} - \Lambda)^{-1} \\ (\mathbf{V} - \bar{\mathbf{V}})\Lambda\bar{\Lambda}(\bar{\Lambda} - \Lambda)^{-1} & (\bar{\mathbf{V}}\Lambda - \mathbf{V}\Lambda)(\bar{\Lambda} - \Lambda)^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \end{bmatrix} \quad (23)$$

where

$$\mathbf{V} = [\mathbf{v}_1 | \dots | \mathbf{v}_n], \mathbf{V}^* = [\mathbf{v}_{n+1} | \dots | \mathbf{v}_{2n}] \quad (24)$$

$$\Lambda = \text{diag}[\lambda_1, \dots, \lambda_n], \Lambda^* = \text{diag}[\lambda_{n+1}, \dots, \lambda_{2n}] \quad (25)$$

Equation (22) becomes

$$\begin{bmatrix} \mathbf{D}_1 & \mathbf{I} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{p}}_1 \\ \dot{\mathbf{p}}_2 \end{bmatrix} + \begin{bmatrix} \mathbf{\Omega}_1 & \mathbf{0} \\ \mathbf{0} & -\mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{T}_1^T \mathbf{f} \\ \mathbf{T}_2^T \mathbf{f} \end{bmatrix} \quad (26)$$

where \mathbf{T}_1 and \mathbf{T}_2 are given by

$$\mathbf{T}_1 = (\mathbf{V}\Lambda^* - \mathbf{V}^*\Lambda)(\Lambda^* - \Lambda)^{-1} \quad (27)$$

$$\mathbf{T}_2 = (\mathbf{V}^* - \mathbf{V})(\Lambda^* - \Lambda)^{-1} \quad (28)$$

and where \mathbf{D}_1 , $\mathbf{\Omega}_1$ are given by Eqs. (18)–(19) (see [10] for details of the calculation). The upper and lower halves of Eq. (26) are

$$\dot{\mathbf{q}} = \mathbf{T}_1 \dot{\mathbf{p}} + \mathbf{T}_2 \ddot{\mathbf{p}} - \mathbf{T}_2 \mathbf{T}_2^T \mathbf{f} \quad (29)$$

$$\dot{\mathbf{q}} = \mathbf{T}_1 \dot{\mathbf{p}}_1 + \mathbf{T}_2 \dot{\mathbf{p}}_2 \quad (30)$$

Eliminate \mathbf{p}_2 from the above two equations to get

$$\ddot{\mathbf{p}}_1 + \mathbf{D}_1 \dot{\mathbf{p}}_1 + \mathbf{\Omega}_1 \mathbf{p}_1 = \mathbf{T}_1^T \mathbf{f} + \mathbf{T}_2^T \dot{\mathbf{f}} \quad (31)$$

When Eqs. (2) and (31) are compared, it becomes obvious that \mathbf{p}_1 can be identified with \mathbf{p} . Therefore, the relationship between $\mathbf{f}(t)$ and $\mathbf{g}(t)$ is

$$\mathbf{g}(t) = \mathbf{T}_1^T \mathbf{f}(t) + \mathbf{T}_2^T \dot{\mathbf{f}}(t) \quad (32)$$

Observe that \mathbf{T}_1 , \mathbf{T}_2 , and hence $\mathbf{g}(t)$ can be readily obtained from the solution of the quadratic eigenvalue problem (3). Upon substitution of Eq. (32) in (2), forced vibration with complex eigenvalues is decoupled in the configuration space.

The relationship between the solution $\mathbf{p}(t)$ of Eq. (2) and solution $\mathbf{q}(t)$ of the original system (1) can be deduced from Eqs. (23), (30) and (31)

$$\mathbf{q} = \mathbf{T}_1 \mathbf{p} + \mathbf{T}_2 \dot{\mathbf{p}} - \mathbf{T}_2 \mathbf{T}_2^T \mathbf{f} \quad (33)$$

The above expression represents a time-varying decoupling transformation in the configuration space. A closer examination of Eq. (33) reveals that it consists of two parts. The first part, $\mathbf{T}_1 \mathbf{p} + \mathbf{T}_2 \dot{\mathbf{p}}$, accounts for time drifts caused by viscous damping in free vibration. The second part, $\mathbf{T}_2 \mathbf{T}_2^T \mathbf{f}$, accounts for time drifts induced by the excitation $\mathbf{f}(t)$. When $\mathbf{f}(t) = \mathbf{0}$, Eq. (33) reduces to $\mathbf{q} = \mathbf{T}_1 \mathbf{p} + \mathbf{T}_2 \dot{\mathbf{p}}$ which, by direct manipulations, is the same as Eq. (13). Thus, the decoupling transformation (33) generalizes the decoupling transformation (13) for free vibration and, therefore, represents **a general decoupling transformation for all non-defective linear dynamical systems**.

To cast Eq. (33) in state space, simply rewrite Eq. (23) in the form

$$\begin{bmatrix} \mathbf{p}(t) \\ \dot{\mathbf{p}}(t) \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{I} \\ \mathbf{\Lambda} & \overline{\mathbf{\Lambda}} \end{bmatrix} \begin{bmatrix} \mathbf{V} & \overline{\mathbf{V}} \\ \mathbf{V}\mathbf{\Lambda} & \overline{\mathbf{V}}\mathbf{\Lambda} \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{q}(t) \\ \dot{\mathbf{q}}(t) \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \mathbf{T}_2^T \mathbf{f}(t) \end{bmatrix} \quad (34)$$

Initial conditions of $\mathbf{p}(t)$ in Eq. (2) and $\mathbf{q}(t)$ in the original system (1) can be connected by putting $t = 0$ in Eq. (34). A flowchart depicting the decoupling method is shown in Fig. 1.

5 REDUCTION TO CLASSICAL MODAL ANALYSIS

The decoupling methodology developed herein is a direct generalization of classical modal analysis. Without loss of generality, assume that all eigenvectors are normalized in accordance with either Eqs. (20)-(21). When real and complex eigenvalues of Eq. (3) occur simultaneously, and the system is classically damped, $\mathbf{V} = \mathbf{V}^* = \mathbf{U}$ [10]. Using Eqs. (27) and (28), it can now be shown that the transformation of excitation in Eq. (32) reduces to $\mathbf{g}(t) = \mathbf{U}^T \mathbf{f}(t)$, while the decoupling transformation in Eq. (33) simplifies to the classical modal transformation $\mathbf{q} = \mathbf{U} \mathbf{p}$. Thus, the decoupling method presented reduces to classical modal analysis for systems that are classically damped.

6 EFFICIENCY OF SOLUTION BY DECOUPLING

Response calculation is probably not the most important reason for decoupling. It is the possibility, for example, of modal reduction and of an investigation of energy distribution among independent coordinates that would make decoupling worthwhile. Nevertheless, it may still be instructive to examine the efficiency of solution of Eq. (1) by decoupling. It will be assumed that the excitation $\mathbf{f}(t)$ and response $\mathbf{q}(t)$ are sufficiently smooth (adequate if twice differentiable).

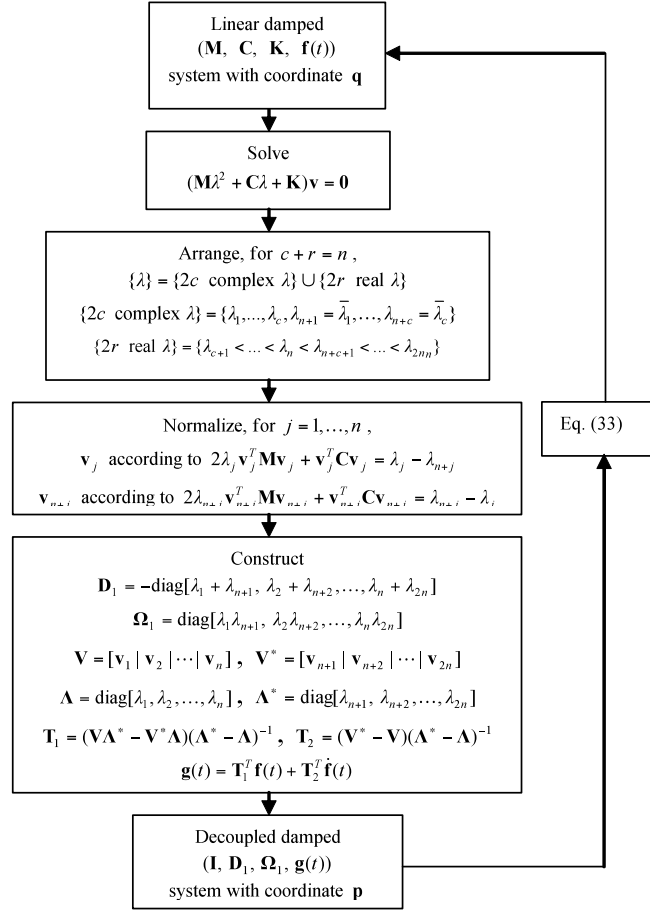

Figure 1: Algorithm for decoupling all linear systems.

One measure of the performance of an algorithm is the number of flops (floating point operations) required to evaluate the response at m points within a given time window. The flops associated with two procedures are compared. (a) In direct numerical integration, a standard procedure is to recast the second-order Eq. (1) in state space as a first-order system of dimension $2n$. The state equation is then discretized, and the resulting difference equation is solved by matrix computations [40]. The estimate of flops of this procedure at m instants is [9, 10, 41-43] $N_1 = 160n^3 + 16mn^2$, where n is the number of degrees of freedom and $m \gg n$ in general. (b) In solving Eq. (1) by decoupling, Eq. (2) is obtained through solution of Eq. (3) and evaluation of Eq. (32). Each independent decoupled system in Eq. (2) is then solved numerically at m instants with the same algorithm used in procedure (a). Subsequently, Eq. (33) is employed to compute the response $q(t)$. The estimate of flops is [9, 10, 41-43] $N_2 = 10mn^2 + 16mn + 213n^3 + 4n^2$. The variations of N_1 and N_2 with n are illustrated in Fig. 2 for a window containing $m = 10^6$ instants.

Figure 2: Comparison of efficiency in response calculation.

It is observed that response calculation by decoupling generally reduces the flops and therefore economizes on both core memory and computing time.

In fact, Fig. 2 is rather conservative because N_2 has been estimated by using the same time step in the integration of all decoupled equations. If an optimal time step is individually chosen for each decoupled equation, N_2 may decrease substantially. Moreover, each decoupled equation may be solved exactly in many applications. On the other hand, the efficiency of response calculation by decoupling depends on the size of the time window. In addition, validity of the flop estimates requires that the excitation is $\mathbf{f}(t)$ sufficiently smooth. Distributional excitation such as an impulse leading to weak solutions ($\mathbf{q}(t)$ less than twice differentiable) are excluded [44, 45]. Thus Fig. 2 should be interpreted as indicative rather than absolute in the comparison of efficiency.

7 NUMERICAL EXAMPLE

A four-degree-of-freedom system possessing both real and complex eigenvalues is decoupled to illustrate the method. The example is taken from [10]. In Eq. (1), let $\mathbf{M} = \mathbf{I}$,

$$\mathbf{C} = \begin{bmatrix} 0.1 & -0.1 & 0 & 0 \\ -0.1 & 0.2 & -0.1 & 0 \\ 0 & -0.1 & 0.2 & -0.1 \\ 0 & 0 & -0.1 & 1.35 \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} 1 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 1.1 \end{bmatrix} \quad (35)$$

and $\mathbf{f}(t) = [0, 0, 0, 1]^T te^{-0.3t} \sin 2t$ and assume zero initial conditions $\mathbf{q}(0) = \mathbf{0}$, $\dot{\mathbf{q}}(0) = \mathbf{0}$. This system is non-classically damped and, therefore, can only be decoupled by the method presented herein. Solution of the quadratic eigenvalue problem (3) yields $c = 3$ pairs of complex conjugate and $r = 1$ pairs of real quadratic conjugate eigenvalues and eigenvectors [10]. From Eqs. (27) and (28),

$$\mathbf{T}_1 = \begin{bmatrix} -0.38 & 0.53 & 0.30 & 0.70 \\ -0.05 & -0.45 & -0.70 & 0.68 \\ 0.52 & -0.66 & 0.64 & 0.64 \\ 1.11 & 0.37 & -0.16 & 0.57 \end{bmatrix} \quad (36)$$

$$\mathbf{T}_2 = \begin{bmatrix} 0.49 & -0.07 & -0.02 & 0.53 \\ 0.71 & -0.07 & 0.03 & 0.31 \\ 0.90 & 0.15 & 0.02 & -0.17 \\ 0.70 & 0.27 & -0.09 & -0.93 \end{bmatrix} \quad (37)$$

It can be checked that the decoupled $(\mathbf{I}, \mathbf{D}_1, \mathbf{\Omega}_1, \mathbf{g}(t))$ system is given by

$$\mathbf{D}_1 = -\text{diag}[\lambda_j + \bar{\lambda}_j (j = 1, 2, 3), \lambda_4 + \bar{\lambda}_4] = \text{diag}[0.65, 0.40, 0.39, 0.41] \quad (38)$$

$$\mathbf{\Omega}_1 = \text{diag}[\lambda_j \bar{\lambda}_j (j = 1, 2, 3), \lambda_4 \bar{\lambda}_4] = \text{diag}[0.46, 1.75, 3.32, 0.04] \quad (39)$$

$$\mathbf{g}(t) = e^{-0.3t} \begin{bmatrix} 1.4t \cos(2t) + (0.70 + 0.90t) \sin(2t) \\ 0.54t \cos(2t) + (0.27 + 0.29t) \sin(2t) \\ -0.18t \cos(2t) - (0.09 + 0.13t) \sin(2t) \\ -1.86t \cos(2t) + (-0.93 + 0.85t) \sin(2t) \end{bmatrix} \quad (40)$$

with initial conditions $\mathbf{p}(0) = \mathbf{0}$, $\dot{\mathbf{p}}(0) = \mathbf{0}$. The decoupled system can be readily solved and solution $\mathbf{q}(t)$ of the original $(\mathbf{M}, \mathbf{C}, \mathbf{K}, \mathbf{f}(t))$ system can be recovered from $\mathbf{p}(t)$ by Eq. (33). As shown in Fig. 3, $\mathbf{g}(t)$, $\mathbf{p}(t)$, and $\mathbf{q}(t)$ are all oscillatory.

Figure 3: Simulation results.

It can be verified that $\mathbf{q}(t)$, whether generated by decoupling or by direct numerical integration, is the same.

8 CONCLUSIONS

A method has been presented to decouple all linear dynamical systems under viscous damping. The decoupling methodology developed herein possesses ample physical insight and it also lends itself to numerical computations. If the linear system is in free vibration, the time varying decoupling transformation in Eq. (33) reduces to a time shifting transformation in Eq. (13). Under classical damping, the decoupling method reduces to modal analysis. Major findings of this paper are summarized in the following statements.

1. In free or forced vibration, all parameters required for the decoupling of a linear system are obtained through the solution of a quadratic eigenvalue problem.

2. Any viscously damped linear system (no restrictions) can be completely decoupled. A flowchart outlining the decoupling procedure is given in Fig. 1.
3. While damped linear systems are decoupled in the configuration space, transformations of initial conditions are prescribed in state space (otherwise initial values are connected at different time instants due to phase synchronization).

To streamline the introduction of new concepts, most formulas have been established with the assumption that eigenvalues of the quadratic eigenvalue problem (3) are distinct. These formulas remain unchanged when Eq. (3) is non-defective (each repeated eigenvalue possesses a full complement of independent eigenvectors). However, a system for which Eq. (3) is defective can still be decoupled by the method presented herein. Due to the lack of practical importance of defective systems (a system is non-defective with probability 1) and because the mathematics becomes quite involved, details on the decoupling of defective systems are deferred to a future paper on general mode-by-mode transformations

Keywords: Dynamic soil-structure interaction, impedance matrix, hybrid Laplace-time domain approach, Convolution Quadrature Method, nonlinear analysis.

Abstract. *Nonlinear dynamic soil-structure interaction problems are usually solved by a sub-structuring technique where the soil-structure system is decomposed into two sub-domains: the nonlinear structure, which can also include a part of the soil showing a nonlinear behavior, and the linear unbounded soil. The present work considers the case where the problem is localized on the building. The effects of the unbounded soil are then represented as a particular type of boundary condition by means of the so-called impedance operator, assumed to be known in the Laplace domain. In this framework, since nonlinearities are taken into account, the problem has to be solved in the time domain. Consequently, the interaction forces are expressed in terms of the Laplace-domain impedance results as a convolution integral between the time impedance coefficients and the nodal displacements located on the interface. In order to compute this convolution product a hybrid Laplace-time domain approach based on a Convolution Quadrature Method is introduced. It allows to express this convolution not only in terms of displacements but also in terms of accelerations and velocities convolutions. The proposed method is finally tested on a soil-structure application modeled with a lumped-parameter system. Satisfactory results are obtained when an elasto-plastic behaviour is accounted for.*

1 INTRODUCTION

The classical dynamic soil-structure interaction method is based on a domain decomposition technique, where the whole soil-structure domain is decomposed into two subdomains: the soil and the structure. Both subdomains lead to a local problem that is solved separately, warranting in a conformal approach that the traction equilibrium and displacement continuity are verified on the soil-structure interface. The main reason for this decomposition is that different numerical methods can be used for the soil and for the structure. On the one hand, the bounded subdomain of the structure can be modeled by means of a Finite Element method which allows to take into account nonlinear phenomena in a straightforward way. On the other, the unbounded linear elastic soil can be computed using a Boundary Element method, the radiation conditions being thus implicitly satisfied. When the soil shows a nonlinear behaviour, the corresponding part of this subdomain should be incorporated to the structure subdomain.

Since engineers are usually more interested in the structural response, the global problem is solved directly in the building and the effect of the soil is taken into account as a particular type of boundary condition. This condition is expressed by means of the so-called impedance operator which, in the present work, is assumed to be known in the Laplace domain. The matrix impedance $s \mapsto \hat{\mathbf{Z}}(s)$, $s \in \mathbb{C}$, i.e. the discretized version of the impedance operator, maps any displacement vector of the soil-structure interface to its corresponding force vector on the same boundary.

When nonlinearities are accounted for, the problem have to be formulated in the time domain. Consequently, the interaction forces on the soil-structure interface denoted by Γ result in a convolution product between the time dynamic impedance coefficients $t \mapsto \mathbf{Z}(t)$ and the degrees-of-freedom of the nodes located on the interface $t \mapsto \mathbf{u}_\Gamma(t)$, $t \in \mathbb{R}$:

$$(\mathbf{Z} * \mathbf{u}_\Gamma)(t) = \int_0^t \mathbf{Z}(t - \tau) \mathbf{u}_\Gamma(\tau) d\tau, \quad 0 \leq t \leq T \quad (1)$$

where the impedance is assumed to satisfy causality properties.

In order to compute this kind of convolution integrals, literature proposes different numerical methods, such as the frequency-time method [1, 2] or the hidden variables method [3], which are based on a frequency domain formulation of the impedance operator. Similarly, some authors have focused on formulations in the Laplace domain [4, 5], showing a special interest when coupled to a Convolution Quadrature Method (CQM) [6].

The approach presented in this article is in essence an extension of the work originally proposed by Moser and al. [7, 8] and Pereira and Beer [9]. A hybrid Laplace-time domain technique is therefore introduced in the following sections in order to numerically evaluate Equation 1. Time is discretized by means of a CQM, so the Laplace transform of the convolution kernel is supposed to be analytic on the complex half-plane $\Re(s) > \sigma_0$ and polynomially bounded for large $|s|$:

$$\|\hat{\mathbf{Z}}(s)\| \leq D|s|^\mu \quad (2)$$

for $D, \mu \in \mathbb{R}$. Particularly, the dynamic impedance matrix will be assumed of the following form:

$$\hat{\mathbf{Z}}(s) = \mathbf{M}_\Gamma s^2 + \mathbf{C}_\Gamma s + \mathbf{K}_\Gamma + \hat{\mathbf{Z}}_{ns}(s) \quad (3)$$

where $\mathbf{K}_\Gamma, \mathbf{C}_\Gamma$ and \mathbf{M}_Γ are the matrices which correspond to the inertial, damping and stiffness effects and where $\hat{\mathbf{Z}}_{ns}(s)$ denotes a non-singular function vanishing for large $|s|$.

2 HYBRID LAPLACE-TIME DOMAIN APPROACH

In this framework, the CQM approximates the convolution integral in Equation 1 by a discrete convolution (time step $\Delta t > 0$):

$$(\mathbf{Z} * \mathbf{u})(n\Delta t) = \sum_{0 \leq n\Delta t \leq t} \Phi_k \mathbf{u}(t - n\Delta t), \quad t = \Delta t, 2\Delta t, 3\Delta t, \dots \quad (4)$$

where coefficients Φ_k correspond to the weights of the generating power series:

$$\sum_{k=0}^{+\infty} \Phi_k \zeta^k = \hat{\mathbf{Z}}(s_{\Delta t}) \quad (5)$$

The complex sampled values $s_{\Delta t}$ of the dynamic soil impedance are given by a rational function of a linear multistep method of order p satisfying strong A -stability conditions. For instance, let $s_{\Delta t}$ be $\frac{\delta(\zeta)}{\Delta t}$ where $\delta(\zeta)$ is the backward differentiation formula of $p = 2$ reading $\delta(\zeta) = \frac{3}{2} - 2\zeta + \frac{1}{2}\zeta^2$.

Nevertheless, paying attention to the physical units of Equation 1, it seems natural to express the convolution not only in terms of displacements, but also in terms of accelerations and velocities. To that end, the polynomial part $\hat{\mathbf{P}}(s)$ of the impedance is factorized yielding to:

$$\hat{\mathbf{Z}}(s) = \hat{\mathbf{Z}}_m(s) \hat{\mathbf{P}}(s) = \hat{\mathbf{Z}}_m(s) \left(\tilde{\mathbf{M}}_{\Gamma} s^2 + \tilde{\mathbf{C}}_{\Gamma} s + \tilde{\mathbf{K}}_{\Gamma} \right) \quad (6)$$

where $\tilde{\mathbf{K}}_{\Gamma}$, $\tilde{\mathbf{C}}_{\Gamma}$ and $\tilde{\mathbf{M}}_{\Gamma}$ are respectively the estimators of the matrices \mathbf{K}_{Γ} , \mathbf{C}_{Γ} and \mathbf{M}_{Γ} presented in Equation 3.

Therefore, the convolution can be written in terms of the Laplace transform as follows:

$$(\mathbf{Z} * \mathbf{u})(t) = \frac{1}{2\pi i} \int_{\sigma_0 + i\mathbb{R}} \hat{\mathbf{Z}}_m(s) \hat{\mathbf{P}}(s) \hat{\mathbf{u}}(s) e^{st} ds \quad (7)$$

The polynomial function $\hat{\mathbf{P}}(s)$ acts thus over the displacement as a differential operator and Equation 1 finally reads:

$$(\mathbf{Z} * \mathbf{u})(t) = (\mathbf{Z}_m * \tilde{\mathbf{M}}_{\Gamma} \ddot{\mathbf{u}})(t) + (\mathbf{Z}_m * \tilde{\mathbf{C}}_{\Gamma} \dot{\mathbf{u}})(t) + (\mathbf{Z}_m * \tilde{\mathbf{K}}_{\Gamma} \mathbf{u})(t) \quad (8)$$

where the interaction force vector (denoted hereafter by $\mathbf{R}_{\Gamma}(t)$) involves in its calculation the evaluation of displacement, velocity and acceleration convolutions.

If a time step $\Delta t > 0$ is chosen, the convolution integral can be discretized again as in Equation 4 leading to:

$$\mathbf{R}_{\Gamma,n} = (\mathbf{Z} * \mathbf{u})(n\Delta t) = \sum_{k=1}^n (\Psi_2^{n-k+1} \ddot{\mathbf{u}}_k + \Psi_1^{n-k+1} \dot{\mathbf{u}}_k + \Psi_0^{n-k+1} \mathbf{u}_k) \quad (9)$$

where matrices multiplying displacement vectors \mathbf{u}_k , velocity vectors $\dot{\mathbf{u}}_k$ and acceleration vectors $\ddot{\mathbf{u}}_k$ are given by:

$$\begin{aligned} \Psi_0^k &= \mathbf{Z}_m^k \tilde{\mathbf{K}}_{\Gamma} \\ \Psi_1^k &= \mathbf{Z}_m^k \tilde{\mathbf{C}}_{\Gamma} \\ \Psi_2^k &= \mathbf{Z}_m^k \tilde{\mathbf{M}}_{\Gamma} \end{aligned} \quad (10)$$

From a numerical point of view, *sub-convolutions* are just unknown at $t = n\Delta t$, since all previous time steps have already been computed. Therefore, Equation 9 can be written by isolating instant n as:

$$\mathbf{R}_{\Gamma,n} = \Psi_2^1 \ddot{\mathbf{u}}_n + \Psi_1^1 \dot{\mathbf{u}}_n + \Psi_0^1 \mathbf{u}_n + \mathbf{R}_{\Sigma(n-1)} \quad (11)$$

Consequently, coefficients $\Psi_i^1 (i = 0, 1, 2)$ are respectively related to instantaneous stiffness, damping and inertia terms and $\mathbf{R}_{\Sigma(n-1)}$ depends only on previous time steps:

$$\mathbf{R}_{\Sigma(n-1)} = \sum_{k=1}^{n-1} (\Psi_2^{n-k+1} \ddot{\mathbf{u}}_k + \Psi_1^{n-k+1} \dot{\mathbf{u}}_k + \Psi_0^{n-k+1} \mathbf{u}_k) \quad (12)$$

3 NUMERICAL APPLICATION

A lumped-parameter model is considered in the following in order to represent the soil-structure system. The nonlinear behaviour is introduced by an elastoplastic spring with one end attached to the upper mass m_1 and the other, to the smaller mass m_2 . A square surface foundation layering on a homogeneous half-space is connected to mass m_2 by means of a rigid body constraint (see Figure 1). The soil impedance seen from the foundation is then computed with a boundary element method in the Laplace domain. For the sake of simplicity, the foundation is modeled to give an impedance in the form of inertial, damping and stiffness terms so that a time reference solution can be straightforwardly obtained. In order to illustrate some properties of the soil-structure system considered in an elastic regime, Table 1 gives the main eigenfrequencies of the structure clamped at its base.

	Pumping	Shaking	Torsional	Rocking
Eigenfrequencies [Hz]	5.43	7.95	99.86	405.34

Table 1: Main eigenfrequencies of the structure clamped at its base.

The soil can be characterized by its shear velocity $C_s = 505 \text{ m.s}^{-1}$ and the elastoplastic behaviour of the spring is modeled with the linear kinematic work hardening law sketched in Figure 1. The elastic deformation is characterized here by the elastic stiffness matrix \mathbf{K}_e which, after reaching the yield of plasticity F_y , becomes $\mathbf{K}_p = 0.1 \mathbf{K}_e$.

Figure 1: (a) Simplified model of a structure on a square surface foundation. (b) Linear kinematic work hardening law of the nonlinear spring K .

Figure 2: Free-field accelerogram applied to m_2 as a representation of the seismic loading.

The loading applied to m_2 in the x -direction e_x corresponds to the earthquake giving the free-field accelerogram $\gamma(t)$ shown in Figure 2, whose maximal acceleration is around $0.3g$.

The governing equations of this numerical model from the non-inertial frame of reference of the structure can be written at $t = n\Delta t$ as follows:

$$\begin{bmatrix} \mathbf{M}_{11} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_{22} + \boldsymbol{\Psi}_2^1 \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}}_{1,n} \\ \ddot{\mathbf{u}}_{2,n} \end{bmatrix} + \begin{bmatrix} \mathbf{F}_{1,n}^{int} \\ \mathbf{F}_{2,n}^{int} \end{bmatrix} = \begin{bmatrix} -\mathbf{M}_1 \mathbf{e}_x \gamma_n \\ -\mathbf{M}_2 \mathbf{e}_x \gamma_n \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ -\mathbf{R}_{\Sigma(n-1)} \end{bmatrix} \quad (13)$$

where $\mathbf{F}_\alpha^{int}(t)$ ($\alpha \in \{1, 2\}$) denote the nonlinear internal efforts in the structure and depend on both displacement and velocity vectors. The interaction forces $\mathbf{R}_{\Gamma,n}$ have been directly substituted by Equation 11. It has to be noticed that the application considered here is particularized to the case where $\tilde{\mathbf{K}}_\Gamma = \tilde{\mathbf{C}}_\Gamma = \mathbf{0}$, that is the case where only inertial terms are taken into account for the computation of the convolution integral:

$$\mathbf{R}_{\Gamma,n} = \sum_{k=1}^n \boldsymbol{\Psi}_2^{n-k+1} \ddot{\mathbf{u}}_{2,k} = \boldsymbol{\Psi}_2^1 \ddot{\mathbf{u}}_{2,n} + \sum_{k=1}^{n-1} \boldsymbol{\Psi}_2^{n-k+1} \ddot{\mathbf{u}}_{2,k} \quad (14)$$

where $\boldsymbol{\Psi}_2^k = \mathbf{Z}_m^k \tilde{\mathbf{M}}_\Gamma$. The coefficients corresponding to \mathbf{Z}_m^k can be efficiently computed by using Fast Fourier Transforms (FFT) [10]:

$$\mathbf{Z}_m^k = \frac{\rho^{-n}}{L} \sum_{l=0}^{L-1} \hat{\mathbf{Z}}_m(s_l) e^{-\frac{2\pi i n l}{L}}, \quad n = 0, 1, \dots, N \quad (15)$$

where ρ represents the radius of a circle in the analyticity domain of $\hat{\mathbf{Z}}_m(s) = s^{-2} \hat{\mathbf{Z}}(s) \tilde{\mathbf{M}}_\Gamma^{-1}$ and $s_l = \frac{\delta(\rho e^{2\pi i l/L})}{\Delta t}$ with $\delta(\zeta)$ the polynomial of the underlying linear multistep method. Assuming that the values of $\hat{\mathbf{Z}}_m$ are computed with precision ϵ_{CQM} , one gets that the error in \mathbf{Z}_m^k is $O(\sqrt{\epsilon_{CQM}})$ when $L = N$ and $\rho^N = \sqrt{\epsilon_{CQM}}$. In addition, the FFT algorithm allows to compute the weights in $O(L \log L)$ operations.

The governing equations are finally solved for displacement by using the modified average acceleration time integration scheme of the Newmark family. This time integration scheme allows to introduce numerical damping by means of the parameter α . Two different yields of plasticity \mathbf{F}_{y1} and \mathbf{F}_{y2} with $\mathbf{F}_{y1} \gg \mathbf{F}_{y2}$. For both cases, Equations 13 have been solved for different accuracies ϵ_{CQM} . In the following, normalized errors during the first T seconds of the earthquake are calculated using the expression $e_T = \frac{RMS(\mathbf{u}-\mathbf{u}_{ref})}{\max(\mathbf{u}_{ref})}$ where RMS and \mathbf{u}_{ref} denote respectively the Root Mean Square and the reference solution. Table 2 presents the errors $e_{10}(\%)$ on the displacement of m_1 in the x -direction. No numerical damping is introduced ($\alpha = 0$).

ϵ_{CQM}	$e_T(\%)$	ϵ_{CQM}	$e_T(\%)$
10^{-04}	5.81	10^{-04}	62.82
10^{-06}	0.76	10^{-06}	2.59
10^{-08}	1.29	10^{-08}	2.73
10^{-10}	1.51	10^{-10}	3.29
10^{-12}	1.53	10^{-12}	3.34

Table 2: Relative errors for different precisions ϵ_{CQM} when the displacement at the top of the structure is computed during $T = 10s$ for (a) \mathbf{F}_{y1} and (b) \mathbf{F}_{y2} , with $\mathbf{F}_{y1} \gg \mathbf{F}_{y2}$ and $\alpha = 0$.

Results presented in Tables 2 show that better agreements with the reference solution are obtained for a precision of $\epsilon_{CQM} = 10^{-06}$ with both yields of plasticity. In addition, it seems that the more nonlinear the response, the larger the error. In fact, if numerical damping is introduced ($\alpha = 0.1$) for the reference solution computed with \mathbf{F}_{y2} and $\epsilon_{CQM} = 10^{-06}$, the measured relative error reduces to $e_{10} = 1.59\%$. The observed dissipation is less important for \mathbf{F}_{y1} . Therefore, the numerical damping introduced by the proposed approach may come from the Newton nonlinear solver.

Figure 3: Displacement at m_1 in the x -direction computed with the hybrid time-Laplace domain approach (black markers) and compared to the reference solution (red line) and to the linear response (blue line) for \mathbf{F}_{y2} .

It should be remarked that if the plasticity yield is chosen sufficiently large, the entire calculation remains linear. Therefore, linear and nonlinear responses can easily be compared using a fixed precision, for example $\epsilon = 10^{-06}$. Figure 3 shows thus the displacement at m_1 in the x -direction compared to the reference solution and also to the linear solution for F_{y2} . It is then observed that the amplitude of displacements is increased as expected. In addition, when the elastoplastic effects are taken into account, the structural response is clearly shifted to the low frequencies because of the reduction in stiffness ($K_{e,i} > K_{p,i}$). However, only one fundamental frequency seems to stand out in the response as if just one equivalent stiffness were present in the system. Hence, the effects of both stiffness K_e and K_p on the response can be highlighted by increasing the yield of plasticity. The response with a larger F_y , plotted in Figure 4, is significantly different from the one plotted in Figure 3 showing in particular a higher frequency content.

Figure 4: Displacement at m_1 in the x -direction computed with the hybrid time-Laplace domain approach (black markers) and compared to the reference solution (red line) for F_{y1} .

Further research has to be pursued in order to investigate if the numerical response is improved when the damping and stiffness parts of the dynamic impedance are also factorized.

4 CONCLUSIONS

The soil-structure interaction problem is solved directly in the building and the impedance operator, defined on the boundary, is used as a particular type of boundary conditions that accounts for the unbounded soil. When nonlinearities are taken into account, the problem is solved in the time domain. Therefore, the influence of the soil is accounted for as a load (interaction forces) computed as a convolution integral in the time domain.

The proposed approach based on the Laplace domain presents some interesting features. On the one hand, it can be combined with IFFT algorithms yielding to small computational costs. On the other hand, it allows to express the convolution integral in terms of inertial, damping and stiffness quantities.

A numerical application considering nonlinear phenomena in the structure has been studied. The convolution integral has been transform to a convolution depending only on acceleration quantities. Very satisfactory results have been obtained when compared to a reference solution. However, it seems that the proposed approach introduces numerical damping when strong elastoplastic behaviour is taken into account.

Keywords: Structural Dynamics, Earthquake Engineering, Angle of Incidence, SSI

Abstract. *The dynamic response of pile foundations and pile supported structures has been extensively studied during the last four decades. Even though, there exists yet the need of achieving a better understanding on different aspects of the problem, such as the response of inclined piles, the influence of the presence of nearby structures, the importance of various kinds of non-linearities, or the influence of the different parameters of the soil-foundation-structure system on the seismic response of the superstructure and on the internal efforts arising along the piles.*

The type of seismic waves impinging on the site, and the angle of incidence of the waves, are important parameters of the seismic excitation. However, vertical incidence of waves is usually assumed in the analysis of the seismic response of piles, and only a small percentage of the large amount of works related to this topic take the angle of incidence into account.

In this work, the influence of the type of wave and its angle of incidence on the seismic response of pile foundations and pile supported structures is investigated using a direct approach. To this end, a frequency-domain boundary element - finite element formulation is used, being the Boundary Element Method used to model the soil as a homogeneous, isotropic, viscoelastic, semi-infinite region; and the Finite Element Method used to model both piles (as Euler-Bernoulli beams) and superstructure (formed by horizontal rigid slabs and extensible vertical elastic piers). The code is able to model the incidence of Rayleigh waves, and also P, SH and SV body waves with a general angle of incidence.

The formulation is briefly presented at the beginning of the paper. Some validation results, in terms of kinematic interaction factors of pile foundations, are presented. Then, different results in terms of internal efforts in piles and inter-storey drift in the superstructure are presented for different types of waves. It is shown that the angle of incidence has a great influence on the structural response, especially in the case of the SV wave, where the critical angle (at which there is a change in the nature of the reflected waves, and whose value depends exclusively on the Poisson's ratio) plays a very important role, as the seismic response of the structure increases greatly around such angle. It is also shown that, in general, the vertical incidence is not the most unfavourable situation.

1 INTRODUCTION

The study presented herein is integrated on a research line focused on the development of numerical models used to determine the dynamic response of structures of different typology. The dynamic response of both deep foundations and piled structures is a topic deeply studied. However, improvements in the comprehension of some aspects of the problem, such as the influence of the direction of propagation of the waves defining the excitation, are still needed.

The numerical methods used to solve the equations of the problem are both the Boundary Element Method (BEM) and the Finite Element Method (FEM). The former allows the treatment of infinite or semi-infinite regions since it implicitly verifies the radiation conditions. Therefore, the BEM is used to model the soil as a homogeneous, isotropic, viscoelastic, semi-infinite region. On the other hand, the FEM is used to model both piles (as Euler-Bernoulli beams) and superstructure (formed by horizontal rigid slabs and extensible vertical elastic columns). The dynamic interaction between the different regions is rigorously formulated using equilibrium and compatibility conditions, leading to a system of equations including unknowns on displacements and tractions on the boundaries of the regions. The system loads are seismic waves of different nature (P, SH and SV waves) with a generic angle of incidence impinging the structural system.

2 MAIN OBJECTIVES

This work investigates the influence of the type of the incident wave and its angle of incidence on the dynamic response of pile foundations and piled buildings in terms of internal efforts in piles and inter-storey drift amplitudes in the superstructure. It also looks into the influence of parameters such as the slenderness of the building on the magnitudes mentioned above. To this end, volumetric P, SH and SV waves propagating through a homogeneous, semi-infinite domain with a generic angle of incidence are taken into account.

3 PROBLEM DEFINITION

3.1 General aspects

In this work, a frequency-domain boundary element - finite element formulation [1] is used, being the Boundary Element Method used to model the soil as a homogeneous, isotropic, viscoelastic semi-infinite region; and the Finite Element Method used to model piles (as Euler-Bernoulli beams) and superstructure (formed by horizontal rigid slabs and extensible vertical columns). A more detailed description of both the numerical aspects of the Boundary Element Method and its use on dynamical problems can be found in [2], while a proper description of the Finite Element Method can be seen in [3].

Once this process is done, the system of equations arising from applying the Boundary Element Method to the soil is coupled with that one coming from the use of the Finite Element Method to model the equations of motion of beams, columns and piles (as seen in [1]), leading to a single system of equations describing the behaviour of the entire problem.

The loads taken into account in the problem are seismic loads. Total displacements and tractions due to the seismic action can be found as the superposition of those caused by the so-called incident field (representing the original waves, coming from a far source) and the scattered field (representing the one produced by the reflection and refraction phenomena). This way, a matrix equation can be written for every domain Ω (see [1, 4]) as:

$$H^{ss} u^s - G^{ss} p^s - \sum_{j=1}^{n_p} G^{spj} q^{sj} + \sum_{j=1}^{n_p} \delta_j \Psi^{sj} F_{p_j} = H^{ss} u_I^s - G^{ss} p_I^s \quad (1)$$

being H^{ss} , G^{ss} and G^{spj} the influence coefficients, u^s and p^s the displacements and tractions of the total field, n_p the number of piles on the domain, q^{sj} the tractions on piles due to the soil, δ_j a parameter taking a unitary value if the j th load line contains the tip of a floating pile and zero otherwise, Ψ^{sj} a three-component vector representing the contribution of the axial force F_{p_j} on the tip of the j th load line and u_I^s and p_I^s the displacements and tractions of the reflected field. The expressions of the latter two values can be found for a generic angle of incidence in [5] (in terms of displacements and tractions) or in [6] (in terms of Lamé's potentials).

3.2 Incident field equations

Let s be a vector defining the direction of propagation of a certain wave and d a vector defining the direction of the particle displacements. These directions are perpendicular in S waves and coincident in P waves. It should also be taken into account that when a wave reaches the free surface of the halfspace, a reflection phenomenon occurs, leading to the propagation of a number of new waves depending on the nature of the incident one. Thus, when an SH wave reaches the free surface, the reflected wave is a single SH wave. If the incident wave is a P or an SV one, then after the process of reflection there appears both a P and an SV waves (see figure 1).

Figure 1: Incident and reflected waves. Incident field

The displacements on the i th direction (x_i , $i = 1, 2, 3$) can be written as:

$$u_i = \sum_{j=1}^n d_i^j A_j e^{-i k_j (s^{(j)} \cdot r)} \quad (2)$$

being u_i the component on the i th direction of the total displacement, n the total number of waves of the problem (i.e., the incident plus the reflected waves), d_i^j the component on the i th direction of the vector containing the direction cosines of the displacements produced by the j th wave, A_j the amplitude of the j th wave, k_j the wave number of the j th wave (defined as the ratio between the excitation frequency ω and the velocity of propagation of the wave) and $s^{(j)} \cdot r$ the dot product of the vector defining the direction of propagation of the j th wave and the vector containing the coordinates of the point where the displacements are calculated.

Once the expressions of the field of displacements are obtained for a point, it is easy to determine the small strain tensor using the compatibility equations. In addition, and provided that the soil is a linear, elastic, homogeneous, isotropic solid, the stress tensor can be obtained using the Hooke's Law.

The boundary conditions of the problem are free surface conditions. Thus, σ_{33} and σ_{23} should be zero in points located on the surface (i.e., those with zero value of their x_3 coordinate). As a consequence of the application of boundary conditions, the angle θ_o of incidence of a wave is equal to the angle θ_1 of the reflected wave of the same kind of the incident one.

Another aspect of interest is that the incidence of an SV wave with a smaller angle than a so-called critical one (directly proportional to the ratio between the velocity of S and P waves on the medium) causes the reflection of both an SV wave and an additional wave. This wave is a P wave in the complex field but represents a surface wave with motions along two perpendicular directions out of phase in the real field. This fact remarkably influences the dynamic response of structures submitted to these types of waves.

4 VALIDATION RESULTS

Once the problem has been briefly explained, it is time to validate the formulation and its computational implementation. To this end, some selected results, in terms of kinematic interaction factors on displacements and rotations at pile caps of different pile foundations are presented.

Some selected results taken from [7] are used to validate the formulation. In these numerical examples, the soil internal damping is $\beta = 0.05$, the ratio between the material moduli is $E_p/E_s = 10^2$ or $E_p/E_s = 10^3$, the ratio between densities is $\rho_p/\rho_s = 1.5$, the piles aspect ratio is $L/d = 20$, and the Poisson's ratios are $\nu_s = 1/3$ (for the soil) and $\nu_p = 0.25$ (for the piles). Results are presented for single piles and groups of 3×3 and 4×4 piles submitted to SH, SV and P waves whose direction of propagation is contained in the x_2x_3 plane.

Figure 2 shows the results obtained using the BEM-FEM model compared with those obtained by Kaynia and Novak using a discrete layer matrix approach. Results of kinematic interaction factors on displacements are presented in terms of the modulus of the horizontal displacement at the pile head ($|u|$) with respect to the modulus of the corresponding free field motion ($|u_{ff}|$). Alternatively, the results of kinematic interaction factors on rotations are presented as the ratio between the modulus of the rotation measured at the pile cap times the pile diameter ($|\phi| d$) and the modulus of the corresponding free field motion. All the results are plotted against the dimensionless frequency, defined as the ratio between the excitation frequency times the pile diameter and the soil shear-wave velocity (i.e., $a_o = \omega d/c_s$). It can be seen that the agreement between the results is very good, with differences reaching 5 or 6 per cent.

5 INFLUENCE OF THE TYPE OF WAVE AND ANGLE OF INCIDENCE ON THE SEISMIC RESPONSE OF PILE FOUNDATIONS AND PILE SUPPORTED STRUCTURES

5.1 Problem definition

The problem studied from now on is sketched in figure 3. The main objective of this example is illustrating the influence of the type of wave and its angle of incidence on the seismic response of pile foundations and pile supported structures. The behaviour of a piled structure is studied. To this end, the superstructure is depicted with a single rigid slab supported by mass-

less flexible columns. This system can represent both a single degree of freedom system (like a one-storey shear building) or an equivalent system defining the behaviour of a multimodal structure according to a specific mode of vibration.

Figure 3: Problem definition

The dynamic behaviour of the structure can be defined by its rigid base fundamental period T , the height h of the resultant of the inertia forces for the first mode, the mass m participating on the first mode and the corresponding structural damping ζ . The horizontal stiffness of the structure is $\mathcal{K} = 4\pi^2 m / T^2$, with a hysteretic damping given by a complex stiffness of the type $k = \mathcal{K} (1 + 2i\zeta)$. The structure is founded on a square 3×3 pile group embedded in a viscoelastic halfspace. Pile groups are defined by the length L and diameter d of the piles, the distance s between adjacent piles, the pile cap mass m_o and its moment of inertia I_o with respect to a horizontal axis going through its center of gravity and by a parameter b measuring half of the width of the foundation. Thus, the movement of the system can be expressed by three degrees of freedom. These degrees of freedom represent horizontal and rocking movements at the rigid pile cap and inter-storey drift in the superstructure.

5.2 Parameters of the problem

Mechanical and geometric properties of soil and foundation are defined by the soil damping ratio $\beta = 0.05$, the Young's modulus ratio $E_p / E_s = 10^2$, the pile-soil densities ratio $\rho_s / \rho_p = 0.7$, the slenderness ratio of the piles $L/d = 15$, the soil Poisson's ratio $\nu_s = 0.4$ and the separation between adjacent piles $s/d = 5$.

The parameters used to depict the dynamic behaviour of the superstructure are the aspect ratios $h/b = 2$ and 4 , the ratio between the stiffnesses of structure and soil $h / (T c_s) = 0.3$, being c_s the shear waves velocity, and the structural damping $\zeta = 0.05$. It is also of interest to know the moment of inertia of the foundation, taken as the 5% of the mh^2 factor, the structure-soil mass ratio $m / (4 \rho_s b^2 h) = 0.2$ and the foundation-structure mass ratio $m_o / m = 0.25$. The values chosen for these three last parameters are considered to be representative for typical constructions.

5.3 Variation of horizontal free-field motion with the angle of incidence

As the following results will be adimensionalized with the horizontal free-field motion at ground surface, it is interesting to study its evolution with the angle of incidence. For this purpose, it is worth noting that the horizontal free-field motion at ground surface is constant with the angle of incidence when the incident wave is an SH one. On the other hand, the

variation of such a magnitude divided by the corresponding amplitude is shown on figure 4 for SV or P incident waves. Note the sharp variation of the values around the critical angle on SV waves ($\theta_{cr} = 52.24^\circ$ for $\nu_s = 0.2$, $\theta_{cr} = 57.69^\circ$ for $\nu_s = 0.3$ and $\theta_{cr} = 65.91^\circ$ for $\nu_s = 0.4$) and the smooth but marked change in the case of P waves.

Figure 4: Variation of horizontal free-field motion at ground surface with the angle of incidence and the Poisson's ratio of the soil. Incident SV and P waves

5.4 Lateral deflection of the building

In this case, deflection amplitude can be defined in terms of variables shown on figure 3 as:

$$u_{def} = u - u_c - \phi h \quad (3)$$

being u the absolute displacement of the vibrating mass. This way, this deflection relates the shear forces F on the base of the structure with the stiffness k of the system ($F = k u_{def}$).

The first set of results is shown on figures 5 and 6. They represent the evolution of the inter-storey drift amplitude with the dimensionless frequency for SH, SV and P incident waves. Results for five different angles of incidence (30, 50, 60, 70 and 90 degrees) are shown. As expected, the deflection shows a maximum around the fundamental frequency of the structure taking SSI into account. For SH, but specially of P waves, the angle of incidence has little influence on the deflection. On the contrary, it shows a very strong influence for the SV wave. Note that u_{def} is normalized by u_{ff} , which for $\theta_o = 30^\circ$ and 50 has significantly smaller values than for the rest of angles. This variation of u_{ff} with θ_o (shown above in figure 4) is in part responsible for the great increment of the deflection for $\theta_o = 30^\circ$. In addition, rotations at pile cap are substantially greater for $\theta_o = 30^\circ$ than for the rest of angles, and since u_{def} depends on such a value (see equation 3), the observed values are justified.

5.5 Internal efforts in piles

This last set of results represents axial, shear forces and bending moments at the pile head of the four representative piles. Two different aspect ratios are considered ($h/b = 2$ and 4) and results are normalized by the corresponding stiffness of a Euler-Bernoulli beam with the properties of the pile.

The results shown on figures from 7 to 15 have a general trend of increasing efforts with the aspect ratio. Like on deflection drift amplitudes, these results also have a peak value around the fundamental frequency of the building taking SSI into account.

It is worth noting that the axial forces arising from the incidence of an SH wave are null on the central piles of the group. This is because the vertical displacement of the center of gravity of the pile cap is also null, rotating the pile cap around an axis passing through the central piles of the group. Therefore, central piles are unloaded.

6 CONCLUSIONS

The influence of the type of wave and its angle of incidence on the dynamic response of pile foundations and superstructures has been studied throughout this work. To this end, the inter-storey drift amplitude and the internal efforts in piles of a piled building modelled as a single degree of freedom system are determined using a BEM-FEM approach. Results are presented in this work for three different incident volumetric waves (P, SH and SV) and two ratios between the height of the superstructure and half the width of the pile cap.

The angle of incidence has a strong influence on the behaviour of piled structures. This effect is particularly marked when the incident wave is an SV one. There exist great differences between the displacements and efforts arising from incident waves of the same amplitude but with angles slightly different from the critical angle. Then, the widely accepted hypothesis of vertical incidence of the waves does not have to necessarily be the most unfavorable situation from the point of view of both piled foundations or superstructures.

ON INTENSITY MEASURE SELECTION FOR NONLINEAR DYNAMIC ANALYSIS OF SOIL-MDOF STRUCTURE INTERACTING SYSTEMS

Abedi Nik Farhad¹, Khoshnoudian Faramarz¹

¹ Department of Civil and Environmental Engineering, Tehran Polytechnic University, Iran

Farnikan@aut.ac.ir

Keywords: Soil-Structure Interaction, Intensity Measure, Ground Motion Scaling, Multi Degree of Freedom Structure

Abstract. *A major source of variability in seismic responses of structures arises from selecting the earthquake Intensity Measure (IM), for conducting nonlinear dynamic analysis, relative to the damaging effects of earthquakes on structures. In this paper, the capability of the six most common IMs on estimation of Engineering Demand Parameters (EDPs) of Soil-MDOF Structure Interacting (SMSI) systems is investigated. Two-dimensional structural models of 5, 10 and 20 stories shear buildings are studied, using elasto-plastic MDOF stick models, whereas the underlying soil is considered as a homogeneous elastic half space and is modeled using the cone model concept. Then, the systems are subjected to 60 representative ground motions. The analyses are done directly in time domain using direct step-by-step integration method. This paper attempts to elucidate the accuracy and efficiency of considered methods for the evaluation of EDPs, in SMSI systems, and to find the most effective IM. For this purpose, two criteria are examined: (a) the median of EDPs in comparison with the predicted values, obtained from regression analyses, and (b) coefficient of variations of EDPs. The results show that a suitable IM for an EDP may differ from one to another in terms of accuracy and efficiency. Finally, the appropriate IM is proposed for each of the considered EDPs.*

1 INTRODUCTION

The selection of the measure of ground motion intensity challenges researchers, since an appropriate intensity measure (IM), can significantly decrease the runtime of the estimation of engineering demand parameter (EDP). This may lead to more reliable evaluations of the seismic performance of the facilities. Researchers have suggested various measure of ground motion intensity. Shome et al. (1998) [1] recommended that scaling of ground motions to a given level of spectral ordinate at the fundamental period of vibration significantly decrease the variability in the maximum demand observed in the structural system. In another study, Cordova et al. (2000) [2] proposed an intensity measure that accounts for period softening to reduce variability at large levels of maximum interstory drift ratio, drift demands larger than 5%, for composite structures. Luco and Cornell (2001) [3] investigated the effects of six different intensity measures on the estimation of the maximum interstory drift ratio for moderate-to-long period buildings using the concepts of efficiency and sufficiency for an intensity measure. Baker and Cornell (2005) [4] proposed a vector IM containing two or three parameters as opposed to the scalar IMs that contain only a single parameter.

Almost all previous studies on IM selection have either dealt only with the response of fixed base SDOF or MDOF structures. The objective in this study is to evaluate six different measures of ground motion intensity using the results of response history analyses in the context of Soil-MDOF Structure Interaction (SMSI) problem. Two types of structural responses are investigated; maximum roof drift ratio (MRDR) and peak floor acceleration, (PFA), may occur anywhere in the height of structure.

2 SOIL-MDOF STRUCTURE NUMERICAL MODEL

As shown in Figure 1, the system under consideration consists of an N-story building and a foundation resting on a soil medium. The structure is modeled as a shear building with equivalent circular plan. Let m_i , I_i , r_i and H_i denote the mass, the mass moment of inertia around its geometric center, the radius of the equivalent circular plan and the height of the mass in the i^{th} story from the foundation surface, respectively.

This research assumes that the characteristics of all stories are the same. The foundation is treated as a circular rigid disk and the flexibility of the foundation is not taken into account. The mass and mass moment of inertia of foundation are expressed by m_0 and I_0 , respectively. The mass of foundation is considered so that foundation uplift does not occur due to design earthquake load, and with considering the empirical relationship between the ratio of m_0 and total mass of structure for typical buildings. In this case, $0.05 \leq (m_0/M) \leq 0.5$ is selected for the considered structures, where M is the total mass of the superstructure.

In order to model soil beneath the structure, a lumped-parameter model is adopted to represent the soil and the interaction mechanisms. The soil beneath the foundation is assumed a homogenous half-space and replaced by a simplified 3DOF system based on the concept of Cone Models. Cone model was proposed by Meek and Wolf (1993) [5] and Wolf (1994) [6] for evaluating the dynamic stiffness and the effective input motion of a foundation on the ground.

To consider the frequency dependency of the rotational spring and dashpot coefficients, the additional internal rotational degree of freedom θ , is assigned to a polar mass moment of inertia, M_θ , and connected to the foundation node using a rotational dashpot, with the high frequency limit of the radiation damping. For the motions in the case of nearly incompressible and incompressible soil, corresponding modifications are performed for the soil with Poisson's ratio greater than 0.3, Wolf (2004) [7].

3 SOIL-MDOF STRUCTURE SYSTEMS CONSIDERED

Table 1 briefly summarizes the interacting system models evaluated in this paper. These specific three buildings are chosen to capture some variation in number of stories and first-mode period of system. The story shear force-interstory drift relationship is modeled by a normal bilinear hysteretic rule with 5% strain hardening ratio. All of the considered structures have the same value of aspect ratio, $H_n/r = 3$, and viscous damping coefficient $\xi_{str} = 5\%$.

For the superstructure, nonuniform distribution of lateral stiffness and yielding strength along the height of the structure are considered. For this purpose, the vertical distribution coefficient in accordance with ASCE7 (2010) [9] method is calculated. The yield strength of structure is determined in basis of the response modification coefficient and the overstrength factor equal to 8 and 2, respectively ($R = 8$ and $\Omega_0 = 2$).

In order to comparison of soil flexibility condition in the studied systems, dimensionless frequency parameter, a_0 , is introduced as an index for the Structure-to-Soil stiffness ratio:

$$a_0 = \frac{\omega_{fix} H_n}{V_s} \quad (1)$$

Where, ω_{fix} is the circular frequency of the fixed base structure.

It should be noted that two different base fixity conditions are considered base on values of dimensionless frequency. $a_0 = 0$ and $a_0 = 3$ which are representative of the fixed base structure and predominant SSI effect, respectively.

Stories	Fundamental Period	
	Interacting System ($a_0 = 3$)	Fixed Base Structure ($a_0 = 0$)
5	0.75	0.55
10	1.20	0.90
20	2.00	1.50

Table 1: Period of systems in flexible and fixed base conditions

4 REGRESSION ANALYSIS AND POINT OF COMPARISON

To evaluate the prediction accuracy of the various IM methods, it may be helpful to establish an estimate of the true response limit. Because of uncertainty in knowledge of ground motion behavior, this prediction is termed the Point of Comparison (POC) [10].

In order to estimate the POC values of response parameters of interest (MRDR and PFA), a large number of SMSI systems analyses are performed. For this purpose, 60 representative ground motions are scaled by 16 incremental scale factor (a total of 5760 independent nonlinear analyses for SMSI systems) and MRDRs and PFAs are recorded for each analysis, along with spectral acceleration at periods of interest, $S_a(\beta_i T_1)$.

To create a predictive equation that relates the spectral accelerations to the observed structural response, regression analysis is used. For this study, the following functional form is selected to model the EDPs of interest.

$$\ln(\text{EDP}) = a_0 + \sum_{i=1}^{11} \left[a_i (\ln S_a(\beta_i T_1)) + b_i (\ln S_a(\beta_i T_1))^2 \right] \quad (2)$$

Where β_i coefficients are selected in eleven different levels to consider the spectral shape of each record, including $\beta = \{0, 0.1, 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 2.0, 2.5, 3.0\}$. Then, a_i and b_i coefficients are determined using least-squares regression.

The values of POC and coefficients of determination, R^2 , of predictive equation obtained from this procedure are shown in Table 2. In general, the selected regression model has good predictive ability as indicated by its R^2 values greater than 90% in the most cases, which indicates that the predictive equation explains more than 90% of variance in $\ln(\text{EDP})$ observed in the raw data.

Structure / System	MRDR		PFA	
	POC	R^2	POC	R^2
5-Story / SSI	0.023	0.945	14.60	0.907
10-Story / SSI	0.016	0.921	17.96	0.903
20-Story / SSI	0.011	0.921	19.85	0.881
5-Story / Fixed	0.020	0.877	16.00	0.932
10-Story / Fixed	0.018	0.906	17.32	0.918
20-Story / Fixed	0.010	0.922	18.70	0.897

5 EVALUATION OF INTENSITY MEASURE METHODS

The objective in this study is to evaluate capability of six common Intensity Measures (IMs) on estimation of EDPs of SMSI systems. As expressed in introduction, Maximum Roof Drift Ratio (MRDR) and peak floor acceleration (PFA), occurring anywhere in the structure, are the focuses on this current paper as EDPs.

Many different methods for scaling to specified severity are proposed in the literature. In this study, the following methods are explored:

IM-1: Scaling the ground motions to a constant peak ground acceleration, PGA.

$$IM_1 = S_a(T = 0) \quad (3)$$

IM-2: Scaling the ground motions to the spectral acceleration measured at the fundamental period of vibration.

$$IM_2 = S_a(T_1) \quad (4)$$

IM-3: Scaling the ground motions to a two-parameter intensity index proposed by Cordova et. al (2000) [2].

$$IM_3 = \sqrt{S_a(T_1)S_a(2T_1)} \quad (5)$$

IM-4: Scaling the ground motions to the intensity measure proposed by Cornell and Luco (2001) [3], base on the ratio of inelastic spectral displacement to the corresponding elastic spectral displacement and participation factors.

$$IM_4 = \frac{S_d^I(T_1, \xi_1, d_y)}{S_d(T_1, \xi_1)} \sqrt{\left[PF_1^{[2]}S_d(T_1, \xi_1)\right]^2 + \left[PF_2^{[2]}S_d(T_2, \xi_2)\right]^2} \quad (6)$$

IM-5: Scaling the ground motions to three-parameter intensity measure proposed by Vamvatsikos and Cornell (2005) [11].

$$IM_5 = \sqrt[3]{S_a(\tau_a)S_a(\tau_b)S_a(\tau_c)} \quad (7)$$

IM-6: Scaling the ground motions in accordance with the provisions of seismic codes such as NEHRP 2003 [12]. In this case, the ground motions are scaled such that for each period between $0.2T_1$ and $1.5T_1$ the average of the five-percent damped response spectra for the suit of ground motion is not less than the corresponding ordinate of the target response spectrum.

Where

- T_1 : Fundamental period of the Soil-MDOF Structure system
- $S_d^I(T_1, \xi_1, d_y)$: The spectral displacement of an elastic-perfectly-plastic oscillator with period T_1 , damping ratio ξ_1 , and yield-displacement d_y
- $S_d(T_1, \xi_1)$: Elastic spectral displacement with period T_1 and damping ratio ξ_1
- $PF_1^{[2]}$: The first-mode participation factor for the story corresponding to the first-two-mode SRSS estimate of EDP.
- τ_a, τ_b and τ_c : Arbitrary periods, which are selected in this research equal to T_2 , T_1 and $1.5T_1$

More descriptions and information about the parameters used in the mentioned intensity measure can be reached in the relevant references.

The Maximum Considered Earthquake (MCE) spectrum, introduced in current building code provisions (ASCE 2010 [9]), is selected as target spectrum. For each of applied ground

motion records, a scale factor is calculated so that the same values of intensity measure is obtained from target spectrum (MCE) and each of the individual ground motion response spectrum.

Three selected structures are analyzed using 60 ordinary ground motion records in the fixed and flexible base conditions. In each case, the quality of distribution of results, their averages and coefficient of variation (COV) are shown in Figure 2 to 4.

6 CONCLUSIONS

The objective of this study was to gain an insight on capability of the six different methods of scaling earthquake ground motions required for nonlinear dynamic analysis of MDOF structure in context of soil-structure interaction problem. For this purpose, two criteria are examined: (a) the mean value of EDPs in comparison with the predicted values, obtained from regression analyses, and (b) dispersion of the response. As shown in figure 2 and 4, the following conclusions can be drawn from the investigation of MRDR results:

- In most cases, with increasing number of stories, the dispersion of MRDR tendency to decrease and concentration of mean of results around POC values increases. In this regard, as indicated in figure 4, IM-3 and IM-5 indicate the lowest values of dispersion in comparison with other methods.
- IM-1 and IM-6 can lead to conservative mean for 5-story and all building considered in comparison with POC value, respectively. The values of COV are between about 50% and 65% for IM-1 and between about 30% and 70% for IM-6, in the considered systems, which may not be desirable.
- Mean of the results obtained through IM-4 represents the least values of response. Accordingly, IM-4 might be taken as an unsafe method in accordance with POC values.
- In comparison with the other methods, e.g. IM-2, 3 and 5, for the case of maximum roof drift ratio (MRDR), IM-3 may be better measure of intensity in terms of estimating the dispersion and mean of the responses, both at fixed and flexible base conditions.

As indicated in figure 3 and 4, for the case of PFA response, the conclusion may be summarized as follows:

- Except for IM-1, in the other cases, along with increasing number of stories, the dispersion of PFA is increasing.
- In general, for the case of the peak floor acceleration, PFA, the dispersion of results due to IM-1 has the lowest values. Therefore, PGA is the best measure of intensity in terms of estimating the dispersion and mean of the response, both at fixed and flexible base structures. Similar conclusion had been presented by Aslani and Miranda (2005) [13] for fixed base structures.

Finally, it can be noted that base on engineering demand parameter of interest, the type of the appropriate measure of ground motion intensity (IM) may be changed. It should be recall that the results presented here are based on a suite of soil-structure models and these models are by no means representative of all classes of systems in existence. It is believed that further work is needed to consider more different types of EDPs and IMs.

Keywords: Basement wall, seismic, lateral earth pressure.

Abstract. *Structural and geotechnical engineers have long relied upon the use of the popular Mononobe-Okabe (M-O) method for determining seismic lateral pressures acting on retaining walls. This limit equilibrium-based method was originally developed for rigid retaining walls with sufficient rigid body displacements to mobilize the active wedge in the backfill soil. In reality, however, certain types of retaining walls, such as basement walls, have variable degrees of flexibility and deformation at different depths. Recently, the Structural Engineers Association of British Columbia (SEABC) initiated a task force to review the problem. The authors are members of this task force committee and have carried out series of dynamic numerical analyses to study lateral earth pressures against basement walls taking into account the flexibility and potential yielding of the wall components. This paper outlines a part of the findings in this study.*
