Basement walls constitute an integral part of tall buildings. These walls should be designed to resist the static and seismically induced lateral earth pressures. Since no guideline exists that specifically addresses seismic design of basement walls, designers use the Coulomb theory to find the static active lateral thrust from soil to the wall and the Mononobe and Okabe (M-O) method [1] to find the total (static and earthquake induced) active lateral thrust during seismic loading. Based on the Coulomb theory and the M-O method the active static and the total (static and earthquake induced) active lateral thrusts on a wall are given by $P_A = \gamma H^2 K_A / 2$ and $P_{AE} = \gamma H^2 K_{AE} / 2$, respectively, where P_A and P_{AE} are the active earth pressure coefficient without and with the earthquake effect, γ is the soil density, and H is the retaining wall height. For a straight wall with level backfill, K_A and K_{AE} are mainly functions of the friction angle of the soil and the angle of wall friction. The K_{AE} is also a function of the horizontal and vertical coefficients of Peak Ground Acceleration (PGA). These limit equilibrium-based methods were originally developed for rigid retaining walls with sufficient rigid body displacements to mobilize the active wedge in the backfill soil. Basement walls, on the other hand, have variable degrees of flexibility and deformation at different depths. The M-O method also assumes that the movement of basement wall will be sufficient to produce minimum active pressure. It also assumes that the soil behind the wall acts as a rigid body and does not account for flexibility of the soil-structure system. The M-O method only provides the total lateral earth pressure, P_{AE} . It does not explicitly indicate anything about the distribution of lateral earth pressure from seismic events. Several studies have been conducted for investigating the distribution of the lateral earth pressures and the point of application of the resultant lateral forces, depending on the mode of deformation of the wall (e.g., see [2–4]).

The current state of practice for design of basement walls is using the Coulomb theory and the M-O method for finding the static and total lateral thrusts, P_A and P_{AE} . It is also the current state of practice to use the PGA for application of the M-O method in the basement wall problems. In this method the soil is assumed to behave as a rigid mass and consequently the inertial force is equally distributed throughout the soil mass. However, wave scattering analyses by Segrestin and Bastick [5] show that for walls in excess of 20 or 30 ft, it is more justified to use an equivalent seismic coefficient. AASHTO LRFD Bridge Design Specification [6] provides a useful guideline for the conventional gravity and semi-gravity cantilever walls, non-gravity walls, and anchor walls. The guideline suggests the use of M-O method to estimate equivalent static force for gravity walls. However for non-gravity walls the guideline is not explicit and suggests the use of the M-O method with a factor for adjusting the PGA as a function of the wall height. For finding the distribution of the total lateral thrust, the P_A is distributed linearly along the wall height as a triangle with zero pressure at the surface and a pressure equivalent to $\gamma H K_A$ at the base. The total active thrust can be divided into the static component, P_A , and a dynamic component $\Delta P_{AE} = P_{AE} - P_A$. It is the current state of practice to distribute the dynamic component ΔP_{AE} as an inverse triangle along the height of the wall with zero pressure at the base of the wall and a pressure equivalent to $\gamma H (K_{AE} - K_A)$ at the ground surface. This distribution of lateral earth pressures is then used for finding the resulting moments in the walls and eventually simplified design of the walls.

The seismic hazard level in the 1995 edition of the National Building Code of Canada [7] for design of buildings had a probability of exceedance of 10% in 50 years. The related PGA hazard under NBCC1995 is 0.24g for Vancouver area. The designers were using the M-O method, as explained above, with this PGA for estimating the seismic lateral pressures and eventually designing the basement walls. The 2005 edition of the National Building Code of Canada [8] suggest a higher seismic hazard level for design of buildings that is probability of

exceedance of 2% in 50 years. For Vancouver, the related PGA hazard under NBCC2005 is as big as 0.46g. Using the M-O method with this high PGA results in a high demand in designing the basement walls and this has raised some concerns for the design engineers on the applicability of the M-O method for the basement walls.

Recently, the Structural Engineers Association of British Columbia (SEABC) initiated a task force to review the problem. The authors are members of this task force committee and have carried out series of dynamic numerical analyses that take into account the flexibility and potential yielding of the wall components, as an effective procedure to study the lateral earth pressures against basement walls. To this end a specific type of wall, designed by the structural engineers using the current state of practice to withstand a seismic event in Vancouver with 10% probability of exceedance in 50 years, has been numerically analyzed in this study. Performance of this wall has been studied for three seismic events with 2% probability of occurrence in 50 years in Vancouver, a higher seismic demand enforced by the NBCC2005. In addition, the dynamic analysis results are compared to the standard methods of determining lateral earth pressures on the wall. The results to date indicate that flexibility of the walls has important effects on the distribution of the seismic lateral pressures on the walls. This paper outlines a part of the findings in this study.

2 PROPERTIES OF WALL

A specific basement wall designed by the structural engineers for this study based on the current state of practice, as explained in the previous section. A PGA of 0.24g was used in M-O equation for design of the wall. This corresponds to a probability of exceedance of 10% in 50 years (NBCC1995), although the current PGA for design is 0.46g (NBCC 2005).

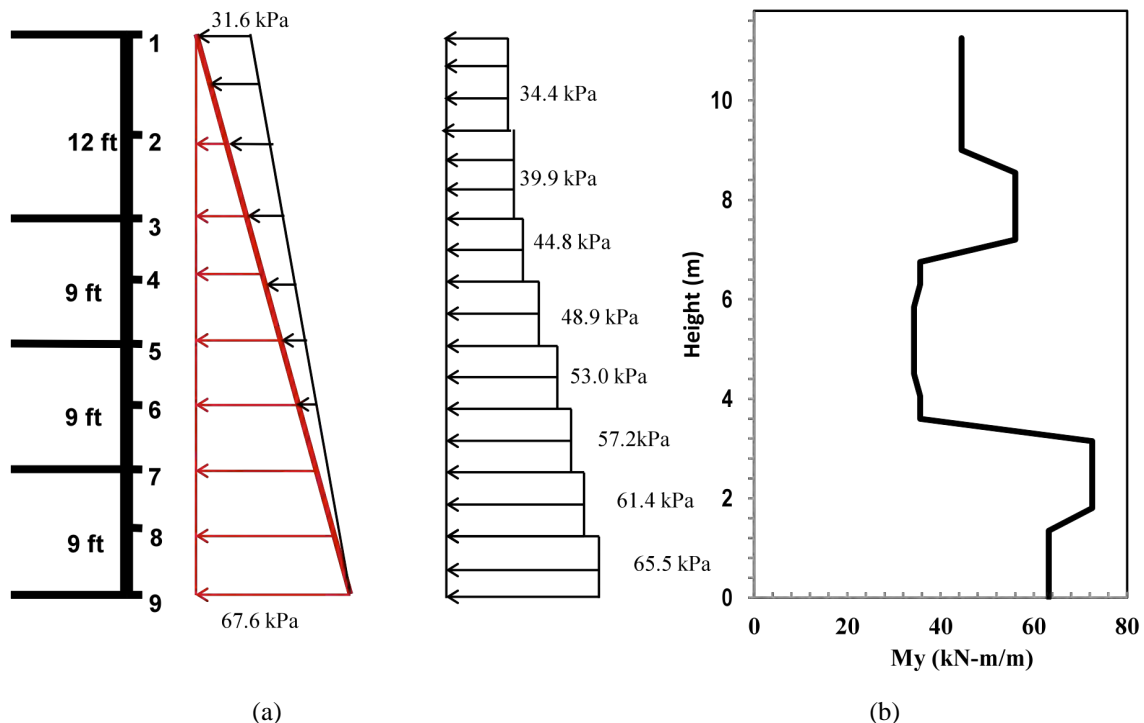

Figure 1: (a) Distribution of the design lateral pressure along the height of the wall for based on the current state of practice for a seismic event with $\text{PGA}=0.24\text{g}$ and a backfill soil with friction angle of 33° ; (b) Resulting designed moment resistance distribution along the height of the wall.

The structural engineers were interested in how the basement wall designs based on the 1995 standard would behave under the 2005 loading. Figure 1(a) depicts the design lateral earth pressure distribution for the basement wall for a friction angle of 33 degrees and seismic coefficient of $PGA=0.24g$. The required moment resistance of the wall is the calculated along its height, as shown in Fig. 1(b), based the distributed pressures on the wall. In this design the structural engineer has not used any load reduction factor or ductility factor for the applied pressures on the wall. Uniform properties of $I= 0.0013 \text{ m}^4$, $A=0.25 \text{ m}^2$, and $E=2.74 \times 10^7 \text{ kN/m}^2$ are considered along the height of the basement wall.

3 DESCRIPTION OF THE MODEL

3.1 Model building

Non-linear seismic response of the basement wall is analyzed by using the two-dimensional finite difference computer program FLAC 6.00 [9]. Different stages of the modeling procedure are presented in Fig. 2. In order to ensure the proper initial stress distribution on the basement the actual construction sequence is modeled. First, a 24.3 m deep and 150 m wide layer of soil is created and brought to equilibrium under gravity forces. The model consists of two soil layers that will be discussed further in the next section. A part of the upper soil layer is then excavated in lifts to a depth of 11.7 m and a width 30m as shown in Fig. 2(a). As each lift was excavated, lateral pressures (shoring) are applied to retain the soil. Then as depicted in Fig. 2(b) the basement wall is constructed and global equilibrium is re-established. In the next stage, as shown in Fig. 2(c), the shoring pressures are removed, and load from the soil is transferred to the basement wall. The flexural behavior of the walls is modeled by elastic-perfectly plastic beam model with yield moments equal to the corresponding moment resistance values as shown in Fig. 1(b).

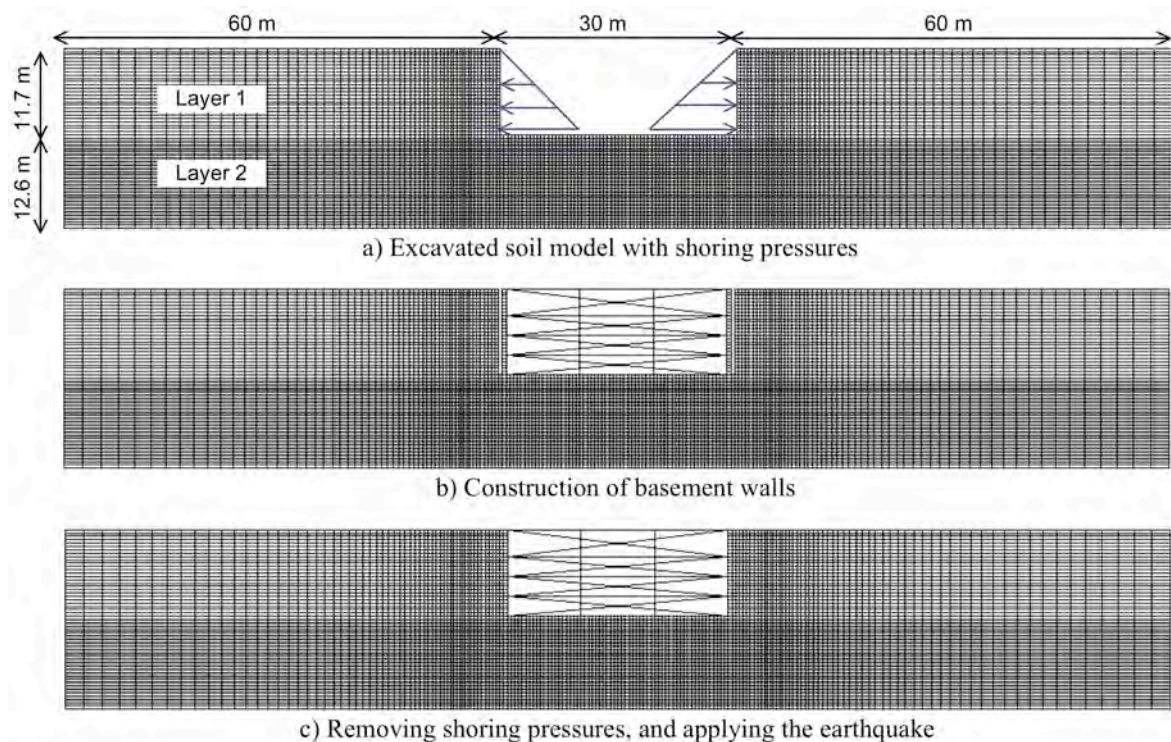

Figure 2: Different stages of modeling procedure in FLAC.

3.2 Properties of soil

Constitutive response of the soil is modeled by a Mohr-Coulomb material model. The required model parameters are elastic bulk and shear moduli, cohesion, and friction and dilation angles of soil. The properties used in conjunction with the Mohr-Coulomb model for layers 1 and 2 of soil, as depicted in Figure 1, are presented in Table 1. Based on the results of a Shake analysis [10] for the present soil profile, the selected ground motions in this study, and a representative modulus reduction curve for the soil, an equivalent shear modulus equal to 30% of elastic shear modulus, i.e. $G=0.3 G_{max}$, was adopted for analysis.

Soil layer	Density (kg/m ³)	Bulk modulus (kPa)	G_{max} (kPa)	G/G_{max}	Cohesion (kPa)	Friction angle (degrees)	Dilations angle (degrees)
1	1950	1×10^5	5×10^4	0.3	0	33	0
2	1950	1×10^5	5×10^4	0.3	20	40	0

Table 1: Example of the construction of one table.

3.3 Ground motions

Ground motions for the analyses are selected from Pacific Earthquake Engineering Research (PEER) strong ground motion database. Based on the results of de-aggregation of the NBCC Uniform Hazard Spectrum (UHS), site class C for Vancouver, candidate input motions are selected in the magnitude range $M=6.5-7.5$ and the distance range 10–30 km using the program Design Ground Motion Library, DGML [11]. Table 2 shows the list of three ground motions selected for this study.

Ground motion	NGA #	Event	Year	Station	Magnitude
G1	162	Imperial Valley	1979	Calexico Fire	6.53
G2	987	Northridge	1994	LA-Centinela	6.69
G3	778	Loma Prieta	1989	Hollister	6.93

Table 2: List of selected ground motions.

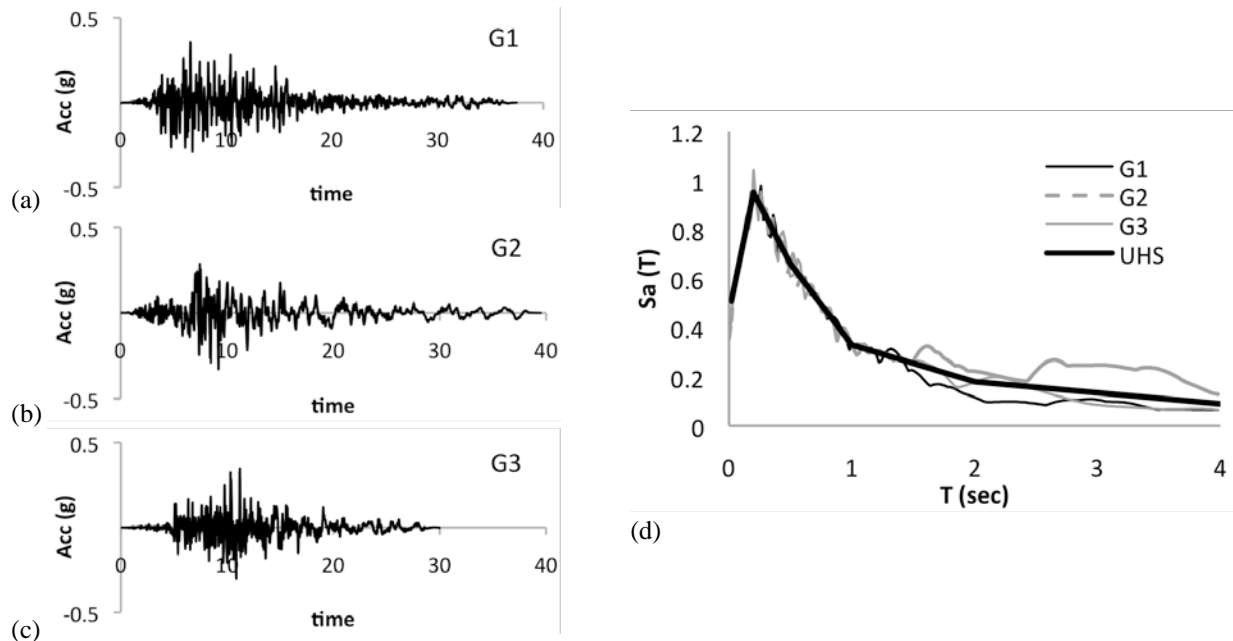

Figure 3: Time histories (a–c) and response spectra (d) of ground motions G1–G3 spectrally matched to UHS in periods 0.02–1.7 sec.

The selected ground motions are linearly scaled to match UHS using the computer program DGML and then spectrally matched to UHS in the period range of 0.02–1.7 sec, as shown in Fig. 3, using computer program SeismoMatch [12]. Figures 3(a-c) show the acceleration time histories of the three spectrally match ground motions and Fig. 3(d) shows the resulting response spectra compared to the UHS.

4 RESULT OF ANALYSIS

Numerical studies are conducted to evaluate the seismic response of basement walls which were designed for a $PGA=0.24g$ that corresponds to a probability of exceedance of 10% in 50 years. The main seismic response parameters of the conducted analyses are: (a) the magnitude and distribution of lateral earth pressures, (b) the resultant lateral forces and the corresponding centers of application of the resultant force, (c) the basement wall bending moment and shear envelopes, and (d) the basement wall deflection envelopes, residual deflections, and drift ratio envelopes. These results are presented and discussed in this section.

Figure 4 shows lateral earth pressure time histories at three different levels along the height of the basement wall due to earthquake G1. The larger amount of stress produced at point 3 is due the existence of the basement floor at this level. In each one of these three elevations the initial static lateral pressures (before the earthquake) are lower than the residual static lateral pressure (after the earthquake).

The resultant lateral earth force at each time is obtained by integrating the lateral stresses along the height of the basement wall at that time. In addition, the moment arm at each time is calculated to track the center of application of the resultant force. The values of the resultant lateral earth force and its center of application are calculated for each time to generate the corresponding time histories for these two quantities during the dynamic simulation.

Figure 4: Numerical results of the lateral earth pressure time histories at different locations along the wall under ground motion G1.

Figure 5 shows the time histories of the resultant lateral earth force and the distance of its center of application from the base of the wall normalized with respect to the wall height (H) for three earthquakes. The corresponding results of a simplified method currently used in practice are also shown in this figure for comparison. In the simplified method, the resultant force (P_{AE}) is obtained by the M-O equation based on a design PGA level and the center of application of the resultant force is calculated assuming that the resulting ΔP_{AE} is applied approximately at a distance of $0.6H$ from the base of the wall. The simplified method is used for the hazard levels of $PGA=0.24g$ (NBCC 1995), for which this wall is designed, and also for $PGA=0.46g$ (NBCC 2005) which corresponds to the UHS that is used for spectral matching of the selected three ground motions in this study. Figures 5(a,c,e) show that the M-O method with $PGA=0.46g$ reasonably predicts the maximum resultant force on the basement wall. Figures 5(b,d,f) show that with $PGA=0.46g$ the simplified method for calculation of the center of application of the results force slightly over-predicts the elevation of the application center of the resultant lateral earth force on the wall at the instance of the maximum resultant force.

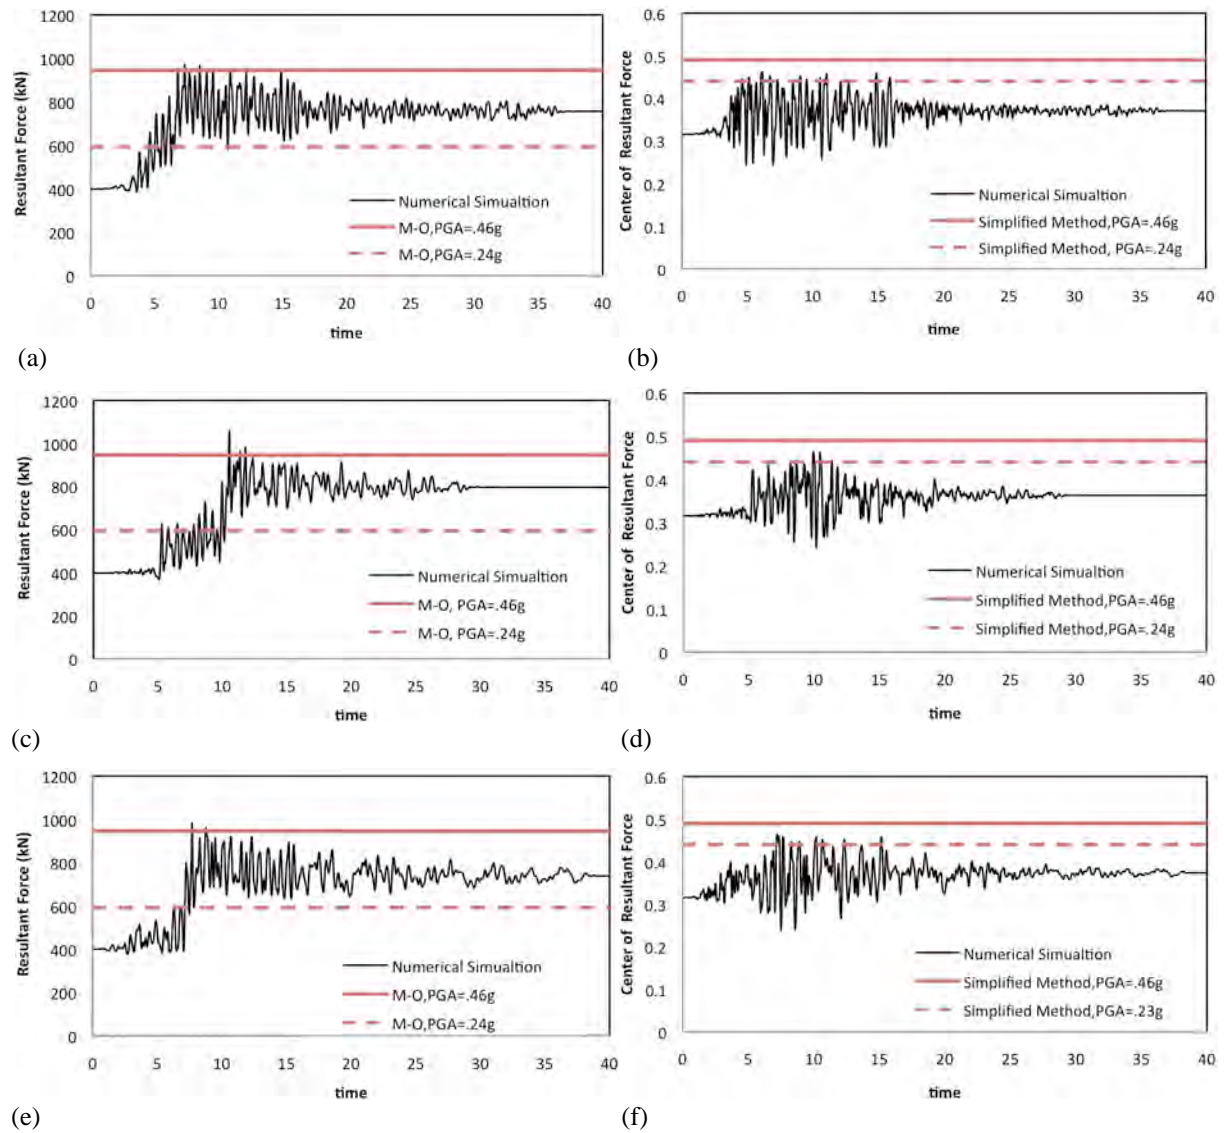

Figure 5: Time histories of the resultant lateral earth forces and the normalized center of the resultant forces for ground motions G1 (a,b), G2 (c,d), and G3 (e,f).

The dashed lines that correspond to the simplified method using $\text{PGA}=0.24g$ are presented in Fig. 5 only as baselines for comparison.

Snapshots of the computed lateral earth pressure distribution along the height of the basement wall at different times are shown in Fig. 6. The results are for the analysis with ground motion G1. The results of numerical analysis are presented at four different times during the analysis. Figure 6(a) shows the analysis results at the beginning of dynamic analysis (symbols) and compares those to the suggested distribution of lateral pressures from Coulomb's theory (solid red line). The numerical analysis results at $t=0$ sec adequately match to those obtained from the Coulomb's theory for static lateral earth pressure distribution. Figures 6(b) and 6(c) present the numerical analysis results at $t=7.7$ sec (the instance of occurrence of maximum lateral earth force on the wall) and $t=10$ sec (an arbitrary time during the shaking phase). These figures also show the suggested results from the simplified design procedure. By comparing the lateral earth pressures at $t=7.7$ sec or $t=10$ sec with the suggested distribution of the simplified method, it is evident that the simplified method cannot predict the lateral earth pressure adequately. The simplified method underestimates the lateral earth pressures at each floor slab level. In addition, for the most of the basement stories in this example, the simplified method overestimates the lateral earth pressures on the walls in between the floor slab levels. In other words, the numerical simulation results indicate that the lateral earth pressures are higher at the proximities of the floor slab locations (due to higher lateral stiffness of the floor slabs) and are lower on the mid height of the walls in between different floor levels (due to higher lateral stiffness of the walls compared to the slabs).

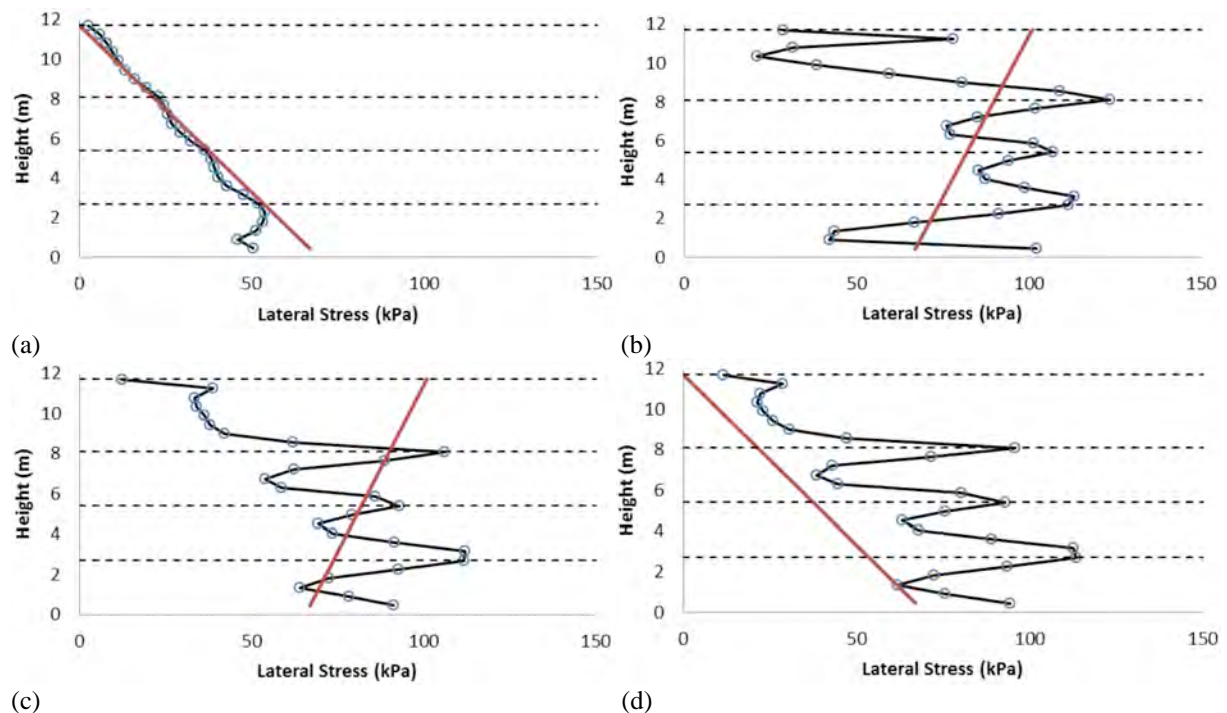

Figure 6: Lateral earth pressure distribution along the height of the basement wall for ground motion G1; symbols representing the results of numerical analysis at (a) $t=0$ sec (initial static pressures), (b) $t=7.7$ sec (the instance of occurrence of maximum lateral earth force on the wall), (c) $t=10$ sec (an arbitrary time during the shaking phase), and (d) $t=42$ sec (residual static pressures), and solid red lines representing the prediction from Coulomb's theory [for (a) and (d)] and the simplified design method [for (b) and (c)].

Finally Fig. 6(d) compares the numerical analysis results after the end of shaking ($t=42$ sec) with the suggested distribution of lateral pressures from Coulomb's theory. Numerical analysis results show a significant increase in the residual static earth pressure at the end of shaking. The significant difference between the two sets for distribution profiles of pressures can be attributed to the wall deformation.

The resulting bending moment and shear envelopes (maximum and minimum) over the wall height during the analysis with ground motion G1 are presented in Figs. 7(a) and 7(b), respectively. It is found that the resulting bending moment and shear envelopes for the three analyzed earthquakes are almost the same, and therefore only the analysis results of the basement wall subjected to ground motion G1 are shown here. In this figure, the limiting values of M_y and V_y correspond to nominal [designed] yield moment and yield shear of the wall sections, respectively. As shown in Fig. 7, the basement walls designed for a hazard level of 10% probability of exceedance in 50 years yields in moment at the mid-height of each basement story and also at each floor level. The shear diagram shows that the shear demand is considerably less than the shear capacity along the height of the wall.

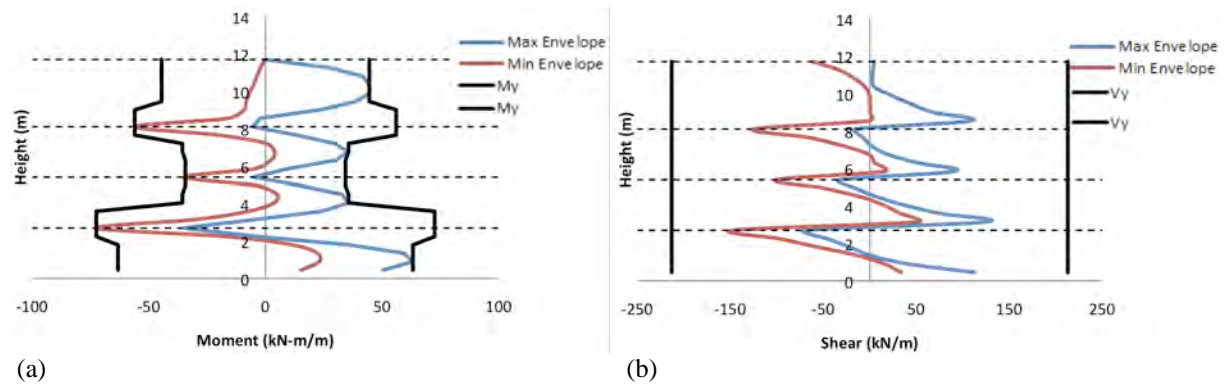

Figure 7: The analysis results for bending moment and shear envelopes for the basement wall subjected to ground motion G1 and the nominal [designed] yield moments and yield shears of the basement wall.

Given that the wall yields at many different levels in the conducted analyses, it is very important to monitor the resulting deformations and drift ratios of the wall. The deformation or the relative displacement of the wall at each level is calculated as the difference between the displacement of the wall at that level and the displacement of the wall at its base. Drift ratio for each story is calculated as shown in Fig. 8. The resulting drift ratio from this figure is a useful indicator to determine the amount of damage to the wall. In this figure h_i is the floor height, $u_{\text{floor,top}}$ and $u_{\text{floor,bottom}}$ are the wall deformations at the floor levels and u_{wall} is the deformation at the mid height of the wall (between the two floors).

The envelopes of relative maximum and minimum displacements along with the residual relative displacements for the analysis with the three ground motions are shown in Fig. 9(a,c,e). The relative displacements are larger between the floors and are smaller at each floor level. The results of relative residual displacement show that the residual relative displacement of the wall at each floor level is approximately zero while in between different floor levels the wall shows some permanent deformations. The envelopes of drift ratios are shown in Figure 9(b,d,f). Maximum displacement and maximum drift ratio occur in the topmost story of the basement.

Figure 8: Definition of drift ratio for each story of the basement wall.

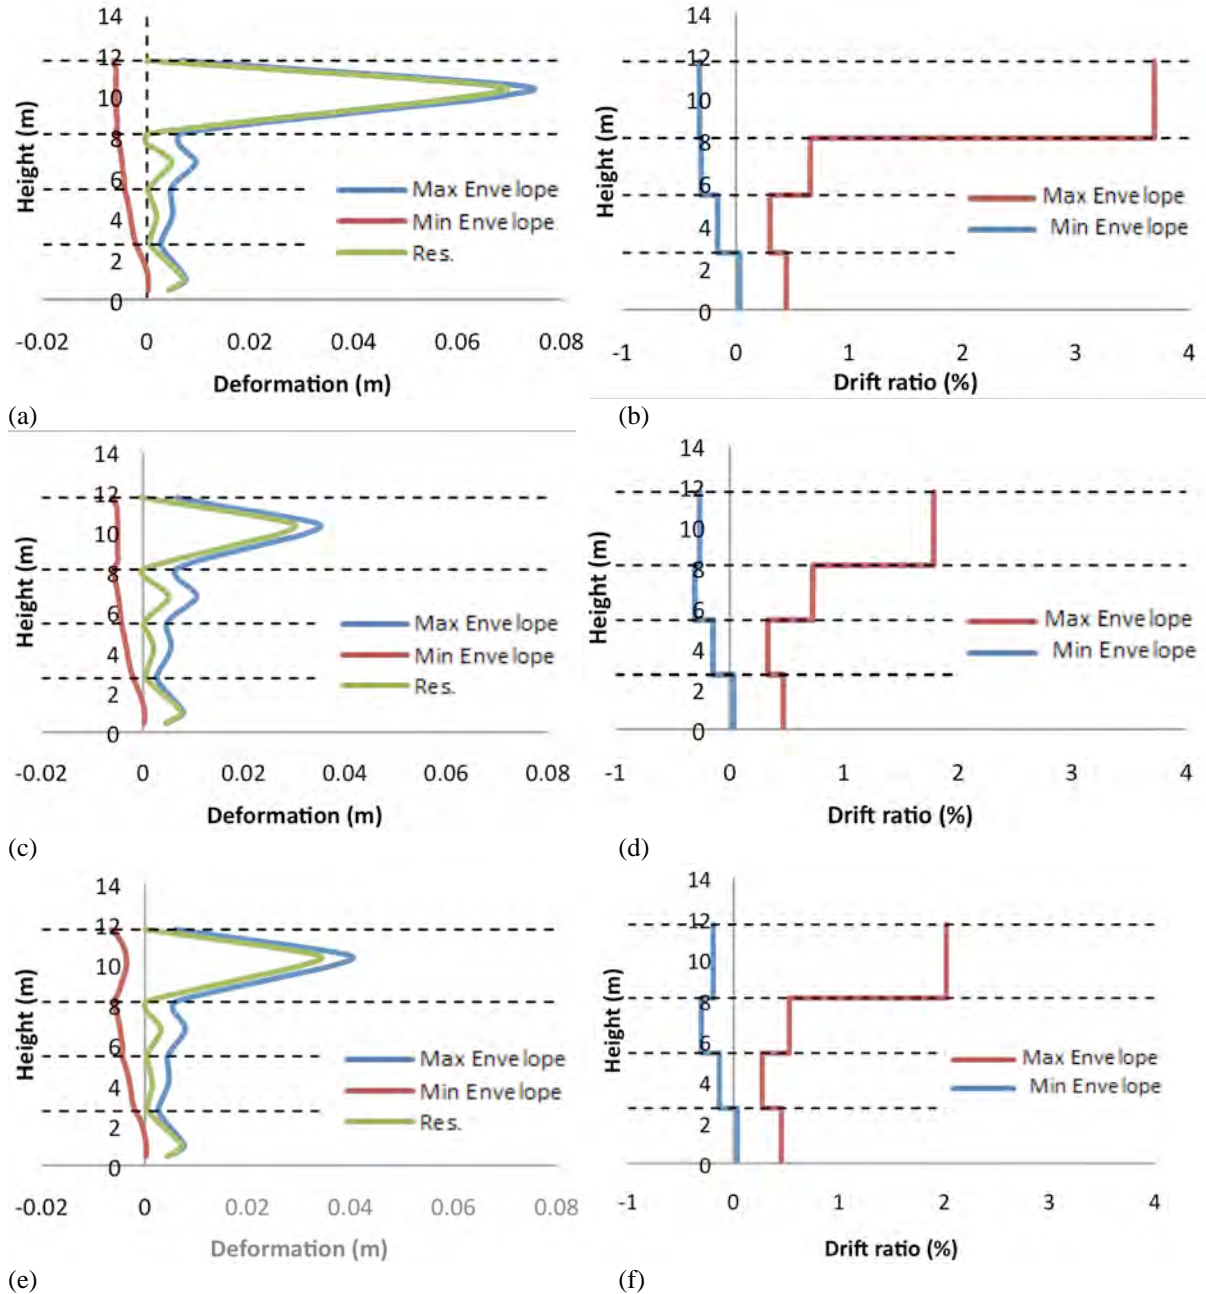

Figure 9: Envelopes of maximum, envelopes of minimum, and values of residual wall deformations (displacements relative to the base of the basement wall) and envelop of maximum and envelopes of minimum story drift ratios for ground motions G1 (a,b), G2 (c,d), and G3 (e,f).

5 SUMMARY AND CONCLUSION

One of the aims of this study was to assess whether existing basement walls designed for a hazard level with 10% probability of exceedance in 50 years (NBCC1995) in Vancouver would be safe when subjected to the higher seismic hazard level of 2% in 50 years which is mandated by the NBCC2005. The seismic pressures against the wall for design were calculated using the M-O procedure. The walls were designed to behave elastically under these pressures. The response of the walls to higher hazard level mandated by NBCC2005 was evaluated using the computer program FLAC.

The M-O pressures for the higher hazard are approximately double the pressures used for the original design. Therefore it was expected that the wall might yield under these elevated pressures and so a nonlinear analysis was carried out including nonlinear soil behavior and yielding of the wall. The analysis was conducted using three different input motions, all of them matched to Vancouver Uniform Hazard Spectrum in the period range 0.05–1.5 sec. The analyses show that M-O accurately predicts the peak resultant force on the wall and the point of application of the resultant force on the wall is consistently at about 0.55H from the base of the wall. This is the location usually assumed in British Columbia for application of M-O resultant force. However, the pressure distribution from the dynamic analysis was radically different from the linear distribution typically assumed in the practice. The total pressure during the earthquake against the top basement level is much smaller than estimated by M-O. At the end of earthquake, the residual pressure are significantly greater the Coulomb's theory.

It was found in Fig. 7(a) that in all levels the wall yields roughly at mid elevation and also yields at the floor levels on the opposite side. The behavior under shear is shown in Fig. 7(b) and it is shown that the shear demand is considerably less than the shear capacity along the height of the wall.

Figure 9 shows the deformations that occur in the wall in terms of displacement relative to the base of the wall and also in terms of drift ratios. The maximum drift ratio in the first level is approximately 4% for one of the motions. For the other motions the drift ratio is 2% in the top level. For the lower three basement levels the drift ratio is less than 1%. These results suggest that apart from the results for motion G1 the drift ratios are in acceptable limits so the elastic design under the seismic hazard of 10% in 50 years is almost adequate to carry the higher hazard of 2% in 50 years, except possibly in the upper basement level. More detailed study on this topic is underway by the authors.

ACKNOWLEDGEMENT

The materials presented in this paper are part of an ongoing study conducted by the authors as members of a task force committee for evaluation of seismic pressure on basement walls; struck by the Structural Engineers Association of British Columbia (SEABC). The authors are grateful for many constructive discussions with the Chairman of the Committee, Dr. Ron De-Vall, and the committee members, Ali Amini, Don Anderson, Michael Belfry, Peter Byrne, Mat Kokan, Jim Mutrie, Ernest Naesgaard, Rob Simpson, and Doug Wallis.

Abstract. *This paper is mainly devoted to enhanced computational algorithms to simulate the load-bearing behavior of reinforced concrete structures under dynamical loading. In order to take into account uncertain data of reinforced concrete, fuzzy and fuzzy stochastic analyses are presented. The capability of the fuzzy dynamical analysis is demonstrated by an example in which a steel bracing system and viscous damping connectors are designed to enhance the structural resistance of a reinforced concrete structure under seismic loading.*

1 INTRODUCTION

The numerical analysis of reinforced concrete (RC) structures under dynamical loads requires realistic nonlinear structural models and computational algorithms. Furthermore, the engineer/designer has to deal with uncertainty which result from variations in material parameters as well as incomplete knowledge about further excitations and the quality of the numerical model itself. The variations in material parameters may be assessed by the uncertainty measure probability. However, the stochastic model cannot be determined precisely because of rare information in most cases. Therefore, an imprecise probability approach is suggested in this contribution bases on the uncertainty measure fuzzy probability resulting in a set of probability models which assessed by membership values. Using this approach, input variables may be also modeled as fuzzy quantities and considered as a special case, if only subjective or linguistic assessments are available.

The incorporation of uncertain input variables within a dynamic structural analysis leads to uncertain structural responses representing the uncertain structural performance close to reality. The uncertain structural responses are determined using fuzzy stochastic dynamic analysis. Thereby, fuzzy stochastic processes result because of the specific dynamic actions. The fuzzy stochastic structural analysis of practical problems requires high performance computational tools in order to deal with a large number of uncertain input variables as well as complex nonlinear structural models. An efficient approach is introduced which is based on α -level optimization and Monte-Carlo simulation using meta-models which partly replace the dynamic structural analyses.

2 UNCERTAINTY IN STRUCTURAL DYNAMICS

2.1 Data models

The input variables – for geometry, material, load etc. – of the numerical simulations of structural behavior are generally uncertain. To describe this uncertainty, traditional stochastic and non-stochastic models are available [6]. In Fig. 1, the models randomness, fuzziness and fuzzy randomness are displayed. The choice of the model depends on the available data.

If sufficient statistical data exist for a parameter and the reproduction conditions are constant, the parameter may be described stochastically. Thereby, the choice of type of probability distribution function affects the result considerably.

Overcoming the traditional probabilistic uncertainty model enables the suitable consideration of imprecision (epistemic uncertainty). Thereby, epistemic uncertainty is associated with human cognition, which is not limited to a binary measure. Advanced uncertainty concepts allow a gradual assessment of intervals. This extension can be realized with the uncertainty characteristic fuzziness. The combination of fuzziness and probabilistic leads to the generalized model fuzzy randomness.

Figure 1: Models of uncertainty.

2.1.1 Fuzzy variables

Often, the uncertainty description for parameters is based on pure expert judgment or samples which are not validated statistically. Then, the description by the uncertainty model fuzziness is recommended. The model comprehends both objective and subjective information. The uncertain parameters are characterized with the aid of a membership function $\mu(x)$ (see Fig. 1b) and Eq. (1)). The membership function $\mu_x(x)$ assesses the gradual membership of elements to a set. Fuzzy variables

$$\tilde{x} = \{(x; \mu_x(x)) \mid x \in X\}; \quad \mu_x(x) \geq 0 \forall x \in X \quad (1)$$

may be utilized to describe the imprecision of structural parameters directly as well as to specify the parameters of fuzzy random variables.

2.1.2 Fuzzy random variables

If, e.g. reproduction conditions vary during the period of observation or if expert knowledge completes the statistical description of data, an adequate uncertainty quantification succeeds with fuzzy random variables. The theory of fuzzy random variables is based on the uncertain data model fuzzy randomness representing a generalized model due to the combination of stochastic and non-stochastic characteristics. A fuzzy random variable \tilde{X} is defined as the fuzzy set of their originals, whereby each original is a real-valued random variable X .

The representation of fuzzy random variables presented in this paper is based on [12]. The space of the random elementary events Ω is introduced. Here, e.g. the measurement of a structural parameter may be an elementary event ω . Each elementary event $\omega \in \Omega$ generates not only a crisp realization but a fuzzy realization $\tilde{x}(\omega) = \tilde{x}$, in which \tilde{x} is an element of the set $\mathbf{F}(\mathbb{R})$ of all fuzzy variables on \mathbb{R} . Each fuzzy variable is defined as a convex, normalized fuzzy set, whose membership function $\mu_x(x)$ is at least segmentally continuous. Accordingly, a fuzzy random variable \tilde{X} is a fuzzy result of the mapping given by

$$\tilde{X} : \Omega \mapsto \mathbf{F}(\mathbb{R}). \quad (2)$$

Based on this formal definition, a fuzzy random variable is described by its fuzzy cumulative distribution function (fuzzy cdf) $\tilde{F}(x)$. The function $\tilde{F}(x)$ is defined as the set of real-valued cumulative distribution functions $F(x)$ which are gradually assessed by the membership $\mu_F(F(x))$. $F(x)$ is the cdf of the original X and is referred to as trajectory of $\tilde{F}(x)$. As result, a fuzzy functional value $\tilde{F}(x_i)$ belongs to each value x_i (see Fig. 2). Thus, $\tilde{F}(x)$ represents a fuzzy function as defined in Section 2.2.1. A fuzzy probability density function

$$\tilde{f}(x) = \{(f(x); \mu_f(f(x))) \mid f \in \mathbf{f}\}; \quad \mu_f(f(x)) \geq 0 \forall f \in \mathbf{f} \quad (3)$$

is defined accordingly. In that, \mathbf{f} represents the set of all probability density functions defined on X .

2.2 Uncertain functions and processes

2.2.1 Fuzzy function

In case that fuzzy parameters depend on crisp or uncertain conditions, they are modeled as fuzzy functions $\tilde{x}(\underline{t}) = \tilde{x}(\underline{\theta}, \underline{\tau}, \underline{\varphi})$ or in the special case of pure time dependency as fuzzy

Figure 2: Fuzzy probability density and cumulative distribution function.

processes $\tilde{x}(\tilde{\tau})$. Arguments may be the time $\tilde{\tau}$, the spatial coordinates $\tilde{\theta}$ and further parameters $\tilde{\varphi}$, e.g. temperature. A fuzzy function $\tilde{x}(\tilde{t})$ enables the formal description of at least piecewise continuous uncertain structural parameters in \mathbb{R} . In the following, a definition of fuzzy functions is introduced. Given are

- the fundamental sets $\mathbf{T} \subseteq \mathbb{R}$ and $\mathbf{X} \subseteq \mathbb{R}$,
- the set $\mathbf{F}(\mathbf{T})$ of all fuzzy variables \tilde{t} on the fundamental set \mathbf{T} ,
- the set $\mathbf{F}(\mathbf{X})$ of all fuzzy variables \tilde{x} on the fundamental set \mathbf{X} .

Then, the uncertain mapping of $\mathbf{F}(\mathbf{T})$ into $\mathbf{F}(\mathbf{X})$ that assigns exactly one $\tilde{x} \in \mathbf{F}(\mathbf{X})$ to each $\tilde{t} \in \mathbf{F}(\mathbf{T})$ is referred to as a fuzzy function denoted by

$$\tilde{x}(\tilde{t}) : \mathbf{F}(\mathbf{T}) \mapsto \mathbf{F}(\mathbf{X}), \quad (4)$$

$$\tilde{x}(\tilde{t}) = \{ \tilde{x}_t = \tilde{x}(\tilde{t}) \mid \forall \tilde{t} \mid \tilde{t} \in \mathbf{F}(\mathbf{T}) \}. \quad (5)$$

In Fig. 3, a fuzzy process $\tilde{x}(\tau)$ is presented, which assigns a fuzzy quantity $\tilde{x}(\tau_i)$ to each time τ_i . For the numerical simulation, a bunch parameter representation of a fuzzy function

 Figure 3: Fuzzy process $\tilde{x}(\tau)$.

$$x(\underline{s}, \underline{t}) = \tilde{x}(\tilde{t}) \quad (6)$$

is applied. Therewith, the fuzziness of both \tilde{x} and \tilde{t} is concentrated in the bunch parameter vector \underline{s} .

For each crisp bunch parameter vector $\underline{s} \in \underline{\tilde{s}}$ with the assigned membership value $\mu(\underline{s})$, a crisp function $x(\underline{t}) = x(\underline{s}, \underline{t}) \in \tilde{x}(\underline{t})$ with $\mu(x(\underline{t})) = \mu(\underline{s})$ is obtained. The fuzzy function

$$\tilde{x}(\underline{t}) = \tilde{x}(\underline{\tilde{s}}, \underline{t}) = \{ (x(\underline{s}, \underline{t}), \mu(x(\underline{s}, \underline{t}))) \mid \mu(x(\underline{s}, \underline{t})) = \mu(\underline{s}) \mid \underline{s} \in \underline{\tilde{s}} \} \quad (7)$$

may thus be represented by the fuzzy set of all real valued functions $x(\underline{s}, \underline{t})$ which may be generated from all possible real vectors $\underline{s} \in \tilde{\underline{s}}$. For every $\underline{t} \in \mathbf{T}$, each of the crisp functions $x(\underline{s}, \underline{t})$ yields values x_t which are contained in the associated fuzzy functional values \tilde{x}_t . The real functions $x(\underline{s}, \underline{t})$ of $\tilde{x}(\underline{t})$ are referred to as trajectories. Numerical processing of fuzzy functions $\tilde{x}(\underline{t}) = x(\tilde{\underline{s}}, \underline{t})$ demands the discretization of their arguments \underline{t} in space and time.

2.2.2 Fuzzy random function

According to Eqs. (2) and (4), a fuzzy random function is the result of an uncertain mapping

$$\tilde{X}(\underline{t}) : \mathbf{F}(\mathbf{T}) \times \Omega \rightarrow \mathbf{F}(\mathbb{R}). \quad (8)$$

Thereby, $\mathbf{F}(\mathbf{X})$ and $\mathbf{F}(\mathbf{T})$ denote the sets of all fuzzy variables in \mathbf{X} and \mathbf{T} respectively [14]. At a specific point \underline{t} , the mapping of Eq. (8) leads to the fuzzy random variable $\tilde{X}_t = \tilde{X}(\underline{t})$. Therefore, fuzzy random functions are defined as a family of fuzzy random variables

$$\tilde{X}(\underline{t}) = \{\tilde{X}_t = \tilde{X}(\underline{t}) \mid \underline{t} \in \mathbf{T}\}. \quad (9)$$

For the numerical simulation, again the bunch parameter representation of a fuzzy random function is applied. For each crisp bunch parameter vector $\underline{s} \in \tilde{\underline{s}}$ with the assigned membership value $\mu(\underline{s})$, a real random function $X(\underline{t}) = X(\underline{s}, \underline{t}) \in \tilde{X}(\underline{t})$ with $\mu(X(\underline{t})) = \mu(\underline{s})$ is obtained. The fuzzy random function $\tilde{X}(\underline{t})$ may thus be represented by the fuzzy set of all real random functions $X(\underline{t}) \in \tilde{X}(\underline{t})$

$$X(\tilde{\underline{s}}, \underline{t}) = \{(X(\underline{t}), \mu(X(\underline{t}))) \mid X(\underline{t}) = X(\underline{s}, \underline{t}); \mu(X(\underline{t})) = \mu(\underline{s}) \mid \underline{s} \in \tilde{\underline{s}}\} \quad (10)$$

which may be generated from all possible real vectors $\underline{s} \in \tilde{\underline{s}}$. The real random function $X(\underline{t}) \in \tilde{X}(\underline{t})$ is defined for all $\underline{t} \in \mathbf{T}$ and referred to as original function. A numerical processing of a fuzzy random function $\tilde{X}(\underline{t}) = X(\tilde{\underline{s}}, \underline{t})$ requires the discretization of their arguments \underline{t} in space and time.

Figure 4: Fuzzy random process $\tilde{X}(\underline{\theta}_j, \tau)$.

3 Fuzzy stochastic analysis

Fuzzy stochastic analysis is an appropriate computational model for processing uncertain data using the uncertainty model fuzzy randomness. Basic terms and definitions related to fuzzy randomness have been introduced, inter alia, by [12]. The formal description of fuzzy randomness chosen by [12] is however not suitable to formulating uncertainty encountered in

engineering tasks. A suitable form of representation with the scope of numerical engineering tasks is given with the so-called α -discretization by [6] and [7].

The numerical simulation under consideration of fuzzy variables and fuzzy functions (fuzzy analysis) may formally be described by the mapping

$$F_{FA}(d) : \quad \tilde{x}(t) \mapsto \tilde{z}(t). \quad (11)$$

According to Eq. (11), the fuzzy variables \tilde{x} and the fuzzy functions $\tilde{x}(t)$ are mapped onto the fuzzy results $\tilde{z}(t)$ with aid of the crisp analysis algorithm d . Every arbitrary deterministic fundamental solution may be used as algorithm d . On the basis of space and time discretization, fuzzy functional values $x(\tilde{s}, \underline{\theta}_j, \tau_i, \underline{\varphi}_k)$ of the function $x(\tilde{s}, \underline{\theta}, \tau, \underline{\varphi})$ are determined at points in space $\underline{\theta}_j$, time τ_i , and a realization of $\underline{\varphi}_k$.

The numerical simulation is carried out with the aid of the α -level optimization [7]. For fuzzy variables \tilde{x} and fuzzy bunch parameter \tilde{s} of the fuzzy functions $x(\tilde{s}, \underline{\theta}, \tau, \underline{\varphi})$, an input subspace E_α is formed assigned to the level α . By multiple application of the deterministic analysis, the extreme values $z_{\alpha,l}(\underline{\theta}_j, \tau_i, \underline{\varphi}_k)$ and $z_{\alpha,r}(\underline{\theta}_j, \tau_i, \underline{\varphi}_k)$ of the fuzzy result variable $\tilde{z}(\underline{\theta}_j, \tau_i, \underline{\varphi}_k)$ are computed. These points are interval bounds of the α -level sets and enable the numerical description of the convex membership function of the fuzzy result variable $\tilde{z}(\underline{\theta}_j, \tau_i, \underline{\varphi}_k)$. For the computation of $\tilde{z}(\underline{\theta}_j, \tau_{i+1}, \underline{\varphi}_k)$ at the time point τ_{i+1} , the procedure must be restarted at $\tau = 0$ due to the interaction within the mapping model.

Fuzzy stochastic analysis allows the mapping of fuzzy random input variables onto fuzzy random result variables. The fuzzy stochastic analysis can be applied for static and dynamic structural analysis and for assessment of structural safety, durability as well as robustness. Two different approaches for computation of the fuzzy random result variables have been developed. The first variant (Fig. 5) bases on the bunch parameter representation of fuzzy random variables by [14]. The second variant utilizes the $l_\alpha r_\alpha$ -representation of fuzzy random variables. The variant to be preferred depends on the engineering task, the available uncertain data and the wanted results [9].

Figure 5: Fuzzy stochastic analysis (FSA).

The fuzzy stochastic analysis is called fuzzy stochastic finite element method (FSFEM), if the deterministic dynamical analysis is based on a finite element (FE) model.

4 DETERMINISTIC DYNAMICAL ANALYSIS OF RC STRUCTURES

4.1 1D – Beams

Plane and spatial beam structures are called 1D-structures. For the physical nonlinear analysis, the cross-sections of the beams are subdivided into layers (plane structures) or fibers (spatial structures). In contrast to the widespread finite element formulations, solutions based on the differential equations for the straight or imperfectly straight beam also exist. A respective approach for plane beam structures is presented here.

The geometrical and physical nonlinear analysis of plane reinforced concrete, prestressed concrete, and steel beam structures is chosen as fundamental model [13]. The beams are subdivided into integration sections, the cross-sections are subdivided into layers. On this basis an incrementally formulated system of second order differential equations for the straight or imperfectly straight beam is solved.

$$\left[\frac{d\Delta \underline{z}(\theta_1)}{d\theta_1} \right]_{(n)}^{[k]} = \underline{A}(\theta_1, \underline{z})_{(n-1)} \cdot \Delta \underline{z}(\theta_1)_{(n)}^{[k]} + \Delta \underline{b}(\theta_1)_{(n)}^{[k-1]} + \underline{d}(\theta_1)_{(n-1)} \cdot \Delta \dot{\underline{z}}(\theta_1)_{(n)}^{[k]} + \underline{m}(\theta_1)_{(n-1)} \cdot \Delta \ddot{\underline{z}}(\theta_1)_{(n)}^{[k]} \quad (12)$$

where $[k]$ – counter of iteration steps; (n) – counter of increments; θ_1 – bar coordinate; Δ – increment; $\underline{z} = \{\underline{z}_1, \underline{z}_2\} = \{u \ v \ \phi; N \ Q \ M\}$ – vector of structural responses; \underline{A} – matrix of coefficients (constant within the increment); \underline{b} – ”right hand side” of the system of differential equations with loads and varying parts resulting from geometrical and physical nonlinearities as well as with forces from unbonded prestressing; \underline{d} – damping matrix; and \underline{m} – mass matrix.

The implicit nonlinear system of differential equations for the differential beam sections is linearized by increments. All geometrically and physically nonlinear components in the $\Delta \underline{b}$ -vector are recalculated after every iteration step, and the \underline{A} -, \underline{d} -, and \underline{m} -matrix are recalculated after the completion of the iteration within the increment.

The solution of the system of differential equations by a Runge-Kutta integration results in the system of differential equations

$$\underline{K}_{T(n-1)} \cdot \Delta \underline{v}_{(n)}^{[k]} + \underline{D}_{T(n-1)} \cdot \Delta \dot{\underline{v}}_{(n)}^{[k]} + \underline{M}_{T(n-1)} \cdot \Delta \ddot{\underline{v}}_{(n)}^{[k]} = \Delta \underline{P}_{(n)} - \Delta \underline{F}_{(n)}^o + \Delta \Delta \underline{F}_{(n-1)} \quad (13)$$

of the unknown incremental displacements $\Delta \underline{v}$, velocities $\Delta \dot{\underline{v}}$, and accelerations $\Delta \ddot{\underline{v}}$ of the nodes.

4.2 2D – folded plate RC structures

Shells, folded plates, shear panels and plates are called 2D-structures. Here, we focus on folded plates which represent the general case for plane 2D structures. They can further be applied to approximate the shape of slightly curved structures. The internal forces are related to the reference plane, which is not stringently the midplane. The cross-section is subdivided into layers to describe the physical nonlinear behavior of reinforced concrete. Over the past years, a new strengthening technology for damaged RC structures has been developed. The thin strengthening layers consist of fine-grained concrete reinforced with textiles made of AR-glass or carbon. The classical layered model with one reference plane for folded plate structures is enhanced to take into account the later applied strengthening layers.

An extended layer model with specific kinematics, the so-called multi-reference-plane model (MRM), is used to describe the load-bearing behavior of RC constructions with textile strengthening. The MRM consists of concrete layers and steel reinforcement layers of the old construction, the strengthening layers comprised of the inhomogeneous material textile concrete (TRC), and the interface layers (Fig. 6). This multilayer continuum has the following kinematic peculiarities. Due to the fact that the modification of the concrete layer thickness is very small and can be neglected, we have $\varepsilon_{33} = 0$. Furthermore, the transverse shear stresses in the concrete layers have no significant influence on the deformation, which means that $\varepsilon_{13} = 0$ and $\varepsilon_{23} = 0$ can be set to zero. The deformation state of the concrete layers may be described by Kirchhoff

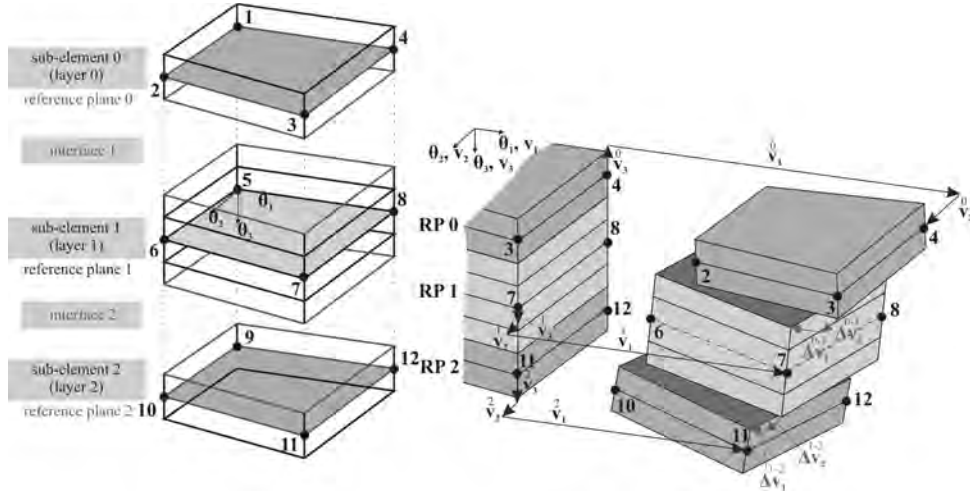

Figure 6: MRM discretization and kinematics.

kinematics. The independent degrees of freedom are assigned to a reference plane which can be selected arbitrarily.

The very thin strengthening layers are subject to the same kinematic assumptions. Kirchhoff kinematics with a reference plane are also assigned to each strengthening layer. The independent degrees of freedom of the strengthening layer lie in the reference plane. The bond between the layers of reinforced concrete and an arbitrary strengthening layer is modeled by an interface. The interface is an immaterial layer of zero thickness. The bonding state is assessed with the help of the relative displacements Δv_1 , Δv_2 , Δv_3 between the contact surfaces. In conjunction with a bonding matrix, the relative displacements enable assumptions regarding delamination and shear failure.

The FE discretization of the MRM is based on the functional of the complementary energy extended by the static transition conditions $\Delta \underline{p} - \underline{p}^+ = 0$ to O_p^r and the equilibrium conditions $\underline{G} \cdot \underline{\sigma}_{el}^e + \underline{p}^e - \rho^e \cdot \ddot{\underline{v}}^e = 0$ in V^e

$$\begin{aligned} \Pi_{mh} = & \int_{\tau_1}^{\tau_2} \sum_{e=1}^n \left\{ \int_{V^e} \left[w_c(\underline{\sigma}_{el}^e) + (\underline{G} \cdot \underline{\sigma}_{el}^e + \underline{p}^e - \rho^e \cdot \ddot{\underline{v}}^e)^T \cdot \underline{v}^e \right] dV + \int_{V^e} (\underline{\sigma}_{el}^e)^T \cdot \underline{\varepsilon}_0^e dV \right. \\ & \left. - \int_{O_p^{r,e}} (\underline{p}^{r,e} - \underline{p}^{+,r,e})^T \cdot \underline{v}^{r,e} dO - \int_{O_v^{r,e}} (\underline{p}^{r,e})^T \cdot \underline{v}^{+,r,e} dO \right\} d\tau \end{aligned} \quad (14)$$

with $w_c(\underline{\sigma}_{el}^e)$ – internal complementary energy; \underline{G} – matrix of differential operators; \underline{p}^+ – external forces in V^e ; ρ^e – density in V^e ; $\ddot{\underline{v}}^e$ – internal acceleration in V^e ; ρ^e ; $\underline{\varepsilon}_0^e$ – initial strain; $\underline{p}^{r,e}$ – internal forces in the boundary surface $O_p^{r,e}$; $\underline{p}^{+,r,e}$ – external forces along the boundary surface $O_p^{r,e}$; $\underline{v}^{r,e}$ – displacements of the boundary surface $O_p^{r,e}$; $\underline{v}^{+,r,e}$ – prescribed displacements of the boundary surface $O_v^{r,e}$; τ – time.

After some transformations, the quasi-static part of the equilibrium conditions $(\underline{G} \cdot \underline{\sigma}_{el}^e + \underline{p}^e)$

and the kinetic energy become visible in the mixed hybrid functional

$$\begin{aligned} \Pi_{mh} = & \int_{\tau_1}^{\tau_2} \sum_{e=1}^n \left\{ \int_{V^e} \left[w_c(\underline{\sigma}_{el}^e) + (\underline{G} \cdot \underline{\sigma}_{el}^e + \underline{p}^e)^T \cdot \underline{v}^e + \frac{1}{2} \rho^e \cdot (\dot{\underline{v}}^e)^T \cdot \dot{\underline{v}}^e \right] dV \right. \\ & + \int_{V^e} (\underline{\sigma}_{el}^e)^T \cdot \underline{\varepsilon}_0^e dV - \int_{O_p^{r,e}} (\underline{p}^{r,e} - \underline{p}^{+,r,e})^T \cdot \underline{v}^{r,e} dO \\ & \left. - \int_{O_v^{r,e}} (\underline{p}^{r,e})^T \cdot \underline{v}^{+,r,e} dO \right\} d\tau. \end{aligned} \quad (15)$$

In extension to the static case [8], [18], this functional may be applied to a layered continuum with dynamic loads. Following the procedure described in [8], [18], the steady-state condition of the mixed hybrid functional

$$\delta \Pi_{mh, NC} = \frac{1}{2} \delta (d^2 \Pi_{mh}) = \sum_{i=0}^k \delta (d^2({}^{(R_i)} \Pi_{mh, NC})) + \sum_{j=1}^k \delta (d^2({}^{(I_j)} \Pi_{mh, NC})) = 0 \quad (16)$$

with

$$\begin{aligned} {}^{(R_i)} \Pi_{mh, NC} = & \int_{\tau_1}^{\tau_2} \left\{ \sum_{e=1}^n \left(\frac{1}{2} \sum_{m=0}^{s_i-1} \left[\int_{V^{e_i, m}} (d\underline{\sigma}_{el}^{e_i, m})^T \cdot d\underline{\varepsilon}_{el}^{e_i, m} dV \right. \right. \right. \\ & + 2 \int_{V^{e_i, m}} (\underline{G} \cdot d\underline{\sigma}_{el}^{e_i, m} + d\underline{p}^{+,e_i, m})^T \cdot d\underline{v}^{e_i, m} dV \\ & + \int_{V^{e_i, m}} \rho^{e_i, m} \cdot (d\underline{v}^{e_i, m})^T \cdot d\underline{v}^{e_i, m} dV \\ & \left. \left. + 2 \int_{V^{e_i, m}} (d\underline{\sigma}_{el}^{e_i, m})^T \cdot d\underline{\varepsilon}_0^{e_i, m} dV \right] \right. \\ & - \int_{(R_i) O_p^{r, e_i}} (d\underline{p}^{r, e_i} - d\underline{p}^{+,r, e_i})^T \cdot d\underline{v}^{r, e_i} dO \\ & \left. \left. - \int_{(R_i) O_v^{r, e_i}} (d\underline{p}^{r, e_i})^T \cdot d\underline{v}^{+,r, e_i} dO \right) \right\} d\tau \end{aligned} \quad (17)$$

$${}^{(I_j)} \Pi_{mh, NC} = \int_{\tau_1}^{\tau_2} \left\{ \sum_{e_j=1(I_j)}^n \int_{O_p^{e_j}} (d^I \underline{\sigma}^{e_j})^T \cdot ({}^{(j|j)} d\underline{v}^{r, e_j} - {}^{(j-1|j)} d\underline{v}^{r, e_{j-1}}) dO \right\} d\tau \quad (18)$$

for a layered continuum with k layers is obtained from Eq. (15). Eq. (17) describes the functional for the sub-element R_i whereas Eq. (18) depicts the functional for the interface I_j . Compared to [8], [18] Eqs. (16), (17) and (18) are extended by inertial forces. In order to account

for physical nonlinearities of the layered continuum, the layer i with the reference plane R_i is subdivided into s_i sub-layers in Eq. (17).

On the basis of Eq. (16), the differential equation of motion can be derived. Thereby, the same stress shape functions, the same boundary displacement shape functions and the same element displacement shape function are chosen within all layers of the continuum.

The stress shape functions are chosen in such a way, that they fulfil strongly the quasi-static part of the equilibrium conditions

$$\underline{G} \cdot d\sigma_{el}^{e_i, m} + d\underline{p}^{+e_i, m} = 0. \quad (19)$$

The evaluation of the steady-state condition, Eq. (16) yields the MRM element and leads to the differential equation of motion

$$\underline{K}_T \cdot d\underline{q} + \underline{M} \cdot d\ddot{\underline{q}} - d\underline{R} - d\underline{R}_K = 0 \quad (20)$$

with \underline{K}_T – tangential system stiffness matrix, \underline{M} – system mass matrix, $d\underline{R}$, $d\underline{R}_K$ – differential load contributions, and \underline{q} – nodal displacement degrees of freedom. The matrix \underline{K}_T and the vectors $d\underline{R}$, and $d\underline{R}_K$ are identical to the corresponding values of the hybrid procedure in [8]. The system mass matrix \underline{M} is specified in [17].

4.3 3D – compact RC structures

Hybrid eight-node hexagonal solid elements for the physical linear static analysis are described in [11]. For the physically nonlinear analysis of reinforced concrete and textile reinforced concrete (TRC), respectively, two kinds of reinforcement are introduced – single fibers and fiber layers (see Fig. 7). The formulation of the hybrid eight-node hexagonal solid element with embedded (textile) reinforcement is outlined in the following.

Starting point is the functional of Hellinger-Reissner

$$\Pi_{HR} = \int_V \left(\underline{\sigma}^T \cdot (\underline{G} \cdot \underline{v}) - \frac{1}{2} \underline{\sigma}^T \cdot \underline{\varepsilon} - \underline{p}_V^{+T} \cdot \underline{v} \right) dV - \int_{O_p} \underline{p}^{+T} \cdot \underline{v} dO \quad (21)$$

with $\underline{\sigma}$, $\underline{\varepsilon}$, \underline{v} – stresses, strains and displacements in the volume V , \underline{p}_V^{+T} – external forces in V and \underline{p}^{+T} – external forces along the boundary surface O_p , and the matrix of differential operators \underline{G} .

Based on it, the Hamilton functional is build

$$H = \delta \int_{\tau_1}^{\tau_2} (K - \Pi_{HR}) d\tau = \delta \int_{\tau_1}^{\tau_2} \left(\frac{1}{2} \int_V \rho \cdot (\dot{\underline{v}})^T \cdot \dot{\underline{v}} dV - \Pi_{HR} \right) d\tau \quad (22)$$

with the kinetic energy K .

The physical nonlinear analysis of reinforced concrete is a non-conservative problem arising e.g. from crack formation, nonlinear material behavior, bonding and damage. In order to solve this non-conservative problem, a differential load change is considered. Under such load change, the existence of a potential is assumed. The differential load change leads to a transition of the structure from the basic condition to a differentially adjacent neighboring condition (NC). The steady-state condition of the neighboring condition is therefore

$$\delta H_{NC} = \frac{1}{2} \delta(d^2 H) = 0 \quad (23)$$

Figure 7: Eight-node solid element with embedded reinforcements.

with

$$\begin{aligned}
 H_{NC} = & \int_{\tau_1}^{\tau_2} \left(\frac{1}{2} \int_V \rho \cdot (d\dot{v})^T \cdot d\dot{v} dV - \int_V \left(d\sigma^T \cdot (\underline{G} \cdot d\underline{v}) - \frac{1}{2} d\sigma^T \cdot d\underline{\varepsilon} - d\underline{p}^+{}^T \cdot d\underline{v} \right) dV + \right. \\
 & \left. \int_{O_p} d\underline{p}^+{}^T \cdot d\underline{v} dO \right) d\tau.
 \end{aligned} \quad (24)$$

The continuum is subdivided into n finite 3D elements. The volume V^e of one finite 3D element e consists of the matrix volume V_m^e and the reinforcement volume V_b^e . Single fibers (sf) and fiber layers (fl) are taken into account. The volume of the reinforcement V_b^e consists then of n_{sf} single fibers and n_{fl} fiber layers. For a function F (e.g. stresses, strains, displacements) holds

$$\begin{aligned}
 \int_{V^e} F dV &= \int_{V_m^e} F_m dV + \int_{V_b^e} F_b dV = \int_{V^e} F_m dV + \int_{V_b^e} F_b dV - \int_{V_b^e} F_m dV \\
 &= \int_{V^e} F_m dV + \sum_{i=1}^{n_{sf}} \int_{V_{sf}^{e,i}} F_{sf}^{e,i} dV + \sum_{j=1}^{n_{fl}} \int_{V_{fl}^{e,j}} F_{fl}^{e,j} dV - \sum_{i=1}^{n_{sf}} \int_{V_{sf}^{e,i}} F_m^{e,i} dV - \sum_{j=1}^{n_{fl}} \int_{V_{fl}^{e,j}} F_m^{e,j} dV.
 \end{aligned} \quad (25)$$

With Eq. (25), the reinforcement is taken into account in Eq. (24)

5 MODEL REDUCTION

The computational cost of a fuzzy stochastic structural analysis of RC structures under dynamic loads is almost completely caused by the nonlinear FE analysis. Thus, the most effective measure to increase the numerical efficiency is to replace the costly deterministic computational model (innermost loop in Fig. 5) by a fast approximation solution based on a reasonable amount of initial deterministic computational results. The fuzzy stochastic analysis can then be performed with that surrogate model, which enables the utilization of an appropriate sample size for the simulation. The surrogate model is designed to describe a functional dependency between the structural parameters \underline{x} and the structural responses \underline{z} in the form of a response surface approximation

$$\underline{z} = f_{RS}(\underline{x}). \quad (26)$$

Figure 8: 3D pictorial view of the upgraded structure with scheme of the bracing system configuration.

For response surface approximation a variety of options exist (see [10], [16]). The suitability of the particular developments primarily depends on the properties of the computational model. Due to the very general properties of the FE analysis in structural analysis of textile strengthened RC structures, which can hardly be limited to convenient cases, a high degree of generality and flexibility of the approximation is demanded. In this context, an artificial neuronal network provides a powerful basis for response surface approximation. This approach can extract information from initial deterministic computational results and can subsequently reproduce the structural response based on the extracted information only. According to the universal function approximation theorem, artificial neural networks are capable of uniformly approximating any kind of nonlinear functions over a compact domain of definition to any degree of accuracy. There is virtually no restriction for a response surface approximation with the aid of artificial neural networks.

In the case, that the global structural behavior is dominated from few eigen modes, the number of degrees of freedom can be reduced. In the following example, a simplified 2-DOF model is used as equivalent system for the whole structure.

6 EXAMPLE

6.1 Investigated structure

The investigated building (Fig. 8) has a rectangular plan whose dimensions are $10.80 \times 20.40 \text{ m}^2$. The elevation of the first floor is 7.40 m, whereas the second one is at 11.10 m. It is characterized by a RC structure framed in the longitudinal direction only and is designed against vertical loads without account for seismic action. Columns and beams have rectangular $40 \times 50 \text{ cm}^2$ and $40 \times 70 \text{ cm}^2$ cross-sections, respectively. The T-shaped hollow tile RC floors have a 6 cm thick concrete slab, so that the total depth of the first floor is 36 cm, whereas the second, at the roof level, is 30 cm.

In [4], the results of the vulnerability evaluation have been published. Thereby, a three-dimensional FEM model with beam elements of the structure has been created considering

Figure 9: Deformed shapes of the fundamental vibration modes for one principal directions.

floors like rigid diaphragms in the horizontal plane. Two nonlinear static analyses and a set of linear and nonlinear time history analyses have allowed to evaluate the vulnerability of the structure in the as-built condition and the effectiveness of the upgrading interventions. First of all, a calculation of the natural frequencies of the system has been carried out. Relevant values are 2.075 s^{-1} in Θ_1 direction (longitudinal, see Fig. 9) and 0.796 s^{-1} in Θ_2 direction (transverse). The mass participation factors are higher than 95% for such modes, so that the structure can be assumed as a matter of fact as made of two mutually independent SDOF systems in both Θ_1 and Θ_2 direction. This consideration assumes relevance in the determination of the optimal value of the damping devices. In fact, a design procedure for viscous devices based on simplified 2-DOF system can be used when the structural dynamic behavior can be interpreted through two SDOF systems [1], [5].

A peak ground acceleration (PGA) of 0.25 g has been assumed in the analysis, considering the combination of site effect and the importance of the structure regard to collapse.

The time history analysis has shown an excessive deformability of the original structure, not compatible with the structural safety and immediate occupancy requirement after seismic events [2], [3]. The assumed upgrading interventions are aimed at reducing the lateral floor displacements of the structure by means of steel braces fitted with additional energy dissipation devices. Such devices connect the original structure at the first floor level with rigid steel braces and act due to the relative displacements occurring between the original structure and the steel braces. The study, presented in this paper, has been carried out considering the connection with purely viscous devices. As shown in [4], the reduction of horizontal floor displacements obtained thanks to the addition of this kind of devices is greater than the one obtained with a rigid connection of the original structure to the steel braces.

6.2 Uncertain input parameters

No technical documentation regarding the history of the structure is available, apart from the period of erection, which can be dated at the end of the 60s of XX century, on the basis of oral testimony.

Because of the lack of technical data and in order to find information about, the quality of structural materials, some characterization tests have been carried out on concrete core bored specimens and steel bars taken out of the structure. In result of the tests, the mechanical resistance of concrete is evaluated by means of fuzzy quantities. The concrete compressive and

Figure 10: Fuzzy load-displacement dependency of the existing RC frame structure.

tensile strength are modeled as fuzzy triangular numbers $\tilde{f}_{ck} = \langle 14, 16.5, 20 \rangle \text{ N/mm}^2$ and $\tilde{f}_t = \langle 1.5, 2.0, 2.5 \rangle \text{ N/mm}^2$, respectively. A magneto-metric survey has been also carried out in order to locate the position and the diameter of steel bars in beams and columns. For the numerical study, twelve steel bars with a fuzzy cross-sectional area $\tilde{A} = \langle 2.69, 3.14, 3.21 \rangle \text{ cm}^2$ are considered. In order to assess the seismic vulnerability of the existing structure, nonlinear static analyses have been carried out under consideration of fuzzy resistance variables. The response of the as-built structure along both principal directions has then been evaluated in terms of fuzzy capacity curves F - d (Fig. 10). These curves have been represented in an approximate way by means of equivalent SDOF nonlinear relationships. Thereby, the kernel curve with $\mu(d(F)) = 1$ is scaled according to

$$\tilde{d}(F) = {}_{1.0}d(F) + \tilde{a} \cdot F \quad (27)$$

with $\tilde{a} = \langle -3.3, 0.0, 6.0 \rangle 10^{-3}$. The steel braces are also modeled as SDOF system with fuzzy stiffness \tilde{K} and fuzzy mass \tilde{M} . Two variants are investigated especially: Variant 1 $\tilde{K}_1 = \langle 39, 40.8, 43 \rangle \text{ MN/m}$ with $\tilde{M}_1 = \langle 1.1, 1.3, 1.5 \rangle \text{ t}$ and Variant 2 $\tilde{K}_1 = \langle 50, 52.5, 55 \rangle \text{ MN/m}$ with $\tilde{M}_1 = \langle 1.2, 1.55, 1.8 \rangle \text{ t}$. The uncertainty of the viscosity c_x of the connecting devices is with a fuzzy scaling factor according to $\tilde{c} = \tilde{b} \cdot c_x$ with $\tilde{b} = \langle 0.9, 1.0, 1.1 \rangle$.

6.3 Fuzzy structural analysis

Nonlinear time-history analyses of the simplified 2-DOF system have then been performed considering the seismic input of Taiwan (1999) earthquake, scaled to PGA value of 0.25 g. Fig. 11 displays the time-history of the ground acceleration of the Taiwan earthquake. The fuzzy maximum displacement \tilde{v}_{TD} at the top of the structure has been calculated on the basis of the fuzzy displacement-time dependency, as shown for one realization in Fig. 12. The parameter study with variation of the viscosity of damping devices yields a fuzzy function $\tilde{v}_{TD}(c_x)$ as presented in Fig. 13 for the Taiwan earthquake.

Keywords: Shear vibration, periodic composite beam, fuzzy non-stationary stochastic excitation, uncertain parameters of structure

Abstract. *In the paper the problem of the shear vibration of a finite periodic composite beam with uncertain parameters as the model of a high building under a stochastic excitation is considered. The solution of the problem was found using the random dynamic influence function which allows applying the perturbation method while the average tolerance approach allows passing from differential equations with periodic variable coefficients to differential equations with constant coefficients. Different types of uncertainty of the structure parameters and the excitation process have been considered, namely: fuzzy numbers, random variables, random functions, fuzzy random variables, fuzzy random functions and fuzzy stochastic processes. This allows a wide analysis of complex problems of the shear vibrations of periodic composite beams with fuzzy random parameters under fuzzy stochastic excitations. Much attention has been focused on for obtaining the solution in the most general case.*

1 INTRODUCTION

The dynamics response of the sheared beams or sheared plates as models of multistorey buildings was subjects of research by some authors [1-4]. In all the cases the homogeneous models have been assumed which do not exactly describe the real structure. Each storey of the building consists of two parts with different stiffnesses and masses. For this reason as a model of the building we can consider a sheared periodic beam. In most cases it is assumed that the parameters of the structure are deterministic. On the other hand, the structural parameters like geometry characteristics, material and damping properties might be uncertain to some extent. Their uncertainty may have a strong influence on the reliability of the structure in the dynamic context and be the crucial factor which determines the safety of the structure. Dynamic analysis of structures often involves two kinds of uncertainty. One of them is the randomness and the other one is the fuzziness which describe imprecision. The random variability is described by use of probability theory and the imprecision by use of fuzzy sets. Very often sufficient statistical data are not available in this case a fuzzy function (fuzzy process) or fuzzy random variable (fuzzy stochastic process) is possible to employ for modeling purposes. The concept of fuzzy random variables allows to combine both randomness and imprecision.

In the paper the problem of the shear vibration of a finite periodic composite beam as the model of high building with uncertain parameters (fuzzy random variables) under a fuzzy stochastic excitation is considered. The solution of the problem was found based on the fuzzy random dynamic influence function while the average tolerance approach allows passing from differential equations with periodic variable coefficients into differential equations with constant coefficients. The tolerance averaging method proposed by Woźniak [5-7] has several advantages and may be used as an alternative to the well-known homogenization method. The idea of random dynamic influence function has been presented in [8-10]. The fuzzy set theory was initiated by Zadeh [11]. The concept of fuzzy random variables was introduced by Kwarkernaak [12], Puri and Ralescu [13] and combines both randomness and imprecision. The dynamic response of the system with deterministic parameters under fuzzy stochastic excitation has been considered among other in the papers [14-20]. The definition of the variance of fuzzy random variables can be found in the papers [21-23]. The application of the uncertain forecasting in engineering and computational mechanics based on fuzzy stochastic processes is presented in the monographs [24,25].

2 GENERAL SOLUTION

Let us consider stochastic vibrations of a periodic straight cantilever beam of length h with a varying cross-section as a model of the building. The differential equation of motion of the sheared beam has the form

$$-[K(\mathbf{b}_\alpha, x)u_{\alpha,x}(\mathbf{b}_\alpha, x, t)]_{,x} + c(\mathbf{b}_\alpha, x)\dot{u}_\alpha(\mathbf{b}_\alpha, x, t) + m(\mathbf{b}_\alpha, x)\ddot{u}_\alpha(\mathbf{b}_\alpha, x, t) = p_\alpha(x, t), \quad (1)$$

where $u_\alpha(\mathbf{b}_\alpha, x, t)$ denotes the vertical displacement of the beam, $K(\mathbf{b}_\alpha, x) = (\kappa FG)_\alpha(x)$, $m(\mathbf{b}_\alpha, x)$, $c(\mathbf{b}_\alpha, x)$ are, respectively, the shear rigidity of the beam, mass of the beam per unit length and the damping coefficient, all of which are random functions of the spatial coordinate x , $x \in [0, h]$. Furthermore, G is the shear modulus of elasticity, κ is the shear stiffness factor that depends on the cross-sectional shape and F is the cross-sectional area. The function $p_\alpha(x, t)$ represents the excitation process of the beam in space and time. The symbol $(\cdot)_{,x}$ and the superimposed dot denote differentiation in space and time, respectively.

The fuzzy random parameters of the beam are presented as a vector $\mathbf{b}_\alpha = [b_{\alpha 1}, b_{\alpha 2}, \dots, b_{\alpha r}]^T$,

where the superscript T denotes the transposition operation. It is assumed that the expected value $E[\mathbf{b}_\alpha]$ and the covariance matrix $\mathbf{C}_{\mathbf{b}_\alpha \mathbf{b}_\alpha} = [\text{cov}(b_{\alpha i}, b_{\alpha j})]_{i,j} = E[\mathbf{b}_\alpha \mathbf{b}_\alpha^T] - E[\mathbf{b}_\alpha] E[\mathbf{b}_\alpha^T]$ are known. The symbol $E[\cdot]$ is the expectation operation. Possible random beam parameters include: the Kirchhoff modulus, the damping coefficient and the dimensions of the beam cross-section. It is assumed that the excitation process of the structure is a fuzzy stochastic process. Additionally, we assume that the structural and load parameters are mutually independent. The solution will be found within the correlation theory; therefore exact knowledge of the probability distributions of these random variables is not required.

In particular cases we can consider different types of the uncertainties of the structure and load parameters. They are fuzzy numbers, random variables (random functions) or in most general cases fuzzy random variables (fuzzy random function - fuzzy stochastic processes).

The boundary conditions of the cantilever beam have the form

$$u_\alpha(\mathbf{b}_\alpha, 0, t) = 0, \quad u_{\alpha,x}(\mathbf{b}_\alpha, h, t) = 0. \quad (2)$$

In the particular case when $K(\mathbf{b}_\alpha, x) = K(\mathbf{b}_\alpha) = (\kappa GF)_\alpha = \text{const}$, $c(\mathbf{b}_\alpha, x) = c(\mathbf{b}_\alpha) = \text{const}$ and $m(\mathbf{b}_\alpha, x) = m(\mathbf{b}_\alpha) = \text{const}$, Eq. (1) has the form

$$K(\mathbf{b}_\alpha) u_{\alpha,xx}(\mathbf{b}_\alpha, x, t) + c(\mathbf{b}_\alpha) \dot{u}_\alpha(\mathbf{b}_\alpha, x, t) + m(\mathbf{b}_\alpha) \ddot{u}_\alpha(\mathbf{b}_\alpha, x, t) = p_\alpha(x) f_\alpha(t). \quad (3)$$

The standard methods of analyzing the rod dynamics are effective only if the coefficients in Eq. (1) are constant. The quantities $K(\mathbf{b}_\alpha, x)$, $c(\mathbf{b}_\alpha, x)$ and $m(\mathbf{b}_\alpha, x)$ in this study are modeled as periodic fields and are rapidly varying l -periodic functions

$$K(\mathbf{b}_\alpha, x) = K(\mathbf{b}_\alpha, x+l), \quad c(\mathbf{b}_\alpha, x) = c(\mathbf{b}_\alpha, x+l), \quad m(\mathbf{b}_\alpha, x) = m(\mathbf{b}_\alpha, x+l). \quad (4)$$

The length l is the height of a single storey of the building and is small as compared with the height h of the building ($l \ll h$).

It is difficult to find the solution of Eq. (1) because the coefficients are strongly periodic. We solve Eq. (1) basing on the concepts of the tolerance-averaged model [5-7]. Using this procedure it is possible to transform Eq. (1) to the form of a system of averaged differential equations with constant coefficients. This approximation describes the effect of the structural length parameter of the beam. We define $\Omega = (0, h)$, $\Delta(x) = (x-l/2, x+l/2)$, $l \ll h$, $x \in \Omega^0$, $\Omega^0 = \{x \in \Omega^0 : \Delta x \in \Omega\}$. The periodic functions will be averaged by means of the formula

$$\langle g(x, t) \rangle = \frac{1}{l} \int_{x-\frac{l}{2}}^{x+\frac{l}{2}} g(\xi, t) d\xi, \quad x \in \Omega^0, \quad (5)$$

where $g(x, t)$ is an arbitrary function defined on $\Omega = (0, h)$.

We base on Conformability Assumption [5-7] that the function $u(x, t)$ conforms to the l -periodic structure of the beam and together with all its derivatives it is periodic-like. Let us introduce the following decomposition of this function:

$$u_\alpha(\mathbf{b}_\alpha, x, t) = w_\alpha(\mathbf{b}_\alpha, x, t) + v_\alpha(\mathbf{b}_\alpha, x, t), \quad (6)$$

where $w(\mathbf{b}_\alpha, x, t)$ is the averaged part of the function $u(\mathbf{b}_\alpha, x, t)$ and $v(\mathbf{b}_\alpha, x, t)$ will be referred to as the fluctuating part of the function $u(\mathbf{b}_\alpha, x, t)$.

The modeling decomposition from Eq. (6) makes it possible to introduce two kinds of basic unknowns, namely function $w(\mathbf{b}_\alpha, x, t)$ which is a slowly varying function and $v(\mathbf{b}_\alpha, x, t)$ is an oscillating l -periodic-like function. Using Galerkin approximation we obtain the fluctuating function in the form

$$v_\alpha(\mathbf{b}_\alpha, x, t) = g^A(x) v_\alpha^A(\mathbf{b}_\alpha, x, t), \quad (7)$$

(the summation convention over $A=1,2,\dots$ holds), where $g^A(x)$ are a priori known oscillating l -periodic-like functions and the new unknown amplitudes $v_\alpha^A(\mathbf{b}_\alpha, x, t)$ are sufficiently regular and slowly varying functions.

The functions $g^A(x)$ should satisfy conditions

$$\langle g^A(x) \rangle = \frac{1}{l} \int_{x-\frac{l}{2}}^{x+\frac{l}{2}} g^A(x) dx = 0 \quad (8)$$

and

$$\langle m(\mathbf{b}_\alpha, x) g^A(x) \rangle = \frac{1}{l} \int_{x-\frac{l}{2}}^{x+\frac{l}{2}} m(\mathbf{b}_\alpha, x) g^A(x) dx = 0 \quad (9)$$

Using the decomposition of Eqs. (6) and (7) and taking into account the Tolerance Averaging Approximation [5-7] after some manipulations we obtain the following system of $N+1$ equations with constant coefficients for unknown functions $w(\mathbf{b}_\alpha, x, t)$ and $v^A(\mathbf{b}_\alpha, x, t)$, for $x \in \Omega_0$

$$\begin{aligned} & - \langle K(\mathbf{b}_\alpha, x) \rangle w_{\alpha,xx}(\mathbf{b}_\alpha, x, t) - \langle K(\mathbf{b}_\alpha, x) g_{,x}^A(x) \rangle v_{\alpha,x}^A(\mathbf{b}_\alpha, x, t) \\ & + \langle c(\mathbf{b}_\alpha, x) \rangle \dot{w}_\alpha(\mathbf{b}_\alpha, x, t) + \langle m(\mathbf{b}_\alpha, x) \rangle \ddot{w}_\alpha(\mathbf{b}_\alpha, x, t) = \langle p_\alpha(x, t) \rangle, \\ & \langle K(\mathbf{b}_\alpha, x) g_{,x}^B(x) \rangle w_{\alpha,x}(\mathbf{b}_\alpha, x, t) + \langle K(\mathbf{b}_\alpha, x) g_{,x}^B(x) g_{,x}^A(x) \rangle v_\alpha^A(\mathbf{b}_\alpha, x, t) \\ & + \langle c(\mathbf{b}_\alpha, x) g^B(x) g^A(x) \rangle \dot{v}_\alpha^A(\mathbf{b}_\alpha, x, t) + \\ & \langle m(\mathbf{b}_\alpha, x) g^B(x) g^A(x) \rangle \ddot{v}_\alpha^A(\mathbf{b}_\alpha, x, t) = \langle p_\alpha(x, t) g^A(x) \rangle, \end{aligned} \quad (10)$$

where $A, B=1,2,\dots,N$.

It has been assumed that the damping coefficient fulfills $c(\mathbf{b}_\alpha, x) = 2\beta m(\mathbf{b}_\alpha, x)$, where $\beta = \text{const}$ and hence $\langle c(\mathbf{b}_\alpha, x) g^A(x) \rangle = 0$. The derivation of the beam equations (10) is analogous to the derivation of the rod equations [8].

2.1 Eigenvalue problem

Let us consider a deterministic eigenvalue problem. In this case we assume

$$\langle m(\mathbf{b}_\alpha, x) g^A(x) \rangle = \frac{1}{l} \int_{x-\frac{l}{2}}^{x+\frac{l}{2}} m(\mathbf{b}_\alpha, x) g^A(x) dx = 0 \quad (11)$$

and

$$p_\alpha(x, t) = 0, \quad c(x) = 0 \quad (12)$$

After introducing (11) to equations (10) and taking into account (12) we obtain for $A = B = 1$

$$\begin{aligned} \langle K(x) \rangle W_{,xx}(x) + \langle K(x) g^1_{,x}(x) \rangle V^1_{,x}(x) + \omega^2 \langle m(x) \rangle W(x) &= 0, \\ \langle K(x) g^1_{,x}(x) \rangle W_{,x}(x) + \langle K(x) [g^1_{,x}(x)]^2 \rangle V^1(x) + \\ -\omega^2 \langle m(x) [g^1(x)]^2 \rangle V^1(x) &= 0. \end{aligned} \quad (13)$$

From the second of Eqs. (13) one obtains

$$V^1(x) = \frac{\langle K(x) g^1_{,x}(x) \rangle}{\omega^2 \langle m(x) g^1(x) g^1(x) \rangle - \langle K(x) g^1_{,x}(x) g^1_{,x}(x) \rangle} W_{,x}(x). \quad (14)$$

Introducing relationship (14) to the first of Eqs. (13) one obtains the differential equation in the following form

$$\begin{aligned} [\langle K(x) \rangle + \frac{[\langle K(x) g^1_{,x}(x) \rangle]^2}{\omega^2 \langle m(x) g^1(x) g^1(x) \rangle - \langle K(x) g^1_{,x}(x) g^1_{,x}(x) \rangle}] W_{,xx}(x) \\ + \omega^2 \langle m(x) \rangle W(x) = 0, \end{aligned} \quad (15)$$

which can be written shortly as

$$W_{,xx}(x) + \lambda^2 W(x) = 0, \quad (16)$$

where

$$\lambda^2 = \frac{\omega^4 \langle m(x) \rangle \langle m(x) (g^1(x))^2 \rangle - \omega^2 \langle m(x) \rangle \langle K(x) (g^1_{,x}(x))^2 \rangle}{\omega^2 \langle K(x) \rangle \langle m(x) (g(x))^2 \rangle - \langle K(x) \rangle \langle K(x) (g^1_{,x}(x))^2 \rangle + (\langle K(x) g^1_{,x}(x) \rangle)^2} \quad (17)$$

The solution of the equation (16) has the form

$$W(x) = A \sin \lambda x + B \cos \lambda x \quad (18)$$

Boundary conditions for cantilever beam have the form

$$W(0) = 0, \quad W_{,x}(h) = 0 \quad (19)$$

Therefore the eigenfunctions and eigenvalues are given by

$$W_n(x) = \sin \lambda_n x, \quad \lambda_n = \frac{\pi}{h} (n - \frac{1}{2}), \quad n = 1, 2, 3, \quad (20)$$

From the relationship (14) one obtains

$$V^1_n(x) = \frac{\langle K(x) g^1_{,x}(x) \rangle \lambda_n}{\omega^2 \langle m(x) g^1(x) g^1(x) \rangle - \langle K(x) g^1_{,x}(x) g^1_{,x}(x) \rangle} \cos \lambda_n x, \quad (21)$$

and the eigenfrequencies

$$\omega_{n1/2}^2 = \frac{1}{2} \left\{ \frac{\langle K(x)(g_{,x}^1(x))^2 \rangle}{\langle m(x)(g^1(x))^2 \rangle} + \lambda_n^2 \frac{\langle K(x) \rangle}{\langle m(x) \rangle} \pm \sqrt{\left[\frac{\langle K(x)(g_{,x}^1(x))^2 \rangle}{\langle m(x)(g^1(x))^2 \rangle} - \lambda_n^2 \frac{\langle K(x) \rangle}{\langle m(x) \rangle} \right]^2 + 4\lambda_n^2 \frac{(\langle K(x)g_{,x}^1(x) \rangle)^2}{\langle m(x) \rangle \langle m(x)(g^1(x))^2 \rangle}} \right\}. \quad (22)$$

In the case of a uniform beam ($K(x) = K = \text{const.}$, $m(x) = m = \text{const.}$) the eigenfrequencies have the form

$$\omega_n = \lambda_n \sqrt{\frac{K}{m}} = \lambda_n v_s. \quad (23)$$

The quantity $v_s = \sqrt{K/m}$ represents the shear wave velocity in the beam.

2.2 Forced vibration of the beam

The aim of this chapter is to find the general solution for probabilistic characteristics of the system response for arbitrary excitation stochastic process $p_\alpha(x, t) = q_\alpha(x) f_\alpha(t)$, where $q_\alpha(x)$ is a fuzzy deterministic function. The problem is being solved within the correlation theory. When the parameters of Eqs. (10) are random the problem can be solved only if the right sides of the equations (10) are deterministic. To overcome these difficulties we introduce the random dynamic influence function $H_\alpha(\mathbf{b}_\alpha, x, t) = H_{w\alpha}(\mathbf{b}_\alpha, x, t) + g^A(x) H_{v\alpha}^A(\mathbf{b}_\alpha, x, t)$ (RDIF) [8,9] which satisfies the following equations

$$\begin{aligned} & -\langle K(\mathbf{b}_\alpha, x) \rangle H_{w\alpha,xx}(\mathbf{b}_\alpha, x, t) - \langle K(\mathbf{b}_\alpha, x) g_{,x}^A(x) \rangle H_{v\alpha,x}^A(\mathbf{b}_\alpha, x, t) + \\ & + \langle c(\mathbf{b}_\alpha, x) \rangle \dot{H}_{w\alpha}(\mathbf{b}_\alpha, x, t) + \langle m(\mathbf{b}_\alpha, x) \rangle \ddot{H}_{w\alpha}(\mathbf{b}_\alpha, x, t) = \langle q_\alpha(x) \rangle \delta(t), \\ & \langle K(\mathbf{b}_\alpha, x) g_{,x}^B(x) \rangle H_{w\alpha,x}(\mathbf{b}_\alpha, x, t) + \langle K(\mathbf{b}_\alpha, x) g_{,x}^B(x) g_{,x}^A(x) \rangle H_{v\alpha}^A(\mathbf{b}_\alpha, x, t) + \\ & + \langle c(\mathbf{b}_\alpha, x) g^B(x) g^A(x) \rangle \dot{H}_{v\alpha}^A(\mathbf{b}_\alpha, x, t) + \langle m(\mathbf{b}_\alpha, x) g^B(x) g^A(x) \rangle \ddot{H}_{v\alpha}^A(\mathbf{b}_\alpha, x, t) = 0, \end{aligned} \quad (24)$$

with initial conditions

$$H_{w\alpha}(\mathbf{b}_\alpha, x, 0) = 0, \dot{H}_{w\alpha}(\mathbf{b}_\alpha, x, 0) = 0, H_{v\alpha}^A(\mathbf{b}_\alpha, x, 0) = 0, \dot{H}_{v\alpha}^A(\mathbf{b}_\alpha, x, 0) = 0. \quad (25)$$

If the random dynamic influence function $H(\mathbf{b}, x, t) = H_w(\mathbf{b}, x, t) + g^A(x) H_v^A(\mathbf{b}, x, t)$ is known then the response of the beam to be found can be presented in the following form:

$$\begin{aligned} u_\alpha(\mathbf{b}_\alpha, x, t) &= w_\alpha(\mathbf{b}_\alpha, x, t) + g^A(x) v_\alpha^A(\mathbf{b}_\alpha, x, t) = \int_{t_0}^t H_\alpha(\mathbf{b}_\alpha, x, t-\tau) f_\alpha(\tau) d\tau = \\ &= \int_{t_0}^t H_{w\alpha}(\mathbf{b}_\alpha, x, t-\tau) f_\alpha(\tau) d\tau + g^A(x) \int_{t_0}^t H_{v\alpha}^A(\mathbf{b}_\alpha, x, t-\tau) f_\alpha(\tau) d\tau. \end{aligned} \quad (26)$$

where if $t_0 = 0$ then one considers transition vibrations and for $t_0 = -\infty$ one considers the steady-state vibration case.

On the basis of the relationship (26) we can obtain the expected value of the beam response

$$\begin{aligned}
 E[u_\alpha(\mathbf{b}_\alpha, x, t)]_\alpha &= E[w_\alpha(\mathbf{b}_\alpha, x, t)]_\alpha + g^A(x)E[v_\alpha^A(\mathbf{b}_\alpha, x, t)]_\alpha = \\
 &= \int_{t_0}^t E[H_\alpha(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau = \\
 &= \int_{t_0}^t E[H_{w\alpha}(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau + g^A(x) \int_{t_0}^t E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau,
 \end{aligned} \tag{27}$$

and the covariance of the displacement

$$\begin{aligned}
 Cov_{uu_\alpha}[x_1, x_2, t_1, t_2]_\alpha &= \\
 &= \int_{t_0}^{t_1} \int_{t_0}^{t_2} E[H_\alpha(\mathbf{b}_\alpha, x_1, t_1-\tau_1) H_\alpha(\mathbf{b}_\alpha, x_2, t_2-\tau_2)]_\alpha Cov_{ff_\alpha}[\tau_1, \tau_2]_\alpha d\tau_1 d\tau_2 + \\
 &+ \int_{t_0}^{t_1} \int_{t_0}^{t_2} Cov_{HH_\alpha}[x_1, x_2, t_1-\tau_1, t_2-\tau_2]_\alpha E[f_\alpha(\tau_1)]_\alpha E[f_\alpha(\tau_2)]_\alpha d\tau_1 d\tau_2,
 \end{aligned} \tag{28}$$

where the covariance of RDIF can be estimated from

$$\begin{aligned}
 Cov_{HH_\alpha}[x_1, x_2, t_1, t_2]_\alpha &= E[H_\alpha(\mathbf{b}_\alpha, x_1, t_1) H_\alpha(\mathbf{b}_\alpha, x_2, t_2)]_\alpha + \\
 &- E[H_\alpha(\mathbf{b}_\alpha, x_1, t_1)]_\alpha E[H_\alpha(\mathbf{b}_\alpha, x_2, t_2)]_\alpha
 \end{aligned} \tag{29}$$

and $Cov_{ff_\alpha}[\tau_1, \tau_2]_\alpha$ denotes the time covariance of the excitation force.

The variance of the beam displacement is equal to

$$\begin{aligned}
 \sigma_{u_\alpha}^2(x, t) &= Cov_{uu_\alpha}[x, x, t, t]_\alpha = \\
 &= \int_{t_0}^t \int_{t_0}^t E[H_\alpha(\mathbf{b}_\alpha, x, t-\tau_1) H_\alpha(\mathbf{b}_\alpha, x, t-\tau_2)]_\alpha Cov_{ff_\alpha}[\tau_1, \tau_2]_\alpha d\tau_1 d\tau_2 + \\
 &+ \int_{t_0}^t \int_{t_0}^t Cov_{HH_\alpha}[x, x, t-\tau_1, t-\tau_2]_\alpha E[f_\alpha(\tau_1)]_\alpha E[f_\alpha(\tau_2)]_\alpha d\tau_1 d\tau_2.
 \end{aligned} \tag{30}$$

Due to the relationship (27) one obtains

$$\begin{aligned}
 E[u_\alpha(\mathbf{b}_\alpha, x, t)]_{\alpha l} &= \min \left\{ \int_{t_0}^t E[H_{w\alpha}(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau + \right. \\
 &+ g^A(x) \int_{t_0}^t E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau \left. \right\},
 \end{aligned} \tag{31}$$

and

$$\begin{aligned}
 E[u_\alpha(\mathbf{b}_\alpha, x, t)]_{\alpha r} &= \max \left\{ \int_{t_0}^t E[H_{w\alpha}(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau + \right. \\
 &+ g^A(x) \int_{t_0}^t E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, t-\tau)]_\alpha E[f_\alpha(\tau)]_\alpha d\tau \left. \right\}.
 \end{aligned} \tag{32}$$

Using α -level optimization procedure [24] for arbitrary $\alpha = \alpha_k \in [0,1]$ or the max-min in the extension principle [11], the smallest and the largest expected values at an established point x and time t can be found.

The lower and upper endpoints of the covariance could be defined using (28) as

$$\begin{aligned} Cov_{uu_\alpha} [x_1, x_2, t_1, t_2]_{\alpha l} &= \\ &= \min \left\{ \int_{t_0}^{t_1} \int_{t_0}^{t_2} E \left[H_\alpha (\mathbf{b}_\alpha, x_1, t_1 - \tau_1) H_\alpha (\mathbf{b}_\alpha, x_2, t_2 - \tau_2) \right]_{\alpha} Cov_{ff_\alpha} [\tau_1, \tau_2]_{\alpha} d\tau_1 d\tau_2 + \right. \\ &\quad \left. + \int_{t_0}^{t_1} \int_{t_0}^{t_2} Cov_{HH_\alpha} [x_1, x_2, t_1 - \tau_1, t_2 - \tau_2]_{\alpha} E[f_\alpha(\tau_1)]_{\alpha} E[f_\alpha(\tau_2)]_{\alpha} d\tau_1 d\tau_2 \right\}, \end{aligned} \quad (33)$$

and

$$\begin{aligned} Cov_{uu_\alpha} [x_1, x_2, t_1, t_2]_{\alpha r} &= \\ &= \max \left\{ \int_{t_0}^{t_1} \int_{t_0}^{t_2} E \left[H_\alpha (\mathbf{b}_\alpha, x_1, t_1 - \tau_1) H_\alpha (\mathbf{b}_\alpha, x_2, t_2 - \tau_2) \right]_{\alpha} Cov_{ff_\alpha} [\tau_1, \tau_2]_{\alpha} d\tau_1 d\tau_2 + \right. \\ &\quad \left. + \int_{t_0}^{t_1} \int_{t_0}^{t_2} Cov_{HH_\alpha} [x_1, x_2, t_1 - \tau_1, t_2 - \tau_2]_{\alpha} E[f_\alpha(\tau_1)]_{\alpha} E[f_\alpha(\tau_2)]_{\alpha} d\tau_1 d\tau_2 \right\}. \end{aligned} \quad (34)$$

In the particular case if the load of the beam is a “white-noise” stationary stochastic process then $Cov_{ff_\alpha} (\tau_1 - \tau_2)_{\alpha} = \sigma_{f_\alpha}^2 \delta(\tau_1 - \tau_2)$ and the variance is given by the formula

$$\begin{aligned} \sigma_{u_\alpha}^2 (x, t)_{\alpha} &= \sigma_{f_\alpha}^2 \int_{t_0}^t E[H_\alpha^2 (\mathbf{b}_\alpha, x, t - \tau)]_{\alpha} d\tau + \\ &\quad + E[f_\alpha^2]_{\alpha} \int_{t_0}^t \int_{t_0}^t Cov_{HH_\alpha} (x, x, t - \tau_1, t - \tau_2)_{\alpha} d\tau_1 d\tau_2. \end{aligned} \quad (35)$$

Accordingly, we have obtained the formulas for the second-order probabilistic moments of the response of the structure.

We look for solutions of the system of Eqs. (24) in the form

$$H_{w\alpha} (\mathbf{b}_\alpha, x, t) = \sum_{n=1}^{\infty} y_{n\alpha} (\mathbf{b}_\alpha, t) \sin \lambda_n x, \quad (36)$$

and

$$H_{v\alpha}^A (\mathbf{b}_\alpha, x, t) = \sum_{n=1}^{\infty} z_{n\alpha}^A (\mathbf{b}_\alpha, t) \cos \lambda_n x \quad (37)$$

where $\lambda_n = \pi(n-1/2)/h$, $n=1, 2, 3, \dots$

In the particular case of $A=1$ one obtains from Eqs. (24):

$$\begin{aligned}
 & \ddot{y}_{n\alpha}(\mathbf{b}_\alpha, t) + 2\beta_\alpha(\mathbf{b}_\alpha) \dot{y}_{n\alpha}(\mathbf{b}_\alpha, t) + \omega_{n\alpha}^2(\mathbf{b}_\alpha) y_{n\alpha}(\mathbf{b}_\alpha, t) + \\
 & + \lambda_n \frac{\langle K(\mathbf{b}_\alpha, x) g_{,x}^1(x) \rangle}{\langle m(\mathbf{b}_\alpha, x) \rangle} z_{n\alpha}^1(\mathbf{b}_\alpha, t) = \frac{2}{H \lambda_n} \delta(t), \\
 & \ddot{z}_{n\alpha}^1(\mathbf{b}_\alpha, t) + 2\beta_{v\alpha}(\mathbf{b}_\alpha) \dot{z}_{n\alpha}^1(\mathbf{b}_\alpha, t) + \omega_{v\alpha}^2(\mathbf{b}_\alpha) z_{n\alpha}^1(\mathbf{b}_\alpha, t) + \\
 & + \lambda_n \frac{\langle K(\mathbf{b}_\alpha, x) g_{,x}^1(x) \rangle}{\langle m(\mathbf{b}_\alpha, x) (g^1(x))^2 \rangle} y_{n\alpha}(\mathbf{b}_\alpha, t) = 0.
 \end{aligned} \tag{38}$$

$$\text{where } 2\beta_\alpha(\mathbf{b}_\alpha) = \frac{\langle c(\mathbf{b}_\alpha, x) \rangle}{\langle m(\mathbf{b}_\alpha, x) \rangle}, \quad \omega_{n\alpha}^2(\mathbf{b}_\alpha) = \lambda_n^2 \frac{\langle K(\mathbf{b}_\alpha, x) \rangle}{\langle m(\mathbf{b}_\alpha, x) \rangle} = \lambda_n^2 \bar{v}_{s\alpha}^2(\mathbf{b}_\alpha),$$

$$2\beta_{v\alpha}(\mathbf{b}) = \frac{\langle c(\mathbf{b}_\alpha, x) (g^1(x))^2 \rangle}{\langle m(\mathbf{b}_\alpha, x) (g^1(x))^2 \rangle}, \quad \omega_{v\alpha}^2(\mathbf{b}_\alpha) = \frac{\langle K(\mathbf{b}_\alpha, x) (g_{,x}^1(x))^2 \rangle}{\langle m(\mathbf{b}_\alpha, x) (g^1(x))^2 \rangle}.$$

The initial conditions have the form

$$y_{n\alpha}(\mathbf{b}_\alpha, 0) = 0, \quad \dot{y}_{n\alpha}(\mathbf{b}_\alpha, 0) = 0, \quad z_{n\alpha}^1(\mathbf{b}_\alpha, 0) = 0, \quad \dot{z}_{n\alpha}^1(\mathbf{b}_\alpha, 0) = 0 \tag{39}$$

Let us consider the steady-state vibration ($t_0 = -\infty$) of the beam under stationary, stochastic excitation. In this case the solutions (26-30) have the following form: for the expected value

$$\begin{aligned}
 E[u_\alpha(\mathbf{b}_\alpha, x, \infty)]_\alpha &= E[w_\alpha(\mathbf{b}_\alpha, x, \infty)]_\alpha + g^A(x) E[v_\alpha^A(\mathbf{b}_\alpha, x, \infty)]_\alpha = \\
 &= E[f_\alpha]_\alpha \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau = \\
 &= E[f_\alpha]_\alpha \int_0^\infty E[H_{w\alpha}(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau + g^A(x) E[f_\alpha]_\alpha \int_0^\infty E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau,
 \end{aligned} \tag{40}$$

for the covariance:

$$\begin{aligned}
 & Cov_{uu_\alpha}[x_1, x_2, \infty, \infty]_\alpha = \\
 &= \int_0^\infty \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x_1, \tau_1) H_\alpha(\mathbf{b}_\alpha, x_2, \tau_2)]_\alpha Cov_{ff_\alpha}[\tau_1 - \tau_2]_\alpha d\tau_1 d\tau_2 + \\
 &+ E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty Cov_{HH_\alpha}[x_1, x_2, \tau_1, \tau_2]_\alpha d\tau_1 d\tau_2,
 \end{aligned} \tag{41}$$

and for the variance:

$$\begin{aligned}
 & \sigma_{u_\alpha}^2(x, \infty)_\alpha = Cov_{uu_\alpha}[x, x, \infty, \infty]_\alpha = \\
 &= \int_0^\infty \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau_1) H_\alpha(\mathbf{b}_\alpha, x, \tau_2)]_\alpha Cov_{ff_\alpha}[\tau_1 - \tau_2]_\alpha d\tau_1 d\tau_2 + \\
 &+ E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty Cov_{HH_\alpha}[x, x, \tau_1, \tau_2]_\alpha d\tau_1 d\tau_2.
 \end{aligned} \tag{42}$$

The lower and upper endpoints of the expected value and variance can be found based on the relationships (40) and (42)

$$\begin{aligned}
E[u_\alpha(\mathbf{b}_\alpha, x, \infty)]_{\alpha l} &= \min \left\{ E[f_\alpha]_\alpha \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau \right\} = \\
&= \min \left\{ E[f_\alpha]_\alpha \int_0^\infty E[H_{w\alpha}(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau + g^A(x) E[f_\alpha]_\alpha \int_0^\infty E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau \right\},
\end{aligned} \tag{43}$$

$$\begin{aligned}
E[u_\alpha(\mathbf{b}_\alpha, x, \infty)]_{\alpha r} &= \max \left\{ E[f_\alpha]_\alpha \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau \right\} = \\
&= \max \left\{ E[f_\alpha]_\alpha \int_0^\infty E[H_{w\alpha}(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau + g^A(x) E[f_\alpha]_\alpha \int_0^\infty E[H_{v\alpha}^A(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau \right\},
\end{aligned} \tag{44}$$

and

$$\begin{aligned}
\sigma_{u_\alpha}^2(x, \infty)_{\alpha l} &= \min \left\{ \int_0^\infty \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau_1) H_\alpha(\mathbf{b}_\alpha, x, \tau_2)]_\alpha \text{Cov}_{ff_\alpha}[\tau_1 - \tau_2]_\alpha d\tau_1 d\tau_2 + \right. \\
&\quad \left. + E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty \text{Cov}_{HH_\alpha}[x, x, \tau_1, \tau_2]_\alpha d\tau_1 d\tau_2 \right\},
\end{aligned} \tag{45}$$

$$\begin{aligned}
\sigma_{u_\alpha}^2(x, \infty)_{\alpha r} &= \max \left\{ \int_0^\infty \int_0^\infty E[H_\alpha(\mathbf{b}_\alpha, x, \tau_1) H_\alpha(\mathbf{b}_\alpha, x, \tau_2)]_\alpha \text{Cov}_{ff_\alpha}[\tau_1 - \tau_2]_\alpha d\tau_1 d\tau_2 + \right. \\
&\quad \left. + E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty \text{Cov}_{HH_\alpha}[x, x, \tau_1, \tau_2]_\alpha d\tau_1 d\tau_2 \right\}.
\end{aligned} \tag{46}$$

In the case of the “white noise” excitation the variance has the form

$$\sigma_{u_\alpha}^2(x, \infty)_\alpha = \sigma_{f_\alpha}^2 \int_0^\infty E[H_\alpha^2(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau + E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty \text{Cov}_{HH_\alpha}(x, x, \tau_1, \tau_2)_\alpha d\tau_1 d\tau_2. \tag{47}$$

The randomness of the structural parameters is included in the random dynamic influence function $H_\alpha(\mathbf{b}_\alpha, x, t) = H_{w\alpha}(\mathbf{b}_\alpha, x, t) + g^A(x) H_{v\alpha}^A(\mathbf{b}_\alpha, x, t)$ which depends on the uncertain parameter vector \mathbf{b} . Here, another difficulty arises in the determination of the expected values and the second moment (covariance) of the RDIF which are in Eqs. (27-35) and (40-47). This problem can be solved using the perturbation method [8,9] or the Monte Carlo Method.

If the excitation process is of the type of non-stationary kinematic excitation following relationships should be introduced in the above general solution $\langle q_\alpha(x) \rangle = \langle m_\alpha(x) \rangle$, $f_\alpha(t) = -\ddot{z}_\alpha(t) = e_\alpha(t) X_\alpha(t)$, where $e_\alpha(t)$ is a fuzzy deterministic envelope and $X_\alpha(t)$ is a fuzzy stationary stochastic process.

3 MODEL OF THE BUILDING

Each storey of the building consists of two parts with different stiffnesses and masses. For this reason as a model of the building we can consider a beam composed of a periodic array of two linearly elastic, homogeneous and isotropic constituents with perfect interfaces. Let us assume that the Kirchhoff moduli $G(x)$ are fuzzy random variables and are equal to $b_{1\alpha} = G_{1\alpha}$ on $(0, a)$ and $b_{2\alpha} = G_{2\alpha}$ on (a, l) . The fuzzy random variables $G_{1\alpha}$ and $G_{2\alpha}$ are assumed to be mutually independent. The other variables are deterministic and are equal to, respectively,

F_1, κ_1, ρ_1 on $(0,a)$ and F_2, κ_2, ρ_2 on (a,l) where ρ_1 and ρ_2 are denote mass density. One introduces only one ($N=1$) shape function $g^1(x)$, which is piecewise linear, Fig.1.

Figure 1:

Figure 2:

In this case we have

$$\begin{aligned}
 \langle K(x) \rangle_\alpha &= G_{1\alpha} \kappa_1 F_1 \frac{a}{l} + G_{2\alpha} \kappa_2 F_2 (1 - \frac{a}{l}), \\
 \langle K(x) g_{,x}^1(x) \rangle_\alpha &= G_{1\alpha} \kappa_1 F_1 \frac{a}{l} - G_{2\alpha} \kappa_2 F_2 (1 - \frac{a}{l}), \\
 \langle K(x) g_{,x}^1(x) g_{,x}^1(x) \rangle_\alpha &= \frac{1}{3} [G_{1\alpha} \kappa_1 F_1 \frac{a}{l} - G_{2\alpha} \kappa_2 F_2 (1 - \frac{a}{l})], \\
 \langle m(x) \rangle &= F_1 \rho_1 \frac{a}{l} + F_2 \rho_2 (1 - \frac{a}{l}), \\
 \langle m(x) g^1(x) g^1(x) \rangle &= \frac{1}{3} [F_1 \rho_1 \frac{a}{l} + F_2 \rho_2 (1 - \frac{a}{l})], \\
 \langle c(x) \rangle &= 2\beta [F_1 \rho_1 \frac{a}{l} + F_2 \rho_2 (1 - \frac{a}{l})], \\
 \langle c(x) g^1(x) g^1(x) \rangle &= \frac{2\beta}{3} [F_1 \rho_1 \frac{a}{l} + F_2 \rho_2 (1 - \frac{a}{l})].
 \end{aligned} \tag{48}$$

For the particular case $a = l/2$ it is

$$\begin{aligned}
 \langle K(x) \rangle_\alpha &= \frac{1}{2} (G_{1\alpha} \kappa_1 F_1 + G_{2\alpha} \kappa_2 F_2), \\
 \langle K(x) g_{,x}^1(x) \rangle_\alpha &= \frac{1}{2} (G_{1\alpha} \kappa_1 F_1 - G_{2\alpha} \kappa_2 F_2), \\
 \langle K(x) g_{,x}^1(x) g_{,x}^1(x) \rangle_\alpha &= \frac{1}{6} (G_{1\alpha} \kappa_1 F_1 - G_{2\alpha} \kappa_2 F_2), \\
 \langle m(x) \rangle &= \frac{1}{2} (F_1 \rho_1 + F_2 \rho_2), \\
 \langle m(x) g^1(x) g^1(x) \rangle &= \frac{1}{6} (F_1 \rho_1 + F_2 \rho_2), \\
 \langle c(x) \rangle &= \beta (F_1 \rho_1 + F_2 \rho_2), \\
 \langle c(x) g^1(x) g^1(x) \rangle &= \frac{\beta}{3} (F_1 \rho_1 + F_2 \rho_2).
 \end{aligned} \tag{49}$$

Using the perturbation method [8, 9] we obtain the following set of differential equations:

- Zeroth order equations

$$\begin{aligned}
 & - \frac{(\bar{G}_{1\alpha} \kappa_1 F_1 + \bar{G}_{2\alpha} \kappa_2 F_2)}{F_1 \rho_1 + F_2 \rho_2} H_{w\alpha,xx}^0(x,t) - \frac{4(\bar{G}_{2\alpha} \kappa_2 F_2 - \bar{G}_{1\alpha} \kappa_1 F_1)}{F_1 \rho_1 + F_2 \rho_2} H_{v\alpha,x}^{10}(x,t) + \\
 & + 2\beta \dot{H}_{w\alpha}^0(x,t) + \ddot{H}_{w\alpha}^0(x,t) = \frac{2\langle q(x) \rangle}{F_1 \rho_1 + F_2 \rho_2} \delta(t), \\
 & \frac{12(\bar{G}_{2\alpha} \kappa_2 F_2 - \bar{G}_{1\alpha} \kappa_1 F_1)}{l^2 (F_1 \rho_1 + F_2 \rho_2)} H_{w\alpha,x}^0(x,t) + \frac{48(\bar{G}_{1\alpha} \kappa_1 F_1 + \bar{G}_{2\alpha} \kappa_2 F_2)}{l^2 (F_1 \rho_1 + F_2 \rho_2)} H_{v\alpha}^{10}(x,t) + \\
 & + 2\beta \dot{H}_{v\alpha}^{10}(x,t) + \ddot{H}_{v\alpha}^{10}(x,t) = 0.
 \end{aligned} \tag{50}$$

- First order equations (for $i=1,2$.)

$$\begin{aligned}
 & -\frac{(\bar{G}_{1\alpha}\kappa_1 F_1 + \bar{G}_{2\alpha}\kappa_2 F_2)}{F_1\rho_1 + F_2\rho_2} H'_{wi\alpha,xx}(x,t) - \frac{4(\bar{G}_{2\alpha}\kappa_2 F_2 - \bar{G}_{1\alpha}\kappa_1 F_1)}{F_1\rho_1 + F_2\rho_2} H''_{vi\alpha,x}(x,t) + \\
 & + 2\beta \dot{H}'_{wi\alpha}(x,t) + \ddot{H}'_{wi\alpha}(x,t) = \frac{1}{F_1\rho_1 + F_2\rho_2} R_{1i\alpha}(x,t), \\
 & \frac{12(\bar{G}_{2\alpha}\kappa_2 F_2 - \bar{G}_{1\alpha}\kappa_1 F_1)}{l^2(F_1\rho_1 + F_2\rho_2)} H'_{wi\alpha,x}(x,t) + \frac{48(\bar{G}_{1\alpha}\kappa_1 F_1 + \bar{G}_{2\alpha}\kappa_2 F_2)}{l^2(F_1\rho_1 + F_2\rho_2)} H''_{vi\alpha}(x,t) + \\
 & + 2\beta \dot{H}''_{vi\alpha}(x,t) + \ddot{H}''_{vi\alpha}(x,t) = \frac{1}{F_1\rho_1 + F_2\rho_2} R_{2i\alpha}(x,t),
 \end{aligned} \tag{51}$$

where

$$\begin{aligned}
 R_{11\alpha}(x,t) &= H^0_{w\alpha,xx}(x,t) - 4H^{10}_{v\alpha,x}(x,t), \\
 R_{21\alpha}(x,t) &= \frac{12}{l^2} H^0_{w\alpha,x}(x,t) - \frac{48}{l^2} H^{10}_{v\alpha}(x,t), \\
 R_{12\alpha}(x,t) &= H^0_{w\alpha,xx}(x,t) + 4H^{10}_{v\alpha,x}(x,t), \\
 R_{22\alpha}(x,t) &= -\frac{12}{l^2} H^0_{w\alpha,x}(x,t) - \frac{48}{l^2} H^{10}_{v\alpha}(x,t).
 \end{aligned} \tag{52}$$

In particular case if $G_{1\alpha} = G_{2\alpha} = G_\alpha$ than the equations 47-50 have the forms

$$\begin{aligned}
 \langle K(x) \rangle_\alpha &= G_\alpha [\kappa_1 F_{1\alpha} \frac{a}{l} + \kappa_2 F_{2\alpha} (1 - \frac{a}{l})], \\
 \langle K(x) g^1_{,x}(x) \rangle_\alpha &= G_\alpha [\kappa_1 F_{1\alpha} \frac{a}{l} - \kappa_2 F_{2\alpha} (1 - \frac{a}{l})], \\
 \langle K(x) g^1_{,x}(x) g^1_{,x}(x) \rangle_\alpha &= \frac{1}{3} G_\alpha [\kappa_1 F_{1\alpha} \frac{a}{l} - \kappa_2 F_{2\alpha} (1 - \frac{a}{l})].
 \end{aligned} \tag{47a}$$

for the particular case $a = l/2$

$$\begin{aligned}
 \langle K(x) \rangle_\alpha &= \frac{G_\alpha}{2} (\kappa_1 F_{1\alpha} + \kappa_2 F_{2\alpha}), \\
 \langle K(x) g^1_{,x}(x) \rangle_\alpha &= \frac{1}{2} G_\alpha (\kappa_1 F_{1\alpha} - \kappa_2 F_{2\alpha}), \\
 \langle K(x) g^1_{,x}(x) g^1_{,x}(x) \rangle_\alpha &= \frac{1}{6} G_\alpha (\kappa_1 F_{1\alpha} - \kappa_2 F_{2\alpha}).
 \end{aligned} \tag{48a}$$

- Zeroth order equations

$$\begin{aligned}
 & -\frac{\bar{G}_\alpha(\kappa_1 F_{1\alpha} + \kappa_2 F_{2\alpha})}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} H_{w\alpha,xx}^0(x,t) - \frac{4\bar{G}_\alpha(\kappa_2 F_{2\alpha} - \kappa_1 F_{1\alpha})}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} H_{v\alpha,x}^{10}(x,t) + \\
 & + 2\beta \dot{H}_{w\alpha}^0(x,t) + \ddot{H}_{w\alpha}^0(x,t) = \frac{2\langle q(x) \rangle}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} \delta(t), \\
 & \frac{12\bar{G}_\alpha(\kappa_2 F_{2\alpha} - \kappa_1 F_{1\alpha})}{l^2(F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2)} H_{w\alpha,x}^0(x,t) + \frac{48\bar{G}_\alpha(\kappa_1 F_{1\alpha} + \kappa_2 F_{2\alpha})}{l^2(F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2)} H_{v\alpha}^{10}(x,t) + \\
 & + 2\beta \dot{H}_{v\alpha}^{10}(x,t) + \ddot{H}_{v\alpha}^{10}(x,t) = 0.
 \end{aligned} \tag{49a}$$

- First order equations (for $i=1,2$.)

$$\begin{aligned}
 & -\frac{\bar{G}_\alpha(\kappa_1 F_{1\alpha} + \kappa_2 F_{2\alpha})}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} H_{w\alpha,xx}^I(x,t) - \frac{4\bar{G}_\alpha(\kappa_2 F_{2\alpha} - \kappa_1 F_{1\alpha})}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} H_{v\alpha,x}^{II}(x,t) + \\
 & + 2\beta \dot{H}_{w\alpha}^I(x,t) + \ddot{H}_{w\alpha}^I(x,t) = \frac{1}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} R_{1\alpha}(x,t), \\
 & \frac{12\bar{G}_\alpha(\kappa_2 F_{2\alpha} - \kappa_1 F_{1\alpha})}{l^2(F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2)} H_{w\alpha,x}^I(x,t) + \frac{48\bar{G}_\alpha(\kappa_1 F_{1\alpha} + \kappa_2 F_{2\alpha})}{l^2(F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2)} H_{v\alpha}^{II}(x,t) + \\
 & + 2\beta \dot{H}_{v\alpha}^{II}(x,t) + \ddot{H}_{v\alpha}^{II}(x,t) = \frac{1}{F_{1\alpha}\rho_1 + F_{2\alpha}\rho_2} R_{2\alpha}(x,t),
 \end{aligned} \tag{50a}$$

Let us consider the shear vibration of a homogeneous beam. The random influence function has the form

$$H_\alpha(x,t) = \frac{2}{hm_\alpha} \sum_{n=1}^{\infty} \frac{q_n}{\Omega_{n\alpha}} e^{-\beta t} \sin \Omega_{n\alpha} t \sin \lambda_n x, \tag{53}$$

where $2\beta = \frac{c}{m}$, $(\Omega_{n\alpha})^2 = \lambda_n^2 \frac{G_\alpha F}{m} - \beta^2 = (\omega_{n\alpha})^2 - \beta^2$, $\lambda_n = \frac{\pi}{h}(n - \frac{1}{2})$, $\omega_n^2 = \lambda_n^2 \frac{K}{m} = \lambda_n^2 v_s^2$,

$$q_n = \int_0^h q(x) \sin \lambda_n x dx.$$

We assume that the Kirchhoff modulus G_α is a fuzzy random variable. The other beam parameters are assumed to be deterministic. The random functions describing the load were assumed to be fuzzy weakly stationary stochastic processes, $E[f_\alpha(t)]_\alpha = E[f_\alpha]_\alpha = \text{const.}$, $C_{ff_\alpha}(t_1, t_2) = C_{ff_\alpha}(t_1 - t_2) = C_{ff_\alpha}(t)$. Let us assume that the time and space correlation of the load process is of the “white noise” type, namely that the covariance functions has the form $C_{ff_\alpha} = \sigma_{f_\alpha}^2 \delta(t)$. The solution will be found for the steady-state, i.e. $t_0 = -\infty$. The expected value is equal to

$$E[u_{\alpha\beta}(\mathbf{b}_\alpha, x, \infty)]_{\alpha\beta} = E[f_\alpha]_\alpha \int_{-\infty}^t E[H_\alpha(x, t - \tau)] d\tau = \frac{2E[f_\alpha]}{Fh} E\left[\frac{1}{G_\alpha}\right]_\alpha \sum_{n=1}^{\infty} \frac{q_n}{\lambda_n^2} \sin \lambda_n x. \tag{54}$$

In order to find the probabilistic characteristics the function of the random variables has been expanded into Taylor series around the mean value and restricted to three first items (components) of the expansion. The expected value of the response has form

$$E[u_\alpha(\mathbf{b}_\alpha, x, \infty)]_\alpha = \frac{2E[f_\alpha]_\alpha}{Fh} \frac{(1+v_{G_\alpha}^2)}{E[G_\alpha]_\alpha} \sum_{n=1}^{\infty} \frac{q_n}{\lambda_n^2} \sin \lambda_n x, \quad (55)$$

where v_{G_α} is standard deviation of the Kirchhoff modulus.

The variance of the beam displacement for the steady-state vibrations ($t \rightarrow \infty$) can be shown in the form

$$\sigma_{u_\alpha}^2(x, \infty)_\alpha = \sigma_{f_\alpha}^2 \int_0^\infty E[h_\alpha^2(\mathbf{b}_\alpha, x, \tau)]_\alpha d\tau + E^2[f_\alpha]_\alpha \int_0^\infty \int_0^\infty Cov_{hh_\alpha}(x, x, \tau_1, \tau_2)_\alpha d\tau_1 d\tau_2. \quad (56)$$

After calculating the integrals in the equation (56) one obtains

$$\begin{aligned} \sigma_{u_\alpha}^2(x, \infty)_\alpha &= \frac{\sigma_{f_\alpha}^2 (1+v_{G_\alpha}^2)}{Fh^2 m \beta E[G_\alpha]_\alpha} \sum_{n=1}^{\infty} \frac{q_n^2}{\lambda_n^2} \sin^2 \lambda_n x + \\ &+ \frac{16\sigma_{f_\alpha}^2 \beta}{h^2 m^2} \sum_{n=1}^{\infty} \sum_{\substack{k=1 \\ n \neq k}}^{\infty} q_n q_k E\left[\frac{1}{(2\beta^2 + \omega_{n\alpha}^2 + \omega_{k\alpha}^2)^2 - 4\Omega_{n\alpha}^2 \Omega_{k\alpha}^2} \right]_\alpha \sin \lambda_n x \sin \lambda_k x. \end{aligned} \quad (57)$$

4 NUMERICAL EXAMPLE

For the testing the approach presented the shape functions of the expected value and standard deviation of the displacements on a top of multistorey tall building with averaged structure parameters have been calculated. The calculations have been done assuming that the expected value of the shear stiffness is a fuzzy number of triangular shape functions. Other quantities are being treated as deterministic parameters. The results obtained for the coefficient of variation of the shear stiffness equal to 0.1 are shown in the Figures 3 and 4.

Figure 3. The shape function of the expected value of the displacement

Figure 4. The shape function of the standard deviation of the displacement

5 SUMMARY AND CONCLUSIONS

- The model of a vibrating shear beam has been generalized on the finite periodic composite beam with uncertain parameters. Different types of uncertainty of the structure parameters and the excitation process have been considered, namely: fuzzy numbers, random variables, random functions, fuzzy random variables, fuzzy random functions and fuzzy stochastic processes. This allows for investigating a wide analysis of complex problems of the shear vibrations of periodic composite beams with fuzzy random parameters under fuzzy stochastic excitations. Much attention has been focused on for obtaining the solution in the most general case. Presented model of the finite periodic composite beam with uncertain parameters has been proposed as a model of multistory building. It has been assumed, that each storey has two different stiffnesses: one for the part without windows and doors and another one with windows and doors.
- For obtaining the solution within the correlation theory the fuzzy random dynamic influence function has been introduced, which allows for applying the perturbation method or Monte Carlo simulation.
- The difficulty connected with solving the differential equations with periodic variable coefficients has been overcome by applying the average tolerance approach, which transforms the differential equations with periodic variable coefficients into the averaged differential equations with constant coefficients.
- For the steady-state vibration of the beam with fuzzy random parameters under stationary stochastic excitation the expressions for calculating the expected value and variance of the beam displacements are given.

Abstract. *The tuned liquid column dampers (TLCDs) have been shown to be effective vibration control devices for flexible structures subjected to long-duration, periodic or harmonic excitations. Their potential applications for seismic protection and retrofitting were recently explored. The optimum TLCD parameters are normally obtained based on the implicit assumption that the involved variables are deterministic. However, it is well known that the efficiency of TLCDs may be jeopardized if its parameters are not properly tuned to the vibrating mode of interest, for instance as consequence of the unavoidable presence of uncertain variables. Thus, the optimization of damper parameters considering model uncertainties has attracted a great deal of interest. The robust design of TLCDs for the passive control of mechanical systems under random ground motion is investigated in the present paper by coupling random vibration analysis and credibility theory in order to take into account fuzzy uncertainties. In doing so, two antithetical objective functions are considered, and they are the expected value and the variance of an appropriate displacement-based fuzzy structural index. Specifically, this latter one is introduced to characterize the performance variability due to the existence of fuzzy uncertainties affecting, both the system and random loading parameters. A numerical study is performed to demonstrate the applicability of the developed approach.*

1 INTRODUCTION

Base isolation, passive energy dissipation and active control are three current philosophies for enhancing structural performances and safety against natural and manmade hazards. Among the most popular passive control devices, the tuned mass dampers and the tuned liquid dampers are commonly used. A tuned mass damper (TMD) consists of a large mass attached to the structure through a spring and a dashpot, and dissipates energy when it is tuned to the frequency of the structure. The tuned liquid damper (TLD) consists of a container which is partially filled with liquid which dissipates energy through the sloshing action of a liquid in the container. For optimum results, the sloshing frequency is tuned to the frequency of the structure. Tuned liquid column dampers (TLCDs) are a class of tuned liquid dampers that impart indirect damping to the primary structure through oscillations of the liquid column in a U-shaped container which includes at least one orifice. It has been also investigated a type of TLCD that have different cross-sections in the horizontal and vertical columns, termed liquid column vibration absorbers (LCVAs). These devices are summarized in Fig. 1.

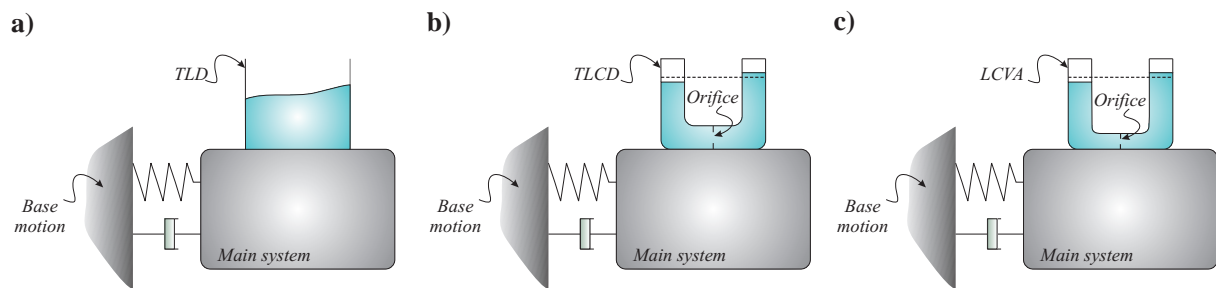

Figure 1: Tuned liquid damper (a), Tuned liquid column damper (b) and Liquid column vibration absorber (c).

Potential advantages of TLCDs over the conventional inertial devices (e.g., TMDs) are that the system is inexpensive and requires minimum maintenance and its vibration characteristics (e.g., tuning and damping) are well defined and can be easily modified. For instance, its natural frequency is only determined by the length of the liquid column, and its damping can be overall accounted for by the so-called head loss coefficient that depends on the orifice size in the horizontal column. Additionally, water storage already available in tall buildings can be utilized without introducing excessively extra large mass. The effectiveness of TLCD as protection strategy was primarily addressed for controlling the wind-induced vibration of towers [1] and tall buildings [2]. In doing this, the most of the studies consider a single-degree-of-freedom (SDOF) model of primary system equipped with a TLCD and subject to white noise type of wind loading [3]. On the contrary, the assessment of the TLCD performances for protecting structural systems subject to earthquake load is comparatively less. In this field, the effectiveness of the TLCD performances was investigated in [4] with regard to non-stationary random vibrations simulating an earthquake loading.

All mechanical parameters governing the adopted passive protection strategy have to be properly optimized in order to meet the maximum possible protection level. In doing so, the analysis of all sources of uncertainty is a crucial step of the design process. In this regard, it may be noted that earlier studies were mainly conducted by assuming deterministic protected mechanical systems subject to uncertain dynamic loads, i.e. [3][4][5]. However, this simplification may jeopardize the effectiveness of the adopted protection strategy. In fact, it was reported that the uncertainty in mechanical system parameters might have equal or sometimes even greater influence on the response than the uncertainty in the dynamic excitations [6]. Since passive protection systems do not have any feedback from the structural response, improved design strategies should be preferred for taking into account all possible sources of

uncertainty and their effects on the expected performances. For instance, Marano and co-authors [7][8] investigated the effects due to uncertain mechanical systems parameters for robust optimum design strategies of TMDs. In doing this, the authors considered SDOF systems subject to stationary filtered white noise process and the sensitivity of a performance index against the fluctuations of the uncertain structural parameters is considered via direct perturbation method. The application of low-order perturbation methods allow a probabilistic analysis by considering few statistical moments of the uncertain parameters (e.g., mean and variance) and do not require full statistical descriptions (e.g., the joint probability density functions). Although researchers and practitioners are familiar with stochastic calculus, a pure probabilistic standpoint in designing these devices may present several limitations.

Since fuzziness is frequently involved in modeling random processes and variables, it is not so reasonable to take into account randomness while ignoring the existence of fuzziness aprioristically [9]. On the contrary, more consistent analysis may be carried out by relaxing conventional probabilistic-based methods in order to include non-probabilistic forms of uncertainty appropriately [10][11]. For instance, the reliability based optimum design of TMDs in seismic vibration control of structures with bounded uncertain parameters was presented in [12]. The optimum design of TLCDs under stochastic earthquake considering uncertain bounded system parameters was discussed in [13]. A procedure for the analysis of structural systems subject to random vibrations considering fuzzy variables was proposed in [14]. A robust-based optimization problem for TMDs was illustrated in [15] which take into account stochastic ground motion and fuzzy variables.

This paper addresses the robust design of TLCDs under stochastic ground motion considering fuzzy uncertainties. In detail, the dynamic loading is modeled as a stationary filtered white noise process whereas both load and system parameters are considered as fuzzy variables. As a consequence, a general performance index is affected by fuzziness itself. Therefore, we propose the application of the credibility measure in order to extract two representative crisp measures. The first one is based on the expected operator for fuzzy variables which needs to be minimized in order to improve the effectiveness of the TLCD. The second one, based on the variance operator for fuzzy variables, must be minimized in order to increase the robustness against fuzzy uncertainties. As these measures have an opposite behavior within typical design solution spaces, a multi-objective optimization problem can be formulated in order to define a collection of solutions (in Pareto sense) which are capable of ensuring a satisfactory trade-off between mechanical performances and robustness against the variability due to the uncertain (fuzzy) parameters. Numerical examples at the end will demonstrate the feasibility of the proposed approach of designing TLCDs.

2 DYNAMIC RESPONSE OF TLCD-STRUCTURE SYSTEM

The description of a SDOF system equipped with a TLCD under stochastic ground motion is provided in this section. The stochastic dynamic response analysis of the combined TLCD-structure is evaluated as in [13], by using the state space formulation in time domain and by solving the final Lyapunov equation.

2.1 TLCD system and liquid motion equation

The TLCD considered in the present study is a U-shaped pipe attached to the main system which is modeled as a SDOF system with properties in accordance with the specified mode of vibration. A schematic diagram of a SDOF system equipped with a TLCD under base excitation is shown in Fig. 2.

Figure 2: Layout of a SDOF system equipped with a TLCD.

The main geometrical and physical data for the TLCD are: cross-sectional area A , the length of the horizontal portion of the tube B_h , the vertical height of the liquid inside the tube h and the density of the liquid ρ . The main system to be protected has a mass equal to m_s , a linear stiffness k and a viscous damping c_s . The total length of the liquid column is $L_e = 2h + B_h$. The mass of the liquid $m_l = \rho A L_e$ can be considered as part of m_s . An orifice is installed in the horizontal portion of the pipe and ξ denotes the coefficient of head loss which depends on its opening ratio. The orifice is typically placed at the centre of the horizontal portion of the tube. The combined TLCD-structure is subject to base acceleration (see Fig. 2), for instance due to an earthquake. The relative horizontal displacement of the SDOF system is x whereas the displacement of the liquid surface (with reference to the unperturbed original configuration) is denoted as y (the time variable is omitted throughout the paper to improve the readability of various equations). In order to derive the motion equation of the liquid within the U-shaped pipe, the following hypotheses are used: (i) the sloshing behavior on the liquid surface is negligible; (ii) the flow is incompressible (i.e., the flow rate is constant); (iii) the dimension of the column cross-section is much smaller than the horizontal length of a TLCD. The equation of motion of the liquid column is [16]:

$$\rho A L_e \ddot{y} + \frac{1}{2} \rho A \xi |\dot{y}| \dot{y} + 2 \rho g A y = -\rho A B_h (\ddot{x} + \ddot{z}_b) \quad (1)$$

In the above, g is the gravitational acceleration. It is evident in the second term of Eq. (1) that the TLCD response is non-linear as a result of the drag-type forces induced by the orifice. Within the framework of random vibration theory, the motion equation in Eq. (1) is usually linearized via stochastic equivalent linearization technique. First, a linear system is chosen to represent the original non-linear system:

$$\rho A L_e \ddot{y} + 2 \rho A c_p \dot{y} + 2 \rho g A y = -\rho A B_h (\ddot{x} + \ddot{z}_b) \quad (2)$$

in which c_p is the equivalent damping coefficient for the TLCD after linearization. By minimizing the mean-square error between Eq. (1) and Eq.(2), it can be found:

$$c_p = \frac{\xi \langle |\dot{y}| \dot{y} \rangle}{4 \langle \dot{y}^2 \rangle} \quad (3)$$

where $\langle \cdot \rangle$ is the operator of expectation. If x is a zero-mean stationary Gaussian process, c_p is:

$$c_p = \frac{\xi \sigma_{\dot{y}}}{\sqrt{2\pi}} \quad (\sigma_{\dot{y}} : \text{standard deviation of the liquid velocity}) \quad (4)$$

In Eq. (4), the standard deviation of the liquid velocity is not known a priori: therefore, the dynamic analysis is performed by assuming an initial value for c_p (i.e., $c_p=0$) and is updated once the motion equation is solved. This implies an iterative procedure that will be stopped once a convergence criterion is fulfilled (the exact value of c_p is achieved after few iterations). The error due to this linearization depends on the head loss coefficient (the error increases as ξ grows): however, for the most part of engineering applications, Eq. (4) provides very good results. By normalizing Eq. (2) with respect to the mass of the liquid in the container, one obtains:

$$\ddot{y} + \frac{2c_p}{L_e} \dot{y} + \frac{2g}{L_e} y + p\ddot{x} = -p\ddot{z}_b \quad (5)$$

where $p=B_h/L_e$ is the length ratio.

2.2 Motion equation of the SDOF system equipped with a TLCD

The TLCD is used to protect a SDOF linear system as shown in Fig. 2. The equation of motion of the main system equipped with TLCD is:

$$(m_s + \rho AB_h + 2\rho hA)\ddot{x} + c_s\dot{x} + k_s x = -(m_s + \rho AB_h + 2\rho hA)\ddot{z}_b - \rho AB_h\ddot{y} \quad (6)$$

If the variable $m_l = \rho AB_h + \rho Ah$ is considered, then above equation can be expressed as:

$$(m_s + m_l)\ddot{x} + c_s\dot{x} + k_s x = -(m_s + m_l)\ddot{z}_b - \rho A p L_e \ddot{y} \quad (7)$$

The normalization of Eq. (7) with respect to m_s yields:

$$(1 + \mu)\ddot{x} + \frac{c_s}{m_s}\dot{x} + \frac{k_s}{m_s}x = -(1 + \mu)\ddot{z}_b - \mu p \ddot{y}, \quad (8)$$

in which $\mu = (\rho A L_e)/m_s$ is the so-called mass ratio. By introducing the notations of the natural frequency $\omega_s = \sqrt{(k_s/m_s)}$ and the damping coefficient $\xi_s = c_s/(2m_s\omega_s)$ for the main system, Eq. (8) can be rewritten as follows:

$$(1 + \mu)\ddot{x} + 2\xi_s\omega_s\dot{x} + \omega_s^2 x + \mu p \ddot{y} = -(1 + \mu)\ddot{z}_b \quad (9)$$

The tuning ratio $\gamma = \omega_l/\omega_s$ will be also used, where $\omega_l = \sqrt{(2g/L_e)}$ is the frequency of the liquid. Eq. (5) and Eq. (9) can be also expressed in matrix form:

$$\begin{bmatrix} 1 & p \\ \mu p & (1 + \mu) \end{bmatrix} \begin{Bmatrix} \ddot{y} \\ \ddot{x} \end{Bmatrix} + \begin{bmatrix} \frac{2c_p}{L_e} & 0 \\ 0 & 2\xi_s\omega_s \end{bmatrix} \begin{Bmatrix} \dot{y} \\ \dot{x} \end{Bmatrix} + \begin{bmatrix} \frac{2g}{L_e} & 0 \\ 0 & \omega_s^2 \end{bmatrix} \begin{Bmatrix} y \\ x \end{Bmatrix} = -\ddot{z}_b \begin{Bmatrix} p \\ (1 + \mu) \end{Bmatrix} \quad (10)$$

If the state space vector \mathbf{u} is introduced:

$$\mathbf{u} = \{y \quad x \quad \dot{y} \quad \dot{x}\}^T \quad (11)$$

then Eq. (10) is reduced to a standard first-order form:

$$\dot{\mathbf{u}} = \mathbf{A}_* \mathbf{u} + \mathbf{r} \ddot{z}_b \quad (12)$$

where

$$\mathbf{A}_* = \begin{bmatrix} \mathbf{0}_{2 \times 2} & \mathbf{I}_{2 \times 2} \\ \mathbf{M}^{-1}\mathbf{K} & \mathbf{M}^{-1}\mathbf{C} \end{bmatrix} \quad (13)$$

and $\mathbf{r} = \{0 \ 0 \ 1 \ 1\}^T$. In Eq. (13), $\mathbf{0}$ and \mathbf{I} are the null and the unit matrix, respectively (the subscripts denote their size).

2.3 Stochastic model for the ground motion

For base random accelerations, a usual model is obtained via second-order linear filtering of the white noise process. As in several previous studies – see for instance [7] and [13] – the stationary Kanai-Tajimi model is considered in this paper [17][18]. So doing, the excitation at the base is described as follows:

$$\begin{aligned} \ddot{x}_f + 2\xi_f \omega_f \dot{x}_f + \omega_f^2 x_f &= -w \\ \ddot{z}_b &= \ddot{x}_f + w = 2\xi_f \omega_f \dot{x}_f + \omega_f^2 x_f \end{aligned} \quad (14)$$

In which w is a stationary Gaussian zero mean white noise process whose power spectral density (PSD) is S_0 which can be evaluated as follows

$$S_0 = \frac{2\xi_f \sigma_{\ddot{z}_b}^2}{\pi(1 + 4\xi_f^2)\omega_f} \quad (15)$$

The standard deviation of the base motion is related to the peak ground acceleration (PGA):

$$\text{PGA} = 3\sigma_{\ddot{z}_b} \quad (16)$$

Therefore, the dynamic loading model in Eq. (14) depends on two parameters, named the filter frequency ω_f and the filter damping ξ_f .

2.4 Response covariance analysis

The following algebraic matrix equation of order six – the so-called Lyapunov equation – is obtained by taking into account both Eq. (12) and Eq. (14):

$$\mathbf{A}\mathbf{R} + \mathbf{R}\mathbf{A}^T + \mathbf{B} = \mathbf{0}_{6 \times 6} \quad (17)$$

In Eq. (17) the state space matrix \mathbf{A} and \mathbf{B} are, respectively:

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ -2m_{11}g/L_e & m_{12}\omega_s^2 & 0 & -2m_{12}c_p/L_e & 2m_{12}\xi_s\omega_s & 0 \\ 2m_{21}g/L_e & -m_{22}\omega_s^2 & \omega_f^2 & 2m_{21}c_p/L_e & -2m_{22}\xi_s\omega_s & 2\xi_f\omega_f \\ 0 & 0 & -\omega_f^2 & 0 & 0 & -2\xi_f\omega_f \end{bmatrix} \quad (18)$$

$$\mathbf{B} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\pi S_0 \end{bmatrix}, \quad (19)$$

with

$$d_e = (1 + \mu) - \mu p^2 \quad m_{11} = \frac{1 + \mu}{d_e} \quad m_{21} = \frac{\mu p}{d_e} \quad m_{12} = \frac{p}{d_e} \quad m_{22} = \frac{1}{d_e} \quad (20)$$

And the global state space vector is:

$$\mathbf{z} = \{y \quad x \quad x_f \quad \dot{y} \quad \dot{x} \quad \dot{x}_f\}^T \quad (21)$$

The space state covariance matrix \mathbf{R} in Eq. (17) takes the form:

$$\mathbf{R} = \begin{bmatrix} \mathbf{R}_{zz} & \mathbf{R}_{zz} \\ \mathbf{R}_{zz} & \mathbf{R}_{zz} \end{bmatrix}, \quad (22)$$

and each sub-matrix has a size 2×2 . Our main interest is focused in the following quantities:

$$\sigma_x = \sqrt{\mathbf{R}_{zz}(2,2)} \quad (23)$$

$$\sigma_{\dot{y}} = \sqrt{\mathbf{R}_{zz}(1,1)}, \quad (24)$$

that are the standard deviation of the main system displacement equipped with a TLCD and the standard deviation of the liquid velocity, respectively. Eq. (24) is needed to evaluate c_p in Eq. (4).

3 ROBUST DESIGN OPTIMIZATION CONSIDERING FUZZY UNCERTANTIES

Once the covariance response analysis is completed, the structural performance index under investigation is presented. Thus, the adopted uncertain parameters' model is introduced. Consequently, the robust design optimization problem of the TLCD is formalized within the framework of the credibility theory.

3.1 Structural performance index

In order to assess the effectiveness of the TLCD, the response covariance analysis is performed for the unprotected main system. In this case, the covariance matrix \mathbf{R}_0 has size 4×4 and can be evaluated as follows:

$$\mathbf{A}_0 \mathbf{R}_0 + \mathbf{R}_0 \mathbf{A}_0^T + \mathbf{B}_0 = \mathbf{0}_{4 \times 4}, \quad (25)$$

where

$$\mathbf{A}_0 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\omega_s^2 & \omega_f^2 & -2\xi_s\omega_s & 2\xi_f\omega_f \\ 0 & -\omega_f^2 & 0 & -2\xi_f\omega_f \end{bmatrix} \quad (26)$$

$$\mathbf{B}_0 = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\pi S_0 \end{bmatrix}, \quad (27)$$

And the global state space vector is:

$$\mathbf{z}_0 = \{x_0 \quad x_f \quad \dot{x}_0 \quad \dot{x}_f\}^T \quad (28)$$

Finally, the standard deviation of the unprotected main system displacement is:

$$\sigma_{x_0} = \sqrt{\mathbf{R}_{z_0 z_0}(1,1)} \quad (29)$$

Given a set of TLCD parameters, i.e. $\mathbf{d} = \{\gamma, \xi\}$, a dimensionless performance index to assess the efficiency of the TLCD is [7]:

$$\psi(\mathbf{d}) = \frac{\sigma_x(\mathbf{d})}{\sigma_{x_0}} \quad (30)$$

This function represents a direct stochastic displacement-based performance index: in fact, the designed TLCD is effective in seismic protection as $\psi(\mathbf{d})$ tends to zero.

3.2 Consideration of non-probabilistic uncertainties

The performance index in Eq. (30) is carried out under the assumption that the dynamic loading is the only source of uncertainty, and it is assumed as a pure random process. The effects of uncertain structural parameters are generally considered via direct perturbation method in a probabilistic format by considering few statistical moments of the uncertain parameters. Unfortunately, a pure probabilistic standpoint may be an important limitation for some practical applications. This is because few experimental data are available in many cases and, sometimes, literature or expert opinions are the only supports for handling uncertainties. In this perspective, alternative (non-probabilistic) uncertain models should be included.

Several studies – see for instance [12][13][14][15] – demonstrated that non-probabilistic sources of uncertainty can play a significant role in the analysis of structural systems subject to random vibration. For instance, the natural frequency of the main system ω_s is quite difficult to predict accurately (its real value is usually defined by a full-scale field dynamic testing) and is subject to non-structural induced variations (i.e., due to the temperature). Moreover, different numerical techniques for extracting the natural frequencies from dynamic records may lead to dissimilar numerical values. However, the most relevant source of uncertainty in the main system is usually due to the way by which it dissipates energy when subject to dynamic loading and, in turn, in the numerical evaluation of ξ_s . The most important sources of indeterminateness can be detected in the assessment of the filter parameters [15] for which probabilistic models (e.g., probability density functions) are not typically available to designers. On the contrary, expert opinions and existing literature data base are often adopted to se-

lect appropriate values for ω_f and ξ_s . Unfortunately, the variability of the filter parameters does not observe a specific statistical model because of the lack of accurate and consistent information for a statistical treatment. Their numerical values generally depend on the soil type, which is defined using a linguistic-based criterion (stiff, medium or soft soil). Since fuzziness is usually involved in random variables modeling, it is not so reasonable to take into account randomness while ignoring the existence of fuzziness aprioristically [19]. Therefore, an appropriate design of TLCDs needs a more complicated analysis regarding the (different) sources of uncertainty. In this paper ω_s , ξ_s , ω_f and ξ_s are considered as fuzzy variables. The use of fuzzy variables for structures subject to random vibrations was proposed in [14] and [15]. Since each interval is an equally possible fuzzy variable, this approach is a generalized version of that in [12] and [13] based on uncertain bounded system parameters.

3.3 Credibility measure, expected value and variance of fuzzy variables

In order to introduce the robust design optimization problem considering fuzzy variables, some definitions from the credibility theory are required. The credibility space is mathematically defined by the triplet $(\Theta, P(\Theta), \text{Cr})$, where Θ is the nonempty set representing the sample space, $P(\Theta)$ the power set of Θ and Cr the credibility measure. In order to define the credibility measure, we consider an event Q , its possibility $\text{Pos}\{Q\}$ (a crisp number indicating the possibility that this event will occur) and its necessity $\text{Nec}\{Q\}$ (another crisp number denoting the impossibility of the opposite set Q^{opp}). The credibility of the fuzzy event Q (denoted as $\text{Cr}\{Q\}$) is defined as the average between its possibility and necessity of Q :

$$\text{Nec}\{Q\} = 1 - \text{Pos}\{Q^{opp}\} \quad (31)$$

$$\text{Cr}\{Q\} = \frac{1}{2} (\text{Pos}\{Q\} + \text{Nec}\{Q\}) \quad (32)$$

A fuzzy variable \tilde{b} is a measurable function from a credibility space $(\Theta, P(\Theta), \text{Cr})$ to the set of real numbers. For each fuzzy variable, it is possible to define its membership function (MF) $\pi(b)$ as follows [20]:

$$\pi(b) = \min\{2\text{Cr}\{\tilde{b} = b\}, 1\} \quad \forall b \in \mathbb{R} \quad (33)$$

Throughout the paper we will suppose that it is possible to define a fuzzy variable by means of its α -cuts. Specifically, we assume that the generic α -cut of a fuzzy variable is the following closed interval:

$$\bar{b}^\alpha = [b^{\alpha_-}, b^{\alpha_+}] = \{b \in \mathbb{R} \mid \pi(b) \geq \alpha\} \quad \forall \alpha \in (0, 1] \quad (34)$$

and the fuzzy variable \tilde{b} is:

$$\tilde{b} = \bigcup_{\alpha \in (0, 1]} \alpha [b^{\alpha_-}, b^{\alpha_+}] \quad (35)$$

The representation of the expected value for a fuzzy variable is identical to that for a random variable [21]. Based on the Choquet integral, the definition of the expected value of a fuzzy variable proposed in [21] is the following:

$$E[\tilde{b}] = b_E = \int_0^{+\infty} \text{Cr}\{\tilde{b} \geq s\} ds - \int_{-\infty}^0 \text{Cr}\{\tilde{b} \leq s\} ds \quad (36)$$

and

$$\text{Cr}\{\tilde{b} \leq b\} = \frac{1}{2} \left(\sup_{v \leq b} \{\pi(v)\} + 1 - \sup_{v > b} \{\pi(v)\} \right) \quad \forall b \in \mathbb{R} \quad (37)$$

$$\text{Cr}\{\tilde{b} \geq b\} = \frac{1}{2} \left(\sup_{v \geq b} \{\pi(v)\} + 1 - \sup_{v < b} \{\pi(v)\} \right) \quad \forall b \in \mathbb{R} \quad (38)$$

The variance of a fuzzy variable measures the spread of the distribution around its expected value. In perfect analogy with the probabilistic case, the credibility-based definition of the variance of a fuzzy variable is [20]:

$$\text{V}[\tilde{b}] = \text{E} \left[\left(\tilde{b} - b_E \right)^2 \right] \quad (39)$$

In this paper, the expected value operator in Eq. (36) will be performed to obtain the likelihood of an event from fuzzy-type information. Since fuzzy-type outputs can have a different spread around the expected value, the variance operator in Eq. (39) will be adopted to discriminate their degree of indeterminateness. Both information will be important to formalize the robust design of TLCDs. Some closed form expressions of mean and variance for common MFs are available in [20].

3.4 Robust design optimization of TLCD

The following vector of fuzzy variables (that is, a fuzzy vector) is introduced in order to take into account non-probabilistic uncertainties in the optimum design of the TLCD:

$$\tilde{\mathbf{b}} = \{\tilde{b}_{i=1,\dots,4}\} = \{\tilde{\omega}_s \quad \tilde{\xi}_s \quad \tilde{\omega}_f \quad \tilde{\xi}_f\} \quad (40)$$

As a consequence, Eq. (30) is a deterministic function involving fuzzy variables (that is, a type of fuzzy function) and whose output is fuzzy itself:

$$\tilde{\psi}(\mathbf{d}) = \frac{\tilde{\sigma}_x(\mathbf{d})}{\tilde{\sigma}_{x_0}} \quad (41)$$

with

$$\tilde{\psi}(\mathbf{d}) = \psi(\mathbf{d}; \tilde{\mathbf{b}}) \quad \tilde{\sigma}_x(\mathbf{d}) = \sigma_x(\mathbf{d}; \tilde{\mathbf{b}}) \quad \tilde{\sigma}_{x_0} = \sigma_{x_0}(\tilde{\mathbf{b}}) \quad (42)$$

Since fuzzy uncertainties are involved in the proposed analysis, the original displacement-based performance index in Eq. (30) is uncertain (fuzzy) itself. Therefore, instead of aiming to find a single “best” design solution, it may be more interesting to carry out a set of “good” compromise between TLCD performance and sensitivity against fuzziness. This is the key-idea in robust-based design strategies and would be a more consistent way for supporting designers and decision makers. Because “performance” and “sensitivity” are often conflicting objectives, a multi-objective optimization problem has to be solved. In this paper, the robust design optimization of the TLCD is performed by solving the following multi-objective optimization problem

$$\begin{aligned} \min_{\mathbf{d}} \{ & f_1(\mathbf{d}; \tilde{\mathbf{b}}), f_2(\mathbf{d}; \tilde{\mathbf{b}}) \} \\ \text{s.t. } & \mathbf{d}_{\max} \leq \mathbf{d} \leq \mathbf{d}_{\min} \end{aligned} \quad (43)$$

in which

$$f_1(\mathbf{d}; \tilde{\mathbf{b}}) = E[\tilde{\psi}(\mathbf{d})] \quad (44)$$

and

$$f_2(\mathbf{d}; \tilde{\mathbf{b}}) = \sqrt{V[\tilde{\psi}(\mathbf{d})]} \quad (45)$$

The minimization of the first objective function f_1 in Eq. (44) aims at improving the effectiveness of the TLCD in seismic protection. On the other hand, the robustness of the protection system against fuzziness is improved by minimizing f_2 in Eq. (45). Moreover, \mathbf{d}_{min} and \mathbf{d}_{max} in Eq. (43) are the lower and upper bound of the candidate design solutions, respectively.

4 COMPUTATIONAL ISSUES

The proposed strategy of the fuzzy-based robust design of TLCDs needs the analysis of two important computational issues. The first one deals with the resolution strategy for solving the multi-objective optimization in Eq. (43). The second aspect is related to the evaluation of the fuzzy performance index in Eq. (41).

4.1 Solving the multi-objective optimization problem

Since Eq. (44) and Eq. (45) involve crisp outputs only, all existing algorithms for solving multi-objective optimization problems can be used. Therefore, a standard genetic algorithm based multi-objective optimization algorithm [22] is used in this paper. Having so done, all solutions within the Pareto set are equally optimal: it is up to the designer to select a solution in this set depending on the application. The initial population is uniformly generated, the population size is 200, the maximum number of iterations is 500. The multi-objective genetic algorithm is stopped once the average change in the spread of Pareto solutions is less than 1.0×10^{-4} . The fitness scaling rank strategy has been chosen as fitness scaling function and the tournament selection (with tournament size equal to 4) as selection operator. The arithmetic crossover with a crossover fraction equal to 80% is selected as crossover operator. An adaptive feasible strategy is performed as mutation operator.

4.2 Calculation of the fuzzy performance index

An approximation of the output MF in Eq. (41) for a given design vector \mathbf{d} can be obtained by repeating a interval analysis at a number of cuts, see for instance [23]. So doing, the interval analysis at each α -cut becomes the central point for computing the MF of the fuzzy performance index in Eq. (41). In this paper, the Taylor series expansion based approach is chosen [12][13] because of its competitiveness from a computational standpoint.

Let be an α -cut of the i th fuzzy variable in the following form:

$$\bar{b}_i^\alpha = [b_i^{\alpha_-}, b_i^{\alpha_+}] = [b_i^c - \Delta b_i, b_i^c + \Delta b_i] \quad (46)$$

with

$$b_i^c = \frac{b_i^{\alpha_+} + b_i^{\alpha_-}}{2} \quad (47)$$

and $\mathbf{b}^c = \{b_i^c\}$ for $i=1, \dots, 4$. By making use of interval extension in interval mathematics and assuming a monotonic behavior as in [12] and [13], the α -cut of the fuzzy performance index is:

$$\bar{\psi}^\alpha = [\psi^{\alpha_-}, \psi^{\alpha_+}] \quad (48)$$

where

$$\psi^{\alpha_-} = \psi^c - \sum_{i=1}^4 |\psi_{b_i}^c| \Delta b_i \quad \psi^{\alpha_+} = \psi^c + \sum_{i=1}^4 |\psi_{b_i}^c| \Delta b_i \quad (49)$$

in which the superscript c denotes that the corresponding quantity is evaluated at $\mathbf{b}=\mathbf{b}^c$

$$\psi^c = \psi(\mathbf{b}^c) = \frac{\sigma_x(\mathbf{b}^c)}{\sigma_{x_0}(\mathbf{b}^c)} = \frac{\sigma_x^c}{\sigma_{x_0}^c} \quad (50)$$

$$\psi_{b_i}^c = \psi_{b_i}(\mathbf{b}^c) = \frac{\partial \psi}{\partial b_i} \bigg|_{\mathbf{b}=\mathbf{b}^c} \quad (51)$$

Taking into account the above definitions, the computational procedure is based on the following steps that must be repeated as many times as the number of α -cuts.

At the beginning, the following Lyapunov equations have to be solved:

$$\mathbf{A}^c \mathbf{R}^c + \mathbf{R}^c (\mathbf{A}^c)^T + \mathbf{B}^c = \mathbf{0}_{6 \times 6} \quad (52)$$

$$\mathbf{A}_0^c \mathbf{R}_0^c + \mathbf{R}_0^c (\mathbf{A}_0^c)^T + \mathbf{B}_0^c = \mathbf{0}_{4 \times 4} \quad (53)$$

from which

$$\sigma_x^c = \sqrt{\mathbf{R}_{zz}^c(2,2)} \quad \sigma_{x_0}^c = \sqrt{\mathbf{R}_{z_0 z_0}^c(1,1)} \quad (54)$$

The central point of the α -cut of fuzzy performance index ψ^c which appears in Eq. (49) is obtained by introducing the results of Eq. (54) in Eq. (50).

Now, Eq. (49) needs the calculation of the following quantity:

$$\psi_{b_i}^c = \frac{\sigma_{x, b_i}^c \sigma_{x_0}^c - \sigma_x^c \sigma_{x_0, b_i}^c}{(\sigma_{x_0}^c)^2} \quad (55)$$

where

$$\sigma_{x, b_i}^c = \frac{1}{2} \frac{\mathbf{R}_{zz, b_i}^c(2,2)}{\sqrt{\mathbf{R}_{zz}^c(2,2)}} \quad \sigma_{x_0, b_i}^c = \frac{1}{2} \frac{\mathbf{R}_{z_0 z_0, b_i}^c(1,1)}{\sqrt{\mathbf{R}_{z_0 z_0}^c(1,1)}} \quad (56)$$

The quantities in Eq. (56) are evaluated by solving the first-order Lyapunov equations:

$$\mathbf{A}^c \mathbf{R}_{b_i}^c + \mathbf{R}_{b_i}^c (\mathbf{A}^c)^T + (\mathbf{A}_{b_i}^c \mathbf{R}^c + \mathbf{R}^c (\mathbf{A}_{b_i}^c)^T + \mathbf{B}_{b_i}^c) = \mathbf{0}_{6 \times 6} \quad (57)$$

$$\mathbf{A}_0^c \mathbf{R}_{0, b_i}^c + \mathbf{R}_{0, b_i}^c (\mathbf{A}_0^c)^T + (\mathbf{A}_{0, b_i}^c \mathbf{R}_0^c + \mathbf{R}_0^c (\mathbf{A}_{0, b_i}^c)^T + \mathbf{B}_{0, b_i}^c) = \mathbf{0}_{4 \times 4} \quad (58)$$

The calculation of the derivatives for the matrices in Eq. (57) and Eq. (58) is straightforward and thus omitted for sake of conciseness. The procedure is summarized in Fig. 3.

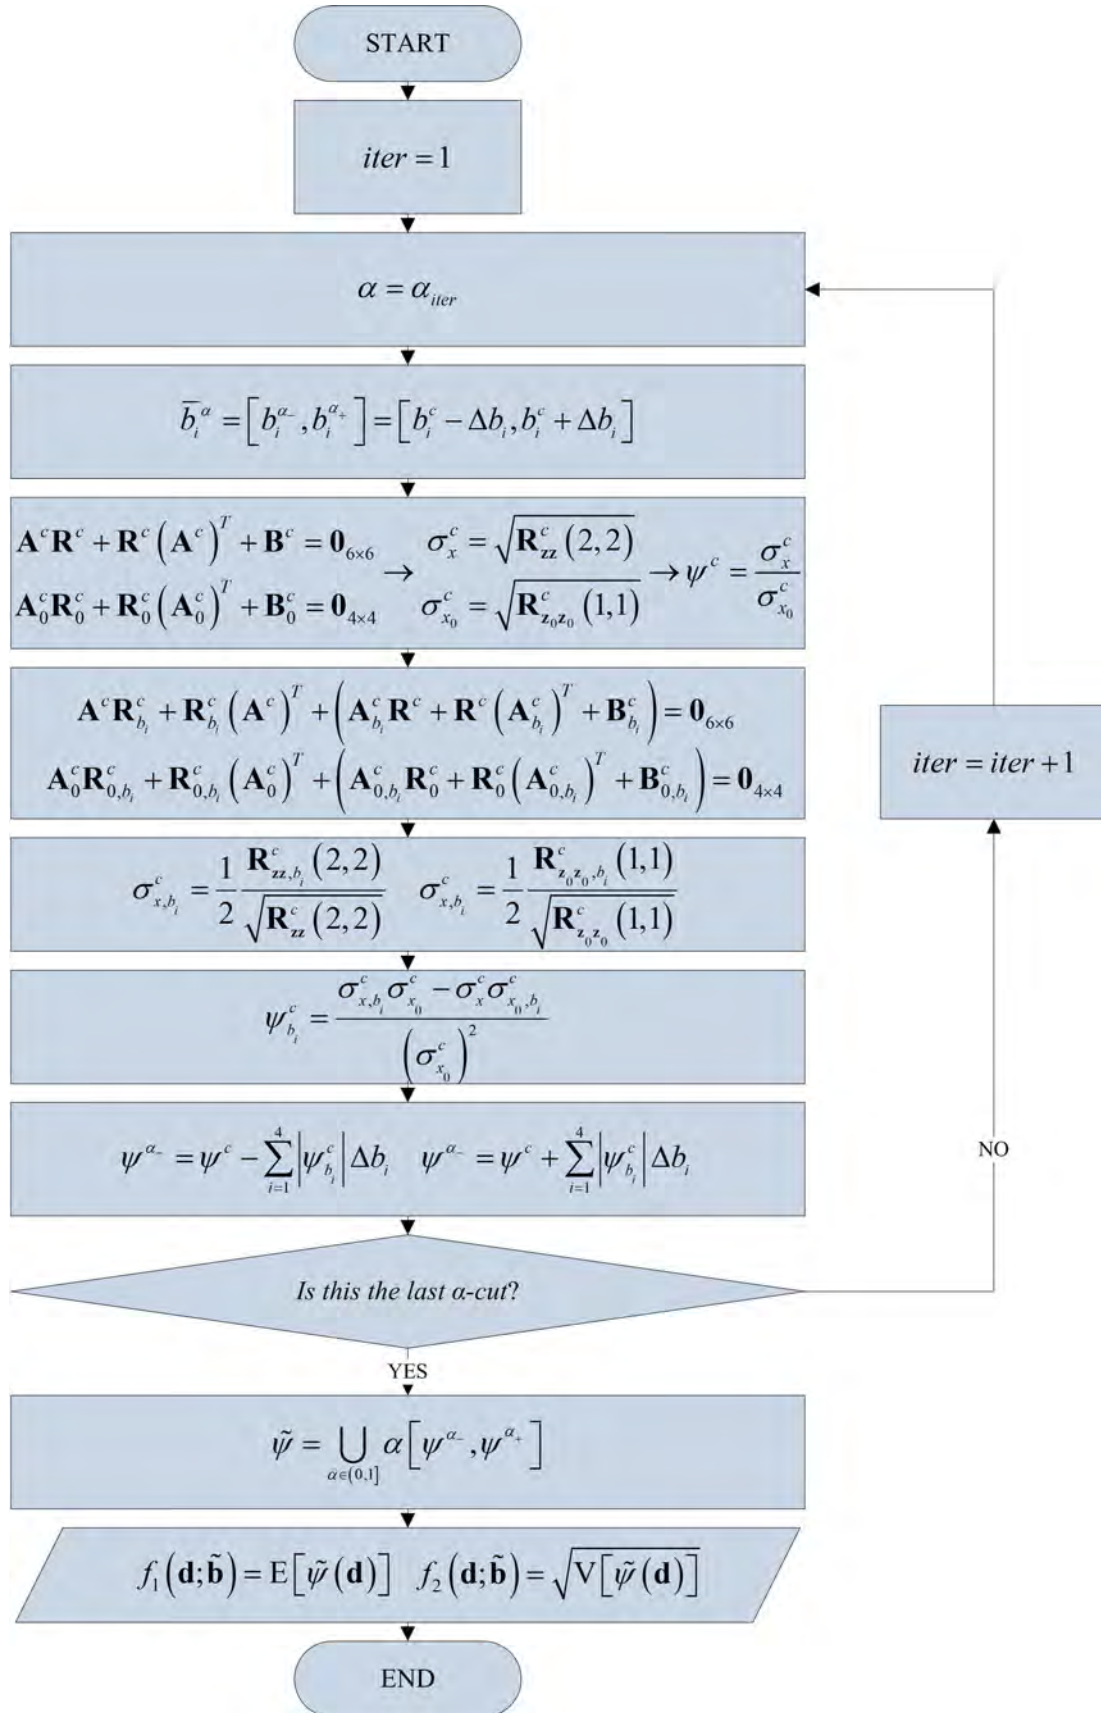

Figure 3: Flow-chart of the resolution strategy to compute fuzzy performance index and objective functions.

The monotonic response assumption over the range of uncertain parameter values ensures that no turning points exist on the performance index surface in the parameter space. As a consequence, the upper and lower bounds of the considered α -cut exist at some combination of the end points of the α -cuts of the uncertain parameters. Some preliminary numerical investigations verified that the performance index in Eq. (30) has a monotonic behavior over a range of numerical values of practical interest, as those in the following applications.

5 NUMERICAL APPLICATIONS

This section provides results of numerical study in order to demonstrate the applicability of the proposed design strategy of TLCDs.

5.1 Example

Since the design variable is a 2D vector, a graphical visualization of the objective functions can be obtained, thus showing the conflict between TLCD performance – as evaluated by means of f_1 in Eq. (44) and robustness against fuzzy uncertainties, as evaluated by means of f_2 in Eq. (45). A list of the adopted numerical values is given in Tab. 1. Fuzzy variables in Tab. 1 have a triangular MF ($e_1/e_2/e_3$) in which e_2 denotes the core value ($\mu(e_2)=1$) and the closed interval $[e_1, e_3]$ the support ($\mu(e_1) \rightarrow 0^+$ and $\mu(e_3) \rightarrow 0^+$).

Problem data	Numerical value
$\tilde{\omega}_s$	(1.0 π /1.5 π /2.0 π) rad/s
$\tilde{\xi}_s$	(0.02/0.03/0.04)
μ	0.01
p	0.70
$\tilde{\omega}_f$	(4.5 π /9 π /13.5 π) rad/s
$\tilde{\xi}_f$	(0.40/0.60/0.80)

Table 1: Numerical data.

The considered search space is $\mathbf{d}_{min}=\{0.85,0.01\}$ and $\mathbf{d}_{max}=\{1.15,1.20\}$. The surfaces representing all values of the objective functions over the design space are shown in Fig. 4 and Fig. 5 (the mesh grid size is 50 \times 50). Looking at the performances only (Fig. 4), acceptable results are obtained by selecting the tuning ratio close to 1 – i.e. γ within [0.96,1.00] – and by taking the coefficient of head loss values ξ within [0.40,0.90]. Therefore, it seems that designers can choose the final solution which best fit their (practical, economical, etc.) needs within a quite large number of alternatives. However, looking at the robustness of the final performances (Fig. 5), the designers should note some issues to be addressed in selecting the candidate solutions space. In fact, a very large variability of the final performances is observed in Fig. 5 for ξ within [0.40,0.90] and γ within [0.95,1.02]. In ξ approaches 0.50 and $\gamma \rightarrow 1.03$, then the final standard deviation up to one order of magnitude. Therefore, it is expected that the performance variability strongly influences the design strategy for ξ . Where the best values for the tuning ratio occur, if ξ is chosen to met the best performance – that is, within [0.40,0.90] – then a very small variation for γ may lead to a non-proportional and very

large worsening of the robustness because the gradient in that zone of the search space is very high. On the other hand, if ξ falls between 0.12 and 0.30, then unexpected variations for γ (i.e. manufacturing errors, bad estimation of the MF for ω_s) will not cause an excessive worsening of the TLCD's robustness.

Figure 4: Objective function f_1 over the design space.

Figure 5: Objective function f_2 over the design space.

The Pareto front and the set of non-dominated solutions in Fig. 6 and Fig. 7 confirm the above analysis. A linear trade-off exists between f_1 and f_2 (Fig. 6, on the left). The most of the non-dominated solutions are the couples $(\gamma, \xi) \in [0.960, 0.981] \otimes [0.025, 0.30]$.

Although better performances can be obtained by increasing the coefficient of head loss (γ close to 0.985 and ζ between 0.60 and 0.70), the final performance will be more susceptible to large variations due to unexpected errors affecting γ .

Figure 6: Pareto front and optimal solutions.

Figure 7: Distribution of the Pareto optimal solutions over the search space.

5.2 Sensitivity analyses

Two parameters – the mass ratio μ and the length ratio p – were considered as deterministic input data in Tab. 1. A sensitivity analysis may be carried out for them in order to understand their effects on the selection of the best TLCD parameters.

Different Pareto fronts and non-dominated solutions sets for varying mass ratio are depicted in Fig. 8. As expected, the optimal tuning ratio decreases as μ grows. Moreover, better performances are achieved when μ increases. For medium and high performances, the robust-

ness decreases as μ grows. The trade-off between performance and robustness is still linear. The three Pareto front in Fig. 8 have some common points, which indicates that it is possible to obtain the same performance as well as robustness under different mass ratios scenarios by properly tuning the TLCD parameters.

The effects of the length ratio p on the final set of the non-dominated solutions are less evident. As the length ratio increases, the optimal value for γ decreases. It seems that the Pareto fronts are stretched and rotate on the worst performance point ($f_1 \rightarrow 1$) as p increases.

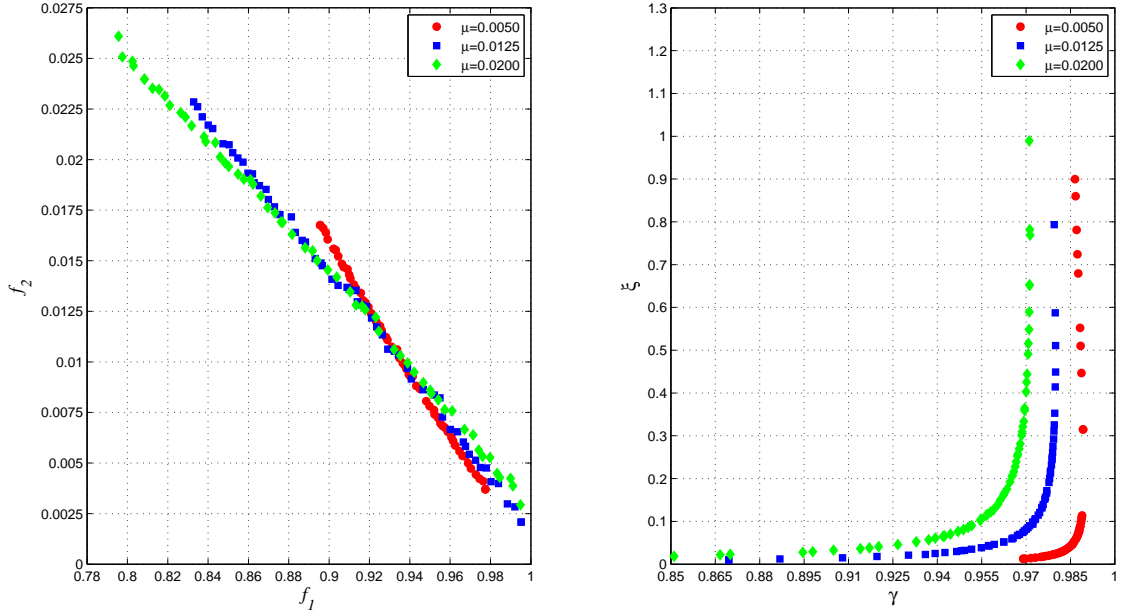

Figure 8: Pareto fronts and optimal solutions with varying mass ratio μ .

Figure 9: Pareto fronts and optimal solutions with varying length ratio p .

6 CONCLUSIONS

The paper presented an approach for incorporating fuzziness in the optimum design of TLCDs subject to stochastic ground motion. The main features of the proposed approach are: (i) the use of the Taylor series expansion for computing the final fuzzy performance index and (ii) the application of the credibility theory to define the objective functions of the final multi-objective optimization problem. The main advantage of the proposed procedure deals with its versatility in considering different sources of uncertainties in the robust design of TLCDs.

Numerical applications confirm the important role of non-probabilistic sources of uncertainty in random vibrations problems and the effectiveness of our approach in supporting the design of TLCDs. From a practical standpoint, numerical results show that the robustness against (fuzzy) uncertainties influences typical parameters for TLCDs with respect to the case when they are designed taking into account random dynamic loadings only. In fact, we found that smaller values for the coefficient of head loss may be preferred to avoid an excessive variability of the final performances as consequence of unexpected fluctuations of the tuning ratio.

Abstract. *In situ soil remediation requires a good knowledge about the processes that occur in the subsurface. Groundwater transport models are needed to predict the flow of contaminants. Such a model must contain information on the material layers. This information is obtained from in situ point measurements which are costly and thus limited in number. The overall model is thus characterised by uncertainty. This uncertainty has a spatial character, i.e. the value of an uncertain parameter can vary based on the location in the model itself. In other words the uncertain parameter is non-uniform throughout the model. On the other hand the uncertain parameter does have some spatial dependency, i.e. the particular value of the uncertainty in one location is not totally independent of its value in a location adjacent to it. To deal with such uncertainties the authors have developed the concept of interval fields. The main advantage of the interval field is its ability to represent a field uncertainty in two separate entities: one to represent the uncertainty and one to represent the spatial dependency. The main focus of the paper is on the application of interval fields to a geohydrological problem. The uncertainty taken into account is the material layers' hydraulic conductivity. The results presented are the uncertainties on the contaminant's concentration near a river. The second objective of the paper is to define an input uncertainty elasticity of the output. In other words, identify the locations in the model, whose uncertainties influence the uncertainty on the output the most. Such a quantity will indicate where to perform additional in situ point measurements to reduce the uncertainty on the output the most.*

1 INTRODUCTION

In recent years, the study of uncertainties in numerical modeling has gained a lot of attention. Probabilistic and non-probabilistic methods were developed for dealing with scalar parameter uncertainties. However, scalar parameter uncertainties are not the only kind of uncertainties influencing numerical models. Often scalar parameter uncertainties represent uncertainties that have uncertainty on a smaller scale spatial dimension too. The spatial influence of such uncertainties is often neglected, as it is assumed captured by assumptions of uniformity and homogeneity. This neglect is not without reasons, for a thorough discretisation of an uncertain property over the spatial domain would result in an explosion of independent uncertainties and thus a drastic increase in the computation time for the uncertainty analysis. However, a go-between approach is possible when certain patterns describing the spatial behaviour of an uncertainty are available. Taking into account the patterns reduces the explosion of uncertainties in going from one spatially uniform uncertainty to a thorough discretisation of the spatial domain. The authors have developed an interval field approach [1] to formalize these notions.

The paper first presents the general problem of interval finite element analysis and the interval field approach to it. Secondly, a section details the choice of certain spatial patterns in the interval field approach, based on random field analogies. Next, the concept of input uncertainty elasticity of the output is introduced in the context of spatial uncertainties. In the next section the geohydrological problem is introduced and the obtained results are presented. The paper concludes with some suggestions for further research.

2 INTERVAL AND INTERVAL FIELD ANALYSIS

This section first describes the general concept of Interval Finite Element (IFE) analysis and the method used to deal with it. Next the interval field concept is introduced to deal with dependent uncertain quantities.

2.1 Interval Finite Element analysis

Generally an IFE problem can be represented by [2]:

$$\mathbf{y}^s = \{\mathbf{y} \mid (\mathbf{x} \in \mathbf{x}^I)(\mathbf{y} = f(\mathbf{x}))\} \quad (1)$$

with \mathbf{x}^I the interval vector representing the bounds on the input uncertainties and $f(\mathbf{x})$ the function representing the input-output relationship. The solution is expressed as a set \mathbf{y}^s , rather than an interval vector \mathbf{y}^I to stress that certain value combinations of components within a hypercubic approximation of the uncertain vector result \mathbf{y} are not necessarily physically coherent. However in most cases the individual ranges of only some components of \mathbf{y} are really of interest. Several implementation strategies for interval numerical analysis have been proposed. Because global optimisation based strategies yield physically correct results, they are more and more acknowledged as the standard approach for non-intrusive IFE analysis. The core of this analysis (the $f(\mathbf{x})$) is a black-box FE calculation which can roughly be any analysis (for example a static or dynamic structural analysis, but also a heat-conductivity problem, hydrogeological problem or vibro-acoustic problem), limited only by the capabilities of the FE solver. The global optimisation based solution strategies actively search in the non-deterministic input interval space for the combination that results in the minimum or maximum value of an output quantity. In theory, the global optimisation approach results in the exact interval vector.

However, despite the smooth behaviour of typical objective functions, the computational cost of the global optimisation based approach remains high. Hence, most research on this method

focuses on fast approximate optimisation techniques. The approximating technique used in this paper starts by building a Kriging response surface based on a number of initial sample points. From this preliminary response surface the optimal additional samples are determined by focusing on the location of the possible extremes of the approximated output quantity in the uncertainty space [3]. The response surface is thus improved by additionally sampling the core FE-model till a pre-specified maximum number of samples are taken. Subsequently, global optimisation and anti-optimisation is performed on this response surface model to yield the bounds on the considered output quantity. For a thorough discussion of this adaptive response surface optimisation method, the interested reader is referred to [4].

For completeness the extension of an interval number to a fuzzy set is presented. A fuzzy set [5] is a set in which every member has a degree of membership, represented by the membership function $\mu_x(x)$, associated with it. If $\mu_x(x) = 1$, x is definitely a member of the fuzzy set. If $\mu_x(x) = 0$, x is definitely not a member of the fuzzy set. Analysis using fuzzy sets is very often done by using so-called α -cuts. An α -cut contains all the x for which $\mu_x(x) > \alpha$ is true. These α -cuts are essentially classical intervals, which means that the interval analysis is the basis of a fuzzy analysis.

2.2 Interval fields

The interval field framework as developed in [1] has an explicit and an implicit implementation. For the application presented here the explicit implementation is needed.

For a spatially dependent uncertainty, the interval vector \mathbf{x}^I containing an independent interval component for every spatial location is not a realistic description. Furthermore, it would result in an infeasibly high dimensional optimisation problem. To describe spatially dependent variation, numerical modelling approaches often use some type of shape functions (e.g. the modes used to represent the dynamic behaviour of a structure using the modal superposition technique). The actual solution is a linear combination of these shape functions.

Accordingly, the explicit interval field \mathbf{x}^F is defined as a superposition of n_b base vectors ψ_i using interval factors α_i^I :

$$\mathbf{x}^F = \sum_{i=1}^{n_b} \alpha_{x,i}^I \psi_{x,i} \quad (2)$$

The base vectors represent a limited set of reference patterns over the spatial domain, each of which is scaled by an interval factor. The components of the interval fields themselves (the local value of the uncertainty) are coupled through the reference patterns. Once the reference patterns are chosen, the definition of the interval field requires the specification of the interval factors that define the field on x , which can be assembled in a classical (hypercubic) interval vector α_x^I . In matrix notation, the interval field is denoted as:

$$\mathbf{x}^F = [\psi_x] \alpha_x^I \quad (3)$$

The application of an explicit interval field on the input side of an analysis is rather straightforward. Since expert knowledge about the modelled system dominates the definition of the uncertainties, the freedom in choosing the base vectors is ideal to reflect this knowledge (for example: the sinusoidal (= base vector) deviation of the thickness of a rolled plate with uncertain amplitude (= interval factor)). The main limitation of the explicit interval field is that its definition only allows a linear relation between the base vectors and the interval factors.

The application of an explicit interval field on the output side of an analysis is less straightforward. The base vectors and interval factors are determined by the analysis itself. Furthermore,

in order to obtain an explicit interval field that introduces no conservatism in its derived response variables (i.e. derivatives of the primary response variables), the output interval factors should be completely independent. An analysis of the application of the interval field approach to the output of static FE analysis is presented in [6].

Once the spatially dependent uncertainty on the input side of an analysis is defined by means of an explicit interval field, the dimensions of the uncertainty space are drastically reduced. This allows for the use of the adaptive response surface technique as described in the above subsection.

3 THE CHOICE OF BASE VECTORS

The use of the explicit interval field on the input side of an analysis requires the selection of appropriate base vectors and interval factors. This section first presents the factors influencing the selection of these base vectors and interval factors. The choice for base vectors and interval factors based on random field expansions is explained in the next subsection.

3.1 Factors influencing the choice of base vectors

- The bounds on the uncertainty on a model parameter x are specified by two functions of the spatial coordinate \mathbf{r} , one function for the upper bound $\bar{x}(\mathbf{r})$ and one for the lower bound $\underline{x}(\mathbf{r})$ of the uncertainty. The linear combination of the base vectors with the interval factors that makes up an interval field must remain within these bounds for any value of the interval factors.
- The base vectors must represent the expert's knowledge of the spatial dependency of the model parameter. Most often knowledge about this dependency is limited and the set of base vectors preferably allows for a range of small and large scale dependency.
- The number of base vectors and corresponding interval factors to represent the input uncertainty will influence the calculation time to get the output uncertainty.

3.2 Base vectors derived from random field expansion

In an attempt to construct a base vector set that takes into account the above described factors, the expansion of a random field is studied.

The objective of a random field is to represent a spatial variation of a specific model property by a stochastic variable defined over the region on which the variation occurs [7]. A random field can thus be denoted as $H(\mathbf{r}, \theta)$ with \mathbf{r} the spatial coordinate and θ the outcome of a random phenomenon. A random field is a random variable for a given \mathbf{r}_0 and is a realization of the field for a given θ_0 . The specification of a random field generally comes down to the specification of the spatial evolution of the first two statistical moments of the field variable and a corresponding covariance function, expressing the spatial dependency of the field variable. In most cases the random field is considered to be weakly stationary, resulting in a constant for the first few statistical moments throughout the spatial domain (i.e. zero mean and unit variance). Furthermore the covariance function for weakly stationary random fields depends only on the distance between observation points, not on their actual location.

The application of the concept of random fields in a numerical modelling framework requires some sort of discretisation of the spatially varying stochastic field over the defined geometry. A good overview of methods can be found in the report by Sudret and Der Kiureghian [8]. The

technique studied here is the Karhunen-Loève expansion [9] that has gained particular attention in literature. This approach is based on the spectral decomposition of the autocovariance function $C_{HH}(\mathbf{r}_1, \mathbf{r}_2)$. The set of deterministic functions over which any realization of the field $H(\mathbf{r}, \theta_0)$ is expanded is defined by the eigenvalue problem:

$$\int_{\omega} C_{HH}(\mathbf{r}_1, \mathbf{r}_2) \varphi_i(\mathbf{r}_2) d\omega_{\mathbf{r}_2} = \lambda_i \varphi_i(\mathbf{r}) \quad (4)$$

with ω the spatial domain and $i = 1, \dots$. Once the eigenfunctions are found the random field can be expressed as:

$$H(\mathbf{r}, \theta) = \sum_{i=1}^{\infty} \sqrt{\lambda_i} \xi_i(\theta) \varphi_i(\mathbf{r}) \quad (5)$$

with $\{\xi_i\}$ a set of orthonormal random variables. In stochastic analysis, this expansion is truncated after N terms to reduce the computational costs.

Several features of the random field expansion can be used in the interval field implementation after some adaptations. To begin, an off-set function $f_{mid}(\mathbf{r})$ to describe the mid value of the model parameter throughout the spatial domain is calculated

$$x_{mid}(\mathbf{r}) = \frac{\bar{x}(\mathbf{r}) + \underline{x}(\mathbf{r})}{2} \quad (6)$$

The eigenfunctions $\varphi_i(\mathbf{r})$ of the covariance function are then used as base vectors $\psi_i(\mathbf{r})$ for the interval field with

$$\psi_i(\mathbf{r}) = \lambda_i \varphi_i(\mathbf{r}) |\varphi_i(\mathbf{r})| \quad (7)$$

and replacing the orthonormal random variables $\{\xi_i\}$ by interval factors $\alpha_i^I \in [-1 \ 1]$. These adaptations make sure that for $N \rightarrow \infty$ the interval field will assign a value from the interval $[-1 \ 1]$ to the model parameter throughout the spatial domain. This unit interval is then scaled by the difference function

$$x_{dif}(\mathbf{r}) = \bar{x}(\mathbf{r}) - \underline{x}(\mathbf{r}) \quad (8)$$

describing the actual range of uncertainty on the model parameter for every location in the model. The description of the model parameter by the interval field is thus

$$\mathbf{x}^F = x_{mid}(\mathbf{r}) + \sum_{i=1}^N (\lambda_i \varphi_i(\mathbf{r}) |\varphi_i(\mathbf{r})| \alpha_i^I) (x_{dif}(\mathbf{r})) \quad (9)$$

With this equation the considerations from the first and last item in the list of influencing factors is accounted for. Next is the issue of uncertainty about the spatial dependency.

The base vectors taken from the expansion of a random field with a given autocovariance function only take into account the given correlation length L . In [10] a method is described to take into account interval correlation lengths with interval fields. Essentially the method relies on building an interval field description for the base vectors themselves in the correlation length space using a limited number of autocovariance expansions. In this way the base vectors are depending on the correlation length and can be calculated by a simple matrix vector product. The resulting interval field for the model parameter can thus be summarised by

$$\mathbf{x}^F = x_{mid}(\mathbf{r}) + \sum_{i=1}^N (\lambda_i(L) \varphi_i(\mathbf{r}, L) |\varphi_i(\mathbf{r}, L)| \alpha_i^I) (x_{dif}(\mathbf{r})) \quad L \in [L_{min} \ L_{max}] \quad (10)$$

This approach only introduces one additional interval to represent the uncertainty about the amount of spatial dependency. The solution strategy to find the uncertainty on the output remains the same, for example a response surface based optimisation and anti-optimisation, with only one additional dimension in the uncertainty space.

4 INPUT UNCERTAINTY ELASTICITY OF THE OUTPUT

To assess the relative importance of an input uncertainty on an output uncertainty, the concept of input uncertainty elasticity of the output is introduced in general terms and then applied to the case of spatial uncertainty.

4.1 General concept

As in economics, an elasticity R is defined as the ratio of the relative change (more precisely, the derivative with respect to some quantity) in one parameter Y to the relative change in an other parameter X

$$R_X^Y = \frac{\Delta Y}{\Delta X} \frac{X}{Y} \quad (11)$$

Let Y be the range of the uncertain output and X be the range of the uncertain input. The reduction (i.e. the Δ) on the range of the interval for the input X , will affect the range of the interval for the output Y to a greater or lesser extent. The relative magnitude of this influence is described by the input uncertainty elasticity of the output R_X^Y .

4.2 Spatial uncertainty context

In the context of spatial uncertainty, the influence of an input uncertainty on an output uncertainty has a spatial component. The influence of an uncertain input parameter will depend on the spatial distribution of its uncertainty. Figure 1 shows in a generic way the influence of the spatial uncertainty distribution. For an investigated spatial location the amount of uncertainty $x_{dif}(\mathbf{r})$ is reduced and some sort of coherent distribution of the uncertainty is assumed over the spatial domain (as illustrated at the top left in the figure). The uncertainty analysis is carried out for this spatial uncertainty distribution and a resulting uncertainty (an interval) for the output is found (bottom left). By repeating this for other investigated spatial locations, one finds the combined result which is shown at the right of the figure. It presents the different output uncertainties for several investigated spatial locations. This data is then used to calculate the input uncertainty elasticity of the output over the spatial domain. In this context the R_X^Y is in particular usefull to identify the spatial location where an input uncertainty influences the output uncertainty the most. In allocating resources to reduce the uncertainty, the spatial location with the highest R_X^Y should get priority.

An appropriate selection of the $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$ is needed to make a study over the spatial domain to give a scalar field of input uncertainty elasticities of the output. Important choices to be made in the selection of $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$ to investigate a particular spatial location's uncertainty influence are listed below. Figure 2 shows $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$ for three cases. The first case, at the left on the figure, is the reference case. The two other cases illustrate particular choices for $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$ explained in the list below.

Important choices to be made in the selection of $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$:

- the magnitude of the reduction of $x_{dif}(\mathbf{r})$ for the investigated spatial location. The second case in figure 2 shows a reduction of 50% for $x_{dif}(0.2)$, the third case shows a reduction of 90% for $x_{dif}(0.7)$.

Figure 1: Concept to determine R_X^Y in a spatial context

- the magnitude of the reduction of $x_{dif}(r)$ in the local influence zone of the investigated spatial location. By reducing the amount of uncertainty for the investigated spatial location, the amount of uncertainty for the region around the investigated spatial location is also affected. In this so called local influence zone, a transition from the reduced amount of uncertainty to the reference amount of uncertainty is needed. In this paper a quadratic transition is suggested.
- the magnitude of the local influence zone of the investigated spatial location. The second case in figure 2 shows a zone of influence from -0.1 to $+0.1$ around the investigated spatial location 0.2 . The third case shows a zone of influence from -0.3 to $+0.3$ around the investigated spatial location 0.7 .
- the change in $x_{mid}(r)$. If $\bar{x}(r)$ and $\underline{x}(r)$ are not changed symmetrically with respect to $x_{mid}(r)$ in the reference case, then $x_{mid}(r)$ is affected as well. For simplicity this influence is not presented here.

These notions are explained further in the case study.

5 GEOHYDROLOGICAL CASE STUDY

A geohydrological case study was chosen to apply the above presented techniques. The case study deals with a groundwater pollution problem where benzene was spilled and is now being transported in groundwater to a river. To characterize the flow and transport of the benzene spill, a groundwater flow and transport model was built in HYDRUS3D. First, the problem together with its uncertainty is described and the results of a fuzzy analysis without taking into account the spatial dependency are presented. Next, the spatial dependency is introduced and an investigation of the input uncertainty elasticity of the output is performed.

Figure 2: Choices in the selection of $\bar{x}(\mathbf{r})$ and $\underline{x}(\mathbf{r})$

Material Layer	Minimum K	Maximum K
1	1.4	2.1
2	8	12
3	3.6	5.4
4	2.6	3.9
5	4	6

Table 1: Intervals for the hydraulic conductivity K [m/day], ordered from top to bottom.

5.1 Problem description

The governing equation for solute transport in groundwater is a convection-diffusion equation based on conservation of mass. Convection is determined by groundwater flow which is based on the constitutive equation for variably saturated flow in porous media, called the Darcy Buckingham equation. For the solute (the contaminant: Benzene) and ground water flow problem at hand the following input was given:

- FE-model (14661 nodes) for the HYDRUS3D [11] solver (see figure 3). The dimensions of the problem are 1100 m in the length direction and between 32 and 36.5 m in the depth direction. In the time domain a period of 11000 days (approximately 30 years) is calculated. A deterministic run of this model takes 10 minutes.
- Intervals for the material properties, i.e. the saturated hydraulic conductivity K (see table 1) of the five different material layers.

A river is situated at the left side of the domain (see the red ellipse on figure 3) and the two sources of the contaminant are in the middle of the domain (see the red arrows on figure 3).

Figure 3: FE-model for solute and ground water flow showing the five different material layers.

The requested output is the concentration of the contaminant over time at the river given the uncertainties on the material properties.

5.2 Fuzzy analysis without spatial uncertainty

In the first fuzzy analysis, the uncertainty on the material properties is represented by fuzzy numbers. The hydraulic conductivity of each layer is considered independent and modelled as a triangular fuzzy number with the given intervals (see table 1) as base and the mid value as the top of the triangle. In each material layer the hydraulic conductivity is considered homogeneous through space. Figure 4 shows for example the spatial fuzzy number in blue and a possible sample of the fuzzy number in red for the hydraulic conductivity of material layer 1. Two types of fuzzy analyses were performed:

- Reduced Transformation Method (TM) [12] with 5 alpha-cuts, resulting in 161 samples.
- An optimisation on a Kriging response surface (ARSM) [4] that was built using 32 initial latinhypercube samples and 32 additional samples.

Additionally, a reference Monte Carlo Simulation using 200 samples was performed at each alpha-level, based on a uniform distribution within the interval at each alpha-level. Figure 5 shows the fuzzy concentration through time for location 11 (at the river, 3 m below the surface). In blue is the result of the reduced transformation method ($5 * 32 + 1$ samples); in green is the result of the optimisation on a Kriging response surface (32 initial + 32 additional samples); in red is the result of the Monte Carlo Simulation ($5 * 200$ samples). From these results it is clear that the TM and ARSM results are close to each other. The MCS result, despite being the computationally most expensive, does not yield good results for the maxima: the value given by the TM is an actual solution of the problem (i.e. a genuine sample) and results in higher maxima. The ARSM has problems identifying the proper minima since it tends to give negative (non-physical) results.

5.3 Fuzzy analysis with spatial uncertainty

In this fuzzy analysis, only the uncertainty on the hydraulic conductivity in material layer 1 is taken into account. The other hydraulic conductivities are set at their minimal value. To model the spatial uncertainty for the hydraulic conductivity of material layer 1, the following assumptions are made:

Figure 4: The spatial fuzzy number in blue and a sample of it in red for the hydraulic conductivity of material layer 1, assuming homogeneity.

Figure 5: The fuzzy concentration at the river, 3 m below the surface.

Figure 6: The spatial fuzzy number in blue and the four base vectors for membership level 0 in colours for the hydraulic conductivity of material layer 1, including spatial uncertainty.

- The upper bound $\bar{x}(\mathbf{r})$ and lower bound $\underline{x}(\mathbf{r})$ are given by a constant, namely the maximum and minimum of the interval given in table 1.
- The base vectors are derived from an exponential autocovariance function

$$C_{HH}(x_1, x_2) = e^{-\frac{|x_1 - x_2|}{L}} \quad (12)$$

as described in section 3.2. The first four eigenfunctions are used. Since a limited number of base vectors is used, the upper and lower bound on the uncertainty are not exactly satisfied throughout the domain. A scaling factor to adjust the maximal possible value of the interval field in the spatial domain to the requested bounds is applied. For a correlation length $L = 500$ m, the resulting base vectors are shown in 6.

To check the influence of taking into account the spatial uncertainty, two analyses (TM and ARSM) with the non-spatial uncertainty (i.e. uncertain, but homogeneous hydraulic conductivity of material layer 1) are performed as well. In total, the following types of analyses were performed:

- non-spatial uncertainty, Reduced Transformation Method (TM) with 5 alpha-cuts, resulting in 11 samples.
- non-spatial uncertainty, optimisation on a Kriging response surface (ARSM) that was built using 6 initial latinhypercube samples and 12 additional samples.
- spatial uncertainty, with correlation length between 500 and 2000 m, optimisation on a Kriging response surface (ARSM) that was built using 20 initial latinhypercube samples and 30 additional samples.

Figure 7: The fuzzy concentration at the river, 3 m below the surface.

Figure 7 shows the fuzzy concentration through time for location 11 (at the river, 3 m below the surface). The influence of taking into account the spatial uncertainty results in slightly narrower fuzzy numbers. This suggests that assuming homogeneity for the hydraulic conductivity of material layer 1 gives conservative bounds on the contaminant's concentration for the studied case.

5.4 Input uncertainty elasticity of the output

By performing an additional point measurement to determine the hydraulic conductivity in one location, the uncertainty on the contaminant's concentration will be reduced. To determine the optimal measurement location an input uncertainty elasticity of the output is calculated. The following assumptions, referring to section 4.2 and figure 8, are made:

- The magnitude of the reduction of the uncertainty for the considered measurement location is a design parameter. By selecting a more accurate measurement device, the uncertainty remaining after measurement is a choice of the expert. In figure 8 the influence of an increasing measurement accuracy on the bounds and the base vectors is shown.
- The magnitude of the reduction of the uncertainty in the local influence zone is an uncertainty. $f_{dif}(\mathbf{r})$ increases from the value at the measurement location to the reference value at the end of the local influence zone. In the presented analysis a quadratic function of the distance to the measurement location is chosen.
- The magnitude of the local zone of influence is an uncertainty. What is the extent of the influence of a measurement in one location on the rest of the spatial domain? Since a comparison between the input uncertainty elasticities of the output for different locations is of interest, the magnitude of this local zone of influence is chosen to be a fixed value. In

Figure 8: The influence of a measurement in the middle of the domain on the bounds of the uncertainty (in blue) and the base vectors (in colours), with a zone of influence of 330 m to both sides of the measurement location.

Design Parameter	Sampled values
Measurement location	110, 330 and 550 m from river
Measurement accuracy	50% reduction and 100% reduction of uncertainty
Uncertain Parameter	Range
Extent of influence	value chosen is 330 m.
Correlation length	[500 2000] m

Table 2: Parameters in the input uncertainty elasticity of the output analysis.

figure 8 the bounds and base vectors for an influence up to 330 m to both sides is shown, as it is used in the analysis.

- The actual outcome of the measurement gives a value for $f_{mid}(\mathbf{r})$ in the measurement location. Until the measurement is done, this is also an uncertainty that influences the actual bounds on the output uncertainty. In the presented analysis the value of $f_{mid}(\mathbf{r})$ is considered a constant and unchanged by a measurement.

To summarize: the measurement location and the accuracy of the measurement are design parameters, whereas the influence of the measurement and the spatial correlation length are uncertainties. For the influence of the measurement a fixed magnitude is assumed and the correlation length is modelled as an interval. The values used in the analysis are presented in table 2. For a choice of the design parameters, the uncertainty analysis was carried out using the ARSM method with 20 initial samples and 30 additional samples. The results are presented in figure 9. The bounds on the contaminant's concentration are presented for location 11 (at the river, 3 m below the surface) at the end time of the simulation (approx. 30 years) as a function of the measurement location and the accuracy of the measurement. Based on this information the input uncertainty elasticity of the output is calculated using equation (11) with X and Y respectively the range on the hydraulic conductivity and the range on the contaminant's concentration. The results are presented in table 3, the reference is the range on the uncertainty

Figure 9: The results of the uncertainty analysis to determine the input uncertainty elasticity of the output

Measurement location [m]	110	330	550
Measurement accuracy [-]			
0.5	0.33	0.10	0.20
1.0	0.21	0.15	0.13

Table 3: The input uncertainty elasticity of the output.

before measurement. From this table 3 it becomes clear that performing an input uncertainty reduction (i.e. a measurement of the hydraulic conductivity in material layer 1) at 110 m from the river provides the greatest reduction in uncertainty on the output (i.e. the concentration of the contaminant at the considered location and time). Furthermore, for this measurement location increasing the uncertainty reduction from 50% to 100% will not decrease the uncertainty on the output with the same amount. In other words, a measurement with an uncertainty reduction of 50% will have a $\frac{0.33}{0.21} \approx 1.5$ times higher relative uncertainty reduction on the output than a measurement with an uncertainty reduction of 100%. For a measurement at 330 m from the river the inverse is true: the extra effort of reducing the input uncertainty from 50% to 100% gives a 1.5 times higher relative uncertainty reduction on the output. Based on this information and knowledge of the actual costs of a measurement campaign an informed decision can be made concerning where and how accurate to measure.

6 CONCLUSION

From a methodological point of view, the paper introduces interval fields as an easy conceptual tool to deal with spatial uncertainty. The implementation of the interval field based on correlation length is made possible by deriving certain base vectors from the random field expansion technique. This allows for taking into account uncertainty on the correlation length. Furthermore, the concept of input uncertainty elasticity of the output is introduced in a spatial uncertainty context.

From an applied point of view, the paper shows the applicability of the interval field to a geohydrological problem of realistic complexity. The adaptive response surface technique proves to be very useful in practice. Certainty on the value of the correlation length often is a problem. The feasibility of dealing with the correlation length as an interval is shown. The concept of input uncertainty elasticity of the output in a spatial uncertainty context is proven to be useful to determine the optimal location of a measurement (i.e. an uncertainty reduction) to reduce uncertainty on the output.

Keywords: Structural Dynamics, Seismic Engineering, Interval Analysis, Response Spectrum.

Abstract. *Seismic analysis is an essential procedure to design a structure subjected to a system of suddenly applied loads due to earthquake excitations. However, throughout conventional seismic analyses, the structure is subjected to a limited number of recorded earthquake excitations. Moreover, the presence of variations and uncertainties in the recorded excitations from different earthquakes is not considered in current seismic analysis procedures. One of the methods to quantify the impreciseness and uncertainty is the interval or unknown-but-bounded representation.*

In this work, a new computationally feasible method for seismic structural analysis with interval uncertainty in the response spectrum is developed, which is capable of obtaining the bounds on the structure's dynamic response. Using this method, first, the response spectra from various recorded earthquakes are combined as an interval function and the interval earthquake response spectrum is constructed. Then, using the developed interval function, the response spectrum analysis is performed and the structure's dynamic response is obtained. This method shows that calculating the bounds on the dynamic response does not require a Monte-Carlo simulation procedure. An example problem that illustrates the developed algorithm with comparison to the different solutions is presented.

1 INTRODUCTION

In structural engineering, design of an engineered system requires that the performance of the system is guaranteed over its lifetime. In the case where the structure is subjected to loads induced by earthquake excitations, seismic analysis is a crucial procedure for reliable design. Using conventional seismic analysis procedures, the structure is subjected to a limited number of recorded earthquake excitations. However, the conventional procedures do not simultaneously consider the presence of variations and uncertainties in the recorded excitations in the analysis.

Treating uncertainty in the seismic analysis of a structure requires two major considerations: first, quantification of variations and uncertainties in the earthquake response spectra; and second, development of schemes that are capable of considering the presence of uncertainty throughout the solution process. Those developed schemes must be consistent with the structure's physical behavior and must also be computationally feasible.

The set-theoretic (unknown-but-bounded), or interval representation of vagueness is one possible method to quantify the uncertainty. The interval representation of uncertainty in the parametric space has been motivated by the lack of detailed probabilistic information on possible distributions of parameters and computational issues in obtaining solutions.

In this work, a new method for seismic structural analysis with interval uncertainty in the response spectrum is developed which is capable of bounding the structure's dynamic response. Using this method, first, the response spectra from various recorded earthquakes are combined as an interval function (with respect to frequency or period) and the interval earthquake response spectrum is constructed. Then, response spectrum analysis is performed using the constructed interval function to obtain the structure's upper-bounds of dynamic response.

This work represents the synthesis of two historically independent fields, seismic structural analysis and interval analysis. In order to represent the background for this work, a review of development of both fields is presented. First, a background and the analytical procedure for seismic structural analysis are presented. Next, a background and fundamentals of interval uncertainty analysis are presented. Following that, the new method for seismic analysis with response spectrum is introduced. Next, the upper-bounds on dynamic response of the structure are determined. Finally, exemplar and numerical results are presented that are followed by observations and conclusions.

2 DETERMINISTIC SEISMIC STRUCTURAL ANALYSIS

2.1 Historical background

Modern theories of structural dynamics were introduced mostly in mid 20th century. Biot (1932) [1] introduced the concept of earthquake response spectra and Housner (1941) [2] was instrumental in the widespread acceptance of this concept as a practical means of characterizing ground motions and their effects on structures. Newmark (1952) [3] introduced computational methods for structural dynamics and earthquake engineering. Anderson (1952) [4] developed methods for considering the effects of lateral forces on structures induced by earthquake and wind. Also, Hudson (1956) [5] developed techniques for response spectrum analysis in engineering seismology. Veletsos (1957) [6] determined natural frequencies of continuous flexural members. Rosenblueth (1959) [7] introduced methods for combining modal responses and characterizing earthquake analysis. Biggs (1964) [8] developed dynamic analyses for structures subjected to blast loads. Moreover, Penzien and Clough (1993) [9] further developed numerical methods for dynamics of structures and modal analysis.

2.2 Review of response spectrum analysis

The method of response spectrum analysis for computing the dynamic response of a multiple degree-of-freedom structure to a system of dynamic loads can be sequenced as following:

1. Define the structural properties.
 - Determine the stiffness matrix $[K]$ and mass matrix $[M]$.
 - Assume the modal damping ratio ζ_n .
2. Perform a generalized eigenvalue problem between the stiffness and mass matrices.
 - Determine natural circular frequencies (ω_n).
 - Determine mode shapes $\{\phi_n\}$.
3. Compute the maximum modal response.
 - Determine the maximum modal coordinate $D_{n,\max}$ using the excitation response spectrum for the corresponding natural circular frequency and modal damping ratio.
 - Determine the modal participation factor Γ_n .
 - Compute the maximum modal response as a product of maximum modal coordinate, modal participation factor and mode shape.
4. Combine the contributions of all maximum modal responses to determine the maximum total response using square root of sum of squares (SRSS) or other combination methods.

3 INTERVAL ANALYSIS

3.1 Historical background

The concept of representation of an imprecise real number by its bounds is quite old. In fact, Archimedes (287-212 B.C.) [10] defined the irrational number (π) by an interval, $(3+10/71 < \pi < 3+1/7)$ which he found by approximating the circle with the inscribed and circumscribed 96-side regular polygons. The introduction of digital computers in the 1950's provided impetus for further interval analysis as discrete representations of real numbers with associated truncation error. Interval mathematics was further developed by Sunaga (1958) [11] who introduced the theory of *interval algebra* and its applications in numerical analysis. Also, Moore (1966) [12] introduced *interval analysis*, interval vectors and interval matrices as a set of techniques that provides error analyses for computational results.

Interval analysis provides a powerful set of tools with direct applicability to important problems in scientific computing. Alefeld and Herzberger (1983) [13] presented an extensive treatment of interval linear and non-linear algebraic equations and interval methods for systems of equations. Moreover, Neumaier (1990) [14] investigated the methods for solution of interval systems of equations.

The concept of interval systems has been further developed in analysis of structures with interval uncertainty. Muhanna and Mullen (1999) [15] developed fuzzy finite-element methods for solid mechanics problems. For the solution of interval finite element method (IFEM) problems, Muhanna and Mullen (2001) [16] introduced an Element-by-Element interval finite element formulation, in which a guaranteed enclosure for the solution of interval linear systems of equations was achieved. The research in interval eigenvalue problem began to emerge as its wide applicability in science and engineering was realized. Modares and Mullen (2004) [17] introduced a method for the solution of the parametric interval eigenvalue problem resulting from semi-discretization of structural dynamics which determines the exact bounds of the natural frequencies of a structure with uncertainties in their mechanical characteristics.

3.2 Interval (convex) variable

A real interval is a closed set defined by extreme values as (Figure 1):

$$\tilde{Z} = [z^l, z^u] = \{z \in \mathfrak{R} \mid z^l \leq z \leq z^u\} \quad (1)$$

Figure 1: An interval quantity.

One interpretation of an interval number is a random variable whose probability density function is unknown but non-zero only in the range of interval. Another interpretation of an interval number includes intervals of confidence for α -cuts of fuzzy sets.

This interval representation transforms the point values in the deterministic system to inclusive set values in the system with bounded uncertainty. Interval arithmetic is a computational tool that can be used to represent uncertainty as 1) a set of probability density functions, 2) In Dempster-Shafer models for epistemic probability and, 3) α -cuts in fuzzy sets, etc. In this work, the symbol (\sim) represents an interval quantity.

3.3 Interval arithmetic operations

Considering $\tilde{X} = [a, b]$ and $\tilde{Y} = [c, d]$ as two interval numbers, the basic interval arithmetic operations are:

$$\text{Addition:} \quad \tilde{X} + \tilde{Y} = [a + c, b + d] \quad (2)$$

$$\text{Subtraction:} \quad \tilde{X} - \tilde{Y} = [a - d, b - c] \quad (3)$$

$$\text{Multiplication:} \quad \tilde{X} \times \tilde{Y} = [\min(ac, ad, bc, bd), \max(ac, ad, bc, bd)] \quad (4)$$

$$\text{Division:} \quad \frac{\tilde{X}}{\tilde{Y}} = [a, b] \times \left[\frac{1}{d}, \frac{1}{c}\right], (0 \notin [c, d]) \quad (5)$$

Interval Vector (2-D):

$$\tilde{V} = \begin{Bmatrix} \tilde{X} \\ \tilde{Y} \end{Bmatrix} = \begin{Bmatrix} [a, b] \\ [c, d] \end{Bmatrix} \quad (6)$$

which represents a “box” in 2-D space as the enclosure (Figure 2).

Figure 2: An interval vector

3.4 Functional dependency and sharpness considerations of interval operations

Considering $\tilde{X} = [-2, 2]$ and $\tilde{Y} = [-2, 2]$ as two independent interval numbers, the functional dependent interval multiplication results in:

$$\tilde{X} \times \tilde{X} = [0, 4]$$

In contrast, the functional independent interval multiplication results in:

$$\tilde{X} \times \tilde{Y} = [-4, 4]$$

In interval operations, the functional dependency of intervals must be considered in order to attain sharper results. In fact, the issue of sharpness and overestimation in interval bounds is the key limitation in the application of interval methods. Naïve implementation of interval arithmetic algorithms (substituting interval operations for their scalar equivalence) will yield bounds that are not useful for engineering design. Therefore, there is a need to develop algorithms to calculate sharp or nearly sharp bounds to the underlying set theoretic interval problems.

4 SEISMIC ANALYSIS USING INTERVAL RESPONSE SPECTRUM

The developed method for seismic analysis of structures using interval response spectrum enhances the conventional dynamic response spectrum analysis by: a) introducing an interval response spectrum constructed from a cluster of recorded excitation and, b) obtaining the bounds on the structure's dynamic response. The method is composed of following steps:

1. Define the physical or geometrical characteristics.
 - Determine the stiffness matrix $[K]$ and mass matrix $[M]$.
 - Assume the modal damping ratio ζ_n .
2. Perform an interval eigenvalue problem between the stiffness and mass matrices.
 - Determine the natural circular frequencies ω_n .
 - Determine the mode shapes $\{\varphi_n\}$.
3. Construct interval response spectrum.
 - Create a cluster of response spectra obtained from various recorded earthquakes.
 - Determine interval response spectrum as an interval function of excitation frequency.
4. Compute the interval modal response.
 - Determine the interval modal coordinate \tilde{D}_n using the interval response spectrum for the corresponding natural circular frequency and assumed modal damping ratio.
 - Determine the modal participation factor Γ_n .
 - Compute the interval modal response as the product of interval modal coordinate, modal participation factor and mode shape.
5. Combine and maximize the contributions of all interval modal responses to determine the maximum total response using SRSS or other combination methods.

4.1 Interval Response Spectrum

In order to construct interval response spectrum, first, a cluster of response spectra obtained from various recorded earthquake excitations is combined. Then, by enclosing all the response spectra, an interval response spectrum function is determined which is an interval function of frequency or period. Moreover, additional uncertainties in response spectra can also be considered. Figure 3 depicts an example for an interval response spectrum.

Figure 3: An interval response spectrum

4.2 Bounding Dynamic Response

The interval modal coordinate \tilde{D}_n is determined using the interval response spectrum evaluated for the corresponding natural circular frequency ω_n and assumed modal damping ratio (Figure 4).

Figure 4: Determination of \tilde{D}_n corresponding to a ω_n from an interval response spectrum.

If excitation is proportional, the modal participation factor is obtained as:

$$\Gamma_n = \frac{\{\varphi_n\}^T [M] \{r\}}{\{\varphi_n\}^T [M] \{\varphi_n\}} \quad (7)$$

$$\{r\} = \{1 \quad 1 \quad \dots \quad 1\}^T$$

The interval modal response is determined as the product of interval modal coordinate, modal participation factor and mode shape as:

$$\{\tilde{U}_n\} = (\tilde{D}_n)(\Gamma_n)\{\varphi_n\} \quad (8)$$

Finally, the contributions of all interval modal responses are combined and maximized to determine the maximum total response using SRSS or other combination methods as:

$$\{U_{\max}\} = \max \left(\sqrt{\sum_{n=1}^N \{\tilde{U}_n\}^2} \right) \quad (9)$$

in which the upper-bounds of response due to presence of variations and uncertainty in the response spectra is obtained.

5 NUMERICAL EXAMPLE

In this example, the bounds of the dynamic response of a 2-D truss structure subjected to multiple ground-motions are obtained using the developed method (Figure 5.)

Figure 5: The structure of 2-D truss

The Young's moduli for all elements is $E = 200 \text{ GPa}$. The load on first floor, second floor and roof are $10,000 \text{ kN}$, $10,000 \text{ kN}$ and $8,000 \text{ kN}$, respectively. The length of all horizontal and vertical members is 4m . The areas of the members are: $A_1 = A_6 = A_7 = A_8 = A_{12} = 65 \text{ cm}^2$, $A_2 = A_3 = 100 \text{ cm}^2$, $A_4 = 75 \text{ cm}^2$, $A_{10} = A_{11} = 35 \text{ cm}^2$.

5.1 Construction of interval response spectrum

For this example, ten recorded seismic response spectra are used which are obtained from five recent major earthquakes (two spectra per each earthquake measured in perpendicular directions). Table 1 summarizes the earthquakes' information. Figure 6 depicts the ten historical response spectra, and the bounding interval response spectrum.

Earthquake Location	Earthquake Date	Recording Location	Distance from Epicenter
Chile	Feb. 27, 2010	Concepcion, Chile	109 km
Samoa	Nov. 29, 2009	Afimalu, Samoa	179 km
Sumatra	Nov. 9, 2007	Sikuai Island, West Sumatra	392 km
Sumatra (aftershock)	Nov. 12, 2007	Sikuai Island, West Sumatra	165 km
Haiti	Jan. 12, 2010	Presa de Sabaneta, Dominican Republic	144 km

Table 1: Information for the earthquakes used in the example problem.

Figure 6: Constructed interval response spectrum for the example problem.

5.2 Solution

The problem is solved using the present method and the results are compared with solutions for 10^4 Monte Carlo Simulations using uniformly distributed random variables. The structure's degrees-of-freedom are statically condensed to only three lateral degrees-of-freedom (one per floor).

Using the obtained interval response spectrum, interval modal coordinates \tilde{D}_n for structure's natural periods are determined. The results are shown in Figure 7 and summarized in Table 2.

Figure 7: Determination of interval modal coordinates from interval response spectrum

Mode	Natural period T_n (sec)	Interval modal coordinate \tilde{D}_n (cm)
1	0.44	[0.10 , 5.97]
2	0.67	[0.27 , 14.52]
3	2.02	[0.95 , 30.14]

Table 2: Interval modal coordinates

Next, the upper-bounds of modal responses are determined. Then, the dynamic response for each floor is obtained by combining modal responses using SRSS method. The analysis procedure is performed using both present method and Monte-Carlo simulations and the results are compared. Table 3 summarizes the results.

Mode	Maximum Response U_{\max} (cm) (<i>present method</i>)	Maximum Response U_{\max} (cm) (<i>simulation</i>)
1	10.64	10.50
2	25.53	25.42
3	40.56	40.48

Table 3: The structure's upper-bounds of dynamic responses

Figure 8 depict the structure's response obtained from both present method and Monte-Carlo simulation solution geometrically.

Figure 8: Geometric depiction of the structure's upper-bounds of dynamic responses

5.3 Observations

The results show that using the present method, the obtained sharp solutions are upper-bounds to solutions obtained by methods that produce inner-bound results such as Monte-Carlo simulation. Moreover, the proposed method is computationally feasible because of its non-iterative process.

6 CONCLUSIONS

- In this work, a finite-element based method for seismic structural analysis with interval uncertainty in the response spectrum is developed.
- This method enhances the conventional response spectrum analysis for considering the presence of variation and uncertainty in the ground excitation.
- For a given set of recorded ground motions for various earthquakes, the response spectra are combined as an interval response spectrum used in the analysis procedure defined in the developed methodology.
- The method is capable of obtaining sharp results for the structure's dynamic response.
- This method is computationally feasible and it shows that the bounds on the dynamic response can be obtained without any iterative procedure such as Monte-Carlo simulation procedure.
- The computational efficiency of the proposed method makes it attractive to introduce uncertainty into seismic analysis of structures.

Abstract. *It is well known that damage observations on buildings after severe earthquakes exhibit interdependence with the seismic intensity parameters, like peak ground acceleration, response-spectra, Arias intensity and strong motion duration. Numerical elaboration of structural systems quantified the interrelation degree by correlation coefficients. In addition, the seismic response of buildings is directly depended on the ground excitation. Consequently, the seismic response of buildings evaluated by a numerical analysis is directly depended on the used accelerogram and its intensity parameters. Among the several response quantities, the focus is on the overall damage indices (DIs) because they summarize the post-earthquake status of buildings on a single value, which can be easily handled. The Maximum Inter-Storey Drift Ratio (MISDR) and the damage index as defined by Park/Ang ($DI_{G,PA}$) characterize effectively the structural damages caused to buildings during earthquakes. Intervals for the values of the damage indices are defined to classify the damage degree in low, medium, large and total. This paper presents an Adaptive Neuro-Fuzzy Inference System (ANFIS) for the classification of seismic damages. The structural damage is presented by means of the two previously mentioned damage indices (MISDR and $DI_{G,PA}$). The seismic excitations are simulated by a set of artificial accelerograms and their intensity is described by a set of well-known seismic parameters. The proposed system was trained (using nonlinear dynamic analyses) and tested on an eighth-story reinforced concrete structure. The numerical results have shown that the fuzzy technique that is implemented in the proposed method contributes to the development of an efficient blind prediction of the seismic damage potential that an accelerogram possesses. The recognition scheme achieves correct classification rates over 90%.*

1 INTRODUCTION

Seismic accelerograms are records of ground acceleration versus time during earthquakes that cannot be described analytically. However, several seismic parameters have been presented in the literature during the last decades that can be used to express the intensity of a seismic excitation and to simplify its description. Post-seismic field observations and numerical investigations have indicated the interdependency between the seismic parameters and the damage status of buildings after earthquakes [1, 2]. The latter can be expressed by proper damage indices. The Maximum Inter-Storey Drift Ratio (MISDR) and the global damage index as defined by Park/Ang ($DI_{G,PA}$) characterize effectively the structural damage caused to buildings during earthquakes and thus, are used as metrics to classify the damage degree into 4 categories, low, medium, large and total. In this context, the damage degrees denote undamaged or minor damage-repairable damage-irreparable damage-partial or total collapse of the building, respectively.

This paper suggests a technique based on an Adaptive Neuro-Fuzzy Inference System (ANFIS) for seismic structural damage classification. A total set of 200 artificial accelerograms has been used and were correctively assigned to one of the above four categories with performances up to 90% and 87% of accuracy, for MISDR and $DI_{G,PA}$, respectively. High classification rates indicate that the proposed methodology is suitable for adaptive predictive control of the behavior of the concrete construction used, for any unknown seismic signal. The proposed method is applied to an eight-story reinforced concrete frame building, designed after the rules of the recent Eurocodes.

2 DAMAGE INDICES

MISDR is an overall structural damage index (OSDI) that can define the level of post-seismic corruption in a building [3, 4] and can be evaluated by the following equation:

$$MISDR = \frac{|u|_{\max}}{h} 100 [\%] \quad (1)$$

Where $|u|_{\max}$ is the maximum absolute inter-storey drift and h the inter-storey height.

Additionally, the OSDI after Park/Ang ($DI_{L,PA}$) is used to describe the structural damage [5]. First, the local damage index according to Park/Ang is calculated. The local damage index is a linear combination of the damage caused by excessive deformation and that contributed by the repeated cyclic loading effect that happens during an earthquake. The local DI is given by the relation:

$$DI_{L,PA} = \frac{\theta_m - \theta_r}{\theta_u - \theta_r} + \frac{\beta}{M_y \theta_u} E_T \quad (2)$$

Where θ_m is the maximum rotation during the load history, θ_u is the ultimate rotation capacity of the section, θ_r is the recoverable rotation at unloading, β is a strength degrading parameter (0.1-0.15), M_y is the yield moment of the section and E_T is the dissipated hysteric energy. The global damage index after Park/Ang is a linear combination of the maximum ductility and the hysteretic energy dissipation demand forced by the earthquake on the structure. Thus, the global damage index after Park/Ang ($DI_{G,PA}$) is given by:

$$DI_{G,PA} = \frac{\sum_{i=0}^n DI_L E_i}{\sum_{i=0}^n E_i} \quad (3)$$

where E_i is the energy dissipated at location i and n is the number of locations at which the local damage is calculated.

The two aforementioned global DIs are well known and used extensively in earthquake engineering, as they are experimentally proved to express the behavior of a structure [5-10]. In Table 1, intervals for the values of the DIs are defined to classify the damage degree in low, medium, large and total [11]. These categories refer to minor, repairable damage, irreparable damage and severe damage or breakdown of the building, respectively.

Structural Damage Indices	Structural Damage Degree			
	Low	Medium	Large	Total
MISDR	≤ 0.5	$0.5 < MISDR \leq 1.5$	$1.5 < MISDR \leq 2.5$	> 2.5
$DI_{G,PA}$	≤ 0.3	$0.3 < DI_{G,PA} \leq 0.6$	$0.6 < DI_{G,PA} \leq 0.8$	> 0.8

Table 1: Structural damage classification according to MISDR and $DI_{G,PA}$.

3 SEISMIC INTENSITY PARAMETERS

An accelerogram is the recording of the acceleration of the ground during an earthquake. Accelerograms exist in variant forms, and thus their similarity cannot be extracted directly. Therefore, a computer supported analysis has been done and a set of 20 features has been produced to describe the destructiveness of seismic excitations.

Table 2: Seismic intensity parameters.

In this study the parameters that have been selected are the following: peak ground acceleration PGA, peak ground velocity PGV, the term PGA/PGV, spectral acceleration (SA), spectral velocity (SV), spectral displacement (SD), central period (CP), absolute seismic input energy (E_{inp}), Arias intensity (I_A), strong motion duration after Trifunac/Brady (SMD_{TB}), seismic power ($P_{0.90}$), root mean square acceleration (RMS_a), intensity after Fajfar/Vidic/Fischinger (I_{FVF}), spectral intensities after Housner (SI_H), after Kappos (SI_K) and after Martinez-Rueda (SI_{MR}), Maximum EPA (EPA_{max}), cumulative absolute velocity (CAV), effective peak acceleration (EPA) and destructiveness potential after Araya/Saragoni (DP_{AS}). Table 2 presents the examined intensity parameters and their literature references, respectively.

4 STRUCTURAL MODEL

Figure 1 presents the examined reinforced concrete structure. The eigenfrequency of the frame is 0.85 Hz. The design of the 8-storey building is based on the recent Eurocode rules EC2 and EC8 [28, 29]. The cross-sections of the beams are T-beams with 40 cm width, 20 cm slab thickness, 60 cm total beam height and 1.45 m effective slab width. The distance between the frames of the structure is 6 m. The structure has been characterized as an “importance class II-ductility class medium” structure according to the EC8 Eurocode. The subsoil is of type C and the region seismicity of category 2 after the EC8 Eurocode (design around acceleration value equal to 0.24 g). External loads are taken under consideration and are incorporated into load combinations due to the rules of EC2 and EC8.

Figure 1: Reinforced concrete frame structure.

With the help of the IDARC software, the characteristics of the building are inserted into the program and a dynamic analysis is taking place, so as to estimate the structural behaviour of the building [7, 30].

5 ANFIS ALGORITHM

ANFIS was introduced in 1993. ANFIS is able to extract a set of fuzzy “if-then” rules and define the membership functions in order to establish the association between inputs and outputs. Its structure is shown in Figure 2. Basically, ANFIS suggests a method that, through the training procedure, can estimate the membership function parameters that serve the fuzzy inference system (FIS) to consequently specify the desired output for a certain given input [31].

Figure 2: ANFIS structure.

ANFIS creates a fuzzy inference system in order to relate a certain input to the appropriate output. FIS interprets inputs into a set of fuzzy membership values and similarly the output membership functions to outputs. During the learning process, all parameters which define the membership functions will change. In order to optimize the model, these parameters are evaluated. Usually a gradient vector is used and an optimization routine could be applied in order to tune the parameters, so as to lead the model to a better generalization performance.

In this work, 20 seismic parameters are used as input data to describe the damage caused by one seismic event, and a total of 200 seismic events are used to train the system. All 20 seismic features have been normalized to belong in the interval $[0, 1]$. The 200 seismic events are distributed equally to all four damage categories in order to create a uniform data set.

First, inputs are related to membership functions (MFs), (Figure 3 shows the initial MF for one of the seismic parameters), to rules to outputs MFs, by using Fuzzy C-Means (FCM) technique [32, 33], which is analyzed later in this section. Next, the input/output data, which is a uniform set of 100 accelerograms, is used for training the model. The membership function parameters are tuned through the training process.

After the training, a model validation procedure is performed. During this procedure, an unknown input data set is presented to the trained fuzzy model for simulation. Thus, it can be evaluated the efficiency of the model. When a checking data set is presented to ANFIS, the fuzzy model selects the appropriate parameters associated with the minimum checking data model error. One crucial point with model validation, is selecting a suitable data set. This set must be representative of the data that the model is trying to simulate, and at the same time distinguishable from the training data. If a large amount of samples is collected, then all possible cases are contained and thus, the training set is more representative. In our case, a total number of 200 seismic excitations are considered as the data set.

FCM is a widely used data clustering technique. Each data point is assigned to a cluster with a membership grade that is specified by a membership grade. It provides a method that shows how to group data points that populate some multidimensional space into a specific number of different clusters.

Figure 3: Initial membership function on input 1.

The purpose of data clustering is to discover similarities between input patterns from a large data set, in order to design an effective classification system.

At first, the FCM algorithm selects randomly the cluster centers. This initial choice for these centers is not always the appropriate. Furthermore, the variation of the cluster centers leads to different membership grades for each one of the clusters. Through the iteration process of the FCM algorithm, the cluster centers are gradually moved towards to their proper location. This is achieved by minimizing the weighted distance between any data point and the cluster centre. Finally, FCM function defines the cluster centers and the membership grades for every data point.

6 RESULTS

Simulation results are summarized in Table 3. The structural damage is presented by means of the two previously mentioned damage indices, MISDR and $DI_{G,PA}$, and the algorithm was tested for both damage indices. Experimental results indicate that using MISDR as metric for structural damage leads to higher performance, up to 90%, compared with the results when using $DI_{G,PA}$ which rates up to 87%.

Structural Damage Index	MISDR	$DI_{G,PA}$
Correct Classification Percentage (%)	90%	87%

Table 3: Comparative table for classification according to structural damage with MISDR and $DI_{G,PA}$.

In Figures 4 and 5, blue circles represent the seismic signals that have been misclassified with ANFIS algorithm using MISDR and $DI_{G,PA}$ respectively.

Figure 4: Classification of 200 seismic signals into 4 damage classes with MISDR as metric. Correct classification percentage: 90%.

Figure 5: Classification of 200 seismic signals into 4 damage classes with $DI_{G,PA}$ as metric. Correct classification percentage: 87%.

7 CONCLUSIONS

This paper presents an efficient algorithm based on ANFIS techniques for seismic signal classification. A number of 20 seismic parameters and a set of 200 artificial accelerograms with known damage effects were used. For each seismic excitation the induced structural damage of the examined building is estimated and quantified according to two widely used damage indices, MISDR and $DI_{G,PA}$. The structural damage is expressed in the form of 4 damage categories. The 4 damage categories (classes) are defined through threshold values of the used damage indices. An ANFIS model is trained and tested. The classification results reveal the effectiveness of the proposed system to estimate the earthquake's impact (damage category) on the examined structure. Classification rates up to 90% in the case of MISDR and 87% in the case of $DI_{G,PA}$ are achieved. The high percentage of correct classification in both cases, prove the efficiency of the method and show that the fuzzy technique that is implemented, contributes to the development of a competent blind prediction of the seismic damage potential that an accelerogram possesses.

Keywords: Probability, Effect Algebras, D-posets, Law of Large Numbers

Abstract. *Effect algebras ([1], [2]) and D-posets ([3]) are equivalent systems important in quantum structures. In the paper an independent sequence of observables on these structures is defined by such a way that a very general version of the law of large numbers may be proved.*

1 INTRODUCTION

In multi valued logic the MV algebras play the same role as Boolean algebras in two valued logic. Therefore probability theory on MV algebras seems to be very important (see ([6])). Of course, there are interesting generalizations of MV algebras: D-posets ([3]) and equivalent effect algebras ([1], [2]). Again probability theory can be constructed on D-posets and particularly on D-posets with product ([4]).

In the paper the law of large numbers is proved for very general D-posets.

In Section 2 some basic notions are defined. The key for the law of large numbers is the new formulation of independence. It is motivated and presented in Section 3. Also the sum of independent observables is defined there. The general law of large numbers is formulated and proved in Section 4. Similarly as in [6] a local representation of a sequence of independent observables by a sequence of random variables seems to be the main idea of the proof.

2 EFFECT ALGEBRAS AND D-POSETS

The concept of an effect algebra was introduced by Foulis and Bennet [1]. We will work with an equivalent algebraic structure, called D-poset introduced by Kôpka and Chovanec ([3]).

Definition 2.1. *Effect algebra is a system $(E, +, 0, 1)$, where $0, 1$ are distinguished elements of E and $+$ is a partial binary operation on E such that*

1. $x + y = y + x$ if one side is defined,
2. $(x + y) + z = x + (y + z)$ if one side is defined,
3. for every $x \in E$ there exists a unique x' with $x' + x = 1$,
4. if $x + 1$ is defined then $x = 0$.

Every effect algebra bears a natural partial ordering given by $x \leq y$ if and only if $y = x + z$ for some $z \in E$. The poset (E, \leq) is bounded, 0 is the smallest element and 1 is the largest element. In every effect algebra, a partial subtraction $-$ can be defined as follows:

$x - y$ exists and is equal to z if and only if $x = y + z$.

The system $(E, \leq, -, 0, 1)$ so obtained is a D-poset defined by Kôpka and Chovanec [3].

Definition 2.2. *The structure $(D, \leq, -, 0, 1)$ is called D-poset if the relation \leq is a partial ordering on D , 0 is the smallest and 1 is the largest element on D and*

1. $b - a$ is defined if and only if $a \leq b$,
2. if $a \leq b$ then $b - a \leq b$ and $b - (b - a) = a$,
3. $a \leq b \leq c \implies c - b \leq c - a, (c - a) - (c - b) = b - a$.

To build a probability theory we need two important mappings equivalent to probability measure and random variable. In our concept we call them state and observable.

Definition 2.3. *A state on a D-poset D is any mapping $m : D \rightarrow [0, 1]$ satisfying the following properties:*

1. $m(1) = 1, m(0) = 0$,

2. $a_n \nearrow a \implies m(a_n) \nearrow m(a), \forall a_n, a \in D,$
3. $a_n \searrow a \implies m(a_n) \searrow m(a), \forall a_n, a \in D.$

Definition 2.4. Let $J = \{(-\infty, t); t \in R\}$. An observable on D is any mapping $x : J \rightarrow D$ satisfying the following conditions:

1. $A_n \nearrow R \implies x(A_n) \nearrow 1,$
2. $A_n \searrow \emptyset \implies x(A_n) \searrow 0,$
3. $A_n \nearrow A \implies x(A_n) \nearrow x(A).$

Theorem 2.5. Let $x : J \rightarrow D$ be an observable, $m : D \rightarrow [0, 1]$ be a state. Define a mapping $F : R \rightarrow [0, 1]$ by the formula

$$F(t) = m(x((-\infty, t))).$$

Then F is a distribution function.

Proof. If $t_n \nearrow t$, then $(-\infty, t_n) \nearrow (-\infty, t)$, hence $x((-\infty, t_n)) \nearrow x((-\infty, t))$ by 3 of Def. 4, and

$$F(t_n) = m(x((-\infty, t_n))) \nearrow m(x((-\infty, t))) = F(t)$$

by 2 of Def. 2.3, hence F is left continuous in any point $t \in R$. Similarly

$$t_n \nearrow \infty \implies F(t_n) \nearrow 1$$

by 1 of Def. 2.4 and 1 and 2 of Def. 2.3. Moreover

$$t_n \searrow -\infty \implies F(t_n) \searrow 0$$

by 2 of Def. 2.4 and 1 and 3 of Def. 2.3. □

Denote by $\mathcal{B}(R)$ the family of all Borel subsets of the real line R . Since F is a distribution function, there exists exactly one probability measure $\lambda_F : \mathcal{B}(R) \rightarrow [0, 1]$ such that

$$\lambda_F([a, b)) = F(b) - F(a)$$

for any $a, b \in R, a < b$.

Recall that in the Kolmogorov theory the mean value $E(\xi)$ of a random variable $\xi : (\Omega, \mathcal{S}, P) \rightarrow R$ is defined as an integral

$$E(\xi) = \int_{\Omega} \xi dP$$

Let $g : R \rightarrow R$ be a Borel measurable function. The transformation formula states

$$E(g \circ \xi) = \int_{\Omega} g \circ \xi dP = \int_R g dP_{\xi} = \int_R g(t) dF(t),$$

where F is the distribution function of ξ . It motivates the following definition.

Definition 2.6. An observable $x : J \rightarrow D$ is integrable, if there exists

$$E(x) = \int_R t dF(t),$$

where F is the distribution function of x .

3 INDEPENDENCE

As a motivation consider a probability space (Ω, \mathcal{S}, P) , where Ω is a non-empty set, \mathcal{S} is a σ -algebra of subsets of Ω and $P : \Omega \rightarrow [0, 1]$ is a probability measure. Two random variables $\xi, \eta : \Omega \rightarrow R$ are independent, if

$$P(\xi^{-1}(A) \cap \eta^{-1}(B)) = P(\xi^{-1}(A)) \cdot P(\eta^{-1}(B))$$

for any Borel sets $A, B \in \mathcal{B}(R)$. Let F_1 or F_2 be distribution functions of ξ or η resp., i.e.

$$F_1(t) = P(\{\omega; \xi(\omega) < t\}),$$

$$F_2(t) = P(\{\omega; \eta(\omega) < t\}).$$

Define Borel probability measures $\lambda_{F_1}, \lambda_{F_2} : \mathcal{B}(R) \rightarrow [0, 1]$ by such a way that

$$\lambda_{F_1}([a, b)) = F_1(b) - F_1(a)$$

$$\lambda_{F_2}([a, b)) = F_2(b) - F_2(a)$$

for any $a, b \in R, a \leq b$. It is very well known that there exists exactly one probability measure

$$\lambda_{F_1} \times \lambda_{F_2} : \mathcal{B}(R^2) \rightarrow [0, 1]$$

such that

$$\lambda_{F_1} \times \lambda_{F_2}(A \times B) = \lambda_{F_1}(A) \cdot \lambda_{F_2}(B)$$

for any $A, B \in \mathcal{B}(R)$. We need to characterize the probability distribution of the sum $\xi + \eta$, i.e.

$$P(\{\omega; \xi(\omega) + \eta(\omega) < t\}), t \in R.$$

Theorem 3.1. *Let $\xi, \eta : \Omega \rightarrow R$ be independent random variables, $\Delta_t = \{(u, v) \in R^2; u + v < t\}, t \in R, T = (\xi, \eta) : \Omega \rightarrow R^2$. Then*

$$P(T^{-1}(\Delta_t)) = \lambda_{F_1} \times \lambda_{F_2}(\Delta_t)$$

for any $t \in R$.

Proof. We have

$$\begin{aligned} P(T^{-1}(\Delta_t)) &= \\ &= P\left(\bigcup_{n=1}^{\infty} \bigcup_{i=-\infty}^{\infty} \xi^{-1}\left(\left[\frac{i-1}{2^n}, \frac{i}{2^n}\right)\right) \cap \eta^{-1}\left((-\infty, t - \frac{i}{2^n})\right)\right) = \\ &= \lim_{n \rightarrow \infty} \sum_{i=-\infty}^{\infty} P\left(\xi^{-1}\left(\left[\frac{i-1}{2^n}, \frac{i}{2^n}\right)\right) \cap \eta^{-1}\left((-\infty, t - \frac{i}{2^n})\right)\right) = \\ &= \lim_{n \rightarrow \infty} \sum_{i=-\infty}^{\infty} P\left(\xi^{-1}\left(\left[\frac{i-1}{2^n}, \frac{i}{2^n}\right)\right)\right) P\left(\eta^{-1}\left((-\infty, t - \frac{i}{2^n})\right)\right) = \\ &= \lim_{n \rightarrow \infty} \sum_{i=-\infty}^{\infty} \lambda_{F_1}\left(\left[\frac{i-1}{2^n}, \frac{i}{2^n}\right)\right) \lambda_{F_2}\left((-\infty, t - \frac{i}{2^n})\right) = \end{aligned}$$

$$\begin{aligned}
&= \lim_{n \rightarrow \infty} \sum_{i=-\infty}^{\infty} \lambda_{F_1} \times \lambda_{F_2} \left(\left[\frac{i-1}{2^n}, \frac{i}{2^n} \right) \times \left(-\infty, t - \frac{i}{2^n} \right) \right) = \\
&= \lim_{n \rightarrow \infty} \lambda_{F_1} \times \lambda_{F_2} \left(\bigcup_{i=-\infty}^{\infty} \left[\frac{i-1}{2^n}, \frac{i}{2^n} \right) \times \left(-\infty, t - \frac{i}{2^n} \right) \right) = \\
&= \lambda_{F_1} \times \lambda_{F_2} \left(\bigcup_{n=1}^{\infty} \bigcup_{i=-\infty}^{\infty} \left[\frac{i-1}{2^n}, \frac{i}{2^n} \right) \times \left(-\infty, t - \frac{i}{2^n} \right) \right) = \\
&= \lambda_{F_1} \times \lambda_{F_2}(\Delta_t).
\end{aligned}$$

If $T = (\xi, \eta) : \Omega \rightarrow R^2$ is a random vector, then $T^{-1} : \mathcal{B}(R^2) \rightarrow \mathcal{S}$ is a mapping such that

$$P(T^{-1}(\Delta_t)) = \lambda_{F_1} \times \lambda_{F_2}(\Delta_t), t \in R.$$

The idea may be realized also in our general case.

Definition 3.2. Let $x_1, \dots, x_n : \mathcal{J} \rightarrow D$ be observables, $\Delta_t^n = \{(u_1, \dots, u_n) \in R^n; u_1 + \dots + u_n < t\}$, $\mathcal{M}_n = \{\Delta_t^n; t \in R\}$. The observables are called to be independent, if there exists a mapping $h_n : \mathcal{M}_n \rightarrow D$ with the following properties:

1. $t_i \nearrow t \implies h_n(\Delta_{t_i}^n) \nearrow h_n(\Delta_t^n)$.
2. $h_n(\bigcup_{t=1}^{\infty} \Delta_t^n) = 1$.
3. $h_n(\bigcap_{t=-1}^{-\infty} \Delta_t^n) = 0$.
4. $m(h_n(\Delta_t^n)) = \lambda_{F_1} \times \dots \times \lambda_{F_n}(\Delta_t^n), t \in R$.

Theorem 3.3. Define $y_n : \mathcal{J} \rightarrow D$ by the equality $y_n((-\infty, t)) = h_n(\Delta_t^n)$. Then y_n is an observable.

Proof. It follows by properties 1 - 3 of the previous Definition.

Definition 3.4. Let $x_1, \dots, x_n : \mathcal{J} \rightarrow D$ be independent observables. Then the observable $y_n : \mathcal{J} \rightarrow D$ defined in previous Theorem is called the sum of observables x_1, \dots, x_n , $y_n = \sum_{i=1}^n x_i$, i.e.

$$\left(\sum_{i=1}^n x_i \right)((-\infty, t)) = h_n(\Delta_t^n), t \in R.$$

Remark. There has been proved in [5] that in so-called Kôpka D-posets there exists the mapping $h_n : \mathcal{M}_n \rightarrow D$ satisfying the properties stated in previous Definition.

4 THE LAW OF LARGE NUMBERS

Recall first the classical weak law of large numbers.

Theorem 4.1. Let (Ω, S, P) be a probability space. Let $(\zeta_n)_{n=1}^{\infty}$ be a sequence of independent random variables having the same distribution function. Let $a = E(\zeta_1) = E(\zeta_2) = \dots$. Then the sequence of random variables

$$\frac{\zeta_1 + \dots + \zeta_n}{n} - a \quad (n = 1, 2, \dots)$$

converges in measure P to 0.

Of course, we haven't told yet, what does convergence in measure mean. In classical probability space (Ω, S, P) a sequence of random variables $(\zeta_n)_{n=1}^\infty$ converges to 0 in measure P , if for each real $\varepsilon > 0$

$$\lim_{n \rightarrow \infty} P(\zeta_n^{-1}([- \varepsilon, \varepsilon])) = 1.$$

In our case, the definition is similar, but at first we need to define an expression $x((a, b))$, where x is an observable and $a, b \in R$.

Definition 4.2. Let $x : \mathcal{J} \rightarrow D$ be an observable on a D -poset D and $\alpha, \beta \in R$. Then

$$x([a, b)) = x((-\infty, b)) - x((-\infty, a)).$$

Definition 4.3. Let $(x_n)_{n=1}^\infty$ be a sequence of independent observables on a D -poset D with a state m . We say that this sequence converges in measure m to 0 if for each $0 < \varepsilon \in R$

$$\lim_{n \rightarrow \infty} m(x_n([- \varepsilon, \varepsilon])) = 1.$$

We are able now to formulate and prove the main result of the paper. We shall use the following notation. If $y : \mathcal{J} \rightarrow D$ is an observable and α, β are real numbers, $\alpha \neq 0$, then $\alpha y + \beta : \mathcal{J} \rightarrow D$ is defined by the formula

$$(\alpha y + \beta)((-\infty, t)) = y((-\infty, \frac{1}{\alpha}(t - \beta))).$$

Theorem 4.4. Let D be a D -poset with a state $m : D \rightarrow [0, 1]$, let $(x_n)_{n=1}^\infty$ be an independent sequence of integrable observables having the same probability distribution, $E(x_n) = a$, ($n = 1, 2, \dots$). Then the sequence

$$\frac{\sum_{i=1}^n x_i}{n} - a$$

converges in measure m to 0.

Proof. Denote $P_n = \lambda_{F_1} \times \dots \times \lambda_{F_n} : \mathcal{B}(R^n) \rightarrow [0, 1]$. Then $(P_n)_n$ presents a consistent system of probability measures:

$$P_n(A \times R) = P_{n-1}(A), A \in \mathcal{B}(R), n \in N$$

We will use the projection $\pi_n : R^N \rightarrow R^n$:

$$\pi_n((u_i)_{i=1}^\infty) = (u_1, u_2, \dots, u_n).$$

Let's take a family of all cylinders \mathcal{C} , i. e. sequences with a finite number of members being fixed:

$$\mathcal{C} = \{A \subset R^N; A = \pi_n^{-1}(B), B \in \mathcal{B}(R_n), n \in N\}$$

By the Kolmogorov consistence theorem there exists a probability measure $P : \sigma(\mathcal{C}) \rightarrow [0, 1]$ such that

$$P(\pi_n^{-1}(B)) = P_n(B) = \lambda_{F_1} \times \dots \times \lambda_{F_n}(B) \quad (1)$$

for any $B \in \mathcal{B}(R^n), n \in N$. Define $\xi_n : R^N \rightarrow R$ by the formula

$$\xi_n((u_i)_{i=1}^\infty) = u_n.$$

We have obtained a Kolmogorov probability space $(R^N, \sigma(\mathcal{C}), P)$, where the mapping ξ_n presents a random variable. The next formula will serve as a tool for "translating" the law of large numbers to D-posets:

$$\begin{aligned} P(\xi_1 + \dots + \xi_n < t) &= P(\pi_n^{-1}(\Delta_n^t)) = P_n(\Delta_n^t) \underbrace{=}_{(1)} \lambda_{F_1} \times \dots \times \lambda_{F_n}(\Delta_n^t) \underbrace{=}_{3.2} m(h_n(\Delta_n^t)) \underbrace{=}_{3.4} \\ &= m\left(\left(\sum_{i=1}^n x_i\right)((-\infty, t))\right) \end{aligned}$$

For simpler notation, let's introduce new two mappings: a random variable $\eta_n : R^N \rightarrow R$ and an observable $y_n : \mathcal{M}_n \rightarrow D$.

$$\eta_n = \frac{1}{n} \left(\sum_{i=1}^n \xi_i \right) - a.$$

$$y_n = \frac{1}{n} \left(\sum_{i=1}^n x_i \right) - a = \left(\sum_{i=1}^n x_i \right) ((-\infty, n(t+a))),$$

Then

$$m(y_n((-\infty, t))) = m\left(\left(\sum_{i=1}^n x_i\right)((-\infty, n(a+t)))\right) = P(\xi_1 + \dots + \xi_n < n(a+t)) = P(\eta_n^{-1}((-\infty, t)))$$

The last thing we need before we can use the Theorem 4.1 is to prove, that ξ_i are independent and $E(\xi_i) = E(x_i) = a \forall i$.

$$\begin{aligned} P((\xi_1, \dots, \xi_n) \in ((-\infty, t_1) \times \dots \times (-\infty, t_n))) &= P(\pi_n^{-1}((-\infty, t_1) \times \dots \times (-\infty, t_n))) = \\ &= \lambda_{F_1} \times \dots \times \lambda_{F_n}((-\infty, t_1) \times \dots \times (-\infty, t_n)) = \lambda_{F_1}((-\infty, t_1)) \dots \lambda_{F_n}((-\infty, t_n)) = \\ &= P(\xi_1 < t_1) \dots P(\xi_n < t_n) \end{aligned}$$

$$E(x_n) = \int_{-\infty}^{\infty} t d\lambda_{F_n}(t)$$

$$\begin{aligned} E(\xi_n) &= \int_{R^N} \xi_n(u) dP(u) = \int_{R^n} u_n dP_n((u_1, \dots, u_n)) = \\ &= \int_{R^n} u_n d\lambda_{F_1} \times \dots \times \lambda_{F_n}((u_1, \dots, u_n)) = \int_R u_n d\lambda_{F_n}(u_n) = E(x_n) \end{aligned}$$

Now all the assumptions of Theorem 4.1 are satisfied, so for all real $\varepsilon > 0$ there holds:

$$\begin{aligned} 1 &= \lim_{n \rightarrow \infty} P(\eta_n^{-1}([-\varepsilon, \varepsilon])) = \lim_{n \rightarrow \infty} P(\eta_n^{-1}((-\infty, \varepsilon))) - \lim_{n \rightarrow \infty} P(\eta_n^{-1}((-\infty, -\varepsilon))) = \\ &= \lim_{n \rightarrow \infty} m(y_n((-\infty, \varepsilon))) - \lim_{n \rightarrow \infty} m(y_n((-\infty, -\varepsilon))) = \lim_{n \rightarrow \infty} m(y_n([-\varepsilon, \varepsilon])) = \\ &= \lim_{n \rightarrow \infty} m\left(\left(\frac{1}{n} \left(\sum_{i=1}^n x_i\right) - a\right)([-\varepsilon, \varepsilon])\right) \end{aligned}$$

Hence,

$$\frac{1}{n} \left(\sum_{i=1}^n x_i \right) - a \longrightarrow 0$$

in measure m and

$$\frac{1}{n} \left(\sum_{i=1}^n x_i \right) \longrightarrow a$$

in measure m . □

Keywords: Inverse Problem, Identification, Impact, Regularization, Truncation Method, Plates

Abstract. *This work deals with reconstruction of distributed force signal resulting from a non punctual object impacting perpendicularly an elastic homogeneous and isotropic rectangular plate. The impacting force is assumed to be uniformly distributed over a rectangular patch of the plate. The direct problem was solved by using modal decomposition method with explicit analytical modes. A discrete problem was written for that by sampling the obtained convolution integral. To extract the pressure signal by deconvolution of the dynamic response measured at a given point of the plate, solution of an inverse problem had been considered. Since this type of problem is known to be ill-posed due to bad conditioning of the involved Toeplitz like matrix, regularization is needed to obtain a physically meaningful solution. A new regularization technique based on truncation filtering was examined. This technique uses as a first step the generalized decomposition of Toeplitz matrix on singular values. Then, regularization of the decomposed form through a truncation filter is performed. The truncation consists in eliminating the first low index terms up to an optimal rank representing the contribution of low amplitude generalized singular values. If the impact force signal has a half sine like standard form, the index corresponding to time instant where the maximum displacement response is obtained was found to be the optimal order of truncation. This technique has proved to be effective in reconstruction of impact pressures through various cases of study and the computational cost was found to be much lower than that of the classical truncation method based on L-curve criterion.*

1 INTRODUCTION

To perform structural health monitoring or reliability analysis of structures, it is essential to provide accurate characterization of input forces experienced during service operation. In common practice, the input force is measured by using a force transducer that is positioned in the load path. On many circumstances, such as a high-speed impact of an object onto a structure, it is difficult to apply this technique such as a bird impacting an aeroplane fuselage. Another technique that has been widely employed for the impact-force signal reconstruction is based on analysis of the inverse problem. This means that the dynamic force is recovered from the data of the measured elastic response. When the impact point is known, the problem is equivalent to operating deconvolution of two signals: the measured response and the transfer function characterizing the dynamics of the structure. In many cases, the deconvolution results in an ill-posed problem in which the data noise strongly affects the solution accuracy. Therefore, it is difficult to obtain an accurate solution for such problems, so that, regularization is needed to obtain a physically meaningful solution.

There are a number of publications which deal with the impact-force reconstruction. In [1, 2, 3] the impact force profile had been reconstructed by using spectral analysis. The proposed method had utilized the convolution theorem that expresses the time domain deconvolution as a simple division in the frequency domain. Later on, various authors [4, 5, 6, and 7] adopted a more systematic approach to regularize the deconvolution problem by using either the singular value decomposition method (SVD) or the generalized singular value decomposition method (GSVD). These authors had considered the problem of a localized impact where the object could be approximated as a single point. In many cases, however, the impacting object is massive and the impact zone could not be approximated as a single point and the impacting force takes the form of a distributed pressure over the impact zone. In more recent works [8, 9, 10, 11] the problem of reconstruction of distributed dynamic loads on structures like Euler beam, thin plates or cylindrical shells had been tackled. The authors had used either the modified modal method or the mode-selection method. Though these methods are robust in comparison with Tikhonov based methods some problems such as the improvement of the selection criterion and the relative high errors on boundaries are still open [11].

Certain researchers have indicated that a major drawback of the Tikhonov-GSVD method is the expensive computational cost associated to GSVD and consequently the method is only suitable for small scale problems.

In the present work, we consider the impact pressure reconstruction problem in the case where a uniform distributed force is applied onto a homogeneous and isotropic elastic rectangular plate. The impacting zone is assumed to be a rectangular patch. For this purpose, the direct solution has been computed at first by using an analytical formula. Then, the regularization method based on GSVD method with truncation filtering was used. The truncation regularization method [12] is a particular case of the general filter factor regularization method and looks a lot like Tikhonov regularization [13], but it is simpler to implement. Here, a new technique of constructing the filter is examined. It is based on an a priori defined truncation order which reduces considerably the computational cost. This new method was tested on several case studies and the obtained results have shown that it is well suited in regularizing pressure reconstruction problems wherever the impact pressure profile is not too different from a half sine shape.

2 MATERIALS AND METHODS

We consider a rectangular plate as shown in figure 1 which has the dimensions a , b and e representing respectively the length, width and thickness. It is assumed to be simply sup-

ported on its ends. The plate is assumed to be made of a homogeneous and isotropic elastic material with Young's modulus E , Poisson's ratio ν and density ρ . The applied force modeling impact is assumed to be uniformly distributed over a rectangular patch of the plate. The dynamic response in terms of displacement, velocity, acceleration or strains is considered at a point which is located at a given distance away from the centre of the loading rectangle, figure 1.

Figure 1: Simply supported rectangular plate showing the loading conditions and the point of response measurement

The equation of motion of a simply supported rectangular plate [14], can be expressed under the following form

$$D\Delta\Delta w(x, y, t) + c\dot{w}(x, y, t) + \rho h\ddot{w}(x, y, t) = q(x, y, t) \quad (1)$$

where x is the horizontal coordinate, y the vertical coordinate, t the time, $w(x, y, t)$ the transverse displacement, $q(x, y, t) = p(t)\mathfrak{I}_{[x_0-u/2, x_0+u/2] \times [y_0-v/2, y_0+v/2]}(x, y)$ the applied loading with \mathfrak{I} the indicative function taking the value one on the domain shown in subscript and zero elsewhere, c the damping coefficient, $D = Ee^3 / (12(1-\nu^2))$ the plate flexural rigidity

$$\text{modulus and } \Delta\Delta w(x, y, t) = \frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^2 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4}.$$

The above governing equation is assumed to be subjected to the following boundary conditions

$$w = 0 \quad \text{and} \quad \frac{\partial^2 w}{\partial x^2} = 0 \quad \text{for } x = 0 \quad \text{and} \quad x = a \quad (2)$$

$$w = 0 \quad \text{and} \quad \frac{\partial^2 w}{\partial y^2} = 0 \quad \text{for } y = 0 \quad \text{and} \quad y = b$$

By applying the modal superposition technique, the displacement $w(x, y, t)$ can be shown to be expressed under the following form

$$w(x, y, t) = \int_0^t h(x_0, y_0, u, v, x, y, t - \tau) p(\tau) d\tau \quad (3)$$

where h is the transfer function given by

$$h(x_0, y_0, u, v, x, y, \tau) = \frac{16}{\rho h \pi^2} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{1}{m n \gamma_{mn}} \sin\left(\frac{m \pi x_0}{a}\right) \sin\left(\frac{n \pi y_0}{b}\right) \sin\left(\frac{m \pi u}{a}\right) \sin\left(\frac{n \pi v}{b}\right) \sin\left(\frac{m \pi x}{a}\right) \sin\left(\frac{n \pi y}{b}\right) \sin(\gamma_{mn} \tau) e^{-\xi_{mn} \omega_{mn} \tau} \quad (4)$$

in which ω_{mn} , γ_{mn} and ξ_{mn} are respectively the circular eigenfrequency, the damped circular eigenfrequency ($\gamma_{mn} = \omega_{mn} \sqrt{1 - \xi_{mn}^2}$) and the damping ratio for a given eigenmode (m, n) .

In many practical circumstances it is possible to represent realistically the impact-force such as a half-sine function, figure 2. Shape of real impact force signal is not too different from this standard profile.

The elastic response $w(x, y, t)$ can be computed over the considered time interval $[0, T_c]$ by integrating explicitly equation (3) where x_0, y_0, u, v, x, y take fixed values. In this work, the selected configuration of the impacted plate is defined by the following parameters values: $a = 2.05$ m , $b = 2.05$ m , $e = 5 \times 10^{-3}$ m , $\xi_{mn} = 0$, $x_0 = y_0 = 0.1025$ m , $u = v = 0.0342$ m , $x = y = 0.041$ m and $T_c = 0.012$ s.

Figure 3 gives the displacement calculated at the point $(x = 0.041\text{m}, y = 0.041\text{m})$. The direct elastic response in terms of displacement which is given in figure 3 is stored and will be used in the following to reconstruct the impact-force signal.

To identify the impact-force acting on the plate over the rectangular domain of impact, the transfer function based approach is used. In more general problems, transfer functions can be determined analytically [15], experimentally [16], or numerically. Here, the transfer function is evaluated analytically through time integration of equations (3) and (4).

To solve the deconvolution problem associated to equation (3), a discrete problem must be written by sampling the convolution integral. This leads in the time domain to the following system of algebraic equations

$$W = HP \quad (5)$$

with

$$H = \begin{pmatrix} H(\Delta t) & 0 & \cdots & 0 \\ H(2\Delta t) & H(\Delta t) & \ddots & \\ H(3\Delta t) & H(2\Delta t) & \ddots & \ddots \\ \vdots & \vdots & \ddots & \ddots & 0 \\ H(N\Delta t) & H((N-1)\Delta t) & \cdots & \cdots & H(\Delta t) \end{pmatrix} \quad \begin{aligned} W &= [w(\Delta t) \quad w(2\Delta t) \quad \cdots \quad w(N\Delta t)]^t \\ P &= [p(\Delta t) \quad p(2\Delta t) \quad \cdots \quad p(N\Delta t)]^t \end{aligned} \quad (6)$$

where H is the Toeplitz like transfer matrix, Δt is the sampling rate and N the total number of samples.

The sampling rate must be selected in order to recover a predefined cut-off frequency in the pressure signal. The matrix H is always ill-conditioned. This means that it can lead to an unstable solution which has no physical meaning. Therefore, to find a physically acceptable solution the deconvolution problem defined by equations (5) and (6) should be regularized.

Here, the regularization technique based on the generalized singular value decomposition (GSVD) is considered. It should be mentioned that the simpler SVD method has failed to regularize the actual problem. The GSVD-regularized solution of problem defined by equations (5) and (6) can be written as follows

$$[P] = [X][\Phi][\Delta]^{-1}[U]^t[W] = [H^*][W] \quad (7)$$

where (X, Δ, U) being the singular factors of H , $[\Phi]$ is the filter factor and $[H^*] = [X][\Phi][\Delta]^{-1}[U]^t$ is the regularized pseudo-inverse of H .

The filter factors goal is to minimize the influence of the low amplitude generalized singular values. Many techniques have been considered in the literature for that purpose. Among them, one finds the regularization techniques: Tikhonov method [13] and GSVD truncation method [5]. In the following the truncation based regularisation technique is used.

The truncation consists of eliminating the first low index terms up to the rank k . This index is called the regularization parameter. The index k should be selected in order to eliminate the small generalized singular values as well as the oscillating singular vectors.

The filter Φ defined by the truncation method writes:

$$\Phi_{ij} = f_i \delta_{ij} \quad i, j = 1, \dots, N \quad (8)$$

To build the filter Φ within the framework of truncation method, the rank k should be specified. The optimal rank should minimize the error between the identified pressure and the real pressure. Classically, the L-Curve method has been applied in order to determine the regularization parameter k by means of a graphical based method. This technique was developed in reference [5]. It is based on searching the optimum of a functional composed of two terms, a residue called $RN = \|W - HP\|_2$ (Residual Norm) and the norm of the solution, designated by $SN = \|P\|_2$ (Semi-Norm). When the k parametric curve defining SN versus RN is plotted, the optimal regularization parameter corresponds to the point of maximum curvature, the corner.

However, in practice, this method is often problematic; for measured data the L-curve is discrete and the determination of such point is delicate, because it is not distinguishable on the graph.

Figure 4. The L-curve associated to truncation filter design showing the corner point defining the optimal truncation order

Here a new heuristic method is proposed to determine the optimal rank truncation. Through various numerical tests conducted on pressure signals having half sine form, the rank defined as the index of the maximum value of the calculated displacement was found to yield a closer form of the real pressure input signal.

3 RESULTS AND DISCUSSION

Figure 5 presents the superposition of the real impact pressure with the pressure profile as obtained by the inverse problem solution for the impact centre zone given by $(x_0 = 0.0683 \text{ m}, y_0 = 0.0683 \text{ m})$ and the point of measurement located at $(x = 0.041 \text{ m}, y = 0.041 \text{ m})$. The pulse period considered is $T = 6 \text{ ms}$. The truncation order which is defined as the index of the maximum value of the calculated displacement is found to be 160. The associated CPU time is 68.94.

Figure 5: Comparison of the reconstructed pressure profile with the real input pressure for the input signal shown in figure 2 with period $T = 0.006 \text{ s}$

Figure 6 presents the superposition of the real impact pressure with the pressure profile as obtained by the inverse problem solution for the case where ($x_0 = 0.0683\text{ m}$, $y_0 = 0.0683\text{ m}$), ($x = 0.041\text{ m}$, $y = 0.041\text{ m}$) and a pulse period $T = 4\text{ ms}$. The associated truncation order is 179.

Figure 6: Comparison of the reconstructed pressure profile with the real input pressure having the form of figure 2 but with a period $T = 0.004\text{ s}$

It is clear that the new proposed method and the L-curve based method permit the exact reconstruction of the signal. However in the new heuristic method for which the order of truncation is defined a priori as the index of the maximum value of the calculated displacement, a lower computational cost is reached. The gain is about 47%. This methodology was proven to yield results that are independent from the impact location, the measurement point and the pulse period. But, it is necessary that the profile of the impacting force should have a half sine like form. This is not a real limitation since most of the impacting force signals have this general form in practice.

4 CONCLUSION

A new heuristic method for reconstruction of distributed force in case of non punctual object impacting an elastic rectangular plate was proposed. This method is based on generalized singular value decomposition of Toeplitz like matrix obtained for the discrete convolution problem relating the displacement dynamical response at a given point and the impact pressure signal. This last was assumed to be uniform over a rectangular patch of the plate and to have a half sine profile. To build the filter needed for regularization of the inverse problem, the truncation based method was used. The order of truncation corresponding to the index of time associated to the maximum measured displacement was found to yield good results. This was proven to be the case independently from the impact location, the measurement point and the pulse period. Even when the signal is not a half sine one, good results are also obtained. The computational cost of this method is lower than that of the classical truncation method, which makes it as a relevant alternative to better build the truncation filter needed for regularizing the deconvolution in inverse problems.

Abstract. *The functionality maintenance of European infrastructures like bridges is acquiring more and more importance due to the huge economic losses related to the interruption of their regular service. In particular, fatigue represents one of the most diffused failure modes occurred in steel and composite steel-concrete bridges: in fact about 80/90% of failures in steel structures are related to fracture and fatigue. Railway bridges endure million of stress cycles during their life and they are expected to be highly vulnerable to such phenomena. Moreover, phenomena like “vibration induced” and “distortion induced” fatigue are still partially uncovered by actual design codes and represent a critical aspects for the assessment of existing bridge remaining life and for the design of new bridges.*

The European research project FADLESS “Fatigue damage control and assessment for railways bridges”, funded by the European Research Found for Coal and Steel (RFCS), aims to define innovative technical guidelines for the assessment and control of existing and new bridges with regard to fatigue phenomena induced by vibrations and distortions produced by train passage. To this purpose, the Project combines experimental and numerical techniques in order to evaluate properly the fatigue damages on critical details induced by vibration and distortion phenomena, taking into account the dynamic train-bridge interaction effects and the actual traffic spectra on European railway lines.

In this paper, preliminary studies performed on the Italian case study, the Panaro Bridge, are reported. In particular, results of the standard fatigue assessment according to Eurocode rules were compared with the actual fatigue damages occurred to deck secondary components to obtain a preliminary critical review of adopted fatigue assessment methodologies. Moreover, experimental tests were designed and performed on the bridge in order to identify global and local vibration modes and to evaluate the strain time-histories under train passages of critical details. Finally, experimental global/local mode shapes were compared to numerical results of the preliminary FE bridge model.

1 INTRODUCTION

Fatigue is a very important failure mode for steel structures. In fact about 80/90% of failures in steel structures are related to fracture and fatigue. In particular, railway bridges endure million of stress cycles during their life and they are expected to be highly vulnerable to such phenomena. Obviously, if a bridge survive to the construction phase without any fractures occurring, fatigue will almost always precede fracture so that, in most practical cases, controlling fatigue is more important than controlling fracture. However, it is also important to design for fracture resistance because fatigue cracks eventually can grow to a critical size at which the member undergoes fracture. Several studies were performed in the past in order to assess the fatigue resistance of steel and steel-concrete composite bridges; such studies were the base of modern codes and standards [1; 2; 3; 4]. Despite of these efforts, the fatigue assessment of railway bridges both considering the design of new bridges and the assessment of existing ones is one of the main issues in current practice.

Such eventuality is due to concurrent events as for example the rapid development of the European railway networks according to the directives of the European Commission [5] the increase of passenger and freight railway traffic, the introduction of new high strength materials, the influence of particular effects like distortion and local vibration not actually covered by fatigue assessment procedures proposed by current codes and standards.

On the other hand, by 2020, new Trans-European Transport Network (TEN-T Project) will include 94 000 km of railways, including around 20 000 km of high-speed rail lines suitable for speeds of at least 200 km/h. Completing the network by 2020 involves the construction of the so-called „missing links“ which will increase the existing rail by 12 500 km. In addition, 12 300 km of rail lines will be substantially upgraded [5].

Completing the networks will have a huge impact in reducing journey time for passengers and goods. For interregional traffic alone the benefits are estimated to be almost EUR 8 billion per year. In addition, freight transport in the EU is expected to increase by more than two thirds between 2000 and 2020, and to double in the new Member States. Freight transport among Member States is expected to show the largest increase overall. Without TEN-T this increase in transport would be impossible to handle, and our rate of economic growth significantly slowed.

An important aspect in design of new lines or in the evaluation of upgrading operations is the convenience that the railway lines will not be restricted to their use by a limited family of trains. On the contrary, they should allow the transit of all vehicle typologies (both traditional, high speed and freight trains), enabling interoperability of the infrastructure by all possible trains. This issue is not only essential from a social and economical point of view, but has also other implications, such as to separate the business of the infrastructure from that of the transport operators, as suggested by the new European directive [6].

The possible presence of new train typologies, characterized by several layouts of weights and axels distributions, introduces new uncertainties on the expected traffic loads and the consequent loading spectra to be adopted in fatigue verification. As a consequence, new operating conditions of European Railway Networks require the assessment of adequacy and effectiveness of actual loading spectra provided by design codes and regulations for fatigue verification purposes. Such spectra, derived from previous studies performed on old railway lines, could lead to an underestimation of actual railway traffic effects.

The knowledge of past and current load spectra, together with predicted future loads, is essential in the evaluation and fatigue analysis of existing bridges. In particular, the information concerning actual loads is very important during rating operations according to the procedures adopted by main Railway Administrator. Therefore, there is a need for accurate and inexpen-

sive methods to determine the actual loads, the strength of the bridge, and its remaining life. There is also a need for verification of live load used for the development of a new generation of bridge design codes.

The increase of circulation speed, the change of the vehicles geometry and masses and the increase of loads that were observed led to a concern in the understanding of dynamic phenomena and in their quantification, and therefore to the improvement of safety checking procedures in structural codes. In particular, the evaluation of effective capability of existing bridges to guarantee the necessary safety level under actual traffic conditions requires the improvement of available design procedures. Figure 1 shows a general framework [7] to be adopted for the fatigue assessment of existing steel structures. Such an approach suggests the use of three different levels of assessment methodologies:

- *Simplified methods*: preliminary evaluation should be conducted by using current codes and recommendations and making conservative assumptions when information is lacking or doubtful; simplified models are adopted for the structures and their details;
- *Enhanced methods*: a detailed investigation should be performed, adopting a refined representation of the structure and of the loads/actions; anyway input data for model analysis can be adopted from current codes;
- *Advanced methods*: advanced evaluation should be carried out to analyze, by means of both numerical and experimental tools, the effective remaining fatigue life of all relevant details.

The application of different evaluation methodologies requires an increasing level of knowledge and information concerning the behaviour of structural components and details. In particular the use of advanced methodologies is actually limited to specialized laboratories and scientific research groups.

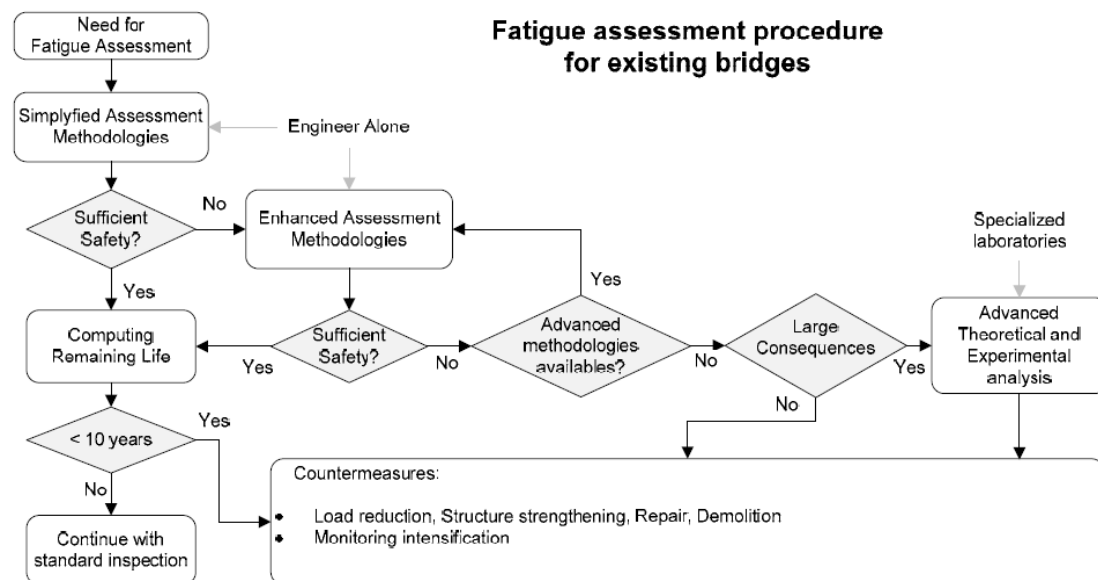

Figure 1: Fatigue assessment procedure for existing steel bridges [7].

Such an approach is mainly due to the fact that, traditionally, it was assumed that the need for the application of advanced analysis methodologies in design of steel and steel-concrete composite bridges can be limited adopting proper detailing that remove the secondary stresses. Such objectives were reached introducing an high number of global and local stiffeners, nec-

essary to guarantee the verifications of static requirements against instability as well. On the contrary, several fatigue problems affected and still affect steel bridges due to several reasons.

Previous experience shows that most cracks found in bridges were caused by distortion of member cross sections and out-of-plane deformation of webs that induced localized bending stresses [8]. In older bridges, transverse stiffeners and attachment plates were not welded to the tension flange of welded I-girders and box girders for fear that a fatigue crack initiating in the flange would lead to a brittle fracture. This well-intended but outdated practice originated in Europe in the 1930's from unexpected brittle fracture in the oldest welded bridges, and it was at first attributed to welding details, but it was primarily due to the poor quality of steel.

This practice has been the main cause of distortion-induced cracking, which can sometime be prevented by welding stiffeners to the web and to the flanges. Figure 2 shows a crack which formed along the fillet weld attaching a diaphragm connection plate to the web of a plate girder [9]. The fatigue cracking in these gaps typically occurs in a longitudinal direction along the fillet weld toe of the longitudinal web-to-flange joint, at the termination of the vertical fillet weld, or at both locations, as shown in Figure 3 [9].

Figure 2: Examples of distortion induced fatigue crack progression [9].

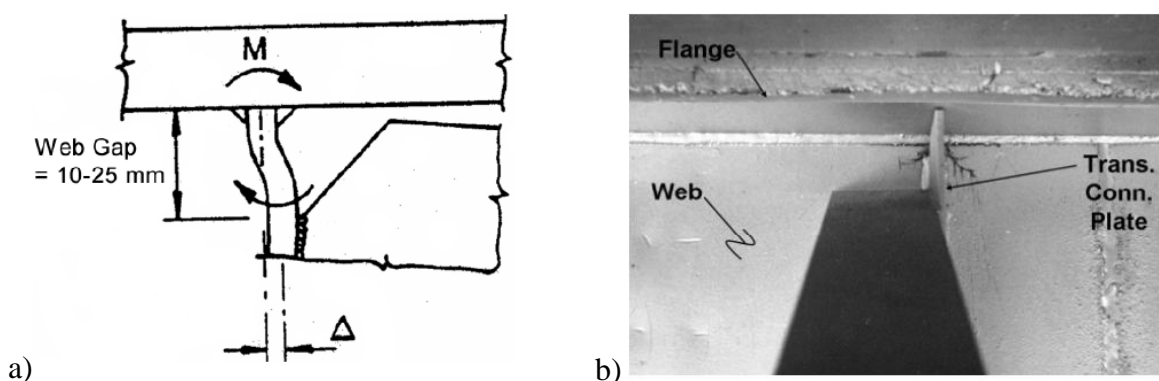

Figure 3: Web gap distortion: a) scheme of the effects; b) example in real bridge [9].

In many cases, the displacement causing this distortion is limited and the cracking arrests as the compliance of the gap increases and the stresses are reduced. Because most of the cracks are longitudinally oriented, there is typically no reason to be concerned about fracture of the girder unless the cracks turn downward and propagate across the web. It is typically a mistake to try to weld repair such cracks, as this restores the high stresses which originally caused the cracking and will certainly restart the cracking at the weld repair [9].

Besides, distortion and vibration induced fatigue phenomena, typically due to low local stiffness distribution in correspondence of critical details, can affect steel and composite bridges. Such phenomenon allows the presence of local vibration modes characterized by low frequencies (0-30 Hz) typically excited during train passages which could produce high local “modal” stresses causing relevant fatigue damages and reducing the remaining fatigue life.

As previously stated, distortion induced or vibration induced fatigue cracking in the web gaps may be solved by a proper detailing which eliminates the secondary stresses causing these cracks. In most cases, the web-gap-cracking can be prevented by rigidly connecting the attachment plates to the tension flange. Where the distortion is displacement controlled, the stresses can be reduced by increasing the flexibility of the connection. If distortion is limited, holes may be drilled or cored at the crack tips to temporarily arrest propagation [9].

Modern design methodologies for steel and steel-concrete composite bridges adopt new materials with very high performances allowing for very slender structures. Such solutions, characterized by improved performance against static loadings, revealed to be exposed to vehicle-bridge interaction effects which influence fatigue behavior.

High structural slenderness implies that non-structural elements, such as ballast, retaining walls and tracks, can affect bridges dynamic behavior caused by train passage. Moreover, the high local slenderness caused by the reduction of plate thickness and stiffeners number, can increase the possibility of obtaining local vibration modes characterized by low frequencies. As a consequence, such local modes can increase the possibility of observing “vibration induced” fatigue damage phenomena. By the way, actual codes and regulations appear inadequate to provide effective tools in order to obtain thorough information about such phenomena.

Moreover, the use of High Performance Steel does not modify the results of fatigue verifications since fatigue behavior does not depend on mechanical or dynamical properties of materials.

Local vibration and distortion phenomena do not affect only steel details/elements. In fact, both in steel-concrete connection systems (such as studs) and concrete slabs between the main girders in steel-concrete composite solutions result highly affected by such phenomena as well. In particular, it will be useful to evaluate the effective load spectra affecting reinforcement bars in concrete slabs directly subjected to the load induced by train passage and the consequent free vibrations.

Main object of the European research project FADLESS “*Fatigue damage control and assessment for railways bridges*”, funded by the European Research Found for Coal and Steel (RFCS) and in course of realization, is to investigate the aforementioned uncertainties on the structural behaviour and integrity of steel and composite steel-concrete bridges with particular attention to the fatigue phenomena. To this aim, a modern procedure for the evaluation of the actual fatigue load and resistance of principal elements and critical details will be assessed for selected case studies representative of the bridge typologies most exposed to such damages.

In particular, the actual fatigue loading spectra will be evaluated taking into account the real and the expected traffic flows, also because of possible reclassification of railway lines, of the global dynamic train-bridge interaction effects and of the local dynamic vibration and distortional effects. Moreover, actual fatigue resistance of the main elements / critical details subjected to distortion induced effects will be evaluated. In such a way, it will also be possible to setup suitable strategies for the evaluation of vibration induced and distortion induced fatigue damaging in steel and composite steel-concrete railway bridges, as well for the control of the crack growth.

In this paper some preliminary results obtained for the Panaro bridge, a study case of FADLESS Project, are illustrated. In particular, standard modelling and fatigue assessment,

experimental tests, model updating and advanced fatigue assessment of Panaro bridge will be described. Objectives of such activities were to: i) investigate the actual dynamic behaviour of the structure; ii) compare the fatigue assessment results obtained by standard and advanced approaches; iii) define preliminary observations to the fatigue assessment methodologies currently adopted in European design codes. Moreover, this first part of the Project will constitute the base for future developments of the research, leading to better comprehension of vibration and distortion fatigue phenomena induced by real traffic on steel and steel-composite railway bridges.

2 THE PANARO BRIDGE

The bow-string steel bridge on the Panaro river, along Bologna-Verona railway line, is the very first Italian railway bridge constructed adopting welded components (Figure 4). This particular bridge, supporting two tracks, has experienced an intense passenger and freight traffic since its construction in the 70's.

The bridge has a span length equal to 75.6 meters and its cross section height varies from 7 to 11 meters (Figure 5). All main components such as lower and upper strings, vertical and diagonal beams, main cross girders, lower and upper bracing diagonals at deck ends are built-up welded members (Figures 6 and 7). All joints are constituted by riveted solutions, thus realizing a very particular structure among steel railway bridges, an uncommon mix between welded components and riveted joints. Lower and upper main bracings are present, together with secondary longitudinal beams, directly supporting the rails, and local track bracings (Figures 8 and 9). End supports are constituted by steel bearings directly in contact with lower main strings (Figures 10 and 11).

Figure 8: General view of deck structure

Figure 9: General view of lower and track bracings

Figure 10: General view of unidirectional bearing

Figure 11: General view of fixed bearing

During its exercise life, some of the secondary elements of the structures showed fatigue damages induced by distortion and vibration phenomena, as reported in Figures 12 and 13. In particular, almost all cross beams of track local bracings (originally fully fixed to the secondary longitudinal girders) experienced the same fatigue damage at the end restraints. Italian authority decided to cut the profiles in order to stop the crack propagation and changed beam end connections into pin joints removing the external bolts, in order to reduce the bending forces induced by distortion phenomena (Figure 12). Moreover, the connection between sleepers and longitudinal girders, obtained by catch bolts anchored to steel plates welded to the upper girder flanges, experienced fatigue damages in the longitudinal plate-flange welding due to vibration effects (Figure 13).

3 STANDARD MODELLING AND FATIGUE ASSESSMENT

Two FE beam models were developed by ANSYS® software for the standard fatigue assessment of Panaro bridge. The first model represented the bridge original resistant scheme, with track bracing cross beams fully fixed to the longitudinal girders (Full Fixed FE Model). The second model represented the actual situation as a results of the local repair interventions, with track bracing cross beams connected by hinge joints to the longitudinal girders (Hinge FE Model) (Figures 14 and 15).

Figure 14: FEM model of the Panaro bridge

Figure 15: Track bracing cross beam connection to secondary longitudinal girders by full fixed/pin joints

All girders were represented by beam elements (BEAM188), except bracing diagonals represented by truss elements (LINK8). All elements were defined according to their actual geometrical axis and connected, where necessary, by proper internal constraints [10]. Those components characterized by variable end cross sections, as longitudinal girders, track and upper bracing cross beams, were represented by I section element in central parts and T sections elements at the ends. This approach was necessary to model properly the bridge stiffness and to obtain reliable force/stress values, as end stiffness greatly influence the intensity of in-plane and out of plane actions induced by distortion phenomena and, consequently, the intensity of local stresses (Figures from 16 to 19).

Figure 16: Side view of secondary longitudinal girders with variable end cross sections

Figure 17: Local view of elements representing secondary longitudinal girders

Figure 18: Side view of upper bracing cross beams with variable end cross sections

Figure 19: Local view of elements representing upper bracing cross beams

The evaluation of dynamic forces induced by train passages into the bridge components was performed according to the Eurocode rules. In particular, element stresses were calculated by incremental dynamic analysis of bridge models subjected to the moving loads of Standard and Heavy train traffic mixes [11]. The total number of train passages was calculated assuming a life cycle of 100 years.

As Eurocode fatigue train models are characterized by different lengths and velocities, the passage of each model was simulated assuming different sampling frequency in order to optimize the calculation times. In particular, analysis frequencies were calculated in such a way that the distance covered by loads between two subsequent steps was equal to 1/10 of secondary longitudinal girder length for each train velocity (Table 1).

In the dynamic analysis, damping characteristics of bridge components were represented assigning to each element a proper value of material damping, calculated as a function of length as specified by Eurocode [11]. Calculated girder material damping varied in the range 0.5% - 2.81%.

Beam element stresses were extracted from the FE models and elaborated in order to calculate the stress time-histories acting on net cross sections. In particular, the four possible combinations of normal stresses induced by the axial force and the two bending moments were considered for each element section. Moreover, vertical and transverse shear stresses acting at end restraint sections of main cross girders and upper bracing cross beams were also considered.

Normal and shear stress spectra were evaluated by rainflow counting technique. Fatigue damages were calculated independently adopting the linear damage accumulation rule of Palmgren-Miner. Fatigue classes of welded built-up members were assumed according to the indications of Eurocode [11], while for riveted components the fatigue classes proposed by Taras and Greiner were considered [12]. Fatigue classes of all bridge components are reported in Table 2.

Train Type	Vel [Km/h]	Length [m]	Analysis Frequency [Hz]
1	200	262.1	120
2	160	281.1	95
3	250	385.52	150
4	250	237.6	150
5	80	270.3	50
6	100	333.1	60
7	120	169.5	75
8	100	212.5	60
9	120	134.8	75
10	120	129.6	75
11	120	198.5	75
12	100	212.5	60

Table 1: Values of frequencies adopted in the dynamic analysis

Constructional detail	Bridge Components	Fatigue Class
One-shear joint with gusset plate	Main Lower and Upper Strings; Main Vertical Beams; Main Diagonals Beams; Main Cross Beams at end sections; Lower and Upper Bracing Diagonals	85 for normal stresses
Structural element with holes subject to bending and axial forces	Main Cross Beams at intermediate sections; Secondary Longitudinal Girders at end sections; Upper Bracing Cross Beams at intermediate Sections	90 for normal stresses
Built-up sections with automatic fillet weld	Secondary Longitudinal Girders at intermediate sections; Track cross beams at intermediate sections	125 for normal stresses
Tee-butt joints with fillet welds	Track cross beams at end sections; Upper Bracing Cross Beams at End Sections	36 for normal stresses 80 for shear stresses

Table 2: Fatigue classes adopted for Panaro bridge components

For each element section, the fatigue damage D_i induced by the i train type was calculated adopting the following simplified approach [1]:

$$D_i = D_{\sigma, \max} + D_{tv} + D_{th} \quad (1)$$

where $D_{\sigma, \max}$ is the maximum damage induced by normal stresses considering the combinations of axial force and bending moments, D_{tv} is the vertical shear damage and D_{th} is the horizontal shear damage. Total fatigue damages obtained from Full Fixed and Hinge Model FE models for Standard and Heavy traffic mixes are reported in Figures from 20 and 24.

Considering the Full Fixed FE Model, that represents the original resistance scheme of Panaro Bridge, it is possible to observe that a significant number of elements showed a fatigue damage greater than 0.1 both for Heavy and Standard traffic mixes. Damage values between 0.1 and 1 were observed on almost all vertical beams while more severe damages, greater than 1, occurred at the end cross sections of track bracing cross beams (as really occurred) and at the connection joints of vertical beams with lower/upper stringers (actually undamaged) (Figure 22). From this point of view, more refined analysis of identified critical details seemed to be necessary for a proper evaluation of actual stress spectra.

Figure 20: Full fixed FE model - Heavy Traffic Mix Damage

Figure 21: Full fixed FE model - Standard Traffic Mix Damage

Figure 23: Hinge FE Model - Heavy Traffic Mix Damage

Figure 24: Hinge FE Model - Standard Traffic Mix Damage

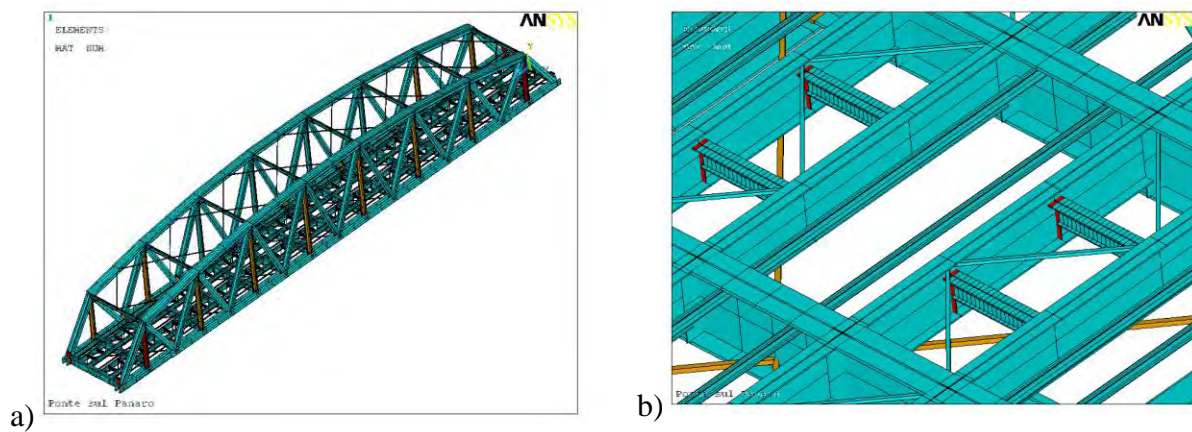

Figure 25: Full Fixed FE Models - Heavy Traffic Mix: general (a) and detailed (b) graphical representation of damaged components (Yellow elements: $-0.1 < \text{Damage} < 1$ --- Red elements: $\text{Damage} > 1$)

Also for the Hinge FE Model a great number of damaged components was observed for Heavy and Standard traffic mixes. Vertical beams showed damage values between 0.1 and 1 and more severe damages, greater than 1, occurred at the connection joints of vertical beams with lower/upper stringers. Nevertheless in the Hinge Model case, that represents the actual resistant scheme of Panaro bridge, the elements representing the end sections of track bracing cross beams did not show any fatigue damage. From these results, it is possible to observe that the local modification of the track bracing cross beams practically cancelled the distortion induced local forces while did not introduce significant variations in the global structural response of the bridge.

It is important to notice in both the Full Fixed and Hinge FE Models the reliability of calculated results is unknown, as expected fatigue damages in some cases really occurred but in others didn't. So, advanced FE models of critical details are necessary in order to obtain a correct evaluation of local stresses. From this point of view, the modelling experience of Panaro bridge confirmed the necessity of advanced analysis approaches in the design of new complex structures and in the assessment of older ones, as the use of standard techniques only could lead to an erroneous evaluation of local effects.

4 EXPERIMENTAL TESTS

Usually steel bridges show a real structural behaviour different from the theoretical one, as every modelling and analysis technique actually available is necessary a simplified representation of more complex structures. From this point of view, experimental tests are very effective tools for the evaluation of real forces and stresses acting into bridge steel components and, consequently, can be adopted as a useful base for a reliable evaluation of fatigue performance.

The experimental tests on Panaro bridge were focused on the structure dynamic identification and on evaluation of the effects induced by train passages. In particular, global and local vibration modes were identified by operative modal analysis technique (OMA) using the ambient vibrations (white noise) as excitation source. Moreover, the effects of train passages were investigated directly recording the strain time-histories on critical details and the horizontal displacement time-histories of the deck unidirectional bearings. Such tests permitted to improve the knowledge of the real structural behaviour and constituted the base for the numerical updating of FE bridge model.

4.1 Global/Local Experimental Dynamic Tests

The experimental dynamic analysis on Panaro bridge was performed in order to obtain the identification of the global vibration modes and, moreover, to evaluate the dynamic characteristics of track bracing cross beams. To this aim, accelerations in the vertical, horizontal and longitudinal directions of suitable structure key points were recorded assuming the ambient vibration as excitation source.

In particular for the identification of global vibration modes, structure accelerations were recorded on eleven sections adopting a multi-step approach, that consists of acquiring data by moving sensors along the structure and keeping some of them fixed as "reference" (Figures 25, 26 and 27). Such "reference" sensors are adopted as common base for merging the vibration modes identified by different recording configurations, thus providing the global identification of the structure [13]. Accelerations were recorded by PCB sensors and LMS Scadas acquisition unit adopting a sampling frequency of 400 Hz for time periods of 15 minutes at least. Some train passages occurred during the acquisition of ambient sources, nevertheless such noises were afterwards cleared from recorded signals before the numerical identification of natural vibration modes, obtained by PolyMAX algorithm [13].

Seven global modes of vibration were clearly identified during the experimental tests. Modal frequencies, damping values and mode shapes are reported in Table 3, together with the mode phase collinearity values (MPC) that is equal to the unity when the complex modal displacement of all recorded nodes have the same phase (i.e. the mode is real). The modal shape extracted for the identified modes are reported in Figure 28.

Mode n°	Frequency [Hz]	Damping [%]	MPC	Mode Shape
1	1.77	0.49		Lateral Bending
2	3.65	0.15		Torsional
3	3.68	0.65		Vertical Bending
4	4.08	0.29		Lateral Bending
5	6.86	0.15		Distorsional
6	10.93	0.24		Torsional
7	12.35	0.25		Vertical Bending

Table 3: Identified global vibration mode of Panaro bridge.

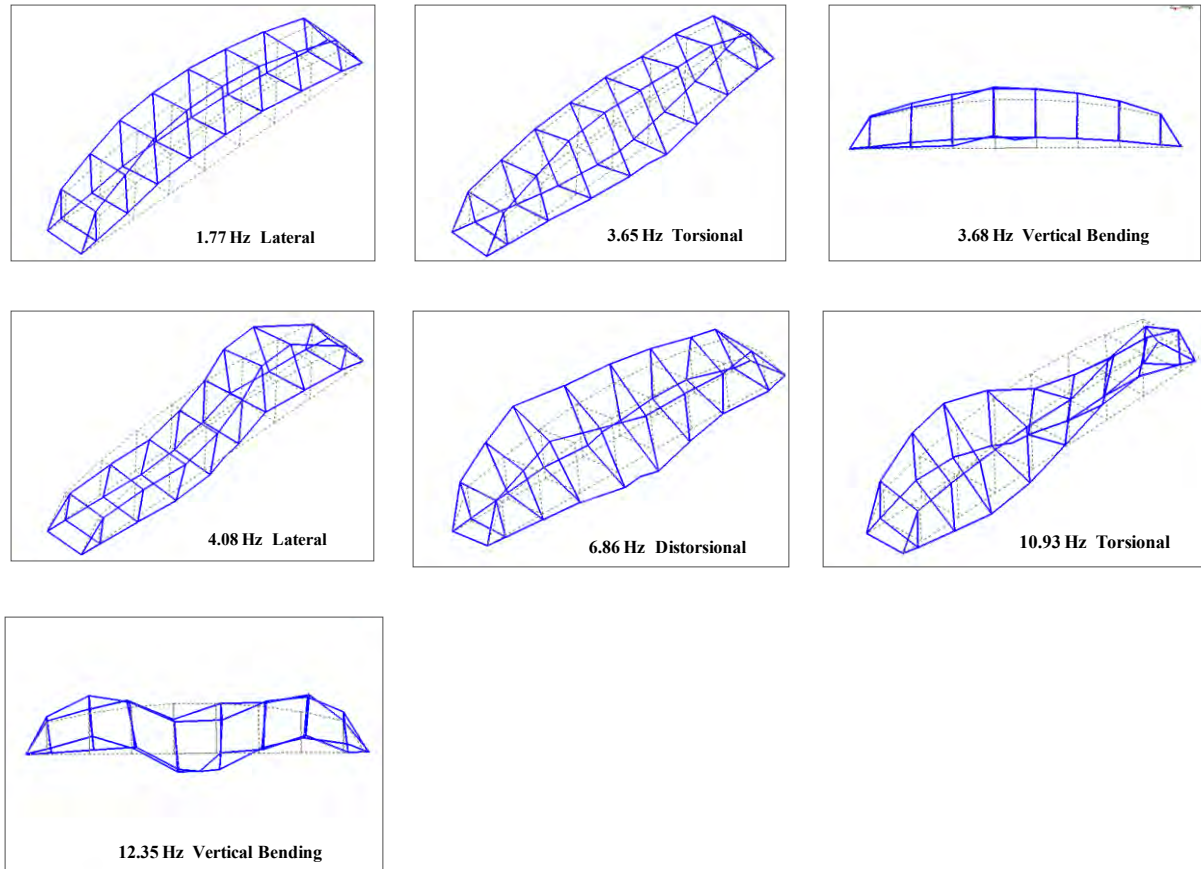

Figure 28: Panaro bridge - shapes of identified global vibration mode

Local dynamic tests were performed on a track bracing cross beam, recording vertical and transverse accelerations of upper flange at midspan and lateral sections (Figure 29). In this case, a single acquisition of all instrumented sections, realized adopting the same recording settings of global tests, permitted to identify clearly three local vibration modes of the cross beam. Modal parameters are reported in Table 4 while the calculated modal shapes are illustrated in Figure 30.

Figure 30: Panaro bridge - vibration mode shapes of track bracing cross beam

4.2 Strain/Displacement Experimental Tests

The effects of train passages were investigated analyzing strains of local details and displacements of external bearings.

In particular, strain time-histories were recorded on the track bracing cross beams and on the steel plates connecting sleepers to the secondary longitudinal girders (Figure 31). It was so possible to investigate the stresses actually induced into track cross beams by distortion phenomena, indirectly evaluating also the effects on internal forces of end restraint modifications from full fixed to hinge joints. Moreover, stress cycles acting into sleeper supporting steel plates were investigated as such secondary components showed extensive fatigue damages due to the vibration of track sleepers.

Stresses induced by train passages into the track bracing cross beam are very low, thus confirming that actually this component is not particularly subjected to distortion phenomena. On the contrary, more intensive actions are present into the sleeper supporting plates, due to distortion and vibration effects induced by sleeper movements under train passages. Such stresses caused extensive fatigue damages on the longitudinal welding connecting supporting

steel plates to the upper flange of secondary longitudinal girders. Stress time-histories recorded at midspan section of track bracing cross beam (CH 4) and at the sleeper supporting plate (CH 10) are reported in Figures 32 and 33.

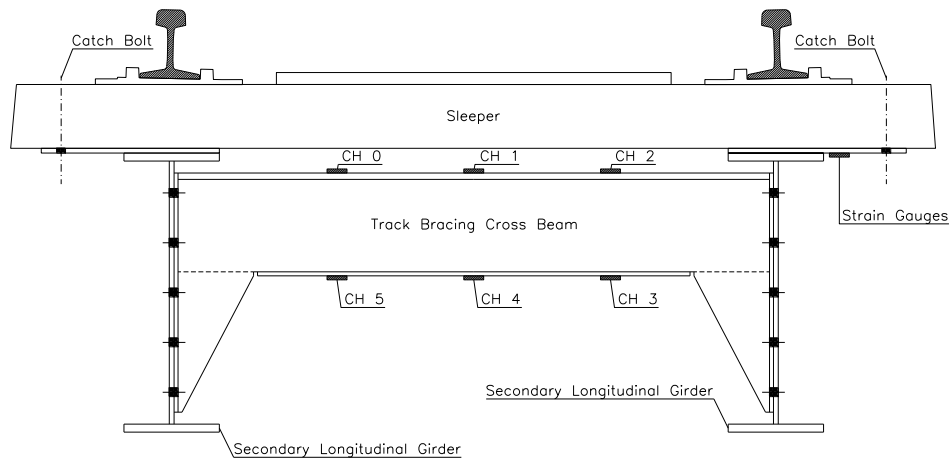

Figure 31: Strain gauge position on track bracing cross beam and sleeper supporting plates.

Figure 32: Midspan section of track bracing cross beam: strain time-history (CH 4)

Figure 33: Strain time-history of sleeper supporting plate (CH 10)

Longitudinal movements of the two unidirectional external bearings were recorded using dynamic optoNCDT laser transducers (Figure 34). It was so possible to investigate the actual horizontal displacement time-histories of Panaro bridge under the passage of different train typologies (an example of recorded signals is reported in Figure 35). The different values of longitudinal displacements recorded for the two external bearings are probably due to torsional/lateral movements induced by asymmetric train passages on the bridge deck. The entity of such lateral bending and torsion depends on train composition, axle loads and speed. From this point of view, such results confirmed the need of considering not only vertical bending but also lateral bending and torsion in order to obtain a reliable evaluation of the dynamic structural response of such complex structures.

5 NUMERICAL UPDATING

The global vibration modes identified in the experimental dynamic tests were adopted as reference for the numerical updating of the FE Hinge model of Panaro bridge, that represents the actual resistant scheme of the structure. To this aim, an automatic optimization procedure was implemented by MODEFRONTIER software (Figure 36). Objective of developed proce-

ture was to minimize simultaneously and independently the differences between experimental and numerical eigenfrequencies by the variation of suitable parameters.

In each sequence cycle, parameter values were changed according to the MOGA-II optimization algorithm and transferred to the ANSYS FE model, in order to extract the first twenty eigenfrequencies and vibration mode shapes [14]. Calculated results were then elaborated by MATLAB to match experimental and numerical mode of vibrations. Mode matching between i^{th} experimental and j^{th} numerical vibration modes was obtained searching the highest MAC_{ij} value, where MAC_{ij} is the modal assurance criterion calculated for ϕ_i and ϕ_j mode shapes normalized to the unity.

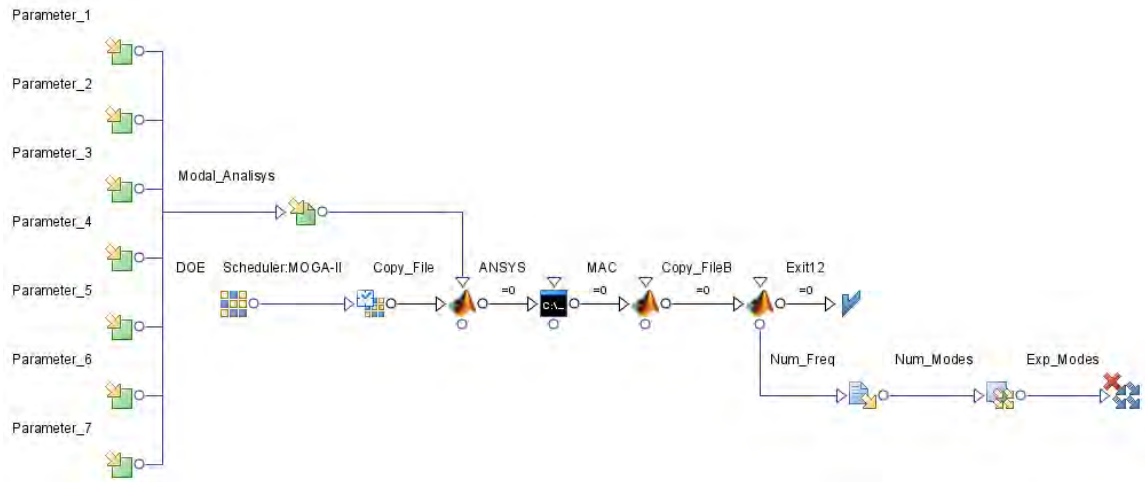

Figure 36: Optimization scheme developed for the FE model updating

After the optimization procedure was calibrated, suitable mechanical parameters had to be selected before the updating of Panaro bridge FE Hinge model. From a preliminary comparison between numerical and experimental vibration modes, a large difference between frequency values was observed, especially for those modes that involve transverse movements (lateral bending and torsion), as reported in Table 4. Some modifications were so introduced into the FE Hinge model before updating, in order to improve the numerical representation of bridge dynamic properties (Table 4).

The rotation center of end bearings, originally assumed at the contact point with the main lower stringers, was moved in the downward direction, using a mass less point element (MASS21), and its position was assumed as an optimization parameter. This modification was due to the observation that the upper bearing surfaces have a circular shape with a unknown radius, with the consequence that the rotation center is lower than the contact point.

Moreover, bearing stiffness were also represented into the FE model by spring elements (COMBIN14). In particular, longitudinal and torsional (rotation along the vertical axis) stiffness of fixed vertical bearings were modeled, while for unidirectional bearings only torsional spring elements were considered. Bearing stiffness were assumed as optimization parameters and their initial values were estimated by two FE models of fixed and unidirectional bearings subjected to unit longitudinal displacement or unit vertical rotation (Figure 37). Spring elements were directly connected to the point elements representing the rotation center of bearings. Vertical/transverse and longitudinal rotation DOFs of point elements representing the rotation center of unidirectional bearings were fixed, while for fixed bearing the longitudinal DOF was also fixed.

At least, also the values of dead loads, represented by equivalent densities of bridge components supporting secondary structures, were assumed as optimization parameters for the FE model updating. All selected optimization parameters are reported in Table 5.

Mode n°	Exp. [Hz]	Mode Shape	FE Hinge Model [Hz]	Δ [%]	Modified FE Hinge Model [Hz]	Δ_M [%]
1	1.77	Lateral Bending	2.284	29.0	1.96	10.5
2	3.65	Torsional	3.844	5.3	3.56	2.4
3	3.68	Vertical Bending	3.989	8.4	3.69	0.4
4	4.08	Lateral Bending	4.864	19.2	4.15	1.8
5	6.86	Distortional	7.377	7.5	6.65	3.0
6	10.93	Torsional	11.829	8.2	10.56	3.4
7	12.35	Vertical Bending	13.763	11.4	12.92	4.6

Table 4: Comparison between numerical and experimental modal frequencies

Figure 37: FE models of fixed (a) and unidirectional (b) bearings

Parameter n°	Description	Value
1	General material density of beam elements (dead weight of components, rivets and connecting plates)	9027.5 kg/m³
2	Material density of upper stringer elements (dead weight of components, rivets, connecting plates, suspended upper runaways)	17477 kg/m³
3	Material density of secondary longitudinal elements (dead weight of components, rivets, connecting plates, rails, sleepers, walking grates)	16854.6 kg/m³
4	Distance between lower stringer axis and bearing centre of rotation	0.174 m
5	Torsional stiffness of fixed bearing	124860 kN*m/rad
6	Torsional stiffness of unidirectional bearing	230690 kN*m/rad
7	Longitudinal stiffness of fixed bearing	1068800 kN/m

Table 5: Selected optimization parameters for numerical updating of Panaro FE model

The sensitivity functions of parameters n° 1-2-3 calculated for the 1st, 3rd and 4th vibration modes are reported in Figures 38a, 38b and 38c. The variation of such density parameters

have a great influence on numerical values of the eigenfrequencies, while a variation of bearing stiffness parameters (n° 5-6-7) lower than 25% did not induced significant variations.

The distance of the bearing rotation centers from lower stringer axis influenced the eigenfrequencies of modes n° 1-3-5-6-7 in the range 0-20 m, while for greater values the frequencies of aforementioned vibration modes could be considered as constant (Figure 38d).

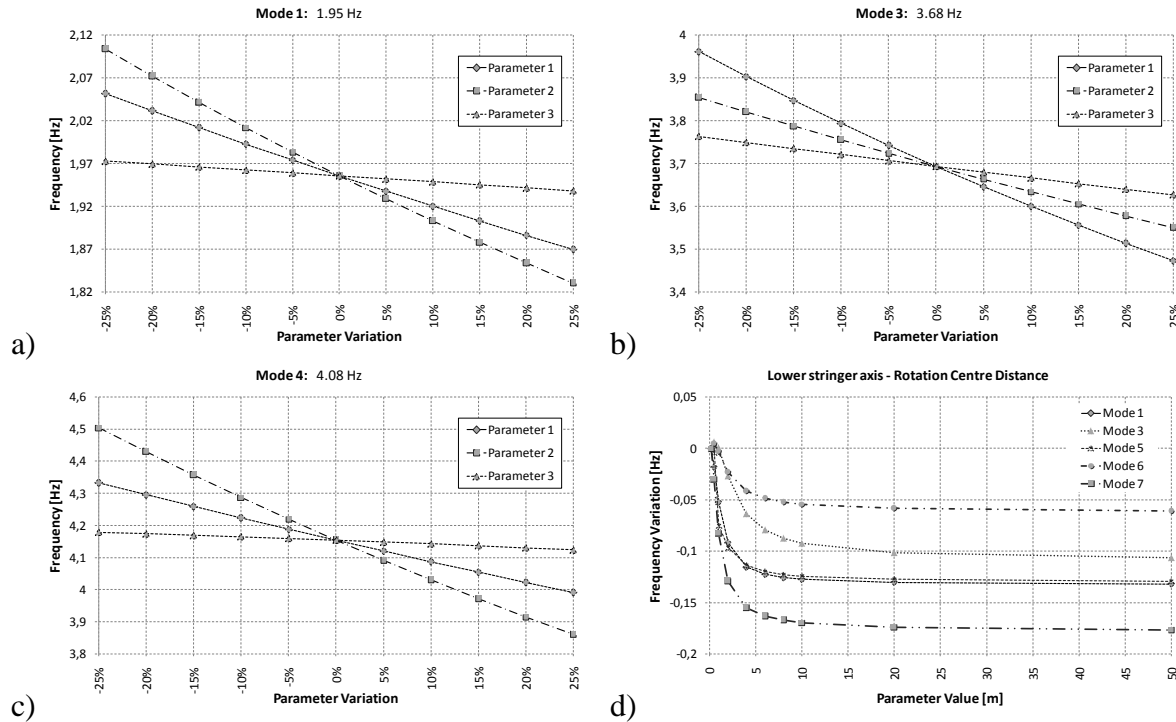

Figure 38: Sensitivity functions of parameter n° 1-2-3-5-6-7 calculated for vibration modes n° 1-3-4

The modeFRONTIER procedure converged to stable parameter configurations after 3560 cycle iterations, taking less than 15 seconds for each cycle for a total computation time equal to 15 hours. The numerical optimization permitted to obtain an updated model characterized by numerical eigenfrequencies very similar to the experimental results (maximum difference of about 4.5%) and high MAC values, reported in Table 6. The complete MAC matrix is reported in Figure 39.

Parameter n°	Initial Value	Final Value	Mode n°	Numerical Freq. [Hz]	Experimental Freq. [Hz]	Δ [%]	MAC
1	9027 kg/m ³	7897 kg/m ³	1	1.82	1.77	2.73	98.7%
2	17477 kg/m ³	18735 kg/m ³	2	3.64	3.65	0.33	98.3%
3	16854 kg/m ³	18068 kg/m ³	3	3.64	3.68	1.06	82.7%
4	0.17 m	76.00 m	4	4.13	4.08	1.27	72.7%
5	124860 kN*m	93645.00 kN*m	5	6.59	6.86	4.00	72.0%
6	230690 kN*m	183270 kN*m	6	10.66	10.93	2.52	75.9%
7	1068800 kN/m	1068800 kN/m	7	12.91	12.35	4.53	68.4%

6 ADVANCED FATIGUE ASSESSMENT

The Updated FE Hinge model of Panaro bridge was used for a further fatigue assessment of case study, comparing results obtained from an advanced modeling/updating approach with standard methodologies. Indeed, one main objective of Fadless Project is the critical review of standard approaches currently adopted for the fatigue assessment of complex structures like bridges. In particular, the Project aims also at evaluating the effectiveness of standard FE modeling techniques and fatigue load models, comparing theoretical results obtained from current design rules with experimental data. From this point of view, the comparison between fatigue damages calculated by an updated model and a standard one constitute a preliminary results in such critical review process.

The number (Figures 39 and 40) and distribution (Figure 41) of damaged components is similar to the standard results calculated by the Hinge Model, while damage intensities are a little lower. From the fatigue assessment point of view, the updating process didn't showed to vary significantly the results obtainable from a global FE model, thus confirming the necessity of refined local analysis of critical details in order to catch properly the actual stress spectra induced by distortion and vibration phenomena.

Figure 39: Updated Model - Standard Traffic Mix Damage

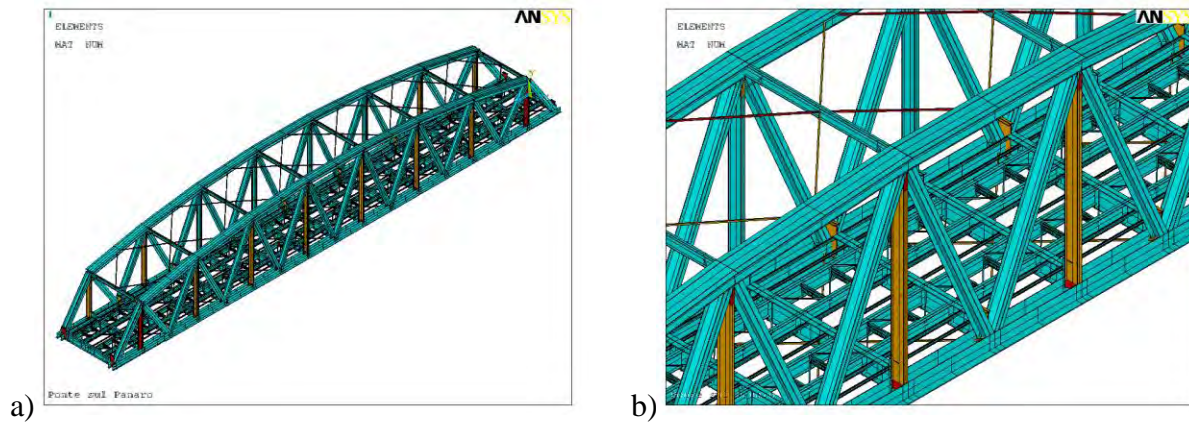

Figure 41: Updated FE Models - Heavy Traffic Mix: general (a) and detailed (b) graphical representation of damaged components (Yellow elements: $-0.1 < \text{Damage} < 1$ --- Red elements: $\text{Damage} > 1$)

7 SOME PRELIMINARY REMARK

Main objective of FADLESS Project are the development of enhanced approaches for the correct evaluation of fatigue damages on steel railway bridges considering in particular the distortion and vibration effects.

The theoretical and experimental analysis performed on Italian case study, the Panaro bridge, permitted to obtain very interesting preliminary results concerning the actual dynamic behavior of such complex structures and the effectiveness of currently adopted modeling approaches at representing the internal distribution of forces/stresses. In particular, standard FE models were used for the fatigue assessment of the bridge, realized according to Eurocode rules. Experimental dynamic analysis permitted to identify global/local vibration modes and to constitute a suitable base for the subsequent numerical updating of developed FE model, obtained by an automatic optimization procedure. Advanced fatigue assessment was performed on the updated FE model and related results were compared to standard ones.

Moreover, critical details concerning the distortion/vibration induced fatigue damages were identified; such details, in the second part of the project, will be the object of further studies including the development of local FE models and the realization of sub-structuring analysis.

At last, suitable long-term monitoring systems will be designed and installed on all case studies in order to identify the actual railway traffic spectra on European bridges, providing the necessary base for a critical review of actually adopted fatigue load models.

Abstract. *The problem of jointly estimating the input forces and states of a structure from a limited number of acceleration measurements is addressed. Utilizing a model-based joint input-state estimation algorithm originally developed for optimal control problems, minimum-variance unbiased estimates of the modal displacements and velocities of a structure as well as the dynamic forces causing these responses, are obtained. The proposed algorithm requires no prior information on the dynamic evolution of the input forces, is easy to implement, and allows online application. Its accuracy and effectiveness are demonstrated using data from a laboratory experiment on an instrumented steel beam and an in situ experiment on a footbridge.*

1 INTRODUCTION

In civil engineering state estimation refers to a model-based identification of quantities (e.g. displacements) that allow a complete description of the state of a structure from vibration response data. State estimators, among which the well-known Kalman filter and its variants, have been proposed for structural systems behaving both linearly and nonlinearly. A small survey is given by Ching et al. in [3]. The state estimates can be used for a variety of purposes including the prediction of stresses and fatigue loading, real-time structural health monitoring, structural control, the determination of response in critical joints, the verification of design calculations, etc. Examples include the work by Papadimitriou et al. [11], in which the Kalman filter is used as part of a methodology for estimating the damage accumulation in a structure due to fatigue from output-only vibration measurements at a limited number of locations. Ching and Beck [2] estimated the unknown states of a structure using a Kalman smoother in an application concerning reliability estimation for serviceability limit states. Smyth and Wu [15] proposed a multi-rate Kalman filter for the fusion of measured displacement and acceleration data sampled at different rates. The filter is designed to circumvent problems related to the integration of accelerometer or the differentiation of displacement data in situations where both these response quantities are available for system monitoring or damage detection. Hernandez and Bernal [9] designed a state estimator for structural dynamic systems based on the assumption that the primary source of uncertainty in the predicted state derives from errors in the matrices of the state-space model. Their estimator distinguishes itself from the related robust Kalman filter (RKF) in that it is derived on deterministic grounds, assumes no process/measurement noise and is significantly simpler to implement. It has been used as part of an iterative scheme for model updating in [7], and has been extended to nonlinear systems in [8], where it was used to estimate the states in a damaged seven-story building from a limited number of acceleration measurements.

In this contribution a joint input-state estimation algorithm is used to identify modal displacements, velocities and input forces using data from a laboratory experiment on an instrumented steel beam as well as an in situ experiment on a footbridge. The algorithm, developed by Gillijns and De Moor [6], has the structure of a Kalman filter, except that the true value of the input is replaced by an optimal estimate. It distinguishes itself from the state estimation methods mentioned above in that the excitation is assumed unknown, whilst there are also no assumptions made about its dynamic evolution (e.g. broadband, so that it can be modeled as a zero mean stationary white process). When the positions of the applied forces are known, the algorithm can be used to jointly estimate the states and input forces. Conversely, when the positions of the applied forces are unknown, a set of equivalent forces is identified. In the latter case the points of application of the forces are randomly chosen and equivalent forces, that would produce the same measured response, are identified at all chosen locations. It is this latter case, corresponding to pure state estimation in the absence of any a priori information regarding the positions or frequency characteristics of the input forces, that will be considered in this paper.

2 MATHEMATICAL FORMULATION

2.1 Equations of motion

Consider the continuous-time governing equations of motion for a linear system discretized in space:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{f}(t) = \mathbf{S}_p(t)\mathbf{p}(t) \quad (1)$$

where $\mathbf{u}(t) \in \mathbb{R}^{n_{\text{DOF}}}$ is the vector of displacement, \mathbf{M} , \mathbf{C} and $\mathbf{K} \in \mathbb{R}^{n_{\text{DOF}} \times n_{\text{DOF}}}$ denote the mass, damping and stiffness matrix, respectively, and $\mathbf{f}(t)$ is the excitation vector. The excitation is factorized into an input force influence matrix $\mathbf{S}_p(t) \in \mathbb{R}^{n_{\text{DOF}} \times n_p}$, and the vector $\mathbf{p}(t) \in \mathbb{R}^{n_p}$ representing the n_p force time histories. Each column of the matrix \mathbf{S}_p gives the spatial distribution of the load time history in the corresponding element of the vector \mathbf{p} . In the case of a point load, the column of \mathbf{S}_p has only a limited number of non-zero entries corresponding to the distribution of the load over the degrees of freedom of the FE mesh. In the case of stochastic loading e.g. due to wind, the columns of the matrix \mathbf{S}_p may result from the decomposition of the load in uncorrelated contributions, e.g. by applying a Karhunen-Loève decomposition [5]. The undamped eigenvalue problem corresponding to (1) reads:

$$\mathbf{K}\Phi = \mathbf{M}\Phi\Omega^2$$

where $\Phi \in \mathbb{R}^{n_{\text{DOF}} \times n_{\text{DOF}}}$ collects as columns the eigenvectors Φ_j , and Ω is a diagonal matrix containing the eigenfrequencies ω_j in rad/s. Introducing the coordinate transformation $\mathbf{u}(t) = \Phi\mathbf{z}(t)$ and premultiplying by Φ^T yields:

$$\Phi^T \mathbf{M} \Phi \ddot{\mathbf{z}}(t) + \Phi^T \mathbf{C} \Phi \dot{\mathbf{z}}(t) + \Phi^T \mathbf{K} \Phi \mathbf{z}(t) = \Phi^T \mathbf{S}_p(t) \mathbf{p}(t). \quad (2)$$

These equations can be decoupled by using the orthogonality conditions corresponding to a set of mass-normalized eigenvectors, $\Phi^T \mathbf{M} \Phi = \mathbf{I}$ and $\Phi^T \mathbf{K} \Phi = \Omega^2$, and assuming proportional damping:

$$\Phi^T \mathbf{C} \Phi = \Gamma$$

where Γ is a diagonal matrix containing the terms $2\xi_j\omega_j$, and ξ denotes a modal damping ratio. The decoupled governing equations of motion in modal coordinates then become:

$$\ddot{\mathbf{z}}(t) + \Gamma \dot{\mathbf{z}}(t) + \Omega^2 \mathbf{z}(t) = \Phi^T \mathbf{S}_p(t) \mathbf{p}(t). \quad (3)$$

2.2 Continuous-time state-space model

By introducing the state vector $\mathbf{x}(t) \in \mathbb{R}^{n_s \times n_s}$, $n_s = 2n_{\text{DOF}}$:

$$\mathbf{x}(t) = \begin{pmatrix} \mathbf{u}(t) \\ \dot{\mathbf{u}}(t) \end{pmatrix}$$

and utilizing the superficial identity $\mathbf{M}\dot{\mathbf{u}} - \mathbf{M}\dot{\mathbf{u}} = \mathbf{0}$, the second-order equations of motion (1) can be written as a first-order continuous-time state equation:

$$\dot{\mathbf{x}}(t) = \mathbf{A}_c \mathbf{x}(t) + \mathbf{B}_c \mathbf{p}(t) \quad (4)$$

where the system matrices $\mathbf{A}_c \in \mathbb{R}^{n_s \times n_s}$ and $\mathbf{B}_c \in \mathbb{R}^{n_s \times n_p}$ are defined as:

$$\mathbf{A}_c = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\mathbf{M}^{-1}\mathbf{C} \end{bmatrix}, \quad \mathbf{B}_c = \begin{bmatrix} \mathbf{0} \\ \mathbf{M}^{-1}\mathbf{S}_p \end{bmatrix}.$$

Consider next the measurement data vector $\mathbf{d}(t) \in \mathbb{R}^{n_d}$, containing the n_d observed quantities expressed as a linear combination of the displacement, velocity and acceleration vectors as follows:

$$\mathbf{d}(t) = \mathbf{S}_a \ddot{\mathbf{u}}(t) + \mathbf{S}_v \dot{\mathbf{u}}(t) + \mathbf{S}_d \mathbf{u}(t) \quad (5)$$

where \mathbf{S}_a , \mathbf{S}_v and $\mathbf{S}_d \in \mathbb{R}^{n_d \times n_{\text{DOF}}}$ are selection matrices for acceleration, velocity and displacement, respectively, in which the locations of the measurements and/or difference relations can be specified. Using equation (1) and the definition of the state vector, equation (5) can be transformed into its state-space form:

$$\mathbf{d}(t) = \mathbf{G}_c \mathbf{x}(t) + \mathbf{J}_c \mathbf{p}(t) \quad (6)$$

with the output influence matrix $\mathbf{G}_c \in \mathbb{R}^{n_d \times n_s}$ and direct transmission matrix $\mathbf{J}_c \in \mathbb{R}^{n_d \times n_p}$ defined as:

$$\mathbf{G}_c = \begin{bmatrix} \mathbf{S}_d - \mathbf{S}_a \mathbf{M}^{-1} \mathbf{K} & \mathbf{S}_v - \mathbf{S}_a \mathbf{M}^{-1} \mathbf{C} \end{bmatrix}, \quad \mathbf{J}_c = [\mathbf{S}_a \mathbf{M}^{-1} \mathbf{S}_p].$$

Equations (4) and (6) together form the continuous-time state-space model for the full-order system described by equation (1). If a model reduction is performed, i.e. if the dynamics of the system are represented by a reduced number n_m of modal coordinates $\mathbf{z}(t) \in \mathbb{R}^{n_m}$ as $\mathbf{u}(t) = \Phi_r \mathbf{z}(t)$, $\Phi_r \in \mathbb{R}^{n_{\text{DOF}} \times n_m}$, the state vector is transformed accordingly:

$$\mathbf{x}(t) = \begin{bmatrix} \Phi_r & \mathbf{0} \\ \mathbf{0} & \Phi_r \end{bmatrix} \zeta(t).$$

The modal state vector $\zeta(t) \in \mathbb{R}^{2n_m}$ now collects the modal coordinates:

$$\zeta(t) = \begin{pmatrix} \mathbf{z}(t) \\ \dot{\mathbf{z}}(t) \end{pmatrix}$$

and the expressions for the reduced-order continuous-time system matrices $\mathbf{A}_c \in \mathbb{R}^{2n_m \times 2n_m}$, $\mathbf{B}_c \in \mathbb{R}^{2n_m \times n_p}$, $\mathbf{G}_c \in \mathbb{R}^{n_d \times 2n_m}$ and $\mathbf{J}_c \in \mathbb{R}^{n_d \times n_p}$ in the modal state-space model:

$$\dot{\zeta}(t) = \mathbf{A}_c \zeta + \mathbf{B}_c \mathbf{p}(t) \quad (7)$$

$$\mathbf{d}(t) = \mathbf{G}_c \zeta(t) + \mathbf{J}_c \mathbf{p}(t) \quad (8)$$

can be shown to reduce to:

$$\mathbf{A}_c = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\Omega^2 & -\Gamma \end{bmatrix} \quad (9)$$

$$\mathbf{B}_c = \begin{bmatrix} \mathbf{0} \\ \Phi^T \mathbf{S}_p \end{bmatrix} \quad (10)$$

$$\mathbf{G}_c = \begin{bmatrix} \mathbf{S}_d \Phi - \mathbf{S}_a \Phi \Omega^2 & \mathbf{S}_v \Phi - \mathbf{S}_a \Phi \Gamma \end{bmatrix} \quad (11)$$

$$\mathbf{J}_c = [\mathbf{S}_a \Phi \Phi^T \mathbf{S}_p]. \quad (12)$$

2.3 Discrete-time state-space model

Using a sampling rate of $1/\Delta t$, the state-space model of equations (4) and (6) - or the modal model of equations (7) and (8) - can be discretized to yield its discrete-time equivalent:

$$\mathbf{x}_{k+1} = \mathbf{A} \mathbf{x}_k + \mathbf{B} \mathbf{p}_k \quad (13)$$

$$\mathbf{d}_k = \mathbf{G} \mathbf{x}_k + \mathbf{J} \mathbf{p}_k \quad (14)$$

where $\mathbf{x}_k = \mathbf{x}(k\Delta t)$, $\mathbf{d}_k = \mathbf{d}(k\Delta t)$, $k = 1, \dots, N$ and:

$$\mathbf{A} = e^{\mathbf{A}_c \Delta t}, \mathbf{B} = [\mathbf{A} - \mathbf{I}] \mathbf{A}_c^{-1} \mathbf{B}_c, \mathbf{G}_c = \mathbf{G}, \mathbf{J}_c = \mathbf{J}.$$

3 JOINT INPUT-STATE ESTIMATION

In this section the joint input-state estimation algorithm developed by Gillijns and De Moor for linear systems with direct feedthrough of the unknown input to the output [6] is presented. Having direct feedthrough corresponds, from a structural dynamics point of view, to the situation where the measured quantities are accelerations, which is commonly the case. More details on the derivation of this algorithm and a proof of optimality, in a minimum-variance unbiased sense, can be found in [6].

The linear system under consideration is the discrete-time state-space system of equations (13) and (14), supplemented with random variables \mathbf{w}_k and \mathbf{v}_k representing the stochastic system and measurement noise, respectively:

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{B}\mathbf{p}_k + \mathbf{w}_k \quad (15)$$

$$\mathbf{d}_k = \mathbf{G}\mathbf{x}_k + \mathbf{J}\mathbf{p}_k + \mathbf{v}_k. \quad (16)$$

The noise vectors $\mathbf{w}_k \in \mathbb{R}^{n_s}$ and $\mathbf{v}_k \in \mathbb{R}^{n_d}$ are assumed to be mutually uncorrelated, zero-mean, white signals with known covariance matrices $\mathbf{Q} = \mathbb{E}\{\mathbf{w}_k \mathbf{w}_k^T\} \geq \mathbf{0}$ and $\mathbf{R} = \mathbb{E}\{\mathbf{v}_k \mathbf{v}_k^T\} > \mathbf{0}$. Results can easily be generalized to the case where \mathbf{w}_k and \mathbf{v}_k are correlated by applying a preliminary transformation to the system [1, 6]. Results can also be generalized to systems with both known and unknown inputs [6].

A state estimate $\hat{\mathbf{x}}_{k|l}$ is defined as an estimate of \mathbf{x}_k given $\{\mathbf{d}_n\}_{n=0}^l$ and its error covariance matrix $\mathbf{P}_{k|l}$ as $\mathbb{E}[(\mathbf{x}_k - \hat{\mathbf{x}}_{k|l})(\mathbf{x}_k - \hat{\mathbf{x}}_{k|l})^T]$. An initial unbiased state estimate $\hat{\mathbf{x}}_{0|-1}$ and its covariance matrix $\mathbf{P}_{0|-1}$ is assumed known. The initial state estimate $\hat{\mathbf{x}}_0$ is assumed independent of \mathbf{w}_k and \mathbf{v}_k for all k . Finally, it is assumed that the rank of the direct transmission matrix \mathbf{J} equals the number of applied forces n_p , and that the pair (\mathbf{A}, \mathbf{G}) is observable. It can be proven that the latter two assumptions are almost always valid when dealing with structural dynamic systems.

The filter is initialized using the initial state and its variance, $\hat{\mathbf{x}}_{0|-1}$ and $\mathbf{P}_{0|-1}$; hereafter it computes the force and state estimates recursively in three steps: the input estimation, the measurement update, and the time update:

Input estimation:

$$\tilde{\mathbf{R}}_{[k]} = \mathbf{G}\mathbf{P}_{[k|k-1]}\mathbf{G}^T + \mathbf{R} \quad (17)$$

$$\mathcal{M}_{[k]} = \left(\mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \mathbf{J} \right)^{-1} \mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \quad (18)$$

$$\hat{\mathbf{p}}_{[k|k]} = \mathcal{M}_{[k]} (\mathbf{d}_{[k]} - \mathbf{G}\hat{\mathbf{x}}_{[k|k-1]}) \quad (19)$$

$$\mathbf{P}_{\mathbf{p}[k|k]} = \left(\mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \mathbf{J} \right)^{-1} \quad (20)$$

Figure 1: The measurement setup

Measurement update:

$$\mathbf{L}_{[k]} = \mathbf{P}_{[k|k-1]} \mathbf{G}^T \tilde{\mathbf{R}}_{[k]}^{-1} \quad (21)$$

$$\hat{\mathbf{x}}_{[k|k]} = \hat{\mathbf{x}}_{[k|k-1]} + \mathbf{L}_{[k]} (\mathbf{d}_{[k]} - \mathbf{G} \hat{\mathbf{x}}_{[k|k-1]} - \mathbf{J} \mathbf{p}_{[k|k]}) \quad (22)$$

$$\mathbf{P}_{[k|k]} = \mathbf{P}_{[k|k-1]} - \mathbf{L}_{[k]} (\tilde{\mathbf{R}}_{[k]} - \mathbf{J} \mathbf{P}_{\mathbf{p}[k|k]} \mathbf{J}^T) \mathbf{L}_{[k]}^T \quad (23)$$

$$\mathbf{P}_{\mathbf{x}\mathbf{p}[k|k]} = \mathbf{P}_{\mathbf{p}\mathbf{x}[k|k]}^T = -\mathbf{L}_{[k]} \mathbf{J} \mathbf{P}_{\mathbf{p}[k|k]} \quad (24)$$

Time update:

$$\mathbf{x}_{[k+1|k]} = \mathbf{A} \hat{\mathbf{x}}_{[k|k]} + \mathbf{B} \hat{\mathbf{p}}_{[k|k]} \quad (25)$$

$$\mathbf{P}_{[k+1|k]} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \end{bmatrix} \begin{bmatrix} \mathbf{P}_{[k|k]} & \mathbf{P}_{\mathbf{x}\mathbf{p}[k|k]} \\ \mathbf{P}_{\mathbf{p}\mathbf{x}[k|k]} & \mathbf{P}_{\mathbf{p}[k|k]} \end{bmatrix} \begin{bmatrix} \mathbf{A}^T \\ \mathbf{B}^T \end{bmatrix} + \mathbf{Q} \quad (26)$$

It is mentioned that when $\mathbf{B} = \mathbf{J} = \mathbf{0}$, the Kalman filter is obtained. In the above, the system matrices are for ease of notation not indexed. The algorithm can, however, also be applied to time-variant systems by simply adding the appropriate subscripts, i.e. \mathbf{A}_k , \mathbf{B}_k , \mathbf{G}_k and \mathbf{J}_k .

4 EXPERIMENTAL RESULTS

In this section the effectiveness of the proposed algorithm is illustrated by means of a laboratory experiment on an instrumented steel beam as well as an in situ experiment on a footbridge.

4.1 Laboratory experiment on a steel beam

A steel beam with an IPE100 cross section, a length of 3m, and plates of 150x150x15 mm welded to its ends, is suspended at both ends from a steel frame using flexible springs to simulate free-free boundary conditions. A series of accelerometers is placed along the beam to record its response to an impact force, applied with an instrumented hammer. The aim here is to use a subset of the measured accelerations to identify the remaining (measured) accelerations.

Vertical accelerations on the top flange of the beam were measured at 17 different cross sections using 19 accelerometers (PCB 338B35, sensitivity ± 100 mV/g). The force was applied eccentrically with an impact hammer (PCB 086C03, mass 0.136 kg) at one of the free-free beam

Figure 2: Positions of the sensors and applied force.

ends. The measurement setup and positions of the sensors and applied force are shown in figures 1 and 2. The modal parameters of the beam were identified in a Operational Modal Analysis with eXogenous inputs (OMAX) test [13] for the frequency range 0 – 900 Hz. More details on this test and its results can be found in [10]. The identified modal parameters were used to tune the Young's modulus of the steel and the stiffness of the springs in a FE model. A comparison between the identified and computed eigenmodes is shown in table 1. Except for the torsional modes, whose contribution to the acceleration response considered is almost negligible, a good correspondence is found between the measured and experimental eigenfrequencies. All modes are very lightly damped with damping ratios below 0.5 % of critical.

No.	FEM	Experimental

Table 1: Comparison between the undamped eigenfrequencies f_{udi} of the FE model of the beam and those that were experimentally obtained. The experimental damping ratios ξ_i and MAC values between the measured mass-normalized mode shapes and the ones obtained from the FE model, are shown as well.

The 15 modes from the FE model, consisting of 3 rigid body, 5 bending and 7 torsional modes, are used to construct a reduced-order modal state-space model of the beam. Originally sampled at 10 kHz, all data used in the inverse calculations are resampled at a lower rate in order to include only frequencies within the range of the identified modes. Using a decimation factor of 5, the data is low-pass filtered using a Chebychev Type I filter at 800Hz and subsequently resampled at 2 kHz.

Of the 19 measured accelerations, 10 are used to identify the modal states and input forces, from which the acceleration (or displacement, strain, etc.) at any other point in the structure can be calculated as $\hat{\mathbf{d}} = \mathbf{G}\hat{\mathbf{x}} + \mathbf{J}\hat{\mathbf{p}}$. It is assumed that no a priori information on the positions of the forces is available and a set of equivalent forces are assumed to act at all measurement locations used for the identification, i.e. at positions $a_1, a_3, a_4, a_6, a_9, a_{11}, a_{15}, a_{17}, a_{18}$ and a_{19} . The accelerations identified at the remaining locations are compared to the measured data during a period of 1 s. The covariance matrices \mathbf{Q} , \mathbf{R} and $\mathbf{P}_{0|-1}$ are assigned values of $1e^{-10}$, $1e^{-1}$ and $1e^{-10}$ on the diagonal, respectively. In accordance with what they represent, these values are chosen so as to have the order of the square roots of the diagonal elements of \mathbf{R} and \mathbf{Q} corresponding to a small percentage of the highest peaks in the measured response and the states (displacements/velocities), respectively. The small values in $\mathbf{P}_{0|-1}$ indicate a low level of uncertainty regarding the initial state estimate. It is mentioned that the results are, however, not strongly influenced by these values and similar results are obtained for a large range of \mathbf{Q} , \mathbf{R} and $\mathbf{P}_{0|-1}$.

Figure 3: a) Complete and b) detail of the measured (black) and identified (grey) time history of the acceleration at sensor a_7 .

Figure 4: Frequency spectrum of the measured (black) and identified (grey) acceleration at sensor a_7 .

Figures 3 to 8 show the results obtained when the beam is excited with the hammer at $t = \pm 0.15s$. Measured accelerations are plotted against those identified for three randomly chosen locations, namely a_7 , a_{13} and a_{16} . The accelerations are compared in the time as well as in the frequency domain, and a detail of the acceleration time history at the time of impact is presented as well. A good reconstruction is obtained at all 3 locations.

Figure 5: a) Complete and b) detail of the measured (black) and identified (grey) time history of the acceleration at sensor a_{13} .

Figure 6: Frequency spectrum of the measured (black) and identified (grey) acceleration at sensor a_{13} .

Figure 7: a) Complete and b) detail of the measured (black) and identified (grey) time history of the acceleration at sensor a_{16} .

4.2 In situ experiment on a footbridge

Analogous to the previous test case, a subset of the accelerations measured during an in situ test on a footbridge is used to identify modal states and a set of equivalent forces. The identified modal states and forces are subsequently used to calculate the accelerations at the remaining measured positions and a comparison is made. The footbridge, depicted in figure 9, is located in Wetteren (Belgium), and has been used as an in situ test case for Operational Modal Analysis (OMA) [12] and previously mentioned OMAX techniques. It is a steel bridge that crosses the E40 highway between Brussels and Ghent at Wetteren, with a short and long bow-string span of 30.33m and 75.23m, respectively.

For the OMAX tests, measurements have been performed in a total number of 72 channels

Figure 8: Frequency spectrum of the measured (black) and identified (grey) acceleration at sensor a_{16} .

Figure 9: The footbridge in Wetteren, Belgium.

during different setups. The locations of the sensors are shown in figure 10. The data used in the current example was obtained during excitation of the bridge by means of a drop weight system. The drop weight was applied at point 34, in the vertical direction, and during the setup accelerations were measured in 16 channels. In the following, 8 of the measured accelerations will be used to identify the modal states and to reconstruct the accelerations at the 8 remaining locations. Equivalent loads are assumed to act in the directions and at the locations of the 8 measured accelerations. The actual load on the structure consists of the drop weight as well as a high level of ambient excitation due to traffic underneath the bridge and wind.

Of the 16 measured accelerations, 4 vertical and 4 lateral accelerations were identified as optimal for the identification. These are the vertical accelerations in points 2, 3, 24 and 34 on the bridge deck, the lateral accelerations on the bridge deck at points 14 and 19, and the lateral accelerations of the bow at points 45 and 48. With the optimal 8 accelerations as input, the proposed algorithm is used to identify 7 ‘unmeasured’ vertical accelerations at points 8, 12, 14, 25, 30, 36 and 41 on the bridge deck, and the lateral acceleration at point 12 on the bow.

The system matrices are constructed from an updated finite element (FE) model of the bridge. In the FE model, developed using the FE program ANSYS, the bridge deck is modeled using the ANSYS shell element SHELL63. The longitudinal and transversal beams of the bridge deck, as well as the bows, connections of the bows, and supports, are modeled using the beam element BEAM188. A 3D truss element, LINK8, is used to model the cables, taking into account the effective stiffness E_{eff} of the cable based on the tensile cable force. The model has a total of

Figure 10: Positions of the sensors.

16007 nodes and 2210 elements. The first 4 modes calculated with the model are shown in figure 11.

Figure 11: Results from the FE modal analysis for the first 4 modes. Top: transversal displacements, middle: vertical displacements, bottom: displacement vector sum.

The FE model is updated using a set of experimental modal parameters obtained during an OMAX test [14] in which the actuator was a pneumatic artificial muscle (PAM) developed by the Acoustics and Vibration Research Group of the Vrije Universiteit Brussel [4]. Table 2 presents a comparison between the eigenfrequencies of the updated FE model and those that were identified experimentally. The experimental damping ratios as well as the MAC values between the mass-normalized mode shapes and the ones obtained from the FE model are shown in the table. The 22 eigenmodes of the FE model, in conjunction with the corresponding identified modal damping ratios, are used to construct a reduced-order modal state-space model of the structure. As before, all data used in the inverse calculations are resampled at a lower rate. Using a decimation factor of 23, the data is low-pass filtered using a Chebychev Type I filter at 17.39 Hz and subsequently resampled at 43.48 Hz. A period of 9 s, in which the impact from the drop-weight is applied at $t = 2.3$ s, is analysed.

As in the previous examples equivalent forces are assumed to act at all measurement locations. The covariance matrices \mathbf{Q} , \mathbf{R} and $\mathbf{P}_{0|-1}$ are assigned values of $1e^{-10}$, $1e^{-1}$ and $1e^{-10}$ on the diagonal, respectively. In figures 12 to 15, 4 of the 8 identified accelerations are compared to those measured. The results are for the vertical accelerations at points 12, 25 and 41 (figures 12 to 14), and the lateral acceleration at point 12 (figure 15).

The identified accelerations are of lesser quality than those in the laboratory experiment, which can partly be explained by the fact that the updated FE model of the footbridge represents the structure considerably less accurately than the one used in the laboratory experiment (cfr.

MAC values in tables 1 and 2). Also, the number of sensors used is small compared to the geometrical and modal complexity of the footbridge. Taking these circumstances into account

Figure 14: a) Time history and b) frequency spectrum of the measured (black) and identified (grey) vertical acceleration at point 41.

Figure 15: a) Time history and b) frequency spectrum of the measured (black) and identified (grey) lateral acceleration at point 12.

the identification is in fact very reasonable, especially those in the vertical direction. Moreover, the accuracy of the identification is similar for both the ambient part of the acceleration from $t = 0 - 2.3$ s, where the vibrations are caused by low amplitude traffic loads, and the remaining stronger intensity part of the acceleration caused by the drop weight. The identification of the lateral acceleration is considerably less good between the resonance frequencies (cfr. figure 15b), but the dominant frequency components are still well identified. It can be concluded that the proposed algorithm performs well even when a significant amount of modeling error is present.

5 CONCLUSIONS

An existing model-based joint input-state estimation algorithm requiring no prior information on the dynamic evolution of the input forces, was used to estimate the state of a structure from a limited number of acceleration measurements. The algorithm's accuracy and applicability were tested using data from a laboratory experiment on an instrumented steel beam as well as an in situ experiment on a footbridge. It is concluded that the algorithm is capable of accurately estimating the state of a structure from a limited number of noise-contaminated acceleration measurements, also when a relatively high level of modeling error is present and no prior information on the positions or nature of the input forces is available.

Abstract. *The scope of this paper is to identify the parameters affecting the dynamic response of an existing R/C bridge, based on low ambient amplitude vibration measurements and numerical predictions using complex finite element models. For this purpose, the instrumented, 2nd Kavala Bypass Ravine Bridge constructed along the Egnatia Motorway Greece is studied and a refined three- dimensional (3D) FEM is developed that takes into consideration the coupling and dynamic interaction of the overall superstructure-foundation-soil and deck-abutment-embankment system. The instrumentation schemes and the necessary algorithms applied for computing the modal characteristics of the bridge are discussed, while the modelling assumptions made for the soil-structure system are comparatively assessed and justified for various models of different levels of complexity. Given the large number of the system's degrees of freedom, a manual, modal-based FEM updating method is also presented. The results show good agreement between the measured and computationally predicted dynamic characteristics of the structure. They also show that the accurate estimation of the pier, deck and bearings stiffness is a key parameter for reliable system identification.*

1 INTRODUCTION

Structural health monitoring and identification of structural modes of existing civil engineering projects is nowadays a major component of system maintenance and management especially for highway transportation networks. The modal characteristics of structures can be evaluated either by identification systems that are based on ambient (i.e., due to traffic and wind) and earthquake-induced vibrations or by modal analysis of finite element models (FEMs). Important information can be derived by the comparative assessment between the results of the two methodologies as scientists can investigate the structural integrity of structures and also validate the reliability of the FEMs that are developed for the analysis, design and assessment of structures.

An identification system based on ambient vibrations involves the presence of factors imposing ambient vibrations to a structure, monitoring of the structural response (measured acceleration time histories) and the development of an appropriate mathematical algorithm. Such an algorithm uses the measured output data as an input for the prediction of the modal frequencies, modal damping ratios and mode shapes through classically damped or non-classically damped modal models. A significant number of methods [1] and the respective software have been developed for the identification of modal properties, based on ambient vibrations, both in the time and frequency domain. The methods, based on output measurements only, make the assumption that the input can be well represented by a vector white noise process. Recent developments are also reported in Peeters and De Roeck [2] and Basseville et al. [3] using time domain stochastic subspace identification methods, in Beck et al. [4] using time domain least-squares methods based on correlation functions of the output time histories, in Verboven [5], Gauberghe [6] and Brincker et al. [7] using frequency domain least-squares methods based on full cross-power spectral densities (CPSD), and in Peeters and Van der Auweraer [8] based on half spectra. Bayesian and maximum likelihood statistical methods have also been proposed, for example, in Katafygiotis and Yuen [9], Guillaume et al. [10] and Verboven [5].

On the other hand, the estimation of dynamic characteristics using modal-based analysis of finite element models requires appropriate software to carry out dynamic analysis. However, in the case of extended structures such as bridges, the compliance and damping of the supporting soil has to be taken into consideration as it may affect significantly both the dynamic characteristics of the soil-foundation-superstructure and the embankment-abutment-superstructure system. An efficient way to account for this phenomenon is to de-couple the problem into a kinematic and an inertial sub-structure (Mylonakis and Gazetas [11]). Alternatively, a holistic numerically modelling of the entire soil, structure and foundation system is also feasible (i.e. Wolf [12]).

Despite above advances, it is still quite common to observe differences between the measured dynamic characteristics of the structure and the dynamic characteristics predicted numerically by FEMs. For that reason, mathematical algorithms have been developed based on the identified modal characteristics (e.g. Mottershead and Friswell [13], Bohle and Fritzen [14], Teughels et al. [15], Lam et al. [16], Christodoulou and Papadimitriou [17]) that permit the re-estimation of the structural parameters of the finite element models and the minimization of the induced error. These algorithms use the identified modal data and formulate them as weighted least-squares problems in which the optimal values of the structural parameters of a FEM are obtained by minimizing a measure of the residuals between the measured and numerically predicted modal characteristics. Alternatively, the structural parameters of the finite element model can be automatically updated, based on the identified modal data, without the development of a mathematical algorithm. This automatic

model updating procedure solely consists of a sequential parametric analysis for different values of the structural parameters, until the percentage of error between the measured and predicted modes is minimized. Both the aforementioned calibration procedures for model updating provide an insight into the epistemic uncertainties related to the simplified assumptions and idealizations inevitably made during the development of FEMs. These uncertainties include the uncertainty in the model topology, the uncertainty in the boundary conditions of the model and the uncertainty in the material properties.

Along these lines, the scope of this paper is to qualitatively and quantitatively validate the uncertainties associated with the modeling assumptions made and to estimate which of them influences most the reliability of the results, at least for the particular bridge studied. For that purpose, a modal identification approach based on ambient vibrations, three FEMs of different modeling complexity and two model updating methods (automatic and manual) were implemented. The description of the bridge, the methodology adopted and the comparative assessment of the results obtained are presented in the following.

2 DESCRIPTION OF THE BRIDGE STUDIED

2.1 Structural system

The 2nd Kavala Bypass Ravine Bridge, shown in Figure 1, is a newly built bridge located in Section 13.7 of Egnatia, a major 670km highway constructed on the traces of the ancient Roman path, crossing northern Greece from its western to its eastern border. Its overall length is 170m and comprises two statically independent branches, with four identical simply supported spans of 42.5m. Each span is built with four precast post-tensioned I-beams of 2.80m height that support a continuous deck of 26cm thickness and 13m width. The I-beams are supported by 2 abutments (A1 and A2) and by 3 piers (M1, M2 and M3) through laminated elastomeric bearings. Each abutment has 4 cyclic bearings and each pier has 8 rectangular bearings. The piers have a 4×4m hollow cross-section, 40cm wall thickness and heights equal to 30m (M1, M3) and 50m (M2), all supported with large caissons on relatively stiff soil (corresponding to soil class “A” according to both the Greek Seismic Code and the Eurocode 8 soil classification). The four spans of the deck are interconnected through a 2-m long 20-cm thick continuity slab over the piers.

2.2 Instrumentation

Between the two identical branches of the 2nd Kavala Bypass Ravine Bridge only the southern branch is instrumented. The instrumentation consists of a 24-accelerometer array [1], one at each deck side and located at the middle of each bridge span. More specifically, the accelerometers are installed both on the external sidewalk of the deck and on the internal New Jersey barrier of the deck. As shown in Figure 2, 18 of the 24 sensors are installed on the deck and two at the top of each of the three piers (six in all) next to the laminated elastomeric bearings so that adequate information is provided to distinguish between the pier and bearing stiffness. The sensors on the deck have a 3-letter label that follow the above explained convention: The last letter denotes the orientation of the uniaxial sensor (L: longitudinal, T: transverse, V: vertical). The previous one denotes the side of the bridge deck on which the sensor lies (R: right, L: left). Finally, the first letter denotes the bridge section that the sensor lays on (A1, B1, C1 or D1). The numbers next to each sensor label denotes the length of the cable used to connect the sensor to each recording unit. The sensors on the piers follow the same convention used for the sensors on the deck with the exception that the letters U1, U2

and U3 refer to the top of the piers. The particular layout of the instrumentation permits the recording of the dynamic response of the bridge under ambient loads.

This recording system has start/common trigger capabilities to enable synchronous data acquisition. The trigger threshold can be set independently for each sensor, and the user can define the sensors that will cause a system trigger. The systems are equipped with GPS boards as well as with external GSM/GPRS cellular modems that allowed telematic control and data transfer to the user offices.

3 IDENTIFICATION OF STRUCTURAL MODES VIA AMBIENT VIBRATIONS

The methodology of identifying structural modes via ambient vibrations is based [1] on a least squares minimization of the measure of fit between the cross power spectral density (CPSD) matrix $\hat{S}(k\Delta\omega) \in \mathbb{C}^{N_0 \times N_0}$ and the CPSD matrix $S(k\Delta\omega; \psi) \in \mathbb{C}^{N_0 \times N_0}$. The $\hat{S}(k\Delta\omega)$ matrix is estimated from the measured output acceleration time histories and the $S(k\Delta\omega; \psi)$ matrix is predicted by a modal model. In Equation 1 N_0 is the number of measured degrees of freedom (DOF), $\Delta\omega$ is the discretization step in the frequency domain, $k = \{1, \dots, N_\omega\}$ is the index set corresponding to frequency values $\omega = k\Delta\omega$, N_ω is the number of data in the indexed set, and ψ is the parameter set to be estimated.

$$E(\psi) = \sum_{k=1}^{N_\omega} \text{tr} \left[S(k\Delta\omega; \psi) - \hat{S}(k\Delta\omega)^{*T} \left(S(k\Delta\omega; \psi) - \hat{S}(k\Delta\omega) \right) \right] \quad [1]$$

Gauberghe [6], as described in Equation 2, gives the CPSD matrix $S(k\Delta\omega; \psi)$ with the assumption of general non-classically damped modes. In Equation 2 m is the number of contributing modes in the frequency range of interest, λ_r is equal to $(-\zeta_r \omega_r \pm j\omega_r - 1 - \zeta_r^2)$ and is the complex eigenvalue of the r -th contributing mode. In Equation 2 ω_r is the r -th modal frequency, ζ_r is the r -th modal damping ratio, $\phi_r \in \mathbb{C}^{N_0 \times N_0}$ is the complex mode shape of the r -th mode, $A \in \mathbb{C}^{N_0 \times N_0}$, $B \in \mathbb{C}^{N_0 \times N_0}$ are real symmetric matrices accounting for the contribution of the out-of-bound modes to the selected frequency range of interest, and $g_r \in \mathbb{C}^{N_0 \times N_0}$ are vector quantities that depend on the characteristics of the modal model and the CPSD of the white noise input vector, while the symbol u^* denotes the complex conjugate of a complex number u .

$$S(\omega; \psi) = \sum_{r=1}^m \left[\frac{\phi_r g_r^T}{(j\omega) - \lambda_r} + \frac{\phi_r^* g_r^{*T}}{(j\omega) - \lambda_r^*} + \frac{g_r \phi_r^T}{-(j\omega) - \lambda_r} + \frac{g_r^* \phi_r^{*T}}{-(j\omega) - \lambda_r^*} \right] \quad [2]$$

$$+ \frac{1}{(j\omega)^4} A + B$$

The CPSD matrix in Equation 2 is defined by the parameters ω_r , ζ_r , ϕ_r , g_r , $r = 1, \dots, m$, A and B . The modal parameter set ψ contains the above mentioned parameters and has to be identified. For non-classically damped modal models, the total number of parameters is $2m(1 + 2N_0) + N_0^2 + N_0$.

The objective is the minimization of Equation 1 and that can be carried out efficiently [18], significantly reducing computational cost, by recognizing that the error in Equation 1 is quadratic with respect to the complex modeshapes ϕ_r and the elements in the matrices A and B . This observation is used to develop explicit expressions that relate the parameters ϕ_r , A and B to the vectors g_r , the modal frequencies ω_r and the damping ratios ζ_r , so that the number of parameters involved in the optimization is reduced from $2m(1 + 2N_0) + N_0^2 + N_0$ to $2m(N_0 + 1)$. This reduction is considerable for a relatively large number of measurement points. Applying the optimality conditions in Equation 1 with respect to the components of ϕ_r , A and B , a linear system of equations results for obtaining ϕ_r , A and B with respect to the g_r , ω_r and ζ_r , $r = 1, \dots, m$. The resulting nonlinear optimization problem with respect to the remaining variables g_r , ω_r and ζ_r , where $r = 1, \dots, m$, is solved in Matlab using available gradient-based optimisation algorithms.

The starting values required in the optimization are obtained from a two-step approach as follows. In the first step, conventional least squares complex frequency algorithms [5] are employed, along with stabilization diagrams, to obtain estimates of the modal frequencies ω_r and modal damping ratios ζ_r and distinguish between the physical and the mathematical modes. These values in most cases are very close to the optimal values. In the second step, given the values of ω_r and ζ_r , the values of the residue matrices $R_r = \phi_r g T_r \in \mathbb{C}^{N_0 \times N_0}$ in Equation 2 are obtained by first recognizing that the objective in Equation 1 is quadratic with respect to R_r , A and B , then formulating and solving the resulting linear system of equations for R_r , A and B , and finally applying singular value decomposition to obtain estimates of ϕ_r and g_r from R_r . Usually, this two-step approach gives results that are very close to the optimal estimates. However, for closely spaced and overlapping modes it is often recommended to solve the original nonlinear optimization problem with respect to g_r , ω_r and ζ_r , $r = 1, \dots, m$, using the estimates of the two-step approach as starting values.

4 ALTERNATIVE FINITE ELEMENT MODELS DEVELOPED

Three FEMs of increasing modeling complexity were created based on the exact geometrical and material properties that were used for design. The first model is an one-dimensional (i.e., frame type), fixed-base model (hereafter called “1D-Fixed”), the second is a three-dimensional, fixed-base (“3D-Fixed”) and the third is a model for which the whole soil-foundation-structure system has been simulated in 3D space (“3D-3D Soil”). The numerical simulation of the 1D-Fixed model was carried out with the computer program COMSOL 2005 multi-physics, while the numerical simulation of the other two 3D models was carried out with ABAQUS 6.8.

The 1D-Fixed model of the Kavala bridge [1] was simulated using three-dimensional, two node, beam-type finite elements for the modeling of the structural elements (deck, I-beams, piers and bearings). This model is shown in Figure 3 and has 900 degrees of freedom. The cross-sectional parameters of each one of the longitudinal beam elements are those of an equivalent cross-section that accounts for the section of the post-tensioned beam, as well as the corresponding effective width of the deck plate. The transverse beams at the two ends of the span correspond to the existing cross-beams above the bearings, whereas the other four transverse beams represent the coupling of the longitudinal beams in the transverse direction due to the presence of the deck. Adjacent spans are interconnected with a 20-cm thick 2-m long plate. The piers and the abutments bearing are assumed fixed at their base.

Figure 3: Overview of the fixed base, 1D superstructure finite element model (1D-Fixed).

Figure 4: Overview and fundamental mode in the transverse direction (top) of the fixed base, 3D superstructure finite element model (3D-Fixed), as well as modelling details of the deck, stoppers and bearings (bottom).

The 3D-Fixed model of the Kavala bridge was simulated using three-dimensional eight node brick-type finite elements to model the entire superstructure. This model is shown in Figure 4 and has approximately 241,000 degrees of freedom. The mesh size of the elements used for bearing modeling was $0.25 \times 0.25\text{m}$ while an average mesh size for the concrete sections was $0.75 \times 0.75\text{m}$. In this refined 3D FEM the deck, the I-beams, the piers, the bearings and the stoppers were modeled in maximum detail in 3D space. The abutments are considered as non-deformable, whereas the piers are assumed to be rigidly connected to the foundation, ignoring, in this version of the model, soil-structure interaction effects. Similarly, the piers and the abutment bearings are assumed fixed at their base.

The 3D-3D Soil model of the Kavala bridge is shown in Figure 5 and has approximately 960,000 degrees of freedom. In a similar fashion to the previous model, the superstructure is modeled in maximum possible detail. In addition, the entire soil-foundation-superstructure system is simulated, considering the exact geometry of the abutment-backfill-embankment system and the middle piers-caisson-soil substructure system. Mesh size for the superstructure was taken identical to the previous 3D-Fixed model and was also set equal to $2 \times 2\text{m}$ for the surrounding and supporting soil. In order to reduce the computational time required, an additional, equivalent model of the 3D-3D Soil was also developed, after establishing a level of agreement between the two models by ensuring identical dynamic characteristics. This model is shown in Figure 6, 407,000 degrees of freedom and considered a smaller, though, adequate part of the soil volume. Given the compatibility of the two latter models in terms of system stiffness and damping, most analyses cases were carried out with this model instead of the initial 3D-3D Soil model.

Figure 5: Overview and fundamental mode in the transverse direction of the 3D soil-foundation-superstructure finite element model (3D-3D Soil).

Figure 6: Overview and fundamental mode in the transverse direction of the equivalent 3D-3D Soil model as well as modelling details of the abutment-embankment system and the pier foundation subsoil.

5 FINITE ELEMENT MODEL UPDATING METHODOLOGY

The objective in a FEM updating methodology is to estimate the values of the structural parameter set $\theta \in \mathbb{R}^{N_\theta}$ of a class of linear FEMs so that the modal frequencies and modeshapes $\{\omega_r(\theta), \phi_r(\theta) \in \mathbb{R}^{N_0}, r = 1, \dots, m\}$ predicted by the linear class of models best matches, in some sense, the experimentally obtained modal data $\{\hat{\omega}_r, \hat{\phi}_r \in \mathbb{R}^{N_0}, r = 1, \dots, m\}$ contained in the set ψ , where m is the number of observed modes, and N_0 is the number of recorded DOFs. The optimal values of the parameter set θ are obtained by minimizing the weighted modal residuals [17].

$$J(\theta; w) = \sum_{r=1}^m \left[w_{w_r} \frac{[w_r(\theta) - \hat{w}_r]^2}{[\hat{w}_r]^2} + w_{\phi_r} \frac{\|\beta_r \phi_r(\theta) - \hat{\phi}_r\|^2}{\|\hat{\phi}_r\|^2} \right] \quad [3]$$

The first norm in Equation 3 represents the difference between the measured and the model predicted frequency for the r -th mode, while the second norm represents the difference between the measured and the model predicted modeshape components for the r -th mode, where $\beta_r = \hat{\phi}_r^T \phi_r(\theta) / \phi_r^T(\theta) \phi_r(\theta)$ is a normalizing scalar guaranteeing that the measured $\hat{\phi}_r$ is closest to $\phi_r(\theta)$ for given θ . The weighting factors $w_{\omega_r} \geq 0$ and $w_{\phi_r} \geq 0$, $r = 1, \dots, m$, satisfy the condition $\sum_{r=1}^m [w_{\omega_r} + w_{\phi_r}] = 1$. The objective function $J(\theta; w)$ represents an overall measure of fit between the measured and the model predicted modal characteristics. Herein, conventional weighted least squares methods are used which assume equal weight values. Finally, the optimization of $J(\theta; w)$ in Equation 3 with respect to θ can readily be carried out numerically using any available gradient-based algorithms for optimizing a nonlinear function of several variables. This procedure is described more detailed in Ntotsios et al. [19].

The above mentioned mathematical algorithm was applied for the updating of the 1D-Fixed model of the Kavala bridge. For that purpose, a Matlab code was developed in interaction with the computer program COMSOL, wherein the structure was simulated. In contrast, given the large number of degrees of freedom of the 3D-Fixed model and the 3D-3D Soil model of the Kavala bridge, their model updating was performed manually through a sequential parametric analysis scheme. The concept behind this simplified, manual updating approach for the 3D finite element models is described in detail in Section 6.

6 COMPARATIVE ASSESMENT OF THE PREDICTED AND MEASURED RESPONSE

6.1 Measured and predicted structural modes of Kavala Bridge

The accelerometers installed along the deck and at the top of the three piers recorded the bridge's response and the acceleration time histories were then used as input to the model updating mathematical algorithm described in Section 3. Through this procedure, two transverse, one longitudinal and four bending modes were identified, whose modal frequencies are summarized in Table 1. Since the scope of the present research work was to validate, both qualitatively and quantitatively, the modeling assumptions made and to identify their relative impact on the numerically predicted structural response, the three finite element models developed were assessed comparatively.

The first comparison was made between the 1D-Fixed and 3D-Fixed models and aimed to identify the differences that arise by the inherent simplifications of the one dimensional modeling in contrast to the refined three dimensional modeling of the piers, I-beams, bearings and stoppers. For this reason, the soil compliance was deliberately not accounted for. The results of the predicted modal frequencies from the above models (i.e., 1D-Fixed and 3D-Fixed) are shown in Table 1. It can be seen that the agreement between the two models was very good (it is only the first two bending modes where the difference exceeds 10%), a fact that reveals that the assumptions made for the simplified 1D-Fixed model were reasonable. Despite their agreement though, it was evident that both models fail to predict well the actual, measured response as they exhibit large deviations from the identified modal frequencies that exceed 55% in the longitudinal direction and 34% and 58% respectively for the first two modes, in the transverse direction. In general, it is observed that the modes measured via

ambient vibrations are on average 32% higher than those predicted by the two finite element modes, thus, the real structure is identified as significantly stiffer than predicted using the 1D and 3D fixed-base models.

A second comparison was made between the 3D-Fixed and the 3D-3D Soil models in order to quantify the importance of soil compliance on the predicted dynamic characteristics of the structure. The results of this analysis are shown in Table 2. It has to be noted herein that in case that the soil volume is modeled along with the superstructure, the identification of the modal frequencies of the entire soil-structure system is not as straightforward as it is in the case of a fixed structure, due to the enormous amount of the vibrating soil volume and the strong coupling among the structural and the soil modes. As a result, the characterization of modes as “transversal” or “bending” has to be made very carefully on the basis of both modal participation factors and modal shape visualization.

In terms of the predicted modal frequencies (Table 2), as anticipated, the refined consideration of abutment-backfill-embankment and pier-foundation-soil flexibility leads to lower values of modal frequencies. In particular, the 1st longitudinal mode is found 10% more flexible while the reduction of bending modal frequencies varies between 20-30%. However, compared to the identified modal frequencies, the particular 3D-3D soil model leads to an even more flexible (36% on average) prediction of structural response. This result clearly indicates that model refinement and soil-structure interaction simulation alone, cannot guarantee reliable representation of system stiffness unless appropriate model updating is performed in advance.

6.2 Finite element model updating

As mentioned earlier, for low amplitude vibrations, the structure was found to be much stiffer as one could numerically predict, regardless of model refinement. Given the fact that the finite element model used was indeed as complex and refined as possible, the model-induced (i.e., epistemic) uncertainty can be deemed as relatively low. As a result, the deviations between the identified and numerically predicted modal frequencies can be attributed primarily to the uncertainty in the material properties, which seem to be a key parameter for the reliable estimation of the dynamic characteristics of the structure.

Initially, the updating of model 1D-Fixed was carried out according to the procedure outlined in Section 5. For the case of the 3D models though, this procedure was not feasible for two main prohibitive reasons; due to the large number of the degrees of freedom of the soil-structure system but also because there was no communication protocol between the software ABAQUS used for the 3D simulations and the Matlab program running the model updating algorithm. For that reason, a different strategy was developed the manual updating of the 3D models towards the identification of the nearly-optimal fit between the identified and numerically predicted response. The workflow of this strategy is illustrated in Figure 7 and can be summarized into the following steps:

- Automatic model updating was performed for the case of the 1D-Fixed model. The results of the updated structural properties [1] of the 1D-Fixed model are presented in Table 3 (hereafter called “model updating Case 1”).
- The above identified properties were used as the first, best guess for the case of the 3D-Fixed model. Table 4 shows that the average percentage of error between the measured and the predicted modal frequencies has decreased from 31.94% to 4.8% for the 1D-Fixed model and from 32.65% to 6.13% for the 3D-Fixed verifying the trend of

manual model updating was correct. It was also observed that both models predict higher values of frequencies to all modes compared with the ones identified via ambient vibrations, with the exception of the 1st longitudinal and the 2nd transverse mode.

- (c) Given the refinement of the 3D-3D soil model and its capabilities to consider superstructure-foundation-soil and deck-abutment-embankment interaction, it was evident that the model updating factors predicted in step (b) would not necessarily be valid. For this reason, the 3D-3D Soil model was only initially updated based on the “Case 1” combination of structural parameters (Table 5). It can be seen that the average percentage of error between the measured and the predicted modal frequencies was decreased from 36.39% to 5.55%. In order to improve the convergence, sequential parametric analysis was conducted. The idea was to gradually modify specific structural parameters through a step-by-step parametric analysis scheme, until a nearly-optimal fit was achieved (Figure 7).

structural parameter	Model Updating Method
	Manual
	Case 2
E bearings	12.0
E deck	1.45
E piers	1.63

Table 6: Modal updating results for the 3D-3D Soil FEM through a proposed manual procedure.

The results of this parametric analysis resulted in the “Case 2” combination of updated structural parameters, summarized in Table 6. Table 7 shows the improvement of the modal frequencies predicted by the 3D-3D Soil for structural parameters combination “Case 2”, compared to the modal frequencies predicted by the 1D-Fixed for “Case 1”. By comparing Cases 1 and 2 (Tables 3 and 6), as well as the final modal frequencies predicted by the initial 1D-Fixed and the refined 3D-3D soil models, it is clear that the accurate soil-structure interaction modeling is a key parameter for reliable modal updating of the system.

It is also observed that both updated procedures (algorithmic and manual) showed that the Young Modulus of Elasticity for the bearings, the deck and the piers had to be significantly

increased compared to the values assumed in the initial design. In particular, the bearing stiffness has to be increased by a factor of 12, while the concrete modulus of elasticity by a factor of 1.43 for the deck and 1.63 for the piers. With respect to the bearings, this can be clearly attributed to the low deformation (strain) levels that are developed under ambient vibrations at which the bearing stiffness is significantly lower than that assumed during design.

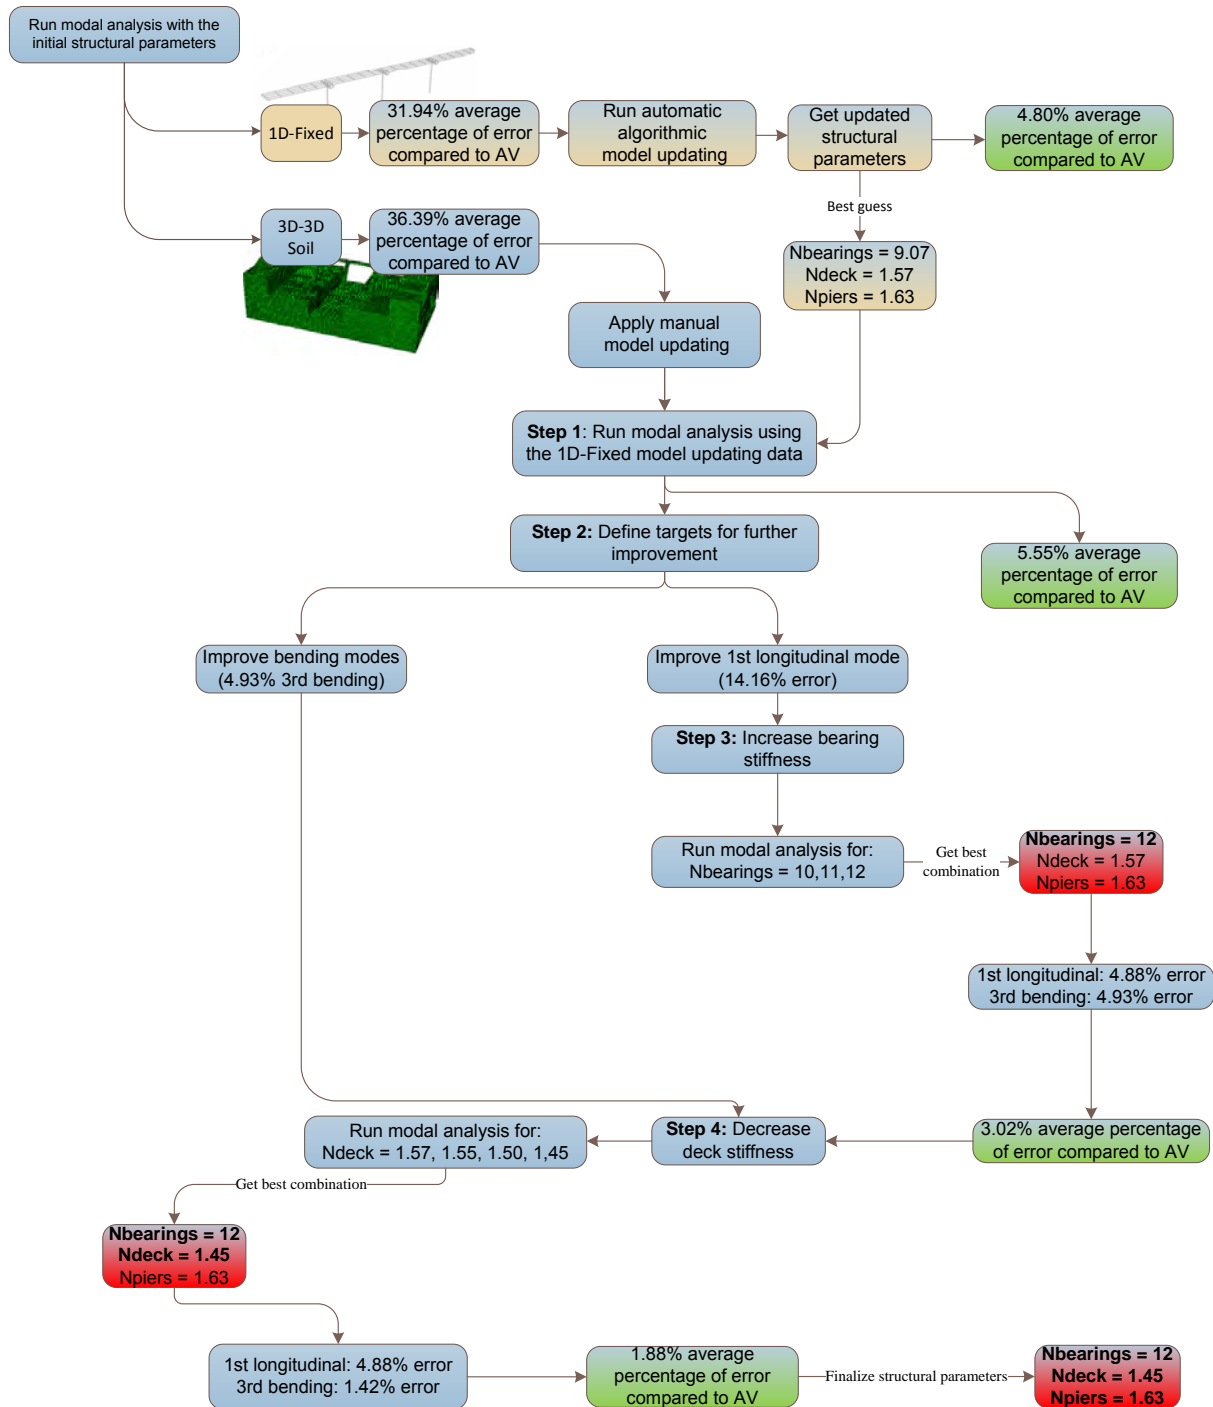

Figure 7: Manual model updating strategy.

The differences in the material properties of concrete can also be attributed to a series of contributing factors such as: (a) the definition of the modulus of elasticity according to the code used, which is calculated at strains higher than the ones imposed by ambient vibrations, (b) strengthening of concrete due to aging, (c) friction mechanisms that were activated at low levels of strain and (d) construction practices and quality control issues related to the casting of concrete. It is interesting to notice though, that similar deviations have been computed in numerous studies (i.e., [1]) and hence it is an issue that has to be investigated further.

7 CONCLUSIONS

This paper aimed to identify the parameters that affect the dynamic response of the instrumented, 2nd Kavala Bypass Ravine Bridge constructed along the Egnatia Motorway Greece. Using alternative finite element models of various levels of complexity and modeling refinement in terms of consideration the dynamic interaction of the overall superstructure-foundation-soil and deck-abutment-embankment system, the modal frequencies of the bridge are computer and compared with the ones identified using ambient vibrations. The main conclusions drawn from this study can be summarized as follows:

- A good agreement was observed, on the basis of the predicted modal frequencies of the bridge, between the 1D-Fixed and the 3D-Fixed models, thus indicating that the simplifying assumptions made for the first were reasonably accurate. However, the initial prediction of the two models leads to considerably lower (34%-58%) modal frequencies than the ones identified, hence yielding model updating inevitable.
- Introduction of the soil compliance through the more refined 3D-3D soil model which simulated the overall soil-structure system led to a further reduction of the modal frequencies, by 10% in the 1st longitudinal direction and by 25% on average in the transverse direction.
- The model updating strategy that was followed for the case of the most complex and comprehensive 3D-3D soil model, eventually led to good agreement of the predicted modal frequencies with the identified ones and the average error was reduced to 1.88% (without exceeding 4.9% at any mode). The updated FEMs revealed that the differences

initially computed, were due to the higher actual stiffness of the elastomeric bearings, the piers and the deck as compared to the values that were assumed during design.

- The differences between the design assumptions and the actual structural properties under ambient vibrations can be attributed to the low deformation (strain) levels, the definition of the modulus of elasticity according to the code used, which is calculated at strains higher than the ones imposed by ambient vibrations, strengthening of concrete due to aging, friction mechanisms as well as to construction practices during concrete casting.
- Consideration and numerical modeling of soil-structure interaction, abutment-backfill-embankment and pier-foundation-soil geometry and properties, may not affect the dynamic characteristics drastically in terms of their absolute values, but due to significant modal coupling, had a considerable effect on the prediction of the final, modified structural parameters. This effect is anticipated to be further pronounced in case of softer soil profiles. As a result, the accurate soil-structure interaction modeling is deemed to be a key parameter for reliable modal updating of extended bridge-soil systems.

Abstract. *With the recent technological advances and the evolution of advanced smart systems for damage detection and signal processing, Structural Health Monitoring (SHM) emerged as a multidisciplinary field with wide applicability throughout the various branches of engineering, mathematics and physical sciences. However, significant challenges associated with modeling the physical complexity of systems comprising these structures remain. This is mainly due to the fact that numerous uncertainties associated with modeling, parametric and measurement errors could be introduced. In cases where these uncertainties are significant, standard identification and damage detection techniques are either unsuitable or inefficient. This study presents a robust data assimilation approach based on a stochastic variation of the Kalman Filter where polynomial functions of random variables are used to represent the inherent process uncertainties. The presented methodology is combined with a non-parametric modeling technique to tackle structural health monitoring of a four-story shear building. The structure is subject to a base motion specified by a time series consistent with the El-Centro earthquake and undergoes a preset damage in the first floor. The purpose of the problem is localizing the damage in both space and time, and tracking the state of the system throughout and subsequent to the damage time. The application of the introduced data assimilation technique to SHM enhances the latter's applicability to a wider range of structural problems with strongly nonlinear dynamical behavior and with uncertain and complex governing laws.*

1 INTRODUCTION

With the recent technological advances and the evolution of advanced smart systems for damage detection and signal processing, Structural Health Monitoring (SHM) emerged as a multidisciplinary field with wide applicability throughout the various branches of engineering, mathematics and physical sciences. Typically, the SHM problem can be addressed as a statistical pattern recognition paradigm with three main components:

- 1) A numerical model that accurately represents the governing system dynamics
- 2) Real-time data acquisition and management system
- 3) A sequential data assimilation technique that relies on a set of observational data to calibrate and update the underlying dynamic principles governing the system under observation.

In such context, numerous uncertainties associated with modeling, parametric and measurement errors could be introduced. In cases where these uncertainties are significant, standard identification and damage detection techniques are either unsuitable or inefficient. Therefore, the need rises for robust system identification algorithms that can tackle the aforementioned challenges. This has been a very active research area over the past decade [3, 4, 6, 8, 9, 11, 12].

Sequential data assimilation has been widely used for structural health monitoring and system identification problems. Many extensions of the Kalman Filter were developed as adaptations to important classes of these problems. While the Extended Kalman Filter may fail in the presence of high non-linearities, Monte Carlo based Kalman Filters usually give satisfactory results. The Ensemble Kalman Filter (EnKF) [1, 2] was recently used for damage detection in strongly nonlinear systems [4], where it is combined with non-parametric modeling techniques to tackle structural health monitoring for non-linear systems. The EnKF uses a Monte Carlo Simulation scheme for characterizing the noise in the system, and therefore allows representing non-Gaussian perturbations. Although this combination gives good results, it requires a relatively accurate representation of the non-linear system dynamics. It also requires a large ensemble size to quantify the non-Gaussian uncertainties in such systems and consequently imposes a high computational cost.

This study presents a system identification approach based on coupling robust non-parametric non-linear models with the Polynomial Chaos methodology in the context of the Kalman Filtering techniques [10]. The proposed approach uses a Polynomial Chaos expansion [7] of the nonparametric representation of the system's non-linearity to statistically characterize the system's behavior. A filtering technique that allows the propagation of a stochastic representation of the unknown variables using Polynomial Chaos is used to identify the chaos coefficients of the unknown parameters in the model. The introduced filter is a modification of the EnKF that uses the Polynomial Chaos methodology to represent uncertainties in the system. This allows the representation of non-Gaussian uncertainties in a simpler, less taxing way without the necessity of managing a large ensemble. It also allows obtaining the probability density function of the model state or parameters at any instant in time by simply simulating the Polynomial Chaos basis.

2 THE POLYNOMIAL CHAOS KALMAN FILTER (PCKF)

The Kalman Filter is an optimal sequential data assimilation method for linear dynamics and measurement processes with Gaussian error statistics. The PCKF builds on the mathematics of the original Kalman Filter to allow the propagation of a stochastic representation of the unknown variables using Polynomial Chaos. In the PCKF, the model state is given by,

$$x = \sum_{i=0}^P x_i \psi_i(\xi), \quad (1)$$

where, $P + 1$, is the number of terms in the Polynomial expansion of the state vector, $\{\psi_i\}$ is set of Hermite polynomials function of the Gaussian random variable, ξ . Consequently, the covariance matrix of the model state is defined around the mean, the zero order term, of the stochastic representation,

$$\begin{aligned} P &\approx \left\langle \left(\sum_{i=0}^P x_i \psi_i - x_0 \right) \left(\sum_{i=0}^P x_i \psi_i - x_0 \right)^T \right\rangle \\ &\approx \left\langle \left(\sum_{i=1}^P x_i \psi_i \right) \left(\sum_{i=1}^P x_i \psi_i \right)^T \right\rangle \\ &\approx \sum_{i=1}^P x_i x_i^T \langle \psi_i^2 \rangle, \end{aligned} \quad (2)$$

where, P is the covariance matrix, and $\langle \rangle$ denotes the mathematical expectation. The Polynomial Chaos representation depicts all the information available through the complete probability density function, and therefore allows the propagation of all the statistical moments of the unknown parameters and variables.

The observations are also treated as random variables represented via a Polynomial Chaos expansion with a mean equal to the first-guess observations. Since the model and measurement errors are assumed to be independent, the latter is represented as a Markov process

2.1 Analysis Scheme

For computational efficiency, the dimensionality and order of the Polynomial Chaos expansion are homogenized through out the solution. These parameters are initially defined based on the uncertainty within the problem at hand and are assumed to be constant thereafter. Since the model state and measurement vectors are assumed independent, the Polynomial Chaos representation of these variables has a sparse structure.

Let \mathbf{A} be the matrix holding the chaos coefficients of the state vector $y \in R^n$,

$$\mathbf{A} = (x_0, x_1, \dots, x_P) \in R^{n \times (P+1)}, \quad (3)$$

where $P + 1$ is the total number of terms in the Polynomial Chaos representation of x and n is the size of the model state vector. The mean of x is stored in the first column of \mathbf{A} and is denoted by x_0 . The state perturbations are given by the higher order terms stored in the remaining columns. Consequently, the state error covariance matrix $\mathbf{P} \in R^{n \times n}$ is defined as:

$$\mathbf{P} = \sum_{i=1}^P x_i x_i^T \langle \psi_i^2 \rangle \quad (4)$$

Given a vector of measurements $d \in R^m$, with m being the number of measurements at each occurrence, a Polynomial chaos representation of the measurements is defined as

$$d = \sum_{j=0}^P d_j \psi_j(\xi), \quad (5)$$

where the mean d_0 is given by the actual measurement vector, and the higher order terms rep-

resent the measurement uncertainties. The representation d can be stored in matrix form as:

$$\mathbf{B} = (d_0, d_1, \dots, d_p) \in R^{m \times (P+1)}. \quad (6)$$

Based on Eq. 5, the measurement error covariance matrix, \mathbf{R} , is defined as:

$$\mathbf{R} = \sum_{i=1}^P d_i d_i^T \langle \psi_i^2 \rangle \in R^{m \times m} \quad (7)$$

The Kalman Filter forecast step is carried out by employing a stochastic Galerkin scheme, and the assimilation step consists if the traditional Kalman Filter correction step applied on the Polynomial Chaos expansion of the model state vector,

$$\sum_{i=0}^P x_i^a \psi_i = \sum_{i=0}^P x_i^f \psi_i + \mathbf{P}\mathbf{H}^T (\mathbf{H}\mathbf{P}\mathbf{H}^T + \mathbf{R})^{-1} \left(\sum_{i=0}^P d_i \psi_i - \mathbf{H} \sum_{i=0}^P x_i^f \psi_i \right) \quad (8)$$

where, \mathbf{H} is the observation matrix, and the superscripts f and a represent the forecast and analysis states respectively. Projecting the above equation on an approximating space spanned by the Polynomial Chaos $\{\psi_i\}_{i=0}^P$ yields,

$$x_i^a = x_i^f + \mathbf{P}\mathbf{H}^T (\mathbf{H}\mathbf{P}\mathbf{H}^T + \mathbf{R})^{-1} (d_i - \mathbf{H}x_i^f) \quad \text{for } i = 0, 1, \dots, P. \quad (9)$$

In matrix form, the assimilation step is expressed as:

$$\mathbf{A}^a = \mathbf{A}^f + \mathbf{P}\mathbf{H}^T (\mathbf{H}\mathbf{P}\mathbf{H}^T + \mathbf{R})^{-1} (\mathbf{B} - \mathbf{H}\mathbf{A}^f) \quad (10)$$

3 NUMERICAL EXAMPLE

The efficiency of the presented method is assessed by applying it to the structural health monitoring of the four-story shear building shown in Figure 1. This model has a constant stiffness on each floor and a 5% damping ratio in all modes. All structural elements of this frame are assumed to involve hysteretic behavior, and it is supposed that a change in the hysteretic loop of the first floor element occurs at some point. It is of utmost importance to localize that point in time and track the state of the system throughout and subsequent to that point.

Figure 1: Shear Building Under Analysis

A synthetically generated dataset representing measurements of the displacements and veloci-

ties at each floor is obtained by representing the hysteretic restoring force by the Bouc-Wen model, which is therefore considered as the exact hysteretic behavior of the system. Thus, the equation of motion of the system is given by,

$$M\ddot{u}(t) + C\dot{u}(t) + K_{el}u(t) + (1 - \alpha)K_{in}z(x, t) = -M\tau\ddot{u}_g(t) \quad (11)$$

where, M , C , K_{el} , and K_{in} are the mass, damping, elastic and inelastic stiffness matrices respectively; α is the ratio of the post yielding stiffness to the elastic stiffness, τ is the influence vector, u is the displacement vector, x is the inter-story drift vector, and z is an n -dimensional evolutionary hysteretic vector whose i^{th} component is give by the Bouc-Wen model as,

$$\dot{z}_i = A_i\dot{x}_i - \beta|\dot{x}_i||z_i|^{n_i-1} - \gamma_i\dot{x}_i|z_i|^{n_i}, \quad i = 1, \dots, n \quad (12)$$

A , β , and γ are the Bouc-Wen model parameters. The adopted values for these parameters are shown in Table 1.

Model Coef.	Pre-Change	Post-Change
α	0.15	0.15
β	0.1	10
n	1	1
γ	0.1	10
A	1	1

Table 1: Bouc-Wen Model Coefficients

The structure is subject to a base motion specified by a time series consistent with the El-Centro earthquake shown in Figure 2, and a change of the first floor hysteric behavior is assumed to take place five seconds after the excitation. A monitoring scenario where it is assumed that measurements are available every 5 time steps is adopted. A nonparametric representation of the system nonlinearity is adopted, and the filtering technique is used to characterize the latter representation in order to capture any ambiguous behavior of the structure examined.

Figure 2: The Elcentro Excitation Applied to the Structure

4 NON-PARAMETRIC REPRESENTATION OF THE NON-LINEARITY

The proposed filtering methodology is combined with a non-parametric modeling technique to tackle structural health monitoring of non-linear systems but instead of adopting a deterministic nonparametric representation of the non-linearity, a stochastic representation via Polynomial Chaos is used. The basic idea behind the non-parametric identification technique used is to determine an approximating analytical function \hat{F} that approximates the actual system non-linearities, with the form of \hat{F} including suitable basis functions that are adapted to the problem at hand [8]. For general non-linear systems, a suitable choice of basis would be the list of terms in the power series expansion in the doubly indexed series,

$$S = \sum_{i=0}^{i_{\max}} \sum_{j=0}^{j_{\max}} u^i \dot{u}^j, \quad (13)$$

where u and \dot{u} are used to represent the system's displacement and velocity respectively. Therefore, if $i_{\max} = 3$ and $j_{\max} = 3$, the basis functions become:

$$\text{basis} = \{1, \dot{u}, \dot{u}^2, \dot{u}^3, u, u\dot{u}, u\dot{u}^2, u\dot{u}^3, u^2, u^2\dot{u}, u^2\dot{u}^2, u^2\dot{u}^3, u^3, u^3\dot{u}, u^3\dot{u}^2, u^3\dot{u}^3\} \quad (14)$$

In the proposed method the displacements and velocities are stochastic processes represented by their Polynomial Chaos expansion. Thus, the approximating function is also expressed as a stochastic process via a Polynomial Chaos representation. The model adopted within the Kalman Filter is hence given by

$$M\ddot{u}(t) + F(u, \dot{u}) = -M\tau\ddot{u}_g(t) \quad (15)$$

where, F is the non-parametric representation of the non-linearity whose i^{th} floor component is given by

$$\begin{aligned} F^i &\approx \sum_j F_j^i(u, \dot{u}) \psi_j \\ F^i &\approx \sum_j a_j^i \psi_j \left(\sum_k (u_k - u_k^{i-1}) \psi_k \right) + \sum_j a_j^{i+1} \psi_j \left(\sum_k (u_k^i - u_k^{i+1}) \psi_k \right) \\ &+ \sum_j b_j^i \psi_j \left(\sum_k (u_k^i - u_k^{i-1}) \psi_k \right)^2 + \sum_j b_j^{i+1} \psi_j \left(\sum_k (u_k^i - u_k^{i+1}) \psi_k \right)^2 \\ &+ \sum_j c_j^i \psi_j \left(\sum_k (\dot{u}_k^i - \dot{u}_k^{i-1}) \psi_k \right) + \sum_j c_j^{i+1} \psi_j \left(\sum_k (\dot{u}_k^i - \dot{u}_k^{i+1}) \psi_k \right) \\ &+ \sum_j d_j^i \psi_j \left(\sum_k (u_k^i - u_k^{i-1}) \psi_k \right) \left(\sum_l (\dot{u}_l^i - \dot{u}_l^{i-1}) \psi_l \right) \\ &+ \sum_j d_j^{i+1} \psi_j \left(\sum_k (u_k^i - u_k^{i+1}) \psi_k \right) \left(\sum_l (\dot{u}_l^i - \dot{u}_l^{i+1}) \psi_l \right) \end{aligned} \quad (16)$$

In the above equation, $\{a_j\}$, $\{b_j\}$, $\{c_j\}$, and $\{d_j\}$ represent the chaos coefficients of the unknown parameters to be identified. The fourth order Runge-Kutta method is used for the time stepping and a stochastic Galerkin approach is employed to solve the system at each time step.

5 RESULTS

In the numerical example, it is assumed that observations of displacements and velocities from all floors are available. The noise signals perturbing both the model and measurements are modeled as first order, one dimensional, independent, Polynomial Chaos expansions having zero-mean and an RMS of 0.05 and 0.001 respectively. The parametric uncertainties on the other hand, are modeled as second order, one dimensional, Polynomial Chaos expansions whose coefficients are to be determined in accordance with the available observations. This is done to incorporate the possibility that the unknown parameters may deviate from Gaussianity. Furthermore, it is assumed that the first floor undergoes a change in its hysteretic behavior 5 seconds after the ground excitation. The purpose of the application is to detect this behavioral change.

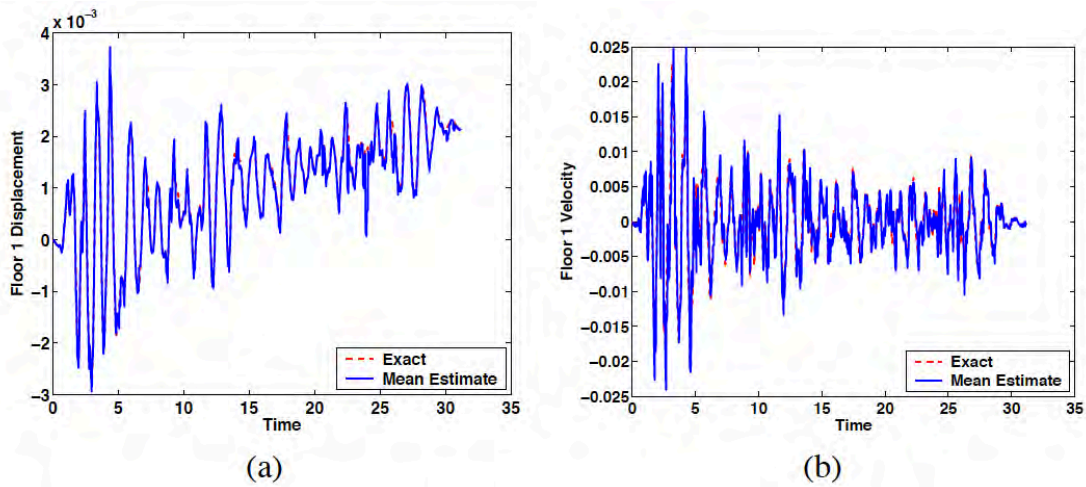

Figure 3: Estimate of the first floor parameters, (a) displacement, (b) velocity

Figure 3 and Figure 4 describe the tracking of the displacement and velocity for the first and fourth floor respectively. Excellent match between the results estimated using the Polynomial Chaos based Kalman Filter and the true state is observed.

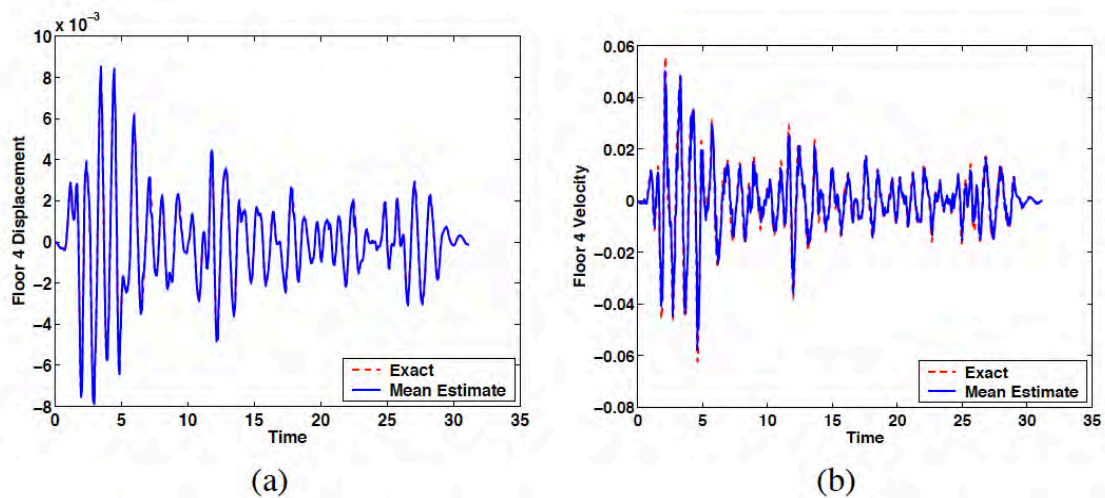

Figure 4: Estimate of the fourth floor parameters, (a) displacement, (b) velocity

Figure 5 presents the evolution of the mean of the unknown parameters identified by the

proposed filtering technique. Error bars representing the scatter in the estimated parameters are also present in Figure 5. The different jumps within the parameters are associated with the perks in the corresponding excitation.

Figure 5: Estimate of the mean floor parameters

Further investigation of the parameters indicates that the main changes take place in the first floor following the 5sec time interval. Note that the parameters a and c in floors 1 and 2 undergo the greatest jumps since they are associated with inter-story drift and velocity, respectively. One of the main advantages of using the Polynomial Chaos Kalman filter is that it provides a scatter around the estimated parameters. This is represented by the probability density functions corresponding to each of the estimated parameters. Figure 6 presents the probability density functions of the estimated floor 1 parameters.

Figure 6: Probability density functions of the estimated floor 1 parameters

6 CONCLUSIONS

The combination of Polynomial Chaos with the Ensemble Kalman Filter renders an efficient data assimilation methodology that competes with other Kalman Filtering techniques while maintaining a relatively low computational cost. Although the proposed method employs traditional Kalman Filter updating schemes, it preserves all the error statistics, and hence allows the computation of the probability density function of the uncertain parameters and variables at all time steps. This is achieved by simply simulating the Polynomial Chaos representation of these parameters. Together with the non-parametric representation of the nonlinearities, the approach constitutes an effective system identification technique that accurately detects any changes in the systems behavior. The Polynomial Chaos representation of the non-parametric model for the nonlinearities is a robust innovative approach that permits damage identification and tracking the dynamical state beyond that point. Using Polynomial Chaos, the uncertainty associated with the assumed non-parametric model is inherently present and thus represents the actual nonlinearity in a more accurate way.

Abstract. *Full-scale shake table seismic experiments and low amplitude vibration tests on a masonry building are carried out to assess its seismic performance as well as study the effectiveness of a new textile material for retrofitting masonry structures against earthquakes. The un-reinforced and the retrofitted with glass fiber reinforced polymer (GFRP) strips masonry buildings were subjected to a series of earthquake excitations of increasing magnitude in order to progressively induce various small, moderate and severe levels of damage to the masonry walls. The performance of the original and retrofitted building states is evaluated. Changes in the dynamic characteristics (lowest four modal frequencies and damping ratios) of the building are used to assess and quantify the damage states of the masonry walls. For this, the dynamic modal characteristics of the structure states after each earthquake event were estimated by performing low-amplitude impulse hammer and sine-sweep forced vibration tests. The retrofitting actions restored the stiffness characteristics of the reinforced masonry structure to the levels of the original undamaged un-reinforced structure. The results show that despite a similar dynamic behavior identified, corresponding to reduction of the modal frequencies, the un-reinforced masonry building was severely damaged, while the reinforced masonry building was able to withstand, without visual damage, the induced strong seismic excitations. The GFRP textile material, optimally wrapped along the masonry walls following existing guidelines, was proven to be very effective in reinforcing the masonry building to withstand earthquake events significantly larger in magnitude than the ones caused severe damage to the un-reinforced building.*

1 INTRODUCTION

A large number of masonry structures exist in high seismicity regions throughout the world. Most masonry structures have been designed without following design procedures recommended by modern seismic codes. Such structures are vulnerable to damage and collapse due to moderate and large earthquakes. Un-reinforced brick masonry buildings perform poorly under (lateral) seismic forces, failing in out-of-plane bending, in-plane bending and shear. Although being the most widely used type of construction in the world it is not capable of dissipating energy through inelastic deformation. They are designed to resist primarily gravity and wind loads. Retrofitting techniques provide the means of stiffening and strengthening these structures to withstand earthquakes. Several retrofitting strategies have been proposed in the past. A large number of tests on the components of the masonry structures have been also performed to study the effectiveness of the retrofitting on the component level. Among the retrofitting techniques, repair technologies based on fiber-reinforced polymer (FRP) are effective and practical alternatives for stiffening and strengthening masonry building. Tests on complete masonry structures also have been performed on shake tables and the performance of masonry structures has been evaluated under the action of earthquakes. These tests have provided valuable information on the seismic performance of full scale masonry buildings or the components of the masonry.

A major problem in classical reinforced textile structure is their low working capacity due to missing dissipative plastic deformation capacity. In a large number of recent publications [1-17] on masonry reinforcement by fiber reinforced plastics, it is reported that masonry fails in a brittle manner with the load capacity dropping substantially and suddenly. This is in agreement with the field observations of specialized engineers working in high seismicity regions. Premature bonding of FRP occurs due to high concentration of interface shear stresses and normal peeling stress in the vicinity of the reinforcement. The brittle mode of failure is reflected in the low strains at failure and therefore in a minimum energy absorption. In addition, the mode of deformation, including the crack pattern, depends on the wall boundary conditions and reaction zones, which were not real in most of the cases examined in the Laboratory. These observations are particularly valid for dynamic (cyclic) loading, in-plane and out-of-plane, developing during earthquakes. At the same time reinforcement by FRP (mainly externally bonded carbon or glass fiber reinforced polymer) increases substantially the masonry load capacity, the static bending capability and the overall stiffness. This could be separated into two components: the nonlinear one representing the stiffness contribution of the masonry materials and a rather linear part representing the stiffness contribution of the fibre reinforcement.

Experimental and field data should be assessed to improve the masonry wall reinforcement design in order to increase the overall stiffness, strength and ductility (energy absorption capability) under real boundary conditions that prevail on full scale structures. The aim is to optimize strength and deformability in a synergistic interaction in order the reinforcement to become an integral structural part. The reinforcement design should ensure, through strengthening and deformability, that highly stressed zones are not developing in the reinforced masonry and also in the surrounding un-reinforced masonry and that the building will resist: out-of-plane bending, in-plane bending, in-plane shear, combined with axial load.

The objective of this study is twofold. The first objective is to experimentally investigate the seismic performance of full-scale, single room, un-reinforced masonry buildings and to validate the effectiveness of glass FRP strips as retrofitting techniques in an effort to improve the masonry wall stiffness, strength and ductility to withstand earthquakes. The second objective is to investigate and monitor the health of the structure through low amplitude dynamic

testing and correlate the change in the dynamic characteristics of the structure to the intensity of ground shaking, the damages observed and the retrofitting actions carried using repair techniques and strengthening with glass fiber reinforced polymer (GFRP) material bands. The change of the dynamic characteristics, such as modal (resonant) frequencies and modal damping ratios, with damage and strengthening actions on the building are useful damage or strengthening index indicators. These indicators can be used for evaluating the degree of damage induced under seismic actions and the level of retrofitting steps required in order to restore the stiffness of the structure.

A series of shake table tests followed by low amplitude vibration tests were performed on a masonry building at its un-reinforced and reinforced configurations. The masonry building was designed in full scale to resemble typical brick masonry building types, encountered in countryside. The un-reinforced masonry building was subjected to a series of progressively intensified earthquakes until it was severely damaged, evident by the large crack openings in the four walls of the building. Then it was repaired, strengthened with GFRP strips until its original stiffness is recovered and re-tested with a similar second series of progressively intensified earthquakes to evaluate the effectiveness of the reinforcement. A new multifunctional GFRP textile material, developed under the European research project POLYTECT [18], is considered as retrofitting solution for un-reinforced masonry structures. Appropriate damage indices based on the observed evolution of the modal frequencies are introduced to monitor the health of the masonry structure and evaluate the effectiveness of retrofitting actions. Three different building and reinforcement configurations have been studied. The present study reports results from the third building and reinforcement configuration which was optimally designed based on existing guidelines and the experience from the tests on the first two masonry structures. The full-scale experimental tests are aimed to improve design retrofitting guidelines for masonry structures, taking into account realistic boundary conditions at the sides of the masonry walls, wall continuity at the corners and wall openings from windows and doors.

This study is organized as follows. Section 2 introduces the masonry building, the geometrical characteristics, the material properties identified from component tests, and the finite element model based on simplified assumptions on composite brick-mortar wall behavior. Details for the shake table facility and the building instrumentation are provided in Section 3. Section 4 presents the experimental set-up, giving details about the series of seismic experiments performed on the un-reinforced and the reinforced building along with the observed damages during the tests. Section 5 concentrates on the post-earthquake low-amplitude vibration tests performed to trace the modal characteristics of the masonry structure under the progressively intensified seismic events and retrofitting actions. It presents and discusses results for the correlation of the identified resonant frequencies and damping ratios with intensity of seismic excitation and stiffness degradations due to damage caused from the applied seismic events or stiffness restoration resulted from strengthening actions. Conclusions are summarized in Section 6.

2 DESCRIPTION OF MASONRY BUILDING AND MODELING

2.1 Building description with geometry

A full-scale single-story (one-room) brick-masonry building is designed and constructed in the laboratory. The un-reinforced brick building is representative of existing masonry buildings in Greece, particularly in the countryside. A picture of the intact building resting on the shake table is shown in Figure 1. The geometry of the masonry structure is shown in Figure 2. The masonry structure consists of four single masonry brick walls with two opposite

doors and windows, and a reinforced concrete roof. The four walls of the masonry building are anchored on the shake table. The top view dimensions are 3.19m parallel to the X-axis and 2.78m parallel to the Y-axis. The structure height is 2.26m (including 10 cm concrete roof thickness). The door's width and height is 0.70m and 1.64m, respectively and it is placed on the center of the two opposite wall's width. The window's width and height is 0.70m and 0.70m, respectively and it is placed on the center of the two opposite wall's width. The layout of the door and window openings results in a symmetric building, avoiding eccentricities as much as possible. All the surrounding walls are 8.5 cm thick, determined by the width dimension of the bricks.

Figure 1: A picture of the intact masonry building.

2.2 Building materials and component tests

The construction of the masonry wall panels was based on common practices in Greece. The bricks used were common bricks used for the construction of masonry structures. The building brick is a rectangular, hollow multicored, clay prism of long dimension 187mm (parallel to the holes), height 112mm (perpendicular to the holes and along the vertical direction) and width 85mm (perpendicular to the holes and along the horizontal direction), weighting about 1.70 Kg.

Components tests were conducted separately on bricks, mortar and brick-mortar assemblies in order to understand their mechanical behavior and obtain their mechanical properties. These tests were performed using the mechanical testing equipment available on the Institute of Mechanics of Materials and Geostrutures (IMMG). The tests included compression tests along directions parallel and perpendicular to the brick holes, as well as shear tests. In particular, based on the tests carried out on brick-mortar assemblies, consisted of a small number of building bricks bonded by mortar, the constitutive parameters in compression, tension and shear of the brick-mortar panels were experimentally measured. Compression tests on panels with the loading direction parallel to the brick holes confirmed higher peak strength values (nominal value of 4 MPa at 0.4% strain) but lower stiffness in comparison with loading of bricks normal to the holes where a nominal peak strength value of 3 MPa at 0.17% strain was measured. The mortar joint shear strength was found to be 0.7 to 0.75 MPa. Each compression tests was repeated for several specimen and a significant variation in the stiffness was ob-

served. For example, the stiffness for the compression test with loading of bricks normal to the holes varied from 2.3 to 3.5 GPa. Similar ranges of variations were observed for the compression tests with loading parallel to the brick holes.

Figure 2: Geometric of masonry building.

2.3 Finite element model of the masonry building

A detailed finite element model of the masonry building at its undamaged un-reinforced state was created based on the geometric details and the material properties of the reinforced concrete roof and the masonry walls. The structure was designed in the COMSOL Multiphysics [19] finite element modelling environment. The finite element model for the structure was created using three-dimensional tetrahedral solid finite elements to model the whole structure. The elements along the basement are fixed in the direction of motion and the same applies for those linking the four walls and the concrete roof. The nominal values of the mechanical properties of the brick-mortar components and the reinforced concrete roof are used to construct a nominal linear finite element model of the masonry structure from the behavior of its components. Based on existing mechanical tests and the low strain levels expected to be experienced by the reinforced concrete roof during low-amplitude vibration tests, the roof was assumed to be homogeneous isotropic with material properties as follows: elasticity modulus $E = 30$ GPa, Poisson ratio $\nu = 0.2$ and density $\rho = 2500$ Kg/m³. A homogeneous orthotropic material was assumed for the masonry walls to roughly account for the periodic structure of the brick-mortar elements. Based on the experimentally obtained stress-strain relationships,

the following nominal values for the mechanical properties were assumed for the composite brick-mortar units: elasticity modulus parallel to the brick's holes $E_1 = 1.8$ GPa, elasticity modulus vertical to the brick's holes $E_2 = 2.3$ GPa, shear moduli $G_1 = 0.64$ GPa and $G_2 = 0.82$ GPa, Poisson ratio $n_1 = n_2 = 0.4$ and average density $r = 1000$ Kg/m³. The finite element model is shown in Figure 3. It consists of 8341 solid finite elements and has 50553 degrees of freedom.

The linear finite element model of the building was constructed as a reference model in order to understand the dynamic behavior of the building under the various low intensity seismic excitations and gain an insight into the modal characteristics (modal frequencies and mode shapes) of the building. The model constitutes a simplified modeling of the complex behavior of the composite brick-mortar system. A more accurate modeling based on homogenization theories is expected to yield a much better description of the behavior of the masonry walls. In addition, the reinforcement using GFRP strips introduced extra modeling complications. However, such modeling is out of the scope of the present study.

Figure 3: Finite element model of the masonry building using tetrahedral solid elements.

3 SHAKE TABLE FACILITY AND BUILDING INSTRUMENTATION

3.1 Shake table description

The tests were performed at IMM. A unidirectional textile shake table was designed and constructed at IMM for carrying out the seismic test campaign. The dimensions of the shaking table are 4m by 3m. The table is accelerated using a displacement controlled servo-hydraulic system, developed and validated within the European Research Project "POLYTECT" [18]. The table has the following two original characteristics. It is not metallic but textile table, produced by a honeycomb panel (glass reinforced PEEK), manufactured by IMM based on the patented DIRIS architecture (Directionally Reinforced, Integrated, Stretched, Sing yarn) [20]. This panel is light, weighting only 210 Kg and extremely stiff, ex-

hibiting the highest shear strength in in-plane and out-of-plane loading [21]. The actuation-control mechanism of the servofvalve is piezoelectric, reacting much faster and more precisely than the ones available in the market. Exploiting the previous capabilities, the shaking table possesses the following characteristics. It is capable of sinusoidal, random, shock and arbitrary time history excitation, it has a maximum payload of 10 Ton, maximum displacement of ± 120 mm, maximum acceleration of 4 g (with 10 Tons payload), and frequency limit of 100 Hz. The reaction-actuating unit of the shake table facility is shown in Figure 4. The previous technical characteristics classify the facility as one of the few operating in Europe but with one distinction: its very low cost of construction (<10% of the equivalent European facilities) and operation.

Figure 4: The reaction-actuating unit of the shake table facility (left) with a masonry structure (right).

3.2 Building instrumentation

As many as twelve (12) uni-axial accelerometers, six (6) piezo beam and six (6) K-beam capacitive accelerometers, were mounted on the shake table and the structure in order to record the severity of the seismic excitation and the vibration levels experienced by the structure along all three directions, as well as to identify the structural modal characteristics from low amplitude vibration tests. The sensor locations along with the monitoring directions are shown in Figure 5. The sensor configurations depend on the series of the two tests conducted on the un-reinforced and reinforced masonry building. Only six (6) sensors were placed on the structure as shown in Figure 5(a) during the series of tests conducted for the un-reinforced masonry structure. Twelve (12) sensors were placed on the structure as shown in Figure 5(b) during the series of tests conducted for the reinforced masonry structure. For the reinforced structure, three different sensor configurations were employed based on the series of tests conducted and the experience gained from previous tests on similar reinforced masonry structures.

In general, up to as many as five sensor locations on the base of the structure were activated during the tests in order to monitor the acceleration of the shake table in all directions. Two of the acceleration positions (sensors 4 and 7) measure the horizontal base acceleration along the x -direction of the motion of the shake table. One sensor (sensor 12) measures along the horizontal y -direction perpendicular to the direction of motion and two sensors (sensors

11 and 13a) measure along the vertical z -direction in order to check possible rocking effects during the motion of the shake table.

A group of sensors was placed at the roof level to monitor the global motion of the masonry unit, and another group was placed at approximately the mid-height of the front wall to monitor in-plane and out-of-plane vibrations of the wall. A set of sensors was also placed on the roof to monitor the vibrations along its vertical direction and the out-of-plane motion of the roof. The sensor location was carefully designed so that all the response of the structure during the excitations from the earthquakes imposed by the shake table is carefully monitored and the important low frequency modes are identified during the low amplitude forced vibration tests performed after each seismic event. Experience from tests performed on very similar structures were used to design the sensor locations and directions.

Figure 5: Sensor configurations (positions) and hammer impact points on the masonry structure, (a) un-reinforced building, (b) reinforced building.

4 SHAKE TABLE SEISMIC EXPERIMENTS AND DAMAGE RESULTS

The objectives of the experiments are twofold. The first objective is to study the seismic performance of the un-reinforced masonry building and to evaluate the effectiveness of GFRP strips for retrofitting the structure to withstand earthquakes. The second objective is to investigate the change in the dynamic characteristics of the structure in terms of the intensity of ground shaking and correlate this change with the intensity of the shaking and the damage observed.

The un-reinforced masonry building was subjected to a series of progressively intensified earthquake events until it was severely damaged, evident by the large crack openings in the four walls of the building. Then it was repaired, strengthened with glass fiber reinforced polymer (GFRP) strips and re-tested using a second series of progressively intensified seismic events. The objective of the seismic experiments is to investigate the vulnerability of the un-reinforced building and then investigate the effectiveness of the GFRP reinforcement on the masonry building to withstand the second series of seismic events.

Section 4.1 describes the series of shake table strong motion tests performed on the un-reinforced masonry structure and reports the damages induced in terms of crack formation and openings in the masonry walls. Section 4.2 describes the repair procedure for the damaged masonry structure followed by the reinforcement of the masonry walls by GFRP strips. The results of second series of shake table tests performed on the retrofitted structure are presented

in Section 4.3. The correlation of damage with the dynamic characteristics of the masonry structure during the various excitation phases is presented in Section 5.

4.1 Shake table tests of the un-reinforced masonry building

The seismic excitations exerted by the shake table were generated by scaling the intensity and the time of an artificial accelerogram, compatible with the elastic spectrum provided by the European Code EC8 for acceleration level $a_g = 0,15g$. The artificial accelerogram is shown in Figure 6(a). The shake table command displacement time histories are obtained by double integration of the artificial accelerations. Figure 4(b) compares the corresponding command displacement time history fed to the shake table with the real displacement time history actually induced and measured at the shake table.

Figure 6: (a) Artificial earthquake shaking compatible with elastic spectrum provided by EC8 for $a_g = 0,15g$,
(b) Comparison between the command and the recorded displacement time history at the shake table.

A series of six (6) seismic excitation events were conducted that correspond to various peak ground acceleration (PGA) values selected to represent various levels of seismic intensity. These intensity levels were accomplished at the shake table by either scaling the intensity of the command displacement in the table, or scaling the time over which the earthquake was applied, or a combination of intensity and time scaling. Table 1 reports the information on the six seismic events, including the corresponding scale in intensity and time, and the actual PGA values recorded by the acceleration sensor placed on the shake table. In addition to the peak ground accelerations (PGA) along the direction of motion, the theoretical PGA values are also reported normalized so that they coincide with the measured PGA values for the unscaled earthquake excitation. It can be seen that the acceleration at the base has exceeded 2.5g.

The un-reinforced masonry building sustained the first five seismic events without suffering any serious visible damage. The last seismic event, which was theoretically intensified almost 8 times the original seismic event, heavily damaged the building with large crack openings developed along the walls and propagated mainly through the mortar. The four sides of the masonry building after the application of the sixth seismic event are shown in Figure 7. Based on visual inspection, the sixth seismic event generated shear failure of many bricks and mortar, diagonal cracking on the walls, extensive flexural faults and measurable shear sliding in the walls 1, 2, 5 and 6. Larger crack opening were observed on the two sides of the wall with the window openings that extend along the direction of motion. The other two sides of the building walls, with the door openings that extend along the perpendicular direction of motion, also sustained serious damage. All the walls were damaged but it seems that the in-plane shearing (walls 1-2 and 5-6) produced more damage than the out of plane loading (walls 3-4 and 7-8). Overall, during the action of the sixth seismic event, the masonry building sustained serious visual damage, with the walls losing their structural integrity and posing increased threat to occupants due to high risk of collapse to future seismic excitations.

Seismic Event	Intensity Scale (% of European Earthquake)	Time Scale (sec)	PGA Recorder Values (g)	PGA Theoretical Values (g)
1st	20%	20	0.10	0.06
2nd	60%	20	0.29	0.19
3rd	100%	20	0.32	0.32
4th	100%	15	0.52	0.57
5th	100%	10	0.99	1.28
6th	100%	7	2.50	2.56

4.2 Repair of damaged masonry building and reinforcement with GFRP strips

The heavily damaged masonry building walls were repaired and strengthened. The restoration event refers to retrofitting of the damaged parts and application of an optimally designed GFRP strip reinforcement. Specifically, for retrofitting the damaged parts, the concrete roof was lifted, the cracked mortar and broken bricks along all four side walls of the building were removed and new mortar and bricks were placed. At the end the roof was bonded on the brick walls, as previously. The walls were carefully examined and small open cracks were cleaned with pressurized air and filled with pressurized epoxy in order to repair the structure and provide the necessary continuity between the different components.

The repairing design consists also of external reinforcement by bonding peripherically, tensioned glass fibre thermoplastic (GFRP) strips, with spacing in agreement with the CNR-DT/2004 guidelines [22]. Specifically, after the repair work was completed, the masonry walls were reinforced by GFRP strips against out-of-plane and in-plane loading, according to the CNR-DT/2004 guide. Figure 8 show the GFRP strip reinforcement along the masonry building walls 1-2 and 3-4. Exactly the same reinforcement patterns were applied along the masonry building walls 5-6 and 7-8. A schematic diagram of the reinforcement is also shown in Figure 9 and covers all four sides of the masonry walls along horizontal, vertical and diagonal directions. The GFRP strips are 150 mm wide, 3 mm thick and have 4 kN tensile strength.

Figure 8: A picture of the repaired masonry building with reinforced GFRP strips; (a) sides 1-2, (b) sides 3-4.

Figure 9: A schematic diagram of the reinforcement on the masonry building; (a) sides 1-2 and 5-6, (b) sides 3-4 and 7-8.

The GFRP strips were bonded on the bricks, initially by polymer and then by polymer-cement plaster of B.G. Polymers. The patterns – positioning of the strips were designed to maximize the out-of-plane resistance for the walls with the doors (sides 3, 4, 7 and 8) and the in-plane resistance to shear for the walls with the windows (sides 1, 2, 5 and 6) along the direction of loading. To this end the strips are parallel in the walls with the doors and diagonal in the remaining walls with windows. The thin and flexible strips allow the masonry to move (to micro-slide) and therefore to mobilize more effectively reaction mechanisms to absorb energy. Also the symmetry of the strip layout prevents eccentric stiffness and strengthening that may cause twisting.

It should be noted that the retrofitting actions are expected to partly restore the stiffness of the structure. The degree of stiffness restoration will be examined in the next section. In addition, the ultimate strength of the reinforced structure is expected to be much higher since the structure was retrofitted with the GFRP strips. Also, the existence of the GPFR reinforcement provides the reinforced structure with ductility and higher capability of absorbing energy at low strains.

4.3 Shake table tests of masonry building repaired and reinforced with GFRP strips

A new series of earthquake excitation tests were conducted on the retrofitted building by scaling the intensity and time of the 2009 L' Aquila W-E earthquake accelerogram, shown in Figure 10. Thirteen (13) seismic excitation events were included in the new series of tests. The thirteen excitations correspond to various intensity levels of the L' Aquila earthquake. As before, the different intensity levels were accomplished at the shake table by either changing the intensity of the command displacement in the table or scaling the time over which the earthquake was applied. Table 2 reports the information on the thirteen seismic excitation events, including the corresponding scale in intensity and time. It also gives the PGA values along the direction of motion.

Figure 10: 2009 W-E component of L' Aquila earthquake shaking.

Seismic Event	Intensity Scale (% L' Aquila Earthquake)	Time Scale (sec)	PGA Recorded Values (g)	PGA Theoretical Values (g)
1 st	20%	20	0.15	0.07
2 nd	60%	20	0.29	0.21
3 rd	100%	20	0.35	0.35
4 th	100%	15	0.41	0.62
5 th	100%	12	0.93	0.97
6 th	100%	11	0.61	1.15
7 th	100%	10	1.16	1.40
8 th	100%	9	1.39	1.73
9 th	100%	8	1.50	2.19
10 th	100%	7	2.90	2.85
11 th	100%	6	3.90	3.89
12 th	100%	6	3.90	3.89
13 th	100%	7	4.00	2.80

Table 2: Excitation characteristics of the seismic events applied on the reinforced building

In contrast to the severe damage observed for the un-reinforced building at the end of the sixth seismic event, no damage was observed in terms of visible cracks on the mortar, the bricks or the interfaces between them. The integrity of the masonry walls, seeing as a unit of bricks and mortar, and the integrity at the interface between the masonry walls and the table or the roof, was preserved. Comparing the characteristics of the two series of shake table seismic tests applied on the un-reinforced and reinforced building in Tables 1 and 2, respectively, it is obvious that in the case of the reinforced building, higher peak ground accelerations are recorded. Specifically, the last earthquake applied on the reinforced building has a ground shaking with PGA almost two times the PGA of the base shaking for the sixth earthquake applied on the un-reinforced building. Despite this stronger shaking of the reinforced building, the reinforced masonry performed very well and withstood the very strong ground shaking with no visible damage. It can be concluded that the reinforcement was sufficient to maintain the structural integrity of the masonry walls.

5 DAMAGE EVALUATION BASED ON DYNAMIC CHARACTERISTICS

The health state of the structure after each shake table test was evaluated by monitoring the modal dynamic characteristics such as modal (resonant) frequencies and modal damping ratios. These characteristics were identified by carrying out very low-amplitude forced vibration tests after each seismic event. These low-amplitude vibration tests, described in Section 5.1, are used to measure the modal characteristics and correlate the evolution of these characteristics with the stiffness degradation and observed damage caused by the seismic events. The reduction of the lower modal frequencies of the masonry structure after the application of each earthquake event is used as a damage index [23] to provide an overall measure of the damage state of the masonry structure at its un-reinforced and reinforced configurations.

5.1 Post-earthquake low amplitude forced vibration tests

The low amplitude vibration tests were performed with a PCB086D20 impulse hammer equipped with a medium tip head in order to excite the important lower modes of the masonry structure needed for the evaluation of its dynamic characteristics, such as modal frequencies, modal damping ratios and mode shapes. The vibration tests were performed before the shaking table tests were initiated and immediately after each earthquake event was inflicted by the shaking table on the structure. The purpose of the impulse hammer tests was to identify the dynamic characteristics of the structure and mainly to trace the change in the modal frequencies and the damping ratios as a function of the severity of the seismic excitation and the observed damage.

After each earthquake event, a total of 6 impulse hammer tests were conducted. The impact force was inflicted along the two horizontal directions and one vertical direction in order to excite all lower important modes of the structure. The impact points and directions are shown in Figure 5(b) with blue (broken) arrows. Two independent tests per each excitation direction were performed. Each impulse hammer test lasted only a few seconds allowing to speed up considerably the whole procedure of acquiring data from the structure.

During the first four (4) seismic tests (1st, 2nd, 3rd, and 4th) the building was instrumented with 10 sensors (sensors 0, 1, 2, 3, 4, 5, 10, 11, 12 and 13 in Figure 5(b)). During the 5th, 6th and 7th seismic tests the building was instrumented with 12 sensors: sensors were added at positions 6 and 7 in Figure 5(b) and the sensors 5(a) and 13(a) in the set up shown in Figure 5(b) were re-positioned (at locations (5b) and 13(b) in Figure 5(b)) on the roof of the building as shown in Figure 5(c). This sensor relocation was necessary in order to monitor the *z*-direction and take more accurate measurements of the out-of-plane mode of the concrete roof

where strong motion was detected. During the final six (6) seismic events (8th to 13th events) the building was again instrumented with 12 sensors. The location of sensor 13(b) in sensor configuration shown in Figure 5(b) was changed to its original location 13(a).

To verify the reliability and accuracy of the dynamic characteristics obtained by analyzing the very low vibration results obtained from the impulse hammer tests, a sine sweep test campaign was also independently conducted using a eccentric mass shaker mounted at the top of the concrete roof. The roof shaker was used to excite the structure and compute the modal frequencies from the power spectral densities of the recorded acceleration signals. Complete frequency sweeps from 1 to 50 Hz with increasing step of 0.1 Hz were carried out. The low vibration levels that resulted from these tests were significantly higher than the vibration tests resulted from the impulse hammer tests. In contrast to the impulse hammer series of 6 tests lasting a couple of minutes after each earthquake event, each sine sweep test lasted a period of half an hour. Such experiments were performed only for the initial un-reinforced structure and yielded the same natural frequencies as the impulse hammer tests. Thus, it was not deemed necessary to perform these time-consuming sine sweep experiments for the reinforced masonry structure.

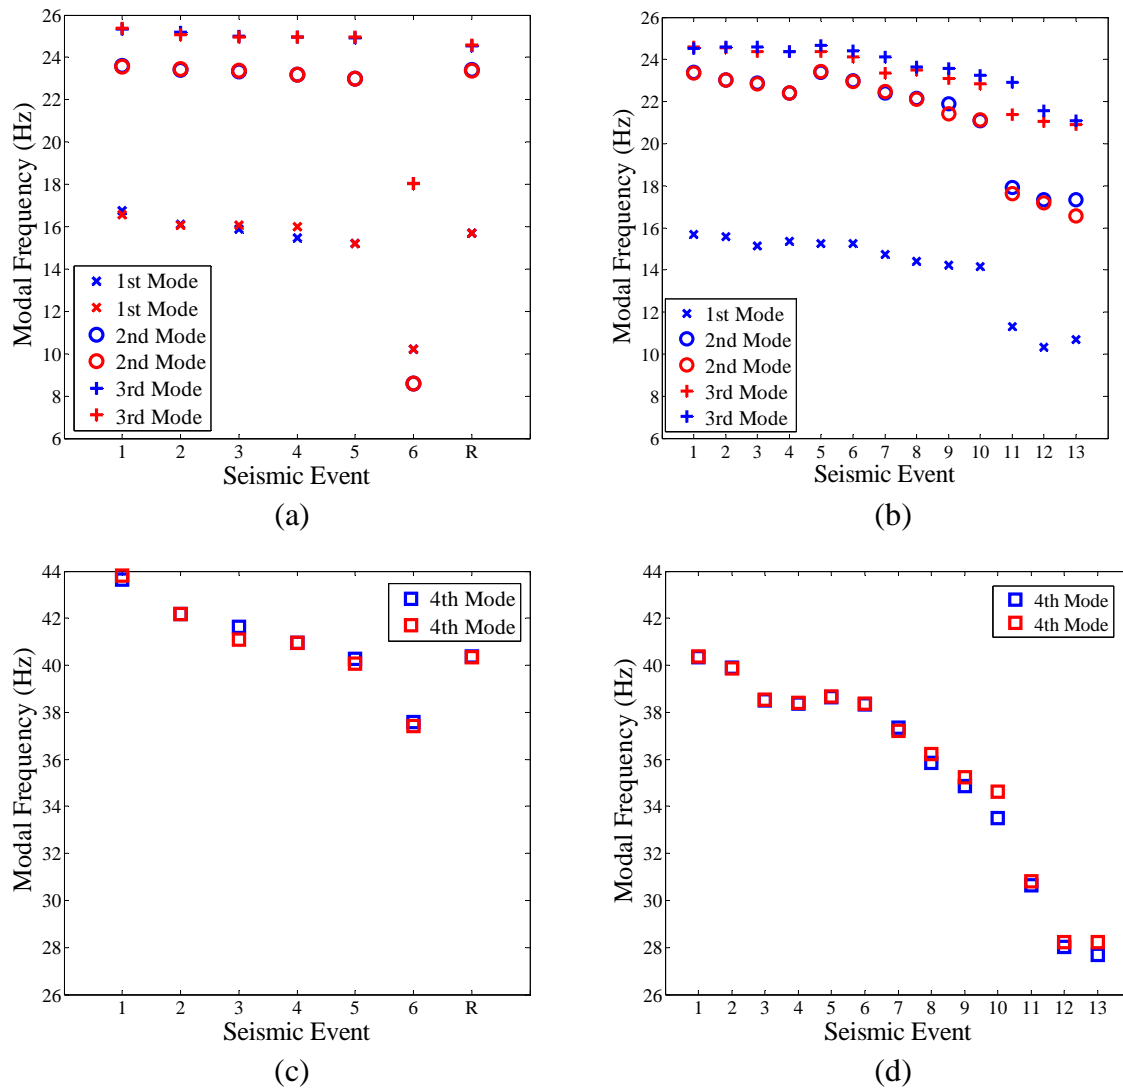

Figure 11: Evolution of modal frequencies as a function of the seismic events (a,c) un-reinforced building, (b,d) reinforced building.

The recorded acceleration time histories and the impulse force for each test were used to obtain the frequency response functions and then the PolyMAX frequency domain method [24] was applied to identify the modal characteristics of the structure. For this, the modal identification, graphical user interface, toolbox MI-Tool developed in SDLab of the University of Thessaly [25] was conveniently used to estimate the modes. The identified modal frequencies and modal damping ratios for the lowest four modes are reported in Figures 11 and 12 as a function of the seismic event for both the un-reinforced and the reinforced building. For each seismic event, more than one modal frequencies may be shown that results from the analysis of multiple vibration tests available. Representative mode shapes identified by the measurements are shown in Figure 13 and should be compared to the mode shapes in Figure 14 predicted by the nominal finite element model developed in Section 2.3. The length of the arrows in Figure 13 denotes the magnitude of each component of the mode shape along the measured DOF. It is clear that the first lowest mode in Figure 13(a) corresponds to the first shear mode in the horizontal y -direction perpendicular to the direction of the shake table motion, the second lowest mode in Figure 13(b) corresponds to the first shear mode in the horizontal x directions which is along the direction of the shake table motion, the third mode in Figure 13(c) is dominated by the first bending mode (out-of-plane mode) of the concrete roof, while the fourth mode in Figure 13(d) corresponds to a torsional mode of the building that arise from the rotation of the roof with respect to the vertical z -direction.

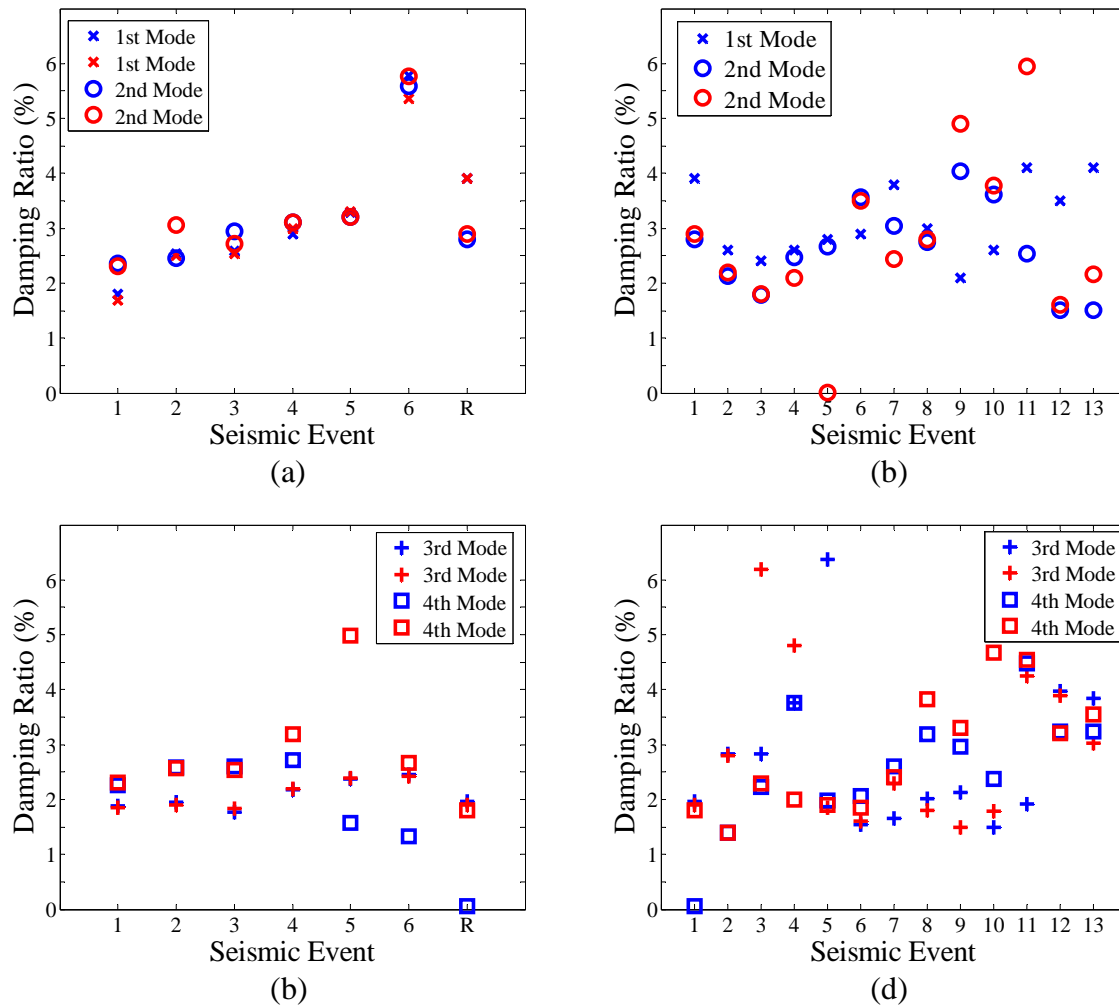

Figure 12: Evolution of modal damping ratios as a function of the seismic events (a,c) un-reinforced building, (b,d) reinforced building.

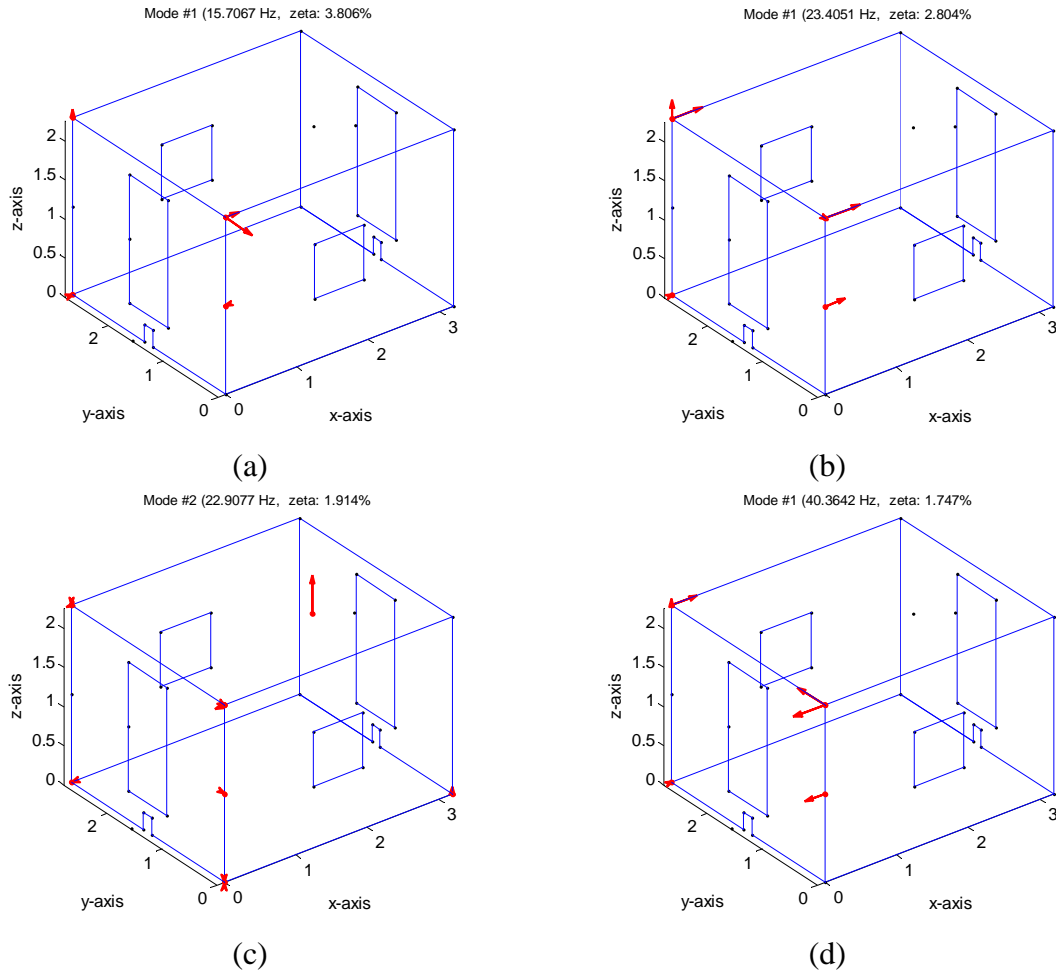

Figure 13: Identified mode shapes (a) first mode, (b) second mode, (c) third mode, (d) fourth mode.

5.2 Correlation of dynamic characteristics with seismic intensity, building damage and retrofitting actions

The change (reduction or increase) of the lowest four modal frequencies observed in Figure 11 is due to the change in stiffness of the masonry building caused by damage under the applications of the seismic events or by the retrofitting actions. The results in Figure 11 confirm that the identified values of the modal frequencies are highly dependent on the intensity levels of the seismic events and the corresponding health state of the building. The PGAs of the seismic events are shown as a functions of the seismic events in Figures 15(a) and 15(b) for the un-reinforced and the reinforced building, respectively.

Specifically, from the results in Figures 11(a) and 11(c), one clearly observes that earthquake shaking damages internally the structure causing a stiffness degradation, manifested as a reduction in the values of the modal frequencies. As the intensity of the earthquake event increases the values of all four modal frequencies reduce. However, for the first five seismic events no visible cracking in the masonry walls was evident for the case of the un-reinforced masonry structure. The small reduction of the modal frequencies observed is an indication of internal damage caused by non-visible micro cracking in the mortar and the interface between the mortar and the bricks. A large reduction in the modal frequency is observed after the sixth earthquake event which is due to significant stiffness deterioration caused by the severe damage in the masonry walls. As mentioned before, under the action of the sixth seismic event all four masonry walls sustained large crack openings, shown in Figure 7.

Figure 14: Model predicted mode shapes (a) first mode, (b) second mode, (c) third mode, (d) fourth mode.

Figure 15: Evolution of PGA as a function of the seismic events (a) un-reinforced building, (b) reinforced building.

After the building was repaired and reinforced with the GFRP strips, the identified modal frequencies of the retrofitted structure shown as the reinforcement event “R” in Figures 11(a) and 11(c) have increased substantially to almost the initial values of the modal frequencies of the un-reinforced building at its original un-damaged state. Thus the strengthening resulted in recovering the original stiffness levels of the un-reinforced building.

Based on the results obtained in Figures 11(b) and 11(d) for the re-tested reinforced masonry building, a similar reduction in the modal frequency values is observed as the intensity of the seismic events increases. The first ten seismic events reduced slightly the modal frequencies, while the last three strong seismic events reduced the modal frequencies considerably. However, no visible cracking in the reinforced masonry walls was evident for all earthquake tests for the case of reinforced masonry structure. The reduction in modal frequencies is again due to stiffness degradation and it is an indication of internal damage caused by micro cracking in the mortar and the interface between the mortar and the bricks. Such reduction was also observed for the first five seismic events for the un-reinforced building and it seems to indicate that the same damage mechanism was triggered even for the reinforced structure. This is consistent with similar results observed in [26].

The aforementioned results provide clear evidence that the changes in modal frequency are correlated with (a) stiffness degradation in the structure caused by damage after a seismic event, or (b) stiffness improvement caused by the retrofitting and strengthening actions using GFRP strips. This evolution (reduction or increase) of the modal frequencies can be used as a damage or strengthening index indicator. In addition, the availability of the modal frequency values of the undamaged building is useful for stiffness restoration of the damaged building using repair and strengthening actions. When the modal frequencies of a building are available using vibration measurements before a damaging event, then the restoration steps for a damaged building can be continued up to the level where the modal frequencies of the retrofitted structure reach (or even exceed) the original values of the undamaged building. This is a safe, validated procedure confirming that the initial stiffness of the structure is restored. However, if the modal frequencies of the undamaged building are not known and the building is damaged after an earthquake, the level of repairing cannot be defined with sufficient precision. Numerically predicted modal frequencies of the undamaged building based only on simplified finite element models for masonry walls, provide only qualitative information and not accurate quantitative information about the actual dynamic characteristic of the building. To provide a more accurate quantitative prediction of the building dynamic properties, numerical models should be developed that properly take into account the highly complex composite nature of the masonry walls and the boundary conditions resulting from the presence of window and door openings, the connections of the walls at the corners as well as the connections of the walls with the floor and the roof.

Based on the results in Figure 12, the damping ratios of the lowest four modes at low vibration levels under which the post-earthquake vibration tests were conducted range from 1% to 6%. The damping ratio values for the lowest three modes of the un-reinforced building tend to increase with the intensity of the seismic event. This indicates that damage causes the damping ratios of the structure to increase in general. The overall increase of damping ratios with damage is consistent with results reported for other structures. However, a certain increasing tendency is not clear for the reinforced building. The use of the evolution of the damping ratio values as a damage index indicator is not suitable partly due to the fact that the fluctuation in the estimates of the modal damping ratios from repeated vibration tests using experimental modal analysis techniques is relatively high and this fluctuation may mask the real correlation that may exist between the modal damping ratios and the damage or strengthening actions on the structure.

Concluding, progressively increasing the intensity of the seismic event has an effect on the stiffness of the un-reinforced and reinforced structure as it is observed by the reduction in the modal frequencies. The un-reinforced brittle masonry walls sustained/suffered severe damage, losing structural integrity and posing increasing threat to occupants. The GFRP strips, however, maintained the integrity of the structure, causing no visible damage. GFRP strips are considered as one of the promising retrofitting strategies for protections of seismically excited masonry structures.

6 CONCLUSIONS

A series of progressively intensified shake table seismic vibration tests were performed on an un-reinforced and a reinforced and re-tested full-scale masonry structure in order to evaluate its seismic vulnerability and to validate the effectiveness of the reinforcement to withstand earthquakes. Low amplitude vibration tests were carried out to monitor the evolution of the dynamic characteristics of the structure after each seismic test. The un-reinforced masonry building was severely damaged with large visible crack openings manifested at all masonry walls. The retrofitted masonry building was obtained from the severely damaged un-reinforced masonry building by fixing the cracked masonry walls and bonding on the masonry walls specially designed GFRP bands. Despite the larger amplitude earthquake events applied on the reinforced building, no visible cracks were observed. The GFRP material, covering 20% of the masonry wall surfaces, was proven to be very effective in reinforcing the masonry building to withstand earthquake events significantly larger in magnitude than the ones caused severe damage to the un-reinforced building.

It was demonstrated that changes in modal frequency are correlated with stiffness degradation caused by minor to severe damage in the masonry walls after a seismic event, as well as correlated with stiffness improvement caused by repair and GFRP strip strengthening actions. The reduction or increase of the modal frequencies identified from low-amplitude vibration tests can be respectively used as damage or strengthening index indicators. Severe damage due to large crack formations along the un-reinforced masonry walls, is associated with significant stiffness reduction manifested as substantial shift in the lowest four modal frequency values, especially for the mode with the dominant deflections in the direction of shaking. Repair and strengthening with GFRP strips can restore and even exceed the stiffness to the original values of the un-damaged un-reinforced structure. The identified modal frequency reductions of the reinforced building under the series of earthquake tests were of similar level as the un-reinforced building. The observed reductions in modal frequencies of the reinforced masonry structure are attributed to the formation of non-visible micro-cracks between the brick and the mortar material which affected the stiffness of the masonry walls and thus the building's global dynamic characteristics. The damping ratios of the lowest four modes identified from low amplitude vibration tests also show a general increasing tendency with the intensity of seismic excitation and the level of damage. However, such tendency may be hidden by the large fluctuations in the identified values of the modal damping ratios.

The shift of identified modal (resonant) frequencies with the intensity of excitation using low-amplitude vibration tests allows the assessment of the stiffness degradation after each loading event or improvement after a strengthening event. This procedure seems sufficient for developing a vibration-based damage or repairing assessment technique.

It was experimentally demonstrated that reinforcement based on the proposed GFRP material bands significantly stiffens and strengthens the structure. The proposed reinforcement applied before or after a damaging seismic event is useful for reducing the vulnerability and seismic risk of brick masonry structures. Optimally placed GFRP strips are thus considered as

one of the promising retrofitting strategies for protections of seismically excited masonry structures.

Abstract. *In general the condition of a structure can be assessed in terms of a performance indicator. For example, this can be the strength of a structure. An asset manager is concerned with ensuring that the performance of a structure does not fall below a given minimum level. This can be achieved by inspecting or monitoring the structure. As the performance indicator decreases with time, the asset manager can decide to take pre-emptive measures to restore the condition to its initial level, thus avoiding getting too close to the minimum required level. In order to work this way, it is important to define a reliable performance indicator. Following an inventory of structures which are prone to some form of degradation over time, a modular bridge expansion joint was selected as a case to be considered in this investigation.*

In order to determine the observability of known failure mechanisms in terms of modal and spectral data an experiment is set up which can simulate the construction under these circumstances. Further, a Finite Element Model of the construction is made, which is tuned to the experimental setup. This model is used to validate the applied inverse modeling technique to identify the failure parameters. The inverse modeling is performed using a genetic algorithm.

Through inverse modeling of the monitor data, changes over time of the identified failure parameters are obtained. In order to predict the development of the observed failure parameters in the future, these changes over time are incorporated in a prediction model. Taking uncertainties into account, stochastic processes are used to describe the degradation process. Thus, different types of processes can be used, e.g. Markov chains for discrete state changes in time or Gamma processes for continuous quantities in time. By continuously updating the prediction model with the monitor data, a risk based maintenance management tool is obtained by which pro-active and well-planned maintenance actions can be decided on. The developed methodology is applied to a full scale monitoring system of a real bridge in the Netherlands.

1 INTRODUCTION

Bridge expansion joints generally require a lot of maintenance. Replacing an expansion joint usually requires closing off (part of) the bridge which, together with the cost of the joint itself, makes this type of maintenance very expensive and a possible cause of major traffic disruptions. In order to determine the best moment to perform maintenance it is advantageous to be able to continuously monitor the state of the expansion joint. At the moment the condition of joints is normally checked by carrying out visual inspections at regular intervals. These visual inspections rely heavily on the experience and judgement of the inspector while some types of damage may not be visible at all. This introduces a relatively large uncertainty which, given the cost of replacement of the expansion joint, is highly undesirable. If the remaining serviceable lifetime can be estimated in a non-invasive manner with greater certainty the cost savings involved could therefore be substantial.

In this paper the non-invasive detection of damages to a modular bridge expansion joint by ambient vibration monitoring will be discussed as a possible alternative to visual inspection. The theoretical background behind this technique is presented in section 2. The current investigation consists of four distinct parts: lab tests on part of a joint, damage detection by inverse modeling, extrapolation of detected damages using a degradation model and extraction of guidelines for ambient vibration measurements. These are subsequently discussed in sections 3 through 6. In section 7 the ongoing effort of validation of these techniques using a real bridge are briefly discussed. A summary and conclusions are given in section 8.

2 THEORY

2.1 Damage detection

From experience it is known that structural damage can manifest itself through changes in natural frequencies, modal shapes and damping factors [1]. Changes in the frequencies and modal shapes of lower eigenmodes are generally an indication of global damage whereas changes at higher eigenmodes are often indicative of local damage. In the case of localized damage the amount of change in modal shape is usually highly frequency dependent and especially pronounced near the damaged part of the structure and behind it (as observed from the direction of the excitation source).

When trying to solve the inverse problem of determining damage parameters from a measured dynamic system response several practical problems are encountered [2]. One of these is the relatively limited amount of sensors in any practical measurement setup, as a result of which the observation of local changes in mode shapes due to local damage becomes a matter of chance. This might be mediated somewhat by the placement of sensors in positions where damage is most likely (i.e. near welds or areas of high stress) but it doesn't solve the problem completely.

More serious are the problems related to ill-conditioning, such as the question of uniqueness: it is conceivable that different types of damage have very similar effects on the observables monitored in the experiment, in which case the type of damage that has occurred can only be extracted from the measurement data with great difficulty, if at all. Among the possible solutions to this problem are the judgemental placement of sensors (ideally based on model calculations done before the actual measurements), the use of high precision sensors, placing a large number of sensors and measuring over long periods of time.

In addition to all of the above the number of parameters that can be varied in a typical (FEM) model of even a single joint is very large. This means that it is impossible to try and fit all of them to the measurement data. Therefore a small number of possible damages has to be

selected and only the parameters involved in those damage mechanisms are used as model input. However, it is obvious that any damage mechanism not considered beforehand will thus be overlooked. For these types of damage the model will therefore only be able to detect that a change has occurred, without being able to specify its cause.

2.2 Ambient vibration monitoring

In lab tests both the static and the dynamic response of the joint to a known excitation are measured (see section 3). However, for the purpose of monitoring real-life systems the use of artificial excitation sources has several drawbacks, for instance:

- The size of real-life systems is usually large, which means powerful excitation devices are needed. These devices are expensive and cumbersome, requiring a lot of time for their installation. Furthermore, in certain situations their size may be prohibitive
- The excitation of the structure due to traffic is generally much stronger than that due to (powerful) artificial excitation devices. Therefore, in order to perform sufficiently sensitive measurements, the bridge normally has to be closed off

As a result it has become common practice to monitor the dynamic response of a structure to ambient excitations (i.e. road traffic, wind, earthquakes etc.) instead. In the analysis these ambient forces are usually modeled as white noise. Although this assumption may introduce a modeling error and, given the statistical nature of the ambient forces, measurements have to be taken over a sufficiently large period of time, these shortcomings are normally outweighed by the advantages over artificial excitation.

2.3 Evolutionary algorithms

The solution process for any inverse problem is inherently iterative in nature. Many different algorithms have been developed for this purpose. Inverse modeling of damages is a global optimization problem where many local minima in solution space might exist. A global optimizer therefore has to be chosen, such as Monte Carlo methods, swarm-based optimization algorithms or neural networks. For the current investigation genetic algorithms were chosen, which belong to the more general class of evolutionary algorithms.

While many different implementations of evolutionary algorithms exist they are all based on the same general principles, inspired by the processes of reproduction and natural selection in nature. The concepts common to these implementations will briefly be discussed.

An individual is a trial solution to the problem and therefore consists of a complete set of parameter values that is necessary for the description of such a solution. In a first step the value of every parameter is chosen at random, each within a range set by the user. A given number of individuals (called a population) is generated this way, after which the quality of each individual is evaluated. This evaluation proceeds through a fitness function which quantifies the agreement between the trial solution and the target solution. The general idea is now to use the information contained in the best solution(s) (called parent(s)) in the generation of a new set of trial solutions (offspring). The creation of new trial solutions in each generation based on the best solution(s) from last generation ensures that the best solution will progressively improve. This process continues cyclically until the fit has converged.

The most popular evolutionary algorithm is probably the genetic algorithm. In this method the parameter values from two parents are randomly combined to create the offspring. To protect the algorithm from getting stuck in a local minimum of the error landscape some parameter values are changed at random for a small number of solutions, called a mutation. To make

sure that the best solutions do not deteriorate between generations they are allowed to survive unaltered from one generation to the next (elitism). The solution process is depicted in figure 1.

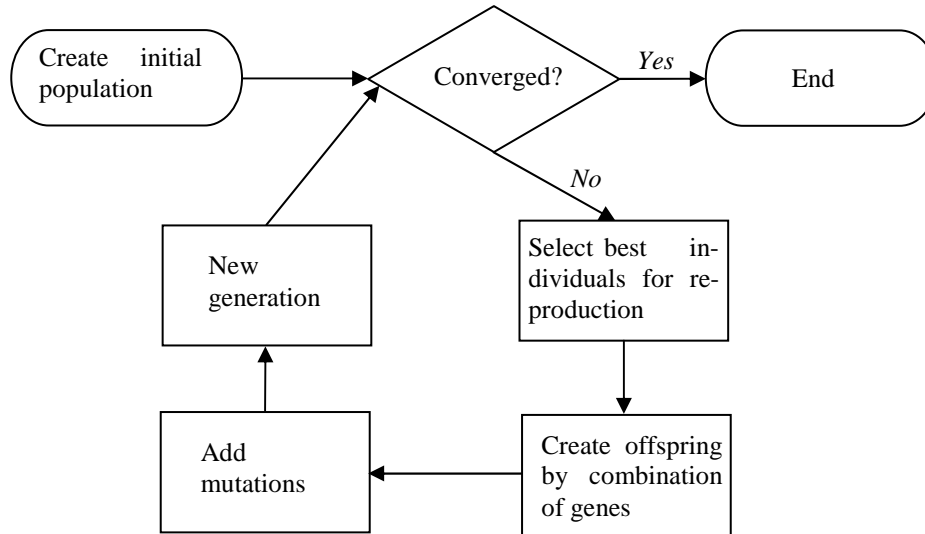

Figure 1: Genetic algorithm flowchart

As can be concluded from the above the genetic algorithm is basically stochastic in nature. This means that, depending on the complexity of the parameter space under investigation, convergence will be harder to achieve with increasing size of the parameter space. Although this effect can be countered by increasing the population size this will also increase the computational cost. For this reason it is very important to restrict parameter space as much as possible before a calculation is started. Unless the fitness function values for different possible solutions are suspected to be very close to each other it is therefore good practice to only include the parameters the final solution is most sensitive to in an initial fit and include the remaining parameters in a second, independent fit where the parameter range for the first set of parameters is much reduced.

3 LAB TESTS

3.1 Test setup

The full-size expansion joint mimicked in the lab tests is depicted in Figure 2. It is comprised of an edge beam, three center beams and a second edge beam arranged in the longitudinal direction of the joint with interposed elastomeric strip seals. The center beams are supported on cross bars (support bars) which bridge the structural gap. Each center beam has an individual set of support bars ensuring an independent movement of the center beams relative to each other. Support bars are placed at about 2m intervals and are grouped in sets of three. Each such set of support bars is inserted within a metal box which is fixed to the main structure. Each support bar rests on two sliding bearings.

Figure 2: An example of a modular bridge expansion joint

The type of joint investigated can be prone to a number of different damage mechanisms as observed in the past:

- Wear and tear of sliding supports
- Wear and tear of control springs
- Failure of center beams or support bars
- Failure of weld joints between support bar and center beam
- Misalignment or breaking off of sliding supports
- Defects in strip seals

The experimental model consists of one single center beam on 5 support bars. The selected center beam is the first of the three center beams and is therefore located asymmetrically with respect to the support bar. The center beam is modelled using a HEM100 profile which has similar section properties as the beam used in the real expansion joint. The support bars on the other hand have identical dimensions as the real ones. The same sliding supports (sliding bearing and sliding spring) are used as in the real joint. The whole structure rests on two concrete plates placed in a bed of mortar of about 2 cm thickness on top of the laboratory floor. The sliding bearings and sliding springs are kept in place by a top steel plate which is fixed to the concrete plate via two threaded rods. The sliding bearing and spring can be positioned in such a way to simulate a closed joint as well as an open joint. Details of the lab model of the joint can be seen in Figures 3 and 4. The configuration depicted is that of a closed joint.

Figures 3 and 4 show side and top views of the lab model, respectively. The lab model has a total length of 7.5m, with support bars at intervals of approximately 1.8m. For reference purposes, a grid is defined consisting of 5 vertical lines numbered 1 to 5 and two horizontal lines indicated by 'a' and 'b'. The 5 vertical lines correspond to the positions of the support bars. Lines 'a' and 'b' correspond to the long and short ends of the support bar, respectively. A Cartesian coordinate system is chosen such that the x -axis is parallel to the center beam, the y -axis is perpendicular to the center beam and the z -axis points upwards.

Figure 3: Side view of the lab model

Figure 4: Top view of the lab model (schematic)

In the lab tests the objective is the reverse of that in the subsequent parts of the project: to investigate the effect of damage to the joint on measurable parameters in order to determine which quantities should be monitored. Several different observables were therefore monitored in the lab tests: accelerations of the center beam parallel and perpendicular to the road surface, strains and deflections of the support bars in the vertical direction (w.r.t. the road surface) and sound at some distance from the joint. An extensive set of measurements of both the static and dynamic response of the lab joint was carried out using accelerometers, strain gauges, microphones and laser triangulation sensors. The lab model allowed mimicking of all known damages mentioned in the previous section apart from the first (wear and tear of sliding supports) and the last (defects in strip seals).

3.2 Results

For lack of space only a small part of the tests which were performed are presented here. A single dynamic excitation of a 1000 kg weight impacting the center beam in vertical (negative z) direction between support bars 3 and 4 was therefore selected. Some of the recorded responses will be presented in section 4: here only the conclusions are discussed.

Control spring failure was not detected with the chosen observation quantities. This holds for any excitation position and any excitation direction.

A half saw cut in the support bar can be detected, though the effects are not significant. The main change is increased damping in the damaged support.

A half saw cut in the center beam can be detected with the investigated observation parameters. Compared to the effects of a half saw cut in one of the support bars the effects of a cut in the center beam are similar but more pronounced.

Loose joints can only be detected with the chosen observation parameters when the central beam is excited in y -direction and the dynamic parameters are determined in the same direction. In this case the main changes are larger displacements above the supports and different bending moments in the support bars. For the excitation considered in this paper, which is in the z -direction, no significant change is observed.

The failure of a support is very easily detectable: in the case of a single support this leads to the occurrence of a low frequency mode at about 25 Hz. At this mode the support bar vibrates at high amplitudes and low damping.

The effects of combined failures can roughly be superimposed.

4 INVERSE MODELING

4.1 Model definition

A finite element model of the bridge joint was constructed in Matlab. The model is very flexible, allowing the number of structural members (beams and support bars), the joint geometry and all material parameter values each to be set by a single variable. For a given set of parameter values it will then calculate eigenfrequencies, eigenmodes and the system response to a given input. This setup was chosen because it gives optimization routines written in Matlab direct access to all relevant parameters. An example of a bridge joint created with this Matlab script is given in Figure 5. In the following all relevant components of the model will be discussed in more detail.

First the number of beams and support bars, their sizes and their positions relative to each other and to the joint supports need to be specified. The number of elements to be used for each joint section is also selected. Based on this geometric information the script will construct a global coordinate system as well as local coordinate systems for both the beams and support bars; however, in this paper the global axis system indicated in Figure 4 will be referred to exclusively. It will then derive the coordinates of each element. In addition, in order to be able to fully specify how beams and support bars are connected, a small connection element which also carries its own local axis system is introduced between beams and support bars.

After this is done the material parameters for the beams, support bars and connection elements need to be specified: Young's Modulus (E), shear modulus (G), mass per unit length (Mu) and torsional mass per unit length (J). The connections between support bars and joint supports, which are made of rubber, are modeled as a spring-damper system in all 6 degrees of freedom (translations and rotations around all three local axes), corresponding with a total of 12 degrees of freedom (i.e. 6 for the springs and 6 for the dampers).

Figure 5: An example of a bridge joint model with a single beam and five support bars generated with the joint Matlab script. Each cross indicates a node of the FEM model. Also indicated is the axis system.

Each section of the joint is modeled as a Timoshenko beam with independent bending along the local y - and z -axes and torsion along the local x -axis. To this end the script has to be provided with five additional geometric parameters each for the beams, support bars and connections: cross sectional area, shear cross sectional area, bending inertia about the local y - and z -axes and torsional inertia about the local x -axis.

After the model has been defined the system matrices are set up and the eigenmodes and eigenfrequencies are calculated. When a time-dependent force acting on the system is now defined the response in each mode can be derived using the Newmark routine, after which all modal responses are added to yield the total system response. In this process a modal damping factor can be specified for each individual mode. Since the number of modes involved is usually so large that it is impractical to actually do so, in practice the damping values are obtained by interpolation from a table containing damping factors at a number of fixed frequencies.

4.2 Model tuning

Before a start can be made with the modeling of damages, the parameter values which are not precisely known from the experiment have to be fit by comparison of measured and calculated system responses for the undamaged joint. This process, termed model tuning, will be discussed in the following.

The model presented here contains 22 parameters for which their values were deemed to be uncertain enough to be included in the tuning process: the cross sectional area, shear cross sectional area, bending inertia about the x - and y -axes and torsional inertia about the z -axis for the connection element between beam and support bars; the six spring stiffnesses for the connection between support bars and joint supports; and eleven modal damping values at various frequencies.

For the tuning of the model a single measurement from the experiment was chosen, namely a dynamic excitation in z -direction (vertical), in the middle between support bars 3 and 4 (hereafter denoted as position 3.5). Even though the time trace of the corresponding excitation force is available from the measurements, in environmental vibration monitoring this excitation force is often unknown and therefore modeled as white noise (see section 2.2). For this reason the excitation force time trace was used as input for the Matlab model, in order to en-

able a comparison with the lab data which is as good as possible, but not in the comparison itself. Instead, the mobilities at different positions on the beam were chosen as the monitoring variables, as these contain information about the system as a whole yet are independent of the excitation force. Since the mobility becomes singular for zero force only those mobilities were used in the fitting procedure for which the corresponding force was at least 1% of its maximum value. As a result the mobility spectra throughout this paper feature gaps at those frequencies where this condition doesn't hold.

The parameter optimization problem at hand is clearly complex: it contains many variables (22) and the parameter ranges for most of these variables are very large, spanning several orders of magnitude. Such a parameter space can be very wild and erratic containing many local minima. In order to ensure the stability of the optimization process a global optimizer should therefore be used. For the present investigation a genetic algorithm (see section 2.3) was considered most appropriate and was therefore used throughout. As a fitness function the weighted normalized difference between measured and calculated mobilities was chosen:

$$fitness = \sum_i w_i \|mob_c^i - mob_m^i\| / \|mob_m^i\|, \quad (1)$$

where mob_c and mob_m indicate the calculated and measured mobility, respectively, and the sum runs over all measurement positions that are included in the evaluation. The relative weights w_i of the measured spectra are chosen to be proportional to the maximum mobility values in these spectra with $\sum w_i = 1$. From this definition it can be deduced that for trial solutions of comparable norm as the measured mobility ($\|mob_c^i\| \approx \|mob_m^i\| \forall i$) the given fitness function is approximately normalized, with a value ~ 1 meaning no correspondence whatsoever and 0 indicating perfect agreement. Correspondingly, it can be viewed as a measure of discrepancy between calculated and measured spectra, with for example a value of 0.18 indicating a mismatch of roughly 18%.

In a first attempt to fit the model output to measurement data six response traces were selected, at beam positions 2.5, 3 and 3.5, each in both the x and z direction of the axis system. Using initial estimates for the model parameters the sensitivity of the fitness function to a change in each of these parameters was investigated. The average change in the fitness function value to a change in parameter value by an order of magnitude in either direction was required to be at least $1 \cdot 10^{-4}$. This requirement was not met by two parameters, namely the damping values at both extreme ends of the specified frequency range (75 and 3000 Hz). The remaining 20 parameters were included in a genetic algorithm fit in the frequency range 0-500 Hz with a population size of 1000 and 40% elitism (400 individuals). On an average PC (a 3 GHz dual-core machine with 3GB internal memory) this calculation ran for approximately 48 hours before finishing at generation 57. A comparison between measured and fitted spectra showed some discrepancies, especially where the responses in the x -direction and at higher frequencies (> 350 Hz) were concerned. This may be because the excitation may not have been purely in the z -direction, because no direct coupling between the bending modes in both orthogonal directions has been included in the model or (in the case of the high-frequency modes) because the element size is too coarse for an accurate description.

Given the above result and the fact that most features which are indicative of damage are expected to be observable in the response curve in the z -direction at lower frequencies (≤ 350 Hz) a second global fit was made using only the mobilities in the z -direction and a frequency range of 0-350 Hz. All 22 parameters were included in the fit, which again had a population size of 1000 with 40% elitism, ran for another 48 hours and finished at generation 58. This fit converged to roughly the same corner of parameter space as the previous one, indicating that

the global optimum had indeed been reached. In a third and last optimization step a local optimizer including all 22 parameters was run on the obtained solution to give the global minimum. The result, with a fitness function value of 0.2780, is displayed in Figures 6 through 8. As can be seen the correspondence is rather good, especially given the fact that the absolute response in Figure 7 is over 2 orders of magnitude smaller than at the other two positions and measurement noise may therefore be relevant here.

Figure 6: Measured and calculated mobilities in the z -direction in the middle between support bars 2 and 3 for an excitation force in z -direction between support bars 3 and 4

Figure 7: Measured and calculated mobilities in the z -direction above support bar 3 for an excitation force in z -direction between support bars 3 and 4

Figure 8: Measured and calculated mobilities in the z -direction in the middle between support bars 3 and 4 for an excitation force in the same direction and position

4.3 Damage detection

As mentioned in section 2.1 in the current measurement setup the total number of parameters in the model is much larger than the number of available measurement traces. Given the possible non-uniqueness of a solution to the inverse problem it is unwise to try and unambiguously fit all parameters to the available data. The effects of the types of damage, to be considered by the model, on the model parameters should therefore be estimated before a fit is attempted. Here the same damages as investigated in the lab test (section 3.2) were included.

Control spring failure

This type of damage was modeled as zero support bar spring stiffness in the x -direction, the effect of which was not visible on any of the spectra observed here. This type of damage will therefore not be discussed further.

Support failure

In the lab tests the effects of sliding supports breaking off was investigated by removing a single sliding support of the third support bar, on the side furthest away from the beam, as well as by removing both sliding supports for the same support bar in a second test. This was modeled by setting all support bar spring stiffnesses for the respective sliding support(s) equal to zero. For the missing support on a single side it was also found that the best agreement between model and experiment could be found if the modal damping factor at 75 Hz was reduced from 15 % to 9 % while the damping factor at 118 Hz was increased from 0.3164 % to 0.65 %. The spectrum at position 3 for this one-sided damage case is given in Figure 9.

From this spectrum it can be deduced that a new mode has appeared at around 26 Hz which is especially strong over the support bar. Although the frequency of this mode is slightly overpredicted by the model (28 Hz) the agreement in position and relative mode intensities is very good. Even more subtle effects are reproduced very well: at all frequencies apart from the new mode the response is observed to be slightly higher at position 2.5, slightly

lower at position 3.5 and significantly lower at position 3, and the peak at around 118 Hz which for the undamaged case is present at position 3 has disappeared for the damaged case, all in accordance with model predictions. A decreased response in the main mode at 118 Hz in the spectra at positions 2.5 and 3.5 is fitted by the aforementioned increased modal damping factor at this frequency. It can therefore be concluded that this type of damage is clearly visible in the spectra presented here and identification of this damage mode should therefore be possible.

Figure 9: Effect of a single sliding support breaking off on the mobility spectrum at position 3

Half saw cut in a support bar

In the lab experiments this type of damage to a support bar was tested by making a cut in the vertical direction (the long axis of its cross section) over the full width of the support bar. In this configuration the cross sectional area, shear cross sectional area, bending inertia about the z -axis and torsional inertia about the x -axis all decrease linearly with increasing depth of the cut while the bending inertia about the y -axis decreases with the third power of this depth. For a different type of cut or different geometries like that of the beam, however, these dependencies could be different. Nevertheless, the same dependency was assumed for the beam as well (with x - and y -axes interchanged following its different orientation).

The effect the cut in support bar number 3 has on the measured mobilities is displayed in Figure 10. The only effect that can be observed at positions 2.5 and 3.5 is an increased damping in the main mode at 118 Hz. It was found that the measured spectra could best be reproduced using a modal damping value of 0.7% at this frequency. At position 3 the response at all frequencies up to about 250 Hz is significantly higher for the damaged case, most notably in the 118 Hz-mode. All these effects are accurately predicted by the model used here. Nevertheless, the absolute changes in the measured responses are relatively small, especially when considering the fact that a 50% cut was used for this experiment. Normally, actual cracks will of course be much smaller and their effects therefore even less visible than observed here.

Additionally, comparing the observed changes to the mobility spectra with other damage mechanisms considered in the current investigation, the question of uniqueness of the effects of this type of damage to a support bar arises once again. In a real life situation it is therefore unlikely that the existence of a crack in a support bar can be deduced from the mobilities observed here.

Figure 10: Effect of a 50% cut in support bar 3 on the mobility spectrum at position 2.5

Half saw cut in center beam

From the measured spectra (see Figures 11 and 12) it can be deduced that, most interestingly, the frequency of the main mode at positions 2.5 and 3.5 has decreased by 6 Hz and the intensity has decreased considerably as well. These effects are reproduced very well by the model, although the actual intensity of the responses for positions 2.5 and 3.5 is somewhat underestimated. Around the same frequency the peak in the mobility spectrum at position 3 seems to have split up into two separate peaks, one at a slightly lower and another at a slightly higher frequency. Whereas this splitup and the resulting frequencies are again reproduced by the model the intensity of the lower frequency mode (corresponding with the main peak at positions 2.5 and 3.5) is severely underestimated. It can be concluded nevertheless that the effect of a 50% cut in the beam can be observed very well and can clearly be distinguished from the effects of other types of damage. However, as with the crack in a support bar discussed above, it is questionable whether a clear response will be visible for a more real-life situation where the expected crack depth is small.

Loose joint

A weld failure between beam and support bar was reproduced in the model by setting all moments of inertia for the connection element to zero. Simultaneously the cross sectional area and shear cross sectional area for this element should be lowered. The actual value to be used is hard to predict since it is an effective value: upward motion of the beam is unhindered in case the connection between beam and support bar has failed, corresponding with zero area for the connection element. Downward motion of the beam, however, is unaltered since the support bar itself is still present. The reduction factor to be used for the cross sectional area and shear cross sectional area was therefore deduced from a comparison between the model

and experiment. A value of $1e-3$ was found to give the best correspondence. Lastly, the modal damping factor for the main mode at 118 Hz was increased to 0.5%. The resulting model calculations and a comparison with experiment are given in Figure 13.

Figure 11: Effect of a 50% cut in the beam on the mobility spectrum at position 2.5

Figure 12: Effect of a 50% cut in the beam on the mobility spectrum at position 3

Figure 13: Effect of failure of a weld between beam and support bar at position 3 on the mobility spectrum at this position

Not surprisingly the largest effect for this type of damage can be observed above the support bar, where a very strong mode has appeared at a frequency of 79 Hz. The same mode is also present in the other two spectra, although much more weakly. Furthermore the intensity distributions are changed in all spectra, most notably above the support bar where it is much stronger in the range 0-250 Hz than for the undamaged case. All these effects, including even the minor changes in relative mode intensities at positions 2.5 and 3.5, are predicted perfectly by the model. The only blemish is the fact that in the damaged case the intensity for the new mode at 79 Hz is overestimated, in contrast with the underestimated response for the undamaged case. The predicted effects can also clearly be distinguished from those of other damages. Combined with the fact that weld failure is a binary effect which will always lead to the same amount of damage it can be safely concluded that this type of damage can easily be detected and identified. However, the fact that the cross sectional area and shear cross sectional area had to be fitted to the experimental data rather than determined from first principles is somewhat disappointing. It might be that the value of $1e-3$ used here is different for other joint geometries or even other types of excitation and should therefore be redetermined for every analysis.

Combined damages

With respect to combined damages the inverse modeling confirms the conclusions obtained from the experiments: the effects of combined damages can well be approximated by adding the effects of each separate type of damage.

5 DEGRADATION MODEL

5.1 Defect initiation and growth

The process of degradation can often be well described as random due to poor inspection, lack of data or other sources of uncertainty. Stochastic processes have been widely used in order to investigate inspection strategies under stochastic degradation (see for example [3] and [4]). When the degradation process is to be modeled by continuous quantities in time, for example wall thickness loss or corrosion growth in time, then the gamma process is more natural [5]. When the degradation process is modeled by changes of one state to another in time then Markov chains are more suitable [6]. According to [5] the gamma process has been successfully fitted to data on creep of concrete, fatigue crack growth, corroded steel gates, thinning due to corrosion and chloride ingress into concrete. On the basis of the gamma deterioration process, case studies have been performed to determine optimal dike heightening, optimal sand nourishment sizes, optimal decisions for steel coatings and optimal inspection intervals for high speed railway tracks, berm breakwaters, steel pressure vessels, automobile brake pads, and block mats and rock dumping of the Eastern-Scheldt barrier in the Netherlands. In this paper a tool that investigates deterioration through the gamma process is introduced. The model is taken from [7]. The Poisson process is used to model initiation times while the gamma process is used to model deterioration growth.

The Poisson process is a counting process. This is a random function $N: \mathbb{R}^+ \rightarrow \mathbb{R}$ such that:

- $N(0) = 0$ and $N(t) \in \{0, 1, 2, 3, \dots\}$ for all t
- if $s < t$ then $N(s) < N(t)$

Following [8] the homogeneous Poisson process will be defined by equation (2). $N(a_i, b_i]$ denotes the number of events (degradation initiation in our case) falling in the half-open interval $(a_i, b_i]$ with $a_i < b_i \leq a_{i+1}$.

$$P\{N(a_i, b_i) = n_i, i = 1, \dots, k\} = \prod_{i=1}^k \frac{[\lambda(b_i - a_i)]^{n_i}}{n_i!} e^{-\lambda(b_i - a_i)} \quad (2)$$

The parameter λ can be interpreted as the mean rate of occurrence or intensity. The non-homogeneous Poisson process with time dependent rate $\lambda(t)$ can be defined exactly as in equation (2) with the quantities $\lambda(b_i - a_i) = \int_{a_i}^{b_i} \lambda dx$ replaced whenever they occur by quantities:

$$\Lambda(a_i, b_i) = \lambda \int_{a_i}^{b_i} m(x) dx \quad (3)$$

In this case, the parameter λ will be referred to as the proportionality constant. In a general framework this parameter may be used in a Bayesian analysis. It will be considered uncertain and in order to update the model we could use the number of defect observed in a given time interval.

In a gamma process a random variable X has a gamma distribution with shape parameter $v > 0$ and scale parameter $u > 0$ if its probability density function is given by:

$$ga(x | v(t), u) = \frac{u^{v(t)}}{\Gamma(v(t))} x^{v(t)-1} e^{-ux} I_{(0, \infty)}(x) \quad (4)$$

where $I_A(x) = 1$ for $x \in A$ and $I_A(x) = 0$ for $x \notin A$, and $\Gamma(a) = \int_{z=0}^{\infty} z^{a-1} e^{-z} dz$ is the gamma function for $a > 0$. If $v(t)$ now is a non-decreasing, right continuous, real valued function for

$t \geq 0$ with $v(0) \equiv 0$ then the gamma process with shape function $v(t) > 0$ and scale parameter $u > 0$ is a continuous-time stochastic process $\{X(t); t \geq 0\}$ such that:

- $X(0) = 0$ with probability one
- $X(s) - X(t) \sim ga(\cdot | v(s) - v(t); u)$ for all $s > t \geq 0$
- $X(t)$ has independent increments

From this definition the first hitting time distribution can be derived, which is the distribution of the first time at which the defect size is larger than a given defect size y . It is denoted by T_y and it is given by

$$F_{T_y}(t) = P(T_y \leq t) = P(X(t) \geq y) = \int_y^\infty ga(x, v(t), u) dx \quad (5)$$

5.2 Deterioration process

The deterioration process will be defined following [7] as a combination of defect initiation and defect growth. Defects will initiate according to a Poisson process (homogeneous or not) and will grow independently according to the gamma process. The probability density function (pdf) of the k^{th} arrival time ($S_k : 1 \leq k \leq n$) conditional on n defect initiations up to time t (for fixed t) is given by

$$f_{S_k|N(t)} = n(s) = \frac{n!}{(k-1)!(n-k)!} \left(\frac{\Lambda(s)}{\Lambda(t)} \right)^{k-1} \left(1 - \frac{\Lambda(s)}{\Lambda(t)} \right)^{n-k} \frac{\lambda(s)}{\Lambda(t)} \quad (6)$$

The depth D_k of the k^{th} defect at time t will be defined as the growth according to a gamma process in the time interval between its initiation and t , that is, $D_k = X(t - S_k)$. Assuming that the process $X(\cdot)$ is independent of the arrival times S_k and using equation (6) we obtain:

$$P(D_k \leq x | N(t) = n) = \int_0^t P(X(t-s) \leq x) f_{S_k|N(t)=n}(s) ds \quad (7)$$

Under our assumption that we have knowledge that n defects have initiated up to time t we could ask what the distribution is of the size of a randomly selected defect at time t . This is given in the equation below.

$$P(D_k \leq x | N(t) = n) = \int_0^t P(X(t-s) \leq x) \frac{\lambda(s)}{\Lambda(t)} ds \quad (8)$$

5.3 Failure probability

We assume that our component fails as soon as a defect is deeper than a certain defect size y . Let $N_x(t)$ denote the number of defects deeper than x for $x > 0$ up to time t . Then the probability that no system failure occurs up to t is given by $P(N_y(t) = 0)$. It may be shown that the process $N_x(t)$ is also a Poisson process with intensity given by

$$\Lambda_x(t) = \lambda \int_0^t F_{T_x}(t-s) m(s) ds \quad (9)$$

We define the event $A_x(t)$ as the event of observing at least one defect larger than x within the time interval $(0, t]$. Since the event $N_x(t)$ is also a Poisson process then

$$P(A_x(t)) = 1 - e^{-\Lambda_x(t)} \quad (10)$$

5.4 Structural assessment

The idea behind full-scale measurements is that ambient vibrations measured by e.g. strain meters are used as input for the damage detection model described in section 4. This will result in information regarding the number of defects present in the joint, the types of defects and the extent of each. These data could then be used to continuously update estimates of the degradation model parameters described above: the proportionality constant λ describing the rate of occurrence of defect initiation and the shape parameter ν and scale parameter u describing the progression of defects after initiation. In absence of sufficient data to determine reliable values for the latter two parameters they can be estimated by structural experts from typical times after which certain levels of degradation are expected to be reached. With increasing measurement time the defect parameter estimates will become more accurate, enabling the asset manager to reliably determine when specified minimum performance criteria will be reached and maintenance should be planned.

6 SETTING UP AN EXPERIMENT

In the previous sections all aspects of damage detection using inverse analysis have been discussed in theory and checked against lab experiments on a bridge joint. It was found that under these controlled conditions at least some types of damage can indeed be detected and the corresponding damage parameters derived. This result shows that the more general approach to inverse analysis also applies to a bridge joint. The success or failure of a certain type of experiment can often be reliably predicted before the actual experiment is even performed.

When setting up an experiment for an inverse problem one should in general follow the procedure outlined in Figure 14, which starts with a definition of the parameters that are to be determined in the analysis (for the case discussed in this paper the different types of damage which are to be distinguished). A model of the problem can then be set up and its response to different types of input (for example the different damage types) analyzed. This will provide the user with information about the number of detectors that has to be used as well as their optimal placement in order to avoid ill-conditioning. The amount of detail used at this stage is of critical importance. This is also the point where, in the case of environmental vibration monitoring, the question should be answered which (preferably force-independent) parameters should be monitored (for example mobilities). Lastly, the effect of the excitation location(s) and possible locations of damage should be considered, since for many types of damage changes in observables are mainly visible near these locations.

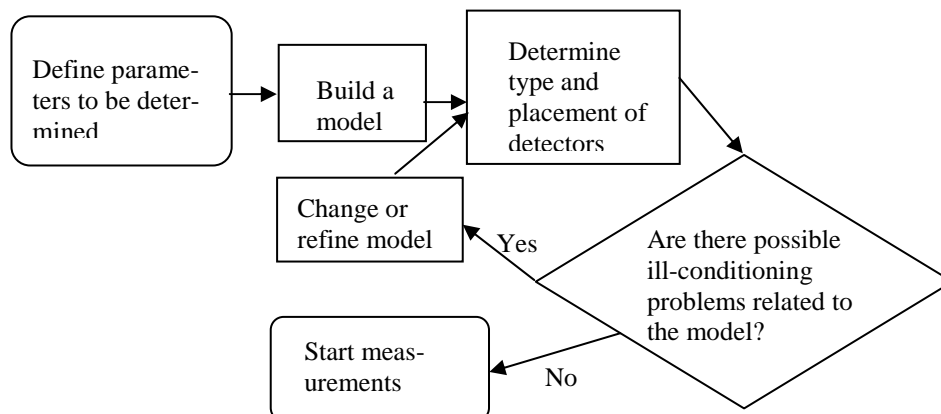

Figure 14: Procedure for setting up an inverse detection experiment

Using the information obtained above the user should be able to assess from calculated sensitivities whether any ill-conditioning is to be expected and whether all parameters of interest can be uniquely determined. If not the user can attempt to change or refine the model based on these observations in order to remedy the situation. Only when all issues have been solved can the experiment be started. If a problem persists despite changes to the model and/or detector placement it has to be concluded that it is not possible to reliably detect the parameters the user is interested in with the type of experiment under consideration.

After an experiment has been conducted the system response as predicted by the model needs to be fit to the actual response by variation of model parameters which are not well known (tuning of the model). In the current investigation it was found that in practical situations a model response (such as for the FEM model used here) quickly becomes so complex that a local optimization routine can no longer be used. A genetic algorithm was therefore chosen, which performed very well. As a good alternative neural networks could also be considered but their use was not explored here. The genetic algorithm might also be used to determine the optimal detector placement as part of the setup of an experiment as outlined in the previous paragraph.

In the case of continuous measurements the response of the tuned model can be compared with the measurement data at every timestep. When the discrepancy is greater than a predetermined threshold it is concluded that damage has occurred and a refit of the model will be requested to determine the type of damage and the corresponding damage parameters. Since the model will usually contain far too many parameters to be able to determine all of them possible damages will have to be explicitly specified and included in the model refit as possible causes for the observed change in system response. This does mean that the damage detection system will only be able to identify those damages which have been considered at the outset of the experiment.

For the types of damage which occur gradually it is also important to determine at which point damage becomes visible as a change in variables. The answer to this question obviously depends on many different factors such as the level of detail of the model used in the analysis and the measurement noise. The threshold on the fitness function used to identify damages should be set accordingly. If, for example, a change in the fitness function value of 0.01 is taken as an indication of damage and the cause of this change is a crack in a beam, then for the model considered here a crack with a minimum depth of 1.5% of the beam height, corresponding with 1.8 mm, should be observable. Depending on the cause for the formation of this crack this may or may not coincide with the moment of crack appearance.

7 FULL-SCALE TESTS

In order to test the models described above full-scale measurements are performed on a bridge in the Netherlands. From mid to end June 2010 a monitoring system was installed in order to measure strain deformation in steel parts. However, given the recent installation of these strain gauges as compared to the bridge design lifetime insufficient information has yet been obtained to derive the necessary defect parameters. Detailed results of this ongoing effort will be presented in future publications.

8 CONCLUSIONS

In this paper lab measurements of the dynamic response of a damaged bridge expansion joint were discussed. It was found that several of the more common types of damage could reliably be discriminated and quantified through the use of genetic algorithms for the determination of key parameters in a FEM model. Given these promising results full-scale tests were

started on an actual bridge expansion joint installed in a highway bridge in the Netherlands. Since no results from the full-scale tests are available yet thought should be given to the question as to how far the results obtained for the lab model can be extended to a full-size bridge joint. The number of model parameters for a full-sized joint is obviously larger than that for the lab model, but this is offset by the fact that the overall geometry of a joint is very regular. This means that, although larger, the model for the full-sized joint will most likely not be any more complex. The same types of spectra and effects can therefore be expected. Moreover, since lateral movement of the actual joint will be much more constricted than was the case for the lab model, unlike the lab model case it might even be possible to use the mobility spectra in this direction in the fitting procedures, which might help to alleviate some of the ill-posedness which was observed in the lab tests.

The quality of data from the actual bridge joint depends on many factors such as the number, type and sensitivity of the detectors used in the experiment, their placement and the amount of traffic across the bridge. However, given suitably large averaging times there is principally no reason to assume that data obtained for the full-sized joint should be of lower quality than those obtained from the lab tests. Since in the lab tests mobilities were observed, which are independent of the excitation force, the use of ambient vibrations as an excitation source should also not affect the suitability of the method investigated here. In conclusion, damage detection by environmental vibration monitoring is a feasible method for use with a bridge expansion joint.

Keywords: Bayesian, Operational Modal Identification, Wireless Sensor Network, Spectral Decomposition.

Abstract. *Structural health monitoring (SHM) employing wireless sensor networks (WSN) is becoming increasingly popular in recent years. A Bayesian spectral decomposition (BSD) method employing a distributed computing strategy is presented for structural modal identification in WSN using output-only response data. This method uses the statistical properties of the largest eigenvalue of the output spectral matrix to obtain not only the optimal values of the updated modal frequencies and damping ratios but also their associated uncertainties by calculating the posterior joint probability distribution of these parameters. Mode shapes are obtained by singular value decomposition (SVD) of the output spectral matrix at corresponding discrete frequencies closest to their optimal values. This method identifies each mode, the modal frequency and damping ratio and the mode shape separately, which takes advantage of variable separation and can distribute the computational effort to several computational units, thus becoming suitable for implementation in wireless sensor network that provides such distributed computing environment. In addition, energy is conserved through the use of a novel distributed computing strategy. The efficacy and efficiency of the proposed methodology is demonstrated using numerical simulations.*

1 INTRODUCTION

Experimental modal analysis (EMA) using vibration data has been widely used over the years because of its importance in model updating, response prediction, vibration control and health monitoring. Many modal identification algorithms, both in the time and frequency domain, have been developed in the past three decades. Particularly, much attention has been devoted to the identification of modal parameters in the case where no input but only response measurements are available. These techniques, referred to as operational modal analysis or output-only modal identification or ambient modal identification, provide an in-operation testing solution for modal parameter identification with no need for external artificial excitations and take advantage of the ambient excitations such as micro-tremors, traffic, wind, waves and earthquakes, etc. Operational modal identification is proved to be very useful in civil engineering, where it is very difficult and expensive to excite infrastructures such as buildings and bridges with actuators to obtain artificially induced vibrations.

In recent years, the emerging wireless sensor networks (WSN) for structural health monitoring (SHM) have attracted a lot of attention from both the academic and industrial communities [1]. Wireless sensor networks have the potential to improve SHM dramatically with onboard computation and wireless communication capabilities. Compared with traditional wired structural monitoring systems, wireless sensors can locally process measured data and transmit only the important information through wireless communication, allowing for the distribution of the computation burden across the network. Moreover, there is no extensive wiring between sensors and data acquisition system, which allows for a fast and flexible implementation, and easier maintenance. Inspired by these advantages, WSN are becoming immensely popular in structural health monitoring in recent years.

Though the wireless sensor network has the potential to improve SHM dramatically, limited resources on wireless sensors preclude direct application of existing algorithms in wireless sensor networks [2]. For example, the wireless sensors have limited computation speed, limited memory space and limited energy powered by batteries. Algorithms designed to be implemented in WSN should take account of such limitations, and it is preferable to process the data in a decentralized way. On the other hand, uncertainties are abundant in civil engineering and statistical methods for modal identification based on output-only measurements have been well developed and have been attracting more attention recently. Statistical methods are very powerful because they explicitly treat uncertainties entering the mathematical models of the structure and the excitations. Bayesian statistical approaches for modal identification have been proposed by Katafygiotis and Yuen [3-4] using ambient data under a Bayesian statistical framework. As a result, they not only obtain the optimal values of the updated parameters by maximizing the posterior probability density function (PDF), but also allow for the quantification of uncertainties associated with the identified parameters of interest. However, the critical issue that always remains is the efficient determination of optimal values and their covariance matrix. Usually, the optimal values are solved by multidimensional numerical optimization and the covariance matrix is determined by finite difference. When the number of identified parameters is moderate to large, which is typical in modal identification of civil infrastructures, numerical optimization in maximizing the posterior PDF is very challenging and requires lots of computation effort to obtain the optimal values, which would preclude such algorithms from being implemented in wireless sensor networks. A method that not only has most of the advantages related to Bayesian statistical algorithms for uncertainty treatment but also reduces much of the computation effort is desirable.

Au (2011) developed a fast Bayesian FFT method for ambient modal identification with separate modes [5], which allows for fast computation of the optimal values and covariance

matrix. In this work, we present a Bayesian spectral decomposition (BSD) method for modal identification using ambient data which is based on the statistical properties of the largest eigenvalue of the output spectral matrix. This method identifies each mode, the modal frequency and damping ratio and the mode shape separately. As a result, the number of parameters to be identified by numerical optimization reduces to four for each mode. After the optimal modal frequencies have been obtained, mode shapes are determined by singular value decomposition of the output spectral matrix at corresponding frequencies. Moreover, a distributed computing strategy is proposed for energy conservation in WSN. A numerical example is presented to demonstrate its procedures and features.

2 THEORETICAL ASPECTS

Some of the theoretical aspects related to the presented work are briefly discussed in the following sections.

2.1 Bayesian spectral density method

Let the acceleration time history measured at N_s DOFs of a structure be $\mathbf{Y}_N = \{\mathbf{y}(m) \in \mathbb{R}^{N_s}, m=1, \dots, N\}$, where N is the number of samples per channel. Herein, the measured acceleration is modeled as $\mathbf{y}(m) = \mathbf{x}(m) + \mathbf{n}(m)$, where $\mathbf{x}(m)$ is the acceleration response of the structural model defined by a set of model parameters $\boldsymbol{\theta}$, the parameters to be identified; $\mathbf{n}(m)$ is the prediction error which accounts for the difference between the model response and measured data, due to measurement noise and modeling error. Based on \mathbf{Y}_N we introduce the following discrete estimator of the spectral density matrix

$$\mathbf{S}_{y,N}(\omega_k) = \mathbf{y}_N(\omega_k) \mathbf{y}_N(\omega_k)^H \quad (1)$$

where the superscript H denotes conjugate transpose, $\mathbf{y}_N(\omega_k)$ denotes the (scaled) Fourier transform of the vector process $\mathbf{y}(t)$ at frequency ω_k , as follows:

$$\mathbf{y}_N(\omega_k) = \sqrt{\frac{\Delta t}{2\pi N}} \sum_{m=0}^{N-1} \mathbf{y}(m) e^{-j\omega_k m \Delta t} \quad (2)$$

where $j^2 = -1$, Δt is the sampling interval, $\omega_k = k\Delta\omega$, $k = 0, \dots, N_1 - 1$ with $N_1 = \text{INT}(N/2)$, $\Delta\omega = 2\pi/T$, and $T = N\Delta t$. The scaling factor of the FFT in Eq(2) is defined such that the spectral density is two-sided with respect to the circular frequency in rad/s.

For a liner classically damped structure subjected to white noise excitation and independent and identical distributed (i.i.d.) Gaussian prediction error, Katafygiotis and Yuen (2001) derived the PDF for the spectral density matrix and applied it to Bayesian modal identification [3]. Consider a set of independent, identically distributed, time histories $\mathbf{Y}_N^{(1)}, \dots, \mathbf{Y}_N^{(M)}$. Assuming that $N \rightarrow \infty$, the corresponding Fourier transforms $\mathbf{y}_N^{(m)}(\omega_k)$, $m = 1, \dots, M$ are independent and follow an identical complex N_s -variate normal distribution with zero mean, and the average spectral density estimate

$$\mathbf{S}_{y,N}^M(\omega_k) = \frac{1}{M} \sum_{m=1}^M \mathbf{S}_{y,N}^{(m)}(\omega_k) = \frac{1}{M} \sum_{m=1}^M \mathbf{y}_N^{(m)}(\omega_k) \mathbf{y}_N^{(m)}(\omega_k)^H \quad (3)$$

follows a central complex Wishart distribution of dimension N_s with M degrees of freedom. The PDF of this distribution is given by:

$$p(\mathbf{S}_{y,N}^M(\omega_k)) = \frac{\pi^{-N_s(N_s-1)/2} M^{N_s(M-N_s)} |\mathbf{S}_{y,N}^M(\omega_k)|^{M-N_s}}{(\prod_{p=1}^{N_s} (M-p)! |E[\mathbf{S}_{y,N}(\omega_k)]|^M} \exp(-M \text{tr}[E[\mathbf{S}_{y,N}(\omega_k)]^{-1} \mathbf{S}_{y,N}^M(\omega_k)]) \quad (4)$$

where $|A|$, $\text{tr}[A]$ and $E[A]$ denote the determinant, the trace and the expectation, respectively, of a matrix A . Note that this PDF exists only when $M \geq N_s$. Furthermore, it can be shown that in the limit when $N \rightarrow \infty$ the matrices $\mathbf{S}_{y,N}^M(\omega_k)$ and $\mathbf{S}_{y,N}^M(\omega_l)$ are independently Wishart distributed for $k \neq l$.

On the other hand, for a high sampling rate and long duration of data, the term $E[\mathbf{S}_{y,N}(\omega_k)]$ in Eq(4) can be expressed as

$$E[\mathbf{S}_{y,N}(\omega_k)] = \mathbf{\Phi} \mathbf{H}_k \mathbf{\Phi}^T + \mathbf{S}_{n0} \quad (5)$$

where $\mathbf{\Phi} \in \mathbb{R}^{N_s \times N_m}$ is the mode shape matrix confined to the measured DOFs (the i -th column corresponds to the i -th mode shape); \mathbf{S}_{n0} is the spectral density matrix (constant) of the prediction error; \mathbf{H}_k is the spectral density matrix of the modal response with (i, j) element given by

$$H_k(i, j) = \frac{S_{ij} \omega_k^4}{[(\omega_i^2 - \omega_k^2) + 2j\omega_k \omega_i \zeta_i][(\omega_j^2 - \omega_k^2) - 2j\omega_k \omega_j \zeta_j]} \quad (6)$$

It should be noted that this is only valid for acceleration response, and the exponential of ω_k in the numerator will be the values 0 or 2 when the response corresponds to displacement or velocity, respectively.

In the context of modal identification the set of modal parameters $\boldsymbol{\theta}$ consists of the natural frequencies, damping ratios, mode shapes, spectral density matrix of modal excitations and spectral density of the prediction error. Assuming a non-informative prior distribution, the posterior PDF of $\boldsymbol{\theta}$ given the spectral density data is proportional to the likelihood function

$$p(\boldsymbol{\theta} | \mathbf{S}_{y,N}^{M,k_1,k_2}) \propto p(\mathbf{S}_{y,N}^{M,k_1,k_2} | \boldsymbol{\theta}) \simeq c_1 \prod_{k=k_1}^{k_2} \frac{|\mathbf{S}_{y,N}^M(\omega_k)|^{M-N_s}}{|E[\mathbf{S}_{y,N}(\omega_k)]|^M} \exp(-M \text{tr}[E[\mathbf{S}_{y,N}(\omega_k)]^{-1} \mathbf{S}_{y,N}^M(\omega_k)]) \quad (7)$$

where c_1 is a normalizing constant.

The most probable parameters $\hat{\boldsymbol{\theta}}$ are obtained by minimizing the log-likelihood function $L(\boldsymbol{\theta})$

$$p(\boldsymbol{\theta} | \mathbf{S}_{y,N}^{M,k_1,k_2}) \propto \exp[-L(\boldsymbol{\theta})] \quad (8)$$

where

$$L(\boldsymbol{\theta}) = M \sum_{k=k_1}^{k_2} \left[\ln |E[\mathbf{S}_{y,N}(\omega_k)]| + \text{tr}[E[\mathbf{S}_{y,N}(\omega_k)]^{-1} \mathbf{S}_{y,N}^M(\omega_k)] \right] \quad (9)$$

Furthermore, with a sufficient large amount of data, the posterior PDF of the parameters $\boldsymbol{\theta}$ can be well-approximated by a Gaussian distribution $N(\hat{\boldsymbol{\theta}}, \mathbf{H}^{-1}(\hat{\boldsymbol{\theta}}))$ with mean $\hat{\boldsymbol{\theta}}$ and covariance matrix $\mathbf{H}^{-1}(\hat{\boldsymbol{\theta}})$, where $\mathbf{H}(\hat{\boldsymbol{\theta}})$ denotes the Hessian of $L(\boldsymbol{\theta})$ calculated at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$. Consider a second order expansion for the log-likelihood function

$$L(\boldsymbol{\theta}) \simeq L(\hat{\boldsymbol{\theta}}) + \mathbf{J}(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) + \frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \mathbf{H}(\hat{\boldsymbol{\theta}})(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \quad (10)$$

Note that the first term is a constant, and the second term vanishes since the gradient vector $\mathbf{J}(\hat{\boldsymbol{\theta}})$ equals to zero due to the minimization nature. Substituting Eq.(10) into Eq.(8), the posterior PDF can be approximated by a Gaussian distribution

$$p(\boldsymbol{\theta} | \mathbf{S}_{y,N}^{M,k_1,k_2}) \propto \exp\left[-\frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T \mathbf{C}(\hat{\boldsymbol{\theta}})^{-1}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})\right] \quad (11)$$

where $\mathbf{C}(\hat{\boldsymbol{\theta}}) = \mathbf{H}(\hat{\boldsymbol{\theta}})^{-1}$ is the posterior covariance matrix, inverse of the Hessian matrix.

The critical issue that remains is the efficient determination of the most probable parameters and their covariance. In the original method, the optimal values are solved by numerical optimization and the Hessian is determined by finite difference. In particular, the objective function is a nontrivial nonlinear function of the modal parameters, so the determination of most probable parameters is computationally very demanding. In addition, the inverse of $E[\mathbf{S}_{y,N}(\omega_k)]$ is ill-conditioned in a resonance frequency band. If all the most probable parameters were to be found by numerical optimization then the computational effort grows with the number of measured DOFs N_s and the number of contributed modes N_m . By noting the symmetry of the spectral density matrix of modal excitations and the normalization characteristic of mode shapes, there are $2N_m + N_m(N_s-1) + N_m(N_m+1)/2 + N_s = O(N_m^2 + N_m N_s)$ parameters to be identified. The growth of the dimension with N_s is a major issue because it can be moderate or large in typical civil engineering applications (e.g., $N_s > 10$). The growth of the dimension with N_m , although quadratic, is not significant because one can focus on a resonance frequency band dominated by a small number of modes. For well-separated modes one can identify each mode separately and $N_m=1$ in this case.

In the next section we shall analyze the statistical property of the largest eigenvalue of the output spectral matrix and utilize it to effectively determine the optimal values of modal frequency and damping ratio and their covariance matrix when the structure has separated modes.

2.2 Modal identification with single mode

Assume that in a resonance frequency band the response is dominated by a single mode and only the spectral density data in this band are used for modal identification. For simplification, the spectral density of the prediction error is assumed to be the same for all measured DOFs. In this case, the parameters $\boldsymbol{\theta}$ consist of the natural frequency ω , damping ratio ζ , mode shape $\Phi \in \mathbb{R}^{N_s}$, spectral density S_f of the modal excitation and the prediction error S_n . Here the modal index is omitted for simplification. It is assumed that the mode shape is normalized to have unit norm, i.e., $\|\Phi\|^2 = 1$.

We start by examining the mathematical structure of $E[\mathbf{S}_{y,N}(\omega_k)]$ in Eq.(5). In this case,

$$E[\mathbf{S}_{y,N}(\omega_k)] = \alpha_k \Phi \Phi^T + S_n \mathbf{I}_{N_s} \quad (12)$$

where

$$\alpha_k = \frac{S_f}{(\beta_k^2 - 1)^2 + (2\zeta\beta_k)^2} = S_f A_k \quad (13)$$

where $\beta_k = \omega/\omega_k$, and $A_k = 1/[(\beta_k^2 - 1)^2 + (2\zeta\beta_k)^2]$ is the modal dynamic amplification. To facilitate deriving the analytical form of largest eigenvalue, we shall express $E[\mathbf{S}_{y,N}(\omega_k)]$ in a more suitable form. The key is to express $E[\mathbf{S}_{y,N}(\omega_k)]$ via a suitable eigendecomposition. Define a set of orthonormal bases $\mathbf{E} = \{e_j \in \mathbb{R}^{N_s} : j = 1, \dots, N_s\}$, where $e_1 = \Phi \in \mathbb{R}^{N_s}$ and $\{e_2, e_3, \dots, e_{N_s}\}$ form an orthonormal basis in the complement subspace. Using this basis, the identity matrix can be represented as $\mathbf{I}_{N_s} = \sum_{j=1}^{N_s} e_j e_j^T$, so the Eq.(12) can be rewritten as

$$E[\mathbf{S}_{y,N}(\omega_k)] = \alpha_k e_1 e_1^T + S_n \sum_{j=2}^{N_s} e_j e_j^T = (\alpha_k + S_n) e_1 e_1^T + S_n \sum_{j=2}^{N_s} e_j e_j^T \quad (14)$$

The eigenvalues of $E[\mathbf{S}_{y,N}(\omega_k)]$ are $\alpha_k + S_n, S_n, \dots, S_n$, with corresponding eigenvector e_1, e_2, \dots, e_{N_s} , and the largest eigenvalue d_k of $E[\mathbf{S}_{y,N}(\omega_k)]$ is

$$d_k = \alpha_k + S_n = \frac{S_f}{(\beta_k^2 - 1)^2 + (2\zeta\beta_k)^2} + S_n \quad (15)$$

A considerable amount of mathematical effort has been devoted on finding distributions for the eigenvalues of a Wishart matrix. Let s_k be the largest eigenvalue of $\mathbf{S}_{x,N}^M(\omega_k)$. According to Ref. [6], the largest eigenvalue s_k are asymptotically independently normally distributed with

$$E(s_k) = d_k, \quad \text{var}(s_k) = \frac{2d_k^2}{M} \quad (16)$$

In the context of modal identification, assuming a non-informative prior distribution, the posterior PDF of $\boldsymbol{\theta}$ given the eigenvalue data is proportional to the likelihood function

$$p(\boldsymbol{\theta} | \mathbf{s}_k^{k_1, k_2}) \propto p(\mathbf{s}_k^{k_1, k_2} | \boldsymbol{\theta}) \simeq \prod_{k=k_1}^{k=k_2} \frac{\sqrt{M}}{\sqrt{4\pi d_k}} \exp\left(-\frac{M(s_k - d_k)^2}{4d_k^2}\right) \quad (17)$$

In the context of wireless sensor network, in order to utilize the distributed computing capacity, the whole network may be divided into n clusters of sensors. In this case, each cluster can determine a posterior PDF based on its own data, and n sets of posterior PDF will be obtained. The fusion of all the information obtained by various clusters can be conducted in Bayesian manner. Take one cluster as a priori, continuously include the data in other clusters, then the final posterior PDF $p(\boldsymbol{\theta} | \mathbf{s}_k^{n, k_1, k_2})$ will be a product of the n posterior PDFs corresponding to all clusters,

$$p(\boldsymbol{\theta} | \mathbf{s}_k^{n, k_1, k_2}) \propto p(\mathbf{s}_k^{n, k_1, k_2} | \boldsymbol{\theta}) \simeq \prod_n \prod_{k=k_1}^{k=k_2} \frac{\sqrt{M}}{\sqrt{4\pi d_k}} \exp\left(-\frac{M(s_k - d_k)^2}{4d_k^2}\right) \quad (18)$$

The most probable parameters $\hat{\boldsymbol{\theta}}$ are obtained by maximizing the posterior PDF $p(\boldsymbol{\theta} | \mathbf{s}_k^{n, k_1, k_2})$. This is equivalent to minimizing $L(\boldsymbol{\theta}) = -\ln[p(\mathbf{s}_k^{n, k_1, k_2} | \boldsymbol{\theta})]$. Various optimization algorithms can be employed to minimize $L(\boldsymbol{\theta})$ and obtain the optimal parameters $\hat{\boldsymbol{\theta}}$, and then central difference or analytical formulas can be used to calculate the Hessian matrix $\mathbf{H}(\hat{\boldsymbol{\theta}})$.

Furthermore, it is found that the updated PDF of the parameters $\boldsymbol{\theta}$ can be well approximated by a Gaussian distribution $N(\hat{\boldsymbol{\theta}}, \mathbf{H}^{-1}(\hat{\boldsymbol{\theta}}))$ with mean $\hat{\boldsymbol{\theta}}$ and covariance matrix $\mathbf{H}^{-1}(\hat{\boldsymbol{\theta}})$.

2.3 Mode shape identification and assembling

The mode shapes can be identified as follows: since the modal frequency ω is identified in the previous section, the nearest discrete frequency $\omega_k \rightarrow \omega$ can be obtained. From Eq. (14), we know that the corresponding singular vector \mathbf{u}_k is an estimate of the r^{th} mode shape Φ with unitary normalization. The principle for mode shape identification is the same as that of FDD method [9].

The mode shapes extracted from a particular cluster of sensors are referred to as local mode shapes. The local mode shapes have to be rescaled and assembled to global mode shapes. Consider the global mode shape Φ^Ω for the r^{th} mode, along with local mode shapes $\Phi^{\Omega_1}, \Phi^{\Omega_2}, \dots, \Phi^{\Omega_n}$ associated with respective clusters of sensors $\Omega_1, \Omega_2, \dots, \Omega_n$. The local mode shapes Φ^{Ω_i} and Φ^{Ω_j} associated with two neighboring clusters with overlapped sensors can be expressed as

$$\Phi^{\Omega_i} = \begin{pmatrix} \phi_{i1} \\ \phi_{i2} \\ \vdots \\ \phi_{ip} \\ \phi_{i1} \\ \vdots \\ \phi_{io} \end{pmatrix} \text{ and } \Phi^{\Omega_j} = \begin{pmatrix} \phi_{j1} \\ \phi_{j2} \\ \vdots \\ \phi_{jq} \\ \phi_{j1} \\ \vdots \\ \phi_{jo} \end{pmatrix} \quad (19)$$

where o is the number of overlapping nodes, and p and q are the number of non-overlapping nodes in the i^{th} and j^{th} clusters, respectively. To allow assembly, the mode shapes in Equation (19) should be rescaled to have the same values at the overlapping nodes, i.e.

$$\begin{pmatrix} \phi_{i1} \\ \vdots \\ \phi_{io} \end{pmatrix} = R_j \begin{pmatrix} \phi_{j1} \\ \vdots \\ \phi_{jo} \end{pmatrix} \quad (20)$$

where R_j is a rescaling factor for the mode shape Φ^{Ω_j} . The global mode shape is the union of the local mode shapes as

$$\Phi^\Omega = \bigcup_{i=1}^n R_i \Phi^{\Omega_i} \quad (21)$$

In the presence of noise, the rescaling factors to Equation (20) for any $o > 1$ does not exist in general. Therefore, the rescaling factors R_i ($i=1, 2, \dots, n$) must be approximately determined, for example as a solution in the least-square sense [7-8]. Using the rescaling factors, the local mode shapes are scaled and assembled to obtain the global mode shape. At the overlapping nodes, the local mode shapes are averaged to obtain the associated values of the global mode shape.

3 APPLICATION IN WIRELESS SENSOR NETWORKS

In this section, a distributed computing strategy is adopted to implement this algorithm. This distributed computing strategy can reduce the data amount of wireless transmission and take advantage of decentralized computing capacity of the wireless sensor networks (WSN). Because wireless communication often consumes more energy than other parts, algorithms which require transmission of long time history records should be avoided. Pre-processing data locally will not only make it possible to transmit smaller amount of important information but also take advantage of the autonomous computing capacity of smart sensors. A two-level hierarchical architecture is proposed for the application of WSN for Bayesian modal identification. There are three types of sensors classified by their functions in the network: gateway node, cluster head nodes and leaf nodes. The schematic network architecture is shown in Figure 1.

Figure 1. Two-level hierarchical architecture of WSN

Both the leaf nodes and cluster head nodes perform data acquisition, and each node calculates the FFT and then the auto-spectral density. Using Peak-Picking method, the potential modal frequencies can be obtained. Once all the local modal frequencies from leaf nodes and cluster head nodes are collected centrally in the gateway node, the first task is to pick out the true modes. The true modes should be identified obviously in the majority of clusters, while the noise modes will randomly appear. Thus, if a specific natural frequency is identified in a substantial number of clusters, it is considered as a true mode. FFT data around these modal frequencies are sent to cluster head nodes, and then cross-spectrum around these frequencies can be calculated in the cluster head node. In the cluster head node, SVD is performed in the vicinity of the modes to be identified, and then corresponding singular values (eigenvalues) are sent to the gateway node. Using Bayesian inference, modal frequencies and damping ratios together with their uncertainties are obtained in the gateway node and then the gateway node returns modal frequencies to each cluster head node. Thus, local mode shapes in each cluster can be obtained using SVD at the corresponding closest discrete frequencies. Finally, each cluster head node reports local mode shapes to the gateway node. A global mode shape is assembled in the gateway node by comparing the overlapping nodes in each cluster. After that, finalized modal parameters and their uncertainties are sent to PC via USB cable.

4 NUMERICAL EXAMPLE

In this example, we use simulated data from an 8-story shear building shown in Figure 2. It is assumed that this building has a uniformly distributed floor mass $m=1\times 10^5\text{kg}$ and inter-

storey stiffness $k=2.5 \times 10^8 \text{ N/m}$, and Rayleigh's damping with corresponding damping ratios $\zeta_1 = \zeta_2 = 1\%$ is assumed. The structure is assumed to be subjected to a base acceleration given by stationary Gaussian white noise with a spectral density of $0.0025 \text{ m}^2 \text{ s}^{-3} \text{ rad}^{-1}$. It is assumed that the accelerations at each floor were measured using a sampling interval $\Delta T = 0.01 \text{ sec}$. The time duration for one data set is 1000 s and 10 data sets are collected. The measurement noise at different sensors is assumed to be i.i.d. Gaussian white noise with $\text{RMS} = 0.1 \text{ ms}^{-2}$. Therefore, the spectral density estimation calculated by Eq. (3) follows a Wishart distribution with $M=10$ degrees of freedom and their eigenvalues asymptotically follows a Gaussian distribution.

Figure 2. 8-storey shear building

The measurements can be taken by wireless sensors, which are grouped into two clusters: cluster A and cluster B. Cluster A consists of sensor #1, #2, #3, #4 and #5, one of which (excluding the overlapping nodes) is served as cluster head. Cluster B consists of sensor #4, #5, #6, #7 and #8, one of which (excluding the overlapping nodes) serves as cluster head. The overlapping nodes for these two clusters are sensor #4 and #5, which are used for global mode shape assembling. From the auto-spectrum in each sensor node, we know that there are three significant modes.

Table 1 shows the identified results from the output measurements. It shows the estimated optimal values $\hat{\theta}$, the calculated standard deviations σ , coefficient of variance (COV), the value of a 'normalized distance' β . The parameter β represents the absolute value of difference between the identified optimal and actual value, normalized with respect to the corresponding calculated standard deviation. Thus, β expresses how many standard deviations away the identified value of a given parameter is from the target value. It can also be seen that

the COV of damping is larger than that of natural frequency, which means it contains more uncertainty.

The mode shapes are identified using SVD of the output spectral matrix at the nearest discrete frequencies, and the corresponding singular vector \mathbf{u}_k is an estimate of the r^{th} mode shape Φ with unitary normalization. The global mode shapes are assembled using least square method. The identified results are tabulated in table 2. The modal assurance criterion (MAC) values between theoretical values and identified ones are listed in the end column. The MAC values shows that the identified results closely match the theoretical ones.

	Actual θ	Optimal $\hat{\theta}$	S.D. σ	C.O.V	$\beta = \theta - \hat{\theta} / \sigma$
ω_1	6.2851	6.2831	0.0022	0.0004	0.8948

5 CONCLUSIONS

A Bayesian spectral decomposition (BSD) method for identifying modal parameters using output-only data is presented. This method takes advantage of the Bayesian spectral density approach (BSDA) and frequency domain decomposition (FDD) method, and avoids their limitations. Comparing with BSDA, this method reduces the dimension of identified parameters in the optimization problem to only four for each mode. It can identify each mode separately, which renders the method suitable for implementation in wireless sensor networks. Comparing with FDD, this method considers the uncertainty in a Bayesian statistical framework. It avoids the subjective peak-picking procedures for modal frequency identification and the accuracy of damping ratio is also remarkable. It obtains not only the optimal values of the modal frequencies and damping ratios but also their associated uncertainties by calculating the posterior joint probability of these parameters. The quantification of these uncertainties is very important when one plans to use modal parameters estimates for further processing.

The proposed method along with the distributed computing strategy may be suitable to be implemented in wireless sensor networks by utilizing the autonomous computing capacity of each wireless sensor. The proposed distributed computing strategy can reduce the amount of wireless communication and thus conserve the energy in an efficient manner.

Abstract. *In this paper we propose the results of an experimental investigation addressed to identify mass, stiffness and damping matrices of a two-story building model. The goal of our research is to set up a quick procedure to design control laws for mitigating structural vibrations and/or detecting damage of structure itself. We placed on each floor a 4507 Bruel & Kjaer accelerometer connected to 6160 Bruel & Kjaer Pulse spectrum analyzer, then we excited the structure by 8202 Bruel & Kjaer impact hammer and through the recorded I/O data we identified the modal model. Once obtained the system modal parameters, we identified mass, stiffness and damping matrices of the structure. We are going to exploit these experimental results for designing a virtual passive controller. This apparatus is composed of an electric actuator placed on the top of the building connected to a NI-CompactRio System.*

1 INTRODUCTION

System identification is the art of determining a mathematical model of a physical system by combining information obtained from experimental data with that derived from an a priori knowledge. There are several types of system identification algorithms in relation to different goals one wants to pursue. In mechanical engineering, applied system identification allows to get modal parameters of a dynamical system using force and vibration measurements. These parameters are typically used to design optimal control laws whereas in the field of structural health monitoring they are used to detect and evaluate system damage. A very powerful algorithm to perform system identification is Eigensystem Realization Algorithm with Data Correlation using Observer/Kalman Filter Identification (ERA/DC OKID) [1, 2, 3, 4]. This numerical procedure is able to construct a state-space representation of a mechanical system starting from input and output measurements even in presence of process and measurement noise. On the other hand, when all degrees of freedom are instrumented with a force and/or an acceleration transducer, an efficient numerical procedure can be implemented to construct a second-order model of the mechanical system starting from state-space representation (MKR) [5, 6, 7]. Experimental investigations show that ERA/DC OKID correctly determines system natural frequencies and damping ratios whereas MKR method properly identifies mass and stiffness matrices but it fails in estimating damping matrix because actual measurements are never noise-free. Nevertheless, if the real system is lightly damped, authors propose an efficient procedure [8, 9] for identifying in a direct way system damping matrix from state-space realization by assuming proportional damping hypothesis.

2 MATHEMATICAL BACKGROUND

2.1 System Modelling

Consider a multiple degrees of freedom mechanical system. Let $\mathbf{M} \in R^{n_2 \times n_2}$, $\mathbf{K} \in R^{n_2 \times n_2}$ and $\mathbf{R} \in R^{n_2 \times n_2}$ be the mass, stiffness and damping matrices, respectively. The system equations of motion can be expressed in matrix notation as:

$$\mathbf{M} \ddot{\mathbf{x}}(t) + \mathbf{R} \dot{\mathbf{x}}(t) + \mathbf{K} \mathbf{x}(t) = \mathbf{F}(t) \quad (1)$$

where $\mathbf{x}(t) \in R^{n_2}$, $\dot{\mathbf{x}}(t) \in R^{n_2}$, $\ddot{\mathbf{x}}(t) \in R^{n_2}$ are vectors of generalized displacement, velocity and acceleration, respectively, and $\mathbf{F}(t) \in R^{n_2}$ is the vector of forcing functions.

On the other hand, if the response of the dynamic system is measured by the $m \in N$ output quantities in the output vector $\mathbf{y}(t) \in R^m$, then the output equations can be written in a matrix form as follows:

$$\mathbf{y}(t) = \mathbf{C}_d \mathbf{x}(t) + \mathbf{C}_v \dot{\mathbf{x}}(t) + \mathbf{C}_a \ddot{\mathbf{x}}(t) \quad (2)$$

where $\mathbf{C}_d \in R^{m \times n_2}$, $\mathbf{C}_v \in R^{m \times n_2}$ and $\mathbf{C}_a \in R^{m \times n_2}$ are respectively the output influence matrices for displacement, velocity and acceleration. These output influence matrices simply describe the relation between the vectors $\mathbf{x}(t)$, $\dot{\mathbf{x}}(t)$, $\ddot{\mathbf{x}}(t)$ and the measurement vector $\mathbf{y}(t)$, which in general can be a linear combination of system generalized displacement, velocity and acceleration.

Let $\mathbf{z}(t) \in R^n$ be the state vector of the system:

$$\mathbf{z}(t) = \begin{bmatrix} \mathbf{x}(t) \\ \dot{\mathbf{x}}(t) \end{bmatrix} \quad (3)$$

where $n \in N$ is the dimension of the system state vector. The forcing function $\mathbf{F}(t)$ over the period of interest at a certain specific location can be expressed using a vector $\mathbf{u}(t) \in R^r$ containing $r \in N$ input quantities according to this relation:

$$\mathbf{F}(t) = \mathbf{B}_2 \mathbf{u}(t) \quad (4)$$

where $\mathbf{B}_2 \in R^{n_2 \times r}$ is an input influence matrix characterizing the locations and type of inputs. The equations of motions and the output equations can both be respectively rewritten in terms of the state vector as follows:

$$\dot{\mathbf{z}}(t) = \mathbf{A}_c \mathbf{z}(t) + \mathbf{B}_c \mathbf{u}(t) \quad (5)$$

$$\mathbf{y}(t) = \mathbf{C} \mathbf{z}(t) + \mathbf{D} \mathbf{u}(t) \quad (6)$$

where $\mathbf{A}_c \in R^{n \times n}$ is the state transition matrix, $\mathbf{B}_c \in R^{n \times r}$ is the state influence matrix, $\mathbf{C} \in R^{m \times n}$ is the measurements influence matrix and $\mathbf{D} \in R^{m \times r}$ is the direct transmission matrix. These matrix can be computed in this way:

$$\mathbf{A}_c = \begin{bmatrix} \mathbf{O} & \mathbf{I} \\ -\mathbf{M}^{-1} \mathbf{K} & -\mathbf{M}^{-1} \mathbf{R} \end{bmatrix} \quad (7)$$

$$\mathbf{B}_c = \begin{bmatrix} \mathbf{O} \\ \mathbf{M}^{-1} \mathbf{B}_2 \end{bmatrix} \quad (8)$$

$$\mathbf{C} = \begin{bmatrix} \mathbf{C}_d - \mathbf{C}_a \mathbf{M}^{-1} \mathbf{K} & \mathbf{C}_v - \mathbf{C}_a \mathbf{M}^{-1} \mathbf{R} \end{bmatrix} \quad (9)$$

$$\mathbf{D} = \mathbf{C}_a \mathbf{M}^{-1} \mathbf{B}_2 \quad (10)$$

Equations (5) and (6) constitute a continuous-time state-space model of a multiple degrees of freedom dynamical system. Using the preceding definitions, the state-space complex eigenvalues problem can be stated as follows:

$$(\mathbf{A}_c - \lambda_c \mathbf{I}) \psi = \mathbf{0} \quad (11)$$

where $\lambda_{c,j} \in C$, $j = 1, 2, \dots, n$ and $\psi_j \in C^n$, $j = 1, 2, \dots, n$ will be referred as system modal parameters. State-space model eigenvectors can be usefully grouped according to the following matrix notation:

$$\mathbf{\Psi} = \begin{bmatrix} \psi_1 & \psi_2 & \dots & \psi_n \end{bmatrix} \quad (12)$$

where $\mathbf{\Psi} \in C^{n \times n}$ is a matrix constituted of system eigenvectors stacked by columns. Multi-body model eigenvectors $\mathbf{W} \in C^{n_2 \times n}$ obtained from equation (1) and state-space model eigenvectors $\mathbf{\Psi} \in C^{n \times n}$ obtained from equation (5) are mathematically interconnected by the following formula:

$$\mathbf{\Psi} = \begin{bmatrix} \mathbf{W} \\ \mathbf{W} \mathbf{\Lambda}_c \end{bmatrix} \quad (13)$$

where $\mathbf{\Lambda}_c \in C^{n \times n}$ is a diagonal matrix whose elements are system eigenvalues.

2.2 Eigensystem Realization Algorithm with Data Correlation (ERA/DC) using Observer/Kalman Filter Identification (OKID)

The basic development of the state-space realization is attributed to Ho and Kalman. The Ho-Kalman procedure uses the generalized Hankel matrix to construct a state-space representation of a linear system from noise-free data. This methodology has been modified and substantially extended by Juang [1, 2] to develop the Eigensystem Realization Algorithm with Data Correlation (ERA/DC) to identify modal parameters from noisy measurement data. Recently, a method named Observer/Kalman Filter Identification (OKID) has been developed by Juang [3, 4] to compute the Markov parameters of a linear system from which the state-space model and a corresponding observer are determined simultaneously. This method is entirely formulated in time-domain and it is capable of handling general response data.

Conventional time-domain system identification methods use only the system Markov parameters [4] to determine A , B , C and D . On the other hand, OKID uses the combined system and observer gain Markov parameters [4]. These parameters are computed directly from time-domain input and output measurements and are used to identify A , B , G , C and D by the time-domain method named ERA/DC [4].

Basically, the ERA/DC OKID procedure consists in three steps: 1) computation of Markov parameters; 2) realization of state-space model; 3) modal parameters identification.

2.3 Modal Parameters Identification

The ERA/DC OKID procedure is a time-domain identification method which compute a minimum realization of system and the observer gain matrix starting from the combined system and observer gain Markov parameters [4]. A realization is a triplet of matrices $\{\hat{A}, \hat{B}, \hat{C}\}$ that satisfies the discrete-time state-space equations. Obviously, the same system has an infinite set of realizations which will predict the identical response for any particular input. Minimum realization means a model with the smallest state space dimension among all the realizable systems that have the same input-output relations.

All minimum realizations have the same set of eigenvalues and eigenvectors, which are the modal parameters of the system itself. Assume that the state matrix \hat{A} has a complete set of linearly independent eigenvectors $\hat{\psi}_j$, $j = 1, 2, \dots, n$ with corresponding eigenvalues $\hat{\lambda}_j$, $j = 1, 2, \dots, n$:

$$\hat{A} \hat{\Psi} = \hat{\Psi} \hat{\Lambda} \quad (14)$$

where $\hat{\Lambda} \in R^{n \times n}$ is the diagonal matrix of the eigenvalues and $\hat{\Psi} \in C^{n \times n}$ is a matrix formed by the eigenvectors stacked per columns. The realization $\{\hat{A}, \hat{B}, \hat{C}\}$ can be transformed in the realization $\{\hat{\Lambda}, \hat{\Psi}^{-1} \hat{B}, \hat{C} \hat{\Psi}\}$ by using spectral decomposition. The diagonal matrix $\hat{\Lambda}$ contains the informations of modal damping rates and damped natural frequencies. The matrix $\hat{\Psi}^{-1} \hat{B}$ defines the initial modal amplitudes and the matrix $\hat{C} \hat{\Psi}$ the mode shapes at the sensor points. All the modal parameters of a dynamic system can thus be identified by the unique triplet $\{\hat{\Lambda}, \hat{\Psi}^{-1} \hat{B}, \hat{C} \hat{\Psi}\}$. This discrete-time realization can be transformed to its continuous-time counterpart $\{\hat{\Lambda}_c, \hat{\Psi}^{-1} \hat{B}_c, \hat{C} \hat{\Psi}\}$ by using the zero-order-hold assumption. Finally, assuming that all the identified system modes are underdamped, modal damping rates and damped natural frequencies can be computed from the diagonal matrix $\hat{\Lambda}_c \in C^{n \times n}$ as follows:

$$\begin{cases} \hat{\omega}_{n,i} = \sqrt{\hat{\varepsilon}_i^2 + \hat{\omega}_{d,i}^2} & , \quad i = 1, 2, \dots, n_2 \\ \hat{\xi}_i = \frac{-\hat{\varepsilon}_i}{\sqrt{\hat{\varepsilon}_i^2 + \hat{\omega}_{d,i}^2}} & , \quad i = 1, 2, \dots, n_2 \end{cases} \quad (15)$$

where $\hat{\varepsilon}_i$, $i = 1, 2, \dots, n_2$ and $\hat{\omega}_{d,i}$, $i = 1, 2, \dots, n_2$ are respectively the real and imaginary part of the system eigenvalues $\hat{\lambda}_{c,j}$, $j = 1, 2, \dots, n$.

In many practical applications the hypothesis of proportional damping can be assumed as satisfied, especially in the case of structural systems in which damping is small and no a priori informations about its nature are available. Proportional damping assumption is the following:

$$\mathbf{R} = \alpha \mathbf{M} + \beta \mathbf{K} \quad (16)$$

where \mathbf{M} and \mathbf{K} are the mass and stiffness matrices, respectively, whereas α and β are proportional coefficients. If the system is lightly damped, authors propose a simple and efficient method to identify damping matrix starting from identified state space representation [8, 9]. The proportional damping assumption implies that the identified modal damping are related to the identified natural frequencies according to the following equations:

$$\hat{\xi}_i = \frac{\hat{\alpha}}{2\hat{\omega}_{n,i}} + \frac{\hat{\beta}\hat{\omega}_{n,i}}{2}, \quad i = 1, 2, \dots, n_2 \quad (17)$$

where $\omega_{n,i}$, $i = 1, 2, \dots, n_2$ are the identified natural frequencies. These equations can be grouped in a matrix from to yield:

$$\begin{bmatrix} \frac{1}{2\hat{\omega}_{n,1}} & \frac{\hat{\omega}_{n,1}}{2} \\ \frac{1}{2\hat{\omega}_{n,2}} & \frac{\hat{\omega}_{n,2}}{2} \\ \vdots & \vdots \\ \frac{1}{2\hat{\omega}_{n,n_2}} & \frac{\hat{\omega}_{n,n_2}}{2} \end{bmatrix} \begin{bmatrix} \hat{\alpha} \\ \hat{\beta} \end{bmatrix} = \begin{bmatrix} \hat{\xi}_1 \\ \hat{\xi}_2 \\ \vdots \\ \hat{\xi}_{n_2} \end{bmatrix} \quad (18)$$

At this point the proportional coefficients α and β that optimal fits the identified natural frequencies $\omega_{n,i}$, $i = 1, 2, \dots, n_2$ in the least-square sense can be computed taking the pseudo-inverse matrix:

$$\begin{bmatrix} \hat{\alpha} \\ \hat{\beta} \end{bmatrix} = \begin{bmatrix} \frac{1}{2\hat{\omega}_{n,1}} & \frac{\hat{\omega}_{n,1}}{2} \\ \frac{1}{2\hat{\omega}_{n,2}} & \frac{\hat{\omega}_{n,2}}{2} \\ \vdots & \vdots \\ \frac{1}{2\hat{\omega}_{n,n_2}} & \frac{\hat{\omega}_{n,n_2}}{2} \end{bmatrix}^\dagger \begin{bmatrix} \hat{\xi}_1 \\ \hat{\xi}_2 \\ \vdots \\ \hat{\xi}_{n_2} \end{bmatrix} \quad (19)$$

This approximation represents a simple and useful mathematical tool to deals with real experimental data.

3 CONSTRUCTION OF SECOND ORDER MODEL FROM IDENTIFIED STATE-SPACE REPRESENTATION

Consider the following matrices:

$$\mathbf{V}_c = \begin{bmatrix} \mathbf{R} & \mathbf{M} \\ \mathbf{M} & \mathbf{O} \end{bmatrix} \quad (20)$$

$$\mathbf{S}_c = \begin{bmatrix} -\mathbf{K} & \mathbf{O} \\ \mathbf{O} & \mathbf{M} \end{bmatrix} \quad (21)$$

$$\mathbf{B}_3 = \begin{bmatrix} \mathbf{B}_2 \\ \mathbf{O} \end{bmatrix} \quad (22)$$

Using these definitions, a symmetric formulation of system continuous-time state-space model can be developed:

$$\mathbf{V}_c \dot{\mathbf{z}}(t) = \mathbf{S}_c \mathbf{z}(t) + \mathbf{B}_3 \mathbf{u}(t) \quad (23)$$

$$\mathbf{y}(t) = \mathbf{C} \mathbf{z}(t) + \mathbf{D} \mathbf{u}(t) \quad (24)$$

where the matrices $\mathbf{V}_c \in R^{n \times n}$, $\mathbf{S}_c \in R^{n \times n}$ and $\mathbf{B}_3 \in R^{n \times r}$ are all symmetric matrices. The symmetric formulation of system state-space model can be easily reconnected to the typical one (5) noting that the output equations are unchanged and that system transition matrix and state influence matrix can be computed in this way:

$$\mathbf{A}_c = \mathbf{V}_c^{-1} \mathbf{S}_c \quad (25)$$

$$\mathbf{B}_c = \mathbf{V}_c^{-1} \mathbf{B}_3 \quad (26)$$

The advantages of reformulating system state-space model in this way is that now the associated eigenvalues problem is kept symmetric. Indeed:

$$\mathbf{S}_c \boldsymbol{\Psi} = \mathbf{V}_c \boldsymbol{\Psi} \boldsymbol{\Lambda}_c \quad (27)$$

In general, these eigenvectors can be arbitrarily scaled but if the scaling is chosen such that:

$$\boldsymbol{\Psi}^T \mathbf{V}_c \boldsymbol{\Psi} = \mathbf{I} \quad (28)$$

$$\boldsymbol{\Psi}^T \mathbf{S}_c \boldsymbol{\Psi} = \boldsymbol{\Lambda}_c \quad (29)$$

then, for a proportionally damped system, the real and imaginary parts of the components of these complex eigenvectors are equal in magnitude. Once that the symmetric eigenvalues problem has been solved, it can be proved [5, 6, 7] that a transformation matrix can be computed in order to extract multibody model eigenvectors matrix $\hat{\mathbf{W}}$ from state-space realization $\{\hat{\mathbf{A}}, \hat{\mathbf{B}}, \hat{\mathbf{C}}\}$. Finally, using this method it is possible to construct a second-order model of the mechanical system by using the following formulae:

$$\begin{cases} \hat{\mathbf{M}} = (\hat{\mathbf{W}} \hat{\boldsymbol{\Lambda}}_c \hat{\mathbf{W}}^T)^{-1} \\ \hat{\mathbf{K}} = -(\hat{\mathbf{W}} \hat{\boldsymbol{\Lambda}}_c^{-1} \hat{\mathbf{W}}^T)^{-1} \\ \hat{\mathbf{R}} = -\hat{\mathbf{M}} \hat{\mathbf{W}} \hat{\boldsymbol{\Lambda}}_c^2 \hat{\mathbf{W}}^T \hat{\mathbf{M}} \end{cases} \quad (30)$$

This numerical procedure is referred as MKR algorithm [5, 6, 7].

4 SYSTEM IDENTIFICATION OF A TWO-STORY BUILDING MODEL

We have set up a two-story building model composed of four steel pillars and two aluminum beams as showed in figure (??). The first floor pillars have a section $1mm \times 35mm$ and are $300mm$ long while the second floor pillars have a section $1mm \times 35mm$ and are $350mm$ long. The two beams are $200mm$ long with a square section $45mm \times 45mm$. On the first and on the second floor there are two piezoelectric accelerometers as showed in figure (1). The 4507 Bruel & Kjaer accelerometers are connected to 6160 Bruel & Kjaer Pulse spectrum analyzer. The excitation signal is produced by the 8202 Bruel & Kjaer impact hammer, which is connected to the spectrum analyzer too.

Figure 1: Experimental Apparatus

4.1 CASE-STUDY 1

We have studied two experimental configuration. In the first case, we analyzed the two-story building frame. In the second case, we placed an additional mass on the first floor. In figure (2) is showed the force measurement applied on the first floor and in figure (3) there is the system response corresponding to the input. In order to get statistically meaningful results, we repeated the experimental acquisition ten times but in the figures (2), (3) is showed only the first test.

Once the acquisition has been performed, we used ERA/DC OKID to get a state-space representation of the system. The following matrices represent the realization corresponding to the input and output measurements, figures (2), (3):

$$\hat{\mathbf{A}} = \begin{bmatrix} 0.6220 & -0.7789 & -0.0003 & -0.0021 \\ 0.7839 & 0.6191 & 0.0031 & -0.0012 \\ -0.0036 & 0.0061 & 0.9623 & 0.2616 \\ 0.0041 & 0.0044 & -0.2676 & 0.9634 \end{bmatrix} \quad (31)$$

$$\hat{\mathbf{B}} = \begin{bmatrix} 0.0541 \\ -0.0268 \\ 0.0412 \\ 0.0363 \end{bmatrix} \quad (32)$$

$$\hat{\mathbf{C}} = \begin{bmatrix} -37.8710 & -5.0124 & -5.8513 & 1.8479 \\ 26.5700 & 3.2700 & -7.2966 & 2.2001 \end{bmatrix} \quad (33)$$

$$\hat{\mathbf{D}} = \begin{bmatrix} 3.6387 \\ 0.0739 \end{bmatrix} \quad (34)$$

Figure 2: CASE 1 - Force Measurement

Figure 3: CASE 1 - Acceleration Measurements

Examining the singular value $\bar{\Sigma}_n$ of the Hankel matrix $\bar{H}(0)$ showed in figure (4) it is possible to determine the order of the system. Indeed, there are only 4 singular values whose magnitude is not negligible: it means that the system state has dimension $\hat{n} = 4$. Obviously, the same system has an infinite set of realizations which will predict the identical response for any particular input. Minimum realization means a model of the smallest state space dimensions among all realizable systems that have the same input-output relation. All minimum realizations have the same set of eigenvalues and eigenvectors, which are the modal parameters of the system itself:

$$\hat{\Lambda} = \text{diag}(0.6205 + 0.7814i, 0.6205 - 0.7814i, 0.9629 + 0.2646i, 0.9629 - 0.2646i) \quad (35)$$

$$\hat{\Psi} = \begin{bmatrix} 0.0013 + 0.7059i & 0.0013 - 0.7059i & -0.0007 - 0.0019i & -0.0007 + 0.0019i \\ 0.7082 & 0.7082 & 0.0016 + 0.0008i & 0.0016 - 0.0008i \\ -0.0069 - 0.0030i & -0.0069 + 0.0030i & -0.0015 + 0.7031i & -0.0015 - 0.7031i \\ 0.0016 - 0.0071i & 0.0016 + 0.0071i & -0.7111 & -0.7111 \end{bmatrix} \quad (36)$$

System eigenvectors are graphically showed in figure (5). The discrete-time realization can

Figure 4: CASE 1 - Hankel Matrix Singular Values

Figure 5: CASE 1 - System Eigenvalues and Eigenvectors

be transformed to its continuous-time counterpart by using the zero order hold assumption and subsequently modal damping rates and natural frequencies can be computed from the diagonal matrix $\hat{\Lambda}_c \in \mathbb{C}^{n \times n}$ to yield:

$$\hat{f}_{n,1} = 2.7314 \quad [Hz] \quad (37)$$

$$\hat{f}_{n,2} = 9.1638 \quad [Hz] \quad (38)$$

$$\hat{\xi}_1 = 0.0054 \quad [\] \quad (39)$$

$$\hat{\xi}_2 = 0.0025 \quad [\] \quad (40)$$

The optimally damping coefficients $\hat{\alpha}$ and $\hat{\beta}$ that fit identified natural frequencies in the least-square sense can be computed according to equations (19) to yield:

$$\hat{\alpha} = 0.1755 \quad (41)$$

$$\hat{\beta} = 3.2283 \cdot 10^{-5} \quad (42)$$

Finally, using the MKR algorithm a mechanical model of system mass, stiffness and damping matrices can be computed:

$$\hat{\Phi} = \begin{bmatrix} -0.1317 + 0.0758i & 0.1582 - 0.1057i \\ 0.0927 - 0.0527i & 0.2034 - 0.1319i \end{bmatrix} \quad (43)$$

$$\hat{M} = \begin{bmatrix} 0.2913 & 0.0153 \\ 0.0153 & 0.3387 \end{bmatrix} \quad [kg] \quad (44)$$

$$\hat{K} = \begin{bmatrix} 630.44 & -425.83 \\ -425.83 & 439.01 \end{bmatrix} \quad [kg/s^2] \quad (45)$$

$$\hat{R} = \begin{bmatrix} 6.9208 & -3.6833 \\ -3.6833 & 5.6759 \end{bmatrix} \quad [kg/s] \quad (46)$$

where $\hat{\Phi}$ is system eigenvectors matrix scaled according to equations (28), (29). While in the case of mass \hat{M} and stiffness \hat{K} matrices the experimental results of the MKR algorithm are acceptable, the identified damping matrix \hat{R} appears to be incongruous. Authors propose a different estimation of damping matrix (??optimal damping)) based on the identified proportional coefficients $\hat{\alpha}$ and $\hat{\beta}$. The resulting \hat{R} matrix is the following:

$$\hat{R} = \begin{bmatrix} 0.0715 & -0.0111 \\ -0.0111 & 0.0736 \end{bmatrix} \quad [kg/s] \quad (47)$$

this damping matrix is a better estimation of actual system damping.

4.2 CASE-STUDY 2

In the second case, we placed an additional mass on the first floor. In figure (6) is showed the force measurement applied on the first floor and in figure (7) there is the system response corresponding to the input. Even in this case, in order to get statistically meaningful results, we repeated the experimental acquisition ten times but in the figures (6), (7) is showed only the first test.

Figure 6: CASE 2 - Force Measurement

Figure 7: CASE 2 - Acceleration Measurements

Once the acquisition has been performed, we used ERA/DC OKID to get a state-space representation of the system. The following is the realizations corresponding to the input and output measurements, figures (6), (7):

$$\hat{\mathbf{A}} = \begin{bmatrix} 0.7776 & -0.6220 & 0.0041 & -0.0044 \\ 0.6205 & 0.7848 & 0.0014 & -0.0011 \\ -0.0116 & 0.0064 & 0.9799 & 0.1867 \\ 0.0072 & -0.0023 & -0.1848 & 0.9824 \end{bmatrix} \quad (48)$$

$$\hat{\mathbf{B}} = \begin{bmatrix} -0.0524 \\ -0.0317 \\ -0.0561 \\ 0.0124 \end{bmatrix} \quad (49)$$

$$\hat{\mathbf{C}} = \begin{bmatrix} -5.4178 & -3.7972 & -1.9582 & 1.7973 \\ 12.0353 & 8.4148 & -1.8316 & 1.9635 \end{bmatrix} \quad (50)$$

$$\hat{\mathbf{D}} = \begin{bmatrix} -2.7906 \\ -0.0621 \end{bmatrix} \quad (51)$$

Indeed, examining the singular value $\bar{\Sigma}_n$ of the Hankel matrix $\bar{H}(0)$ showed in figure (8) it is possible to determine the order of the system. In fact, there are only 4 singular values whose magnitude is not negligible: it means that the system state has dimension $\hat{n} = 4$. Now system modal parameters can be computed to yield:

$$\hat{\mathbf{\Lambda}} = \text{diag}(0.7812 + 0.6213i, 0.7812 - 0.6213i, 0.9812 + 0.1857i, 0.9812 - 0.1857i) \quad (52)$$

$$\hat{\mathbf{\Psi}} = \begin{bmatrix} 0.7075 & 0.7075 & 0.0015 + 0.0008i & 0.0015 - 0.0008i \\ -0.0041 - 0.7065i & -0.0041 + 0.7065i & 0.0044 - 0.0057i & 0.0044 + 0.0057i \\ -0.0046 + 0.0161i & -0.0046 - 0.0161i & 0.7089 & 0.7089 \\ -0.0047 - 0.0081i & -0.0047 + 0.0081i & 0.0049 + 0.7053i & 0.0049 - 0.7053i \end{bmatrix} \quad (53)$$

System eigenvectors are graphically showed in figure (9). The discrete-time realization can be transformed to its continuous-time counterpart by using the zero order hold assumption and

Figure 8: CASE 2 - Hankel Matrix Singular Values

Figure 9: CASE 2 - System Eigenvalues and Eigenvectors

subsequently modal damping rates and natural frequencies can be computed from the diagonal matrix $\hat{\Lambda}_c \in C^{n \times n}$ to yield:

$$\hat{f}_{n,1} = 1.9056 \quad [Hz] \quad (54)$$

$$\hat{f}_{n,2} = 6.8439 \quad [Hz] \quad (55)$$

$$\hat{\xi}_1 = 0.0075 \quad [\] \quad (56)$$

$$\hat{\xi}_2 = 0.0028 \quad [\] \quad (57)$$

Now it is straightforward to note that the effect of the additional mass is the reduction of system natural frequencies whereas the damping ratios are roughly unaffected. At this point the optimal damping coefficients $\hat{\alpha}$ and $\hat{\beta}$ that fits in the least-square sense the identified natural frequencies can be computed according to equations (19) to yield:

$$\hat{\alpha} = 0.1752 \quad (58)$$

$$\hat{\beta} = 3.4355 \cdot 10^{-5} \quad (59)$$

This parameters have almost the same magnitude compared to the preceding case. Finally, using the MKR algorithm a mechanical model of system mass, stiffness and damping matrices can be computed to yield:

$$\hat{\Phi} = \begin{bmatrix} 0.0168 + 0.0824i & -0.0579 - 0.1785i \\ -0.0395 - 0.1840i & -0.0705 - 0.1657i \end{bmatrix} \quad (60)$$

$$\hat{M} = \begin{bmatrix} 1.3771 & 0.0119 \\ 0.0119 & 0.5566 \end{bmatrix} \quad [kg] \quad (61)$$

$$\hat{K} = \begin{bmatrix} 630.44 & -425.83 \\ -425.83 & 439.01 \end{bmatrix} \quad [kg/s^2] \quad (62)$$

$$\hat{R} = \begin{bmatrix} 59.9062 & -34.1418 \\ -34.1418 & 38.4897 \end{bmatrix} \quad [kg/s] \quad (63)$$

where $\hat{\Phi}$ is system eigenvectors matrix scaled according to equations (28), (29). Even in this case, while the identified mass \hat{M} and stiffness \hat{K} matrices are satisfactory acceptable, the identified damping matrix \hat{R} appears to be in some way incongruous. On the other hand, by using the proposed formulae (19), the result is the following:

$$\hat{R} = \begin{bmatrix} 0.2739 & -0.0223 \\ -0.0223 & 0.1231 \end{bmatrix} \quad [kg/s] \quad (64)$$

this damping matrix is a better estimation of actual system damping. Note that there is a marked difference between results of case-study 1 and case-study 2. Indeed, the introduction of the additional mass on the first floor increases the magnitude of the first element of identified mass matrix \hat{M} .

5 CONCLUSIONS

In this paper we performed an experimental investigation on a two-story frame in order to identify a second-order mechanical model, that is to derive system mass, stiffness and damping matrices. First, we identified system modal parameters through Eigensystem Realization Algorithm with Data Correlation using Observer/Kalman Filter Identification (ERA/DC OKID) [4]. Then we obtained mass, stiffness and damping matrices using a numerical method (MKR) proposed by [5, 6, 7]. Authors also proposed a new method to identify damping matrix from modal parameters [8, 9]. The structure was excited by an impulse yielded by 8202 Bruel & Kjaer impact hammer and the response was recorded by 4507 Bruel & Kjaer accelerometers connected to 6160 Bruel & Kjaer Pulse spectrum analyzer. The identification procedure was carried out several times, changing system mass and stiffness, and the results obtained are in good agreement with our FEM simulations. This work is the first step of our research project aimed at setting up a new virtual passive controller in order to regulate structural vibrations.

Abstract. *Finite element (FE) model updating and validation techniques are formulated as single and multi-objective optimization problems. A multi-objective optimization framework results in multiple Pareto optimal models that are consistent with the measured data and the residuals used to measure the discrepancies between the measured and the FE model predicted characteristics. The uncertainty in the Pareto optimal models can then be propagated to predict the uncertainty in the response predictions. Gradient-based optimization algorithms, such as the Normal Boundary Intersection algorithm, are used to compute the Pareto optimal solutions. These iterative algorithms require repeated solutions of the FE model for various values of the model parameters, as well as repeated computation of the gradients of the response characteristics involved in the residuals. For FE models with very high number of degrees of freedom, of the order of millions, repeated solutions of the FE models can be computationally very demanding. Component mode synthesis (CMS) methods are integrated into the updating method in order to reduce the computational effort required for performing the single- and multi-objective optimization problems. Exploiting certain schemes often encountered in FE model parameterization, it is shown that CMS allows the repeated computations to be carried out efficiently in a significantly reduced space of generalized coordinates, avoiding the solution of the fixed-interface/constrained modes and the assembling of reduced system matrices at each iteration. The final computational cost is associated with that of estimating the response characteristics of the reduced system at each iteration.*

1 INTRODUCTION

Structural model updating methods (e.g. [1]) have been proposed in the past to reconcile mathematical models, usually discretized finite element models, with experimental data. The estimate of the optimal model from a parameterized class of models is sensitive to uncertainties that are due to limitations of the mathematical models used to represent the behavior of the real structure, the presence of measurement and processing error in the data, the number and type of measured modal or response time history data used in the reconciling process, as well as the norms used to measure the fit between measured and model predicted characteristics. The optimal structural models resulting from such methods can be used for improving the model response and reliability predictions [2], structural health monitoring applications [3-6] and structural control [7].

Structural model parameter estimation problems based on measured data, such as modal characteristics (e.g. [3-6]) or response time history characteristics [8], are often formulated as weighted least-squares problems in which metrics, measuring the residuals between measured and model predicted characteristics, are build up into a single weighted residuals metric formed as a weighted average of the multiple individual metrics using weighting factors. Standard optimization techniques are then used to find the optimal values of the structural parameters that minimize the single weighted residuals metric representing an overall measure of fit between measured and model predicted characteristics. Due to model error and measurement noise, the results of the optimization are affected by the values assumed for the weighting factors.

The model updating problem has also been formulated in a multi-objective context [9,10] that allows the simultaneous minimization of the multiple metrics, eliminating the need for using arbitrary weighting factors for weighting the relative importance of each metric in the overall measure of fit. The multi-objective parameter estimation methodology provides multiple Pareto optimal structural models consistent with the measured data and the residuals used to measure the discrepancies between the measured and the finite element model predicted characteristics, in the sense that the fit each Pareto optimal model provides in a group of measured modal properties cannot be improved without deteriorating the fit in at least one other modal group. The Normal Boundary Intersection algorithm [11] is used to compute the Pareto optimal solutions.

Optimization algorithms used in the model updating methodology require repeated computations of the finite element model for various values of the model parameters. In addition, gradient-based algorithms require the estimation of the gradients of the residuals. For finite element models with a very high number of degrees of freedom, of the order of a few millions, the model updating methods require very high computational effort. Dynamic reduction techniques can be incorporated in the finite element model updating formulation to alleviate the computational burden.

In this work, a framework is presented for integrating component mode synthesis (CMS) [12,13] methods into existing finite element model updating methods in order to reduce the time consuming operations involved. The CMS allows the repeated computations to be carried out in a significantly reduced space of generalized coordinates. CMS techniques divide the structure into sub-structural components with mass and stiffness matrices that are reduced using fixed-interface and constrained modes. For structural components behaving linearly, an efficient model updating technique arises for component mass and stiffness matrices that depend linearly on only one of the free model parameters to be updated. In this case the reduced mass and stiffness matrices of a component also depends linearly on the free model parameter, allowing significant computational savings to be achieved during optimization by avoiding

the repeated computation of the fixed-interface and constrained modes of each component during the iterative process. Using the resulting linear representation of the assembled mass and stiffness matrices of the reduced system in terms of the model parameters, computationally efficient algorithms [14] can be used to further reduce the computational cost involved in estimating the gradients and Hessians of the objective functions representing the modal residuals.

2 FINITE ELEMENT MODEL UPDATING FORMULATION

2.1 Modal residuals

Let $D = \{\hat{\omega}_r^{(k)}, \hat{\phi}_r^{(k)} \in R^{N_0}, r = 1, \dots, m, k = 1, \dots, N_D\}$ be the measured modal data from a structure, consisting of modal frequencies $\hat{\omega}_r^{(k)}$ and mode shape components at N_0 measured DOFs, where m is the number of observed modes and N_D is the number of modal data sets available. Consider a parameterized class of linear structural models used to model the dynamic behavior of the structure and let $\underline{\theta} \in R^{N_\theta}$ be the set of free structural model parameters to be identified using the measured modal data. The objective in a modal-based structural identification methodology is to estimate the values of the parameter set $\underline{\theta}$ so that the modal data $\{\omega_r(\underline{\theta}), \phi_r(\underline{\theta}) \in R^{N_d}, r = 1, \dots, m\}$, where N_d is the number of model degrees of freedom (DOF), predicted by the linear class of models best matches, in some sense, the experimentally obtained modal data in D . For this, let

$$\varepsilon_{\omega_r}(\underline{\theta}) = \frac{\omega_r^2(\underline{\theta}) - \hat{\omega}_r^2}{\hat{\omega}_r^2} \quad (1)$$

and

$$\varepsilon_{\phi_r}(\underline{\theta}) = \frac{\|L\Phi(\underline{\theta})\underline{\beta}_r(\underline{\theta}) - \hat{\phi}_r\|}{\|\hat{\phi}_r\|} \quad (2)$$

$r = 1, \dots, m$, be the measures of fit or residuals between the measured modal data and the model predicted modal data for the r -th modal frequency and modeshape components, respectively, where $\|\underline{z}\|^2 = \underline{z}^T \underline{z}$ is the usual Euclidian norm, the matrix $L \in R^{N_0 \times N_d}$ is an observation matrix comprised of zeros and ones that maps the N_d model DOFs to the N_0 observed DOFs, $\Phi(\underline{\theta}) \in R^{N_d \times m}$ is the matrix of the modeshapes predicted by the model, and $\underline{\beta}_r(\underline{\theta}) = [\Phi^T(\underline{\theta})L^T L \Phi(\underline{\theta})]^{-1} [L \Phi(\underline{\theta})]^T \hat{\phi}_r$ is a normalization vector that guaranties that the distance of the measured modeshape $\hat{\phi}_r$ from the space spanned by the model predicted modeshapes in $L\Phi(\underline{\theta}) \in R^{N_d \times m}$ is minimal.

It should be noted that for modes that are not closely spaced, the elements $\beta_{jr}(\underline{\theta})$ of the normalization vector $\underline{\beta}_r(\underline{\theta})$ are expected to have values close to zero for $j \neq r$ and so the measure of fit $\varepsilon_{\omega_r}(\underline{\theta})$ is approximately the same as $\varepsilon_{\phi_r}(\underline{\theta}) = \|L\phi_r(\underline{\theta})\beta_{rr}(\underline{\theta}) - \hat{\phi}_r\| / \|\hat{\phi}_r\|$. However, for closely spaced modes, the measure of fit $\varepsilon_{\phi_r}(\underline{\theta})$ in (2) is used to express the fact that any vector in the subspace spanned by the identified modeshapes for these closely spaced

modes is also a modeshape. Thus, any of the identified closely spaced modeshapes should be expected to be a linear combination of the model predicted modeshapes for the closely spaced modes. This fact is reflected in the use of the measure of fit $\varepsilon_{\underline{\phi}_r}(\underline{\theta})$ in (2).

In order to proceed with the model updating formulation, the measured modal properties are grouped into n groups. Each group contains one or more modal properties. The modal properties assigned in the i th group are identified by the set $g_i(k)$, $i = 1, \dots, n$ and $k = 1, 2$, with any element in the set $g_i(k)$ is an integer from 1 to m . An element in the set $g_i(k)$ with $k = 1$ refer to the number of the measured modal frequency assigned in the group i , while the elements of the set $g_i(k)$ with $k = 2$ refer to the number of the measured modeshape assigned in the group i . For the i th group, a norm $J_i(\underline{\theta})$ is introduced to measure the residuals of the difference between the measured values of the modal properties involved in the group and the corresponding modal values predicted from the model class for a particular value of the parameter set $\underline{\theta}$. The measure of fit in a modal group is the sum of the individual square errors in (1) for the corresponding modal properties involved in the modal group. Specifically, the measure of fit is given by

$$J_i(\underline{\theta}) = \sum_{r \in g_i(1)} \varepsilon_{\omega_r}^2(\underline{\theta}) + \sum_{r \in g_i(2)} \varepsilon_{\underline{\phi}_r}^2(\underline{\theta}) \quad (3)$$

The grouping of the modal properties $\{\omega_r(\underline{\theta}), \underline{\phi}_r(\underline{\theta}), r = 1, \dots, m\}$ into n groups and the selection of the measures of fit (residuals) $J_1(\underline{\theta}), \dots, J_n(\underline{\theta})$ are usually based on user preference. The modal properties assigned to each group are selected by the user according to their type and the purpose of the analysis.

2.2 Multi-objective identification

The problem of identifying the model parameter values $\underline{\theta}$ that minimize the modal or response time history residuals can be formulated as a multi-objective optimization problem stated as follows [10]. Find the values of the structural parameter set $\underline{\theta}$ that simultaneously minimizes the objectives

$$\underline{y} = \underline{J}(\underline{\theta}) = (J_1(\underline{\theta}), \dots, J_n(\underline{\theta})) \quad (4)$$

subject to inequality constrains $\underline{c}(\underline{\theta}) \leq \underline{0}$ and parameter constrains $\underline{\theta}_{low} \leq \underline{\theta} \leq \underline{\theta}_{upper}$, where $\underline{\theta} = (\theta_1, \dots, \theta_{N_\theta}) \in \Theta$ is the parameter vector, Θ is the parameter space, $\underline{y} = (y_1, \dots, y_n) \in Y$ is the objective vector, Y is the objective space, $\underline{c}(\underline{\theta})$ is the vector function of constrains, and $\underline{\theta}_{low}$ and $\underline{\theta}_{upper}$ are respectively the lower and upper bounds of the parameter vector. For conflicting objectives $J_1(\underline{\theta}), \dots, J_n(\underline{\theta})$, there is no single optimal solution, but rather a set of alternative solutions, known as Pareto optimal solutions, that are optimal in the sense that no other solutions in the parameter space are superior to them when all objectives are considered.

Using multi-objective terminology, the Pareto optimal solutions are the non-dominating vectors in the parameter space Θ , defined mathematically as follows. A vector $\underline{\theta} \in \Theta$ is said to be non-dominated regarding the set Θ if and only if there is no vector in Θ which dominates $\underline{\theta}$. A vector $\underline{\theta}$ is said to dominate a vector $\underline{\theta}'$ if and only if

$$J_i(\underline{\theta}) \leq J_i(\underline{\theta}') \quad \forall i \in \{1, \dots, n\} \quad \text{and} \quad \exists j \in \{1, \dots, n\} : J_j(\underline{\theta}) < J_j(\underline{\theta}') \quad (5)$$

The set of objective vectors $\underline{y} = \underline{J}(\underline{\theta})$ corresponding to the set of Pareto optimal solutions $\underline{\theta}$ is called Pareto optimal front. The characteristics of the Pareto solutions are that the residuals cannot be improved in any group without deteriorating the residuals in at least one other group. The multiple Pareto optimal solutions are due to modelling and measurement errors. The level of modelling and measurement errors affect the size and the distance from the origin of the Pareto front in the objective space, as well as the variability of the Pareto optimal solutions in the parameter space.

2.3 Weighted modal residuals identification

The parameter estimation problem is traditionally solved by minimizing the single objective

$$J(\underline{\theta}; \underline{w}) = \sum_{i=1}^n w_i J_i(\underline{\theta}) \quad (6)$$

formed from the multiple objectives $J_i(\underline{\theta})$ using the weighting factors $w_i \geq 0$, $i = 1, \dots, n$, with $\sum_{i=1}^n w_i = 1$. The objective function $J(\underline{\theta}; \underline{w})$ represents an overall measure of fit between the measured and the model predicted characteristics. The relative importance of the residual errors in the selection of the optimal model is reflected in the choice of the weights. The results of the identification depend on the weight values used. Conventional weighted least squares methods assume equal weight values, $w_1 = \dots = w_n = 1/n$.

2.4 Computational issues

The proposed single and multi-objective identification problems are solved using available single- and multi-objective optimization algorithms. The optimization of $J(\underline{\theta}; \underline{w})$ in (6) with respect to $\underline{\theta}$ for given \underline{w} can readily be carried out numerically using any available gradient-based algorithm for optimizing a nonlinear function of several variables. The set of Pareto optimal solutions can be obtained using available multi-objective optimization algorithms. A very efficient algorithm for solving the multi-objective optimization problem is the Normal-Boundary Intersection (NBI) method [11]. Each Pareto optimal solutions is obtained by solving a single-objective optimization problem using gradient based optimization algorithms. Thus, the computational time is of the order of the number of points used to represent the Pareto front multiplied by the computational time required to solve a single-objective problem for computing each point on the front.

It is obvious that the search for the Pareto optimal models require repeated computations of the finite element model for various values of the model parameters. In addition, gradient-based algorithms require the estimation of the gradients of the residuals. For finite element models with a very high number of degrees of freedom, of the order of a few millions, the computational time involved for repeatedly solving the large-scale eigen-problems may be excessive, especially if the number of iterations is high. The objective of this work is to examine the conditions under which substantial reductions in the computational effort can be achieved using dynamic reduction techniques such as component mode synthesis methods. Dividing the structure into components and reducing the number of physical coordinates to a much smaller number of generalized coordinates certainly alleviates part of the computational effort. However, at each iteration one needs to re-computed the eigen-problem for each component which can be a very time consuming operation. It is shown that for certain parameterization schemes, often encountered in finite element model updating formulations, the repeated

solutions of the component eigen-problems are avoided, reducing substantially the computational demands in finite element model updating formulations.

3 COMPONENT MODE SYNTHESIS

In component mode synthesis [12,13] a structure is divided into several components. Reduction techniques are applied on a number of these components, while the rest are the non-reduced parts of the structure which could be left un-altered. For each component, the unconstrained DOFs are divided into the boundary DOFs, denoted by the subscript b and the internal DOFs, denoted by the subscript i . The boundary DOFs of a component are common with the DOFs of adjacent components, while the internal DOFs of a component are not shared with any adjacent component.

The stiffness and mass matrices $K^{(s)}$ and $M^{(s)}$ of a component s are partitioned to blocks related to the internal and boundary DOFs, with the undamped equation of motion of a component given by

$$\begin{bmatrix} M_{ii}^{(s)} & M_{ib}^{(s)} \\ M_{bi}^{(s)} & M_{bb}^{(s)} \end{bmatrix} \begin{Bmatrix} \ddot{\underline{u}}_i^{(s)} \\ \ddot{\underline{u}}_b^{(s)} \end{Bmatrix} + \begin{bmatrix} K_{ii}^{(s)} & K_{ib}^{(s)} \\ K_{bi}^{(s)} & K_{bb}^{(s)} \end{bmatrix} \begin{Bmatrix} \underline{u}_i^{(s)} \\ \underline{u}_b^{(s)} \end{Bmatrix} = \begin{Bmatrix} \underline{f}_i^{(s)} \\ \underline{f}_b^{(s)} + \underline{r}_b^{(s)} \end{Bmatrix} \quad (7)$$

where $\underline{f}_i^{(s)}$ and $\underline{f}_b^{(s)}$ are the external forces, while $\underline{r}_b^{(s)}$ are the reaction forces on the component from the adjacent components at the boundary DOFs. The indices i and b are sets containing the internal and boundary DOFs of the component s .

In component mode synthesis, the physical displacement coordinates $\underline{u}^{(s)}$ of a component are represented in terms of the generalized coordinates $\underline{p}^{(s)}$ of the component by the Ritz coordinate transformation

$$\underline{u}^{(s)} = \Psi^{(s)} \underline{p}^{(s)} \quad (8)$$

According to the Craig-Bampton fixed-interface-mode method, the physical coordinates of the component are related to the generalized coordinates using the fixed-interface normal modes and the interface constrained modes as follows

$$\underline{u}^{(s)} = \begin{Bmatrix} \underline{u}_i^{(s)} \\ \underline{u}_b^{(s)} \end{Bmatrix} = \Psi^{(s)} \underline{p}^{(s)} = \begin{bmatrix} \Phi_{ik}^{(s)} & \Psi_{ib}^{(s)} \\ 0_{bk}^{(s)} & I_{bb}^{(s)} \end{bmatrix} \begin{Bmatrix} \underline{p}_k^{(s)} \\ \underline{p}_b^{(s)} \end{Bmatrix} \quad (9)$$

where $\Phi_{ik}^{(s)}$ is the interior partition matrix of kept fixed-interface modes satisfying the eigenproblem

$$K_{ii}^{(s)} \Phi_{ik}^{(s)} = M_{ii}^{(s)} \Phi_{ik}^{(s)} \Lambda_{kk}^{(s)} \quad (10)$$

with all boundary DOFs for the considered component restrained, and the $\Psi_{ib}^{(s)}$ is the interior partition matrix of the constrained-modes given by $\Psi_{ib}^{(s)} = -[K_{ii}^{(s)}]^{-1} K_{ib}^{(s)}$. The matrix $\Lambda_{kk}^{(s)} = \text{diag}(\omega_j^{2(s)})$ is diagonal containing the eigenvalues $\omega_j^{2(s)}$ of the kept fixed-interface normal modes. The fixed-interface modes $\Phi_{ik}^{(s)}$ are considered mass normalized, satisfying

$$\Phi_{ik}^{(s)T} M_{ii}^{(s)} \Phi_{ik}^{(s)} = I_{kk}^{(s)}, \quad \Phi_{ik}^{(s)T} K_{ii}^{(s)} \Phi_{ik}^{(s)} = \Lambda_{kk}^{(s)} \quad (11)$$

The reduced set of component equations of motion in generalized coordinates is

$$\hat{M}^{(s)} \ddot{\underline{p}}^{(s)} + \hat{K}^{(s)} \underline{p}^{(s)} = \hat{\underline{f}}^{(s)} + \hat{\underline{r}}^{(s)} \quad (12)$$

where the reduced mass, stiffness matrix and force vectors for the component are given in terms of the original matrices and force vectors in the form

$$\hat{M}^{(s)} = \Psi_{ik}^{(s)T} M^{(s)} \Psi_{ik}^{(s)}, \quad \hat{K}^{(s)} = \Psi_{ik}^{(s)T} K^{(s)} \Psi_{ik}^{(s)}, \quad \hat{\underline{f}}^{(s)} = \Psi_{ik}^{(s)T} \underline{f}^{(s)} \quad \text{and} \quad \hat{\underline{r}}^{(s)} = \Psi_{ik}^{(s)T} \underline{r}^{(s)} \quad (13)$$

with the partitions for the mass and stiffness matrices given respectively by

$$\begin{aligned} \hat{M}_{kk}^{(s)} &= I_{kk}^{(s)} \\ \hat{M}_{kb}^{(s)} &= \hat{M}_{bk}^{(s)T} = \Phi_{ik}^{(s)T} M_{ii}^{(s)} \Psi_b^{(s)} + \Phi_{ik}^{(s)T} M_{ib}^{(s)} \\ \hat{M}_{bb}^{(s)} &= (\Psi_b^{(s)T} M_{ii}^{(s)} + M_{bi}^{(s)}) \Psi_b^{(s)} + \Psi_b^{(s)T} M_{ib}^{(s)} + M_{bb}^{(s)} \end{aligned} \quad (14)$$

and

$$\begin{aligned} \hat{K}_{kk}^{(s)} &= \Lambda_{kk}^{(s)} \\ \hat{K}_{kb}^{(s)} &= \hat{K}_{bk}^{(s)T} = 0_{kb}^{(s)} \\ \hat{K}_{bb}^{(s)} &= K_{bb}^{(s)} - K_{bi}^{(s)} [K_{ii}^{(s)}]^{-1} K_{ib}^{(s)} = K_{bb}^{(s)} + \Psi_b^{(s)T} K_{ib}^{(s)} \end{aligned} \quad (15)$$

In the substructure assembly process, the vector $\underline{p} = [\underline{p}^{(1)T}, \dots, \underline{p}^{(s)T}]^T$ of all generalized coordinates for each components is introduced. Letting $\underline{q} = [\underline{p}_k^{(1)T}, \dots, \underline{p}_k^{(s)T}, \underline{u}_b^T]^T$ be the vector of independent generalized coordinates formed from the generalized coordinates (fixed-interface modal and boundary coordinates) of all components, the following transformation holds

$$\underline{p} = S \underline{q} \quad (16)$$

where the component coupling matrix S couples the independent generalized coordinates with the generalized coordinates of each component. Using the continuity of displacement/rotations and the equilibrium of forces along the shared boundaries of the components, the equations of motion in the reduced space of independent generalized coordinates takes the final form

$$\hat{M}^{CB} \ddot{\underline{q}} + \hat{K}^{CB} \underline{q} = S^T \hat{\underline{f}} \quad (17)$$

where the assembled mass and stiffness matrices for the reduced system are given by

$$\hat{M}^{CB} = S^T \begin{bmatrix} \hat{M}^{(1)} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \hat{M}^{(s)} \end{bmatrix} S \quad \text{and} \quad \hat{K}^{CB} = S^T \begin{bmatrix} \hat{K}^{(1)} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \hat{K}^{(s)} \end{bmatrix} S \quad (18)$$

Solving the eigen-problem

$$\hat{K}^{CB} \underline{Q} = \hat{M}^{CB} \underline{Q} \Lambda \quad (19)$$

associated with the reduced mass and stiffness matrices \hat{M}^{CB} and \hat{K}^{CB} , respectively, one obtains the modal frequencies in $\Lambda = \text{diag}(\omega_i^2)$ and the mode shapes \underline{Q} of the reduced system. The mode shapes of the original structure are assembled from the reduced ones. Specifically, using (8) and (16), the physical mode shapes are recovered as follows

$$\Phi = \begin{bmatrix} \Psi^{(1)} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \Psi^{(s)} \end{bmatrix} S Q \quad (20)$$

4 MODEL UPDATING USING COMPONENT MODE SYNTHESIS

Next, the component mode synthesis procedure is integrated into the finite element formulation. We limit the presentation for the case for which the stiffness and mass matrices depend linearly on the model parameters to be estimated using the measured data. Specifically, it is assumed that the mass and stiffness matrix takes the form

$$\begin{aligned} K &= K_0 + \sum_{i=1}^{N_\theta} K_{,j} \theta_j \\ M &= M_0 + \sum_{j=1}^{N_\theta} M_{,j} \theta_j \end{aligned} \quad (21)$$

This implies that the component mass and stiffness matrix as well as their partitions admit a similar representation. Specifically, the following is true for a component stiffness and mass matrix

$$\begin{aligned} K^{(s)} &= K_0^{(s)} + \sum_{i=1}^{N_\theta} K_{,j}^{(s)} \theta_j \\ M^{(s)} &= M_0^{(s)} + \sum_{j=1}^{N_\theta} M_{,j}^{(s)} \theta_j \end{aligned} \quad (22)$$

Let $J = \{j_1, \dots, j_s\}$ be a set of index values with $j_1 \cup \dots \cup j_s = \{1, \dots, N_\theta\}$, where j_s is a subset of the set J , with integer elements, denoting the parameters in the set $\underline{\theta}$ on which the structural component s depends on. Note that more than one components are allowed to depend on a parameter in the set $\underline{\theta}$.

Consider the following three special cases of structural component parameterization. In the first case, the mass and stiffness matrix of a component s do not depend on the model parameters $\underline{\theta}$. In this case the set j_s is empty. The component fixed-interface and constrained modes are independent of the parameter values. Only a single analysis is required to estimate the fixed-interface and constrained modes. Within the model updating iteration scheme, these component modes are computed once and are then used in the iterations involved, thus reducing the computational effort for assembling the reduced system from these components at each iteration.

In the second case, the mass or stiffness matrix of a structural component s depends only on one model parameter in the set $\underline{\theta}$. In this case the subset j_s contains only one element and the stiffness or mass matrices take the form

$$K^{(s)} = \bar{K}_{,j_s}^{(s)} \theta_{j_s} \quad \text{or} \quad M^{(s)} = \bar{M}_{,j_s}^{(s)} \theta_{j_s} \quad (23)$$

Equivalently, the partitions of the component mass and stiffness matrices take the form

$$K_{ii}^{(s)} = \bar{K}_{ii,j_s}^{(s)} \theta_{j_s}, \quad K_{ib}^{(s)} = \bar{K}_{ib,j_s}^{(s)} \theta_{j_s}, \quad K_{bb}^{(s)} = \bar{K}_{bb,j_s}^{(s)} \theta_{j_s} \quad (24)$$

or

$$\mathbf{M}_{ii}^{(s)} = \bar{\mathbf{M}}_{ii,j_s}^{(s)} \theta_{j_s}, \quad \mathbf{M}_{ib}^{(s)} = \bar{\mathbf{M}}_{ib,j_s}^{(s)} \theta_{j_s}, \quad \mathbf{M}_{bb}^{(s)} = \bar{\mathbf{M}}_{bb,j_s}^{(s)} \theta_{j_s} \quad (25)$$

In the case of stiffness dependence of the parameter θ_{j_s} , it can be readily shown that the matrix of the kept eigenvalues and eigenvectors of the component fixed-interface modes are given with respect to the parameter θ_{j_s} in the form

$$\Lambda^{(s)} = \bar{\Lambda}_{,j_s}^{(s)} \theta_{j_s}, \quad \omega_j^{2(s)} = \bar{\omega}_j^{2(s)} \theta_{j_s} \quad \text{and} \quad \Phi_{ik} = \bar{\Phi}_{ik,j_s} \quad (26)$$

where the matrices $\bar{\Lambda}^{(s)}$ and $\bar{\Phi}_{ik}$ are solutions of the following eigen-problem

$$\bar{\mathbf{K}}_{ii,j_s}^{(s)} \bar{\Phi}_{ik,j_s}^{(s)} = \bar{\mathbf{M}}_{ii,j_s}^{(s)} \bar{\Phi}_{ik,j_s}^{(s)} \bar{\Lambda}_{kk,j_s}^{(s)} \quad (27)$$

which is independent of the values of θ_{j_s} . Also the constrained modes, given by $\Psi_{ib}^{(s)} = -[\mathbf{K}_{ii}^{(s)}]^{-1} \mathbf{K}_{ib}^{(s)} = -[\bar{\mathbf{K}}_{ii,j_s}^{(s)}]^{-1} \bar{\mathbf{K}}_{ib,j_s}^{(s)}$, are constant independent of the values of the parameter θ_{j_s} . It should be noted that even in this case only a single component analysis is required to estimate the fixed-interface and constrained modes, independent of the values of θ_{j_s} .

Substituting the stiffness matrices (24) and the eigenproperties (26) of a component into the reduced stiffness matrix (15), one obtains

$$\hat{\mathbf{K}}^{(s)} = \hat{\mathbf{K}}_{,j_s}^{(s)} \theta_{j_s} \quad (28)$$

where $\hat{\mathbf{K}}_{,j_s}^{(s)}$ is given by

$$\begin{aligned} \hat{\mathbf{K}}_{kk,j_s}^{(s)} &= \bar{\Lambda}_{kk,j_s}^{(s)} \\ \hat{\mathbf{K}}_{kb,j_s}^{(s)} &= \hat{\mathbf{K}}_{bk,j_s}^{(s)T} = \mathbf{0}_{kb}^{(s)} \\ \hat{\mathbf{K}}_{bb,j_s}^{(s)} &= \bar{\mathbf{K}}_{bb,j_s}^{(s)} - [\bar{\mathbf{K}}_{ii,j_s}^{(s)}]^{-1} \bar{\mathbf{K}}_{ib,j_s}^{(s)} \bar{\mathbf{K}}_{ib,j_s}^{(s)} \end{aligned} \quad (29)$$

and it is independent on values of the the model parameters. Finally, substituting (28) into (18), the stiffness matrix of the reduced system admits the representation

$$\begin{aligned} \mathbf{K}^{CB} &= \mathbf{K}_0^{CB} + \sum_{i=1}^{N_\theta} \mathbf{K}_{,j}^{CB} \theta_j \\ \mathbf{M}^{CB} &= \mathbf{M}_0^{CB} + \sum_{j=1}^{N_\theta} \mathbf{M}_{,j}^{CB} \theta_j \end{aligned} \quad (30)$$

where the matrices \mathbf{K}_0^{CB} and $\mathbf{K}_{,j}^{CB}$ are given by

$$\hat{\mathbf{K}}_0^{CB} = \mathbf{S}^T \begin{bmatrix} \ddots & 0 & 0 \\ 0 & \hat{\mathbf{K}}^{(0)} & 0 \\ 0 & 0 & \ddots \end{bmatrix} \mathbf{S} \quad \text{and} \quad \hat{\mathbf{K}}_{,j}^{CB} = \mathbf{S}^T \begin{bmatrix} \ddots & 0 & 0 \\ 0 & \hat{\mathbf{K}}^{(s)} & 0 \\ 0 & 0 & \ddots \end{bmatrix} \mathbf{S} \quad (31)$$

It is important to note that the matrices $\hat{\mathbf{K}}_0^{CB}$ and $\hat{\mathbf{K}}_{,j}^{CB}$ are independent of $\underline{\theta}$. In order to save computational time, these constant matrices are computed and assembled once and, therefore,

there is no need this computation to be repeated during the iterations involved in optimization algorithms for model updating. This aforementioned procedure saves significant computational time since it avoids (a) re-computing the fixed-interface and constrained modes and (b) assembling the reduced matrices from these components, at each iteration step involved in model updating.

In the third case, the mass and stiffness matrices of a component depend on more than one model parameters. In this case the subset j_s contains more than one element. The stiffness and mass matrices are given by

$$\begin{aligned} K^{(s)} &= K_0^{(s)} + \sum_{j \in j_s} K_{,j}^{(s)} \theta_j \\ M^{(s)} &= M_0^{(s)} + \sum_{j \in j_s} M_{,j}^{(s)} \theta_j \end{aligned} \quad (32)$$

The fixed-interface and constrained modes have to be recomputed in each iteration involved in the model updating procedure and used to form the reduced stiffness and mass matrices of the components. This iterative computation, however, is usually confined a small number of components with sets j_s involving more than one elements.

5 CONCLUSIONS

Component mode synthesis methods were presented to substantially reduce the computational effort required in the iterative optimization algorithms used for finite element model updating. Exploiting certain schemes often encountered in finite element model parameterization, the mass and stiffness matrices of the reduced system are shown to depend linearly on the model parameters with the mass and stiffness sensitivity matrices to be assembled once and to remain constant during the iteration process. The only time consuming operation left is associated with the solution of the eigen-problem of the reduced system, avoiding the expensive estimation of the component eigen-problems at each iteration. In the proposed model updating formulation, the division of the structure into components is controlled by the parameterization scheme. The methodology is particularly efficient for large-scale finite element models where the solution of the component eigen-problem may be a computationally demanding operation. The methodology described in this work is also applicable to damage detection methods based on finite element model updating methods. According to available damage detection methods [6], the structure is subdivided into one components with properties that remain unchanged during the search for the damaged sub-structure and components with mass and stiffness properties that depend linearly on the parameter indicative of damage.

Keywords: Multi-time-step Method, Implicit-explicit Integration, Generalized- α Method, Numerical Dissipation.

Abstract. *We present an implicit-explicit multi-time-step method for structural dynamics using the family of Generalized- α methods. With the proposed partitioned method, one can divide a complex structural domain into several subdomains and solve the individual subdomains separately. The solution of the original global problem is retrieved by enforcing the prescribed velocity continuity at subdomain interfaces like the method of Gravouil and Combescure (GC method). For large-scale simulations, e.g., to solve a global-local Finite Element model with a coarse global model of the whole structure and several refined local models of parts of the structure, the proposed scheme can be effective. In order to implement the Generalized- α method to the multi-time-step integration, first we derive a new predictor-corrector form of the implicit Generalized- α method from the implicit method previously introduced by Arnold and Brüls. Secondly, we propose a new predictor-corrector form of the explicit Generalized- α method. Both the implicit method and the explicit method are the one-step four-stage variants of the Generalized- α methods. Finally, we built our partitioned scheme with the extended Generalized- α methods. The multi-time-step method is obtained based on the Prakash and Hjelmstad's method (PH method). We study the convergence of the current multi-time-step method by examining a single degree of freedom model problem. It is found that the current multi-time-step method maintains second-order accuracy, both with a unique time scale and with different time scales in each subdomain. Moreover, the current multi-time-step method is not dissipative at subdomain interfaces. Its numerical dissipation is solely introduced by the Generalized- α methods in each subdomain.*

1 INTRODUCTION

In transient structural dynamics, partitioned time integration schemes are appealing for simulation of complex engineering systems with large-scale Finite Element (FE) models [8, 7]. By dividing a structural domain into several subdomains, partitioned time integration methods use different time steps and/or different integration methods to different subdomains, according to their individual physical and computational considerations [12, 4, 9, 10, 11]. For example, a steel railway bridge can be modelled with a coarse model of the whole structure including several refined models of the fatigue-critical connections [17, 16]. Classical monolithic algorithms use a uniform time step for all elements. Refined local models ask for a relatively small time step because of numerical accuracy and/or stability requirements. It creates a heavy computational task for the global simulation. On the contrary, partitioned integration schemes use a big time step for the global model and a small time step for the refined local models. As a result, the computational cost of the global problem is reduced while the accuracy of the solution for the refined local models is maintained [20].

Fatigue assessment of existing steel railway bridges becomes more and more important in Europe and North America, because of the aging of the structures [21, 18]. For fatigue life estimation, one needs to calculate the bridge responses under and after the train passages by transient analysis. For calibration of the Finite Element model, operational modal analysis is often performed [13]. To improve the computational efficiency and accuracy for the transient analysis, the competitive advantages of the multi-time-step methods over the monolithic methods are exploited.

Among the monolithic methods, the Generalized- α method is well known by its optimal numerical dissipation for both linear and non-linear dynamic problems [3, 15, 6]. In this paper, we extend the Generalized- α method to implicit-explicit integration with different time steps in different subdomains. The proposed partitioned scheme is built on the method previously introduced by Prakash and Hjelmstad (PH method) [20]. The PH method enables implicit/explicit Newmark methods to be coupled with different time steps in each subdomain. Their method is energy preserving and unconditionally stable as long as the stability requirement of individual subdomains is satisfied. Moreover, the PH method solves the subdomain interface problem only at each coarse time step instead of at each small time step. Therefore, it is computationally more efficient in comparison to other methods [19].

The paper is organized as follows. In Section 2, we give the formulas of the extended Generalized- α methods. In Section 3, we study the properties of the proposed monolithic methods. In Section 4, we build the multi-time-step method with the extended Generalized- α methods and examine its properties by a numerical test in Section 5. In Section 6, the conclusions are presented.

2 EXTENSIONS OF THE GENERALIZED- α METHOD

We consider here the implicit Generalized- α method as introduced by Arnold and Br uls[1]. The predictor-corrector form of their method can be written as:
Equilibrium equation:

$$\mathbf{M}\ddot{\mathbf{u}}_{n+1} + \mathbf{C}\dot{\mathbf{u}}_{n+1} + \mathbf{K}\mathbf{u}_{n+1} = \mathbf{F}_{n+1} \quad (1)$$

Predictors:

$$\tilde{\mathbf{u}}_{n+1} = \mathbf{u}_n + \Delta t \dot{\mathbf{u}}_n + \Delta t^2 \left(\frac{1}{2} - \frac{\beta}{1 - \alpha_m} \right) \mathbf{a}_n + \Delta t^2 \beta \frac{\alpha_f}{1 - \alpha_m} \ddot{\mathbf{u}}_n \quad (2)$$

$$\tilde{\dot{\mathbf{u}}}_{n+1} = \dot{\mathbf{u}}_n + \Delta t \left(1 - \frac{\gamma}{1 - \alpha_m} \right) \mathbf{a}_n + \Delta t \gamma \frac{\alpha_f}{1 - \alpha_m} \ddot{\mathbf{u}}_n \quad (3)$$

Correctors:

$$\mathbf{u}_{n+1} = \tilde{\mathbf{u}}_{n+1} + \Delta t^2 \beta \frac{1 - \alpha_f}{1 - \alpha_m} \ddot{\mathbf{u}}_{n+1} \quad (4)$$

$$\dot{\mathbf{u}}_{n+1} = \tilde{\dot{\mathbf{u}}}_{n+1} + \Delta t \gamma \frac{1 - \alpha_f}{1 - \alpha_m} \ddot{\mathbf{u}}_{n+1} \quad (5)$$

Recurrence relation:

$$(1 - \alpha_m) \mathbf{a}_{n+1} + \alpha_m \mathbf{a}_n = (1 - \alpha_f) \ddot{\mathbf{u}}_{n+1} + \alpha_f \ddot{\mathbf{u}}_n, \mathbf{a}_0 = \ddot{\mathbf{u}}_0 \quad (6)$$

The recurrence equation (6) defines \mathbf{a} in function of $\ddot{\mathbf{u}}$. \mathbf{a} is considered as the acceleration-like auxiliary variable, whereas $\ddot{\mathbf{u}}$ is known as the true acceleration [1].

A consistent explicit form of the Generalized- α method is defined by replacing (1) with the following equilibrium equation:

$$\mathbf{M} \ddot{\mathbf{u}}_{n+1} + \mathbf{C} \dot{\mathbf{u}}_{n+1} + \mathbf{K} \tilde{\mathbf{u}}_{n+1} = \mathbf{F}_{n+1} \quad (7)$$

We implement the extended Generalized- α methods by the following $\ddot{\mathbf{u}}$ -form:

$$\tilde{\mathbf{M}} \ddot{\mathbf{u}}_{n+1} = \mathbf{F}_{n+1} - \mathbf{C} \tilde{\dot{\mathbf{u}}}_{n+1} - \mathbf{K} \tilde{\mathbf{u}}_{n+1} \quad (8)$$

where $\tilde{\mathbf{M}}$ is defined by

$$\tilde{\mathbf{M}} = \tilde{\mathbf{M}}^I = \mathbf{M} + \Delta t \gamma \frac{1 - \alpha_f}{1 - \alpha_m} \mathbf{C} + \Delta t^2 \beta \frac{1 - \alpha_f}{1 - \alpha_m} \mathbf{K}, \quad (9)$$

$$\tilde{\mathbf{M}} = \tilde{\mathbf{M}}^E = \mathbf{M} + \Delta t \gamma \frac{1 - \alpha_f}{1 - \alpha_m} \mathbf{C}. \quad (10)$$

$\tilde{\mathbf{M}}^I$ and $\tilde{\mathbf{M}}^E$ are the effective mass matrices for the implicit method and the explicit method, respectively. At each time step, the acceleration $\ddot{\mathbf{u}}_{n+1}$ is solved by Equation (8) and then \mathbf{u}_{n+1} , $\dot{\mathbf{u}}_{n+1}$ and \mathbf{a}_{n+1} are updated by Equations (4)-(6).

Both the extended implicit and explicit Generalized- α methods use the integration parameters defined by the following formulas:

$$\alpha_m = \frac{2\rho - 1}{\rho + 1}, \alpha_f = \frac{\rho}{\rho + 1}, \beta = \frac{1}{4} \left(\frac{1}{2} + \gamma \right)^2 \text{ and } \gamma = \frac{1}{2} - \alpha_m + \alpha_f \quad (11)$$

where $\rho = \rho_\infty$ is the spectral radius of the implicit method at the infinite frequency limit and $\rho = \rho_b$ is the spectral radius of the explicit method at the bifurcation point. Note that Equation (11) adopts the same formulas as the implicit Generalized- α method of Chung and Hulbert [3], but it is different from the explicit Generalized- α method of Hulbert and Chung [15]. We will justify these parameters in Section 3.

Moreover, the extended Generalized- α methods can be written in the following form:

$$\overline{\mathbf{M}} \overline{\mathbf{U}}_{n+1} = \overline{\mathbf{F}}_{n+1} - \overline{\mathbf{N}} \overline{\mathbf{U}}_n \quad (12)$$

where

$$\overline{\mathbf{M}} = \overline{\mathbf{M}}^I = \begin{bmatrix} \mathbf{M} & \mathbf{0} & \mathbf{K} & \mathbf{0} \\ -\Delta t \gamma \frac{1-\alpha_f}{1-\alpha_m} \mathbf{I} & \mathbf{I} & \mathbf{0} & \mathbf{0} \\ -\Delta t^2 \beta \frac{1-\alpha_f}{1-\alpha_m} \mathbf{I} & \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -(1-\alpha_f) \mathbf{I} & \mathbf{0} & \mathbf{0} & (1-\alpha_m) \mathbf{I} \end{bmatrix}, \quad (13)$$

$$\overline{\mathbf{M}} = \overline{\mathbf{M}}^E = \begin{bmatrix} \mathbf{M} - \Delta t^2 \beta \frac{1-\alpha_f}{1-\alpha_m} \mathbf{K} & \mathbf{0} & \mathbf{K} & \mathbf{0} \\ -\Delta t \gamma \frac{1-\alpha_f}{1-\alpha_m} \mathbf{I} & \mathbf{I} & \mathbf{0} & \mathbf{0} \\ -\Delta t^2 \beta \frac{1-\alpha_f}{1-\alpha_m} \mathbf{I} & \mathbf{0} & \mathbf{I} & \mathbf{0} \\ -(1-\alpha_f) \mathbf{I} & \mathbf{0} & \mathbf{0} & (1-\alpha_m) \mathbf{I} \end{bmatrix}, \quad (14)$$

for the implicit method and the explicit method, respectively, and

$$\overline{\mathbf{N}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -\Delta t \gamma \frac{\alpha_f}{1-\alpha_m} \mathbf{I} & -\mathbf{I} & \mathbf{0} & -\Delta t (1 - \frac{\gamma}{1-\alpha_m}) \mathbf{I} \\ -\Delta t^2 \beta \frac{\alpha_f}{1-\alpha_m} \mathbf{I} & -\Delta t \mathbf{I} & -\mathbf{I} & -\Delta t^2 (\frac{1}{2} - \frac{\beta}{1-\alpha_m}) \mathbf{I} \\ -\alpha_f \mathbf{I} & \mathbf{0} & \mathbf{0} & \alpha_m \mathbf{I} \end{bmatrix} \quad (15)$$

$$\overline{\mathbf{U}}_n = \begin{Bmatrix} \ddot{\mathbf{u}}_n \\ \dot{\mathbf{u}}_n \\ \mathbf{u}_n \\ \mathbf{a}_n \end{Bmatrix}, \quad \overline{\mathbf{F}}_{n+1} = \begin{Bmatrix} \mathbf{F}_{n+1} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (16)$$

The damping terms are omitted for simplicity of the expression.

3 ANALYSIS OF THE EXTENDED GENERALIZED- α METHOD

3.1 Relation of the extended implicit method to the method of Chung and Hulbert

In this subsection, we show the relation between the extended implicit method in Section 2 and the method of Chung and Hulbert [3].

The Chung and Hulbert's method [3] includes only three numerical variables \mathbf{a} , $\dot{\mathbf{u}}$, \mathbf{u} and therefore it is a one-step three-stage method [22]. In contrast, the extended implicit Generalized- α method includes four numerical variables \mathbf{a} , $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, \mathbf{u} and therefore it is a one-step four-stage method. By joining the recurrence equation (6) with the basic formulas of the Chung and Hulbert's method [3], we obtain the following one-step four-stage variant of their method:

$$\hat{\mathbf{M}} \hat{\mathbf{U}}_{n+1} = \hat{\mathbf{F}}_{n+1} - \hat{\mathbf{N}} \hat{\mathbf{U}}_n \quad (17)$$

where

$$\hat{\mathbf{M}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & (1-\alpha_f) \mathbf{K} & (1-\alpha_m) \mathbf{M} \\ \mathbf{0} & \mathbf{I} & \mathbf{0} & -\Delta t \gamma \mathbf{I} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & -\Delta t^2 \beta \mathbf{I} \\ -(1-\alpha_f) \mathbf{I} & \mathbf{0} & \mathbf{0} & (1-\alpha_m) \mathbf{I} \end{bmatrix}, \quad (18)$$

$$\hat{\mathbf{N}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \alpha_f \mathbf{K} & \alpha_m \mathbf{M} \\ \mathbf{0} & -\mathbf{I} & \mathbf{0} & -\Delta t (1 - \gamma) \mathbf{I} \\ \mathbf{0} & -\Delta t \mathbf{I} & -\mathbf{I} & -\Delta t^2 (\frac{1}{2} - \beta) \mathbf{I} \\ -\alpha_f \mathbf{I} & \mathbf{0} & \mathbf{0} & \alpha_m \mathbf{I} \end{bmatrix} \quad (19)$$

$$\hat{\mathbf{U}}_n = \begin{Bmatrix} \ddot{\mathbf{u}}_n \\ \dot{\mathbf{u}}_n \\ \mathbf{u}_n \\ \mathbf{a}_n \end{Bmatrix}, \hat{\mathbf{F}}_{n+1} = \begin{Bmatrix} \mathbf{F}(t_{n+1-\alpha_f}) \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (20)$$

with $t_{n+1-\alpha_f} = (1-\alpha_f)t_{n+1} + \alpha_f t_n$. We omit the damping terms for simplicity of the expression like in Equation (12). Note that the stage number is equal to the row dimension of $\hat{\mathbf{U}}_n$ in Equation (20). The recurrence equation (6), which defines the relation between \mathbf{a} and $\ddot{\mathbf{u}}$, is consistent with the Chung and Hulbert's method [6]. For this reason, the convergence properties of the one-step four-stage variant method defined by Equation (17) are inherited from those of the Chung and Hulbert's method [3].

In the following, we show that the extended implicit method is equivalent to the above one-step four-stage variant of the Chung and Hulbert's method.

First, we write the equilibrium equation (1) of the extended implicit method at t_n :

$$\mathbf{M}\ddot{\mathbf{u}}_n + \mathbf{C}\dot{\mathbf{u}}_n + \mathbf{K}\mathbf{u}_n = \mathbf{F}_n \quad (21)$$

We multiply Equation (1) by $(1 - \alpha_f)$ and Equation (21) by α_f . By summing them, we obtain

$$\begin{aligned} \mathbf{M}[(1 - \alpha_f)\ddot{\mathbf{u}}_{n+1} + \alpha_f\ddot{\mathbf{u}}_n] + \mathbf{C}[(1 - \alpha_f)\dot{\mathbf{u}}_{n+1} + \alpha_f\dot{\mathbf{u}}_n] + \mathbf{K}[(1 - \alpha_f)\mathbf{u}_{n+1} + \alpha_f\mathbf{u}_n] \\ = (1 - \alpha_f)\mathbf{F}_{n+1} + \alpha_f\mathbf{F}_n \end{aligned} \quad (22)$$

Substituting Equation (6) into Equation (22), we get:

$$\mathbf{M}\mathbf{a}_{n+1-\alpha_m} + \mathbf{C}\dot{\mathbf{u}}_{n+1-\alpha_f} + \mathbf{K}\mathbf{u}_{n+1-\alpha_f} = \mathbf{F}_{n+1-\alpha_f} \quad (23)$$

where

$$\mathbf{a}_{n+1-\alpha_m} = (1 - \alpha_m)\mathbf{a}_{n+1} + \alpha_m\mathbf{a}_n \quad (24)$$

$$\dot{\mathbf{u}}_{n+1-\alpha_f} = (1 - \alpha_f)\dot{\mathbf{u}}_{n+1} + \alpha_f\dot{\mathbf{u}}_n \quad (25)$$

$$\mathbf{u}_{n+1-\alpha_f} = (1 - \alpha_f)\mathbf{u}_{n+1} + \alpha_f\mathbf{u}_n \quad (26)$$

$$\mathbf{F}_{n+1-\alpha_f} = (1 - \alpha_f)\mathbf{F}_{n+1} + \alpha_f\mathbf{F}_n \quad (27)$$

Equation (23) is given by Chung and Hulbert as the equilibrium equation for their implicit method [3]. With the damping terms omitted, it is equivalent to the first row in the equation system defined by (17).

Secondly, by substituting Equations (2), (3) and (6) into both (4) and (5), we obtain the Newmark time approximation:

$$\mathbf{u}_{n+1} = \mathbf{u}_n + \Delta t\dot{\mathbf{u}}_n + \Delta t^2\left(\frac{1}{2} - \beta\right)\mathbf{a}_n^2 + \Delta t^2\mathbf{a}_{n+1}^2 \quad (28)$$

$$\dot{\mathbf{u}}_{n+1} = \dot{\mathbf{u}}_n + \Delta t(1 - \gamma)\mathbf{a}_n + \gamma\mathbf{a}_{n+1} \quad (29)$$

Equations (28) and (29) are respectively equivalent to the second and the third rows in the equation system defined by (17).

Finally, the implicit Generalized- α method of Chung and Hulbert [3] is defined by Equations (23)-(29). With the damping terms omitted, they are equivalent to the first three rows in the equation system defined by (17). And the recurrence equation (6) is equivalent to the last row in the equation system defined by (17). As a result, the extended implicit method in Section 2 is equivalent to the one-step four-stage variant of the Chung and Hulbert's method [3]. Moreover, the convergence properties of the extended implicit method are inherited from those of the Chung and Hulbert's method [3].

3.2 Relation of the extended explicit method to the method of Daniel

Daniel introduced an explicit form of the Generalized- α method [5], which uses the same integration parameters as the implicit method of Chung and Hulbert [3]. In this subsection, we show the relation between the extended explicit method in Section 2 and the Daniel's method.

The Daniel's method [5] includes only three numerical variables \mathbf{a} , $\dot{\mathbf{u}}$, \mathbf{u} and therefore it is a one-step three-stage method [22]. In contrast, the extended explicit Generalized- α method includes four numerical variables \mathbf{a} , $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, \mathbf{u} and therefore it is a one-step four-stage method. By joining the recurrence equation (6) with the basic formulas of the Daniel's method [5], we obtain the following one-step four-stage variant of his method:

$$\tilde{\mathbf{M}} \tilde{\mathbf{U}}_{n+1} = \tilde{\mathbf{F}}_{n+1} - \tilde{\mathbf{N}} \tilde{\mathbf{U}}_n \quad (30)$$

where

$$\tilde{\mathbf{M}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} & (1 - \alpha_m)\mathbf{M} \\ \mathbf{0} & \mathbf{I} & \mathbf{0} & -\Delta t\gamma\mathbf{I} \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & -\Delta t^2\beta\mathbf{I} \\ -(1 - \alpha_f)\mathbf{I} & \mathbf{0} & \mathbf{0} & (1 - \alpha_m)\mathbf{I} \end{bmatrix}, \quad (31)$$

$$\tilde{\mathbf{N}} = \begin{bmatrix} \mathbf{0} & \Delta t(1 - \alpha_f)\mathbf{K} & \mathbf{K} & \Delta t^2(1 - \alpha_f)(\frac{1}{2} - \frac{\beta}{1 - \alpha_m})\mathbf{K} + \alpha_m\mathbf{M} \\ \mathbf{0} & -\mathbf{I} & \mathbf{0} & -\Delta t(1 - \gamma)\mathbf{I} \\ \mathbf{0} & -\Delta t\mathbf{I} & -\mathbf{I} & -\Delta t^2(\frac{1}{2} - \beta)\mathbf{I} \\ -\alpha_f\mathbf{I} & \mathbf{0} & \mathbf{0} & \alpha_m\mathbf{I} \end{bmatrix} \quad (32)$$

$$\tilde{\mathbf{U}}_n = \begin{Bmatrix} \ddot{\mathbf{u}}_n \\ \dot{\mathbf{u}}_n \\ \mathbf{u}_n \\ \mathbf{a}_n \end{Bmatrix}, \quad \tilde{\mathbf{F}}_{n+1} = \begin{Bmatrix} \mathbf{F}(t_{n+1-\alpha_f}) \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (33)$$

with $t_{n+1-\alpha_f} = (1 - \alpha_f)t_{n+1} + \alpha_ft_n$. We omit the damping terms for simplicity of the expression like in Equation (12). Note that the stage number is equal to the row dimension of $\tilde{\mathbf{U}}_n$ in Equation (33). The recurrence equation (6), which defines the relation between \mathbf{a} and $\ddot{\mathbf{u}}$, is consistent with the Hulbert and Chung's explicit method [15, 6]. Therefore, it is also consistent with the Daniel's method, because the Daniel's method is the result of a similarity transformation on the amplification matrix of the Hulbert and Chung's explicit method [15, 5]. As a result, the convergence properties of the one-step four-stage variant method defined by Equation (30) are inherited from those of the Daniel's method [5].

In the following, we show that the extended explicit method is equivalent to the above one-step four-stage variant of the Daniel's method.

First, we write the equilibrium equation (7) of the extended explicit method at t_n :

$$\mathbf{M}\ddot{\mathbf{u}}_n + \mathbf{C}\dot{\mathbf{u}}_n + \mathbf{K}\tilde{\mathbf{u}}_n = \mathbf{F}_n \quad (34)$$

We multiply Equation (7) by $(1 - \alpha_f)$ and Equation (34) by α_f . By summing them, we obtain:

$$\begin{aligned} \mathbf{M}[(1 - \alpha_f)\ddot{\mathbf{u}}_{n+1} + \alpha_f\ddot{\mathbf{u}}_n] + \mathbf{C}[(1 - \alpha_f)\dot{\mathbf{u}}_{n+1} + \alpha_f\dot{\mathbf{u}}_n] + \mathbf{K}[(1 - \alpha_f)\tilde{\mathbf{u}}_{n+1} + \alpha_f\tilde{\mathbf{u}}_n] \\ = (1 - \alpha_f)\mathbf{F}_{n+1} + \alpha_f\mathbf{F}_n \end{aligned} \quad (35)$$

We write Equation (4) at t_n and then obtain:

$$\tilde{\mathbf{u}}_n = \mathbf{u}_n - \Delta t^2\beta\frac{1 - \alpha_f}{1 - \alpha_m}\ddot{\mathbf{u}}_n \quad (36)$$

We multiply Equation (2) by $(1 - \alpha_f)$ and Equation (36) by α_f . By summing them, we obtain:

$$(1 - \alpha_f)\tilde{\mathbf{u}}_{n+1} + \alpha_f\tilde{\mathbf{u}}_n = \mathbf{u}_{n+1-\alpha_f}^P \quad (37)$$

where,

$$\mathbf{u}_{n+1-\alpha_f}^P = (1 - \alpha_f)\mathbf{u}_{n+1}^P + \alpha_f\mathbf{u}_n, \quad (38)$$

$$\mathbf{u}_{n+1}^P = \mathbf{u}_n + \Delta t\dot{\mathbf{u}}_n + \Delta t^2(1/2 - \frac{\beta}{1 - \alpha_m})\mathbf{a}_n \quad (39)$$

We multiply Equation (5) by $(1 - \alpha_f)$ and add $\alpha_f\dot{\mathbf{u}}_n$ on both sides. By substituting both Equations (3) and (6) into the resulting equation, we obtain:

$$(1 - \alpha_f)\dot{\mathbf{u}}_{n+1} + \alpha_f\dot{\mathbf{u}}_n = \dot{\mathbf{u}}_{n+1-\alpha_f}^P + \Delta t\gamma\frac{1 - \alpha_f}{1 - \alpha_m}\mathbf{a}_{\alpha m} \quad (40)$$

where,

$$\dot{\mathbf{u}}_{n+1-\alpha_f}^P = (1 - \alpha_f)\dot{\mathbf{u}}_{n+1}^P + \alpha_f\dot{\mathbf{u}}_n \quad (41)$$

$$\dot{\mathbf{u}}_{n+1}^P = \dot{\mathbf{u}}_n + \Delta t(1 - \frac{\gamma}{1 - \alpha_m})\mathbf{a}_n \quad (42)$$

$$\mathbf{a}_{\alpha m} = (1 - \alpha_m)\mathbf{a}_{n+1} + \alpha_m\mathbf{a}_n \quad (43)$$

Substituting Equations (6), (37) and (40) into (35), we obtain:

$$\mathbf{M}\mathbf{a}_{\alpha m} - \mathbf{C}(\dot{\mathbf{u}}_{n+1-\alpha_f}^P + \Delta t\gamma\frac{1 - \alpha_f}{1 - \alpha_m}\mathbf{a}_{\alpha m}) - \mathbf{K}\mathbf{u}_{n+1-\alpha_f}^P = \mathbf{F}_{n+1-\alpha_f}, \quad (44)$$

or,

$$\mathbf{M}_T\mathbf{a}_{\alpha m} = \mathbf{F}_{n+1-\alpha_f} - \mathbf{C}\dot{\mathbf{u}}_{n+1-\alpha_f}^P - \mathbf{K}\mathbf{u}_{n+1-\alpha_f}^P \quad (45)$$

where

$$\mathbf{M}_T = \mathbf{M} + \Delta t\gamma\frac{1 - \alpha_f}{1 - \alpha_m}\mathbf{C} \quad (46)$$

Equation (45) is given by Daniel for his explicit method to solve $\mathbf{a}_{\alpha m}$ [5]. With the damping terms omitted, it is equivalent to the first row in the equation system defined by (30).

Secondly, by substituting Equations (2), (3) and (6) into both (4) and (5), we obtain the Newmark time approximation: Equations (28) and (29). They are respectively equivalent to the second and the third rows in the equation system defined by (30).

Finally, the explicit Generalized- α method of Daniel is defined by Equations (28), (29) and (45) [5]. With the damping terms omitted, they are equivalent to the first three rows in the equation system defined by (30). And the recurrence equation (6) is equivalent to the last row in the equation system defined by (30). As a result, the extended explicit method in Section 2 is equivalent to the one-step four-stage variant of the Daniel's method [3]. Moreover, the convergence properties of the extended explicit method are inherited from those of the Daniel's method [3].

We provide some convergence results of the extended explicit Generalized- α method. To reach second-order accuracy, the algorithmic parameters of the extended explicit method are

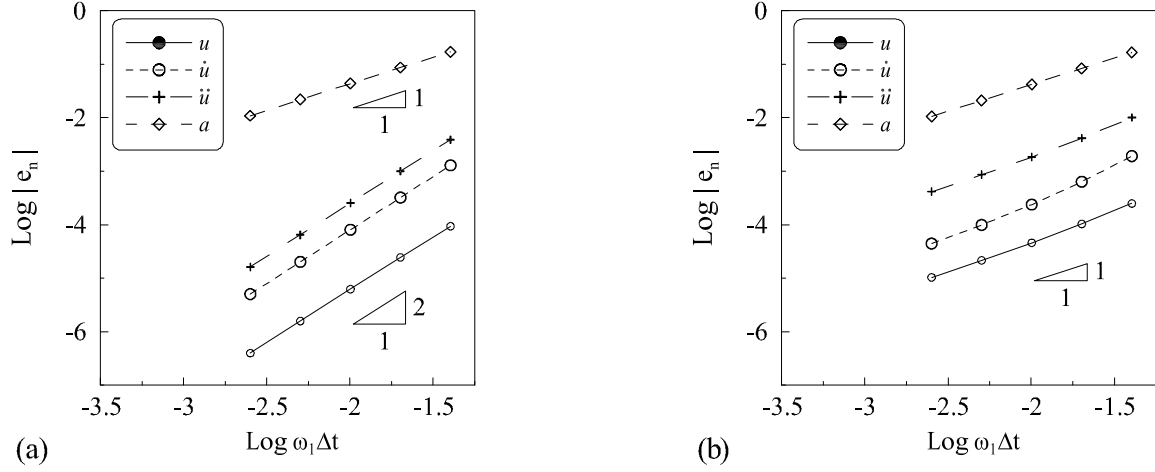

Figure 1: Convergence rate for the extended explicit method with $\rho_b = 0.8$ ($\omega_1 = \sqrt{k_1/m_1}$): (a) with the implicit treatment of the physical damping by Equation (7); (b) with the explicit treatment of the physical damping by Equation (47).

defined by Equation (11), as the Daniel's method [5]. Specifically, the method reduces to first-order accurate, if the physical damping is explicitly treated in the equilibrium equation, i.e.,

$$\mathbf{M}\ddot{\mathbf{u}}_{n+1} + \mathbf{C}\dot{\tilde{\mathbf{u}}}_{n+1} + \mathbf{K}\tilde{\mathbf{u}}_{n+1} = \mathbf{F}_{n+1} \quad (47)$$

Figure 1 plots the numerical error versus the time step for a single degree of freedom mass-spring system: $m_1\ddot{u} + c_1\dot{u} + k_1u = 0$, with $m_1 = 1$, $k_1 = 4\pi^2$, $c_1 = 2m_1\xi_1\sqrt{k_1/m_1}$ and $\xi_1 = 0.005$. The convergence rate of \mathbf{u} , $\dot{\mathbf{u}}$ and $\ddot{\mathbf{u}}$ reduces from two to one with the explicit treatment of the physical damping (Equation (47)). Note that with the implicit treatment of the physical damping \mathbf{u} , $\dot{\mathbf{u}}$ and $\ddot{\mathbf{u}}$ are second-order accurate while \mathbf{a} is only first-order accurate, as shown in Figure 1(a).

The Daniel's method [5] is spectrally identical to the explicit Generalized- α method of Hulbert and Chung [15]. For this reason, the extended explicit method is also spectrally identical to the explicit Generalized- α method of Hulbert and Chung [15]. For example, the bifurcation limit Ω_b and the stability limit Ω_s , when $\mathbf{C} = \mathbf{0}$, are:

$$\Omega_b = (1 + \rho_b)\sqrt{2 - \rho_b} \quad (48)$$

$$\Omega_s = \sqrt{\frac{12(1 + \rho_b)^3(2 - \rho_b)}{10 + 15\rho_b - \rho_b^2 + \rho_b^3 - \rho_b^4}}, \quad (49)$$

respectively. Here, $\Omega = \omega\Delta t$ denotes the non-dimensional angular frequency, being ω the natural angular frequency.

4 APPLICATION TO THE MULTI-TIME-STEP INTEGRATION

4.1 Coupled equations of motion

In this subsection, we briefly state the coupled equations of motion to be solved by the multi-time-step integration scheme. We consider a structural domain Ω , which is partitioned into sd subdomains. By enforcing the velocity continuity at the subdomain interfaces [12], we obtain

Figure 2: Time discretization of the multi-time-step scheme for two subdomains A and B.

the following semi-discrete coupled equations of motion:

$$\mathbf{M}^i \ddot{\mathbf{u}}^i(t) + \mathbf{K}^i \mathbf{u}^i(t) = \mathbf{F}^i(t) + \mathbf{L}^{iT} \boldsymbol{\Lambda}(t) \quad (i = 1, \dots, sd) \quad (50)$$

$$\sum_{i=1}^{sd} \mathbf{L}^i \dot{\mathbf{u}}^i(t) = \mathbf{0} \quad (51)$$

where \mathbf{M}^i and \mathbf{K}^i are the i -th subdomain mass and stiffness matrices, respectively; $\mathbf{F}^i(t)$ is the i -th subdomain load vector; $\mathbf{u}^i(t)$ is the i -th subdomain displacement vector; \mathbf{L}^i are the constraint matrices which express linear relationships at the i -th subdomain interfaces and $\boldsymbol{\Lambda}(t)$ is the vector of Lagrange multipliers. The associated initial value problem consists in determining the function $\mathbf{u}^i = \mathbf{u}^i(t)$ fulfilling Equations (50) and (51) for all $t \in [0, t_f]$, $t_f > 0$, for given initial conditions $\mathbf{u}^i(0) = \mathbf{d}_0^i$ and $\dot{\mathbf{u}}(0) = \mathbf{v}_0^i$.

4.2 The multi-time-step integration scheme

For simplicity, we consider a problem with two subdomains A and B. They are integrated with time steps Δt_A and Δt_B , respectively, with

$$\Delta t_A = m \Delta t_B \quad (52)$$

where m is an integer and defines the number of substeps. As an illustration of the multi-time-step scheme, we advance the solution from t_0 to $t_m = t_0 + \Delta t_A$ by Δt_A in Figure 2.

Hereinafter, we apply the extended Generalized- α methods defined by Equation (12) to solve the coupled equations (50) and (51). The fully discretized equations can be written as:

$$\overline{\mathbf{M}}^A \overline{\mathbf{U}}_m^A = \overline{\mathbf{F}}_m^A + \overline{\mathbf{L}}^A \boldsymbol{\Lambda}_m - \overline{\mathbf{N}}^A \overline{\mathbf{U}}_0^A \quad (53)$$

$$\overline{\mathbf{M}}^B \overline{\mathbf{U}}_j^B = \overline{\mathbf{F}}_j^B + \overline{\mathbf{L}}^B \boldsymbol{\Lambda}_j - \overline{\mathbf{N}}^B \overline{\mathbf{U}}_{j-1}^B, \forall j \in [1, 2, \dots, m] \quad (54)$$

$$\mathbf{L}^A \dot{\mathbf{u}}_m^A + \mathbf{L}^B \dot{\mathbf{u}}_m^B = \mathbf{0}, \quad (55)$$

where

$$\overline{\mathbf{L}}^i = \begin{Bmatrix} \mathbf{L}^{iT} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} \quad (56)$$

and $\overline{\mathbf{M}}$, $\overline{\mathbf{N}}$, $\overline{\mathbf{U}}$ and $\overline{\mathbf{F}}$ are given by Equations (13)-(16). Note that in Equation (55) the velocity continuity at the subdomain interfaces is enforced only at t_m of the coarse time scale [20].

In order to solve the coupled problem (53)-(55), we split the kinematic quantities $\overline{\mathbf{U}}_m$ into two parts:

$$\overline{\mathbf{U}} = \overline{\mathbf{V}} + \overline{\mathbf{W}} \quad (57)$$

where $\overline{\mathbf{V}} = [\ddot{\mathbf{v}}, \dot{\mathbf{v}}, \mathbf{v}, \mathbf{a}_f]^T$ and $\overline{\mathbf{W}} = [\ddot{\mathbf{w}}, \dot{\mathbf{w}}, \mathbf{w}, \mathbf{a}_l]^T$. First, $\overline{\mathbf{V}}_m^A$ and $\overline{\mathbf{W}}_m^A$ of subdomain A at t_m are defined by the following equations:

$$\overline{\mathbf{M}}^A \overline{\mathbf{V}}_m^A = \overline{\mathbf{F}}_m^A - \overline{\mathbf{N}}^A \overline{\mathbf{U}}_0^A \quad (58)$$

$$\overline{\mathbf{M}}^A \overline{\mathbf{W}}_m^A = \overline{\mathbf{L}}^A \boldsymbol{\Lambda}_m \quad (59)$$

The above equations (58) and (59) define the free problem and the link problem of subdomain A, respectively [12].

Secondly, $\overline{\mathbf{V}}_j^B$ and $\overline{\mathbf{W}}_j^B$ of subdomain B are defined by the following equations:

$$\overline{\mathbf{M}}^B \overline{\mathbf{V}}_j^B = \overline{\mathbf{F}}_j^B - \overline{\mathbf{N}}^B \overline{\mathbf{V}}_{j-1}^B, \forall j \in [1, 2, \dots, m] \text{ (if } j = 1, \overline{\mathbf{V}}_0^B = \overline{\mathbf{U}}_0^B) \quad (60)$$

$$\overline{\mathbf{M}}^B \overline{\mathbf{W}}_j^B = \overline{\mathbf{L}}^B \boldsymbol{\Lambda}_j - \overline{\mathbf{N}}^B \overline{\mathbf{W}}_{j-1}^B, \forall j \in [1, 2, \dots, m] \text{ (if } j = 1, \overline{\mathbf{W}}_0^B = \mathbf{0}) \quad (61)$$

The above equations (60) and (61) define the free problem and the link problem of subdomain B, respectively [12].

Thirdly, from Equation (55) we have:

$$\mathbf{L}^A \dot{\mathbf{w}}_m^A + \mathbf{L}^B \dot{\mathbf{w}}_m^B = -(\mathbf{L}^A \dot{\mathbf{v}}_m^A + \mathbf{L}^B \dot{\mathbf{v}}_m^B) \quad (62)$$

We need to define transitional operators in order to connect the kinematic quantities of two subdomains at the intermediate time steps t_j . Note that in (58) and (59) the kinematic quantities of A are only defined at t_m of the coarse time scale. In order to solve this problem, we use the following equation [20]:

$$\boldsymbol{\Lambda}_j = -\mathbf{S}_j + \frac{j}{m} \boldsymbol{\Lambda}_m, \forall j \in [1, 2, \dots, m] \quad (63)$$

with $\mathbf{S}_j = \mathbf{L}^A (\mathbf{F}_j^A - \mathbf{M}^A \ddot{\mathbf{v}}_j^A - \mathbf{K}^A \mathbf{v}_j^A)$.

Below we give a brief derivation of Equation (63), though it is similar to the derivation of the similar equation in [20]. We write the equilibrium equation of subdomain A at the intermediate time step t_j as

$$\mathbf{F}_j^A - \mathbf{M}^A \ddot{\mathbf{u}}_j^A - \mathbf{K}^A \mathbf{u}_j^A + \mathbf{L}^{AT} \boldsymbol{\Lambda}_j = \mathbf{0} \quad (64)$$

From Equation (64), by considering Equation (57) we have:

$$\mathbf{S}_j = \mathbf{L}^A (\mathbf{F}_j^A - \mathbf{M}^A \ddot{\mathbf{v}}_j^A - \mathbf{K}^A \mathbf{v}_j^A) \quad (65)$$

$$\mathbf{T}_j = \mathbf{L}^A (-\mathbf{M}^A \ddot{\mathbf{w}}_j - \mathbf{K}^A \mathbf{w}_j^A + \mathbf{L}^{AT} \boldsymbol{\Lambda}_j) \quad (66)$$

We consider \mathbf{S}_j as the unbalanced interface reaction for the subdomain A free problem. And we consider \mathbf{T}_j as the unbalanced interface reaction for the subdomain A link problem. To derive

(63) we also need to interpolate $\overline{\mathbf{V}}_j^A$ and $\overline{\mathbf{W}}_j^A$ at the intermediate time step t_j , $\forall j \in [1, 2, \dots, m]$ [20]:

$$\overline{\mathbf{V}}_j^A = (1 - \frac{j}{m})\overline{\mathbf{U}}_0^A + \frac{j}{m}\overline{\mathbf{V}}_m^A \quad (67)$$

$$\overline{\mathbf{W}}_j^A = \frac{j}{m}\overline{\mathbf{W}}_m^A \quad (68)$$

Substituting (68) into (66), we obtain:

$$\mathbf{T}_j = -\frac{j}{m}\mathbf{L}^A(\mathbf{M}^A\ddot{\mathbf{w}}_m^A + \mathbf{K}^A\mathbf{w}_m^A) + \mathbf{\Lambda}_j \quad (69)$$

From (59), we have:

$$\mathbf{M}^A\ddot{\mathbf{w}}_j^A + \mathbf{K}^A\mathbf{w}_m^A = \mathbf{L}^{A^T}\mathbf{\Lambda}_m \quad (70)$$

Substituting (70) into (69), we have:

$$\mathbf{T}_j = -\frac{j}{m}\mathbf{\Lambda}_m + \mathbf{\Lambda}_j \quad (71)$$

From (64) for the equilibrium, we have:

$$\mathbf{S}_j + \mathbf{T}_j = 0 \quad (72)$$

Substituting (71) into (72), we have:

$$\mathbf{S}_j - \frac{j}{m}\mathbf{\Lambda}_m + \mathbf{\Lambda}_j = 0 \quad (73)$$

From (73), we get Equation (63).

After substituting (63) into (61), we rearrange Equations (60) and (61). The reason for the rearrangement is to have \mathbf{S}_j in (60) instead of (61) and therefore the link quantity $\overline{\mathbf{W}}_j^B$ is only dependent on the interface tractions $\mathbf{\Lambda}_m$.

$$\overline{\mathbf{M}}^B\overline{\mathbf{V}}_j^B = \overline{\mathbf{F}}_j^B - \overline{\mathbf{N}}^B\overline{\mathbf{V}}_{j-1}^B - \overline{\mathbf{L}}^B\mathbf{S}_j, \forall j \in [1, 2, \dots, m] \text{ (if } j = 1, \overline{\mathbf{V}}_0^B = \overline{\mathbf{U}}_0^B) \quad (74)$$

$$\overline{\mathbf{M}}^B\overline{\mathbf{W}}_j^B = \frac{j}{m}\overline{\mathbf{L}}^B\mathbf{\Lambda}_m - \overline{\mathbf{N}}^B\overline{\mathbf{W}}_{j-1}^B, \forall j \in [1, 2, \dots, m] \text{ (if } j = 1, \overline{\mathbf{W}}_0^B = 0) \quad (75)$$

Note that by summing (74) and (75) the original equation (59) of subdomain B will be recovered. To summarize, we define by Equations (58), (59), (74), (75) and (62) the new multi-time-step scheme.

4.3 Solution procedure

We propose to use the same solution procedure as the PH method [20]. The solution procedure can be represented in the following four stages.

4.3.1 The preliminary stage

In the preliminary stage, first we solve the subdomain A scaled link problem as:

$$\overline{\mathbf{M}}^A \overline{\mathbf{Y}}_m^A = \overline{\mathbf{L}}^A \quad (76)$$

with $\overline{\mathbf{Y}}_m^A = [\ddot{\mathbf{y}}_m^A, \dot{\mathbf{y}}_m^A, \mathbf{y}_m^A, \tilde{\mathbf{a}}_{ml}^A]^T$. Equation (76) is obtained from Equation (59) by assuming $\Lambda_m = \mathbf{I}$. Secondly, we solve the subdomain B scaled link problem as:

$$\begin{bmatrix} \overline{\mathbf{M}}^B & & & & \\ \overline{\mathbf{N}}^B & \overline{\mathbf{M}}^B & & & \\ & & \ddots & & \\ & & & \ddots & \\ & & & & \overline{\mathbf{N}}^B & \overline{\mathbf{M}}^B \end{bmatrix} \begin{Bmatrix} \overline{\mathbf{Y}}_1^B \\ \overline{\mathbf{Y}}_2^B \\ \vdots \\ \overline{\mathbf{Y}}_m^B \end{Bmatrix} = \begin{Bmatrix} \frac{1}{m} \overline{\mathbf{L}}^B \\ \frac{2}{m} \overline{\mathbf{L}}^B \\ \vdots \\ \overline{\mathbf{L}}^B \end{Bmatrix} \quad (77)$$

with $\overline{\mathbf{Y}}_j^B = [\ddot{\mathbf{y}}_j^B, \dot{\mathbf{y}}_j^B, \mathbf{y}_j^B, \tilde{\mathbf{a}}_{jl}^B]^T, j \in [1, 2, \dots, m]$. Equation (77) is obtained from Equation (75) by assuming $\Lambda_m = \mathbf{I}$. Note that from (59) and (75), we have:

$$\overline{\mathbf{W}}_m^A = \overline{\mathbf{Y}}_m^A \Lambda_m \quad (78)$$

$$\overline{\mathbf{W}}_j^B = \overline{\mathbf{Y}}_j^B \Lambda_m, j \in [1, 2, \dots, m] \quad (79)$$

4.3.2 The predictor stage

In the predictor stage, we solve the free problem (58) of subdomain A and the free problem (74) of subdomain B. Specifically, the free problem of B can be written as the following form:

$$\begin{bmatrix} \overline{\mathbf{M}}^B & & & & \\ \overline{\mathbf{N}}^B & \overline{\mathbf{M}}^B & & & \\ & & \ddots & & \\ & & & \ddots & \\ & & & & \overline{\mathbf{N}}^B & \overline{\mathbf{M}}^B \end{bmatrix} \begin{Bmatrix} \overline{\mathbf{V}}_1^B \\ \overline{\mathbf{V}}_2^B \\ \vdots \\ \overline{\mathbf{V}}_m^B \end{Bmatrix} = \begin{Bmatrix} \overline{\mathbf{F}}_1^B - \overline{\mathbf{N}}^B \mathbf{U}_0^B - \overline{\mathbf{L}}^B \mathbf{S}_1 \\ \overline{\mathbf{F}}_2^B - \overline{\mathbf{L}}^B \mathbf{S}_2 \\ \vdots \\ \overline{\mathbf{F}}_m^B - \overline{\mathbf{L}}^B \mathbf{S}_m \end{Bmatrix} \quad (80)$$

4.3.3 The solution of the interface problem

The condensed global interface problem is obtained by substitution of Equations (78) and (79) ($j = m$) into (62).

$$\mathbf{H} \Lambda_m = -(\mathbf{L}^A \dot{\mathbf{y}}_m^A + \mathbf{L}^B \dot{\mathbf{y}}_m^B) \quad (81)$$

with $\mathbf{H} = \mathbf{L}^A \dot{\mathbf{y}}_m^A + \mathbf{L}^B \dot{\mathbf{y}}_m^B$. We solve Equation (81) for Λ_m .

4.3.4 The corrector stage

In the corrector stage, we compute the link quantities $\overline{\mathbf{W}}_m^A$ and $\overline{\mathbf{W}}_j^B$ by Equations (78) and (79). Then, we sum the free quantity $\overline{\mathbf{V}}$ and the link quantity $\overline{\mathbf{W}}$ to obtain $\overline{\mathbf{U}}$ according to Equation (57). Note that the above procedure can be generalized from t_n to t_{n+m} .

Figure 3: A split SDOF mass and spring system

5 A NUMERICAL TEST

Convergence of the proposed partitioned method can't be analysed by a modal approach, because the modal decomposition is no more valid for multi-time-step implicit-explicit schemes [14]. There are two ways for the convergence analysis of the multi-time-step methods: the first is the energy approach [12, 20] and the second is to examine some linear problems using symbolic and numerical computation [2]. Because an appropriate energy norm of the Generalized- α method is difficult to define, we choose to examine the convergence properties of the current method on a linear model problem.

The model problem to be examined is a split single degree of freedom (SDOF) mass-spring system. The SDOF system is split into two subdomains A and B, as shown in Figure 3. We choose to integrate subdomain A with the extended implicit Generalized- α method and subdomain B with the extended explicit Generalized- α method. The system parameters are chosen as follows: $m_A + m_B = 1$, $k_A + k_B = 4\pi^2$ and $r = \frac{m_A}{m_B} = \frac{k_B}{k_A}$. We use the parameter r to adjust the ratio between the angular frequencies of the two subdomains.

Numerical results for the free vibration with a unity initial displacement are given in Figures (4) and (5). The substep number $m = 2$. By choosing $r = \omega_B/\omega_A = 2$, we have $\omega_A\Delta t_A = \omega_B\Delta t_B = 0.5$, being ω_A and ω_B the subdomain angular frequencies. In Figure (4), we see a significant amplitude decay when $\rho = \rho_\infty = \rho_b = 0$. Note that ρ_∞ is for the implicit subdomain A and ρ_b is for the explicit subdomain B. The amplitude decay is much less when $\rho = \rho_\infty = \rho_b = 0.5$. When $\rho = \rho_\infty = \rho_b = 1$, we don't see an amplitude decay by comparing the numerical results to the exact solution. Moreover, the results of the current method with $\rho = \rho_\infty = \rho_b = 1$ are compared to the results of the PH method. As shown in Figure (5), they are almost overlapping each other. Similar numerical results are given in Figure (6) and (7) for $m = 100$. By choosing $r = \omega_B/\omega_A = 5$, we have $\omega_A\Delta t_A = 0.25$ and $\omega_B\Delta t_B = 0.0125$. We see again the different amplitude decay rate of the current method with $\rho = \rho_\infty = \rho_b = 0$, $\rho = \rho_\infty = \rho_b = 0.5$ and $\rho = \rho_\infty = \rho_b = 1$, respectively. Note that with the smaller Δt_A the numerical results for $\rho = \rho_\infty = \rho_b = 1$ are more accurate in comparison to Figure 4. And again the results of the current method with $\rho = \rho_\infty = \rho_b = 1$ almost overlap the results of the PH method, as shown in Figure (7). Because the PH method is energy preserving, the current method is not dissipative at the subdomain interfaces and its numerical dissipation is solely decided by the Generalized- α methods of each subdomain.

We study the convergence rate for the multi-time-step method by plotting the numerical error versus the time step. As shown in Figure 8, the current method is second-order accurate both for the single time scale ($m = 1$) and for the multiple time scales ($m > 1$). We present the results for the current method with $\rho = \rho_\infty = \rho_b = 0.8$ and $r = 10$.

Figure 4: Velocity responses for the current method with $m = 2$ and $\omega_A \Delta t_A = \omega_B \Delta t_B = 0.5$.

Figure 5: Velocity responses: comparison between the current method with $\rho = \rho_\infty = \rho_b = 1$ and the PH method for $m = 2$.

Figure 6: Velocity responses for the current method with $m = 100$, $\omega_A \Delta t_A = 0.25$ and $\omega_B \Delta t_B = 0.0125$.

Figure 7: Velocity responses: comparison between the current method with $\rho = \rho_\infty = \rho_b = 1$ and the PH method for $m = 100$.

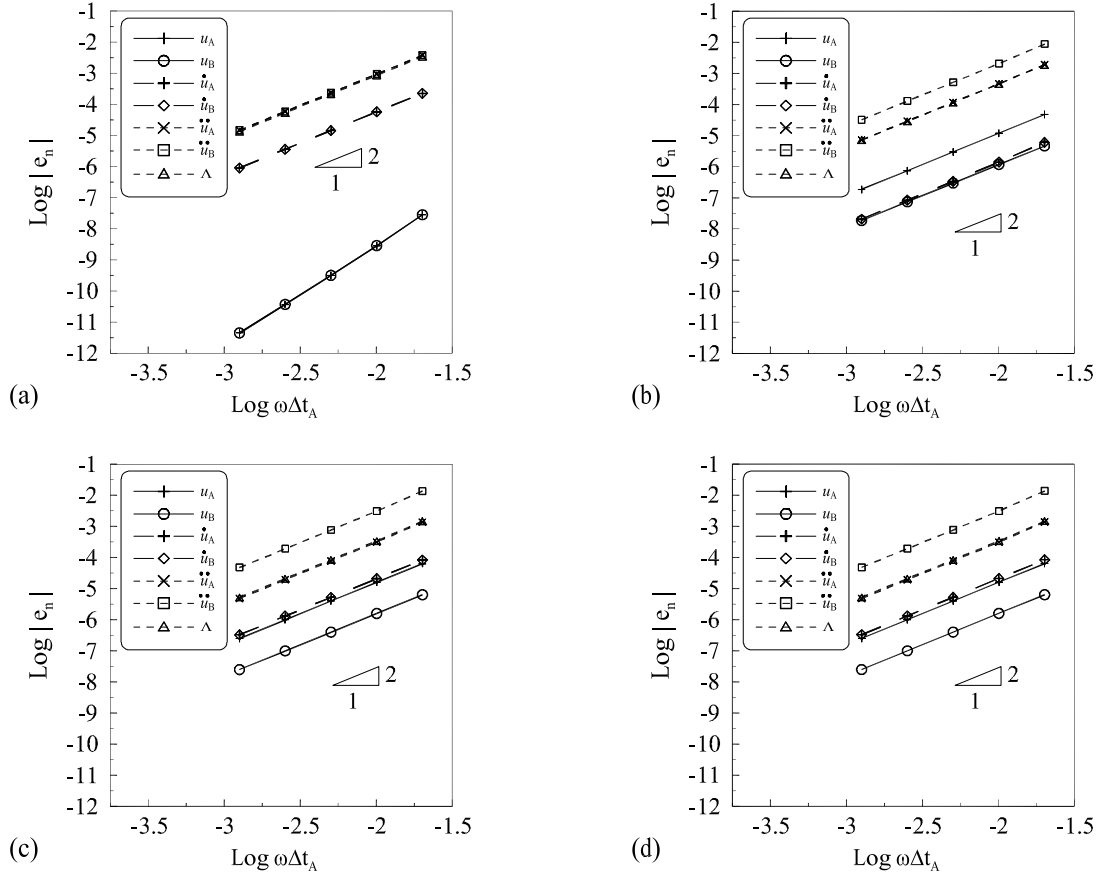

Figure 8: Convergence rate of the current multi-time-step scheme with: (a) $m = 1$; (b) $m = 2$; (c) $m = 20$; and (d) $m = 200$ ($\omega = \sqrt{(k_A + k_B)/(m_A + m_B)}$).

6 CONCLUSIONS

The proposed multi-time-step scheme enables to couple arbitrary Generalized- α methods with different time scales in each subdomain. The Generalized- α methods can either be the extended implicit method or the extended explicit method. Both of them are the variants of the implicit and the explicit Generalized- α methods. The uniform formulas can be used to decide upon their algorithmic parameters. The numerical dissipation of the partitioned method is found to be solely decided by the Generalized- α methods in each subdomain. Moreover, the multi-time-step method is still second-order accurate as the monolithic algorithms in each subdomain. Work is in progress to study the stability of the partitioned method by spectral analysis, though we find in the numerical simulations that the method is still stable when the explicit subdomain satisfies its own stability condition.

Keywords: Fluid-Structure Interaction, Transient Dynamics, Blast Loading.

Abstract. *The simulation of blast loading effects on structures undergoing very large deformations, possibly up to complete failure and fragmentation, requires robust and specific Fluid-Structure Interaction (FSI) algorithms. The FLSR algorithm uses fully non-conforming fluid and structure meshes (the structure is “embedded” within the fluid), that are “strongly” coupled by suitable constraints on velocities near the F-S interface, enforced by Lagrange multipliers. This technique allows using a regular (or even a structured, typically Eulerian) fluid mesh, while the structure is Lagrangian and can undergo failure and fragmentation without the mesh entanglement difficulties that would arise with more traditional (conforming) FSI algorithms. However, the localization of coupled F-S nodes is more expensive than in the conforming case and must be continuously updated, by means of fast search algorithms, as the structure moves and deforms. The strong form of the algorithm (FLSR) is suitable for a Finite Element (FE) description of the fluid domain and has been used with success in large realistic simulations. Application to Node-Centered Finite Volumes (NCFV) requires an additional treatment of numerical fluxes, presented in the paper. Recently a “weak” variant of the algorithm (FLSW) has been developed for use with Cell-Centered Finite Volumes (CCFV) in the fluid domain. Suitable pressure (interaction) forces are used for the coupling, rather than strong conditions on velocities. Like for NCFV, appropriate treatment of numerical fluxes is required. The rationale and implications of this choice are discussed in the paper.*

1 INTRODUCTION

Fluid-structure interaction (FSI) phenomena play an important role in many areas, ranging from aeronautical and space applications, to civil and marine/offshore engineering and to the transport industry, to name just a few. The JRC has been involved for many years in the development of numerical methods for FSI modeling applied to safety studies—initially for the nuclear industry and more recently for conventional power plants (electrical machinery)—to civil engineering (vulnerability of buildings and other critical infrastructures to terrorist attacks) and to land mass transports (blast effects in railway stations, metro lines, rolling stock).

All these studies are characterized by the violent blast loading, resulting either from an accident or from an intentional attack, and by the very short time scale (fast transient dynamics). Strong pressure waves propagate in the fluid and load the surrounding structures, which typically undergo large deformations and in some cases reach complete failure and fragmentation. For this class of problems, an explicit time marching algorithm is usually adopted, where the fluid is modelled as compressible and inviscid (Euler equations). An Arbitrary Lagrangian Eulerian (ALE) formulation is adopted for the fluid sub-domain, while the structure is Lagrangian. These models are implemented in the EUROPLEXUS code [1], developed jointly by the JRC and by the French CEA.

Three different discretization approaches are available in the code for the fluid sub-domain, see Fig. 1: finite elements (FE), node-centred finite volumes (NCFV) and cell-centred finite volumes (CCFV). In the FE case, kinematic variables (such as the velocity \mathbf{v}) are discretized at the element nodes, while state variables (such as the fluid pressure p) are discretized at Gauss points, typically located at the element (shaded area in Fig. 1a) centroid. In the NCFV case, a virtual FV (dual) mesh centred on fluid nodes (shaded area in Fig. 1b) is automatically built up starting from the FE-like (primal) mesh provided in input, and all variables are discretized at the nodes. In the CCFV case, the FV mesh (shaded area in Fig. 1c) looks similar to the FE case, but all variables are discretized at the volume centres. Note that in this case the ~~nodes~~ carry no relevant information other than their position, used to compute the volume.

The coupling between the fluid (ALE) and the structure (Lagrangian) is realized by suitable FSI algorithms. Two broad classes of algorithms are considered here. The first class uses a ~~strong~~ approach, based on constraints imposed on the (velocity of) fluid and structure nodes at the F-S interface. The second class uses a ~~weak~~ approach, based on direct application of fluid pressure forces to the structure. This terminology (strong/weak) is tentatively adopted here in an attempt to characterize the different nature of the two approaches, but it should not be confused with other uses of the same terms in the literature, in particular with weak (i.e. integral) forms in continuum mechanics. Traditionally, strong FSI algorithms are mainly used in FE, while weak FSI algorithms are mainly used in FV.

Yet another classification of FSI algorithms concerns the degree of deformation/damage that the structure can undergo (and thus the type of application). One class of ~~basic~~ algorithms is suitable for large motion and large deformation of structures, but only provided these do not fail. Another class of algorithms can go up to complete *failure*, and *fragmentation*, of the loaded structures.

Finally, FSI algorithms can be classified in three types according to spatial discretization: (nodally) *conforming*, *non-conforming*, and *embedded* (or immersed). The first two types are mostly used in applications without structural failure (but there are exceptions, see Section 3.3), while embedded algorithms are the only ones capable of dealing with extreme loading cases where the structure fails and breaks up in pieces.

Examples of all such different algorithms are shortly presented, by highlighting their characteristics. The paper is organized as follows. Section 2 reviews some algorithms of the basic

type (no structure failure), either conforming or non-conforming, which use the strong approach in a FE or NCFV context. Section 3 presents algorithms of the weak type, in a CCFV context. Section 4 shows embedded algorithms with strong and weak formulations. Some numerical examples are presented in Section 5. Finally, Section 6 contains some conclusions and perspectives for future work.

2 BASIC FSI ALGORITHMS OF THE STRONG TYPE

The basic FSI algorithms—valid for largely deforming (but *not failing*) structures and using a strong approach—are briefly summarized, first in a FE and then in a NCFV context. Readers interested in full details should consult references [2-7]. A sample FSI problem is assumed as a reference, see Fig. 2a (continuous domain). A shell-like structure S is considered, in 2D for simplicity, but a junction (J) completely surrounded by fluid is included for generality. As indicated by colors, the nature of the fluid(s) may be different from one side to the other of the structure (F_1 , F_2 , F_3). Since by assumption the structure cannot fail, these fluids never come into contact and do not mix up with one another.

2.1 Conforming FE discretization

A spatial discretization must be chosen for the two sub-domains. The simplest case is that of a (nodally) conforming mesh, see Fig. 2b. In this case, to each node S of the structure there corresponds one node F of the fluid, and reciprocally (in case of more than one fluid sub-domain, this holds for each sub-domain). The nodes S and F are superposed, i.e. they have the same coordinates, but they are distinct (not merged). At a junction such as J there can be several fluid nodes (one for each fluid sub-domain) matching the same structure node.

The strong approach (*FSA algorithm* [2]) is illustrated in Fig. 3. Assuming an ALE formulation, there are *two* velocity vectors at each node, one for the particles (\mathbf{v}) and one for the mesh (\mathbf{w}). At each couple of matching F-S nodes the constraint on particle velocities reads:

$$\mathbf{v}_F \cdot \mathbf{n} = \mathbf{v}_S \cdot \mathbf{n}, \quad (1)$$

where subscript F indicates the fluid, subscript S indicates the structure and \mathbf{n} is the unit normal to the *discrete* F-S interface at the concerned (fluid) node, see Fig. 3a. This condition on normal velocity components ensures that the fluid can neither traverse the structure wall, nor detach from it. The tangential components of the fluid and structure particle velocities are independent, so that the fluid (assumed inviscid) can freely slide along the structural walls. This is one of the arguments in favor of keeping the fluid and structure nodes distinct (though superposed) in the FSA algorithm: one single node would not provide enough degrees of freedom (dofs) for two distinct tangential velocity components. Computing the discrete normal(s) is not a trivial task in general, see [2-3] for a detailed discussion. In fact, the only (relatively) complex part of the algorithm is the automatic determination of the normal(s) in geometrically complex 3D cases, such as in the presence of junctions, free edges etc. especially when shell elements are used for the structure.

Relations of the form (1) are exactly enforced by Lagrange multipliers; see [2-3]. Thanks to implicit solution of the system of constraints, FSI conditions are automatically coupled with any other (compatible) essential conditions imposed by the user, e.g. blockages, symmetries, contact between solid bodies, etc. This is the only implicit part of the transient dynamic algorithm, which is otherwise completely explicit.

As concerns mesh velocity, which is arbitrary in ALE, the following compatibility condition is (trivially) imposed, see Fig. 3b:

$$\mathbf{w}_F = \mathbf{w}_S = \mathbf{v}_S, \quad (2)$$

ensuring that the fluid and the structure nodes at the F-S interface remain constantly superposed in the motion and deformation process. The second equality in (2) holds because a Lagrangian description is normally adopted for the structure. Then, the first equality provides the value of the fluid mesh velocity \mathbf{w}_F along the F-S interface, necessary to complete the ALE description.

2.2 Non-conforming FE discretization

The FSA algorithm is easily generalized to the case of a nodally non-conforming F-S interface, see [4] and Fig. 4. This generalization is important in practical applications, because typically a finer mesh is needed in the fluid than in the structure—especially if the latter is meshed by shells—in order to obtain an accurate pressure field. The so-called *hierarchical* approach is usually convenient, see Fig. 4b, whereby to each structure node along the F-S interface there always corresponds a fluid node (*matching* nodes), but the inverse is not true in general (*non-matching* nodes) since F-S fluid nodes are more numerous than structure nodes.

For each couple of matching nodes, expressions (1) and (2) continue to hold. At a non-matching fluid node F (see Fig. 5) similar expressions can be written, involving the fluid node itself and the corresponding *point* S^* of the structure (note that this is *not* a node). For the particle velocity, in analogy with (1):

$$\mathbf{v}_F \cdot \mathbf{n}_F = \mathbf{v}_{S^*} \cdot \mathbf{n}_F, \quad (3)$$

where the local normal is now \mathbf{n}_F , perpendicular to the fluid domain. This normal is easily computed because the fluid domain is flat at non-conforming nodes. The constraint is then expressed in terms of nodal dofs (of the structure) by means of suitable shape functions N_I . For example, in the case of Fig. 5a the constraint (3) becomes:

$$\mathbf{v}_F \cdot \mathbf{n}_F = (N_1 \mathbf{v}_{S_1} + N_2 \mathbf{v}_{S_2}) \cdot \mathbf{n}_F. \quad (4)$$

Similarly, for the mesh velocity at non-matching nodes, see Fig. 5b, one has instead of (2):

$$\mathbf{w}_F = \mathbf{w}_{S^*} = \mathbf{v}_{S^*} = (N_1 \mathbf{w}_{S_1} + N_2 \mathbf{w}_{S_2}). \quad (5)$$

2.3 Application to NCFV

The strong FSI algorithms presented so far fit particularly well in a FE discretization of the fluid sub-domain, because the corresponding constraints are imposed at fluid nodes, which coincide (spatially) with structure nodes (in the conforming case) or with other points of the structure (in the non-conforming case). The constraint (1) is quite “natural” in this case, because it expresses the physically intuitive condition that the fluid cannot traverse the solid wall, but is allowed to slide along it.

Exactly the same algorithms can be applied in the NCFV context [5-7], because also in that case fluid velocities are discretized at the “nodes” of the (primal) fluid mesh, which coincide with the FV centroids of the dual mesh, see Fig. 1b. Like in the FE case, enforcement of constraints is obtained via Lagrange multipliers, see [5-7] for details. Note, however, that in this case the constraint (1) is “stronger” than in the FE case, because \mathbf{v}_F represents the velocity of the whole NCFV to which the fluid node belongs, while in FE it is the local value at the node. In fact, in FE the velocity is linearly interpolated over the element, while in NCFV (and also in CCFV) the velocity is uniform (just one value) over the entire finite volume.

3 FSI ALGORITHMS OF THE WEAK TYPE

The weak FSI algorithms considered here do not use constraints, but consist in applying directly to the structure the pressure forces generated by the fluid. These forces are interpreted as “external” forces in computing the equilibrium (in a dynamic sense) of the structure, and are assembled together with any other (user-imposed) external forces and with the internal forces resulting from the stress state in the structure.

The (ALE) fluid nodes at the F-S interface are tied to continuously follow the motion of the structure, and this provides a (weak) feed-back mechanism, influencing the physical state of the fluid. Like in the strong case, eqs. (2) or (5) are used to compute the mesh velocity at conforming or non-conforming fluid nodes at the F-S interface, respectively.

3.1 Conforming CCFV discretization

The weak FSI formulation seems particularly well suited for use with CCFV [8]. In the conforming case, illustrated in Fig. 6, the simplest technique is to merge together each couple of fluid and structure nodes along the F-S interface, rather than keeping them distinct. In this way, the pressure forces computed in the FV act directly on the structure thanks to the standard force assembly procedure. If p is the fluid pressure in the FV, L the length (area in 3D) of its face on the F-S interface, and \mathbf{n}_s the unit normal to the structure (coincident with the normal to the fluid face), see Fig. 6a, the pressure force contribution for this volume is:

$$\mathbf{f}_p = pL\mathbf{n}_s. \quad (6)$$

This force is equally distributed on the nodes of the corresponding face, which belong both to the fluid and to the structure, and therefore contributes to the motion of the structure.

3.2 Non-conforming CCFV discretization

The weak FSI algorithm for a non-conforming (hierarchic) CCFV mesh is shown in Fig. 7. In this case, some fluid nodes on the F-S interface match a corresponding structure node, some don't. Each couple of matching nodes can be merged together, like in the conforming case, but this is not possible for the non-matching fluid nodes. Therefore, the algorithm is set up in such a way that the merging or not of the (matching) nodes has no effect on the solution. In Fig. 7a the matching nodes are kept distinct, for example.

Apart from this, the only difference with respect to the conforming case is the distribution of fluid pressure forces to the structure nodes, see Fig. 7b. Let p_i be the fluid pressure in the i -th FV, L_i the length of its face (area in 3D) on the F-S interface, and \mathbf{n}_s the unit normal to the structure (coincident with the normal to the fluid face), see Fig. 7a. Then, the pressure force contribution for this volume is again given by (6), which becomes in this case:

$$\mathbf{f}_{p,i} = p_i L_i \mathbf{n}_s. \quad (7)$$

This force is supposed to act at the point C_i of the structure coinciding with the centroid of the fluid face (Fig. 7b). Therefore, in the 2D case, if $L_s = L_{Ai} + L_{Bi}$ is the length of the structure face, the force contributions at the two nodes A and B of the structure are:

$$\mathbf{f}_{p,Ai} = (L_{Bi}/L_s)\mathbf{f}_{p,i} \quad ; \quad \mathbf{f}_{p,Bi} = (L_{Ai}/L_s)\mathbf{f}_{p,i}. \quad (8)$$

3.3 Structural failure with CCFV

The CCFV formulation, in conjunction with the present weak FSI algorithm, lends itself to the treatment of structural failure even in the basic cases of conforming or non-conforming meshes (which is *not* the case for FE or CCFV, see Section 4).

Consider a structure separating two fluid sub-domains occupied by the *same type of fluid*, see Fig. 6b for the conforming and Fig. 7a for the non-conforming case. The key observation is that, since in CCFV the velocities are discretized at volume centers (not at nodes), the fluid meshes on either part of the structure can be set up as a *continuous mesh*. That is, assuming that fluid nodes occupy the same positions on either side of the structure, these nodes can be merged together two by two—and this independently from whether they are also merged with structure nodes and from whether the structure mesh is conforming or not with the fluid mesh—as shown in the Figures.

As long as the structure resists, each fluid FV transmits its pressure force to the structure and the corresponding volume face is considered as a boundary face (solid wall). Therefore, no mass or energy numerical fluxes (typical of FV technology) are computed across such faces, and the result is that the fluid cannot traverse the wall.

When the structure fails, the structural element is eroded and no longer takes part in the computation. To let the fluid freely flow across the (failed) wall, it is then sufficient to change the status of the corresponding FV face from solid wall (i.e. no neighbor FV) to internal fluid face. That is, the two FV on either part of the structure suddenly become neighbors.

This technique has been applied with success in some realistic simulations. It does extend the range of application of basic algorithms to the case of structural failure but, if the structure undergoes too large motions (in particular rotation) before failing, it suffers from the same limitations (fluid mesh entanglement) as the basic algorithms.

The condition that the same type of fluid be present in both sub-domains is necessary to let the two fluids mix up after structure failure, assuming that a single-material model is used in the formulation, i.e. a volume (or element) can only contain one type of material. This is often the case in real applications, think e.g. of explosions in buildings where the explosive gas products can often be modeled by the same constitutive equation as the gas (air) which fills and surrounds the building. When this is not the case, e.g. in under-water explosions, one can resort to using a multi-material model (but usually with an associated loss of precision).

3.4 Weak boundary condition algorithm for NCFV

A weak boundary condition algorithm has been implemented for the NCFV fluid model; see [5-7]. It consists of the following evaluation of numerical fluxes. Assume that a NCFV i , currently at pressure p_i , is adjacent to a “solid wall” (either fixed or moving at velocity \mathbf{v}_s) along a facet (portion of the FV boundary) of area F and of unit normal \mathbf{n} . Note that in such a case the node i representing the FV is located on the wall, see Fig. 1. Then the mass flux across the facet is set to zero, the momentum flux is given by $p_i F \mathbf{n}$ and the energy flux is given by $p_i F (\mathbf{v}_i \cdot \mathbf{n})$, where \mathbf{v}_i is the fluid velocity in volume i .

This technique has been used with success in purely Eulerian calculations, where the (solid) wall is fixed ($\mathbf{v}_s = 0$) by definition and no real FSI takes place (the structure is not even modeled). Note that even in such a case using the above expression for the momentum flux does *not* guarantee, in general, that the normal component of the fluid velocity is exactly zero (i.e. that $\mathbf{v}_i \cdot \mathbf{n} = 0$). This is characteristic of a weak formulation and is in line with the fact that \mathbf{v}_i represents the (average) velocity over the entire volume i , not the value at point i (i.e. at the wall).

3.5 Comparison of strong and weak FSI formulations

As shown in the previous Sections, the strong FSI approach is the most natural with a FE discretization of the fluid, because velocities are discretized at fluid nodes and they represent the local value. Exact enforcement of strong constraints by Lagrange multipliers guarantees high precision and consistency of numerical results. In the coupling process, the two sub-domains are treated at the same level (there is no “master” and no “slave”) and the constraints ensure that both the internal forces and the masses of each sub-domain are taken into account in the (coupled) equilibrium equation.

The weak FSI approach is the most natural with a CCFV discretization of the fluid. In this case velocities are discretized at volume centers (and represent the average value for the entire volume), so that imposing strong constraints would be less appropriate than in the FE case. The coupling is qualified as weak because the fluid transmits a pressure force to the structure, but the feedback (structure action on the fluid) only occurs via the motion of the structure, which drives the numerical flux in the fluid at the F-S interface. In a certain sense, the structure acts as a “master”, and the fluid as a “slave”. Furthermore, the fluid mass is typically not taken into account in computing the structure motion (at least not in the non-conforming case). The effect can be negligible with low-density fluids (gases), but not so much with liquids.

The case of NCFV fluid discretization lies somewhat in between. Fluid velocities are discretized at nodes, like in FE, but represent the average value for the entire volume, like in CCFV. Both strong and weak FSI formulations can appear as natural in this case (and have been implemented), each one with its advantages and drawbacks.

4 EMBEDDED FSI ALGORITHMS

The basic FSI algorithms presented so far are built on the ALE formulation for the fluid sub-domain, which allows the fluid mesh to *constantly follow* the structure mesh at the F-S interface. Fluid nodes in the interior of the fluid sub-domain are typically moved (arbitrarily) by a suitable automatic mesh rezoning algorithm, whose primary goal is to prevent the fluid mesh from entangling. The technique is quite elegant and, as long as it can be applied, it provides highly accurate results with a comparably low computational effort (CPU time). However, it suffers from two limitations:

- If the structure motion, especially *rotation*, is too large, then the mesh rezoning algorithm is unable to keep the fluid mesh reasonably regular, and the calculation must stop.
- If the structure *fails* and is either simply eroded or replaced by a set of flying debris (e.g. a cloud of particles), then it is difficult to “sew” the two fluid sub-domains which were previously separated by the structure in order to let the fluid flow through.

The second limitation stems from the fact that in the basic algorithms the fluid nodes at the interface are kept distinct from structure nodes (because fluid velocities are discretized at nodes), and thus the two fluid sub-domains on either part of the structure are not merged together. A notable exception is the weak algorithm for CCFV, see Section 3.3, for which this second limitation does not hold. However, note that the first limitation applies also in the case of Section 3.3, and this considerably reduces the range of applicability of that algorithm.

To overcome these limitations (at the expense of lower accuracy, however), a basically different approach to FSI is taken, see Fig. 8: the structure sub-domain and the fluid sub-domain are discretized in a completely independent manner, and then the structure mesh is *embedded* (or immersed) within the fluid mesh, i.e. the two meshes are simply superposed. With this technique, it is no longer necessary to use an unstructured (conforming or non-conforming) fluid mesh. The fluid mesh can be structured, and even regular, see Fig. 8b. Furthermore, it is

no longer necessary to use an ALE formulation in the fluid sub-domain. This sub-domain can be simply Eulerian (fixed mesh), so that the (background) fluid mesh will never entangle.

In order to prescribe suitable FSI conditions (either in a strong or in a weak manner) between the two sub-domains, it is necessary to find the nodes (or points) of the fluid mesh to be coupled with the structure, i.e. which are sufficiently “close” to the structure. Note that this search is not trivial and must be repeated during the transient calculation as the structure moves and deforms. This must be done with an efficient fast search algorithm, otherwise the computational cost of the search becomes preponderant in realistic applications. For example, a bucket sort algorithm is used in the current implementation.

The *coupled fluid nodes* are defined as all fluid nodes located within the *influence domain* of the structure, the shaded area in Fig. 9a. This influence domain is built up at each time step in the following manner: first, a sphere (circle in 2D) is generated, centered on each node of the structure. The radius of these spheres can either be prescribed by the user, or be computed automatically based on the local size of the fluid mesh. Spheres should be big enough so that at least some fluid nodes fall within them, but not too big. Then, the spheres are connected by quadrangles in 2D (or by cones, prisms and hexahedra in 3D) in the way shown in Fig. 9a. The union of nodal spheres and of all other mentioned geometric entities is the influence domain, used to find the coupled fluid nodes (marked by circles in Fig. 9a). Note that, on one hand, too thin a domain (too small sphere radius) produces some fluid leakage (spurious fluid passage) across the structure. But, on the other hand, too thick a domain (too big sphere radius) ties too much fluid to the motion of the structure (too large “added mass”). Therefore, a good compromise must be found for the sphere radii.

4.1 Embedded FSI algorithm of the strong type

The strong form of the embedded FSI algorithm, called the *FLSR algorithm*, is suitable for use either with FE [10-11] or with NCFV [9]. In both cases the fluid velocities are discretized at nodes. Let F be a coupled fluid node, see Fig. 9b. Then, the closest point of the structure S^* (not a node, in general) is found and then a suitable constraint is imposed on particle velocities. Two alternatives have been tested. The first one is similar to eq. (4) and reads in this case:

$$\mathbf{v}_F \cdot \mathbf{n}_S = \mathbf{v}_{S^*} \cdot \mathbf{n}_S = (N_1 \mathbf{v}_{S_1} + N_2 \mathbf{v}_{S_2}) \cdot \mathbf{n}_S. \quad (9)$$

Note that in the present case the normal to the fluid domain \mathbf{n}_F cannot be defined, so we use the normal to the structure \mathbf{n}_S instead (assuming that it can be computed). This form of the constraint aims at leaving the fluid free to slide along the structure, like in the basic algorithms. However, numerical examples have shown that sometimes this may produce fluid leakage, i.e. spurious (non-physical) passage of fluid across the structure.

The second alternative form of the constraint reads simply:

$$\mathbf{v}_F = \mathbf{v}_{S^*} = N_1 \mathbf{v}_{S_1} + N_2 \mathbf{v}_{S_2}, \quad (10)$$

i.e. the fluid is tied to the structure in all directions (both along the normal and along the tangent). This condition is “stronger” than (9) and may lead to some non-physical loading of the structure along the tangent direction, but it has the advantage that it avoids fluid leakage.

4.2 Application to NCFV

The FLSR algorithm of Section 4.1 works very well with FE fluids [10-11], but when used as such with NCFV it tends to produce spurious fluid leakage, and this irrespective of the width of the chosen structure influence domain (radius of the spheres).

This behavior is due to the way in which transport terms, in particular the transport of density (mass) and of energy, are computed in the different fluid formulations. In FE, transport terms in the governing Euler equations (for conservation of mass and energy) depend (are proportional to) the relative velocity $\mathbf{u} = \mathbf{w} - \mathbf{v}$ between the grid (mesh) and the fluid particles at the fluid nodes (i.e. at the interface between two neighboring elements). Consider for a moment a rigidly blocked structure wall embedded in an Eulerian fluid domain. The grid velocity \mathbf{w} is zero because of the Eulerian description, and the structure velocity \mathbf{v}_s is also zero because the structure is blocked. The FLSR algorithm enforces condition (10) strongly, so that \mathbf{v}_f is zero as well. The result is that the relative velocity \mathbf{u} vanishes at the fluid node, thus no mass and energy are transported across the node (and across the blocked structure).

In NCFV (and more generally in FV) technology, transport terms are represented by so-called *numerical fluxes*. The calculation of such fluxes is more complex in FV than in FE formulations, since it depends on the space order of the chosen algorithm (first or second order) and on the chosen Riemann solver (e.g. Roe's solver or others). The result is that a vanishing relative velocity at a node (i.e. in the corresponding NCFV) does *not* ensure zero local mass and energy fluxes. This is due, *in primis*, to the fact that fluxes are computed not at nodes, but at inter-volume faces, using an interpolated value \mathbf{u}_{ij} of the velocity. Thus, if two volumes i and j are neighbors and \mathbf{u}_i is zero but \mathbf{u}_j is not, then $\mathbf{u}_{ij} \neq 0$ and some mass and energy are exchanged between the two volumes. It would then seem that blocking *two* (or more) consecutive fluid nodes rather than just one (i.e. using a larger sphere radius in the FLSR algorithm) should avoid fluid leakage, because in this case the relative velocity \mathbf{u}_{ij} is strictly zero. However, numerical tests show that unfortunately this is *not* the case (at least when Roe's solver is used): spurious fluid leakage is reduced but not eliminated.

The solution to the above problem consists in explicitly setting to zero the mass and energy numerical fluxes at locations “close” to the structure. Two alternatives have been tested. The first one consists in blocking fluxes between two NC volumes when *both* volumes (i.e. both fluid nodes F_1, F_2) are coupled with the structure, see Fig. 10a. The second one consists in blocking fluxes between two NC volumes when *at least one* of them is coupled with the structure, see Fig. 10b. The second condition is “stronger” than the first one (it blocks more fluxes).

4.3 Embedded FSI algorithm of the weak type

The weak form of the embedded FSI algorithm, called the *FLSW algorithm*, is best suited for use with CCFV. The structure influence domain is built up exactly like for the strong algorithm (FLSR). However, instead of searching for fluid nodes, it is convenient to search directly for the element-to-element interfaces—indicated simply as *faces* in following for brevity—located within the influence domain (*coupled faces*), see Fig. 11a. Recall in fact that in the CCFV case the fluid velocities are discretized at the volume centers, not at the nodes. The numerical fluxes, already introduced above for the NCFV case, are evaluated in this case at face centers, marked by small squares in Figs. 11 and 12.

According to the weak approach, the forces generated by fluid pressure have to be computed and transmitted to the structure. With reference to Fig. 11b, for each coupled face f located between two volumes V_1, V_2 currently at pressures p_1, p_2 , the pressure drop force $\mathbf{f}_{\Delta p}$ is evaluated according to:

$$\mathbf{f}_{\Delta p} = (p_1 - p_2)L\mathbf{n}_f, \quad (11)$$

where L is the length (area, in 3D) of the face and \mathbf{n}_f is the unit normal to the face. Then, as shown in Fig. 12a, the point S^* of the structure closest to the face center is computed. The force (11) is supposed to act at this point S^* and is distributed on the structure nodes A , B according to an expression (in 2D) similar to (8), where $L_S = L_A + L_B$:

$$\mathbf{f}_{\Delta p,A} = (L_B/L_S)\mathbf{f}_{\Delta p} \quad ; \quad \mathbf{f}_{\Delta p,B} = (L_A/L_S)\mathbf{f}_{\Delta p}. \quad (12)$$

Then, exactly as in the NCFV case discussed in Section 4.2, in order to avoid spurious fluid leakage across the structure it is necessary to inhibit the mass and energy numerical fluxes at each coupled face, as illustrated in Fig. 12b (thick shaded line).

Note that expression (11) is the weak equivalent of (10), i.e. the fluid and the structure are coupled in all directions. Alternatively, one may project the pressure drop force along the normal to the structure \mathbf{n}_s (assuming that this can be computed), obtaining the weak equivalent of (9). However, like in the strong case, such an expression risks to produce fluid leakage.

5 NUMERICAL EXAMPLES

Three numerical examples are presented. The first one is an academic problem comparing all the FSI algorithms presented in a relatively simple case: an internal explosion in a 2D rectangular box, with relatively small structural deformations and without structural failure. The second and third examples are realistic applications: blast effects on a railway station with a glass roof (which completely fails), and on a metallic container placed in a long tunnel.

5.1 Explosion in a metallic box

An elasto-plastic deformable box in 2D (plane strain) geometry, see Fig. 13a, contains a 0.4 m long deformable internal wall. The box measures 2 m width by 1 m height, and is filled by air at atmospheric pressure (1 bar). The left compartment contains an explosive bubble of 0.4 m by 0.4 m, represented by air at a higher initial pressure (10 bar). Externally to the box acts a constant atmospheric pressure (1 bar). The structure is uniformly meshed by 64 thin shell elements each 0.1 m long and with a thickness of 0.01 m. The fluid mesh within the box is a uniform grid of 3,200 (i.e. 80×40) four-node quadrilaterals of size 0.025 m, i.e. $1/4$ of the shell element length, so that non-conforming (hierarchical) FSI is used.

This test problem is taken from [9], where FE, NCFV and CCFV solutions were presented, obtained with the basic (non-conforming) strong and weak FSI algorithms, respectively. Here three solutions are added and compared, obtained with FE, NCFV and CCFV using the strong and weak embedded FSI algorithms, respectively. In the embedded case the fluid mesh extends all around the box for an additional 0.2 m. The total number of fluid elements is therefore 5,376 (96×56). A layer of absorbing elements is placed along the external boundary of the fluid mesh in order to simulate an infinite atmosphere and to prevent spurious pressure wave reflections.

All FV solutions shown are second-order in space and time. Calculations are performed up to 5 ms. This is sufficient to see propagation of the pressure waves to the top and to the right part of the box and several reflections. The structural displacements computed at points P9S, P10S and P12S of Fig. 13a are compared in Figs 13b, 13c and 13d, showing very good agreement of all six solutions.

Then, Figs. 14, 15, 16 and 17 compare the fluid velocity field (not shown in the explosive bubble region) and the fluid pressure field, at an intermediate time and at the final time. The agreement is very good for the first three solutions, which use the basic non-conforming FSI

algorithms. The other three solutions, which use the (new) embedded FSI algorithms, show a larger variability, but this has to be expected, given the lower accuracy of such algorithms (for the same fluid mesh). The shown embedded techniques are just a first implementation and can certainly be ameliorated, but already now one can say that results are consistent with the basic algorithms (see the comparison of box displacements in Fig. 13), so that the embedded algorithms can be used to predict structural behavior in applications with failing structures.

5.2 Blast effects in a railway station

Blast effects in railway stations, metro stations and rolling stock have been recently studied at JRC within the RailProtect project; see e.g. [12-14]. In Fig. 18a an historical railway station with a glass roof supported by metallic trusses is shown. A big explosion at the center of the main hall is simulated. Most roof glass panels completely fail and are replaced by clouds of flying debris particles in the simulation.

The numerical model uses about 4.5 million elements, of which more than 90% are fluid FE. The simulation up to 250 ms takes about 2 weeks on a PC (single-processor code version). The FLSR algorithm is used for FSI because of structure failure and fragmentation and of very large rotations of the (macroscopic) flying debris. Figs. 18b and 18e show the model before blast, while Figs 18c and 18f show blast effects at 100 ms. Fig. 18d shows the map of death risk [12-13] for the occupants of the station, automatically computed from blast overpressure and impulse time histories in the fluid sub-domain.

5.3 Blast effects on an ISO container

Standard 20 ft ISO containers are sometimes used as first shelters in peacekeeping, rescue and reconstruction operations. The resistance of such containers to blast loading is studied at the Norwegian University of Science and Technology (NTNU) in Trondheim, Norway [15-16]. Blast tests were carried out in the Large Blast Simulator (LBS) at the Bundeswehr Technical Center for Protective and Special Technologies (WTD 52) in Oberjettenberg, Germany.

Fig. 19a shows one of the experiments in the LBS. The container is placed at one end of a 100 m long tunnel. A blast wave is generated at the other end, propagates along the tunnel and hits the container. Large motions and plastic deformation occur in the container, but failure is much localized and no fragmentation occurs. Fig. 19b shows the FE model of the container (~50 thousand FE), and Fig 19c shows the container within the tunnel. The air in the tunnel is meshed by about 0.6 million fluid FE or FV.

Simulation of the container alone by applying the pressure recorded in the test (no fluid in the model) reproduces well the experiment, see Fig. 19d. However, in order to make predictive simulations the fluid must be modeled as well. Figs. 19e and 19f show two such simulations, for different load cases. The first one uses a FE model of the fluid, and the FLSR algorithm. The second one uses a CCFV model of the fluid—more accurate and less diffusive than FE in modeling the very long propagation of the blast wave in the tunnel—and the FLSW algorithm. These (purely demonstrative) simulations take from 3 to 9 weeks on a PC (single-processor code version) up to 280 or 700 ms of physical time, respectively.

6 CONCLUSIONS AND PERSPECTIVES

The strong and weak approaches to fluid-structure interaction in fast transient dynamics have been shortly reviewed. Examples of basic (either conforming or non-conforming) and of embedded FSI algorithms have been presented and their application with FE, NCFV or CCFV fluid discretization has been discussed.

The embedded FSI algorithms are the latest ones developed and have not yet reached full maturity and validation, at least not at the same level as the basic algorithms. However, numerical results are encouraging and, in any case, these are the only algorithms applicable in extreme loading cases with complete structure failure and fragmentation, typical of blast effect studies.

These algorithms are more general than the basic ones but, as a counterpart, they are less accurate for the same size of the fluid cells (elements or volumes). Therefore, along with improvement of the embedded algorithms by thorough numerical testing, future work will concentrate on implementing mesh adaptivity in the fluid sub-domain, i.e. automatic mesh refinement in fluid zones near an embedded structure wall.

Abstract. *The development of numerical methods for the simulation of thin structures in interaction with a fluid is an industrial issue. In particular, such simulations should be able to predict a possible failure of the shell and the resulting leakage rate in situations involving impacts. This kind of simulations involves three key components: a thin structural model that includes highly nonlinear behaviors leading to failure, a fluid model able to handle sloshing and spatters phenomena, and finally, fluid-structure interactions whose topology can change drastically during calculations. This paper presents a solution based on a meshless method called Smoothed Particles Hydrodynamics (SPH) which is used to model both the fluid and the shell. The fluid-structure interaction is handled via a unilateral contact algorithm adapted to the SPH context. The capabilities of the method are illustrated on several problems involving fracturing shells and by simulating an experiment involving fluid leakage of a tank impacted by a bullet.*

1 INTRODUCTION

The purpose of meshless methods is to discretize a domain with a set of nodes rather than elements for which the connectivity is fixed. The neighbourhood of each node can vary during the calculation which simplifies the treatment of large deformations, cracks and fractures. Meshless methods can be distinguished depending on the approximation functions they use as well as the formulation they rely on (strong or weak form). A detailed overview of meshless methods is presented in [1]. Methods based on the weak form of the equilibrium equations are generally more accurate and stable but the need to perform numerical integrations complicates the treatment of fractures. As a consequence, methods based on the strong form of the equilibrium equations are sometimes preferred to perform simulations involving impacts and fragmentations.

A full SPH fluid-shell interaction model is described in this paper. The SPH method relies on the strong form of the equilibrium equations and was one of the first proposed meshless method [2]. It is traditionally used in fluid dynamics, especially for the simulation of free surface flows. The method has recently been extended to structural dynamics and more specifically to shells theory [3]. This paper is the extension of [3] to the modeling of damage, fracture and failure.

The fundamentals of the SPH method and the corresponding fluid model are presented in the first section of the paper. Then, we explain the application of the SPH method to the Mindlin-Reissner's thick shells theory and its extension to fracture modeling in the second section. The Pinballs method [4] which is used to handle fluid-structure interactions is described in the third section. Finally, the simulation of a water filled tank impacted by a projectile is presented.

2 SPH METHOD AND SPH FLUID MODEL

2.1 SPH method

The SPH method discretizes the domain of interest Ω with a set of N nodes whose neighbourhood can vary in time. Each node represents a material amount m_i chosen so that the total mass of the structure is described correctly $m = \sum m_i$. Nodes interact one with each other through the use of functions for the approximation of a physical field or the approximation of its gradient. These functions have a compact support which means they are non-zero within a domain Ω_{V_i} (i.e. Ω_{V_i} is the neighbourhood of node i) and null elsewhere. The size of the neighbourhood Ω_{V_i} is a fundamental parameter of the method and is often denoted $2h$ in the SPH method. The B3 spline function is often used in the SPH method:

$$w_i(\vec{x}_j) = w_{ij} = C \begin{cases} \frac{3}{2} \left[\frac{2}{3} - \left(\frac{r_{ij}}{h} \right)^2 + \frac{1}{2} \left(\frac{r_{ij}}{h} \right)^3 \right] & \text{if } 0 \leq \frac{r_{ij}}{h} \leq 1 \\ \frac{1}{4} \left[2 - \frac{r_{ij}}{h} \right]^3 & \text{if } 1 < \frac{r_{ij}}{h} < 2 \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where $r_{ij} = \|\vec{x}_i - \vec{x}_j\|$ and $C = 10/7\pi h^2$ in dimension 2. It is a normalization factor that is chosen to ensure the partition of unity property. The approximation of a field $\{f_j\}$, $j = \{1, \dots, N\}$ and its gradient can be written:

$$f(\vec{x}_i) \approx \sum_{j \in \Omega_{V_i}} f_j w_{ij} V_j \quad (2)$$

$$\vec{\nabla} f(\vec{x}_i) \approx \sum_{j \in \Omega_{V_i}} f_j \vec{\nabla} w_{ij} V_j \quad (3)$$

where V_j is the material volume represented by node j .

Figure 1: Definition of the neighbourhood Ω_{V_i} through the B3 spline.

2.2 SPH fluid model

The fluid is assumed to be perfect, weakly compressible and acoustic. The governing equations, once discretized in the updated Lagrangian framework, can be written:

- equilibrium equation:

$$\left(\frac{\partial \vec{v}}{\partial t} \right)_i = - \sum_{j \in \Omega_{V_i}} m_j \left(\frac{p_i}{\rho_i^2} + \frac{p_j}{\rho_j^2} \right) \vec{\nabla} w_{ij} \quad (4)$$

where p is the pressure, ρ density and \vec{v} the velocity vector. We can notice that equation (4) is symmetric so it respects Newton's third law of motion.

- continuity equation:

$$\left(\frac{\partial \rho}{\partial t} \right)_i = \rho_i \sum_{j \in \Omega_{V_i}} \frac{m_j}{\rho_j} (\vec{v}_i - \vec{v}_j) \cdot \vec{\nabla} w_{ij} \quad (5)$$

This equation was chosen because it cancels the density variations when the fluid flow is uniform.

- equation of state:

$$\Delta p_i = c^2 \Delta \rho_i \quad (6)$$

where c is the speed of sound in the fluid.

Artificial linear and quadratic viscosity terms are used to stabilize calculations in presence of shocks.

3 FRACTURING SPH SHELL MODEL

This section presents the application of the SPH method to structural dynamics and more specifically to Mindlin-Reissner's thick shells theory. The model described in [3] is extended in this article for the modeling of shells damage and fracture.

3.1 SPH shell formulation (SPHS)

The SPH method presents three major drawbacks when it is applied to structural dynamics. They are well known and widely discussed in the literature where solutions are found:

- the method has bad consistency properties, especially near the boundary of the SPH domain where nodes have incomplete neighbourhoods. This drawback prevents the method from having good mesh convergence properties. The solution proposed in [5] consists in using Moving Least Square (MLS) approximation functions. These functions are constructed from a polynomial basis of degree n and, as a consequence, exhibit a n order consistency. The approximation in \vec{x} , built around \vec{x}^* , of a data field $\{u_i\}$, $i = \{1, \dots, N\}$, is:

$$u(\vec{x}, \vec{x}^*) = \vec{p}^T(\vec{x}) \vec{a}(\vec{x}^*) \quad (7)$$

\vec{p} is the polynomial basis and \vec{a} is a vector of coefficients obtained by minimizing the following weighted L_2 norm:

$$J = \sum_{j=1}^N [\vec{p}^T(\vec{x}_j) \vec{a}(\vec{x}^*) - u_j]^2 w_j(\vec{x}^*) \quad (8)$$

The weighting function is often the standard SPH B3 spline.

- the SPH method applied to structural mechanics suffers from numerical instabilities. In [6], authors have shown that the Eulerian form of the SPH kernel w_{ij} exhibits a numerical instability in presence of tension stresses. The solution given in [7] consists in using a total Lagrangian formulation for which the kernel is stable.
- finally, most of the meshless methods suffers from the presence of zero energy modes due to the use of the collocation technique (strong form) or the nodal integration technique (weak form). This problem is extensively studied in [7]. Authors show that the use of a total Lagrangian formulation can reduce significantly the development of such zero energy modes. However, it is not sufficient in the case of a shell model because the field of the normals to the mean surface is very sensitive to instabilities that can occur in the curvature of the shell. [7] shows that the problem comes from the fact the kinematic variables and the strains and stresses are carried by the same nodes. The solution from [7] consists in introducing a second set of points denominated Stress Points (SP). These points are similar to Gauss points in the finite elements method (FEM) since they are only used to compute strains and stresses.

The SPH shell formulation is defined according to Mindlin-Reissner's thick shells theory. It relies on the assumption that the thickness e of the structure is small compared to its other dimensions, so the position vector \vec{x} of any point located at a distance ξ from the mean plane can be expressed as:

$$\vec{x}(t) = \vec{x}_m(t) + \xi \vec{n}(t) \quad \xi \in \left[-\frac{e}{2}; +\frac{e}{2}\right] \quad (9)$$

\vec{x}_m is the position of a point in the mean surface of the shell and \vec{n} is the pseudo-normal vector that represents the orientation of the material. Mindlin-Reissner's shells theory takes

into account the influence of transverse shear on the model so that the pseudo-normal vector \vec{n} does not remain normal to the mean plane. The displacement vector in the global coordinate system $R(x, y, z)$ is given as a function of the initial coordinates in the local coordinate system $R_{L0}(x_{L0}, y_{L0}, z_{L0})$ whose direction z_{L0} is normal to the shell:

$$\vec{u}(\vec{x}_{L0}, t) = \vec{u}_m(x_{L0}, y_{L0}, t) + z_{L0} [\vec{n}(x_{L0}, y_{L0}, t) - \vec{n}_0(x_{L0}, y_{L0})] \quad (10)$$

where $\vec{x}_{L0} = \mathbf{G}_{L0} \vec{x}_0$ and \vec{n}_0 is the initial pseudo-normal.

Green-Lagrange strain tensor in R_{L0} is given by:

$$(\mathbf{E})_{R_{L0}} = \frac{1}{2} \left[\frac{\partial \vec{u}_{L0}}{\partial \vec{x}_{L0}} + \frac{\partial \vec{u}_{L0}}{\partial \vec{x}_{L0}}^T + \frac{\partial \vec{u}_{L0}}{\partial \vec{x}_{L0}}^T \frac{\partial \vec{u}_{L0}}{\partial \vec{x}_{L0}} \right] = (\mathbf{E}^m)_{R_{L0}} + z_{L0} (\mathbf{E}^f)_{R_{L0}} \quad (11)$$

Tensor \mathbf{E}^m contains membrane and transverse shear terms which are constant through thickness and \mathbf{E}^f contains bending terms which vary linearly through thickness. Non-linear terms are taken into account.

Plane stresses assumption requires the application of the constitutive law in the mean plane of the shell in its current configuration. As a consequence, a local coordinate system $R_L(x_L, y_L, z_L)$ whose direction z_L is normal to the mean plane at the current point, is defined. Euler-Almansi strains corresponding to membrane and bending effects $(\vec{\varepsilon}_{mf})_{R_L}$ and transverse shear $(\vec{\varepsilon}_c)_{R_L}$ are computed in R_L . Corresponding Cauchy stresses vectors $(\vec{\sigma}_{mf})_{R_L}$ and $(\vec{\sigma}_c)_{R_L}$ are calculated through the use of a plane stresses constitutive law. Membrane and transverse shear resultants N_{ij} and T_i as well as bending moments m_{ij} are then obtained by integration of Cauchy stresses through thickness:

$$\begin{aligned} N_{ij} &= \int_{-e/2}^{e/2} \sigma_{ij}^m d\xi = e \sigma_{ij}^m \\ T_i &= \int_{-e/2}^{e/2} \sigma_{iz}^c d\xi = e \sigma_{iz}^c \\ m_{ij} &= \int_{-e/2}^{e/2} \xi \sigma_{ij}^f(\xi) d\xi = \frac{e^3}{12} \sigma_{ij}^f \end{aligned} \quad (12)$$

Because of the total Lagrangian formulation, the equilibrium equations are finally written in the global coordinate system R by means of Piola-Kirchoff 1 stresses.

3.2 Damage and fracture

Phenomena at the microscopic scale (microvoids and microcracks growth) leading to the failure of the shell are homogenized at the macroscopic scale through the use of continuum damage mechanics. A macroscopic crack appears in a reference volume element (RVE) once its damage variable reaches a critical damage value. The crack propagates at the structure scale when additional RVEs reach the critical damage value. Macroscopic cracks are treated as strong discontinuities in the SPH shell model.

3.2.1 Damage

For metals, damage comes from shear phenomena that favour the apparition of plasticity and from volumetric deformation that favours microvoids and microcracks growth. Damage

criterion beyond which damage occurs is classical for this class of material and can be written [8]:

$$\left[\frac{2}{3}(1 + \nu) + 3(1 - 2\nu) \left(\frac{\sigma_H}{\sigma_{eq}} \right)^2 \right] p - \epsilon_p^s \leq 0 \quad (13)$$

σ_H is the hydrostatic stress, σ_{eq} the equivalent Von-Mises stress, σ_H/σ_{eq} the triaxiality factor, ϵ_p^s an equivalent critical plastic strain, p the accumulated plastic strain and ν the Poisson's ratio. The damage evolution law is then given by [8]:

$$\dot{D} = \frac{D_c}{\epsilon_p^c - \epsilon_p^s} \left[\frac{2}{3}(1 + \nu) + 3(1 - 2\nu) \left(\frac{\sigma_H}{\sigma_{eq}} \right)^2 \right] \dot{p} \quad (14)$$

ϵ_p^c is an equivalent critical plastic strain beyond which the material fails and D_c is the corresponding critical damage which is representative of the fraction of defaults (voids and cracks) in the RVE at failure. The damage evolution law must be coupled with a plasticity model (Von-Mises or Johnson-Cook plasticity for instance).

Numerical simulations performed with a material whose stress-strain curve presents a negative slope (softening or damaging material) are not satisfying since strains and damage are artificially localized in a single element when the failure is imminent. As a consequence, the energy dissipated in the fracture process and the failure time tend to zero as the mesh size decreases to zero. It means that microvoids and microcracks growth rate would be infinite, which is not physically acceptable. This problem is widely discussed in the literature [9] and is known as the numerical localization problem. Authors of [10] show that the problem comes from the transformation of the initial hyperbolic equations of the problems into elliptic equations when material softening occurs. As a consequence, the velocity of the waves in the material becomes complex which means they are trapped in the first element where softening occurs. Solutions proposed in the literature consists in preserving the initial hyperbolic form of the equation by introducing a characteristic length or time in model. This characteristic length or time is representative of the interaction of one element of the mesh with its neighbours. A characteristic time τ_c can be introduced in the model through the use of the following standard delayed damage model [11]:

$$\begin{aligned} &\text{if } D \leq D_c \\ &\quad \dot{D}_r = \frac{1}{\tau_c} [1 - e^{-a\langle D - D_r \rangle}] \\ &\text{otherwise} \\ &\quad \dot{D}_r = 0 \end{aligned} \quad (15)$$

D is the damage given by the damage evolution law, D_r is the regularized or delayed damage and $\langle . \rangle$ is the positive part operator. a is a second material parameter.

3.2.2 Damage-fracture transition

In the model presented in this paper, a crack is defined as the continuous set of fractured REV, see figure 2. This method is attractive since it does not require the explicit representation of the cracks, which simplifies the treatment of crack branching process for example.

Fully damaged REV are handled by introducing strong discontinuities into the model. As a consequence, interactions between SPH points (nodes or SP) through the cracked zone have to be deleted. Thus, the cracked zone is considered to be opaque such that points that are on

Figure 2: Modeling of a crack with SPHS model.

Remark: the method is illustrated with a regular quadrilateral mesh but it is applicable to any mesh constructed through a Vorono diagram.

the opposite side of the crack are excluded in the approximation of the displacement field. The shape of the support of the weighting functions is then represented in figure 2. This method is known as the visibility method [12]. In figure 2, it is obvious that some SPH points can come to the point where they do not have anymore neighbours. In this situation, if the point is a SP, it is chosen to eliminate it from the calculation by setting $D = D_c$. If the point is a node, it is kept in the calculation without interacting with the other points: its motion depends only on the kinetic energy he had at the time step he became a fragment and eventually on the contacts with other parts of the model. As a consequence, we keep two major advantages of meshless methods:

- fractures are simulated without mass and energy loss,
- fragments (i.e. SPH nodes without neighbourhood) can eventually interact with other parts of the model.

Finally, it is necessary to recompute MLS shape functions when fracture occurs since the neighbourhood of the nodes changes. The order of the polynomial basis used to compute MLS shape functions might be lowered when the number of neighbours decreases.

3.3 Numerical examples

3.3.1 Perforation of a plate

This test case is based on a work presented in [13] concerning the experimental and numerical analysis of the failure process of a mild steel sheet subjected to normal impact by hemispherical projectiles. A plug ejection was observed during experiments followed by a petalling process. The number of petals appearing during this process depends essentially on the velocity impact.

Figures 3(a) and 3(b) show the final state of the plate simulated with the SPHS method and compared with the calculations performed in [13] for an impact velocity $V_{imp} = 300 m.s^{-1}$. The model used in [13] is a FEM model with erosion of the element whose accumulated plastic strain exceeds a critical value. Failure time as a function of the impact velocity is plotted in

figure 3(c) for SPHS model and calculations from [13]. The agreement between the various results is good.

Figure 3: Perforation of a plate by an hemispherical projectile.

3.3.2 Fragmentation of explosively driven cylinders

This test case is based on an experimental work presented in [14] concerning the fragmentation of cylinders filled with a high explosive called LX-17. The cylinder is modeled with the SPHS method. The high explosive is modeled with FEM by using Jones-Wilkins-Lee equation of state which is characteristic of explosive materials. Figure 4(a) compares the fragments distribution obtained with the SPHS method with experimental data. Figure 4(b) represents the simulated fragments on the undeformed configuration of the cylinder.

Figure 4: Fragmentation of explosively driven cylinders.

4 FLUID-STRUCTURE INTERACTIONS

Simulations of the failure of thin structures filled with fluid are complex problems for which the fluid-structure interface can change drastically during the transient. The Pinballs method [4] has already demonstrated its capability to handle this kind of problems in the FEM framework.

The method has been extended for the modeling of full SPH fluid-shell interactions in [15]. The main ingredients of the method are recalled in this section.

Each SPH node is filled with a so-called Pinball of spherical shape for fluid nodes and cylindrical shape for shell nodes. The detection of the contact then reduces to a simple geometrical interpenetration check between the Pinballs of the distinct contacting bodies. Once the contact is detected, contact forces are computed by enforcing impenetrability between the two impacting bodies. Contact forces should ensure that for a non viscous fluid:

$$(\vec{v}_1 - \vec{v}_2) \cdot \vec{n} = 0 \quad (16)$$

where \vec{v}_1, \vec{v}_2 are the Pinballs velocities and \vec{n} is a suitable normal direction to the contact surface. Much of the effectiveness and performance of the Pinballs algorithm depends on the choice made for the expression of \vec{n} . The method is primarily intended for impacts problems where sliding and friction are not crucial: the oscillations of the normal \vec{n} to the interface (in the case of large radius Pinballs for example) can cause troubles in the case of two plane bodies sliding. In the particular case of the interaction between a SPH fluid and an SPH shell, the normal \vec{n} is chosen to be the normal of the shell pinballs. The problem is solved through the use of Lagrange multipliers rather than penalty method which requires the introduction of a user-tuned parameter. This method is attractive since the contact detection requires simple geometrical checks. Moreover, the procedure is symmetric since both solids play the same role and no distinction is needed between a master and a slave.

5 APPLICATION: FAILURE PREDICTION OF A TANK UNDER IMPACT

The full SPH model presented in this paper is used to simulate the impact of a bullet onto a steel cylinder, according to the experimental conditions described in [16]. First, the cylinder is empty and the impact produces a simple perforation of the shell as can be seen in figure 5(a). The same was observed in the case of a cylinder filled with water for low velocity impacts. For high velocity impacts, for example $V_{imp} = 730 m.s^{-1}$ in figure 5(c), the impact leads to a longitudinal crack and a fluid leakage.

Both the fluid and the cylinder are modeled with the SPH method described previously. The projectile is assumed to behave like a rigid body. In the case of an empty cylinder, the simulation predicts a simple perforation of the shell, see figure 5(b), which is in agreement with the experimental results. In the case of a water filled cylinder, the simulation predicts a longitudinal crack similar to the one observed in the experiment, see figure 5(d).

6 CONCLUSION

A full SPH method for the simulation of fluid-shell interactions until failure was presented in this paper. The fluid model is very classical in the SPH framework. The method has been extended to the simulation of fracturing shells by using the continuum damage mechanics and introducing strong discontinuities in the model once cracks appeared. The method is attractive since it does not require the explicit representation of the cracks, which simplifies the treatment of crack branching and fragmentation for example. Finally, the method is easily extended to fluid-structure interactions simulations through the Pinballs method. The model was developed in the fast dynamic software EUROPLEXUS.

Abstract. *The aim of this work is to propose a comparison between our new GC+ external code coupler extended to non-linear cases with the new capability Abaqus/co-simulation which is able to couple Abaqus/Explicit with a Finite Element code Abaqus/Standard (Implicit scheme). The external code coupler available in Abaqus version 6.9 called Abaqus/co-simulation is based on the sub-domain decomposition method named GC method. This method has been proposed by Gravouil and Combescure for Newmark time schemes in linear dynamics and, then, extended to non linear dynamics. First, the GC sub-domain decomposition method and the GC+ method issued from a reformulation of the GC method are presented. Then, the use-case called “Airbus plane panel” which will be used to compare our non-linear GC+ code coupler with the co-simulation method of Abaqus 6.9 is described. Finally, obtained results in non-linear cases are presented and discussed. This work is funded by the European project MAAXIMUS.*

1 INTRODUCTION

The main difficulties of the non-linear transient structural computations lie in the computation costs and the memory requirements for storing the data.

The objective of this paper is to propose a method extended to non-linear cases, which permits reduction of time costs as well as memory necessary to solve the problem. All the paper is based on the use of Newmark time integration schemes with different parameters.

A relevant way in order to considerably reduce computational costs is to use sub-domain decomposition methods. In order to accurately represent impacts phenomena, preserve the stability of the time integration scheme and optimize the finite element structural analysis, it is very efficient to decompose the complete structure into several sub-domains associated with appropriate time step and appropriate mesh element size depending on sub-domains.

Several families of decomposition methods can be identified depending on the way of enforcing the continuity of quantities across the interface. The GC method imposing the continuity of velocities at the interface has been proposed by Gravouil and Combescure for Newmark time schemes in linear dynamics [1] and, then, extended to non linear dynamics [2], explicit non linear dynamics [3], coupling of modal sub-domains [4] and space-time automatic refinement techniques [5]. It has been proved that the GC method can produce some numerical dissipation at the interface between sub-domains. Prakash and Hjelmstad [6] have proposed a more complex algorithm for linear transient dynamics (PH method) without dissipation at the interface and which also enforces velocity continuity at the interface. The velocity constraint is applied on the macro time step, contrary to the GC method applying the velocity constraint on the micro time step. Then, Mahjoubi, Gravouil and Combescure [8] proposed a general method in the case of linear transient dynamics, labelled as MGC method, which ensures that the interface energy remains equal to zero for any time integrator. This method is able to couple Simo, Krenk, Verlet, HHT and Newmark time schemes with different time steps. The MGC method imposes on the macro time step the continuity of the velocities at the interface in a weak sense. The GC method has been recently improved by Batti et al. [12] labeled as GC+ method which is energy conserving as PH and MGC methods. In addition, the formulation of the new algorithm appears much simpler than PH and MGC methods.

In the first section of this article, the algorithm of the GC & GC+ sub-domain decomposition methods will be presented in the case of homogeneous time scale and then, in the case of heterogeneous time scales. Then, we will explain how the GC+ method can be extended to non-linear cases. Furthermore, we will present how to set up an external code coupler based on the modified GC+ method. Finally, an industrial example subjected to crash loads will permit us to compare our coupler with Abaqus/co-simulation (an external code coupler developed in Abaqus v6.9 which is using the GC sub-domain decomposition method).

2 THE GC & GC+ METHODS AND THE GC & GC+ COUPLERS IN LINEAR CASES

First, in the case of an identical time step used for each sub-domain of the global structure, the GC and GC+ sub-domain decomposition methods are the same. The difference between these two methods appears in the case of multi time scale.

2.1 A sub-domain decomposition method with mono time step scale (GC=GC+)

The following explanations aim at highlighting the key points of the method. The main idea of the method is to decompose the solution into two parts (free solution and link solution).

Decomposition into a free part and a link part of the complete solution:

The Finite Element Method used for the numerical simulation of a global structure gives the semi-discrete equilibrium equation in space:

$$M a + F_{\text{int}}(u) = F_{\text{ext}} \quad (1)$$

where M is the symmetric, definite, positive mass matrix, F_{ext} the external forces and $F_{\text{int}}(u)$ the internal forces, a the acceleration. The whole structure is decomposed into several sub-domains, denoted by the superscript $k = 1, \dots, s$. In each separated sub-domain k , the equilibrium equation can be rewritten as:

$$M^k a^k + F_{\text{int}}^k = F_{\text{ext}}^k + F_{\text{link}}^k \quad \forall \{1, \dots, s\} \quad (2)$$

with F_{link}^k representing the interface loads applied on the sub-domain k under consideration (interface loads), which can be linked to the kinematic constraints on interfaces of the k sub-domain. The kinematic constraint connecting all sub-domains together is written in a global form, for the whole domain:

$$\sum_{k=1}^s L^k v^k = 0 \quad (3)$$

where L^k is the constraint matrix for a given k sub-domain. The link force is then obtained by introducing Lagrange multipliers Λ for the whole domain:

$$F_{\text{link}}^k = L^{kT} \Lambda \quad (4)$$

2.2 Sub-domain decomposition methods with multi time step scale (GC \neq GC+)

The GC and GC+ sub-domain decomposition methods become different in the case of multi time step scale. The free problem, the condensed problem at the interface and the link problem are not solved in the same order for the two GC & GC+ methods in the case of sub-domains with different time steps. The difference between these methods is schematically presented in Figure 1 in the case of two sub-domains (a sub-domain A with a large time step and a sub-domain B with a small time step).

These sub-domain decomposition methods are used to build up respective external code couplers. A sub-domain is modeled by a separated FE code whereas the mechanical behavior of another sub-domain of the structure is simulated by another FE code. An external code coupler is used to communicate with the separated FE codes simulating each one a sub-domain of the structure. A coupled FE code solves the free and the link problems of a sub-domain whereas the external code coupler manages the computation of the problem of condensation at the interface. Data exchanges between the external code coupler and the coupled FE codes are ensured by pipes.

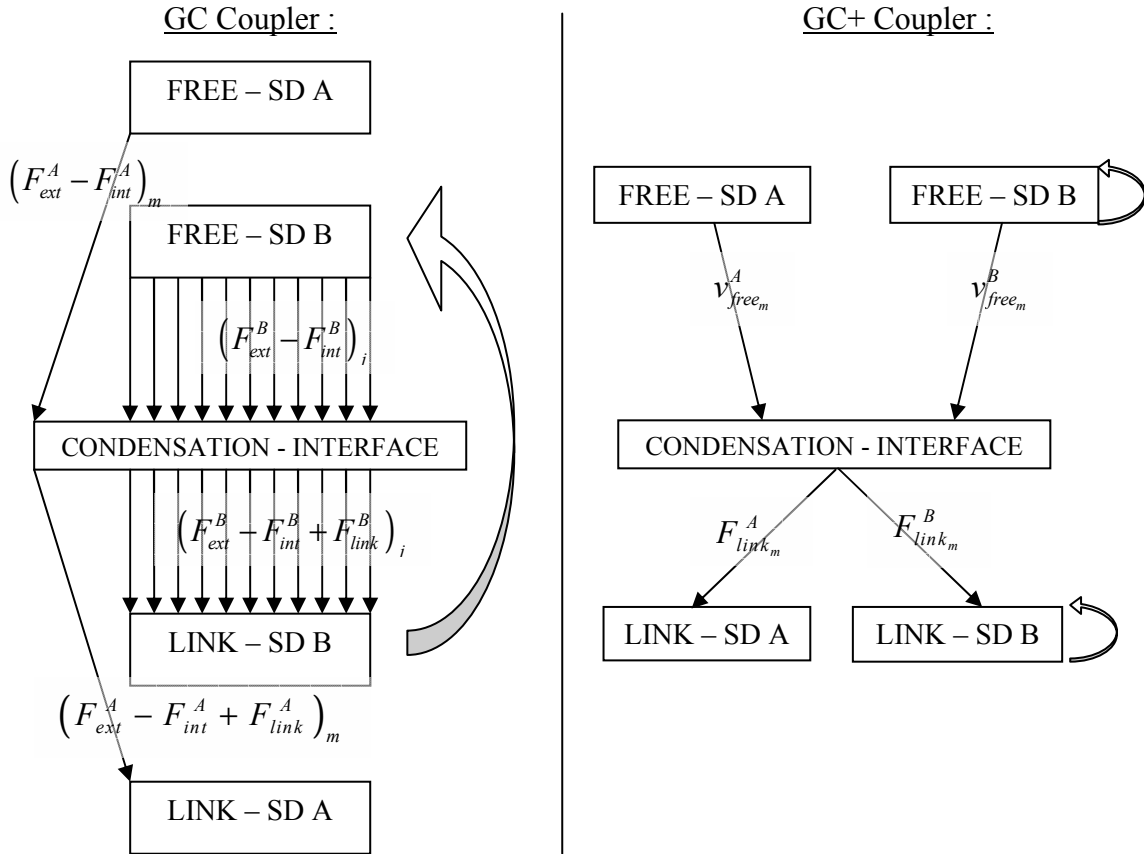

Figure 1: The GC & GC+ couplers.

3 THE GC & GC+ METHODS AND THE GC & GC+ COUPLERS IN NON-LINEAR CASES

First, the GC sub-domain decomposition method presented above already works in the case of non-linearity. So, it is not needed to modify the GC sub-domain decomposition method in non-linear cases.

In this section, we will present the modifications imposed to the previously presented GC+ method in order to be able to extend it to the case of material non-linearities. The case of a coupling of a macro-time step non-linear implicit sub-domain A with a micro-time step non-linear explicit sub-domain B is studied here.

First, a modification of the part of the algorithm corresponding to the non-linear micro explicit sub-domain B is necessary in non-linear cases. This improvement is schematically presented in Figure 2.

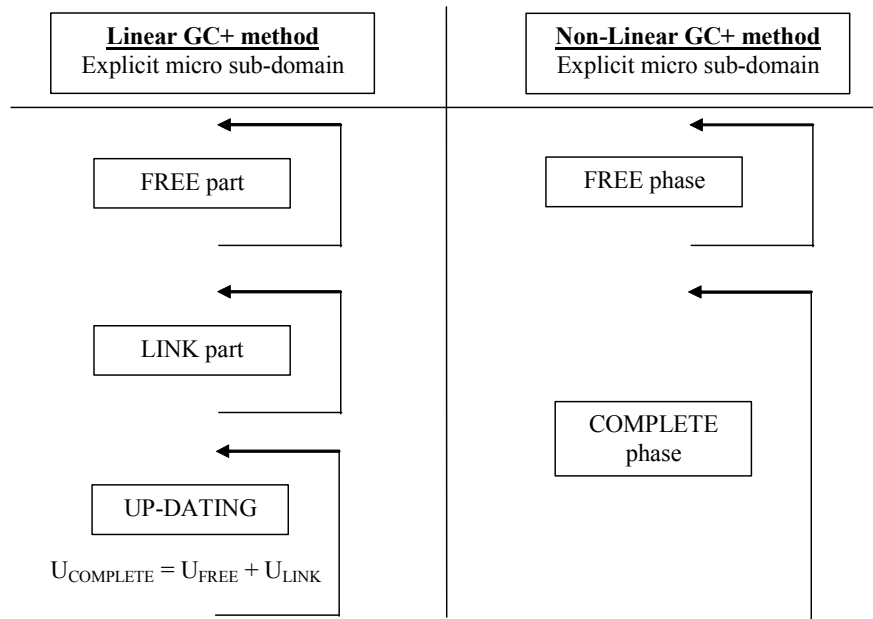

Figure 2: New strategy with GC+ method for coupling a non-linear micro explicit sub-domain.

A complete phase used in the new method permits to avoid the addition of the free and the link parts which is valid only for linear cases and not for non-linear cases.

Secondly, the modification of the part of the algorithm corresponding to the non-linear macro implicit sub-domain A is now presented. The difficulty for an implicit scheme in order to compute non-linearities is to implement an iterative scheme such as Newton algorithm in order to ensure the balance at the end of the implicit time step. At the end of a macro implicit time step, the complete solution has to satisfy a stopping criterion and if it is not the case, a new computation of the macro sub-domain A is done. So, data exchanges between the coupled codes and the external code coupler for a non-linear GC+ external code coupling must be adapted with the stopping criterion of the Newton algorithm.

4 COMPARISON BETWEEN THE EXTERNAL CODE COUPLER GC+ EXTENDED IN NON-LINEAR DYNAMICS AND ABAQUS/CO-SIMULATION

A comparison for a transient non-linear dynamics problem is proposed between the new GC+ non-linear external code coupler and the code coupler available in Abaqus v6.9 named “Abaqus/Co-Simulation” which is built by using the GC sub-domain decomposition method. In this section, a non-linear dynamics application is considered. It is the Airbus plane panel used as Maaximus use-case with an open interface with compatible mesh at the interface between the two chosen (non-linear macro implicit & non-linear micro explicit) sub-domains.

Our GC+ coupler extended in non-linear cases couple here the code CASTEM 2009 developed at the Commissariat à l’énergie atomique (CEA).

A simplified Airbus plane panel is a case of interest for engineering application in the aeronautic field. A panel is a part of a plane’s barrel. The panel is composed by a skin, frames and stiffeners. The panel is pinned along the two small sides of the contour. Charge is applied on the very small zone at the centre of the panel. The mechanical behaviour is assumed to be perfectly plastic for each component of the panel. The application example computed with

external code coupling using two (Macro-implicit & micro-explicit) sub-domains is presented in Figure 3.

Figure 3: Definition of the two sub-domains composing the Airbus panel structure.

The displacements at point P (see Figure 3) obtained by our GC+ external code coupler extended in non-linear cases and obtained by a classical mono-domain explicit code are compared in Figure 4.

Figure 4: Comparison between the GC+ code coupler and the explicit mono-domain computation responses in terms of displacements.

As shown in Figure 4, the prediction ensured by computation done by our non-linear GC+ external code coupler compared to a classical solving using a unique micro explicit FE code used as Reference is very good in terms of maximal vertical displacement response.

The results in terms of displacement at point P given by a classical unique solving Abaqus/Explicit and by the new capability Abaqus/co-simulation (Abaqus/Standard coupled with Abaqus/Explicit) for the Airbus plane panel numerical simulation are compared in non-linear case in Figure 5.

Figure 5: Comparison of results in terms of displacement obtained by the coupler called Abaqus/co-simulation and by a classical explicit computation (Non-linear case).

Contrary to the GC+ code coupler, we can observe in Figure 5, that the prediction in terms of displacements given by Abaqus/co-simulation compared to the reference is not good. At the beginning of simulations, the two obtained time-displacement curves are very close but as long as time passes, we can see that the difference between the two curves increases regularly.

5 CONCLUSION

In this article, we have presented the key equations of the GC & GC+ sub-domain decomposition methods in the case of a same time step used for all the sub-domains composing the structure. Moreover, we have described a linear external code coupler using the GC+ sub-domain method in the case of multi time scales. Then, the extensions of the GC+ sub-domain decomposition method and of the GC+ external code coupling to the non-linear cases have been proposed. The non-linear GC+ external code coupler manages to couple a macro non-linear implicit FE code with a micro non-linear explicit FE code. Finally, a comparison of this GC+ code coupler with Abaqus/Co-simulation which is able to couple Abaqus/Explicit with Abaqus/Standard and based on the GC sub-domain decomposition method.

It seems that Abaqus/Co-simulation available in Abaqus 6.9 should be used with care for displacement responses in material nonlinear case. The proposed GC+ code coupler is already able to couple Castem2009 and Europlexus finite element codes and a possible perspective to this work can be to generalize it for other existing commercial finite element codes (Abaqus, Aster ...).

6 ACKNOWLEDGEMENTS

The authors wish to acknowledge the FP7 European program MAAXIMUS (Grant 213371) piloted by Airbus for its financial support.

Abstract. *Present contribution exposes current R&D issues in the framework of parallel computing for fast transient dynamics involving fluid-structure interaction and coupled models. In particular, simulation of accidental explosive situations often requires simultaneous representation of both fluids with multiple components and structures that may undergo large deformation down to complete ruin. Is especially considered the generic treatment of kinematic links by means of Lagrange Multipliers , and the parallel concurrency it implies amoung solving algorithms throughout the simulation. Current research and investigated solutions are illustrated with industrial examples performed with EUROPLEXUS software.*

1 INTRODUCTION

Simulation of fast transient phenomena arising from accidental situations often requires simultaneous modeling of fluids, both liquids and gases, interacting with surrounding structures that may undergo large deformations down to complete ruin. This yields couplings between various kinds of models, such as Finite Elements, Finite Volumes or SPH particles for the fluids, and Finite Elements, SPH particles or Discrete Elements for the structures (cf. figure 1). Examples of such simulations in explosive fluid-structure interaction are given in [1][2].

Figure 1: Examples of explosive FSI simulations.

Kinematic links between various models is thus a fundamental issue and the choice is made in EUROPLEXUS to verify the link equations exactly by means of Lagrange Multipliers, avoiding the use of user defined penalty parameters to simplify the input process and prevent any dependency of the solution on non-physical parameters. From the algorithmic point of view, this introduces a strong specificity for the temporal solver: time integration scheme is classically central differences explicit scheme, but solving a linear system at each step is necessary to compute link forces, leading to a partially implicit solving procedure.

Parallel handle of both building and solving the system giving Lagrange Multipliers for all the kinematic connections available in the program competes with classical parallel algorithms used in fast transient dynamics software and is addressed by current paper.

2 GENERAL ALGORITHM

2.1 Dynamic equilibrium for fluid-structure interaction with explicit time integration

Conservation of momentum at time t^{n+1} of the time integration process, all quantities assumed to be known at times t^n (displacements, for structure only) and $t^{n+1/2}$ (velocities), takes general form:

$$\begin{aligned}
 \mathbf{M}^{n+1} \ddot{\mathbf{U}}^{n+1} + \mathbf{F}_i(\mathbf{U}^n, \dot{\mathbf{U}}^{n+1/2}) + \mathbf{C}^{n+1T} \boldsymbol{\Lambda}^{n+1} &= \mathbf{F}_{ext}^{n+1} \\
 \mathbf{C}^{n+1} \dot{\mathbf{U}}^{n+3/2} &= \mathbf{B}^{n+1} \\
 \dot{\mathbf{U}}^{n+3/2} &= \dot{\mathbf{U}}^{n+1/2} + \Delta t \cdot \ddot{\mathbf{U}}^{n+1}
 \end{aligned} \tag{1}$$

Forces \mathbf{F}_i represent internal forces for the structure or transport forces for the fluid. The system is completed for the fluid by conservation of mass and energy equations, written in EUROPLEXUS using a Finite Volume formalism, i.e. computing fluxes of quantities through faces of the fluid mesh cells. \mathbf{M}^{n+1} is a diagonal matrix.

Matrix \mathbf{C}^{n+1} is the kinematic connections matrix, linking velocities of both fluid and structural nodes, whose construction is presented in next paragraph. Its dimension, profile and coefficients are all variable with time.

Before computing nodal accelerations allowing advancing to next time-step in the simulation, Lagrange Multipliers are obtained by a condensation procedure, yielding a system of the form:

$$\mathbf{C}^{n+1} \mathbf{M}^{n+1} \mathbf{C}^{n+1T} \mathbf{\Lambda}^{n+1} = \mathbf{H}^{n+1} \mathbf{\Lambda}^{n+1} = \mathbf{S}^{n+1} \quad (2)$$

2.2 Writing fluid-structure interaction links

Two types of fluid-structure links are considered in classical transient explosive simulations [1][3]. First is conform node-to-node links, when the structure coincides with fluid domain's envelop. Second is diffuse links for immersed structures, for which enforcing a conform mesh between fluid and structure generates large extra work for data sets creation and lack of robustness for ALE rezoning of the fluid grid. Figure 2 illustrates both types of links.

Figure 2: Fluid-structure interaction links.

Interaction with conform meshes produces permanent links, whose coefficients are variable along with direction normal to the structure. Diffuse interaction with topologically uncoupled meshes generates links whose support and coefficients are variable with time.

Second type of link is mandatory to deal with problems where structural fragmentation occurs, to simulate fluid flow through created openings, as shown on figure 1-b or on figure 3.

Figure 3: Simulation of an explosion in a metro carriage.

3 PARALLEL SOLUTION WITH DISTRIBUTED MEMORY

3.1 Principle and problematic of *remote* links

Parallel solution in EUROPLEXUS relies on domain decomposition, splitting elements upon available processing units with minimum interface size between subdomains. Formally, system (1) becomes, for example in the case of 3 subdomains:

$$\begin{aligned}
 (a) \quad & \begin{bmatrix} \mathbf{M}_1 & & \\ & \mathbf{M}_2 & \\ & & \mathbf{M}_3 \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{U}}_1 \\ \ddot{\mathbf{U}}_2 \\ \ddot{\mathbf{U}}_3 \end{bmatrix} + \begin{bmatrix} \mathbf{F}_{i1} \\ \mathbf{F}_{i2} \\ \mathbf{F}_{i3} \end{bmatrix} + \mathbf{C}^T \begin{bmatrix} \boldsymbol{\Lambda}_1 \\ \boldsymbol{\Lambda}_2 \\ \boldsymbol{\Lambda}_3 \end{bmatrix} = \begin{bmatrix} \mathbf{F}_{ext1} \\ \mathbf{F}_{ext2} \\ \mathbf{F}_{ext3} \end{bmatrix} \\
 (b) \quad & \mathbf{C} \begin{bmatrix} \ddot{\mathbf{U}}_1 \\ \ddot{\mathbf{U}}_2 \\ \ddot{\mathbf{U}}_3 \end{bmatrix} = \mathbf{B}
 \end{aligned} \tag{3}$$

Parallel acceleration is first achieved by distribution of the work for both internal forces vector computation and fluid-structure links building.

However, connections matrix \mathbf{C} must be considered at global level for the multi-domain system, since links may couple nodes belonging to different subdomains, for example with large displacements of structural fragments through fluid domain. Such links are called *remote* links, to emphasize the fact that they concerns non-local quantities on subdomains.

The problematic associated to these *remote* links is the global treatment they require.

In the rare situation where no link couples degrees of freedom belonging to different subdomains (i. e. no *remote* links in the model), system (3) can be uncoupled and parallelism is straightforward. On the contrary, if couplings exist, a solution procedure implying all subdomains must be provided to compute Lagrange Multipliers.

Existing approach consists in identifying in condensation operator \mathbf{H} blocks that can be solved inside one subdomain, i. e. corresponding to groups of fully local links with only local nodes involved. Figure 4 illustrates the process in the elementary case of 2 subdomains. On each subdomain, dofs are partitioned between those concerned by any *remote* link (or a link coupled to a *remote* link, the two having to be treated simultaneously) and the others.

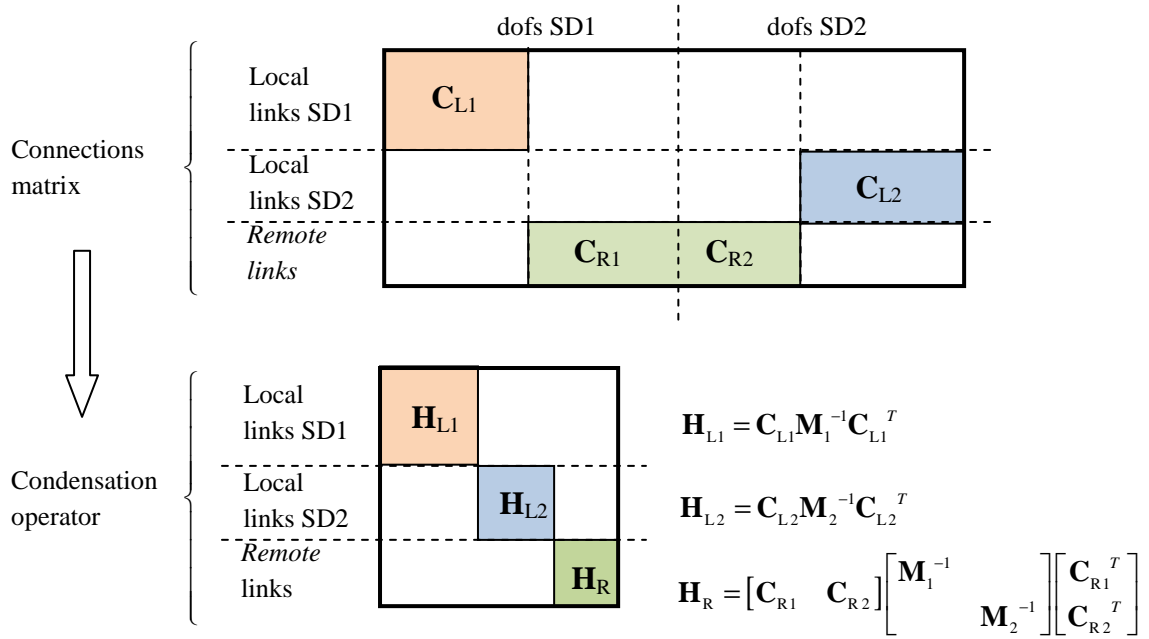

Figure 3: Identification of diagonal blocks in condensation operator.

Global block H_R is then solved on a single processor, resulting in a loss of parallelism all the more important that kinematic couplings between subdomains are numerous. This can severely harm scalability, again for example when large displacements of structural fragments occur, these fragments interacting with initially distant fluid elements.

Let us also notice that building global block H_R requires centralizing all concerned *remote* links data on the processor dedicated to the solution. These communications done, a distributed linear solver is useless to compute Multipliers, since time necessary for data redistribution prior to solution easily compensate parallel acceleration provided by the solver.

3.2 Algorithmic solutions

Keeping the same distributed memory parallel structure for the program, two alternative parallel algorithms can be proposed to deal with the problematic exposed above. They are being developed and tested in the framework of French ANR REPDYN project [4]. In both cases, the point is to increase parallelism for the solution of the problem involving *remote* links.

3.2.1 Correct use of a distributed linear solver

As noticed earlier, this option is worthless if data have to be centralized on one unique processor to build to system to be solved. Instead, to achieve efficiency, a distributed linear solver must start from a matrix whose terms (either its lines or its terms individually) are already equally split upon available resources.

One way to provide such a distribution is to share among all processors data concerning *remote* links (and links coupled to them), yielding block H_R to be solved at global level. This represents a reduced extra-cost in communications, compared to existing transfer from all processors to one unique destination.

Each processor is then able to compute terms of H_R . Its building becomes a parallel task and matrix distribution is controlled in order to benefit from a parallel solver, such as

MUMPS [5][6] for example.

3.2.2 Iterative solution with no operator building

Even if building global block becomes parallel and produces a distributed matrix, linear solver are known to suffer from limited scalability, especially in the present situation where the matrix size is small, the number of linked nodes being far lower than the total number of nodes.

An alternative strategy is to avoid building the operator within an iterative solution of the link problem, using Conjugate Gradient for example. Starting from system (3) with value of Lagrange Multipliers at iteration k , corresponding accelerations are obtained from (3-a):

$$\begin{bmatrix} \ddot{\mathbf{U}}_1^k \\ \ddot{\mathbf{U}}_2^k \\ \ddot{\mathbf{U}}_3^k \end{bmatrix} = \begin{bmatrix} \mathbf{M}_1 & & \\ & \mathbf{M}_2 & \\ & & \mathbf{M}_3 \end{bmatrix}^{-1} \left(\begin{bmatrix} \mathbf{F}_{ext1} \\ \mathbf{F}_{ext2} \\ \mathbf{F}_{ext3} \end{bmatrix} - \begin{bmatrix} \mathbf{F}_{i1} \\ \mathbf{F}_{i2} \\ \mathbf{F}_{i3} \end{bmatrix} - \mathbf{C}^T \begin{bmatrix} \boldsymbol{\Lambda}_1^k \\ \boldsymbol{\Lambda}_1^k \\ \boldsymbol{\Lambda}_1^k \end{bmatrix} \right) \quad (4)$$

Residual on kinematic links is then computed by:

$$\mathbf{S}^k = \mathbf{C} \begin{bmatrix} \ddot{\mathbf{U}}_1^k \\ \ddot{\mathbf{U}}_2^k \\ \ddot{\mathbf{U}}_3^k \end{bmatrix} - \mathbf{B} \quad (5)$$

These two evaluations are parallel steps using operators local to subdomains. For residual computation, vector is obtained by blocks, each block corresponding to links written on a given subdomain.

Preconditioning the algorithm is necessary to speed-up convergence. One preconditioner of interest consists in solving links written on a subdomain, potentially involving dofs it does not own, as if they were not coupled to any other links on another subdomain, which the global link operator classically handles.

Considering again simplified case (4), this first means isolating in *remote* links block of connections matrix the links written locally:

$$[\mathbf{C}_{R1} \quad \mathbf{C}_{R2}] = \begin{bmatrix} \mathbf{C}_{R1}^1 & \mathbf{C}_{R2}^1 \\ \mathbf{C}_{R1}^2 & \mathbf{C}_{R2}^2 \end{bmatrix} \quad (6)$$

Global condensation operator then writes:

$$\mathbf{H}_R = \begin{bmatrix} \mathbf{C}_{R1}^1 & \mathbf{C}_{R2}^1 \\ \mathbf{C}_{R1}^2 & \mathbf{C}_{R2}^2 \end{bmatrix} \begin{bmatrix} \mathbf{M}_1^{-1} & \\ & \mathbf{M}_2^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{C}_{R1}^{1T} & \mathbf{C}_{R1}^{2T} \\ \mathbf{C}_{R2}^{1T} & \mathbf{C}_{R2}^{2T} \end{bmatrix} = \begin{bmatrix} \mathbf{H}_R^1 & \mathbf{H}_{RC} \\ \mathbf{H}_{RC}^T & \mathbf{H}_R^2 \end{bmatrix} \quad (6)$$

$$\begin{aligned} \text{with } \mathbf{H}_R^1 &= \mathbf{C}_{R1}^1 \mathbf{M}_1^{-1} \mathbf{C}_{R1}^{1T} + \mathbf{C}_{R2}^1 \mathbf{M}_2^{-1} \mathbf{C}_{R2}^{1T} \\ \mathbf{H}_R^2 &= \mathbf{C}_{R1}^2 \mathbf{M}_1^{-1} \mathbf{C}_{R1}^{2T} + \mathbf{C}_{R2}^2 \mathbf{M}_2^{-1} \mathbf{C}_{R2}^{2T} \\ \mathbf{H}_{RC} &= \mathbf{C}_{R1}^1 \mathbf{M}_1^{-1} \mathbf{C}_{R1}^{2T} + \mathbf{C}_{R2}^1 \mathbf{M}_2^{-1} \mathbf{C}_{R2}^{2T} \end{aligned}$$

Blocks \mathbf{H}_R^1 and \mathbf{H}_R^2 can be assembled locally on subdomains 1 and 2 respectively, knowing only locally written links and masses of all involved dofs, potentially belonging to another subdomain, which implies small communications.

Ignoring couplings in the preconditioner then consists in neglecting block \mathbf{H}_{RC} in the solu-

tion procedure. A diagonal per block operator is thus obtained, each block locally solved on a subdomain. Extension to any number of subdomains is straightforward.

4 TOWARDS HYBRID PARALLELISM

In addition to scalability improvement for solving kinematic links with domain decomposition, recent hardware evolution suggests an alternative parallelism: a distributed memory approach with domain decomposition between nodes interconnected by a high-performance network, coupled to a shared memory parallel acceleration using local cores inside a node, with optional additional acceleration obtained from GPU(s).

From a theoretical point of view, this allows to lighten concurrency between domain decomposition and kinematic links enforcement for a given number of processing units, provided an efficient multi-CPU/GPU shared memory parallelism.

Again, research in this area is carried out for EUROPLEXUS software in the framework of REPDYN project, in collaboration with MOAIS team from INRIA/LIG laboratory. Dynamic load balancing is handled through KAAPI library [7][8], implementing graph partitioning methods and work stealing between SMP threads.

A strict goal is to achieve a cooperative hybrid parallelism among all available resources efficient for all EUROPLEXUS functionalities. Originality is thus to propose different simultaneous parallel solutions adapting to multiple algorithms occurring together in a coupled simulation, instead of parallel efficiency demonstrations based on restricted model applications, which are classically hard to extend to industrial level.

A NEW POST-PROCESSING PROCEDURE FOR THE INCREASE IN THE ORDER OF ACCURACY OF THE TRAPEZOIDAL RULE AT TIME INTEGRATION OF LINEAR ELASTODYNAMICS PROBLEMS

A. Idesman

Texas Tech University
Box 41021, Lubbock, TX 79409, USA
e-mail: alexander.idesman@coe.ttu.edu

Keywords: elastodynamics; trapezoidal rule; time integration; error estimator; finite elements

Abstract. *In the current presentation, we suggest a very simple and effective post-processing procedure to increase the order of accuracy in time for numerical results obtained at time integration of linear elastodynamics problems by the trapezoidal rule. This technique is based on a new exact, closed-form, a-priori error estimator for time integration of linear elastodynamics equations by the trapezoidal rule with non-uniform time increments. Based on this error estimator, we suggest a new post-processing procedure (containing additional time integration of elastodynamics equations by the trapezoidal rule with few time increments) that systematically improves the order of accuracy of numerical results, with the increase in the number of additional time increments used for post-processing. For example, the use of just one additional time increment for post-processing after time integration with any number of uniform time increments, renders the order of accuracy of numerical results equal to $10/3 = 3.3333$. Numerical examples of the application of the new techniques to a system with a single degree of freedom and to a multi-degree system confirm the corresponding increase in the order of convergence of numerical results after post-processing. Because the same trapezoidal rule is used for basic computations and post-processing, the new technique retains all of the properties of the trapezoidal rule, requires no writing of a new computer program for its implementation, and can be easily used with any current commercial and research codes for elastodynamics.*

1 INTRODUCTION

The application of finite elements in space to linear elastodynamics problems leads to a system of ordinary differential equations in time

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{R}, \quad (1)$$

where \mathbf{M} , \mathbf{C} , \mathbf{K} are the mass, damping, and stiffness matrices, respectively, \mathbf{U} is the vector of the nodal displacement, \mathbf{R} is the vector of the nodal load. Eq. (1) can be also obtained by the application of other discretization methods in space such as the spectral element method, the boundary element method, the smoothed particle hydrodynamics (SPH) method and others. For long-term time integration of semi-discrete elastodynamics equations (1), higher-order accurate methods in time are more computationally effective compared with second order methods. For example, high accuracy in time can be obtained from the unified set of a single step method [1] by the use of higher-order interpolation polynomials in time. However, these methods are not unconditionally stable for elastodynamics. Recently, new high-order accurate methods with a step-by-step time integration scheme have been developed for elastodynamics (see [2, 3, 4, 5, 6, 7, 8, 9, 10] and many others). Most of them are based on semi-discrete equations (1) with the polynomial time approximations of unknown functions. The polynomial coefficients are derived with the use of different approaches such as time-continuous Galerkin (TCG) and time-discontinuous Galerkin (TDG) methods, weighted residual methods, collocation methods and others. The ultimate goal in the development of high-order accurate implicit methods is to construct an unconditionally stable method with controllable numerical dissipation that is much more computationally effective than known second-order methods. Because many high-order accurate methods require the solution of a large system of equations (much larger than a system of equations for second-order methods), the development of effective iterative predictor/multi-corrector solvers is an important component of a high-order method. For example, the predictor/multi-corrector solver suggested in [10] for modified Nørsett methods requires one additional iteration at each time step in order to improve the order of accuracy by one. Many different iterative solvers were developed for the TDG method with linear time approximations of displacements and velocities that correspond to the third order of accuracy (see [2, 3, 8, 9] and others). By the use of three different time increments for each time step, a very effective formulation of fourth-order time-integration methods is obtained from second-order methods in [11]. However, the authors of [11] could not extend their approach to higher orders of accuracy.

To summarize, the development of a computationally effective high-order accurate time-integration method for elastodynamics is still a challenging problem in computational mechanics.

In this paper, we will use a new post-processing procedure (containing additional time integration of elastodynamics equations by the trapezoidal rule with few time increments) that systematically improves the order of accuracy of numerical results, with the increase in the number of additional time increments used for post-processing (see our paper [12]). We should mention that the trapezoidal rule does not include numerical dissipation. However, as was shown in our papers [13, 14, 15, 16], numerical dissipation is not required for long-term integration with the new solution strategy suggested in [13, 14, 16]. It was also shown in [13, 14, 16] that the trapezoidal rule is the best time-integration method (the fastest and most accurate method) for long-term integration of elastodynamics problems (including wave propagation and impact problems) among all implicit second-order time-integration methods.

2 SUMMARY OF THE NUMERICAL TECHNIQUE

In our paper [12], we have developed a new numerical time-integration technique for the increase in the order of accuracy at the integration by the trapezoidal rule. This technique is based on a new exact, closed-form, a-priori error estimator for time integration of linear elastodynamics equations by the trapezoidal rule with non-uniform time increments. Based on this error estimator, we developed a new post-processing procedure that systematically improves the order of accuracy of numerical results, with the increase in the number of additional time increments used for post-processing. The suggested procedure includes time integration at basic computations by the trapezoidal rule with uniform time increments and time integration at post-processing by the trapezoidal rule with few time increments. The sizes of time increments at post-processing (positive and negative time increments are used) are calculated from the new a-priori error estimator and depend on the size and the total number of time increments used at basic computations. For example, the use of just one, three or five additional time increments for post-processing after time integration with any number of uniform time increments at basic computations, renders the order of accuracy of numerical results equal to $10/3$, $14/3$ and 6 , respectively. The sizes of time increments for post-processing should be calculated as follows: $\Delta t = -\sqrt[3]{m}\Delta\bar{t}$ for one time increment; $\Delta t = \alpha_1\Delta\bar{t}$, $\Delta t = \alpha_1\Delta\bar{t}$ and $\Delta t = \alpha_2\Delta\bar{t}$ for three time increments (α_1 and α_2 should be taken from Table 1); $\Delta t = \alpha_1\Delta\bar{t}$, $\Delta t = \alpha_1\Delta\bar{t}$, $\Delta t = \alpha_2\Delta\bar{t}$, $\Delta t = \alpha_2\Delta\bar{t}$ and $\Delta t = \alpha_3\Delta\bar{t}$ for five time increments (α_1 , α_2 and α_3 should be taken from Table 2) where m and $\Delta\bar{t}$ are the number of uniform time increments and the size of time increments at basic computations by the trapezoidal rule.

Table 1. Coefficients α_1 and α_2 for post-processing with three time increments for different numbers m .

m	2	10	50	100	500	1000	10000	100000	1000000
α_1	-1.48091	-2.68405	-4.65819	-5.8846	-10.092	-12.7221	-27.4292	-59.1037	-127.339
α_2	1.65042	3.0607	5.3386	6.75003	11.5871	14.6095	31.5058	67.8914	146.274

Table 2. Coefficients α_1 , α_2 and α_3 for post-processing with five time increments for different numbers m .

m	2	10	50	100	500	1000	10000	100000	1000000

3 NUMERICAL EXAMPLES

3.1 A single degree of freedom system

First let's consider the increase in the order of accuracy by post-processing for time integration of the following elastodynamics equation for a single degree of freedom system:

$$\ddot{u}(t) + 2\xi\dot{u}(t) + \omega^2 u(t) = f(t), \quad (2)$$

with the natural frequency $\omega = \pi = 3.1416$ and the following initial conditions $u(0) = 1$ and $v(0)/\pi = \dot{u}(0)/\pi = 1$. Zero damping ($\xi = 0$) for the observation time $T = 50$, nonzero damping ($\xi = 0.1, 0.2$) for the observation time $T = 5$, zero ($f(t) = 0$) and non-zero load

Figure 1: The relative error in displacements and velocities e at the observation time $T = 50$ versus the total number of time increments n in the logarithmic scale at integration of a single degree of freedom system (no damping $\xi = 0$ and zero load $f(t) = 0$) without post-processing (curve 1) and the subsequent post-processing with one (curve 2), three (curve 3) and five (curve 4) time increments.

($f(t) = 2 + 2t$), and post-processing with one, three and five time increments as described in Section 2 are considered. Different total numbers n ($n = m$ plus the number of time increments used at post-processing) of time increments are used in calculations (the corresponding time increments in basic computations can be calculated as $\Delta \bar{t} = \frac{T}{n}$ for the case of basic computations without post-processing, $\Delta \bar{t} = \frac{T}{((n-1)-\sqrt[3]{n-1})}$ for the case of basic computations and the subsequent post-processing with one time increment, $\Delta \bar{t} = \frac{T}{(n-3+2\alpha_1+\alpha_2)}$ for the case of basic computations and the subsequent post-processing with three time increments, and $\Delta \bar{t} = \frac{T}{(n-5+2\alpha_1+2\alpha_2+\alpha_3)}$ for the case of basic computations and the subsequent post-processing with five time increments).

Figs. 1 - 2 show the relative numerical error $e = \frac{e_{uv}}{\sqrt{u^2(0) + (\frac{v(0)}{w})^2}}$ (with $e_{uv} = \sqrt{[u(t_n) - u_{num}(t_n)]^2 + [\frac{v(t_n) - v_{num}(t_n)}{w}]^2}$ where $u(t_n)$, $v(t_n)$ and $u_{num}(t_n)$, $v_{num}(t_n)$ are the exact and numerical solutions of Eq. (2) for the displacement and velocity at time t_n) versus the number of time increments in the logarithmic scale. At the fixed observation time T and a large number of time increments, the number of time increments n is inversely proportional to a time increment Δt ($n \approx m \approx \frac{T}{\Delta t}$ or $\text{Log } n \approx \text{Log } T - \text{Log } \Delta t$). Therefore, the slope of the curves in Figs. 1 - 2 (which are plotted in the logarithmic scale) describes the order of convergence (order of accuracy) of numerical results at large numbers n of time increments.

As can be seen from Fig. 1, at a large number of time increments n , the order of convergence (order of accuracy) of numerical results after post-processing with one, three and five time increments is in agreement with the analytical estimations reported in Section 2 (see the slope of curves 2, 3 and 4). For example, it also follows from Fig. 1 that at the error of 1% (or $\text{Log } e = -2$) for the observation time $T = 50$, post-processing with one, three and five time increments reduces the total number of time increments by factors of 2.8, 3.8, 4, respectively (compared with the results with no post-processing, curve 1). Post-processing is even more effective if we are interested in more accurate results (for multi-dimensional problems a general solution is the superposition of the solutions for separate modes and requires more accurate results for individual modes). For example, at the error of 0.01% (or $\text{Log } e = -4$) for the ob-

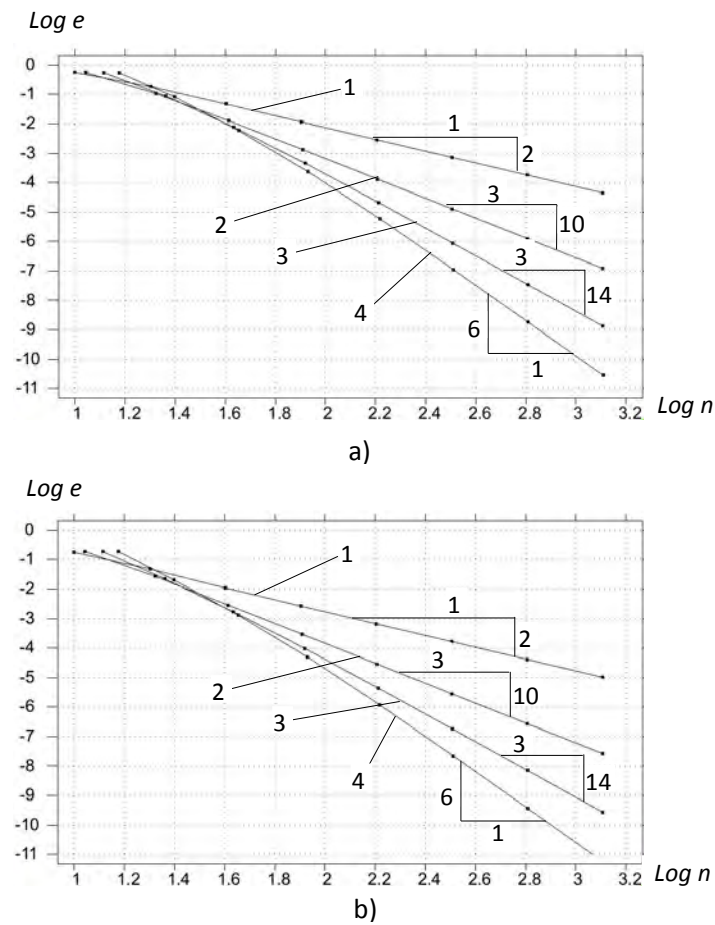

Figure 2: The relative error in displacements and velocities e at the observation time $T = 5$ versus the total number of time increments n in the logarithmic scale at integration of a single degree of freedom system (with zero load $f(t) = 0$ and damping $\xi = 0.1$ (a) and $\xi = 0.2$ (b)) without post-processing (curve 1) and the subsequent post-processing with one (curve 2), three (curve 3) and five (curve 4) time increments.

Figure 3: The numerical error in displacements and velocities \tilde{e}_{uv} at the observation time $T = 5$ versus the total number of time increments n in the logarithmic scale at integration of a single degree of freedom system with damping $\xi = 0.1$ and non-zero loading $f(t) = 2 + 2t$ without post-processing (curve 1) and the subsequent post-processing with one (curve 2), three (curve 3) and five (curve 4) time increments.

servation time $T = 50$, post-processing with one, three and five time increments reduces the total number of time increments by factors of 6, 10, 12, respectively. However, we should also remember that post-processing with one, three and five time increments requires the additional factorization of one, two and three stiffness matrices, respectively. Therefore, the reduction in computation time at the application of the post-processing procedure can be easily calculated if the computation times for the factorization of a stiffness matrix and the back-substitution stage of the solution of a system of linear equations are known for the selected computer code at the given numbers of degrees of freedom.

As can be seen from Figs. 2 and 3, for linear elastic problems with non-zero damping, the order of convergence (order of accuracy) of numerical results after post-processing with one, three and five time increments is in agreement with the analytical estimations described in Section 2. It also follows from Fig. 2 that if after basic computations with the trapezoidal rule the error is smaller than 10% for $\xi = 0.1$ or 5% for $\xi = 0.2$ (for the frequency and observation time used), the suggested post-processing procedure improves the numerical results. For multi-degree problems, numerically solving single degree of freedom problems for the maximum and leading (i.e., those with large amplitudes) modes is recommended in order to roughly estimate the range of time increments at which the suggested post-processing procedure improves the results.

3.2 Harmonic response of an elastic rod

Next we show the application of the post-processing technique described in Section 2 to time integration of the 1-D elastodynamics problem related to harmonic response of an elastic rod. An elastic rod of the length $L = 1$ is considered. Both ends of the rod are fixed, no external loads are applied, the initial velocity is zero, and the initial displacement is proportional to the first harmonic $u_0(x, 0) = \sin(\pi x)$; see Fig. 4a. The observation time is assumed to be $T = 50$, Young's modulus to be $E = 1$, and the density to be $\rho = 1$. A uniform mesh with 100 linear finite elements along the bar is used. The elastodynamics problem was integrated in time by the trapezoidal rule with different numbers m of uniform time increments and the subsequent post-processing with one and three time increments as described in Section 2 (a time increment Δt is calculated similar to that described above for a single degree of freedom system). Numerical results show that a numerical solution can be approximated as $u_n(x, t) = \sin(\pi x)g_1(t)$, where $g_1(t)$ is a function of time only. This means that only frequencies close to π are excited in the numerical solution. For comparison of the accuracy of the numerical results, the following errors in displacements (\tilde{e}_u), velocities (\tilde{e}_v) and the combined error in displacements and velocities (\tilde{e}_{uv}) at time t were calculated: $\tilde{e}_u(t) = \max_{0 \leq x \leq L} [u_a(x, t) - u_n(x, t)] = u_a(L/2, t) - u_n(L/2, t)$, $\tilde{e}_v(t) = \max_{0 \leq x \leq L} \frac{[v_a(x, t) - v_n(x, t)]}{\pi} = \frac{[v_a(L/2, t) - v_n(L/2, t)]}{\pi}$ and $\tilde{e}_{uv}(t) = \frac{\sqrt{\tilde{e}_u^2 + \tilde{e}_v^2}}{u_{max}^0}$, where $u_n(x, t)$ and $v_n(x, t)$ are numerical solutions for displacements and velocities at current time t , and $u_a(x, t) = \sin(\pi x)\cos(\pi t)$, $v_a(x, t) = -\pi \sin(\pi x)\sin(\pi t)$ are the analytical solutions for displacements and velocities at current time t , and the maximum numerical errors in displacements and velocities occur at $x = L/2$, $u_{max}^0 = 1$ is the maximum initial displacement. For this problem, we selected a relatively fine mesh which yields a very small error in space. Therefore, for relatively large time increments, the combined error in displacements and velocities \tilde{e}_{uv} should relate to the global error in time with a scaling factor. Fig. 4b shows the numerical error in displacements and velocities \tilde{e}_{uv} versus the number of time increments n in the logarithmic scale. As can be seen from Fig. 4b, at a large number of time increments, the order of convergence (order of accuracy) of numerical results after post-

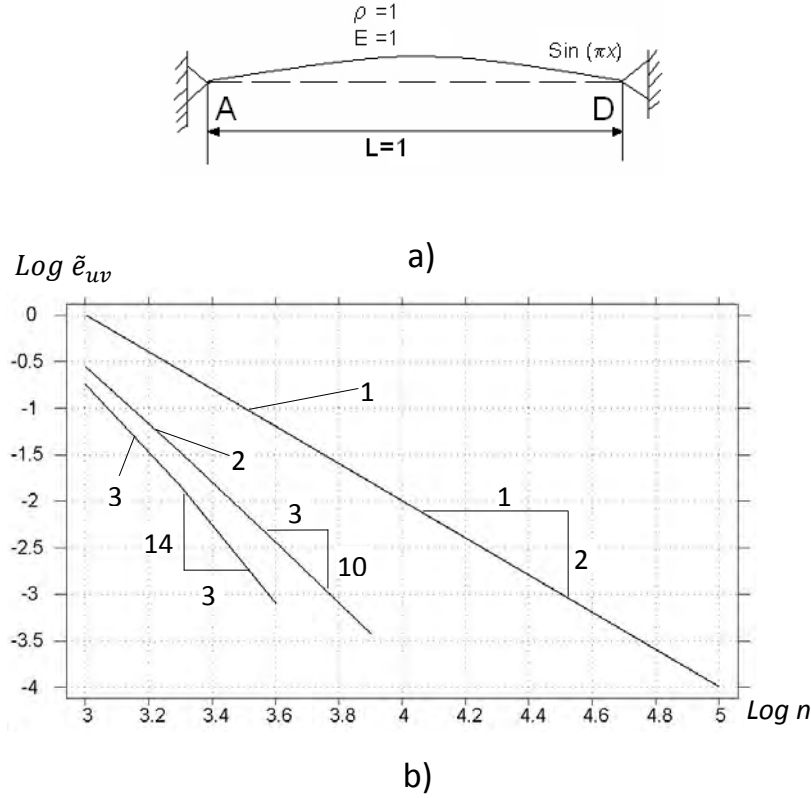

Figure 4: Modeling of harmonic response of an elastic rod (a). The numerical error in displacements and velocities \tilde{e}_{uv} at the observation time $T = 50$ versus the total number of time increments n in the logarithmic scale (b) at time integration by the trapezoidal rule (curve 1) and the subsequent post-processing with one (curve 2) and three (curve 3) time increments.

processing with one (curve 2) and three (curve 3) time increments is in agreement with the analytical estimations reported in Section 2. It also follows from Fig. 4b that at the error of 1% (or $\text{Log } \tilde{e}_{uv} = -2$) for the observation time $T = 50$, post-processing with one and three time increments reduces the total number of time increments n by factors of 3.5 and 4.6, respectively (compared with the results with no post-processing, curve 1). For more accurate results with the error of 0.1% (or $\text{Log } \tilde{e}_{uv} = -3$) at the observation time $T = 50$, post-processing with one and three time increments reduces the total number of time increments n by factors of 5.5 and 8.5, respectively. However, we should also remember that post-processing with one and three time increments requires the additional factorization of one and two stiffness matrices, respectively.

3.3 Impact of an elastic bar against a rigid wall

Here we show the application of the post-processing technique described in Section 2 to time integration of a 1-D impact elastodynamics problem for which all frequencies of the semi-discrete system, Eq. (1), are excited. An elastic rod of the length $L = 4$ is considered. The following boundary conditions are applied: the displacement $u(0, t) = t$ (it corresponds to the velocity $v(0, t) = v_0 = 1$) and $u(4, t) = 0$ (it corresponds to $v(4, t) = 0$). Initial displacements and velocities are zero; i.e., $u(x, 0) = v(x, 0) = 0$. The observation time is assumed to be $T = 2$, Young's modulus to be $E = 1$, and the density to be $\rho = 1$. Zero damping $\mathbf{C} = \mathbf{0}$ and two cases of non-zero Rayleigh damping $\mathbf{C} = b_1 \mathbf{M} + b_2 \mathbf{K}$ with the coefficients $b_1 = 0.005$, $b_2 = 0.01$ and with the coefficients $b_1 = 0.05$, $b_2 = 0.1$ are considered. A uniform mesh with

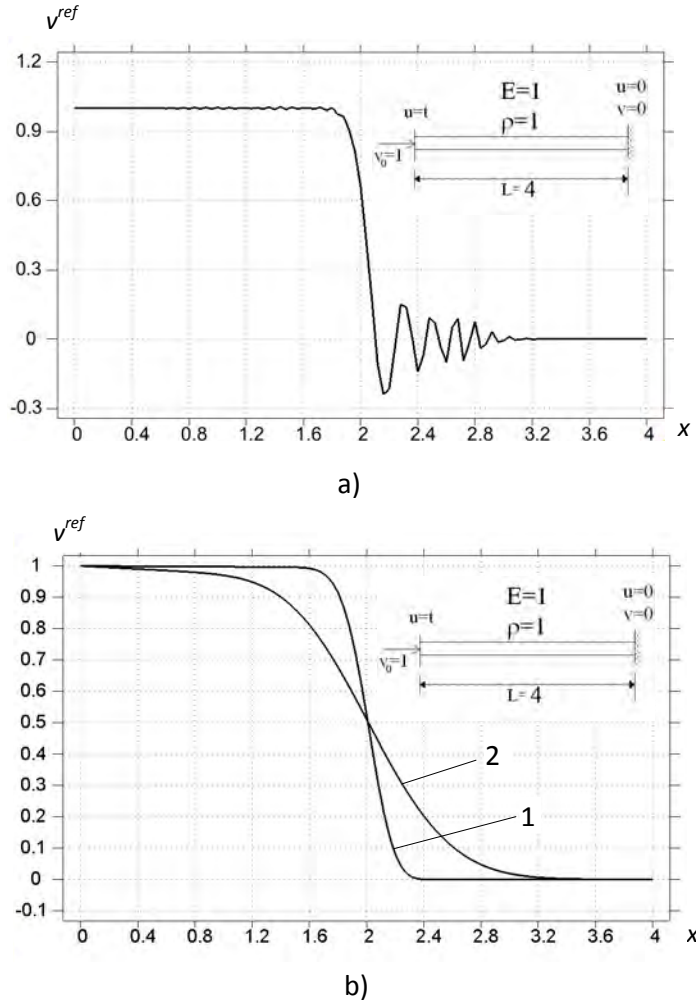

Figure 5: Velocity distribution v^{ref} along the bar at time $T = 2$ for the impact problem with zero (a) and non-zero Rayleigh damping (b). Curves 1 and 2 in b) correspond to the damping coefficients $b_1 = 0.005$, $b_2 = 0.01$ and $b_1 = 0.05$, $b_2 = 0.1$, respectively. The solutions are obtained by the trapezoidal rule with 400000 uniform time increments.

100 linear finite elements along the bar is used. In this paper we will consider the convergence in time of numerical results to a solution of the semidiscrete problem, Eq. (1), which differs from the analytical solution of the continuous impact problem. Because the semidiscrete problem includes 100 degrees of freedom, the simplest way to find the solution of the semidiscrete system is to use accurate time integration of Eq. (1) with very small time increments. This solution, called the reference solution, is obtained by the trapezoidal rule with 400000 time increments and is shown for the velocity v^{ref} in Fig. 5. An accurate numerical solution of the original continuous impact problem with non-zero damping is considered in our papers [14, 16]. To study convergence of the trapezoidal rule after post-processing, the following measure for the velocity error of the semi-discrete system at time $T = 2$ is introduced:

$$e_v(T = 2) = \sqrt{\sum_{i=1}^{100} (v_i^{ref}(T = 2) - v_i^{num}(T = 2))^2}, \quad (3)$$

Figure 6: The numerical error in velocity e_v at the observation time $T = 2$ versus the total number of time increments n for the impact problem in the logarithmic scale at time integration by the trapezoidal rule (curve 1) and the subsequent post-processing with one (curve 2) and three (curve 3) time increments. a), b) and c) correspond to non-zero damping and to Rayleigh damping with the damping coefficients $b_1 = 0.005$, $b_2 = 0.01$ and with the damping coefficients $b_1 = 0.05$, $b_2 = 0.1$, respectively.

where $v_i^{ref}(T = 2)$ and $v_i^{num}(T = 2)$ ($i = 1, 2, \dots, 100$) are the nodal velocities of the reference and numerical solutions at time $T = 2$, respectively.

Fig. 6 shows the numerical error e_v at time $T = 2$ versus the number of time increments in the logarithmic scale. At a large number of time increments, the number of time increments n is inversely proportional to a time increment Δt . Therefore, the slope of the curves at large numbers n of time increments in Fig. 6 (which are plotted in the logarithmic scale) describes the order of convergence (order of accuracy) of numerical results. As can be seen from Fig. 6, the order of convergence (order of accuracy) of numerical results after post-processing with one and three time increments is in agreement with the analytical estimations reported in Section 2 (see the slopes of curves 2 and 3).

4 CONCLUSIONS

In our previous papers, we suggested a new solution strategy for elastodynamics problems and showed that for long-term time integration, a time-integration method at basic computations does not need numerical dissipation even for wave propagation and impact problems. In the current paper, we suggest a very simple and effective post-processing procedure to increase the order of accuracy in time for numerical results obtained by the trapezoidal rule. Because the same trapezoidal rule is used for basic computations and for post-processing, the new technique retains all of the properties of the trapezoidal rule. For example, at zero physical damping $C = 0$, the trapezoidal rule conserves the total energy and the linear and angular momentum of a mechanical system during time integration. We should also mention that the new technique requires no writing of a new computer program for its implementation and can be easily used with any current commercial and research codes for elastodynamics. Of course, post-processing with a time increment, the size of which differs from that used in basic computations, requires the factorization of a tangent matrix and leads to additional computational costs. However, these additional costs are small compared with those for long-term integration by the trapezoidal rule in basic computations.

SPEED ENHANCEMENT OF DYNAMIC BEM ON INEXPENSIVE HARDWARE WITH PARALLEL FORTRAN 2008

A. A. Stamos

Keywords: BEM, dynamic steady-state problems, transient problems, parallel, Fortran 2008.

Abstract. *The Boundary Element Method (BEM) has been extensively used in dynamic problems in structural engineering. The method is computationally intensive and traditionally depends on raw computer processing power to solve larger structures. However, advances on processor speed have stagnated due to physical limits. Instead, processing power is now based on parallel computing. The BEM can benefit from parallel computing, in dynamic problems in the Laplace transform domain, as the computation for each (complex) frequency is independent to each other, and can be executed concurrently by a different core or processor. The volume, in bytes, of the outcome of each frequency computation is small, so that it can be sent through a network with negligible overhead. Thus, the method does not need special hardware and it can be executed equally well by an ordinary, off-the-shelf, multi-core and/or multiprocessor computer, as well as by a typical computer cluster of low bandwidth. The method is implemented using coarrays as described in the upcoming Fortran 2008 standard. The biggest advantage of Fortran 2008 is that remote memory is referred to directly, like an array with the instance identity as index, instead of having to call a subroutine for loading and storing data. A small but sufficient set of easily learned statements and constructs are defined, which make the program much clearer. The method is tested with typical dynamic problems and shows promising results.*

INTRODUCTION

After the invention of the Boundary Element Method (BEM) more than three decades ago, BEM has been used extensively for structural analysis and especially for dynamic problems. BEM is computationally intensive and despite the tremendous advancement of computer systems since its invention, it can still saturate the resources of the typical contemporary computer. BEM software, typically written in FORTRAN, traditionally depends on the raw processing power of single processors, the faster the better. However, advances on processor speed have stagnated due to physical limits. Recent advances on processors now focus on the proliferation of the number of cores per processor. A processing core works almost independently to other cores, and it is inexpensive enough to make parallel computing possible for the individual researcher, and indeed for the casual user. Parallel computing is a form of computation in which many computations are carried out simultaneously operating on the principle that large problems can be divided into smaller independent segments. Each segment is then computed by a different processing core concurrently. Parallel computing may also use different processors on the same physical computer (symmetric multiprocessing), or even processors on different physical computers (distributed computing). Parallel computing is much harder than traditional sequential computing, since the segments are rarely fully independent. Some form of communication and synchronization must happen between the cores, which may lead to race conditions [1]. Various primitives have been developed to aid parallel computing, such as semaphores, condition variables, message passing and RPCs [2], but it is easy to use them inappropriately and produce race conditions, deadlocks and other forms of unpredictable and irreproducible behavior [2]. To make parallel computing easier special libraries and frameworks such as lapack and OPENMP [3] have been developed to hide the underlying use of the parallel primitives. For example [4] used OPENMP to parallelize the integration of the static BEM kernels for each node. The framework, while better than using the raw synchronization primitives, is still awkward to use, it works only with shared memory and it requires to link the appropriate libraries for the specific processor, architecture and Operating System (platform), if they exist. A better solution is to let the compiler handle the primitives and present the user with a few robust high level constructs, conveniently integrated to the syntax of the computer language. This concept, developed in the last century [5], is introduced to the upcoming standard of the FORTRAN language, FORTRAN2008 [6]. FORTRAN2008 introduces a small number parallel statements/constructs which are integrated smoothly with the rest of the language, and accomplish an elegant, platform independent way to develop parallel software for both shared-memory processors and computer clusters (computers linked by not necessarily high-speed network). The present paper exploits FORTRAN2008 to develop a portable, platform independent method for parallelizing dynamic BEM suited for inexpensive networks of existing computers, and inexpensive, run of the mill contemporary multi-core computers, or combination of them. To the knowledge of the author, no previous research on parallelizing BEM with FORTRAN2008 exists, although it is an active field of research in other disciplines [7].

1 PARALLEL COMPUTING

1.1 The emergence of parallel computing

During the last decade the rate of making faster microprocessors has almost halted due to fundamental physical limits such as the speed of light and uncontrolled induction in high fre-

quencies. However the size of the electronic circuits is still becoming smaller and smaller, following the Moore's law [8], which states that the number of transistor in a processor doubles every 18 months. The consequence was to cram many processing units, or cores, in the same die or microprocessor, as substitute to raw processing power. This essentially moved the burden of making faster programs from the processors to the programmers. In theory, the more processing cores the faster a computation will be done. Ideally, if a program needed time t to complete in a single core, and N_{pr} cores were available, then the expected time would be t/N_{pr} . In theory, it would be possible to split the work of the program in separate segments and to run each segment on a different processor at the same time, in parallel. In practice, parallel computing has proved to be very difficult [1]. Computer time t/N_{pr} is very seldom true in practical problems. Some programs simply can not be “parallelized”, either because they do a single computation such as a simple word processor, or the computations they do are strictly sequential, like the time steps in a transient dynamic analysis software, which means that a time step must be completed in order to compute the next one.

If P is the proportion (with respect to time of execution) of the program which can be parallelized, the improved execution time of the program is given by Amdahl's law [9]:

$$t_{MP} = t \cdot \left[(1-P) + \frac{P}{N_{pr}} \right]$$

where $(1-P)$ is the proportion of the program that remains sequential. Again, in practice P is not independent to N_{pr} , as P is in the form of discrete packets, and there is delay due to synchronization and communication which is proportional to the number of cores. Thus, experimental results are necessary to evaluate the utilization of the parallel process. Amdahl's law limits the speed enhancement that a program can achieve through parallel-computing, even with infinite processors. Worse, as the number of processors grows to very high values the speed enhancement dwindles to imperceptibility (Figure 1).

Figure 1. Theoretical and actual relative speed due to $P=0.05$ and synchronization delays.

1.2 Realization of parallel computing

Many attempts with various degrees of success have been used to produce parallel architectures. Usually they depend to Symmetric Multiprocessing, or SMP, which is a multiprocessor computer architecture where two or more identical processors are connected to a single shared main memory. Most common multiprocessor systems today use an SMP architecture. In case of multi-core processors, the SMP architecture applies to the cores, treating them as separate processors. The advantage of this approach is that the various program segments, called threads [2], which run in parallel, can communicate rapidly via the shared memory, and they can synchronize themselves. The disadvantage is that it does not scale well as a processor locks the memory when it updates it. In contrast Non Uniform Memory Architecture (NUMA) multiprocessors and computer networks, or clusters, do not share the same memory and they are linked via a comparatively much slower network. This means that the traffic between the processes must be minimized in order to achieve speed. There are 2 more or less practical ways to achieve parallelizing [1]. One is to instruct each processor core to execute the same operation but to different data (single instruction multiple data – SIMD). Example of this is the WHERE and FORALL constructs in FORTRAN95 [3]. The other is to instruct each processor to execute independent to another, the same or other code (multiple instruction multiple data – MIMD), on the different data. Examples of this are frameworks like OPENMP and PVM [3], and parallel FORTRAN2008 [10]. In order to develop new parallel software, very careful analysis and design must precede the coding and the method [11], and very often compromises must be made.

1.3 Parallel Computing with FORTRAN

FORTRAN95 and FORTRAN2003 has support for Single Instruction Multiple Data (SIMD) [1] through the WHERE and FORALL constructs [3] which are useful for array operations. These are very important as they provide for a platform independent way to implement parallelization with almost no effort, and they are useful in many numerical cases. But they are not suitable for computer clusters and they can not provide for different execution on each processor.

The upcoming FORTRAN2008 [10] standard provides for Multiple Instruction Multiple Data (MIMD) [1], or rather for a special case of it, Single Program Multiple Data, as the instructions are executed from a single FORTRAN program [12]. Many instances (or images) of the same program are run by different processors either in the same computer or in different computers connected to a, not necessarily high-speed, network. Each image is aware of its identity (an integer count) and can follow different execution path according to its identity. In most but the simplest cases, there has to be some means of communications or synchronization among the images, which typically involves calling subroutines of special, often platform dependent, libraries. FORTRAN2008 uses the concept of coarrays [6] which are a solution along these lines, with the difference being much tighter integration with the Fortran language itself, and therefore platform independence. The biggest advantage is that remote memory is referred to directly like an array with the instance identity as index, instead of having to call a subroutine for loading and storing data. These subroutines are still called “under the hood”, but coarrays are designed with legibility in mind. A small but sufficient set of easily learned statements and constructs are defined, which make the program much clearer. A program that runs over several processors is inherently more complicated than a single-threaded program so that clear and well understood statements are extremely important. Apart from the coarray

references, the statement SYNC ALL prevents any image from executing any further statements until all instances reach this statement, thus making sure that all the previous computations have been done by all images. The function NUM_IMAGES() returns the number of parallel instances which run simultaneously, and the function THIS_IMAGE() returns the identity of the current instance, an integer between 1 and NUM_IMAGES(). The construct CRITICAL ... END CRITICAL achieves mutual exclusion of images. It is guaranteed that only one image at a time executes the statements between CRITICAL and END CRITICAL. All images are created at the start of the program and they begin execution at the same time. An image can not be created dynamically at the middle of the program, though it can exit without affecting the remaining images.

Coarrays are part of the upcoming FORTRAN2008 standard. The original proposal of Numrich and Reid [6] was recently scaled back in the draft. A forward implementation of the core features, which were left in the draft, has been introduced in the G95 Fortran compiler [13], available for the x86/Linux, IA64/Linux and x86-64/Linux platforms.

2 STRATEGY OF PARALLEL COMPUTING IN BEM

As stated above, the transient BEM dynamic analysis is inherently a sequential process. The displacements and tractions of the boundary nodes must be known in a previous time step in order to compute the displacements and tractions at the next time step. However, if the governing equations are transformed with the Laplace transform, they do not depend on time, but on the complex frequency s of the Laplace transform [14]:

$$c_{ij}\bar{u}_{ij}(x) = \int \bar{t}_{(n)i}(y)\bar{U}_{ij}(y, x, s) dS - \int \bar{u}_i(y)\bar{T}_{ij}(y, x, s) dS$$

It turns out that for a given complex frequency s , the equations do not depend on any other complex frequency. Thus the computation of each frequency step is completely independent to one another, and can be done in parallel, by different processing cores, or by different processors in different computers.

In theory, any of the loops of the typical dynamic Boundary Element Method program may be made parallel. The typical process of the computations is given in Figure 2. If the inner loops were made parallel, then intermediate results should be sent via the network to an accumulator process, which would probably be more time consuming than the computations. The second outer loop, for each node, could be made parallel, in shared-memory computers but it would probably be time consuming in a network. Furthermore, the solution of the system of equations should also be run in shared-memory computer. This leaves the outer loop which can be parallelized without affecting the bulk of the code of the BEM program. Furthermore, the results of each frequency step (transformed displacements and tractions) are far smaller in gigabytes than the whole matrices. In fact they are so small that they can be transferred through the network with little delay, and thus it is suitable for both shared memory multi-core computers and computer clusters.

A typical transient dynamic BEM program computes 50 frequency steps, which means that up to 50 processors may be used. This exceeds by far the number of cores (typically 4-16) in contemporary processors of inexpensive modern computers. Also, it is enough to keep busy the Local Area Network (LAN) of a standard department in a university or a corporation, when it is used as cluster. The method certainly does not scale well in supercomputers with thousands of processors. However the high cost of supercomputers as well as Amdahl's law

(Figure 1) justify the development of relatively easy parallel method suitable for inexpensive hardware. It must be noted that if the parallelizing is done on multi-core shared memory computer, substantial memory, enough to hold the matrices [A] and [B] of the system of equations for each parallel process, is needed. It is fortunate that huge memory (4GB) is available in modern computers, and that the number of cores is still too small to exhaust it.

Figure 2. Typical algorithm of a dynamic BEM program.

3 IMPLEMENTATION OF PARALLEL COMPUTING IN BEM

In order to maximize the parallelization gain the following rules must hold:

- 1 The volume of data transferred between images, or coarrays references, creates (relatively slow) network traffic and it must be as little as possible.
- 2 The process synchronization delay the images and the synchronization signals between images creates network traffic. The number of synchronization statements must be as little as possible.
- 3 Each process must do as much computational work as possible, unless this breaks the first or second rule. In this case a trade off between the competing rules must be reached through experimentation.

Applying the rules to the case of BEM parallelization, the following steps of the algorithm were concluded:

1. *The first image reads the data.*
2. *Each image except 1 copies the data from image 1.*
3. *Each image pre-processes the data.*
4. *Process 1 keeps a counter of all the frequencies.*
5. *Each image except 1 increments the counter, computes the relevant frequency, and stores the result to co-arrays of image 1.*
6. *Each image except 1 repeats step 5 until all frequencies have been computed and then dies.*
7. *Image 1 does numerical inversion of the Laplace transform.*
8. *Image 1 prints the results.*

There are many points to note in this algorithm:

- 1 In steps 2, 3 and 5 computations are done in parallel.
- 2 In step 2 a lot of distinct variables are transferred which cause noticeable delay in computer clusters but not in shared-memory SMP.
- 3 In step 5 all the results are transferred through an array which cause little delay.
- 4 In step 2 each image performs exactly the same computations. The alternative would let image 1 do the computations (which would gain nothing since the other images would be idle waiting for image 1) and then copy them to the other images, which would be more time consuming.
- 5 Step 5 implies that as soon as an image finishes a frequency step, it gets another one to compute. This means that fast processors in a computer cluster, compute more frequency steps than slow processors. In effect, the requirement to distribute the computing load evenly to the computers according to their relative speed, is automatically satisfied.

4 APPLICATION

The method was tested with a 3D transient dynamic problem; the response of the infinite elastic medium containing a spherical cavity under suddenly applied internal pressure was considered [15]. The problem was solved with a multi-dimensional BEM FORTRAN program [16], which was modified to enable FORTRAN2008 parallel computing. The discretization of the problem led to 1131 degrees of freedom and 1131x1131 full non-symmetric matrices. The Laplace transform was used with 20 complex frequency steps. The following two test runs were performed.

Cores	Time (sec)	Relative speed		Utilization
		Theoretical	Actual	
1	369,0	1,0	1,0	100%
2	223,4	2,0	1,7	83%
3	187,7	3,0	2,0	66%
4	140,0	4,0	2,6	66%

Table 1. Speed enhancement in a 4 core computer.

Figure 3. Speed enhancement in a 4 core computer.

4.1 Symmetric multi-core processing

The program was run in an inexpensive computer with the Intel Core i7 processor which contains 4 cores running at 1.60GHz. The program was run with 1, 2, 3 and 4 cores under the SuSE Linux 11.4 SMP64 Operating System. The results are shown in Table 1. The low utilization is probably due to conflicting access to the common memory. Each core processes data that is much greater than the memory cache provided to each core. Thus each core locks the main memory for writing, delaying the remaining cores. The results are also shown in Figure 3.

4.2 Distributed computing in cluster

The program was run in a cluster of 4 ordinary computers linked by 100Mbps/sec ethernet Local Area Network. The program was run independently in each computer. The specifications of each computer and its relative speed is shown in Table 2. Note that the computers differ.

Computer	Processor	Frequency (Mhz)	Cores	Memory (GB)	Operating System	Time (sec)	Relative Speed
1	AMD Athlon64 3400+	2,4	1	3	SuSE LINUX 11.3 SMP64	698	1,0
2	AMD Athlon64 3800+	2,4	1	4	SuSE LINUX 11.3 SMP64	673	1,0
3	Intel(R) Pentium(R) Dual CPU T3200	3	2	1	SuSE LINUX 11.4 SMP32	520	1,3
4	Intel core i7	1,6	4	4	SuSE LINUX 11.4 SMP64	369	1,9

Table 2. Computer cluster specifications.

The program was also run in the cluster using 1, 2, 3 and 4 computers. Computers 3 and 4 used only 1 of their cores for the computation. In order to calculate the utilization of different computers running in a cluster, their combined theoretical relative speed is the sum of their relative speeds. The results are shown in Table 3.

Computers	Time (sec)	Relative speed		Utilization
		Theoretical	Actual	
1	698,0	1,0	1,0	100%
1+2	351,3	2,0	2,0	98%
1+2+4	205,7	3,9	3,4	86%
1+2+3+4	150,0	5,3	4,7	88%

Table 3. Speed enhancement in a computer cluster.

The utilization is perfect for 2 computers. In the case of computers 1+2+4, one of them computes 1 frequency step more than the others (20 is not divided by 3), and this can be more than 5% of the total time, which explains the sudden drop in utilization. In the case of 1+2+3+4 computers this is also partially true, as the computers have different relative speeds, which explains the slight increase in the utilization. The results are also shown in Figure 4.

Figure 4. Speed enhancement in a computer cluster.

5 CONCLUSIONS

The elegant parallel framework of FORTRAN2008 was used to speed up the BEM. The parallelization of the computation of frequency steps in the Laplace transform domain was implemented. The method scales well and fully exploits a computer cluster. The method exploits the parallel capabilities of modern multi-core computers, but the utilization is lower than that of a computer cluster, probably due to mutual exclusion when two or more cores try to write the shared memory.

The method can also be applied to the dynamic Finite Element Method, in the Laplace transform domain.

Keywords: Base Isolation, Innovative Retrofitting, Existing Building, Conventional Retrofitting, Comparative Analysis, Cost Effectiveness

Abstract. *In recent years seismic isolation technologies in Armenia were extensively applied in construction of new buildings, as well as in retrofitting of existing buildings. Three remarkable projects on retrofitting by base isolation are described in the paper. One of them is retrofitting of a 5-story stone apartment building. The operation was made without resettlement of the occupants. World practice provides no similar precedent in retrofitting of apartment buildings. The other project is retrofitting of the 60 years old non-engineered 3-story stone school building. This building has historical and architectural value. Unique operations which were carried out in order to install the isolation system within the basement of this building and to preserve its architectural appearance are described. Accumulated experience created a good basis for participation in the international competition announced by the Government of Romania for development of the design on retrofitting by base isolation of the 178 years old historical building of the Iasi City Hall. The structural concept, including the new approach on installation of seismic isolation rubber bearings in this building, is described and detailed results of the earthquake response analysis for two cases, i.e. when the building is base isolated and when it has a fixed base, are given. For all three buildings comparative analyses of innovative vs. conventional retrofitting are carried out. Different methods of conventional retrofitting are considered and their costs are compared with the cost of innovative retrofitting by base isolation.*

1 APPLICATION OF BASE ISOLATION FOR RETROFITTING OF BUILDINGS WITH STONE BEARING WALLS

Isolation of structures from horizontal ground motions is gradually becoming a more common method of providing protection from earthquake damage. By reducing the seismic forces transmitted, isolation protects the contents and secondary structural features as well as the main structure; the safety of occupants and passers-by is thus also enhanced. Moreover, it is practicable to design the isolation system so that the structure responds elastically to the design level earthquake. Thus repair cost should be greatly reduced and continued serviceability of the structure assured [1]. The rehabilitation of existing structures by the insertion of isolators at foundation level has been carried out on historic buildings in California such as the Oakland City Hall, San Francisco City Hall [2, 3], Salt Lake City and County Building [4, 5]. For these, isolation may provide the only viable means that is not unduly intrusive and damaging for the appearance of the building. Together with that the retrofitting technique using base isolation has great potential for rehabilitation of ordinary civil structures such as apartment blocks. The first retrofit of stone apartment building of series 1A-450 has been carried out in Armenia [6, 7].

1.1 Retrofitting of the Existing Five-Story Stone Apartment Building

Buildings on typical design of series 1A-450 have been erected in all regions of Armenia. They have the plan dimensions 52x15 m, symmetrical about the center of the long side and the bearing walls with 45-50 cm of thickness located mainly in transverse direction. The horizontal stiffness in the longitudinal direction is provided partly by the R/C frames with strong beams and columns, made inside the body of walls, and by longitudinal walls at the edge parts of the buildings. The analysis of consequences of the 1988 Spitak earthquake has shown that the most vulnerable zones in these buildings are the edge parts where the direction of bearing walls had been changed. It is in these very zones that intensive plastic deformations resulting in failure of the buildings have been developed due to the weak connections between longitudinal and transverse walls.

The developed structural concept aims at retrofitting an existing building by means of seismic isolators using simple working technology [8]. This is a unique pioneering seismic isolation project introduced for an existing 5-story stone building (Fig.1).

Figure 1: General view of the retrofitted by base isolation existing 5-story stone apartment building (a) and a fragments of its isolation system (b)

The idea is to supply this building with seismic isolation in the foundation by gradually cutting the isolators into the walls at the level of foundation upper edge by means of a two-stage system of R/C beams. Base isolation method for existing buildings with bearing walls that envisions placing of seismic isolators at the level of the foundation or the basement solves the problem as shown on Figure 2. According to the innovative technology developed by the first author of this paper (Patent of the Republic of Armenia #579), in the basement bearing walls openings with certain spacing are made to accommodate reinforcement frames of lower and upper pedestals with seismic isolators. Then reinforcement frames are placed between pedestals thus forming lower and upper continuous beams along all bearing walls of the building. The parts of existing walls between seismic isolators are removed creating gaps and the building appears separated from its foundation and linked to it only by seismic isolators. It is very important that openings in walls are made so that two adjacent openings are not made simultaneously; parts of walls existing between seismic isolators should be cut off beginning from the middle of building plan.

The above described operation was made without re-settlement of the dwellers. The world practice has had no similar precedent in retrofitting of apartment buildings. The project was implemented in 1995-1996, was financed by the World Bank and co financed by UNIDO. The high damping rubber bearings (HDRB) for this retrofit project were designed with significant help and support of the UK based Malaysian Rubber Producers' Research Association (MRPRA), particularly of Dr. K.N.G. Fuller. To implement the project 60 HDRBs were used, 28 bearings have been manufactured in MRPRA and 32 in Malaysia by Min Rubber Products Sdn. Bhd. and Sime Engineering Rubber Products Sdn. Bhd.

1.1.1 Design of Isolation System

High damping rubber bearings are a simple economical means of providing isolation. They have the low horizontal stiffness required to give a long vibration period (typically 2 s) to the structure when mounted on the bearings. Their vertical stiffness is high, thus minimizing any rocking of the structure during an earthquake. The damping needed to limit the displacement of the structure and reduce the response at the isolation frequency is incorporated into the rubber compound so that there are generally no needed auxiliary dissipation devices. The bearings can be designed to withstand safely the large horizontal displacements imposed during an earthquake. The service life of the bearings is expected to be several decades [9], and they should require no maintenance. There has been much emphasis on the suitability of base isolation for critically important structures such as hospitals and emergency centers. The protection of both structure and contents, however, would be advantageous for civil structures such as apartment blocks.

The isolators are located by upper and lower recesses provided by annular steel rings bolted to outer steel plates which are connected to the reinforcement in the upper continuous and lower foundation beams; the isolators themselves are not bolted to the structure. This method of connection helps to minimize the cost of the isolators themselves and simplifies their installation on site. Because the bearing is simply located in a recess, no tapped holes for bolted connections are needed in the end-plate. The side, top and bottom rubber cover layers ensure the steel plates are protected from corrosion. In the considered existing building the bearings were not be located in an enclosed, heated basement, but would be exposed to the outside environment. The severe winter weather at the site meant that particular attention had to be paid to the low temperature crystallization resistance of the rubber compound.

The plan of foundation is given in Figure 3, along with the location of the HDRBs and the total static load on each. The range of the vertical loads on bearings is quite high so it was decided to have two types of bearing, but differing only in the shear modulus of the rubber.

Figure 2: Stages of installation of seismic isolation system in the existing building with stone bearing walls

One type (designated Hard) would support loads in the range 740-900 kN and the other (Soft) loads in the range 500-680 kN. This strategy would lead to a somewhat more uniform

distribution of the horizontal seismic forces, and help ensure that the centre of stiffness of the isolation system is close to the projection of the centre of mass of the building on to the ground plan. The latter minimizes the excitation of torsional vibration of the building on the isolators during an earthquake.

An isolation frequency of 0.5 Hz was chosen. For the design earthquake input and a damping in the isolation system of 10%, this implies a design horizontal displacement of 130 mm. The bearings were to operate safely up to 1.5 times of the design displacement. The design parameters including the horizontal stiffness needed for the two types of bearing are summarized in Table 1.

Figure 3: Plan of foundation of the existing 5-story stone apartment building with location of high damping rubber bearings

Bearing type	Hard	Soft
Horizontal stiffness, kN/mm	0.81	0.58
Design vertical load, kN	820	590
Design horizontal displacement, mm	130	130
Max. horizontal displacement, mm	195	195
Max. static vertical load, kN	900	680
Vertical loads (kN) at max horizontal displacement: Max.	1240	980
Min.	440	140

Table 1: Design parameters of isolation bearings

1.1.2 Design of Bearings

Design details and geometrical dimensions of the laminated rubber-steel bearings meeting the requirements listed in Table 1 are given in Table 2 and Figure 4. The rubber shear strain at the design displacement is chosen to be 100%. As it mentioned above the simple recess connection detail was chosen. Such an option necessitates a check that the bearings are safe against roll-out at the maximum horizontal displacement; the check has take account of the reduction in vertical load on some of the bearings due to the overturning of the building at large displacements.

Type	Hard	Soft
Rubber shear modulus [*] , MPa	0.97	0.69
Static compressive stress (max), MPa	8.7	6.5
Critical load (kN)	3260	2360
Load for internal plate yield (kN)	4800	4800
Horizontal displacement at onset of roll-out, mm		
for design vertical load	300	300
for min. vertical load	260	196
Nominal vertical stiffness ^{**} , kN/mm	400	310

* At 100% strain, 0.5Hz

** Estimated using shear rubber modulus in this Table and a bulk modulus of 2500 MPa

Table 2: Design details of bearings

Because the bearings are located in a recess the side cover is reduced from 10 mm to 3 mm layer over the end-plates. The 2 mm thick rubber end cover layers afford corrosion protection to end-plates (Fig. 4).

Figure 4: Geometrical dimensions of the designed HDRB for existing 5-story stone apartment building and location of HDRB by upper and lower recesses provided by annular steel rings bolted to the outer steel plates connected to reinforcement in the upper continuous and lower foundation beams

1.2 Retrofitting of the Existing Three-Story Stone School Building

The considered in this section building (school #4 in the city of Vanadzor) has historical and architectural value for the city. Taking this into account the financing organization - “Caritas Switzerland” - has agreed with the proposal to retrofit this building by base isolation. Below the unique operations, which were carried out in order to install seismic isolation bearings in the considered building are described in detail. The project on retrofitting the school #4 building was initiated by “Caritas Switzerland” in 2001. At that time the donor had carried out the feasibility study and was supposed to start the project using conventional design. The reason for making such a decision was in wide application of conventional retrofitting in the country and also in the unawareness of the donor about retrofitting by base isolation that has been already implemented with high efficiency in the same city.

The school is a 3-story 60 years old building with thick bearing walls constructed using tuff stones. Actually this building is a non-engineered structure with wooden floors. The design for conventional retrofitting of this school envisaged strengthening of bearing walls by reinforced concrete jackets and by construction of R/C frames in addition to the existing walls in order to decrease the distance between the existing walls. Also it was envisaged to replace the wooden floors by the R/C slabs. However, “Caritas Switzerland” being approached with a new proposal to use base isolation for retrofitting of the school instead of conventional retrofitting had changed its initial decision. The following advantages were taken into account: high reliability, lower cost and reduced duration of construction in comparison with conventional retrofitting as well as preservation of the architectural view of the building.

1.2.1 Bearing Structure of the School Building

School building (Fig. 5) has mainly a Π -shape plan and has load-bearing walls located in transverse and longitudinal directions. The thickness of bearing walls in the basement is varying from 600 mm to 1150 mm and in the floors above ground is varying from 600 mm to 700 mm. There is a school sport hall located between the axes “A”-“C” and “5”-“6”. The height of the sport hall is equal to the height of the basement plus the height of the first floor. This, as well as the Π -shape plan, causes significant asymmetry to the building relative to the longitudinal axis “D”. Actually the plan of the building in the limits of the basement and the first floor is almost rectangular while the plans of the second and third floors are of Π -shape.

Figure 5: General view of the retrofitted by base isolation 3-story school building

The school building had survived the 1988 Spitak Earthquake and fortunately the effect of this earthquake on the building was not very damaging. The building received inclined cracks mainly in the walls located around the staircases with the evaluated damage extent between 2 and 3. Therefore, it was decided to strengthen parts of the existing damaged walls by cement injection and/or by reinforced concrete jackets and also to replace the wooden floors by the R/C slabs. These operations were made simultaneously with installation of the base isolation system on the level of the school basement.

1.2.2 Structural Concept of Retrofitting by Base Isolation and Technique of Installation of Rubber Bearings

Seismic isolation interface for the school building was created in the middle part along the height of the school basement [10]. This approach has conditioned some differences in retrofitting of the school building in comparison with the described in the Section 1.1 retrofitting of the apartment building. In the case of the school building the lower continuous beams were structurally connected to the bearing walls of the basement. This has given the possibility to strengthen the bearing walls by means of the lower continuous beams before cutting the building and passing its weight through the seismic isolators to the bearing walls of the basement. Such structural solution permits to reliably carry the concentrated vertical loads by the bearing walls of the basement.

For the given project the medium damping rubber bearings from neoprene have been designed and tested locally. An isolation frequency again was chosen equal to 0.5 Hz. For the design level earthquake and damping in the isolation system of 8-9% the calculated horizontal displacement was equal to 140 mm. The maximal horizontal displacement was equal to 210 mm. Geometrical dimensions are the same as given in Figure 4. The other main parameters of the designed MDRBs are as follows: horizontal stiffness - 0.81 ± 0.1 kN/mm; vertical stiffness - ≥ 300 kN/mm; rubber shear modulus - 0.97 ± 0.15 MPa; critical vertical load - 4500 kN; vertical load at max horizontal displacement - 1500 kN.

The isolators in the school building were also located by the upper and lower recesses, however, the annular steel rings in this case were bolted directly to the anchors. The outer steel plates were also modified and instead of 20 mm thick plates the 6 mm plates were envisaged (Fig. 6). The given modifications in the design of the isolators' sockets have brought to significant reduction of steel consumption. Figure 6 also shows the cross-sections of the basement bearing wall in the place where isolator is installed between the lower and upper pedestals and where there is no isolator but the lower and upper continuous beams are seen from both sides of the bearing wall. All together 41 MDRBs had been manufactured by the Yerevan Factory of Rubber Technical Articles (YFRTA) for retrofitting of school building. The plan of location of seismic isolators on the lower continuous beams is shown on Figure 7.

For the considered building, which has historical and architectural value the technique of installation of seismic isolators has especially important meaning. First of all an infringement of the external view of the building should not take place under any circumstances. Secondly, no one stone of the façade should fall down during making openings in the bearing walls.

There are three different cases of making openings in the existing walls of the basement, which were mainly used at the retrofitting of the building [11]. The relatively simple case is the one, when the opening has the part of existing wall above it (Fig. 8). In this case there is no need to put any additional supports, as the strength of the wall is sufficient in order to avoid falling. When the opening is made, the lower reinforcement frame of the lower pedestal with the isolator socket can be placed and after that binding reinforcement lower frames are passed along both sides of bearing wall through the frame of the lower pedestal (Fig. 9).

At the next step the concrete of the lower pedestal is casted, the isolator is installed (Fig. 10) and above it the upper socket and the reinforcement frame of the upper pedestal are placed. Then the binding reinforcement upper frames are passed through the reinforcement frame of the upper pedestal along both sides of existing bearing wall (Fig.10). After casting the concrete of the upper pedestal all lower and upper pedestals should be connected to each other forming a two-stage system of R/C continuous beams (Fig. 11).

More complicated case of making openings is when any of existing beams or girders is crossing the space of the opening. In this case one of the ends of the existing beam loses its

support (Fig. 12) and it is necessary to create temporary supports in order to carry dead load of the existing building.

Figure 6: Location of MDRB by upper and lower recesses provided by annular steel rings bolted to the anchors connected to the upper and lower continuous beams in school building

Figure 7: Plan of MDRBs' location on the lower continuous beams in the basement of the school building

The operation should be made very carefully in order to avoid any damages in the superstructure after making openings in the existing walls. It is important to make all operations described above as quickly as possible. Therefore, for such cases everything should be prepared in advance and after casting the concrete the temporary supports should be taken out only when concrete gets about 70% of its strength.

Figure 8: Retrofitting of existing 3-story stone school building: the case when the opening has the part of the existing wall above it

Figure 9: The views of the lower reinforcement frames of the lower pedestal installed in the opening together with the isolator socket

Figure 10: The view of the isolator installed in the socket after casting the concrete of the lower pedestal (a), and of the upper reinforcement frame installed in the opening together with the upper socket and with the binding reinforcement upper frames (b)

Figure 11: The views of a two-stage system of R/C continuous beams, which separate the building from its foundation and create the seismic isolation system

Figure 12: Existing beam is crossing the space of the opening and supported by temporary columns

Sometimes it is necessary to install temporary supports inside the opening in the plane of existing walls. In this case the supports should be prepared from steel, as after casting the concrete they will remain in the lower and upper pedestals. Later the parts of such supports between pedestals should be cut.

Most complicated case is the one when the opening does not have any part of existing wall above it. For school building such cases happened at the entrance when openings should be made just beneath the columns and the arches. Before starting to make openings the arches must be temporarily supported (Fig.13a). Then gradually the opening under the column should be made. With this purpose, at the beginning the part of the foundation only under the one quarter of the column section should be taken out (Fig. 13b). This will allow installing under the column a mechanical jack. After that the other part of foundation under another quarter of the column section can be demolished.

When this work is finished a temporary support under the one half of the column section should be installed and the mechanical jack can be taken out (Fig. 14a). Then again gradually the foundation under the other half of the column section should be demolished and this part of the column section also should be temporarily supported. In cases like this the reinforcement frames of the lower and upper pedestals cannot be prepared in advance and should be made in situ (Fig. 14b).

The following operations are similar to those described above. However, during every step of implementation of such complicated cases of retrofitting it is necessary to take care of the condition of the existing structures not permitting development of any damages as these structures are part of the valuable architectural appearance of the building.

Figure 13: Temporary support under the existing arches (a) and the part of the foundation under the one quarter of the column section is taken out (b)

Figure 14: Temporary support under the one half of the existing column section (a), and existing column and the wall behind it are supported temporarily and the reinforcement frame of the upper pedestal is installed (b)

1.3 Retrofitting Design of the Existing Cultural Heritage Iasi City Hall Building (Iasi County, Romania) by Means of Base Isolation

Experience accumulated in Armenia in retrofitting of existing buildings including those of historical and architectural value created a good basis for participation in the international competition announced by the Government of Romania for development of the design on retrofitting by base isolation of the 178 years old historical building of the Iasi City Hall (Fig. 15). Design was developed in cooperation with Romanian company MIHUL S.R.L. It was approved by the Technical Committee for Seismic Risk Reduction (TCSRR, a body especially created by the Government of Romania) on June 1, 2009.

Figure 15: Views of the Iasi City Hall building

The structural system consists of un-reinforced masonry walls with primarily wood horizontal diaphragms. The thicknesses of the interior and exterior walls vary between 40 to 60 cm and up to 100 cm respectively. Stone foundations have been provided under the masonry bearing walls. The building suffered repairable damage after the 1977 Vrancea earthquake. Thus, the bearing walls were repaired by grout injection, reinforced concrete slabs replaced damaged floors, and the tall chimneys were anchored in place using steel ties. The Iasi City Hall is located in the seismic zone C, and based on Romanian Building Code P100-92, the expected peak ground acceleration for that zone is 0.2 g. The soil in the vicinity of the building is classified as stiff clay sensitive to moisture; the ground water table is approximately 6 m below surface [12]. However, the TCSRR has requested to accept the peak ground acceleration (PGA) for retrofitting design of the Iasi City Hall building equal to 0.28 g. TCSRR had justified its request mentioning that either for the 100 years mean recurrence interval

0.2 g PGA shall be multiplied by the importance factor 1.4 according to the Romanian seismic code in force P100-1/2006 or for the 475 years mean recurrence interval PGA at Iasi City, estimated by Probabilistic Seismic Hazard Assessment for Vrancea earthquakes is also equal to 0.28 g.

The key objective of the given work was elaboration of structural concept and the design of retrofitting by base isolation of the Iasi City Hall building, which will ensure cost-effectiveness of the construction works, high reliability of the structure and preservation of the historical and architectural value of this building.

1.3.1 Structural Concept of Retrofitting by Base Isolation of the Iasi City Hall Historical Building

Base isolation method for an existing building with bearing walls that envisions placing of seismic isolators at the level of basement solves the problem according to the innovative technology described in Sections 1.1 and 1.2. It is known that the City Hall building does not have a basement under its whole area. Only a partial basement exists under a part of the building between the axes “3”-“5” and “K”-“P”, as well as the axes “5”-“8” and “M”-“N”. It was proposed based on the accumulated experience [8, 11, 13] on retrofitting of the similar buildings by base isolation to extend the basement throughout the whole building built surface.

This will require to excavate the soil from the inside of the building and to bare the existing foundation walls. Obviously, that these walls before creation of the isolation system must be thoroughly cleaned and washed from the remainders of soil and then adequately strengthened. The suggested structural solution provides for jacketing of the natural stone walls of foundations. The typical thickness of concrete utilized for the jacketing of masonry walls is 5 cm. There is no need for increasing of the thickness of jacketing as in base isolated structures significant reduction of the shear forces takes place. For the same reason there is also no need for cementitious injection of the basement walls. By implementing the shotcrete 5 cm thickness of jacketing could be achieved easily. However, TCSR was insisting on increasing of the thickness of R/C jacket and on increasing of the diameter of reinforcing bars in the jacket. Therefore, finally the thickness of the basement walls jackets was increased from 5 cm to 8 cm and the diameter of reinforcing bars of the jackets steel meshes of 150x150 mm was increased from 5 mm to 8 mm. Also at the level of the basement floor a R/C slab with the thickness of 10 cm was additionally designed. Nevertheless, it was mentioned by the designers that the need in such a slab and in increasing of the jacket's thickness is questionable and not justified.

The new approach on installation of clusters of seismic isolators which was successfully implemented in many buildings in Armenia was also proposed for retrofitting of the Iasi City Hall building (Fig. 16). Immediately above the seismic isolation plane a 150 mm thick reinforced concrete slab, which will cover the basement, was also proposed. This approach will significantly increase the reliability of the whole structure (building plus the isolation system), will bring to increased rigidity of the superstructure (the part of the building above the isolation plane) and will bring to more uniform distribution of seismic forces on isolators.

By implementing the suggested base isolation method a new basement will be created. The height of that basement under the slab is 1.85 m, however under the upper beam of isolation system the height is 1.3 m (Fig. 17). The height of the basement is limited because of the deepness of the foundation walls. This deepness was discovered in-situ through excavation of soil along one of the exterior walls of the building and was equal to 2.4 m approximately. According to the Romanian Codes at least 0.4 m of the foundation walls should remain in the soil. Therefore, the basement could be designed with the mentioned height only. Of course,

Regarding the bearing walls above the isolation interface it is suggested to execute local strengthening of walls where local cracks exist by cement injection in the cracks and by fixing here of 6 mm steel clamps and plastering those parts. This is just a constructive measure, which is actually not required by carried out calculations. Despite this TCSRR has requested to change the mentioned clamps by the steel meshes of 100x100 mm with the reinforcing bars of diameter 8 mm.

1.3.2 Seismic Isolation Laminated Rubber Steel Bearings (SILRSB) to be Applied for Retrofitting of the Iasi City Hall and Some Results of its Earthquake Response Analysis

In order to develop the retrofitting design the Iasi City Hall building was analyzed under the seismic impacts with PGA equal to 0.28g following the request of TCSRR. This committee has also mentioned that according to the Code P100-1/2006 the demand spectral displacement at the period of vibrations of base isolated building equal to 2.0 sec and the damping ratio of 5% for Iasi is 27 cm. Therefore, it was suggested by designers to accept the value of the actual damping ratio for seismic isolators equal to 15%. In this case according to the Annex A of P100-1/2006 the mentioned displacement demand shall be recomputed and reduced by a factor of 0.707 ($27 \times 0.707 = 19.09$ cm). Period of vibrations of the base isolated Iasi City Hall building, as it is given in [15], is the same in longitudinal (X) and in transverse (Y) directions and is equal to 2.13 sec. This means that the calculated displacement demand will actually be equal to $2 \times 2.13 \times 19.09 = 17.92$ cm. TCSRR has also mentioned that “Good practice and the international codes request a total displacement for design increased by 50% with respect to displacement demand”. Satisfying this requirement the final value of a total displacement $D = 17.92 \times 1.5 = 26.88$ cm was accepted for retrofitting design of the Iasi City Hall building.

However, the statement given by TCSRR about a total displacement seems weak and not justified. In Science and Engineering such statements are not acceptable as they are not clear and are made without any references. Also when it is stated as “Good practice ...” shall some one understand that there is a “Better practice...” or “Best practice...” and what has to be done in these cases? Most probably the absence of the extensive experience on base isolation in Romania is forcing the members of TCSRR to require an over designed isolation system, which will bring to artificial increase of the cost of retrofitting of the Iasi City Hall building. Is there a need for that? Those countries, which are currently extensively using seismic isolation technologies for retrofitting or for new construction like Japan [16], Russia [17], China [18], Italy [19], Armenia [13], and others are constantly reporting on reliability and cost effectiveness of these technologies.

If it is so then why seismic isolation should be expensive in Romania? There is a risk that in case of artificial increase of retrofitting cost the Iasi City Hall, being over designed, will become the first and the last building retrofitted by base isolation following the sad experience of USA where because of similar extremely high conservatism seismic isolation is actually dying. But TCSRR was arbitrarily requesting to significantly increase the values of PGA and of design displacement of isolation system. This was forcedly done in the design with the understanding that it will raise the cost of retrofitting works unnecessarily.

Based on the above for creation of seismic isolation system under the Iasi City Hall building the SILRSBs made from neoprene were accepted similar to those used for retrofitting of the apartment and school buildings with the damping factor equal to 15% [14]. Earthquake response analysis of the building was carried out by SAP2000 non-linear program. The design model was developed using different types of finite elements for walls, floor slabs and seismic isolators.

The non-linearity was considered only for seismic isolators because for cases like Iasi City Hall building there is no need to apply non-linearity to superstructure. For the linear model the isolators are given the effective stiffness equal to 0.81 kN/mm. For non-linear model the isolators have initial stiffness equal to 3 kN/mm and post yield stiffness equal to 0.81 kN/mm.

For the analysis TCSRR has requested to select only those acceleration time histories which "... characterized by a corner period of response spectra T_c close to the value of 0.7 sec. The design accelerograms might be also compatible with local soil condition in Iasi, as those conditions have been experienced during the Vrancea 1986 and 1990 earthquakes". Finally 9 accelerograms were selected and scaled to acceleration 0.28g: 4.03.1977 Vrancea Earthquake, EW direction at Buc-INCERC station ($T_c = 0.78$); 30.05.1990 Vrancea Earthquake, EW direction at Buc-Magurele station ($T_c = 0.64$); 30.08.1986 Vrancea Earthquake, NS direction at Iasi station ($T_c = 0.44$); 30.08.1986 Vrancea Earthquake, EW direction at Iasi station ($T_c = 0.36$); 31.05.1990 Vrancea Earthquake, EW direction at Iasi station ($T_c = 0.40$); 30.08.1986 Vrancea Earthquake, NS direction at Istrita station ($T_c = 0.62$); 31.05.1990 Vrancea Earthquake, EW direction at Istrita station ($T_c = 0.64$); 30.08.1986 Vrancea Earthquake, NS direction at Muntele Rosu station ($T_c = 0.70$); 30.05.1990 Vrancea Earthquake, EW direction at Muntele Rosu station ($T_c = 0.72$).

The following results of calculations were obtained: periods of vibrations in X and Y directions are equal to each other and equal to 2.13 sec; floor accelerations along the height of superstructure in both directions are the same and are equal to 0.085g in average, which means that thanks to application of base isolation the input PGA of 0.28g decreases by about 3.3 times; in none of the isolators the vertical force exceeds 1500 kN; superstructure is moving in horizontal direction as an absolutely rigid body without any overturning and this as well as the above results underline the high effectiveness of the implemented base isolation system.

Also it should be mentioned that at small deformations, which correspond to the wind impact, the initial stiffness of rubber bearings is much higher than their effective stiffness and, thus, the ability of the system to provide an intrinsic restraint against wind loading is confirmed. Structural elements above and below the isolation interface are working only in elastic stage. In comparison with the linear analysis non-linear analysis brings to increase (27%) of average displacement of isolation system and to decrease (35%) of average floor accelerations above it. Other average results of calculations by linear and non-linear versions are given below in the Table 3. Figure 18 visually illustrates the reduction of input acceleration in the superstructure of the base isolated Iasi City Hall in longitudinal direction under the impact of the 30.08.1986 Vrancea Earthquake acceleration time history, NS direction recorded at Muntele Rosu station.

To the best demonstration of the effectiveness of the proposed retrofitting by base isolation the Iasi City Hall building was also analyzed as a fixed base structure using the same selected acceleration time histories. The obtained average results are given in Table 4.

It is easy to notice that in base isolated building the maximum average story drift of superstructure is equal to 1.67 mm while in fixed base building this value reaches to 6.23 mm, which is about 3.7 time bigger. The checked stress-strain states show that the fixed base building must be totally strengthened. Otherwise the fixed base building will not resist the earthquake with PGA of 0.28g and even 0.2g. In the same time the retrofitting of this building by base isolation excludes the necessity of strengthening of superstructure. As an example, Figure 19 presents the distribution of in-plane direct stresses and of in-plane shear stresses over the surface of the wall along the axis "G" for fixed base and base isolated buildings and Figure 20 visually illustrates amplification of the input acceleration along the height of the fixed

base building in longitudinal direction under the impact of the 30.08.1986 Vrancea Earthquake acceleration time history, NS direction recorded at Muntele Rosu station.

2 RETROFITTING BY BASE ISOLATION VS. CONVENTIONAL RETROFITTING

Conventional retrofitting techniques to be applied for existing buildings most probably are not acceptable in Armenia and generally in developing low income countries as such techniques require huge investments including those related to the re-settlement of residents. However, still conventional retrofitting is used much more widely and frequently than innovative retrofitting which is conditioned by the lack of knowledge and by conservatism of engineers/designers, developers and building owners. Nevertheless, their vision of the philosophy of retrofitting/strengthening of existing buildings should be and will be changed in the course of time as little by little with more and more applications of innovative retrofitting technologies it become obvious that such technologies are incomparably more effective and reliable structurally and more cost efficient.

2.1 Comparison of Retrofitting Technologies in Armenia

Conventional strengthening/retrofitting techniques are including: stiffening existing wooden floors and roofs by covering them with a layer of reinforced concrete; insertion of reinforced concrete ring-beams into the inner face of external walls at floor and eaves level to tie vertical and horizontal elements together; strengthening of walls (mainly when cracked) by cement injection or by adding a thin layer of cement render reinforced with steel mesh on either side of the wall, etc.

In [20] it is mentioned that in rare instances, base isolation has been used to protect the structure from the ground shaking, but this is very expensive. This statement is not always true and is not reflecting real situation in every country where seismic (base or roof) isolation is widely implementing. For example in Armenia due to seismic isolation the cost of retrofitting is about 2.0 times less in comparison with the cost of conventional retrofitting. In this regard an interesting analysis was carried out by one of the Armenian design company “Project-6” LLC (Director G. Gulanyan). With participation of the first author of this paper the com-

pany has analyzed and compared the cost of strengthening of existing stone apartment buildings of series 1A-450 by different methods (Tab. 5). It was assumed that the cost of the most expensive method of traditional strengthening comprises 100%.

Method of strengthening	Cost in %	Needed action
Traditional method with application of reinforced concrete jackets, frames and floor slabs. This method is applicable for buildings with damage extent from 2 to 3*	100	Evacuation of tenants, move out furniture
Traditional method with application of only reinforced concrete frames. This method is applicable for buildings with damage extent from 1 to 2	43	Evacuation of tenants
Innovative method with application of base isolation and local strengthening of walls only by reinforced concrete jackets. This method is applicable for buildings with damage extent from 2 to 3*	37	Without evacuation of tenants, partial move of furniture
Innovative method with application of base isolation and total strengthening of walls by cement injection. This method is applicable for buildings with damage extent from 2 to 3	31	Without evacuation of tenants, partial move of furniture
The same as previous but with local strengthening of wall by cement injection for buildings with damage extent from 1 to 2	27	Without evacuation of tenants, partial move of furniture
The same as previous without touching the superstructure for buildings with damage extent from 0 to 1	21	Without evacuation of tenants

* This method can also be applied for buildings with damage extent 4, however, with due regard of economic and social factors

Table 5: Comparison of the cost of strengthening of existing stone apartment buildings of series 1A-450 by different methods

From Table 5 it follows that in Armenia the cost of innovative method of strengthening/retrofitting of stone apartment buildings with application of base isolation is 2.5 times less in average in comparison with the cost of traditional methods of retrofitting. And this is of course with consideration of the cost of seismic isolation rubber bearings but without consideration of the cost of evacuation of tenants. It is easy to understand that evacuation of tenants requires huge additional investments in order to provide evacuated tenants with temporary shelters, water, sewer, electricity and relevant infrastructure. Consideration of these additional investments makes in absolutely clear and obvious that at least in those earthquake prone countries where progressive thinking of designers/engineers, developers, building owners and decision-makers, as well as progressive codes are exist and also where it is possible manufacturing or importing low-cost seismic isolators the preference should be given to the innovative methods of retrofitting with application of base isolation. In the result of its analysis “Project-6” had concluded that the most cost effective technique for strengthening of existing buildings is base isolation in combination with cement injection or with polymer-cement slurry injection for total or local strengthening of the damaged bearing walls.

Above several remarkable projects on retrofitting by base isolation are described. One of them is retrofitting of the existing stone apartment building of series 1A-450 in the city of Vanadzor. This project is an actual example of cost effectiveness of retrofitting by base isola-

tion vs. conventional retrofitting. The cost of retrofitting of this building defined in the result of competitive bidding is equal to 165.600 USD including the cost of rubber bearings. Other two similar buildings in the same city were retrofitted conventionally. One was retrofitted with application of reinforced concrete jackets and frames and it cost is equal to 340.000 USD. The other one was retrofitted by insertion only of reinforced concrete horizontal ring-beams and vertical columns into the external and internal bearing walls and it cost is equal to 294.200 USD. These actual examples prove ones again that substantial saving (about 2.0 times) could be achieved thanks to application of base isolation. Also this innovative technology allows avoiding infringement of the external and internal views of the buildings which is extremely important especially at seismic protection of historic buildings and structures of cultural heritage like, for example, the above described building of Iasi City Hall.

2.2 Comparison of Retrofitting Technologies in Romania

Special analysis was carried out by the second author of this paper in order to reveal cost effectiveness of retrofitting by base isolation of the buildings that represent an architectural monument. Four buildings were considered which were strengthened conventionally (Fig. 21, 22, 23 and 24) and the results were compared with those obtained in retrofitting design of Iasi City Hall by application of base isolation.

Structural systems of these buildings as well as of the Iasi City Hall building are similar. They have bearing walls made of brick on the continuous stone masonry foundation. Their floors are made of wooden beams but above the basements (if there are) the floors are made of small brick arches. The shaped limestone of foundations is walled up with dirty sand and lime mortar. The compressive strength of brick corresponds to the grade of 25-50 and of mortar – to the grade of 4-10.

In the considered buildings there were inclined cracks observed along the height of the bearing walls with the opening of 1-3 mm. Most of them occurred around the windows and doors as a possible result of the earthquake impact. Also cracks are usually increase in their number, length and openings by the uneven settlements of the ground under the foundation because of wetting or exceeding its local bearing capacity.

Fig. 21: View of “Georghe Pirvan “ Museum, Bârlad constructed in 1880

Fig. 22: View of Palace of “Alexandru Ioan Cuza” University of Iasi which was constructed in two stages: first in 1894 and then in 1928-1934

Fig. 23: "Alexandru Ioan Cuza" University of Iasi building "D" constructed in 1880 and improved in 1938

Fig. 24: School Inspectorate of Iasi building "A" constructed at the beginning of the 20th century

Conventional strengthening of these buildings included reinforced concrete jacketing of foundations with the thickness of 8-20 cm and the execution of reinforced concrete belts at the bottom and at the top of foundations. Sometimes the belts were designed larger at the bottom to increase the width of foundations. Above the foundations the strengthening included:

- injection of all the cracks with additive cement;
- reinforced concrete jacketing of the bearing walls by shotcrete in 2-3 layers;
- introduction of a system of reinforced concrete elements (additional shear walls, columns, belts);
- reinforced concrete framing of the door and window openings connected to the walls' jackets;
- execution of a continuous belts at the top of the walls;
- replacing the wooden floors by the reinforced concrete slabs, etc.

The major inconvenience of these strengthening systems is the need to remove and restore all the architectural elements inside and outside the building and replacing the original fresco plaster of the monument. In many cases these original elements cannot be removed, and these will require restoration after the next severe earthquake that will affect the building.

Actually the cost of retrofitting of the considered buildings of cultural heritage consist of the cost of structural strengthening and of total architectural restoration, which is not the case in retrofitting by base isolation. During the retrofitting by base isolation the original architectural elements, frescos, etc. are preserved in high proportion and they may need only local intervention with incomparably lower costs. At the conventional retrofitting a very difficult task is restoration of the original finishes that requires high qualified manpower to execute the plasterwork of architectural elements, mosaics, shaping the stones, etc. Table 6 gives the information on retrofitting costs for all considered buildings.

Comparison of the values given in Table 6 shows significant difference in the costs of innovative retrofitting vs. conventional retrofitting. The average cost of structural strengthening by conventional methods is equal to 233 €/sqm which is higher than the cost of retrofitting by base isolation (including the cost of seismic isolators) by 1.14 times. For architectural restoration these figures are 248 €/sqm and 2.16 times, respectively. Thus, finally retrofitting by base isolation costs 1.5 times less then conventional retrofitting. However, above in Section 1.3 was mentioned that in the retrofitting design for Iasi City Hall many additional strengthening measures were envisaged by the requests of TCSRR which actually have artificially increased the cost of retrofitting by base isolation. If to take this into account one can definitely say that cost savings would be much more and the figure of 1.5 may be closer to 2.0 what was obtained for ordinary buildings.

Name of the building	Type of retrofitting	Cost of structural strengthening €/sqm	Cost of architectural restoration €/sqm	Total cost of retrofitting €/sqm
“Georghe Pirvan “ Museum, Bârlad	conventional	230	260	490
Palace of “Alexandru Ioan Cuza” University of Iasi	conventional	240	250	490
“Alexandru Ioan Cuza” University of Iasi building “D”	conventional	230	240	470
School Inspectorate of Iasi building “A”	conventional	230	240	470
Iasi City hall	base isolation	204	115	319

Abstract. *In the beginning of the 70-th a program of analytical and experimental investigations of structure seismoisolation was carried out in Earthquake Engineering Research Center, TsNIISK, Russian Construction State Committee.*

As a result of the research program different structural systems of seismoisolation are designed. Different seismoisolated structures were constructed taking into account the investigation results. More than 500 buildings and historical monuments are seismoisolated in Siberia, Far East, Crimea, Caucasus, Middle Asia and other earthquake hazardous areas of Russian Federation.

Some examples of seismoisolation for upgrading of existing historical buildings, including a bank building and churches in Irkutsk-city (Siberia) are presented. All steps of installment of the steel-rubber supports in the bank building and church foundations are given.

Seismoisolation was used in the designs of two churches in Irkutsk-city as well: Kharlampiyevskaya (Mikhailo-Arkhangelskaya) and Spasskaya churches which are historical and cultural monuments built in 1779-1790 and 1706-1713 accordingly.

The structural concept includes an asymmetric in plan, columnless brick masonry structure. The building consists of several parts with different design, connected by walls in one unit, except for the porch. Its walls do not have bonding with main building walls.

Also two cultural centers have been strengthened in seismic high earthquake hazardous areas using steel-rubber seismic isolation. One is the Chechen Republic Cultural Center Building Complex, which was damaged during the war. The other building was the Gorno-Altaysk National Drama Theater. Both complexes are situated at sites with design seismic intensity MSK 9 degree.

INTRODUCTION

A program of analytical and experimental investigations of structural seismoisolation was carried out Earthquake Engineering Research Center, TsNIISK, Russian Construction State Committee, Eisenberg [1].

The strong motion accelerograms up to the present time demonstrated very different predominant periods of earthquake ground motions not only during different earthquakes but sometimes even during the same earthquake at distant and the close distances, for example, during Loma-Prieta, 1989, earthquake. The mathematical semi-probabilistic models of earthquake inputs were developed which take in consideration the uncertainty of the predicted spectra and other motion parameters of the future earthquakes and artificial design accelerograms were computer generated, Eisenberg [1], in the early 70-th of XX century.

Experimental part of the investigation program included:

1. Shaking table model and fragment tests;
2. Full scale building dynamic tests using large exciters. The maximum dynamic loading of the structure by means of an exciter corresponded to the design load of 9 MM – intensity and more;
3. Static and dynamic tests of the elements of seismoisolation system (flexible supports, dampers, dry friction elements a.a.).

As a result of the research program different structural system of seismoisolation are designed and buildings are constructed recently in Siberia, Far East, Crimea, Caucasus, Middle Asia and others earthquakes dangerous areas. Specific for these systems is that they are simple in construction and are not expensive. Different structures using seismoisolation were constructed taking into account the investigation results. More than 500 buildings and bridges are seismoisolated in Russia and in former USSR countries.

The prevailing amount of constructed seismoisolation systems in Russia is non-rubber seismoisolation. The seismoisolation effect is achieved by using two and sometimes more than two elements. The two elements are 1 – flexibility elements and 2 – dampers. The flexibility elements are flexible columns in the ground storey of the building, or rocking supports (rocking columns, rocking converted mushroom type supports, other configuration rocking supports). The dampers are mild steel hysteretic elements or RC damaged during earthquake diaphragms, or dry friction elements.

The main design demands are large enough critical horizontal displacements of the flexible columns or rocking supports. Several dozens building are constructed on sliding supports and sliding belts of controlled damping. Usually the steel-teflon pairs were the controlled friction elements. Additional elements of seismoisolation used in Russia are horizontal displacement rigid limiters (stops) and reserve disengaging elements for energy dissipation and for frequency spectra adaptation.

Recent years steel-rubber supports were used in some seismoisolated buildings constructed in Russia, Smirnov, et al [6]. Now some buildings with steel rubber seismoisolation supports are in design process. One of these buildings will be constructed at Alexandrov-city, Sakhalin (a 4 storey school building). The steel-rubber supports for this building are produced in China, Shantou, “Vibro-Tech” Company.

As a result of studies in Moscow EERC the seismic safety of buildings with soft ground stories was exonerated. The reason of many buildings with soft ground stories collapses during recent earthquakes was reinforced concrete as material of bearing ground story columns, not the flexibility of the ground story itself. Design of soft ground story buildings with steel columns as seismoisolation elements combined with dampers and fuse elements is presented.

SEISMOISOLATION FOR UPGRADING OF AN EXISTING HISTORICAL BUILDING IN IRKUTSK-CITY, SIBERIA-RUSSIA

A historical building of an Irkutsk Bank needed retrofitting and upgrading as observation and analysis have brought to conclusions that the seismic reliability of the building doesn't meet the current Seismic Building Code requirements. The bank building was retrofitted using seismic isolation to prevent the damage by earthquakes expected in the future (Figure 1).

The building consists of three blocks. The external bearing system is: brick wall, thickness is 64 cm. The internal system is reinforced concrete columns and brick masonry. The building height is 3 to 4 stories, where walls and columns lower storey were cut at their mid height and LRB's (lead rubber bearings) were installed.

The decision to install seismic lead rubber bearings in the mid level of the ground floor was taken to provide maximum seismic isolation of the existing walls and building columns. The total number of seismic bearings to be installed is 108. Every bearing is designed for 2500 kN load. All the bearings have equal dimensions: diameter – 510 mm, height – 216 mm.

The high-damping steel-rubber supports were produced at the Shantou-city (Southern China) "Vibro-Tech Industrial and Development Co Ltd". The dynamic tests of supports were carried out in South China Construction University in Guangzhou with participation of Russian experts. Due to the reduction of seismic force by isolation, strengthening of the structure above isolators has come to be unnecessary. The part of structure below isolators has been strengthened. A specific construction technology of supports installation in the existing building without its exploitation interruption was developed. The site dynamic tests of the full scale building to investigate the dynamic properties of the seismoisolated building and the correlation between the actual and design values were carried out.

Figure 1: General view of an Irkutsk Bank
a – before reconstruction; b – after reconstruction

The numerical analysis of earthquake response of this Building was carried out in EERC, Moscow by J. Eisenberg and V. Smirnov. The results of the investigation are that in case of the seismoisolation high damping (27% of critical damping) supports both response acceleration and response displacements are sufficiently lower comparing to non-isolated existing building.

The maximum response displacements of the seismoisolated building do not exceed 2.5 cm, maximum response acceleration are in the limits of 550 gals. These values are not hazardous for from point of view of the building safety.

The method of seismic isolation of the existing bank building has revealed the advantages of this method comparing to the conventional methods of retrofitting and strengthening of the buildings located in highly hazardous seismic zones.

1. Seismic isolation of the ground floor part of the building enabled to preserve the building exterior look and to avoid architectural features violation.
2. The result of comparative nonlinear analysis of isolated and non-isolated buildings is that both displacement and acceleration in isolated buildings are significantly lower than in non-isolated ones.
3. The method of gradual isolation of lead rubber bearings in the building blocks enables normal work of the bank.

DESIGN OF A CHURCH BUILDING SEISMOISOLATION

The design of church building in Irkutsk-city seismoisolation is now carried out (Figure 2). Kharlampiyevskaya (Mikhailo-Arkhangelskaya) church is a historical and cultural monument built in 1779-1790.

Figure 2: Church buildings

The structural concept includes an asymmetric in plan, columnless brick masonry structure. The building consists of several parts with different design, connected by walls in one unit, except for the porch. Its walls do not have bonding with main building walls. The northern and southern side-chapels have similar structural concept in the form of two-storey parallel bays of different length. On the east side, the bays are completed with the multifaceted apses.

Side-chapels' ground floor is spanned with cylindrical brick vaults, including strippings in the wall vaulted bay. In the first floor, the northern side-chapel narthex and the southern side-chapel refectory are spanned with cylindrical brick vaults. The northern and southern side-chapel churches and the southern side-chapel altar are spanned with octagonal tent brick vaults. The altar apses in the ground and the first floor are spanned with multifaceted closed

brick vaults.

The foundations are of shallow, strip, stone masonry type with the artificial subgrade, consisting of pebble and fine sandy loam mixture poured with mortar. The masonry is made of loam Flemish bricks on mortar. Wall thickness is 1.26–2.35 meters. To provide building earthquake stability seismoisolation system, including metal-rubber supports is used in Mikhailo-Arkhangelskaya church foundations.

In order to reduce lateral seismic loads, metal-rubber isolators are installed on the church building superstructures. It is enabled by pliable bracing between building superstructures and foundation. It also provides seismoisolating support dampening quality. These measures are used to increase building natural period of vibrations and to decrease transmission of earthquake power and ground motion to the building superstructures. Estimated building weight is 158060 kN. Total number of rubber-metal seismoisolating supports are 92.

The following sequence of works was offered for supports installation in the existing church building (Figure 3). Foundation replacement and exterior wall seismoisolation installation are carried out in the following sequence:

1. The mortar is injected via injectors (1), to reinforce the upper zone (4) of ground pad (5) (Figure 3a).
2. The antiseismic belt (8) is provided (Figure 3c, d):
 - 3 meter long trenches (24) are dug with some intervals;
 - Trench bottom is smoothed and covered with two layers of polyethylene film (7);
 - Formwork panels (6) are installed;
 - Support antiseismic belt (8) with embedded parts (26) for seismic supports fixing (Figure 3c).
3. After the support antiseismic belt is arranged in the whole building, each second hole is open in places where seismic supports are to be installed (25), the walls must be fastened (10), pillar formwork (11, 12) is provided, and support columns (14) for seismic supports are cast in situ (Figure 3e).
4. Wells in ground-and-concrete mass (4) are drilled via holes (27), left in support seismic belt, and coupling bolt studs (9) are passed through them. Bolts are tightened, wells pressure grouting via special channels (18) is carried out, and additional strengthening of ground-and-concrete is provided (4).
5. Each second foundation column along the perimeter is dug out (after reaching 70 percent concrete strength), hole bracing is dismantled, and formwork is removed. Then foundation slabs (19) are installed and foundations are connected (31) (Figure 3f, g).
6. The rest foundations are erected with separate foundation slabs connected into a continuous belt.
7. The foundations for the interior walls are laid down in a similar way.
8. After all foundations are ready and the support antiseismic belt is underpinned, the trench under the whole building is to be open for ground floor arranging. Basement solid-cast reinforced-concrete walls (20) and solid-cast reinforced-concrete ceiling over the basement (22), resting on support antiseismic belt and rigidly connected with it are erected (Figure 3g).
9. Cantilevered solid-cast reinforced-concrete plate (21), rigidly built in the outside branch of support antiseismic belt, which has to overlap the distance between the belt and basement wall is installed along exterior walls contour. A horizontal antiseismic joint, 50 mm high, separating the building overground part from the underground part is provided between the upper basement wall batter and cantilevered plate (21). The joint is stuffed with mineral wool plate, wrapped in polyethylene case, and is sealed with thiokol sealant.
10. After complete basement closing seismic supports are erected.
11. Seismic supports underpinning is to be provided in the following succession:

- Seismic supports (16) are hung in the recesses which were left when concreting support columns (Figure 3f, g) to the top embedded parts (27) with four bolts (29);
 - Lower embedded parts (similar to 27) with foundation bolts (15) are hung with the help of four bolts on the lower connecting plates of seismic supports;
 - Reinforced concrete support pads (17) (Figure 3f, g) are concreted under embedded parts, 50 mm gap is to be left between a support pad and an embedded part which must be carefully caulked with firm fine concrete, grade V20.
12. After all seismic supports are installed, they are loaded by filing off and removing support columns (30) from under antiseismic support belt.

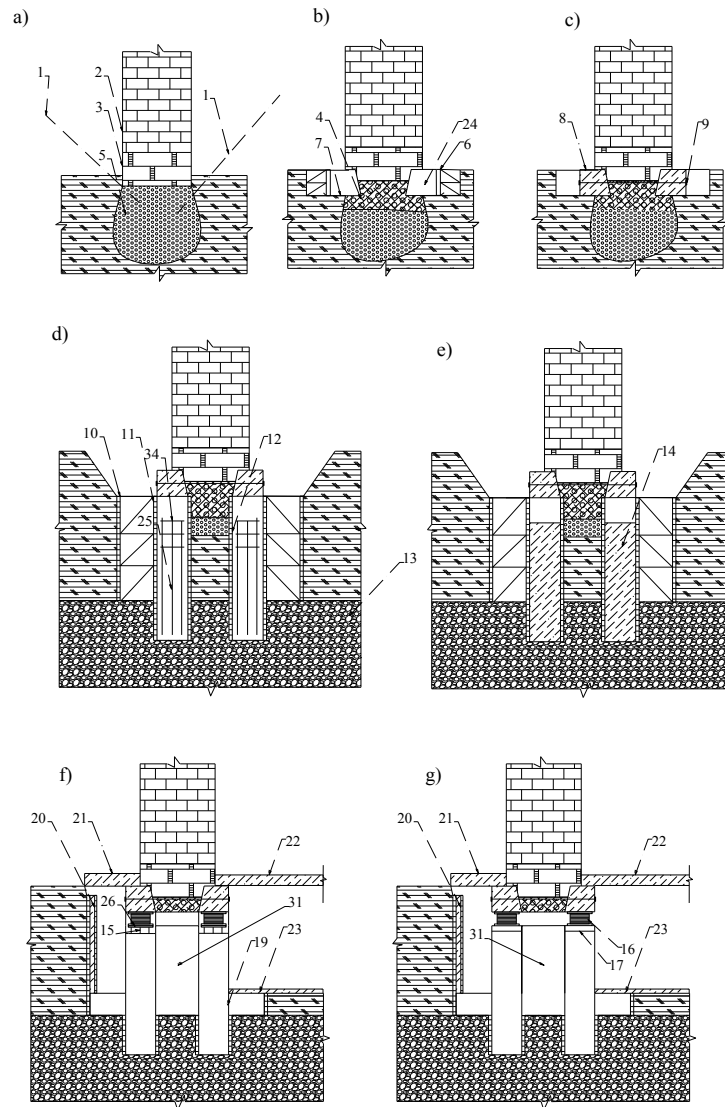

Figure 3: The sequence support installation

CONCLUSIONS

Some new Projects of historical seismoisolated structures used in Russia recently are presented.

Among them are newly constructed buildings and existing buildings, which are strengthened.

Rubber and non-rubber seismoisolation supports were used.

Provisions for seismoisolated buildings of different seismoisolation types were prepared.

Mild steel columns or frames as base isolation elements are presented. Two aspects of their seismoisolation ability are taken into account in design. The one is the building flexibility achieved using these columns. The other aspect is energy dissipation and large enough permissible (safe) horizontal displacement.

Abstract. *This paper reports the outcomes of an experimental test campaign for the validation of the performance of a seismic reinforcing strategy of masonry buildings based on the full covering of the building by means of an innovative multifunctional technical textile. This innovative solution, the “Composite Seismic Wallpaper” is made of glass and polymeric fibres in a multiaxial textile structure featuring embedded fiber optics sensors which is connected to the substrate using a special cementitious matrix. The composite obtained is multifunctional in the sense that on one side it reinforces the structure, increasing its capacity to resist to seismic events, and on the other side, it provides localized and distributed static and dynamic measurements before, during and after a seismic event, by means of the integrated sensors. Recently “Seismic Wallpaper” has been full-scale tested as reinforcement of a two-story stone building. The reinforced building has been tested in shaking table tests campaign to prove the feasibility of the distributed and passive reinforcing solution and to investigate the reliability, in detecting the building dynamics, of Fiber Bragg Grating (FBG) sensors embedded in the textile fabric. Sensors measurements recorded during hammer shock tests and shaking tables have been analyzed towards a modal identification of the building modal parameters. This paper first presents the building modelling by means of finite elements analyses, then describes the buildings dynamics as characterized from experimental tests, finally proposes a methodology for damage detection by means of an inverse problem approach that combines an evolutionary method (Genetic Algorithms) and a plain FEM simulation based model for the localization of damage.*

1 INTRODUCTION

Masonry structures are complex structures, as they are constituted by non-homogeneous materials (i.e., bricks, stones, mortar), they exhibit in-plane and out-of-plane failure mechanism which are prevalently sliding, flexural and shear type and they are prone to damages and fragile collapses when excited by dynamic loads. In particular when excited by seismic loads, masonry structures are subjected to cracks propagations which progressive lead the structure to collapse. In which way the structural collapse due to a seismic action may be avoided or move away it is an open point of discussion in the scientific community as many and different techniques may be considered and may be reliable, depending on the characteristics of the input dynamic load and on the different parameters which may be involved.

Most of masonry buildings are old buildings which have not been designed against earthquakes but only to resist to gravity loads and the effect of seismic loads were. During earthquake, seismic loads introduce severe in-plane and out-of-plane forces to unreinforced masonry buildings, many of them, collapse in out-of-plane bending due to lack of reinforcement.

When dealing with the reinforcement of masonry building against natural hazards such as earthquakes, all the aforementioned considerations should be taken into account.

To this aim, the techniques investigated and adopted for the reinforcement of masonry building aimed at providing more flexibility and ductility to the masonry walls and at preventing out-of-plane and/or in-plane failing mechanism by means of guaranteeing a stronger and reliable confinement and connection of the masonry walls. In general the objective of the retrofitting should be to enhance the earthquake resistance of masonry structures in order to avoid its failure in brittle manner.

Following a short review of the historic developments of masonry reinforcement solutions, as they are reported in the more important codes, guidelines and handbooks, they can be divided in traditional (i.e. conventional) techniques and innovative techniques.

Traditional methods of strengthening are intervention techniques to remedy structural deficiency by means of local or overall modification of damaged or undamaged elements (repair, strengthening or full replacement). The conventional methods are:

- Addition of new structural elements (bracings system; steel, timber or reinforced concrete belts);
- Injection of cement or epoxy grout into cracks to fill cracks and voids;
- Local replacement of damaged masonry bricks and reassembling them with improved mortar and proper reinforcement (reinforcing bars);
- Improving the connection between intersecting walls through construction of a reinforced concrete belt, addition of steel plates in the bed-joints, or insertion of inclined steel bars in drilled holes;
- Strengthening and stiffening of horizontal diaphragms;
- Addition of steel ties (along or transversely to the walls, external or within holes drilled in the walls) to connect walls and to improve the overall behaviour of a masonry building;
- Strengthening of rubble core masonry walls by cement grouting;
- Strengthening of walls by confinement with reinforced concrete jackets or steel profiles.

Among the innovative techniques, three main areas can be identified:

- Seismic Isolation (i.e., base isolation);

- Fiber Reinforced Polymers materials;
- Energy Dissipation Devices (as example passive control devices based on Shape Memory Alloy (SMA)).

Furthermore seismic retrofitting of most of masonry structures requires compliance with restrictive constraints related to the preservation of the original structural features. Any conceived intervention must achieve structural performance yet still respect the appearance and structural mechanism of the original and be as minimally invasive as possible. Therefore, traditional retrofit strategies may not be suitable for such purposes, and structural engineers need to develop specific techniques. Innovative materials, such as textile composites may be helpful with respect to these issues. In fact composites provide a non-intrusive technique to provide reinforcing strength to a structure and are feasible for applications which include localized crack repair, the reinforcement of critical walls, or the wrapping of existing columns.

In addition, conventional methods add significant mass to the structure, encroach upon the available working space, and adversely affect the aesthetics of the repaired portions. The extra mass added to the structure during strengthening increases the earthquake induced inertia forces and may necessitate the strengthening of the footings. Also from this point of view solution based on innovative composites materials should be adopted. In particular Fiber Reinforced Polymer (FRP) composites offer a viable alternative to the conventional strengthening methods as they offer: high strength to weight ratio, resistance to electro-chemical corrosion, larger creep strain, good fatigue strength, potential for decreased installation costs and repairs, non-magnetic properties.

In the field of strengthening, textiles composite materials combined with mortars were used recently as a means of increasing the strength of masonry, either in diagonal compression [5] or in uniaxial compression through confinement [6, 7]. Studies have dealt with strengthening of: walls, through external prestressing [8]; columns, through confinement [9]; walls subjected to in-plane or out-of-plane loading, through externally bonded strips or overlays [10]; walls through near-surface mounted reinforcement [11].

In general solutions of this type are based on narrow fabric/sheets strips of FRP composite materials (carbon or glass fibers based) glued by means of a resin on masonry walls in localized position. Strips reinforcement solutions based textile materials represent an efficient reinforcement strategy. However, striped reinforcements of masonry walls they may excessively increase the walls stiffness and may create stress concentrations, which may change the way the structure is responding to actions such as earthquakes and may transfer to weak zones the capacity of the wall to resist.

A step further should be on one side to investigate innovative materials and on the other side to adopt new strategy for the reinforcement solution. An answer to the first need could be to adopt multi-axial composite textiles, while to address the second issue one strategy is to move from localized (i.e. striped) reinforced solutions to global full-cover solutions.

Both issues have been addressed within the EU funded project Polytect (“Polyfunctional Technical Textiles for Protection against Natural Hazard”) which developed an innovative concept for the reinforcement and protection of masonry buildings against earthquakes by means of a multi-axial composite based skin for the full-covering of masonry walls. This solution, in the following “Composite Seismic Wallpaper”, was awarded at the JEC2010, as innovative product in the Building and Construction Category.

The Composite Seismic Wallpaper is an innovative solution, as it not only provides reinforcement capability by means of a multi-axial FRP, but also because it provides monitoring capability by means of fiber optics sensors embedded into the textile since the manufacturing

stage. The wallpaper represents a progress beyond the state of the art of masonry building reinforcement solutions using textile materials because:

- It reinforces the building by increasing the structural strength;
- It increases the building's ductility, without stiffness increase;
- It monitors the building structural health by means of strain measurements;
- It detects the damage in the building walls.

Furthermore, the aforementioned characteristics of the wallpaper make it suitable for reinforcing application in compliance with Italian and EU codes referring to this topic. In particular it can be stated that the integration of a monitoring system into a reinforcing solution is needed since there is a lack of information on long-term behaviour of reinforcing applications with textiles materials [12]. In fact from paragraph 5.8.5 "Monitoring of the strengthening system" of [12] it can be extracted what follows: "Due to the poor availability of data regarding long term behavior of FRP systems... it is recommended to perform appropriate monitoring to keep the following parameters under control: Temperature... humidity.... displacements and deformations... Potential damage of fibers.... Extensions of defects and delamination...". The seismic wallpaper is an effective and reliable answer to this need.

2 THE COMPOSITE SEISMIC WALLPAPER

From a components point of view, the wallpaper consists of:

- Multi-axial, warp-knitted, AR-glass and Polypropylene (PP) fibres, which constitute the composite fibers (Figure 1);
- Nanoparticle enhanced coatings for the textile fabric;
- Nanoparticle enhanced mortar (the matrix of the composite) to bond the textile to the structure;
- Fibre optic sensors (Figure 2);
- An interrogation system to acquire data from the sensor-embedded textile-mortar composite.

Figure 1: Quadric-axial technical textile

Figure 2: Fiber optic sensors embedded textile

The realization of these components, their processing, and application onto real structures has been investigated within the Polytext project and tested in full-scale seismic tests at the European Centre for Training and Research in Earthquake Engineering (Eucentre) under the “Seismic Engineering Research Infrastructures for European Synergies” (Series) initiative.

An un-reinforced two stories stone building (Figure 3) has been identified to be suitable for the full-scale application of the seismic wallpaper reinforcing solution.

Figure 3: 3D View of the un-reinforced stone building (left); N-S-W-E fronts (right)

The building is made of natural stones which mechanical properties. The roof is wood made and is simply supported to the walls. Its structure is made of longitudinal and transversal beams. The building is 5.80m long (X direction), 4.40m width (Y direction) and 5.80m high (Z direction). The foundation (40cm tall) is made of concrete, while a wood slab is realized in between the first and the second story (Figure 4). The mechanical properties of the materials constituting the building are reported in Table 1 below.

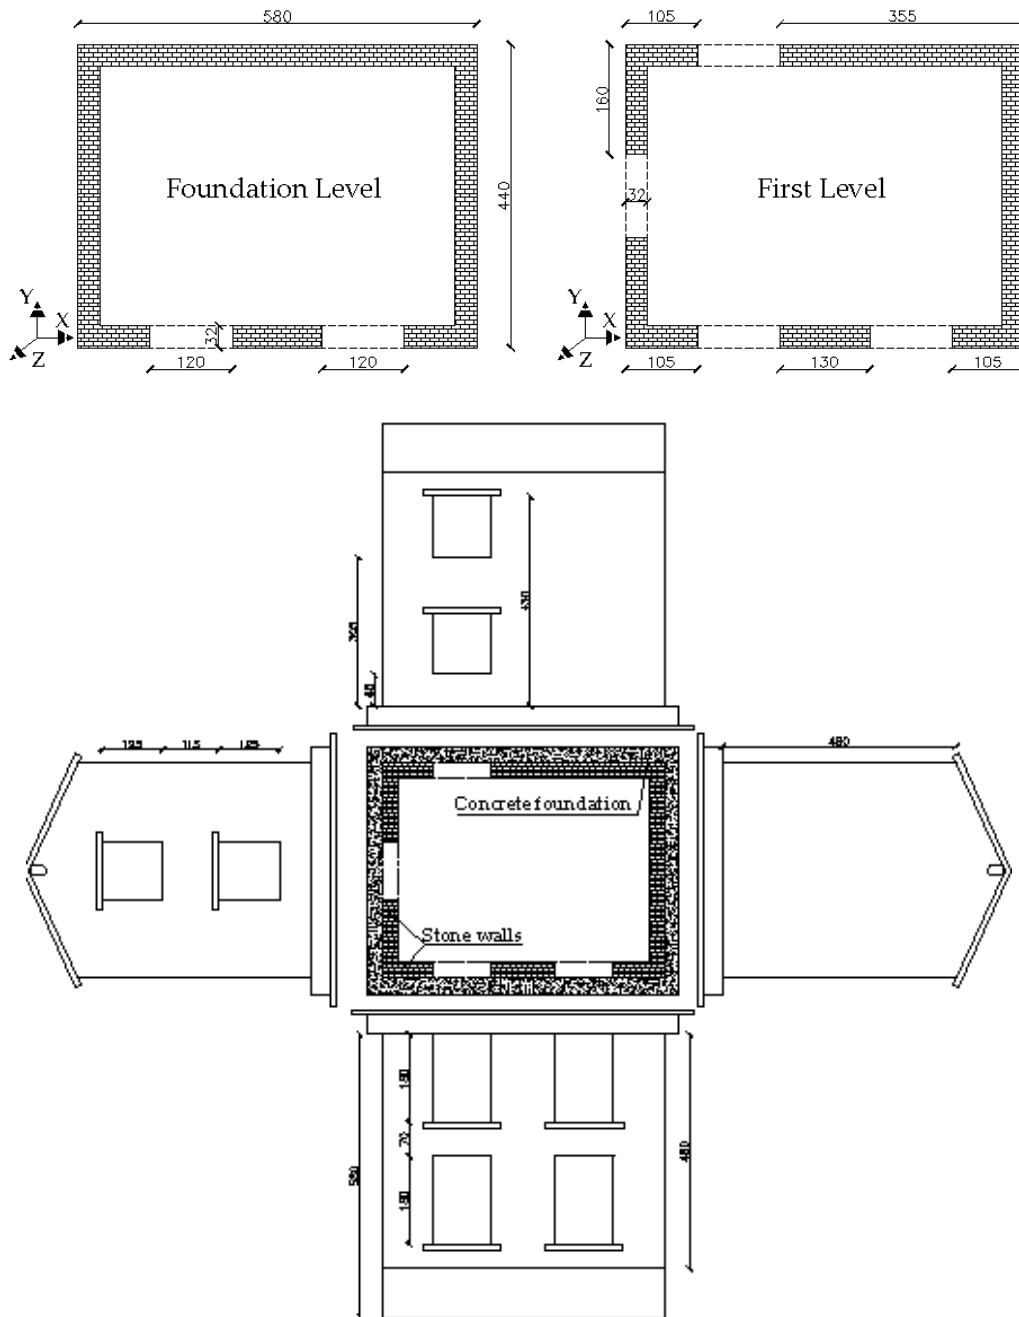

Figure 4: The un-reinforced stone building: plan view (top); sectional view (bottom)

Density	2579 kg/m ³
Young Modulus $E_{x,y}$	2550 MPa
Young Modulus E_z	2550 MPa
Poisson Coefficient ν	0.4
Shear Modulus $G_{xy}=G_{xz}$	840 MPa
Shear Modulus G_{yz}	840 MPa
Maximum compression stress σ_c	3.28 MPa
Maximum tensile stress σ_t	0.137 MPa
Density	750 kg/m ³

Young Modulus E	11000 MPa
Poisson Coefficient ν	0.2
Density	2400 kg/m ³
Young Modulus E	30000 MPa
Poisson Coefficient ν	0.2

Table 1: Mechanical properties of material adopted in the un-reinforced building: natural stone (top); wood (middle); concrete (bottom)

Afterwards the stone building has been reinforced by means of the seismic wallpaper, which has been applied to the stone walls using a mortar compound, constituted of an epoxy-cementitious matrix combined with nanoacrylic polymers. The cohesion of the masonry part of the structure is achieved by using this matrix of ductile type, which benefit is a damping effect through load distribution. The matrix also protects the glass fibres against the alkaline environment of the plaster. In detail (Figure 5), the reinforcement has been realized by means of further steps:

- first the matrix has been applied fresh to the walls external surface, making the surface as smoothed as possible;
- then the textile was rolled out from the roof, applied to the fresh mortar, pushed against it till a mortar penetration into the textile fabric structure was reached,
- finally a second layer of matrix was applied to externally cover the textile.

This procedure guarantees that a perfect bonding between masonry, matrix and textile is reached.

Figure 5: Seismic Wallpaper application procedure

The result is the reinforced building depicted in Figure 6, the grey colour is given by the outer cementitious matrix layer, covering the quadric-axial textile, which mechanical properties are reported in Table 2 below.

Figure 6: View of the reinforced building

Density	2000 kg/m ³
Young Modulus E_x	40000 MPa
Young Modulus $E_{y,z}$	32000 MPa
Poisson Coefficient ν_{xy}	0.14
Poisson Coefficient ν_{xz}, ν_{yz}	0.2
Shear Modulus $G_{xy}=G_{xz}=G_{yz}$	4500 MPa
Maximum tensile stress σ_t	40 MPa
Maximum shear stress σ_s	10 MPa

Table 2: Mechanical properties of the quadric-axial textile

Before and in parallel with the experimental tests carried on at the Eucentre by means of subsequent seismic events of increasing intensity applied to the base of the reinforced building mounted on an uni-axis shaking table, numerical simulation were mandatory to assess the effectiveness of the reinforcing solution, to predict the building behavior and to achieve knowledge of the textile response to dynamic loads.

This process has been developed and is presented within this paper by means of subsequent steps/analysis which from preliminary finite element model (FEM) and numerical investigations of the un-reinforced building, the building as damaged and the reinforced building, is aimed at describing a proper method for the simulation of the inelastic behavior of this innovative technical textile concept.

3 PRELIMINARY FE ANALYSIS AND COMPARISON WITH EXPERIMENTAL RESULTS

Preliminary numerical simulations have been carried out with the aim of understanding the structural behavior of the un-reinforced building (URB) as a mean of comparison with the reinforced building (REB) behavior. It is worth noting that these simulations did not account for any micro-scale modeling of the seismic wallpaper (i.e. of the quadric-axial textile) since this optimization has been performed in a further step of the study, as reported in chapter4. Here

modal as well as non-linear static and non-linear dynamic analyses have been conceived towards the prediction of the building dynamics in terms of modal parameters (frequencies, damping and mode shapes) for both the URR and the REB. The simulations aimed at understanding the benefits of a full-cover solution with respect to traditional strips reinforcing solution in terms of stress distribution, in ductility capability and in dissipation of energy capacity.

The Ansys software has been identified as suitable for the numerical analyses. The classical implicit formulation has been adopted; the Newton-Raphson iteration algorithm has been implemented. A solid model has been conceived for modeling the stone walls, while shell elements have been used for meshing the wood slab and the wood roof. According to the requirements of the analysis performed the Solid45 and/or the Solid65 element have been used for the stone walls, in particular: the Solid45 element (3-D Structural Solid) has been used when simulating a modal analysis, while the Solid65 element has been judged more suitable, due to its nonlinear capability, to be adopted when performing a non-linear analysis. The seismic wallpaper has been modeled as an equivalent homogeneous lamina by means of shell elements, accounting for both the quadri-axial textile (with fiber oriented at 0° , 90° and $\pm 60^\circ$) and the epoxy-cementitious matrix. A perfect contact in between the solid elements (representing the wall stones) and the shell elements for the wallpaper has been simulated. Shell43 4node non-linear element has been chosen, with both bending and membrane capability.

The FEM of the URB as well as of the REB are shown in Figure 7 below.

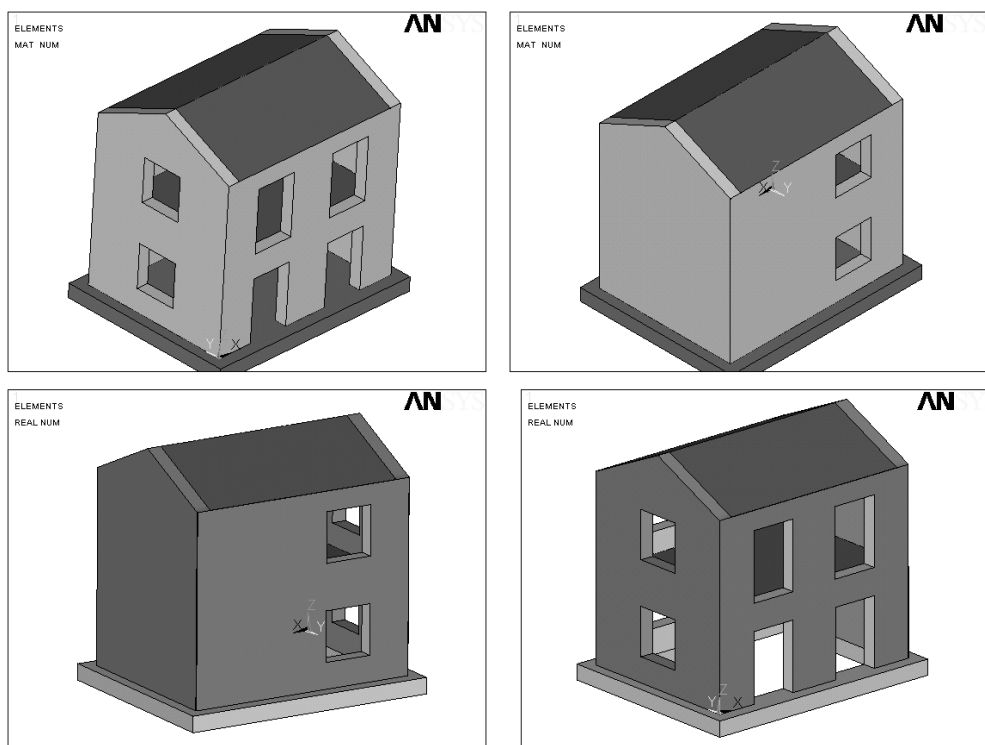

Figure 7: FEM of the un-reinforced building (top) and of the reinforced building (bottom)

3.1 Modal Analysis

The modal analysis aims at predicting the building natural frequencies and modes shapes to be compared with the same parameters identified from experimental tests. In addition a

comparison between the un-reinforced and the reinforced building natural frequencies, as calculated from numerical simulations, is also realized.

Figures 8 reports the displacements field mode shapes for the 1st, the 2nd and the 3rd mode, for the URB and the REB respectively. Table 3 summarizes the results for both configurations in terms of calculated natural frequencies.

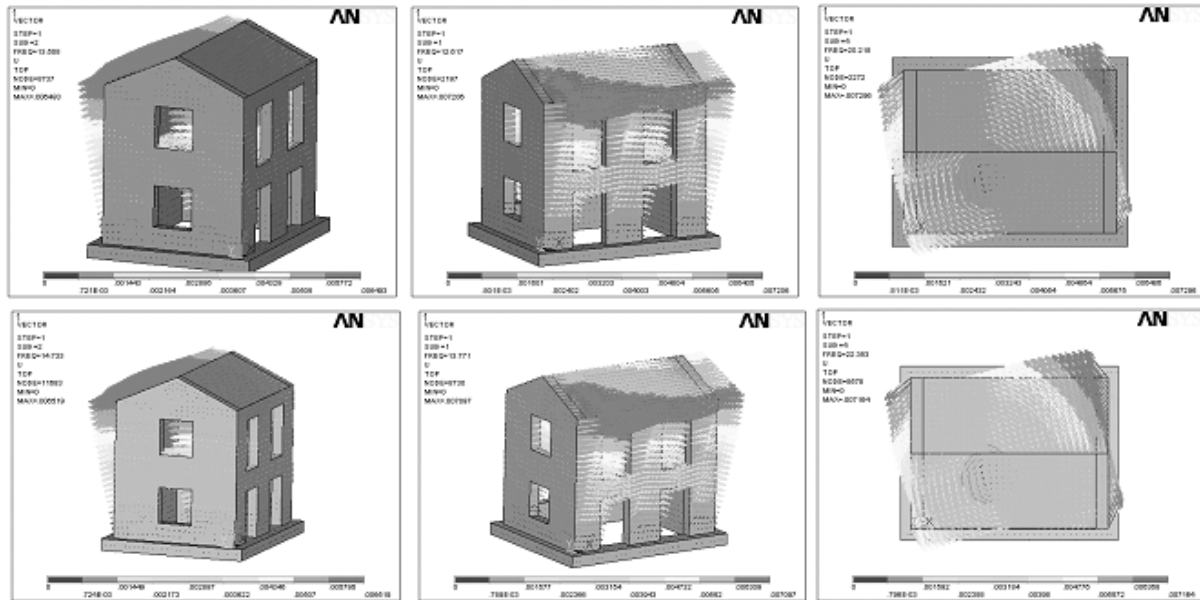

Figure 8: Modal analysis results of the URB (top) and the REB (bottom). Displacements field of the 1st (left plot), 2nd (middle plot) and 3rd (right plot) mode shape

Mode	URB Frequency [Hz]	REB Frequency [Hz]
1 st (translation in Y)	13.51	14.73
2 nd (translation in X)	12.62	13.77
3 rd (torsional)	20.22	22.35

Table 3: Modal analysis results

The results calculated from numerical simulations have been then compared with those coming from experimental ambient vibrations tests carried on for both the URB and the REB. The aim here is to calibrate the numerical model and to give an estimate of the changes the reinforcement is given in terms of the building dynamics.

Four three-axis Geophones have been located on the parapet of the building windows according to the set-up configuration showed of Figure 9. Two sets of ambient vibrations have been recorded at a sampling rate of 265Hz for around half an hour. Two minutes of measurements have been extracted from the global records for both ambient vibration sets. The Operational Modal Analysis (OMA) has been carried on by processing with suitable algorithms (Natural Excitation Technique combined with the Eigensystem Realization Algorithm: Next-ERA) the two minutes records.

Far from the scope of this study, the experimental process is not described in detail. The results are reported in terms of identified natural frequencies for comparison with the numerical calculations (Table 4). The correlation between experimental and numerical natural frequencies is also highlighted in Figure 10, with reference to the URB.

Figure 9: Experimental Ambient Vibration tests sensor set-up

Mode	URB Frequency [Hz]		REB Frequency [Hz]	
	Experimental	Numerical	Experimental	Numerical
1 st (translation in Y)	12.07	13.51	10.30	14.73
2 nd (translation in X)	11.55	12.62	7.41	13.77
3 rd (torsional)	16.27	20.22	18.25	22.35

Table 4: Correlation between experimental and numerical results

With reference to the URB the correlation between numerical and experimental results is good enough (variations in the order of the 10%) to dictate the validity of the FE model. On the contrary for the REB building the difference is quite significant (variation up to 85% on the 2nd natural frequency). The reason comes from the fact that the stone building before being reinforced has been damaged and this damage has not been quantitatively identified while also the crack patterns was not defined. The uncertainties in modeling the existing damage probably caused the not perfect fit between the numerical and the experimental results for the REB. This suggests that a quantification of the damage can be achieved by only micro-scale simulations of the reinforcement as will be presented in chapter 4 of this paper. The preliminary model, with reference to modal analysis, can be considered suitable in defining a reference framework where optimized models can be conceived.

Figure 10: Correlation between experimental and numerical natural frequencies for the URB

3.2 Non-Linear Static Analysis

A non-linear static analysis (pushover) has been carried out to identify the crack patterns and to predict the damage propagation of both the URB and the REB. A distribution of forces proportional to the mass of the building is applied in the longitudinal direction at the level of the first slab and of the wood roof. The force is incrementally increased till the failure level of the stone material is reached. The Solid65 element has been adopted to model the walls stones as it provides the capability to identify the propagation of cracks during the application of the load, as it is suitable for treatment of nonlinear material properties. The element allows cracking in three orthogonal directions, crushing, plastic deformation, and creep. Bilinear stress-strain tension-compression behavior is adopted to simulate the mechanical behavior of the stone elements.

The aim of the analysis for the URB is to show the crack patterns at failure in order to provide a reference case for the simulation of the reinforced building. This allows understanding the benefit in terms of cracks propagation due to the adoption of full-cover reinforcement. In fact, as done for the URB, a pushover analysis has been carried on for the REB. The forces herein applied account for the textile mass.

Figure 11 below reports the results of the simulation for both the URB (top plots) and the REB (bottom plots). In detail the results are depicted in terms of crack patterns (left plots); and plastic strain distribution (right plots).

Figure 11: Pushover analysis results of the URB (top) and the REB (bottom): crack patterns at failure (left plots), plastic strain distribution (right plots)

From Figure 11 it is clear that in terms of plastic strain, a reduction in terms of their amplitude could be reached by the REB with respect to the URB.

To better understand how the reinforcement is modifying the buildings mechanics, a comparison in terms of stress-strain diagram of a control node (located at the top of the frontal wall façade) is given in Figure 12. This allow for quantifying the increase in ductility the REB has been claimed within this paper to give.

Figure 12: Stress and strain diagram of the control node for the URB (blue line) and the REB (grey line)

The REB building exhibits an elastic-plastic behavior with an increase in ductility which is evident by looking at the stress-strain plot in the post-yield field: a decreasing slope corresponding to a brittle material behavior is shown on the top right plot, while a linear horizontal trend (i.e. ductile behavior) is shown by looking at the diagram of Figure 12.

From the pushover analysis it is shown that the full-cover reinforcement allow for accounting a reduction of plasticity and an increase in ultimate strength and ductility of the stone building.

3.3 Non-Linear Dynamic Analysis

Dynamic analyses have been carried out to simulate the building response in its two configurations (URB and REB) under dynamic loads, as those of seismic events. The aim here is to assess in terms of stress-strain distribution the effects of the reinforcement solution.

A series of accelerogram, of increasing intensity, have been simulated. The Montenegro accelerogram scaled at different value of Peak Ground Acceleration (PGA) has been used. It refers to the Montenegro Earthquake happened the 19th of April 1979, with a Magnitude (Ms) of 7.0 and a PGA of 0.22g.

For simplifying the numerical simulations and in accordance to the implicit FE approach (as developed within the Ansys software) instead of a base acceleration, a base displacement is applied to the base nodes of the model. An example of the base displacement time history (referring to the Montenegro accelerogram scaled at 0.1g of PGA) is given in Figure 13 below.

Figure 13: FE dynamic analysis: input displacement time histories referring to the Montenegro accelerogram with PGA scaled to 0.1g

The field vector of the principal stress distribution and the plastic stress distribution at critical time (12.1sec) are chosen as output parameters to be used as a source of comparison in between the URB and the REB results. They allow quantifying the benefits in terms of reduction of the limit stress amplitude and of redistribution (i.e. a more uniform configuration) of the stress field vector due to the full-cover reinforcement. Figure 14 reports these outputs for both the URB (top plots) and the REB (bottom plots).

From Figure 14, it arises that a significant reduction of the plastic strain amplitude is achieved by means of the reinforcement. This is particularly true for the front transversal walls. The beneficial effect of this reduction is obtained thanks to the confinement effect of the full-cover textile reinforcement and to its ability of increasing the building resistance to dynamic loads.

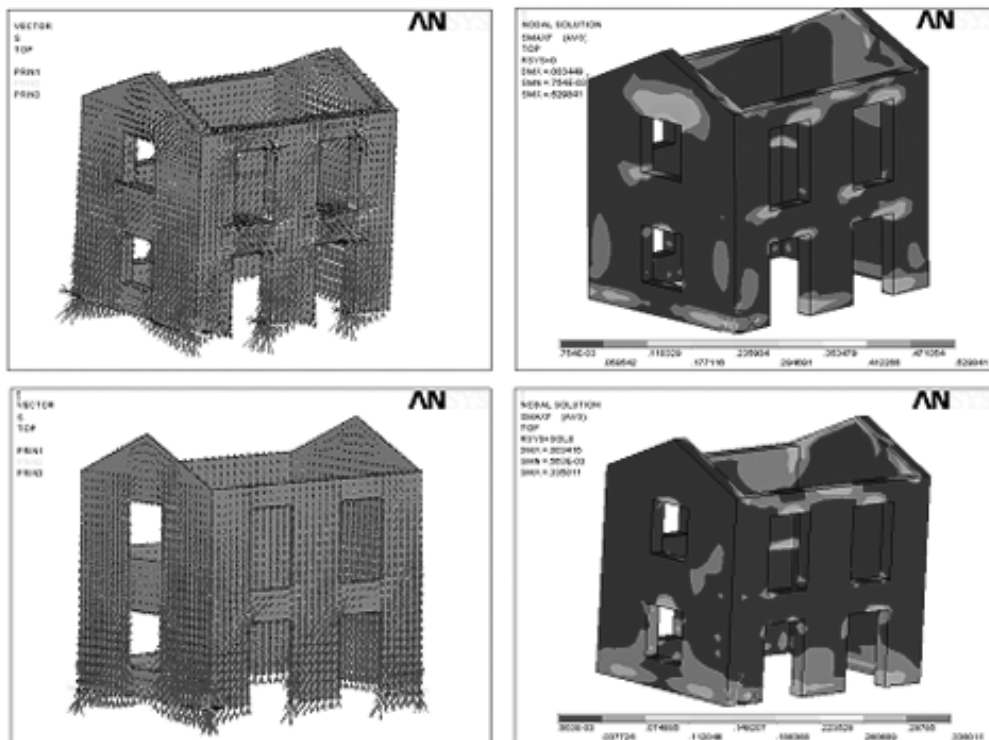

Figure 14: FE dynamic analysis: stress field vector distribution (left) and plastic stress distribution (right) at critical time

4 HEURISTIC TOOL FOR THE SIMULATION OF THE TEXTILE BEHAVIOUR

For the proper simulation of the inelastic behavior of this innovative textile an evolutionary approach will be implemented. This process utilizes Genetic Algorithms (GAs) as the optimizing tool for the identification of the parameters that govern the multiaxial polymer material behavior. This heuristic tool has been chosen for this problem since in contrast to gradient based approaches GAs do not require a straightforward analytical relationship connecting the function to be optimized to the design parameters of the problem. Instead, they can handle even loosely defined problems. A meso-scale approach will be followed, where a finite element algorithm (ANSYS) is used for the simulation of the model structure. The parameters to be identified involve both the setup of the finite element characteristic volume chosen to simulate the polymer textile, i.e. number of layers, thickness, layout, as well as the polymer and masonry material properties, i.e. Elasticity modulus, ultimate strength, etc. This constitutes the setup of the forward problem (Figure 15) which will have to be iteratively solved as part of the evolutionary cycle until convergence is achieved to a minimal error between the experimentally observed and the numerically computed behavior.

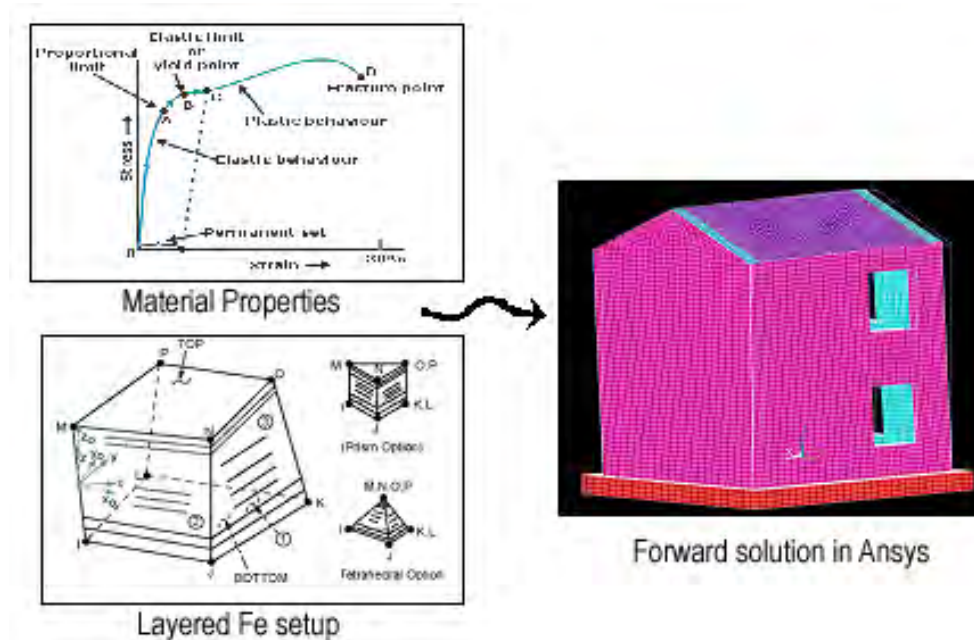

Figure 15: Forward Run

All genetic algorithms are based on the following scheme:

4.1 Representation

Depending on the application the parameters of the problem can be either integer or real numbers. Usually, the set of parameters can be appropriately encoded into a finite length binary string. Once a representation is decided a number of different chromosomes is randomly generated to form the initial population.

4.2 Fitness evaluation/selection

The evaluation of the fitness for each member of the population is carried out through the use of an objective function associated with each problem. The suitability of each chromosome is the criterion based on which this individual will be selected for reproduction. Selection can be

performed through various schemes like “roulette wheel” selection or “tournament” selection. The roulette wheel selection is solely dependent upon the performance (fitness) of each individual. In the case of the second method, the probability of a string selection is also dependent upon the fitness of the “competitive” strings chosen to participate in a tournament round. The latter contributes toward the preservation of the diversity of the population.

4.3 Crossover

This operator is applied with a certain probability, to the pairs of the previously selected individuals (parents). In general the crossover procedure randomly selects a position in the binary string and mutually exchanges the parts of the chromosome before and after this location in order to produce two offsprings.

4.4 Mutation

The use of the crossover procedure as the only means for generating new individuals could result in the loss of the diversity of the population. This problem can be overcome using the mutation operator which involves the random flip of the binary genes of the chromosome for the case of jump mutation, or the alteration of the phenotypic (real) representation of the design parameters by a small increment or decrement for the case of creep mutation. More information on the basic (classic) GA scheme can be found in [10]-[14]. The following figure illustrates the basic workings of the GA-FE optimization scheme.

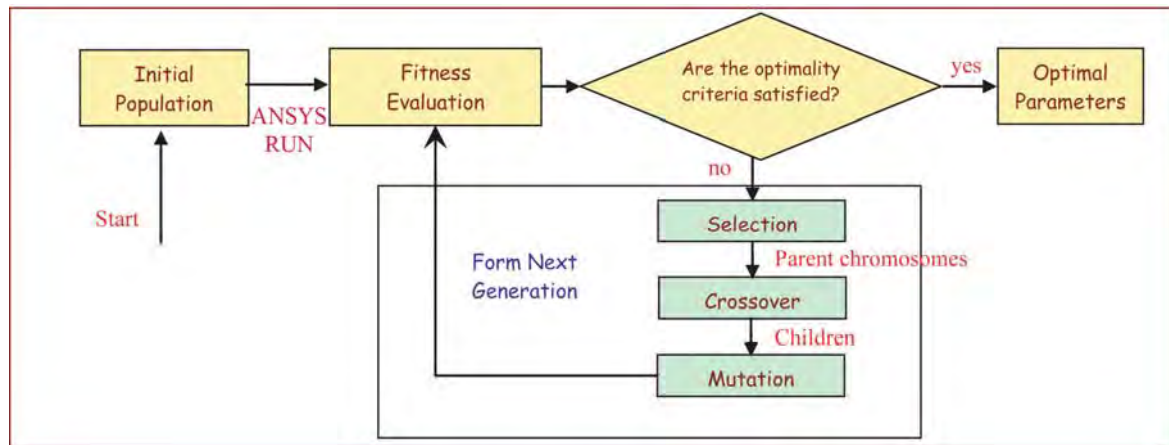

Figure 16: GA-FE Scheme

On a first level, the experimental modal analysis results listed in Table 4 for the Unreinforced Structure will serve as a reference for the calibration of the masonry material properties. On a second level the experimental modal frequencies of the Retrofitted Structure will serve as a reference for the calibration of the polymer elastic properties as well as the representative volume configuration. The error function used to evaluate the fitness of each potential set of parameters in both cases is expressed as the L_2 relative error norm:

$$r = \frac{\|\lambda_e - \lambda_m\|}{\|\lambda_m\|} \quad (1)$$

Where λ_e is the GA estimated eigenvalue vector and λ_m is the experimentally determined one. Finally, the acceleration and strain history results from the shake table test number 3, af-

ter which failure was originally noted will serve as the basis for the proper configuration of the masonry and polymer textile ultimate strength properties.

A full transient time history analysis is generally computationally expensive; therefore a response spectrum analysis will serve as the tool for the forward problem solution in this final stage, cutting down significantly on the computational cost. The fitness function in this case will be defined as the L_2 relative error norm of the maximum displacements and trains obtained from the FE Response Spectrum analysis as compared to the experimentally observed ones during the shake table test.

The finally identified parameters will ultimately be validated using a full on transient time history analysis the results of which will be compared to the actually recorded acceleration and train records at the available sensor locations.

5 DAMAGE DETECTION BY MEANS OF STRAIN MEASUREMENTS

An experimental tests campaign has been carried on aimed at detecting the REB dynamics by means of FBG sensors embedded textile. Hammer tests were performed after each simulated seismic event as reported in Table 5.

Test	Description
1	Modal identification after the 1 st seismic test (Montenegro accelerogram scaled to 0.1g of PGA)
2	Modal identification after the 2 nd seismic test (Montenegro accelerogram scaled to 0.3g of PGA)
3	Modal identification after the 3 rd seismic test (Montenegro accelerogram scaled to 0.4g of PGA)
4	Modal identification after the 5 th seismic test (Montenegro accelerogram scaled to 0.6g of PGA)

Table 5: Experimental modal identification tests chronology

The sensor topology was chosen as shown in Figure 17: a total of 8 FBG sensors (active length of 2m) have been installed on Wall1, 2, 3 and 4. The excitation point is also depicted with a red arrow in Figure 17.

Figure 17: Experimental modal identification tests set-up: 3D view (left); plane view (right)

For each test, two hammer trials along X-direction and two along Y-direction have been conducted. From the data recorded by FBG sensors an Operational Modal Analysis (OMA) has been carried by adopting the ERA algorithm.

For seek of brevity in what follows only the most significant results (for test1 and test4) are depicted in the time (strain Time History) and frequency (Power Spectral Density function – PSD) domain. Singular Values Decomposition (SVD) plots are also showed. Table 6 summarizes the results in terms of identified natural frequencies.

Each sensor records the structural response in terms of axial strain, sampling at 1000Hz, manually down-sampled at 100Hz. Such sampling frequency defines a frequency range 0-50Hz (according to the Nyquist theorem) which is good enough to detect the building natural frequencies, as dictated by the FE modal simulations.

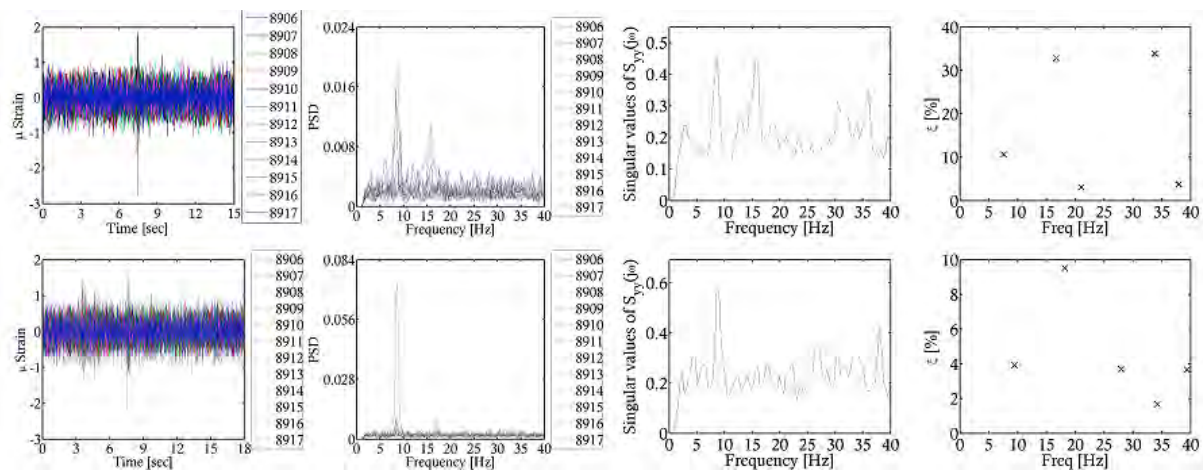

Figure 18: Test1 results for the hammer tests along X (top) and hammer tests along Y (bottom). Calculated displacements Time History (left plot), Power Spectral Density function (middle left plot); Singular Values as obtained by the SVD of the PSD matrix (middle right plot); Identified frequency vs. identified damping from Next-ERA algorithm (right plot)

Figure 19: Test4 results for the hammer tests along X (top) and hammer tests along Y (bottom). Calculated displacements Time History (left plot), Power Spectral Density function (middle left plot); Singular Values as obtained by the SVD of the PSD matrix (middle right plot); Identified frequency vs. identified damping from Next-ERA algorithm (right plot)

Mode	Test1 (1 st seismic test) Freq. [Hz]	Test2 (2 nd seismic test) Freq. [Hz]	Test3 (3 rd seismic test) Freq. [Hz]	Test4 (5 th seismic test) Freq. [Hz]
First mode (Y)	8.98	8.88	12.42	8.98
Second mode (X)	7.60	8.07	7.86	7.78
Third mode (tors)	15.39	15.49	13.92	13.86

Table 6: Identified natural frequencies

To define the evolution/variations of the building natural frequencies from Test1 to Test4, Figure 20 depicts the SVDs as calculated for the hammer tests in the X and Y direction respectively. This graph gives an idea of how, at least for the 1st and the 2nd mode, the natural frequencies associated to translational modes of the building (1st in Y direction, 2nd in X direction) varies according to the different structural configuration of the building after each seismic test.

It is worth noting, as not mentioned previously that some considerations may be done, based on the measurements recorded during the seismic tests, on the structural changes of the stones building and on the development of a progressive failure condition. These following considerations are strongly related to what it is expended to extract from the hammer tests data in terms of frequencies and then of damage detection. In other words if a failure is locally and/or globally identified after a seismic event, this has to corresponds to changes in the building dynamics (i.e. variation of natural frequencies). To understand if a correlation is possible the following considerations should be preliminary highlighted:

- After the 1st seismic test (PGA 0.1g) the #REB was not affected by any damage, the structure resists to the dynamic force easily and not visual damage was detected. From the data processing, no plastic (i.e. permanent) deformation was measured;
- After the 2nd seismic test (PGA 0.3g) the #REB was not affected by any evident damage and no plastic deformations were detected;
- After the 3rd seismic test (PGA 0.4g) the #REB was affected by structural damage which mainly occurred at the top of the windows of wall2, where sensors SN8912 and SN8913 were installed. From the data processing of the measurements recorded during the seismic test, plastic strains were detected;
- After the 4th seismic test (PGA 0.5g) the #REB, localized damage by the 3rd test, was able to respond with no apparent further cracks. No additional plastic deformation was recorded;
- After the 5th seismic test (PGA 0.6g) the #REB was able to resist to the strong seismic shake with evident damages which were globally located on the building walls (above all on Wall1). Additional and significant plastic deformations were recorded during the seismic test. A damaged configuration seems to be the more appropriate to describe the #REB after the 5th test.

Figure 20: Tests 1-4 system identification results: Singular Values as obtained by the SVD of the PSD matrix for the hammer tests in X direction (left), in Y direction (right)

From Figure 20 some trends may be evidenced in terms of 1st in X and 1st in Y (see blue and black lines at the first peak) natural frequencies variations from test1 to test4. Figure 21 highlights them by separating the SVD graphs obtained for Test1 to those of Test4. The values of the natural frequencies depicted in Figure 21 are reported in Table 7 below.

Figure 21: Tests 1-4 system identification results: Singular Values as obtained by the SVD of the PSD matrix for the hammer tests in X direction (top) and in Y direction (bottom): Test1 results (left), Test4 results (right)

From Figure 21 it can be noted that:

- the 1st first mode natural frequency decreases from 8.59Hz to 7.81Hz, which means a reduction of the 9.1%. This indicates also for the building natural movements along the transversal direction (Y axis) that the building stiffness decreased from the 1st to the 5th seismic test, due to cracks opening into Wall2;

- the 2nd mode natural frequency decreases from 8.59Hz to 7.03Hz, which means a reduction of the 18.2% X. This indicates that the REB was either less stiff or its weight was increased after the last seismic test than after the 1st seismic test. As no mass was added, the building after five subsequent seismic tests was less stiff due to cracks openings in localized positions. In addition this was also due to an out-of-plane mechanism of Wall1 along the longitudinal direction (X-axis).

	Test1 (after the 1 st seismic test)		Test4 (after the 5 th seismic test)	
	Freq. [Hz]		Freq. [Hz]	
	First mode (Y)	Second mode (X)	First mode (Y)	Second mode (X)
FBG sensors	8.59	8.59	7.81	7.03

Table 7: Identified natural frequencies for test1 and test4 from SVD

6 CONCLUSIONS

Sensor-embedded reinforcing textiles offer the engineer a new tool for the retrofit of masonry structures. These multifunctional materials reinforce and monitor in one product. As such, they strengthen, reduce seismic risk, and provide the engineer with data that can be utilized to assess a structure in all phases of its life cycle.

The “Composite Seismic Wallpaper”, described along this paper, is an innovative example of such type of multifunctional materials. The main outcomes from an experimental tests campaign, as well as the main results of numerical investigations have been here detailed. The objective was to furnish elements for the validation of the performance of the wallpaper as seismic reinforcement of masonry buildings.

The characterization of the wallpaper behavior is highlighted in Chapter 4, while its ability to be used as a tool for damage detection of cracks in the reinforced structure is reported in Chapter 5.

Keywords: Seismic Isolation, Buildings, Bridges, Plants, Cultural Heritage, Retrofit.

Abstract. *Seismic isolation (SI) has been used in Italy for several applications, which include important retrofits of civil structures and cultural heritage. Some new hospitals, all new civil defence centres and most new schools have already been (or are being) isolated, together with a significant number of dwelling buildings and other constructions. The 2009 Abruzzo earthquake caused an increase of the number of the Italian isolated buildings from about 70 to over 300. Prior to the aforesaid event, the Italian SI systems consisted in High Damping Rubber Bearings (HDRBs) or Lead Rubber Bearings, to which plane surfaces steel-PTFE Sliding Devices (SDs) were added in the last years. Now, Curved Surface Slider devices are also in use. The first Italian building to be retrofitted with SI was a reinforced concrete (r.c.) civic centre in Naples in 2004. Its foundation pillars and walls were cut, approximately 600 HDRBs were installed and a steel beams floor was added above the isolators to stiffen the superstructure base as necessary. In the same year, two 4-storey r.c. dwelling buildings were retrofitted, each with 12 HDRBs and 13 SDs, in Solarino, near Syracuse. In 2005 the first European retrofit with SI in a sub-foundation was completed: it concerned a 3-storey r.c. house in Fabriano that had suffered severe but non-structural damage in the 1997-98 Marche & Umbria quake. For this intervention 56 HDRBs were used. Further retrofits with SI were also performed for churches, schools, further dwelling buildings, tanks, single masterpieces, etc. The significant extension of the use of SI after the Abruzzo quake concerns this and other Italian regions. The new applications include numerous retrofits: at L'Aquila they mainly concern civil and monumental buildings damaged by the quake. In the latter, the SI system will be inserted in a sub-foundation, not to cut the structural elements or existing foundations, and a new method patented by ENEA and Polytechnic of Torino in 2010 will also be used.*

1 INTRODUCTION

Over 16,000 structures in the world have been protected by anti-seismic (AS) systems and devices, mainly by the seismic isolation (SI) or energy dissipation (ED) ones [1-11]. They are located in over 30 countries (Figure 1) and concern both new constructions and retrofits of existing structures of all kinds: bridges and viaducts, civil and industrial buildings, cultural heritage and industrial components and installations, including some high risk nuclear and chemical plants. The use of the AS systems in a civil context already includes not only the strategic structures (civil defence centres, hospitals) and the public ones (schools, churches, commercial centres, hotels, airports), but also residential buildings and even many small private houses. Everywhere, the number of such applications is increasing more and more, although it is strongly influenced by earthquake experience and the availability and features of the design rules used [9].

Most SI systems rely on the use of rubber bearings (RBs), namely High Damping Rubber Bearings (HDRBs), or Lead Rubber Bearings (LRBs) or (mainly in Japan) Low Damping Rubber Bearings (LDRBs) in parallel with dampers of various kinds; in buildings, some plane surfaces steel-teflon (PTFE) Sliding Devices (SDs) are frequently added to the RBs to support their light parts and/or minimize the torsion effect if they are significantly asymmetric in the horizontal plane [9].

Figure 1: Overall number of building applications of seismic isolation in the most active countries (left); overall number of building applications of SI in Italy during years (right). Data refer to the end of 2009.

2 WORLDWIDE APPLICATION OF THE ANTI-SEISMIC SYSTEMS & DEVICES

Japan is largely the worldwide leader for the number of applications of the AS systems (Figure 1). This occurs also thanks to an adequate code and the excellent behaviour of numerous buildings protected by SI during an already significant number of earthquakes (starting from the 1995 *Hyogo-ken Nanbu* event, of magnitude $M = 7.3$). More precisely, in Japan there are now over 6,000 isolated buildings or houses [11, 12], besides several isolated bridges & viaducts and (at the end of 2009) about 3,000 constructions protected by dampers [9, 10]. There the trend is to isolate, on the one hand, even high-rise buildings and sets of buildings supported by common “artificial ground” slabs and, on the other hand, even small private houses. Moreover, recent projects concern three-directional (3D) SI of civil buildings, retrofit of cultural heritage, protection of industrial factories (e.g. for semi-conductors), etc.

The USA are second, with “only” 100÷200 large, new and retrofitted, civil and historical, isolated buildings, but over 650 isolated bridges or viaducts and approximately 1,000 applications of dampers at the end of 2009 [9, 10]. Building application of SI is relatively limited (in spite of the excellent behaviour of some isolated ones during the 1994 *Northridge* earth-

quake), due to a very penalizing code [9, 10].

The Peoples' Republic (P.R.) of China is third, with about 690 isolated buildings and over 100 ones with ED or other systems (at the end of 2009), besides numerous isolated bridges & viaducts [9, 10]. There too application is rapidly increasing. It includes several reinforced concrete (r.c.) and also masonry dwelling buildings, as well as SI of some Liquefied Natural Gas (LNG) tanks. Like in Japan, the use of 3D SI and "artificial grounds" started, together with retrofit of cultural heritage and roof SI of large span structures. The excellent behaviour of some isolated r.c. and masonry buildings during the 2008 *Wenchuan* earthquake (of magnitude M close to 8.0), although this had been largely underestimated [7, 9, 10], is further accelerating the use of AS systems in China.

Forth is the Russian Federation, with about 600 isolated buildings (including retrofits of some important historical constructions) and several new ongoing projects, concerning even high-rise buildings (one, the 27-storey *Sea Plaza* Hotel in Sochi, is protected by Italian HDRBs) [9, 10].

Italy remains fifth and first in Western Europe for the overall number of applications of the AS systems (Section 3) [5, 9, 10, 11]. It is followed by South Korea, Taiwan, Armenia, New Zealand, France, Mexico, Canada and Chile [9, 10]. In Taiwan the present significant use of the AS systems is due to the 1999 *Chi Chi* earthquake and the subsequently enforced new seismic code, which promotes the use of the AS systems. In Armenia the adoption of SI began after the 1988 *Spitak* event and the number of applications per inhabitants is the largest in the world after that in Japan, although this country is still developing [6]. In New Zealand, one of the motherlands of AS devices (in particular of those based on the use of lead) and third for the number of their applications per inhabitants, the isolated structures had an excellent behaviour in the 2010 *Canterbury* earthquake of $M = 7.1$ [10, 11]. In France SI has been used to protect the *Jules Horowitz Reactor* and has been planned for the *ITER* plant for the controlled nuclear fusion in the mainland, while it is obligatory for schools and other public buildings in its Martinique island. Finally, similar to New Zealand, the isolated structures in Santiago had an excellent behaviour in Chile too, during the 2010 *Maule* earthquake of $M = 8.8$ [10, 11].

Important applications of the AS systems also began in Turkey (after the 1999 *Kocaeli* and *Duzce* earthquakes) and other European countries [8-11]: many of them make use of Italian AS devices (in Turkey, Greece, Portugal, Spain) or Italian designs too (in Cyprus, Romania). Italian devices have also been installed in Taiwan, South Korea, Venezuela, Indonesia, the USA, Canada, Iran (where a huge project is in progress for isolating the whole new town of Parand, near Tehran), etc. Finally, Macedonia shall be cited, because it hosts the first modern application of SI worldwide, that to the *Pestolazzi* school in Skopje, erected after the destructive 1963 earthquake: its original poorly laminated and very deteriorated rubber isolators were replaced by HDRBs in 2007 [9-11].

3 APPLICATION OF THE ANTI-SEISMIC SYSTEMS & DEVICES IN ITALY

As mentioned above, Italy is fifth at worldwide level and first in Western Europe for the overall number of applications of the AS systems (Figure 1). There, the use of such systems began in 1975 for bridges and viaducts (*Somplago* viaduct of the *Udine-Tarvisio* freeway, which survived intact the second shock of the 1976 *Friuli* earthquake) and in 1981, namely 4 years before Japan and the USA, for buildings (main building of the new *Fire Command Centre* of Naples, the design of which was "retrofitted" with isolators, dampers and other AS devices as a consequence of the seismic classification of the Naples area in seismic category 3 after the 1980 *Campano-Lucano* earthquake) [1, 2].

In 2009, Italy passed the USA for the number of isolated buildings [5, 8, 9]: those in use were about 70 before the *Abruzzo* earthquake of April 6 of that year ($M = 6.3$), with further

20÷30 under construction or design, and are now approximately 300 (Figure 1). In fact, in Italy, after many years of a rather limited use of the AS systems (due to the lack of design rules to the end of 1998, then to their inadequacy and very complicated and time-consuming approval process to May 2003 [1, 2]), there has been a large increase of the number of new projects in the last years [3, 8-11].

Figure 2: Collapse of the *Francesco Jovine* primary school of San Giuliano di Puglia (Campobasso) during the 2002 *Molise & Puglia* earthquake and search of survivors amid the debris. Prior to the aforesaid earthquake the San Giuliano di Puglia area was not seismically classified (now it is classified in seismic zone 2).

Figure 3: The *Prefettura* building (provincial headquarters of the national government) of L'Aquila, a symbol of lack of prevention of the seismic risk in Italy until 2009 (left), and the *Santa Maria Paganica Church* (right), collapsed after the 2009 *Abruzzo* earthquake.

This occurred first thanks to the new Italian seismic code, enforced in May 2003, which freed and simplified the adoption of the AS systems [1, 2, 5, 8, 9]. This code, which became of obligatory use after the 2009 *Abruzzo* earthquake, was mostly a consequence of the collapse of the *Francesco Jovine* school in San Giuliano di Puglia (due to its bad construction and even worse raising) during the 2002 *Molise & Puglia* event (Figure 2).

An even larger use of the AS systems is now in progress, as a consequence of the heavy damage caused by the 2009 *Abruzzo* earthquake to the conventionally founded civil structures and cultural heritage (Figure 3 and 4) [5, 10, 11]: in particular, 184 pre-fabricated houses were erected in L'Aquila, each on a large isolated large r.c. slab to provisionally host 17,000 homeless persons (at least in the first years). These have been isolated using Italian Curved Surface Slider (CSS) devices, but the use of the traditional HDRBs or LRBs, in conjunction with some SDs, is also going on, for both new constructions and retrofits (Section 4). In particular, the new *Francesco Jovine*, protected by a SI system designed with the collaboration of ENEA and formed by HDRBs and SDs (Figure 5), which has been first Italian isolated school, has

been followed by several further projects of this kind: seismic protection of schools by means of SI, besides that of hospitals and other strategic structures, is now a “priority 1” objective in Italy (see Section 5) [9-11].

Figure 4: Collapse of statues in the L'Aquila Museum after the 2009 *Abruzzo* earthquake. Such a disaster should make the opponents of the development and installation of an adequate seismic protection system for the marble statue of *David of Michelangelo* think it over (this worldwide known masterpiece, exhibited in the *Galleria dell'Accademia* in Florence, is severely fissured at its ankles, which makes it very vulnerable to both seismic and even environmental vibrations [1-4]).

Figure 5: The new *Francesco Jovine* primary school and the “*Tre Torri*” multifunctional complex in San Giuliano di Puglia (now seismic zone 2), supported by a common isolated artificial ground slab, which was certified as safe by A. Martelli in September 2008 (left); their SI system, formed by 61 HDRBs and 12 SDs donated by the Italian manufacturers, during construction (right). These buildings will be seismically monitored [10, 11].

Moreover, the use of the AS systems is going on for bridges and viaducts (those with such systems were already at least 250 in 2009 [4]) and cultural heritage [9-11]: new retrofit techniques using SI, applicable to monumental buildings, will be applied for the reconstruction of L'Aquila (Sect. 4).

It is noted that the application of the AS systems in Italy has greatly benefitted from the collaborations in progress in the framework of the national association GLIS (“GLIS – Isolamento ed altre Strategie di Progettazione Antisismica”, namely “GLIS – Isolation and other Anti-Seismic Design Strategies”) since 1989 at national level and in that of ASSISI (Anti-Seismic Systems International Society) since 2002 at international level.

4 ITALIAN RETROFITS WITH SEISMIC ISOLATION

As previously stressed, the *Abruzzo* earthquake of April 6, 2009 caused an increase of the number of the Italian seismically isolated buildings from about 70 to over 300. Several new Italian hospitals, all new civil defence centres and most new schools have already been (or are

already being) seismically isolated, together with a significant number of dwelling buildings and other constructions [9-11]. SI has also been used for some important retrofits of civil structures and precious masterpieces. Prior to the aforesaid event, in almost all applications, the Italian SI systems consisted in HDRBs or LRBs, to which some SDs were added in the last years. Now, as mentioned in Sect. 3, CSS devices are also in use (mainly at L'Aquila).

Figure 6: The *Rione Traiano Polyfunctional Centre* in Soccavo (Naples) before being retrofitted (left); its finite-element model, which stresses its large asymmetries (at the centre); completion of its external parts, which was carried out in parallel to the insertion of the SI system (right).

Figure 7: Phases of the retrofit of the building of Figure 6, with installation of 4 hydraulic jacks to provisionally support the weight after removal of the pillar part to be replaced by an isolator and to locally lift the building, so as to allow for the subsequent insertion of the isolator (left), and cut of the pillar with a linear saw (at the centre); view of the isolator after its installation and its mechanical fixing to the upper and lower pillar parts (right).

Figure 8: Installation of the steel beams floor in the building of Figure 6 just above the isolators and reinforcement of the pillars (left); the lower floor after cut of the building supporting pillars and walls (at the centre); the building after retrofit completion (right).

4.1 Rione Traiano Polyfunctional Centre in Naples

The first Italian building to be retrofitted with SI was the *Rione Traiano Polyfunctional Centre* in Naples in 2004. It is a large ($100,000 \text{ m}^3$ volume, $33,000 \text{ m}^2$ living area), very asymmetric, 4-storey r.c. building with piled foundations, erected in the years '70s, when the Naples area was not yet considered as seismic, then left incomplete, due to lack of funds (Figure 6) [1, 2]. The intervention was designed by the GLIS members Prof. R. Sparacio of the University of Naples "Federico II", his collaborator F. Cavuoto, Prof. P. Pinto of the University of Rome "La Sapienza" and A. Dusi of NUMERIA (Cremona).

Retrofit with SI was found by the designers to be the only way to avoid demolition and re-construction. Thus, the foundation pillars and walls were cut (Figure 7), approximately 600 HDRBs were installed, the pillars were reinforced and a steel beams floor was added just above the isolators to provide the stiffness necessary to allow for the correct transmission of the horizontal forces to the isolators themselves and to the superstructure (Figure 8). The retrofit method was similar to that used in 1991 for the Rockwell International Building in Seal Bach, near Los Angeles (California, USA).

This retrofit was designed and performed according to the seismic code applicable before the enforcement of the new one in 2003. As required at that time for the isolated buildings, the design was submitted to the approval of the High Council of Public Works (“Consiglio Superiore dei Lavori Pubblici” or CSLP) of the Italian Ministry of Constructions. The overall cost of the intervention was 2.5 M€, namely 80 €/m². Of the total costs, 1.3 M€ concerned the isolators and their insertion, 0.6 M€ the steel slab, 0.5 M€ the ground retaining walls and the structural gaps and 0.1 M€ accessories. In normal conditions 20 HDRBs per week were installed by each workers team (with up to 3 teams, in the most busy period).

Figure 9: The two dwelling buildings in Solarino before being retrofitted (left); horizontal section of one of the buildings, with location of the isolators (at the centre); two superposed HDRBs during their acceptance tests concerning the application of transverse deformations under the design vertical load (right).

Figure 10: A HDRB during its installation in one of the buildings of Figure 9 (left); this building after retrofit completion (at the centre); an isolator laterally deformed during the on-site tests (right).

4.2 Solarino dwelling buildings

The second Italian building retrofit with SI was performed again in 2004. It concerned two 4-storey r.c. dwelling buildings in Solarino (Syracuse), which had also been left incomplete for some years due to lack of funds (Figures 9 and 10) [1, 2]. Each of them was retrofitted by means of 12 HDRBs and 13 SDs. This retrofit too was performed (by Prof. G. Oliveto of Catania University and others) according to the seismic code applicable before the enforcement of the new one in 2003.

After completion of the intervention, one of the buildings was subjected to free vibration pull-back on-site tests (similar to those previously performed in 1990 for one of the 5 isolated buildings, 25 m high, of the *Telecom Italia Regional Centre* in Ancona and, later, for one of

the isolated buildings of the *University of Basilicata* in Potenza and an isolated house in Rapolla, near the same town [1, 2]).

4.3 Fabriano house

In 2005 the first European retrofit with SI in a sub-foundation was completed: it concerned a rather asymmetric 3-storey r.c. dwelling house (11 apartments), which had suffered severe but non-structural damage during the 1997-98 *Marche & Umbria* quake (Figures 11-12).

Figure 11: Vertical and horizontal sections of the original and the retrofitted dwelling house in Fabriano (from left to right).

Figure 12: External and internal non structural damage suffered by the house of Figure 11 in the 1997-98 *Marche & Umbria* earthquake.

Figure 13: Creation of the structural gap around the house of Figure 11 (left); view from the top of the original lower floor and the new underground one after excavation of the latter and construction of new curbs (at the centre); view from the bottom of the new underground floor, the original foundation piles and the new foundations under constructions (right).

This type of intervention (Figure 13-20), which made use of 56 HDRBs of two sizes (400 mm and 450 mm diameters – see Figure 16), was selected by the designer (the GLIS and ASSISi member G. Mancinelli of Fabriano) and funded by the government for economic reasons: in fact, its cost was demonstrated to be 20% lower than that of a conventional intervention (which would have required the demolition of all non-structural elements, reinforcement of pillars and beam-pillar nodes and not easy insertion of shear walls); it also enabled to considerably improve the foundations (which consisted of couples of piles) and to obtain a new underground floor. For this building too, the design was completed before the enforcement of the 2003 new seismic code, thus it was submitted for approval to the CSLP (it was necessary to wait more than 2 years before obtaining such an approval, although this was given based on the documentation that had been provided to CSLP since the beginning!).

Figure 14: Newly built foundation piles, in the part of the house of Figure 11 where the original ones were failing (left and at the centre); pillar eccentric with respect to the original foundation piles (right).

Figure 15: Setting up of the reinforcement of the lower stump of the new pillar (by means of a dummy isolator) and of the lower plate for connecting the isolator in the new underground floor of the house of Figure 11.

The planned construction phases consisted in:

- realization of the ground retaining wall around the house (Figure 13);
- reinforcement or reconstruction of curbs at the existing basement level (Figure 13);
- excavation under the existing basement level at the side of the original foundation piles (Figure 13);
- injection of the new foundations piles around the base of the original ones and realization of the basement of the new underground floor (Figures 13 and 14);
- construction of the r.c. upper stumps of the pillars in the new underground floor, by encompassing the upper part of the original foundation piles, with the upper connection plates for the isolators attached through shanks (Figure 15);
- setting up of the steel reinforcement of the lower stumps of the pillars in the new underground floor, with the lower connection plate for the isolators attached through shanks, using a dummy isolator to correctly fix the distance between the two stumps (Figure 15);

- subsequent construction of the lower stumps of the pillars in the new underground floor;
- construction of the first r.c. slab above the new underground floor (Figure 16);
- insertion of the isolators (Figure 16), superposed to flat jacks (Figure 17), and injection of epoxy resins inside the latter to release the original foundation piles and let the vertical load be carried by the isolators;
- cut of the original foundation columns at the side of the isolators, by leaving the two resulting stumps in place to create a vertical fail-safe system (separated by a few centimetres, in order to avoid contact when the isolated superstructure lowers due to its transverse motion) and completion of the lateral structural gap around the house (Figure 17);

Figure 16: New r.c. slab of the ground level floor of the house of Figure 11 (left); the HDRBs before their installation in the new underground floor (at the centre and right).

Figure 17: Lateral structural gap of the house of Figure 11 before the installation of its protection plates (left); the new underground floor after installation of the HDRBs, but before demolition of the parts of the original foundation piles which were not encompassed by the new pillars (at the centre); an installed HDRB superposed to an epoxy flat jack (right).

Figure 18: HDRBs installed between two original (left) and two newly built (at the centre) foundation piles of the house of Figure 11, before demolition of their parts which were not encompassed by the new pillars; the underground floor after demolition of the aforesaid parts (right).

- installation of the various pipe lines, provided with suitable fixing systems and adequate joints for the interface ones, to let them remain undamaged during the isolated

superstructure motion (Figure 19) and of the protection plates of the structural gap (such as not to hinder both the lateral and the small vertical motions of the isolated superstructure during an earthquake).

However, some unexpected problems were detected during the works, which considerably complicated them and delayed the retrofit completion, e.g.:

- the absence of about 50% of the foundation piles in one of the house two halves (evidently due to the presence of large water quantities in the ground during the initial construction), which may at least partly explain the damages caused by the earthquake and made it necessary to build these piles before going on with the retrofit intervention (Figures 14 and 18);
- eccentricities between the foundation piles and the house original pillars, in some positions (Figure 14), which made it impossible to set up the aforesaid planned fail-safe systems through the simple cut of the old foundation piles at the side of the isolators and forced, on the contrary, to fully demolish the parts of such piles that were not encompassed in the new upper and lower pillar stumps (Figure 18 and 19).

Furthermore, some “classical” construction errors were found, for instance holes in the beams to realize passages for pipes (Figure 20).

Figure 19: A HDBR installed, after demolition of the parts of the original foundation piles which were not encompassed by the new pillars (left); the new underground floor in the aforesaid conditions and after the installation of the pipe lines (at the centre and right).

Figure 20: Holes and breaks in the beams of the house of Figure 11, made during the initial construction to create passages for the pipe lines (left and at the centre); the house after retrofit completion (right).

The building safety was certified by A. Martelli, after the full construction completion (i.e. including the installation of the protection plates of the structural gaps and that of all pipilines). It is noted that, according to the construction permissions obtained, the use of the new

underground floor is not permitted (it is considered as a “technical volume”), although its spaces would allow for its utilization as garage and/or cellars. Should this change of use be permitted in the future, protections of the HDRBs from fire shall be inserted.

4.4 Further retrofits performed or designed before the 2009 *Abruzzo* earthquake

Further retrofits with SI have also concerned other types of buildings, like churches (starting from that of the dome of the *Sanctuary of Madonna delle Lacrime* of Syracuse in 2006, see Figure 21), r.c. and masonry dwelling buildings (starting from that of one at Rocca di Castell’Ottieri, Grosseto, in 2007), schools (starting from that of the *Quasimodo* school at Riposto, Catania, in 2009), hotels (Figure 22), etc. [5].

Figure 21: Seismic retrofit of the *Madonna delle Lacrime Sanctuary* at Syracuse (containing up to 11·000 people), performed in 2007 by uplifting the 22,000 t dome (left) and by inserting isolators with elastic-plastic damping elements (at the centre and right).

Figure 22: New ceiling of the *Crowne Plaza Hotel* in Caserta, set up by the GLIS board member and ASSISI member G.C. Giuliani of Milan in 2006 by constraining it by means of SDs to 3 of the 4 buildings to which it is connected.

Figure 23: One of the 3 tanks of *Polimeri Europa* located in Priolo Gargallo (Augusta, Syracuse, seismic zone 2*), which were seismically retrofitted using U.S. FPS devices in the years 2005-2008 and one of the isolators during and after its installation.

In the years 2005-2008, three chemical tanks of the company *Polimeri Europa* of the Italian ENI Group were also retrofitted in Sicily by means of U.S. CSS devices, namely by the so

called Friction Pendulum System (FPS), after cutting the supporting columns (Figure 23) [11, 13]. This is the only application of SI to chemical plants and components so far existing in Italy. Prior to the 2009 *Abruzzo* earthquake, it was also the only application of Curved Surface Slider (CSS) isolators to Italian structures (a similar intervention, using 3 HDRBs and 8 SDs, had been designed by ENEA, APAT – now ISPRA – and the University of Rome “La Sapienza” for a sphere tank of Enichem, located in the same site [1, 2], but was never performed, although it had been demonstrated to be very effective).

Figure 24: External and internal damages suffered by the *San Giovanni Battista Church* in Apagni (Perugia) during the 1997-98 *Marche & Umbria* earthquake.

Figure 25: The *Santa Croce della Ficarella Church* in Case Basse (Perugia) put in safe conditions after the 1997-98 *Marche & Umbria* earthquake (left) and subsequent conventional restoration works (at the centre and right), which should have been followed by the construction of a sub-foundation and insertion there of a SI system formed by 8 HDRBs with 600 mm diameters and 294 mm height (maximum design displacement = 256 mm).

Figure 26: The *San Giovanni Battista Church* of Figure 24 after the new conventional restoration (left); horizontal section of the church with location of the 8 HDRBs and 6 SDs foreseen by the retrofit design with SI (at the centre); vertical section, where the sub-foundation curb is shown.

In addition, the use of SI in a sub-foundation was planned by ENEA and others for two small old churches, decorated by valuable paintings (of Giotto school) which had been severely damaged by the 1997-98 *Marche & Umbria* earthquake: the *San Giovanni Battista Church* in Apagni, near Sellano (Figure 24), and the *Santa Croce della Ficarella Church* in Case Basse, near Nocera Umbra (Figure 25), which are both located in the Umbrian Perugia Province [1, 2, 14, 15]. They had already suffered similar damages during the 1979 *Valnerina*

earthquake, after which they had been conventionally restored: this stresses the limits of the conventional restoration. Both churches were conventionally retrofitted again and the SI design was developed by the partners of the PROSEESM National Project, which included ENEA (see Figures 26 and 27 for the *San Giovanni Battista Church*) [1, 2]. Such designs were approved by the Regional Technical-Scientific Committee which was entrusted for the examination of the reconstruction designs, but were never funded later!

Figure 27: Details of the retrofit with SI in a sub-foundation designed by ENEA for the *San Giovanni Battista Church* of Figures 24 and 26.

Figure 28: Mevale di Visso as reconstructed with conventional techniques after the damages suffered during the 1979 *Valnerina* earthquake (left) and again heavily damaged after the 1997-98 *Marche & Umbria* event (at the centre and right)

Figure 29: Damage suffered by a house in Mevale di Visso during the 1997-98 *Marche & Umbria* event (left) and vertical sections of isolated houses proposed in the reconstruction designs of ENEA and other partners (at the centre and right).

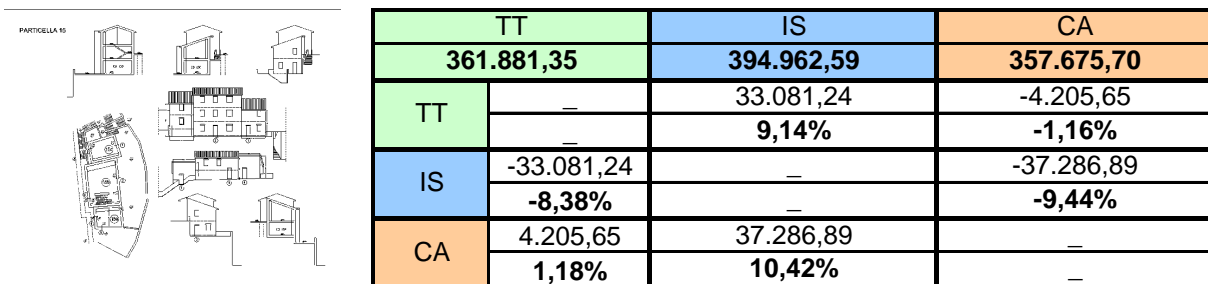

Figure 30: Design selected for the first application of SI in the reconstruction of portions of Mevale di Visso and related cost differences among the various retrofit methods (TT = fixed-base masonry; IS = seismically isolated masonry buildings; CA = fixed base r.c. structure).

Another project that was developed by ENEA and other partners and was technically approved by the Marche Technical-Scientific Committee for a first application after the 1997-98 *Marche & Umbria* earthquake (but, again, never funded until now) concerned the reconstruction of portions of the ancient village of Mevale di Visso (on the Apennines in the Marche Macerata Province), with the original materials and construction methods, but on seismically isolated r.c. slabs [1, 2, 14, 15]. This village (Figures 28 and 29) was severely damaged by several earthquakes during its history, including the aforesaid *Valnerina* and *Marche & Umbria* events. The latter caused the partial collapse of several buildings. The reconstruction designs of ENEA and other partners (Figures 29 and 30) showed that the use of SI requires an additional cost of only 5-9% with respect to the case of simple reconstruction of the masonry buildings without any reinforcement and of 3-11% with respect to that of reconstruction using r.c., namely with respect to two solutions that, in any case, are inappropriate or not permitted in Italy: in the first case due to insufficient seismic protection, in the second because it would be in contrast with the conservation requirements which apply for cultural heritage in Italy.

Figure 31: *Bronzes of Riace*, which were isolated in the Reggio Calabria Museum (seismic zone 1) in the years '90s (left); its present 3-stage HDRBs system (at the centre), which should be soon replaced by an improved SI system; *Dancing Satyr* in the Mazara del Vallo Museum, again protected by a 3-stage HDRBs system (right).

Figure 32: The original statue of *Scylla*, in the Museum of Messina, in seismic zone 1 (left); monument including copies of the statues of *Scylla* and *Neptune* in Messina (at the centre); the SI system developed for protecting the originals of both aforesaid statues in the Museum of Messina (right).

Finally, it is worthwhile citing that SI has also already been used in Italy to protect some unique masterpieces. In particular [1, 2, 14, 15]:

- the *Bronzes of Riace* in the Museum of Reggio Calabria, the bronze statue of *Germanicus Emperor* at the National Museum of Perugia and that of the *Dancing Satyr*

of Mazara del Vallo (Figure 31) have been seismically isolated by means of 3-stage HDRBs systems (an unique isolators stage would cause geometrical instability of the isolators, because their diameter shall be small for such light bronze statues);

- the original marble statues of *Scylla* and *Neptune* in the Museum of Messina have been supported by a SI system formed by SDs and Shape Memory Alloy Devices (SMADs), the latter acting both as dampers and as re-centring elements (Figure 32);
- steel sphere isolators were used to protect display cases in the Assisi Museum;
- four 3D isolators, developed in the framework of the SPACE Project, funded by the European Commission, were installed in the Ercolano Museum to protect a wooden Roman ship, very vulnerable to seismic vibrations even in the vertical direction, which was excavated in that area, after having been buried by materials erupted by Vesuvius in 79 AD for a long time (each of these isolators is formed by 3 steel spheres rolling between steel plane surfaces with a re-centring rubber cylinder for the horizontal excitations and by a spring and a viscous damper for the vertical one, see Figure 33).

Figure 33: Roman ship excavated near Ercolano (Naples) and exhibited in the local museum, which is located in seismic zone 2 (left); one of the four 3D isolators manufactured to protect it (at the centre); shake table tests of its SI system (right).

Figure 34: The dwelling building of Via Borgo dei Tigli 6-8-10 in L'Aquila (Pianola area), before the 2009 *Abruzzo* earthquake (its construction had been just completed before this event).

4.5 Further retrofits planned after the 2009 *Abruzzo* earthquake

As mentioned, the very significant extension of the applications of SI begun after the 2009 *Abruzzo* earthquake concerns this and other Italian regions. Such applications include numerous retrofits. With regard to those in L'Aquila, to be stressed are those:

- beginning for numerous dwelling buildings damaged by the earthquake, partly based on the experience achieved for the retrofit of the previously mentioned Fabri-

- ano house, damaged by the 1997-98 *Marche & Umbria* quake (Figures 34 and 35);
- which should soon begin for some public buildings (e.g. for the town court, the upper storeys of which will be demolished, then reconstructed after the insertion of a SI system at the top of the first floor);
- planned for some monumental buildings, to be partly performed within a collaboration agreement signed between ENEA and L'Aquila municipality in 2010.

Figure 35: Damage caused by the 2009 *Abruzzo* earthquake to the building of Figure 34; its retrofit by means of HDRBs and SDs has been planned, based on a design of the already mentioned GLIS and ASSISi member G. Mancinelli of Fabriano, with safety certification of A. Martelli.

Figure 36: The monumental building *Palazzo Margherita* in L'Aquila before the 2009 *Abruzzo* earthquake (left) and put in safe conditions because of the damages suffered during this event (at the centre); its internal courtyard after the earthquake (right).

The latter will concern *Palazzo Margherita* (Figure 36), the historical *De Amicis* primary school (Figure 37) and other buildings. For these the SI system will be inserted in a sub-foundation, in order not to cut any structural elements, including the existing foundations (according to the conservation requirements to be respected in Italy for cultural heritage). Among others, a new method patented by ENEA and the Polytechnic of Torino will be used (Figure 37): it consists in inserting large tubes below the building, laterally to it, and placing the isolators between the upper and the lower semi-spherical halves of such tubes (the upper ones will be the base of the superstructure, the lower ones will form the surface of the new foundation).

Retrofits of existing buildings, even not damaged by the 2009 *Abruzzo* earthquake or other seismic events, have already been planned in other Abruzzo towns or other Italian regions, as well. With regard to Abruzzo, to be cited are some monumental buildings (including at least one school) to be retrofitted in Sulmona, which is also an earthquake prone town, not distant

from L'Aquila: where possible, SI in a sub-foundation will be used. To select the intervention types and to control their adequate execution, a collaboration agreement between ENEA and the Sulmona municipality is under preparation. The support of GLIS experts to ENEA is also being considered in this agreement.

Figure 37: The *De Amicis* primary school in L'Aquila, damaged by the 2009 *Abruzzo* earthquake (left); sketch of the new sub-foundation technique patented by ENEA and the Polytechnic of Torino in 2010 (right).

Figure 38: Front view of the *Romita High School* for scientific studies in Campobasso, when it was still in use, namely before the 2009 *Abruzzo* earthquake (left); block "C" of the school (at the centre); horizontal section of the school, showing the different blocks (right).

Figure 39: The *Romita High School* in July 2010, after the demolition of blocks "A" and "B" (left); two HDRBs and a SD installed in the underground technical floor of the new block "B" of the school, during its reconstruction (at the centre); state of the reconstruction of the new block "B" in October 2010, before casting of the upper deck, at the side of the original block "C" (right).

With regard to building retrofits with SI planned in other Italian regions, an interesting case to be cited is that of the *Romita High School* for scientific studies in Campobasso (Figure 38), which hosted about 1,300 students, when it was in use [1, 2, 9, 10]. It consists of various blocks, erected in different years. When it was built, Campobasso was not seismically classified (while now it belongs to seismic zone 2), thus, no seismic design was performed for the

school. In addition, the results of investigations performed by a team of experts (including ENEA ones) after the 2002 *Molise & Puglia* earthquake showed that blocks “A” and “B” (Figure 38) were particularly unsafe, even statically, due to very bad quality of the construction materials, and that block “C” was in better but not fully satisfactory conditions.

Based on these results, ENEA immediately advised the school owner (Campobasso Province) to demolish and reconstruct, with SI, at least blocks “A” and “B”. In spite of this, the fear that demolition would have given rise to questions of the population, very difficult to answer, on the static and seismic safety of the other schools of the town, led the owner to decide to first reinforce the unsafe blocks (to make them statically safe) and only later, when possible, to retrofit them with SI or ED. However, such retrofits had not been performed, yet, when the 2009 *Abruzzo* earthquake occurred.

This affair, commented by the first author of this paper during a conversation with a journalist, was reported by his newspaper a few days after the latter event: this led to bitter controversies in Campobasso (with a general strike of the students of the town). Thus, at the end of April 2009, at last, the Campobasso Province accepted the ENEA suggestion to demolish block “A” and “B”, immediately reconstruct block “B” with SI and do the same for block “A”, with the same technique, as soon as the necessary funding would have become available.

As shown by Figure 39, blocks “A” and “B” were both demolished (in July 2010) and reconstruction of block “B” (for which safety will be certified by the first author of this paper) is now in advanced progress (the upper deck was completed in 2010). On the contrary, no funds were found, yet, to reconstruct block “A” too (however, reinforcement rods have been placed in block “A” so as to easily connect them to those of block “B” when it will be built). With regard to block “C”, it is noted that it has been suggested not to demolish it (due to the better construction materials), but to retrofit it by inserting RBs at the top of the pillars of the first floor (Figure 38).

Finally, with regard to the seismic protection of single Italian masterpieces, it is noted that Japanese steel sphere recirculation devices have been used in Italy to isolated the *Worrier of Capetrano* during the 2009 G8 meeting in L’Aquila and that U.S. rolling devices will go on supporting statues that will be returned by the *J. Paul Getty Museum* of Santa Monica (California, USA) to Sicily (Figure 40) [10, 15].

Figure 40: The statue of the *Worrier of Capetrano* (a) exhibited during the G8 Summit of L’Aquila in 2009 (b), protected by a Japanese SI table, which makes use of steel sphere recirculation isolators; one of the 9 statues which have already been isolated at the *J. Paul Getty House* in Santa Monica (California, USA) and their “wheel” rolling SI system (c & d).

5 LEGISLATIVE MEASURES ALREADY ADOPTED BY THE ITALIAN GOVERNMENT TO PROMOTE THE USE OF ANTI-SEISMIC SYSTEMS

The Italian Government, besides making the use of the new seismic code at last obligatory (during Summer 2009, in the framework of the law for the reconstruction in Abruzzo), al-

ready decided some legislative measures to favour the extension of the adoption of the anti-seismic systems and devices (especially of SI), for both erecting new buildings and retrofitting existing ones [9]. These measures were largely based on proposals of GLIS and, in particular, of the first author of this paper. For instance, economic incentives for those adopting such technologies were decided by the Regional Government of Sicily in 2010 and are under discussion at national level and in other regions.

With regard to the seismic protection of schools, it is worthwhile reporting a translation of the whole text of an “agenda” (consistent with a “declaration” of UNESCO-IPRED-ITU [16] and based on a proposal of the first author of this paper [17]) which was submitted by the President of the 8th Commission on Environment, Territory and Public Works of the Italian Chamber of Deputies [18] in the framework of the vote of the 2009 Financial Law and was immediately accepted by the Italian Government [19]:

“The Chamber of Deputies, considering that:

- paragraph 229 of article 2 of the bill under examination contains measures aimed at guaranteeing the safety of schools and, in this framework, in order to ensure the maximum quickness for the completion of the interventions necessary to put the school buildings in safe conditions and to seismically retrofit them, prescribes, in particular, that, within thirty days from the date of enforcement of the financial law itself, the interventions which can be immediately undertaken shall be the first to be identified;
- it shall be stressed in such a framework that, among all construction types, the school buildings, together with hospitals, should be the most protected from earthquakes, which are the events characterized by the highest risk in Italy;
- for such buildings the objective shall be the full safety of the students and the other occupants;
- to this aim, besides preventing the collapse of school buildings in the case of earthquakes (which is the requirement foreseen by the seismic codes, including the new Technical Norms for Constructions), it is also indispensable to guarantee their full integrity, with no damage even to the non-structural elements and the objects contained;
- furthermore, the level of the seismic vibrations transmitted by the ground to the buildings shall be minimized, to prevent panic;
- the aforesaid objectives cannot be achieved by the conventional anti-seismic design, which is based on the «robustness» of structures, while they can be fully achieved thanks to base seismic isolation and can be achieved to a large extent by inserting energy dissipation systems inside the structures themselves;
- more than half of the school buildings existing in our country result to be inadequate to withstand the earthquakes to which they may be subjected;
- for many of such buildings retrofits able to guarantee a sufficient seismic safety are very difficult or too costly, either because they are monumental buildings (thus also subjected to the conservation requirements), or because they are rather old;
- in the first case it would be desirable to assign the buildings to a different use and move the school functions to other structures, possibly of new construction; in the second the best solution would be demolition and subsequent *ex novo* reconstruction;
- for the new school buildings there are no obstacles of technical nature against their construction with seismic base isolation (in Italy 5 new isolated schools have already been completed and further 12 are under construction); in favour of this tech-

nological solution there are, besides the largely higher safety level with respect to a conventionally founded construction, the overall economic balance too (which takes into account not only the construction costs, but also those of demolition and repair, removal and storage of the debris, displacement of the school activities) and the evident environmental and energetic benefits;

- with regard to the sole construction costs, it is worthwhile noting that, in Italy, the school buildings have a limited number of storeys and usually do not need for an underground storey; thus, although the new Italian seismic code allows for lightening the superstructure and foundations of seismically isolated buildings, for school buildings with base isolation some additional construction costs due to the use of such a protection (isolators, an additional storey above them, etc.) have to be foreseen sometimes;
- for interventions on existing school buildings, seismic isolation may be used only if the room necessary for the «rigid body» motion which characterizes the building part supported by the isolators exists or can be created around the building; the related costs may be even significantly lower than those characterizing a conventional retrofit, because it is possible to avoid stripping the structure, strengthening pillars and beam-pillar nodes and inserting shear walls;
- when seismic isolation is not applicable, it is usually possible to seismically improve the buildings by inserting dampers inside them; in this case the cost of dampers is usually largely balanced by the possibility of avoiding stiffening of the structure;
- in Italy the most famous seismically isolated building is the new Francesco Jovine or «Angels of San Giuliano», school; such a school was the first, among those protected by seismic isolation, to be completed in Italy, in September 2008; the isolation system was designed by a team of experts co-ordinated by ENEA and the structure was subjected to inspections during construction and safety certification of an expert of the Agency; ENEA also contributed to the design of the seismic isolation system and/or certified or will certify the safety of further new schools, in Marzabotto (Bologna), Campobasso, Vado (Bologna) e Mulazzo (Massa); to be cited are also the design and safety certification of 4 further new seismically isolated schools in Tuscany, performed in the framework of the Collaboration Agreement on «Applications of seismic isolation and other modern anti-seismic technologies to constructions and buildings, in particular for educational use» signed by Tuscany Region, ENEA and GLIS in 2004;
- previously other existing schools had been seismically improved by means of energy dissipation systems, first of all at Potenza and its province, then in the Marche Region too: among the latter it is worth citing the Gentile Fermi school in Fabriano, of rationalist architecture, which, due to the damages suffered during the 1997-98 Marche and Umbria earthquake, was seismically improved by means of visco-elastic dampers developed in the framework of the EU-funded project REEDS promoted by ENEA;
- ENEA, in the framework of school building, may profitably contribute in its specific competence fields, among which:
 - the development of new anti-seismic devices and, by means of its experimental equipment, tests on such devices and mock-ups of structures protected by them;
 - the definition of seismic input, also by means of on-site seismic tests, and

analysis of local seismic response and seismic micro-zoning, with definition of site-specific spectra and/or acceleration time-histories;

- the evaluation of the seismic vulnerability of existing buildings, also by means of experimental tests on the materials and structures, with the identification of the most suitable techniques for the seismic retrofit of the structures;
- specialist consultancy in support to the structural design, with particular reference to the sizing and verification of the modern seismic protection systems, for both new buildings and retrofits of existing buildings;
- specialist consultancy in support to the installation of the anti-seismic devices;
- inspections during construction and final safety certification of the buildings;
- seismic monitoring of the structures,

commits the Government,

in the framework of the realization of the provisions of paragraph 229 of article 2 of the bill under examination, to evaluate the opportunity of involving ENEA and, in the affirmative, to draw up specific agreements, as to define interventions for the seismic safety of schools which are not only highly effective, but are also both the most advanced with regard to the construction technologies to be adopted and as advantageous as possible as far as costs, safety and functionality are concerned.”

6 CONCLUSIONS AND REMARKS ON THE CORRECT USE OF SEISMIC ISOLATION

The overview reported in Sections 2 and 3 of this paper has stressed the large effects of earthquake experience and seismic design code features on the extent of the use of the AS systems, in particular of the SI technique, in the various countries [9-11]. With regards to the code features, it is noted that, in countries like, for instance, Japan, the USA and Chile, SI is considered as a safety measure additional to the conventional design; consequently, the use of SI obviously always introduces additional construction costs. In spite of this, this technique is being widely adopted by the Japanese, because of their high level of perception of the seismic risk and due to the fact that violent earthquakes are very frequent in Japan.

The aforesaid level of perception is much lower in other countries: this is the reason why, in order to limit or even balance the additional construction cost entailed by the use of SI (and, thus, promote a significant application of such a technique), the seismic codes of other countries (including Italy, the P.R. China, Armenia, etc.) allow for somewhat lowering the seismic forces acting on the superstructure and (consequently) foundations when SI is used.

It is worthwhile stressing, however, that, in the latter countries, a real safety will be ensured to the isolated structures if and only if great care is paid to [10, 11]:

- the selection of the SI devices (taking into account the amplitude of vertical and low frequency vibrations), their qualification, production quality, installation, protection, maintenance and verification that their design features remain unchanged during the entire useful life of the structure;
- some further construction details (structural gaps, their protections, interface elements – like gas and other safety-related pipes, cables, stairs and lifts –, etc.).

Otherwise, the isolators, instead of largely enhancing the seismic protection (as they do, if the aforesaid conditions are satisfied), will make the structure less earthquake resistant with respect to a conventionally founded one and, thus, will expose both human life and the entire SI technology to a great risk [10, 11].

Finally [6], a common key requirement for the optimal performance of all the AS systems and devices (but especially of the isolators) is the realistic and reliable definition of seismic

input, which cannot rely upon the oversimplified routine probabilistic methods, mainly when dealing with displacements definition (on which the design of isolated structures is based): thus, because of the ongoing rapid extension of the use of the AS systems and devices, the need for a considerable improvement of the *Probabilistic Seismic Hazard Assessment* (PSHA) approach, which is at present that in use in several countries (including Italy), is very urgent now, by complementing it through the development and application of deterministic models [20]. This particularly applies to the P.R. China and Italy, to ensure safe reconstruction after the 2008 *Wenchuan* and 2009 *Abruzzo* earthquakes, because in the areas struck by both events a wide use of SI is in progress.

All the aforesaid items were discussed at the already mentioned 8th Commission on Environment, Territory and Public Works of the Italian Chamber of Deputies in February 2011, by also interviewing some experts (including the first author of this paper, as ENEA representative). The aim of the Commission is to agree on a resolution which shall stress again the benefits of SI, clarify the conditions for its correct use and recommend modifications of the current national and European design rules applicable to the seismically isolated buildings, based on the presently available knowledge and technological developments. This resolution should integrate those proposed by the president of the commission, who belongs to a governmental party [21], and by an expert member of an opposition party [21] (these two texts, written with the collaboration of the first author of this paper, have very similar contents and contain the same recommendations). The aforesaid recommendations (where particular attention is given to building retrofits) should be drafted by CSLPP with the collaboration of ENEA (a specific agreement to this purpose should be soon signed between the two institutions).

NUMERICAL SIMULATION OF THE DYNAMIC AND EARTHQUAKE BEHAVIOUR OF GREEK POST-BYZANTINE CHURCHES WITH AND WITHOUT BASE ISOLATION

Keywords: Byzantine Churches, Masonry Structures, Dynamic Response, Earthquake Performance, Base Isolation

Abstract. *The dynamic and earthquake response of Post-Byzantine stone masonry churches, which were subjected to a damaging earthquake sequence in the region of Western Macedonia in Greece, is studied. Two structural systems of the “basilica” form are first examined. Apart from these two “basilica” churches, the behavior of another much older church, which represents a much simpler orthogonal structural formation, is also examined. This is a two-story church with a simple orthogonal vault and a wooden roof that belongs to an 11th century monastic-complex. Two of these churches are also studied together with the introduction of a base isolation system. The performance of each of these three distinct structures is studied under the combination of the gravitational and seismic forces. The predicted performance of the various structural elements, located at the peripheral masonry walls is then checked by applying an assumed Mohr-Coulomb failure envelope that is believed to represent the limit-state stone-masonry behavior. The seismic damage, due to a relatively recent strong earthquake sequence, is utilized to validate the realism of the numerical predictions. The numerical introduction of a base-isolation system was quite effective in lowering the demands and thus resulting for most structural elements in Capacity/Demand ratio values larger than one ($\text{Capacity/Demand} > 1$), which is assumed to indicate acceptable structural performance. However, the introduction of base isolation under an existing old stone-masonry structure is also faced with considerable difficulties, despite the advantages that are shown by the results of numerical investigation. In the particular case of “The Church of The Virgin Mary of Tourniki” these difficulties must be faced because this old church has to be moved in a different location due to flooding. Thus, the placement of a base isolation scheme under this structure in its new location is a feasible solution for this particular case with no significant extra cost. Obviously, thus base isolation scheme should be considered in addition to all other traditional repair and strengthening measures for this church.*

1 INTRODUCTION

During the last thirty years various parts of Greece have been subjected to a number of damaging earthquakes ranging from $M_s=5.2$ to $M_s=7.2$ on the Richter scale. One of the most demanding tasks for counteracting the consequences of all these seismic events was the effort to ensure the structural integrity of old churches, that were built in periods ranging from 400 A.D. up to today; in many cases they sustained considerable damage (ref. 1., Manos et.al. 2008). In what follows, selected results and summary observations are presented of the dynamic and seismic behavior of two specific types of structural systems that are utilized in a considerable number of churches belonging to the so-called Post-Byzantine period (16th to 19th century A.D.). The first is the structural system of the “Basilica” that takes a number of variations in plan and height whereas the second type is a simple box-type structural formation. The present study examines the seismic behavior of two churches belonging to the 1st structural system (“Typical Post-Byzantine Basilica” and “Taxiarhes”) and a church belonging to the 2nd structural system (Virgin Mary at Tourniki). All these churches are located in the region of Western Macedonia – Greece and they were all subjected to the damaging strong Kozani earthquake sequence of May, 1995. The numerical results presented here are part of an attempt to numerically explain the observed behavior. The numerical investigation includes modal analysis results; no attempt was made to compare these results with in-situ measurements for dynamic identification. Next, for all examined structures the numerical analysis predicts the demands imposed on the masonry structural elements by critical load combinations which include earthquake loading as specified by the Greek Seismic Code (ref. 2). Finally, the performance of the various masonry structural elements is evaluated in section 3 by examining the ratio values of the Capacity / Demand. The demands are obtained by assumed strength values, without the incorporation of any safety factors. Space limitations allow only very limited presentation of the observed actual damage. In general, the predicted damage regions agree well with observed damage.

It is obvious that an important next step is the rehabilitation of the damaged masonry. The structural repairs of the stone-masonry churches examined here are inhibited by restrictions arising from retaining the visible stone-masonry architectural formations at the exterior and the frescos at the interior of the masonry walls. An acceptable type of repair is the application of low-pressure lime-mortar injections enriched with ceramic powder, resulting in a modest increase in the capacities of the various structural elements. The application of techniques used for the repair of reinforced concrete structural elements (jacketing or use of fiber reinforcing plastics), utilizing the resultant considerable capacity increase, is not acceptable for the stone masonry of such heritage structures. An alternative solution is lowering the demands by the use of base-isolation as the one investigated here. However, the introduction of base isolation under an existing old stone-masonry structure is also faced with considerable difficulties, despite the advantages that are shown by the results of numerical investigations as the one performed here.

1.1 The “Typical Post Byzantine Basilica”

The first case is a three-nave Post Byzantine “Basilica” structural formation which, in the overall geometry, is typical of a number of churches with similar geometry which were damaged by a strong earthquake sequence in the region of Western Macedonia, Greece during the Kozani Earthquake of 1995. The overall dimensions of this “typical” case are 19m length, 11m width and 6.8m height of the central nave (the level at the top of the roof). The internal colonnades are made of wood (figures 1a, 1b and 1c).

Figure 1. Typical Post-Byzantine "Basilica"

Figure 2a plan

Figure 2 "The church of Taxiarches"

Figure 2b South Elevation

1.2 The "Post Byzantine Basilica church of Taxiarches"

This structural formation is also a 19th century Post Byzantine church of Taxiarches at the village of Rodiani in the prefectures of Kozani, Greece; it was also damaged by the Kozani Earthquake of 1995. The length of the longitudinal walls is 18.7m whereas that of the transverse walls 11.75m, almost similar to the plan dimensions of the 1st church. However, the height of the peripheral walls is 4.85m, lower than that of the 1st case. Moreover, an additional distinct difference from the 1st case is a system of masonry cylindrical vaults, spherical domes and arches which are utilized to support the wooden roof that rises another 2.0m from

the top of the peripheral masonry walls (Figures 2a and 2b). The thickness of the masonry walls varies from 700mm to 1200mm.

1.3. The “church of The Virgin Mary of Tourniki”

This is a simple box-type structural system of rectangular shape, formed by the peripheral walls; a semi-cylindrical apse is part of the East wall, whereas the interior is usually divided into a number of naves by longitudinal colonnades of various dimensions and shapes. The simplest formation of a “Basilica” is that of a single-space rectangular structure without interior separations. Such a structure is also examined in this paper; this is a two-story Basilica, which is devoted to the Virgin Mary and belongs to the Monastic complex of Tourniki.

Such a two-story Basilica (Figure 3) is a rather rare structural system that can be found in the monastic complexes of Mt. Athos. The behavior of this two-story Basilica is numerically simulated by focusing on the super-structure and in particular on the influence of the cylindrical vaulting system that exists at the 1st story level as well as at the roof. The numerical investigation for this 2nd church is extended to study the introduction of a base isolation system.

Fig 3b.

Fig. 3c. Plan

Figure 3d. Cross section

Figure 3. of Virgin Mary of the Monastic complex of Tourniki

1.3.1. Main Features of The church of The Virgin Mary of Tourniki

The establishment of the monastic complex and the building of this church is set at the 11th century A.D. This church is a two-story box-type “Basilica” structural system formed by

two longitudinal walls (North and South) and two transverse walls (East and West) with a thickness of 700mm. The East transverse wall is dominated by two apses (one for each story) with a thickness of 700mm (Figs 3a and 3b). A relatively complex system is constructed at the East transverse wall with the two Apses in order to transfer the gravitational forces of the top East wall and Apse, which are offset by 700mm towards the interior of the church, when compared with the East wall and Apse of the bottom story (Figures 3a to 3d). The top story ceiling is formed by a longitudinal semi-cylindrical vault with a thickness of 350mm which supports the wooden roof together with the peripheral walls that extend appropriately for this purpose. Despite some small differences in the length of the North and South longitudinal walls, the structural system as a whole can be assumed to retain a mid-axis of symmetry with respect to the East-West longitudinal direction. Apart from the difference in the length of the longitudinal walls the exact location of the window openings deviates from this symmetry; however, these deviations are not believed to be very significant. This church was also subjected to the same 1995 strong earthquake when the monastic complex was not in use; damage visible at the cylindrical vaults cannot be linked directly to the event.

2. RESULTS FROM THE MODAL ANALYSIS OF THE POST-BYZANTINE AND THE BYZANTINE BASILICAS

A linear-elastic modal analysis was conducted assuming a value for the Young's Modulus for the masonry walls equal to 2500Mpa. The mass of these stone masonry walls was assumed to be equal to 2.70t/m³. All the walls were numerically simulated by shell F.E. The arches on top of the internal colonnades as well as the wooden roof was also numerically simulated; the Young's Modulus of all the wooden parts was taken equal to 8400Mpa with the corresponding mass equal to 0.66t/m³.

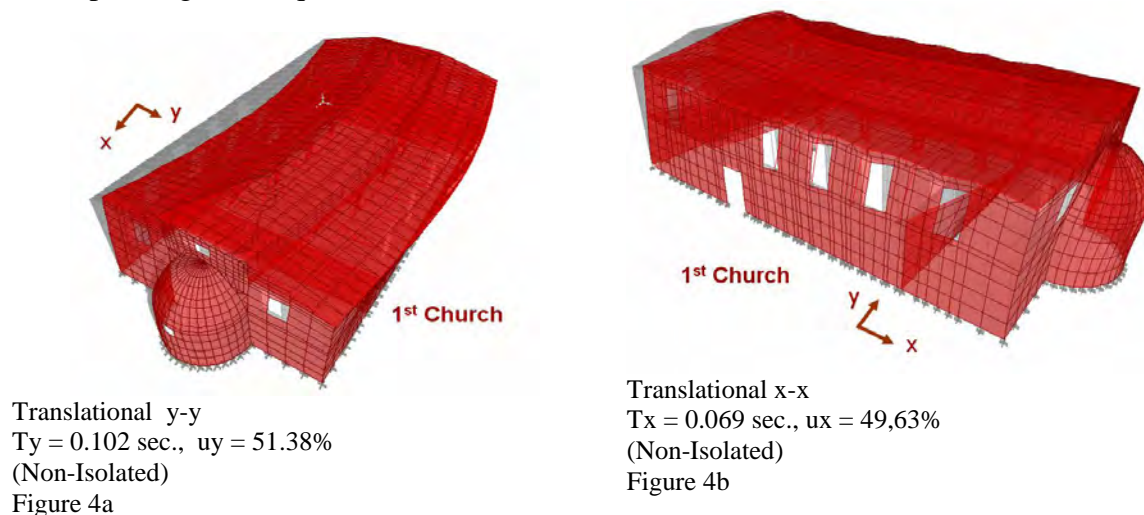

Figure 4. Dynamic characteristics “Typical Basilica”

2.1 The “Typical Post Byzantine Basilica”

Figures 4a and 4b depict the mainly horizontal translational eigen-modes for the 1st structure. The translational eigen-mode in the transverse North-South (y-y) direction is the one with the longest eigen-period (Figure 4a $T = 0.102$ seconds). The structural response in this mode displaces the longitudinal peripheral walls mainly out-of-plane; this is done with the transverse peripheral walls resisting mainly in-plane. The translational eigen-mode in the lon-

itudinal East-West (x-x) direction is the next longest eigen-period (Figure 4b $T = 0.069$ seconds). The structural response in this mode displaces the longitudinal peripheral walls mainly in-plane; this is done with the transverse peripheral walls resisting mainly out-of-plane. Each one of these modes mobilizes approximately 50% of the total mass of the structure. These two modes are next followed by higher modes; however, these latter modes mobilize relatively small portions of the total mass.

2.2 The “Post Byzantine Basilica church of Taxiarches”

In comparison, figures 5a and 5b depict the mainly horizontal translational modes for the 2nd structure. It can be seen that the eigen-periods in both the longitudinal and the transverse directions for the 2nd church are somewhat longer than those of the 1st structure. However, this time the modal mass ratios, that are mobilized by these two translational modes, are noticeably larger than those of the 1st structure. Both these effects must be attributed to the mass of the system of masonry cylindrical vaults, spherical domes and arches.

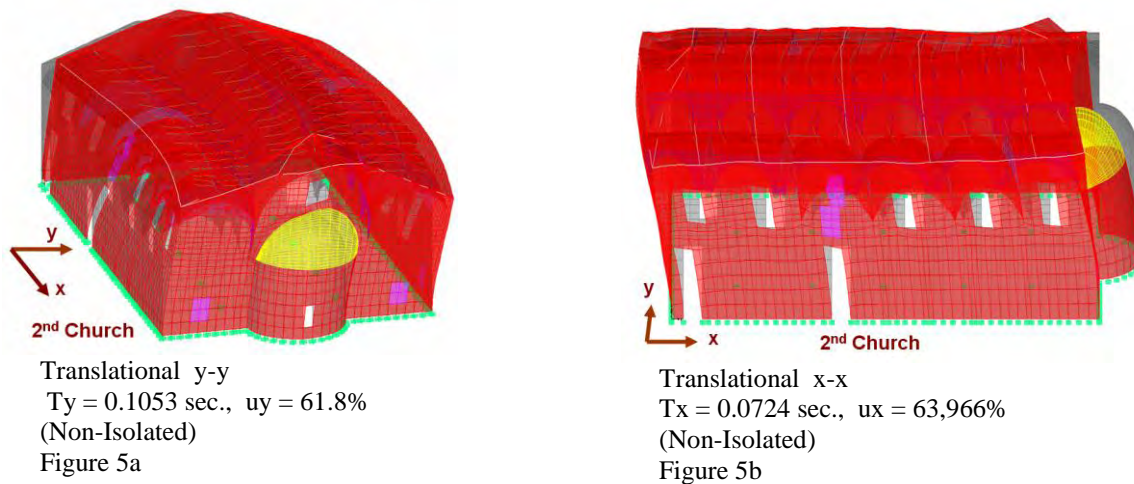

Figure 5. Dynamic characteristics “Church of Taxiarches”

2.3. The “church of The Virgin Mary of Tourniki”

For this structural system the first two horizontal translational mode shapes and eigen-periods are shown in figures 6a and 6b. As can be seen, due to the two-story formation, these two eigen-periods are relatively longer than the corresponding values of the previously examined Post-Byzantine Basilicas. Moreover, these two eigen-modes also mobilize much larger modal mass ratios than the corresponding values of the previously examined Post-Byzantine Basilicas, a fact that must be attributed to the box-type form of this structure; moreover, the peripheral masonry walls have relatively small dimensions to excite them in an out-of-plane manner.

Figure 6. Dynamic characteristics Virgin Mary of Tourniki"

3. THE DEMANDS ON THE STRUCTURE FROM THE GRAVITATIONAL AND EARTHQUAKE LOADING

The behavior of all three structures was examined next when they were subjected to three distinct loading conditions. The forces in all these three loading conditions were applied in a static manner. The structures were assumed to have all three translational degrees of freedom (u_x , u_y , u_z) restrained for all masonry at the foundation level. The first loading case included the dead (G) loads of all parts plus the live (Q) loads (mainly snow at the roof level plus the live load at the level used as women's quarters). During the second and third loading conditions the earthquake forces E_x and E_y were applied along the x-x and the y-y axis, respectively. This was done in a simple way assuming unit acceleration for all the parts of the structure equal to $1g$ (where g is the acceleration of gravity). The dynamic nature of the seismic forces was taken into account in a separate series of simulations presented in the next section.

3.1 The "Typical Post Byzantine Basilica" and the "church of Taxiarches"

The results for the 1st and 2nd Post-Byzantine Basilicas are depicted in figures 7 and 8, respectively. As can be seen in these figures, the structural system of both churches is more flexible in the transverse than in the longitudinal direction. The resistance of the internal colonnades to either the x-x or the y-y seismic forces is very small as these structural elements are quite flexible. The maximum horizontal displacement at the roof level is equal to 1.94mm for the 1st church (0.16mm for the 2nd church) for the loading case E_x whereas it attains the value of 4.447mm for the 1st church (3.86mm for the 2nd church) for the loading case E_y , more than double.

Figure 7a. Deformations for seismic forces Ex

Figure 7b. Deformations for seismic forces Ey

Figure 7c. Deformations for gravity forces

Figure 7 Deformations of "Typical Post Byzantine Basilica"

Figure 8a. Deformations for seismic forces Ex

Figure 8b. Deformations for seismic forces Ey

Figure 8c. Deformations for gravity forces

Figure 8. Deformations "Church of Taxiarches"

The seismic forces are mainly resisted by the in-plane action of the peripheral walls parallel to the direction of these forces as well as by the out-of-plane action of the peripheral walls

normal to the direction of these forces. The maximum value of deformations from the gravitational forces is equal to 0.812mm for the 1st church (1.0mm for the 2nd church); this occurs along the vertical direction at mid-span of the top of the roof. The vertical deformations at the top of the peripheral walls are of the order of 0.1mm to 0.2mm; moreover, the out-of-plane flexibility of the longitudinal walls results, at their top, in out-of-plane deformations of the order of 0.15mm when the structure is subjected to the gravitational forces.

3.2. The “church of The Virgin Mary of Tourniki”

The small size in plan for this church and the box-type form results in relatively small horizontal displacement amplitudes at the roof level for the combination of gravity loads and seismic forces along the x-x and the y-y direction as depicted in figures 9a and 9b, respectively. The maximum value of the horizontal displacements at this level is approximately 3.1mm and develops, as expected, along the direction with the relatively smaller stiffness (North-South, y-y). This structural formation is designated in these figures as non-isolated to differentiate it with the same structure being isolated, as will be presented in section 5.

4. EVALUATION OF THE STRESS RESULTS FOR THE THREE BASILICAS SUBJECTED TO EARTHQUAKE LOADING.

This time the design spectrum of the Greek Seismic Code (Greek Seismic Code 2000, ref. 2) was utilized for seismic zone I (ground design acceleration 0.16g), soil category B, response modification factor $q = 1.5$ and importance factor 1.3. In the spectral dynamic analyses that were conducted, the resultant seismic forces were obtained from the Greek Seismic Code response spectrum and the following loading combinations (G the dead loads, E_x and E_y the earthquake action in the x and y directions). $0.9G+1.4E_y$ / $0.9G+1.4E_x$ / $G+E_y+0.3E_x$ / $G+E_x+0.3E_y$.

From all the load combinations, the most critical in-plane demand values, either in normal or shear stresses, can be identified for all four peripheral walls. This can also be done for the most critical out-of-plane normal stress demand values for all four peripheral walls. For the 2nd church this study was also extended to the masonry vaults and domes of the superstructure. Next, certain commonly used masonry failure criteria were adopted for either in-plane tension-compression or shear or out-of-plane tension. Table 1 lists values which were as-

sumed to be valid for the critical mechanical properties for the masonry segments (refs. [1] and [3]).

Table 1. Assumed Mechanical Characteristics of the Stone Masonry

	Stone Masonry Compressive Strength (N/mm ²)	Stone Masonry Tensile Strength (N/mm ²)	shear strength f_{vko} (N/mm ²)
Upper limit	3.846	0.250	0.192
Lower limit	1.00	0.192	0.192

Moreover, a Mohr-Coulomb failure envelope was adopted for the in-plane shear limit state of the stone masonry, when a σ_n normal stress is acting simultaneously, that is defined through the relationship

$$f_{vk} = f_{vko} + 0.4 \sigma_n \quad (1)$$

where: f_{vko} is the shear strength of the stone masonry when the normal stress is zero; f_{vko} was assumed to be equal to 0.192 N/mm².

East wall – Ratio values of strength over demands

South wall – Ratio values of strength over demands

Figure 10. “Typical Post Byzantine Basilica”

All the masonry parts of the three studied structures were examined in terms of in-plane and out-of-plane stress demands posed by the considered load combinations against the corresponding capacities, as these capacities were obtained by applying the Mohr-Coulomb criterion of equation (1) or the upper stone masonry compressive and tensile strength limits listed in Table 1.

East Wall

South Wall

Figure 11. “Post Byzantine Basilica church of Taxiarches”

Due to space limitations such results are not shown in detail here. Selective results obtained from this evaluation process are shown in figures 10, 11 and 12, for the three studies

churches, respectively. With $R\sigma$ or with $R\tau$ the ratio of the in-plane tensile or shear strength value over the corresponding demand is signified whereas with RM the ratio of the out-of-plane tensile strength value over the corresponding demand is denoted. Ratio values smaller than 1.0 predict a corresponding limit state condition.

Figure 12. The “church of The Virgin Mary of Tourniki”

As can be seen from the capacity over demand ratio values presented in figures 10, 11 and 12 there are regions on the masonry walls that these ratio values are well below 1, indicating damage. All these predicted zones of potential failure are credible, as can be deduced from such damage patterns observed in the three studied structural systems after the 1995 strong earthquake event.

Fig. 13a. Typical Basilica

Fig. 13b. Church at Tourniki

Figure 13. Arrangement of the base isolation scheme

5. THE PREDICTED PERFORMANCE OF THE EXAMINED STRUCTURAL SYSTEMS BY INTRODUCING A BASE ISOLATION

This investigation is next extended to include a base isolation system which was introduced in the structural system representing the “Typical Post Byzantine Basilica”, as it is schematically indicated in figure 13a as well as the one representing the “church of The Vir-

gin Mary of Tourniki” as it is schematically indicated in figure 13b. In figure 14 the design spectrum considered for the non-isolated (fixed) and the isolated structural systems is shown together with the corresponding fundamental eigen-periods of the non-isolated (fixed) and the isolated structural systems. As can be seen in this figure, the dynamic amplification for the non-isolated and the isolated structures is approximately of the same order. This is due to the fact that for seismic isolated structures the response modification factor is given the value of $q=1$ instead of $q=1.5$ that was used for un-reinforced masonry structures. The possibility to use more flexible isolation base isolation schemes is currently investigated.

Figure 14. Design spectrum

Figure 15. Horizontal displacement of base isolated “Typical Post Byzantine Basilica”.

In figures 15 and 16 the deformation demands at the isolation level are depicted for the “Typical Post Byzantine Basilica” and the “church of The Virgin Mary of Tourniki”, respectively. As can be seen they are of the order of 145mm maximum for the first structural system and only 163mm for the second structural system.

What is of the outmost interest, apart from the deformation demands of the base isolation devices, is the effect the introduced base isolation scheme had on the values of the capacity / demand ratio, which were used in the section 4 before to predict numerically the observed earthquake structural damage for these churches (figure 17). This is presented in the following section by comparing these ratio values for the non-isolated structure with the corresponding values of the isolated structure.

0.9G + 1.4Ex

Top $\delta_{\max} = 167.08\text{mm}$ Base $\delta_{\max} = 156.35\text{mm}$

0.9G + 1.4Ey

Top $\delta_{\max} = 179.8\text{mm}$ Base $\delta_{\max} = 163.0\text{mm}$

Figure 16. Horizontal displacement of base isolated Base “church of The Virgin Mary of Tourniki”

Figure 17. Representative damage patterns of the “Typical Basilica”

5.1. The predicted capacity/demand performance of the isolated structures.

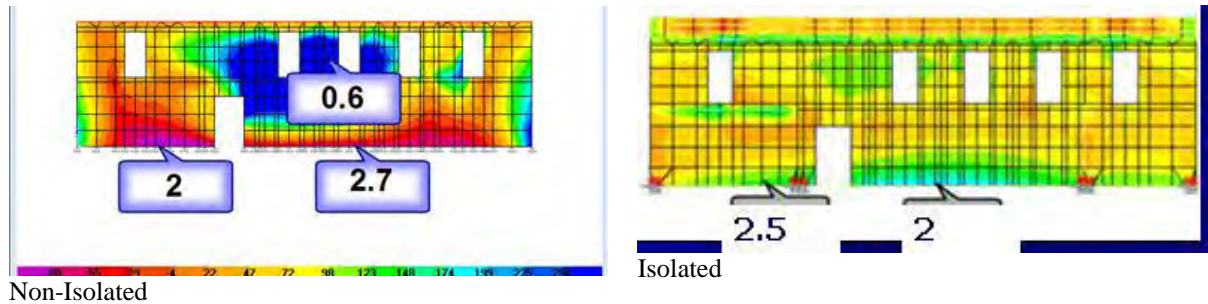

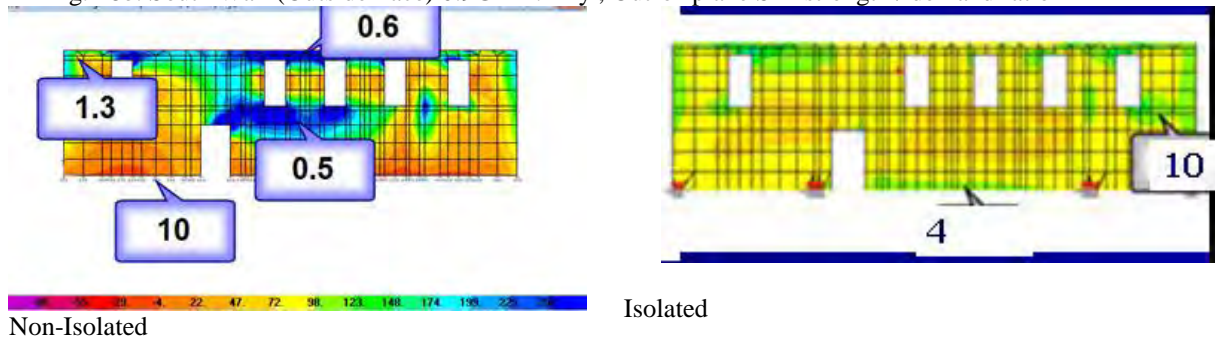

In this section, the results that were obtained for the isolated structures are processed in the same way as presented in section 4 by applying the same failure criteria that were employed for the non-isolated structures. The results of this evaluation must be viewed with the consideration that there is no reduction in the earthquake loads of the isolated structures, due to the moderate flexibility of the used isolation schemes and the employed design spectrum of figure 14 combined with the response modification factor value $q=1.0$ for the isolated structure, as already mentioned. Such a reduction of the earthquake loads will result from the use of a more flexible base isolation scheme than the one employed here.

Non-Isolated

Isolated

Fig. 18b. South Wall (Outside Face) $0.9G + 1.4 E_y$, Out-of-plane S22 strength / demand ratioFig. 18c. South Wall (Inside Face), $0.9G + 1.4 E_y$, Out-of-plane S11 strength / demand ratio
Figure 18. Strength over demand ratio values

5.1.1. The “Typical Post Byzantine Basilica”

In figure 18 the strength over demand ratio values for the “Typical Post Byzantine Basilica” structural system are shown for both the non-isolated as well as the isolated case. These selected results for the non-isolated structure correspond to ratio values well smaller than 1, which as explained in section 4 represents structural damage. As can be seen, for the case of the isolated structure the corresponding strength over demand ratio values at the same locations are well above 1, which indicates that with the introduction of the base isolation scheme structural damage from earthquake loads should be minimized.

Figure 19. Shear Strength / Demand ratio R_τ , Loading $G+E_y$

5.1.2 “The Church of The Virgin Mary of Tourniki”

In figures 19 and 20 the strength over demand ratio values for the “Virgin Mary of Tourniki” are shown for both the non-isolated and the isolated case. The selected results for the non-isolated structure correspond to ratio values well smaller than 1, which, as explained in section 4, represents structural damage. As was the case before, the corresponding strength over demand ratio values at the same locations are well above 1 in almost all cases for the isolated structure. Thus, as expected, structural damage from earthquake loads should be minimized with a base isolation scheme. This improvement in the expected earthquake performance of the studied structural systems will become even better if a more flexible isolation scheme than the one employed here is used.

Obviously, the increased flexibility of the base isolation scheme will result in larger deformation demands of the base isolation devices than the ones predicted here (figures 15 and 16); the selected devices must then pass such relevant checks.

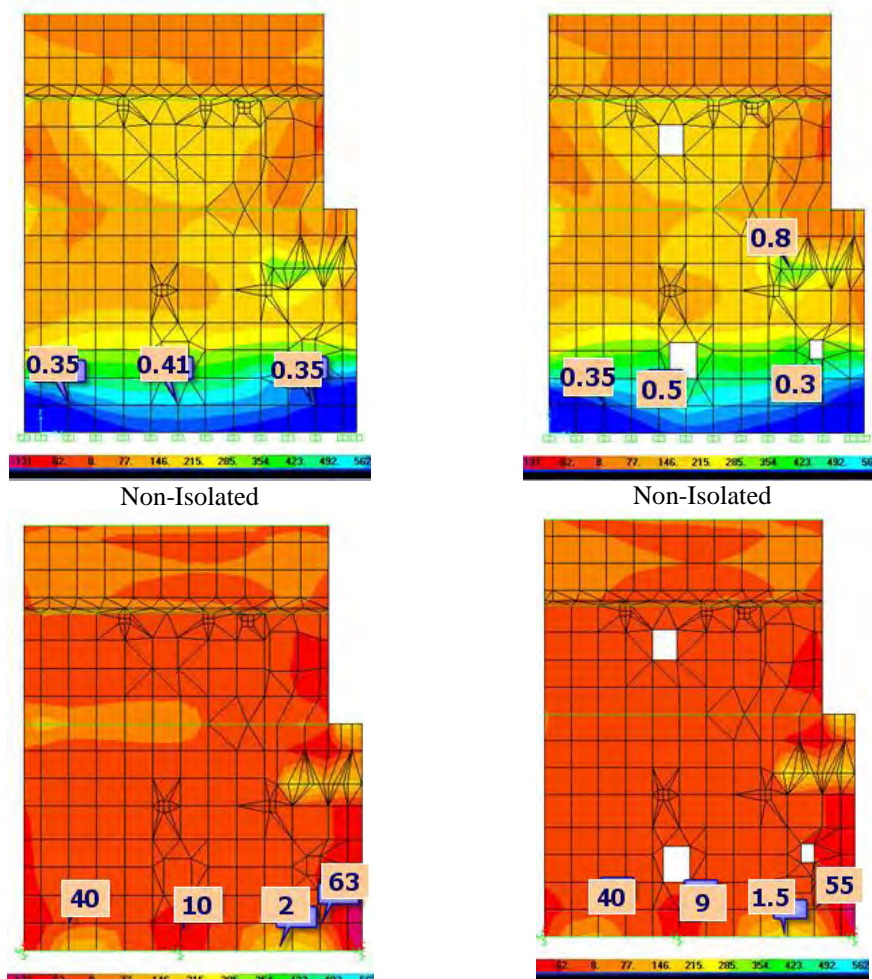

Figure 20. Normal stress Strength / Demand ratio $R\sigma$, Loading G+Ey

At this point it is important to stress the following difficulties in applying a base isolation scheme on an existing structural system especially in the case that the structural system is unreinforced masonry, as is the case of both structural systems that were investigated here. In order to place the base isolation devices under the existing structure a system of additional foundation must be constructed under the masonry walls that will enable such an operation. Such systems have been tried in the past; however, apart from the difficulty in construction

this additional foundation one should also consider the extra cost. Another difficulty is the fact that many times below the existing churches lie older structures; thus the excavation for constructing the additional foundation will unveil such old remains. This is not the case for the structures that were investigated here. On the contrary, “The Church of The Virgin Mary of Tourniki” has to be moved in a different location due to the flooding of the current location, where it was constructed almost eight hundred (800) years ago, from the construction of a dam that already starts filling the valley. In this case, the operation of construction an additional foundation for lifting and sliding this church cannot be avoided. The authors of this paper argue in favor of the placement of a base isolation scheme under this structure in its new location is a feasible solution for this particular case with no significant extra cost. Obviously, thus base isolation scheme should be considered in addition to all other traditional repair and strengthening measures for this church.

6. CONCLUSIONS

1. The numerical results presented here are part of an attempt to numerically explain the observed seismic behavior of Post-Byzantine stone masonry churches. The relatively simplified linear analysis approach together with the adopted failure criteria seems to verify the development of the actual damage in all three examined structural formations. Both predicted and actual damage is mainly concentrated at the keys and supports of the arches and vaults, at the supports of the roofing system as well as at the door and window openings and the bases of the peripheral walls. Further extensive verification is needed for the assumed strength values utilized by the failure criteria. A number of tests are currently under way.

2. The numerical introduction of a base-isolation system for the third structural formation, was quite effective in lowering the demands and thus resulting for most structural elements in Capacity/Demand ratio values larger than one ($\text{Capacity/Demand} > 1$), which is assumed to indicate acceptable structural performance. However, the introduction of base isolation under an existing old stone-masonry structure is also faced with considerable difficulties, despite the advantages that are shown by the results of numerical investigation.

3. In the particular case of “The Church of The Virgin Mary of Tourniki” these difficulties must be faced because this old church has to be moved in a different location due to flooding. Thus, the placement of a base isolation scheme under this structure in its new location is a feasible solution for this particular case with no significant extra cost. Obviously, thus base isolation scheme should be considered in addition to all other traditional repair and strengthening measures for this church.

Abstract: *Experimental investigations about the behavior of Unreinforced Masonry (URM) structures in comparison with masonry structures reinforced with Fibre Reinforced Cement (FRC) is carried out on the large shaking table at the EU Centre in Pavia. The tests were part of the EU project Polyfunctional Technical Textiles against natural Hazards POLYTECT and POLYMAST. Intention of both projects within the 6th and 7th EU Framework Program is the development of multifunctional textiles with embedded sensors.*

For the purpose of the project a 5.8 m tall 2-storey test structure was built. Archetype of the structure was a typical historical building made of natural stones from the earthquake region “Abruzzo” in Central Italy. A 6.3 magnitude earthquake struck this region in 2009 (L’Aquila earthquake) and caused 260 losses, 1,000 injured and 28,000 homeless.

In an optimization process different new developed textile and special mortar combinations were tested with small in-plane shear walls under cyclic horizontal displacements to find the optimal strengthening solution for masonry structures.

In the first test, the unreinforced structure (URM) was analyzed under seismic impact. The ground acceleration was increased till nearly before collapse of the building. This damaged building was the basis for further investigation. For the second test the specimen was repaired and reinforced with a new developed FRC in a full covering solution on the surface outside the structure. The used fabric is a woven glass/polypropylene fibre combination in four directions.

1 INTRODUCTION

Masonry is a material with a high compression strength compared with his low tensile strength. Under horizontal load cases like wind or earthquake seven decisive failure modes are observable in the bricks and the mortar joints caused by low shear and/or tensile strength. In figure 1 these modes are presented. The idea to upgrade the mechanical material properties is in the first instance to add thin fibre materials with a high tensile strength like carbon fibers, glass fibers or others. To design and manufacture technical textiles in an optimal way for seismic retrofit, the real fracture mechanism in masonry structures is very important. Generally there are:

By applying fibre reinforcement on the wall surface one can observe a failure in the fibers, in the fibre matrix, the brick surface or in the interaction areas. Due to the fact that masonry has high compressive strength, but low tensile strength, diagonal cracks form due to a compression strut under lateral gas pass [5]. Not often the cracks are crossing the bricks. The reason for failure [6] and [7] is the different material behavior from bricks and mortar. The soft mortar has a low Young's modulus, but in comparison the bricks are very stiff. As a result the mortar carries more lateral strain than the brick and with the interconnection, the adverse three dimensional load case compression-tension-tension and the low tension strength occurs vertical or diagonal cracks [6], [7]. In most cases gaping cracks are developed if the tension forces are higher than the adhesive tensile strength between mortar and brick.

If fibers are oriented in such a way that they cross existing or potential crack locations, they provide resistance against tensile forces which can prevent or stop crack growth. Especially in sliding joints [2] diagonal fibers prevent the decrement of shear resistance in the wall. This is the main factor for in-plane loading and for the bracing system of a building in earthquake areas. The shear failure occurs by exceeding the adhesive shear strength of the mortar or uncommonly in the stones. Similar to the function of rebar in reinforced concrete the fibers more "bridge over" the cracks by providing tensile strength. However, the fibers do not improve the compressive strength. Different to reinforced concrete is the size of the crack width. Instead of millimeters the fiber reinforcement has to work in the centimeter region. Due to this reason the ductility of the fiber system has a high impact.

Figure 1: Common failure modes in masonry structures

2 THE TEXTILE

With four main characteristics it is possible to construct a special textile for masonry: (a) Amount of fibre directions, (b) respective inclination angle between the fibers, (c) single or different material types and (d) amount of fibers. For the last point the common way is to calculate with the (fibre-)weight per m^2 the required tensile strength. Fiber selection is a design problem with polymer, glass, and carbon fibers being the primary material types. Generally, strip reinforcement calls for uniaxial stiff fibers with epoxy adhesive, in opposite to wide area coverage systems calling for more ductile fibers in a multiaxial weave or warp knit pattern. A matrix compound adhesive in combination with carbon fibers with its low strain capacity is an unfavorable option, while the high tensile strength is advantageous. A better solution is a combination with polypropylene fibers (PPF) and AR-glass fibers (ARGF). The PPF performs a high strain rate capacity till the full force is activated. The AR-glass fibers with high stiffness and tensile strength can overtake the first load until the strains reach the ultimate strain value and break. After breaking the PPF will be activated. Through the weight ratio of PPF and ARGF the ductility from the masonry and the textile is adjustable.

The special weaving technique enables the production of multiaxial textiles with different fibre directions with user defined orientation angles. For different small shear and wall tests 2-axial, 3-axial and 4-axial textiles with integrated optical fibers sensors were produced and tested. The range of the weights per square meter was between 290 g/m^2 and 590 g/m^2 . The weight from the optimized textile was around 425 g/m^2 and had 4 fibre directions. Especially for failure mode [2] fibers in 45° angel over the cracks can stabilize the shear resistance and this effect is very important for the ductile behavior of the structure.

The textile-stone-mortar composite acts like a laminar ductile tensile reinforcement. The optimal functionality is affected through the high adhesive tensile strength between the mortar brick interface, a lot of small cracks in the matrix without bonding decline, the stiff ARGF at the beginning and the ductile PPF after greater cracks in the masonry.

3 THE MORTAR

The mortar is the link between textile and the structure. The fabric is embedded in two 4 mm thick mortar layers not only to get the best possible bonding but also for the protection of the fragile fibers. The different components of the matrix and the textile fibers are the main elements of this reinforcement method. Both have to be designed to ensure maximum ductility. High adhesive tension strength on the stone surface and a high bonding with the fibers are required for any potential matrix. Different matrixes with different properties were tested at the Institute of Reinforced Concrete Structures (KIT-IMB) to determine their performance characteristics when used for the textile masonry composite system. The matrixes tested were: a) one “soft” mortar with high ductility from BG Polymers, b) a high “stiff” epoxy resin system (“Sika 331 W”) and c) an epoxy surfacer with 3 components (“Sikagard 720 Epo-Cem”). The first two compounds are an epoxy-dispersion and the last is a hard mineral granulation. The compression strength is approximately 40 N/mm^2 and the adhesive tensile strength is around $3\text{--}4 \text{ N/mm}^2$.

Small shear tests in size $363 \text{ mm} \times 240 \text{ mm} \times 175 \text{ mm}$ with three sand lime bricks and between 2 mortar joints were produced to simulate the shear failure [2] in masonry walls. The two outer stones were hold and loaded with a compression force in the horizontal direction in such a way that the mortar bed joints are under normal compressive stresses. The mid brick was pushed using a displacement controlled piston. The force and the corresponding vertical

displacement were measured. These tests indicated that the best material solution is between the extreme cases high stiffness (epoxy system) and the high strain rate (BG Polymers). The reason why the cement based epoxy surfacer (“Sikagard 720EpoCem”) represented the best solution was a micro cracking and sliding crack direct over the bed joint. For a ductile behavior very stiff or a soft material is able to reach the same deformation for this effect like a “singularity line”. While the Sikagard has a consistent load decline the BGP is on a lower strength level more volatile. Further developments will prefer cement based mortars like Sikagard 720 EpoCem, because they are working not like epoxy or other glues as an air barrier for the building which causes fungi and other water based damages.

4 EXPERIMENTS

4.1 Scaled wall tests

Scaled wall tests were conducted with different test specimens to select the best materials for the matrix-fibre-system. Small initial shear test specimens with three stones (363 mm x 240 mm x 175 mm) first simulated the failure mode [2] for walls with textile. Maintain tense consistency scaled wall test (1.25 m x 1.25 m) and full-size wall tests (2.5 m x 2.5 m) were conducted. In these tests the different parameters were the mortar matrix, the textiles and the vertical load value. The shear loading in-plane was in the strong inertia force direction with a vertical load between 0.2 and 1.0 MN/m². For the horizontal cyclic displaced head beam the displacement and the horizontal force were measured. Integrated optical sensors were fixed on the edges of the walls and measured continuously the strains in the mortar and textile (see figure 2).

Figure 2: Wall 1.25 m x 1.25 m

Figure 3: Wall 2.5 m x 2.5 m

Representative results of unreinforced masonry (URM) and reinforced masonry (RM) tests (1.25 m x 1.25 m) are shown below in figure 4 and 5. For the RM wall an optimized hybrid multiaxial textile and Sikagard 720 EpoCem was used. The maximum resistance force of the URM wall was 98 kN and the maximum load of the RM structure was 232 kN. This is an increase of 136%. But the more important effect is the increase of ductility of more than 200%.

Figure 4: Hysteresis for the URM wall

Figure 5: Hysteresis for the RM wall

4.2 Shaking table test with an full-scaled unreinforced masonry building

Motivated by like buildings damaged in the L'Aquila earthquake (2009) the EUCENTRE located in Pavia (Italy) emulated a building with the typical archetype with natural stones and a size from 5.8 m high, 5.8 m long and 4.4 m width. A uniaxial shaking table simulated the L'Aquila earthquake with different increasing amplification factors. After 0.4 g PGA the building was nearby destroyed.

Test number	Peak ground acceleration (PGA)
1	0.05 g
2	0.1 g
3	0.2 g
4	0.3 g
5	0.4 g
6	0.4 g with additional steel anchors

Table 1: Test program

The test of the URM structure exhibited common failure modes. The very soft wooden slab at the ground level led to out of plane bending failures in the front side (failure [1] and [2] in figure 6). Diagonal bending/tension cracks trough the mortar joints [5] over the window parts were the most important failures, due to the fact that the front corner in figure 6 was shortly before collapse. Only the wooden beam held this part together with friction and the roof load. A joint sliding [3], for the “in-plane” walls occurred in the cross between windows and doors and on the bottom between the doors [6]. After the shear cracks in the “beam”-parts [5] the front corner was the most moving part in the building and was the reason for the high defor-

mation in this corner. An existing eccentricity though the asymmetrical arrangement of the wall stiffness led to an additional torsion moment which was increased after cracks in the front side and shear point shift toward the walls without openings (figure 7). This led to very high accelerations in the point A (figure 6). High local deformations in this area caused different orientated cracks in this corner region [4] (see figure 8).

Six tests were conducted until the building was damaged that a collapse was imminent. In the last step the peak ground acceleration was the same, but additional installed steel rods (see figure 6) were used to hold the building like a box together.

Figure 6: Crack pattern of the URM building

Figure 7: Deformation of the URM building

Figure 8: Crack patterns

4.3 Shaking table test with an reinforced masonry building

The idea behind the reinforcement method is to stabilize a building after huge cracks with ductile polypropylene fibers, to add more tensile strength with AR-glass fibers and to increase the global displacement ductility for horizontal force diminishing. The strengthening system is so flexible that it can be used as a repairing tool of nearly damaged masonry structures.

The base for the shaking table test with the reinforced building was the structure described in the chapter before. The pre damage structure was repaired and retrofitted with the mortar-textile system through full coverage application in a sandwich practice mortar - fabric - mortar (figure 9).

Figure 9: Masonry building with textile application

The same earthquake load time history was used. The corresponding response spectrum is shown in figure 11. The applied dynamic load was different between the original and the pre-damage sample due to the damages and cracks. During the test the main frequency of the URM building dropped down from 11.55 Hz (0.107 sec.) to 9.31 Hz (0.086 sec.). This caused a slight increase in the horizontal load.

Figure 10: Crack pattern: a) delamination, b) broken glass fibers

Regardless to the higher accelerations, the building reached with marginal cracks under the window location in the front side (figure 10) a maximum peak ground acceleration of 0.6 g without any tendency of stability failure. This was an increase of 50 % compared the un-strengthened URM structure. After inspection of the applied textile only the projected cracks in the stiff glass fibers were visible while the soft polypropylene fibers hold the crack together and worked like a damping spring in the system. Further frequency and system analysis will be presented in the presentation in the workshop.

Figure 11: Response Spectrum of the Montenegro earthquake (1979)

5 CONCLUSIONS

Multi axial fiber reinforcing provides the engineer with a new tool for the seismic retrofit of unreinforced masonry structures. This special mortar/textile system adds strength, improves ductility and provides the opportunity to conduct structural health monitoring. Special optical fibers were used to measure strains online within the textile. The design, manufacturing, and testing of these textiles have occurred and are underway in the EU research project POLYTECT. The testing at the EUCENTRE showed the possibilities of such a system.

Abstract. *This study examines the strengthening of existing deficient reinforced concrete (RC) building by using internal steel frame (ISF). Test results indicated that ISF increased the lateral strength, ductility and energy dissipation capacity of the deficient RC building significantly. The test results were compared with simulations to observe performance levels. A case study building was analyzed to demonstrate the performance of an ISF retrofitted deficient RC building by using an analytical model calibrated with test results. The analyzed building was located at Marmara region in Turkey where the region most susceptible to severe earthquakes. The performance based evaluation with respect to Turkish Earthquake Code indicated that this building should be strengthened under Duzce ground motion demand. After strengthening by using ISF, the building was within the life safety performance level which is the performance level that needs to be satisfied for residential buildings. The modeling strategy and construction details of the ISF are also presented in this study.*

1 INTRODUCTION

Poor performance of reinforced concrete (RC) buildings was demonstrated dramatically in recent earthquakes (Northridge 1994, Kobe 1994, Kocaeli 1999, Taiwan 2003, India 2001) due to insufficient lateral load resisting system. Common deficiencies of RC buildings in many of the developing countries owe either to lack of knowledge about seismic risk or to malpractice and insufficient quality control during construction. The poor quality control results in low strength concrete (in the range of 8 to 15 MPa), insufficient spacing of transverse confining reinforcement in beams, columns and joints, and insufficient splice length at column critical regions that may result in excessive bond slip of plain longitudinal reinforcement. To reduce the effect of these deficiencies on existing structures, seismic retrofitting techniques should be developed. Furthermore, application of the seismic retrofitting techniques should be encouraged to be used by the authority and people live in high seismic regions.

There are many strengthened techniques namely adding structural walls [1-4], steel braces [5-13], FRP diagonal braces integrated in the infill walls [14-16], precast-shear walls that fit perfectly into the existing frame [17], steel frames attached externally to the perimeter of the existing frame [17], and steel frames attached within the frame without using anchors [18]. Although the most commonly used strengthened technique is adding structural wall, this technique requires interrupting building use for a substantial period of time and may conflict with architectural requirements.

The literature review indicated that there is urgent need to develop a rapid, safe and practical strengthening technique. The internal steel frames (ISFs) which are one of the candidate retrofitting techniques are installed within bays of the deficient RC frames. The ISF is intended to easily accommodate wall openings for architectural requirements. In this study, firstly an experimental test frame with and without ISF was examined and then the analytical study was conducted to calibrate test frame with ISF. By using analytical results, the performance level of the frame with ISF was performed with respect to Turkish Earthquake Code (TEC 2007) [19]. Based on calibration of the test frame with ISF, an existing five story residential building was strengthened with ISF and the performance of such building was evaluated by using procedure suggested by TEC 2007 [19]. Duzce earthquake record was utilized in the nonlinear time history analysis to determine the performance points of the building before and after retrofitting. This study also explains the installation procedure of the ISF to the RC frame.

2 TEST FRAME AND ISF INSTALLATION PRODECURE

Two, one bay-by-one story, portal RC frames were examined to determine cyclic performance of the ISF. First test specimen SP1 was reference frame tested without any retrofitting while second specimen SP2 was tested after implementing ISF in the RC frame. Although comprehensive information about the test frames is available in elsewhere [20], a summary was introduced in this study. As shown in Figure 1, the center-to-center span length was 1400 mm and the column height was 1000 mm. The dimensions of the columns were 100 mm \times 150 mm with four 8-mm diameter longitudinal reinforcement plain bars resulting in about 1.33 % longitudinal reinforcement ratio. 4 mm diameter plain bars were used for stirrups. TEC 2007 requires stirrups to be anchor using 135 degree hooks however 90 degree hooks were used for all columns and beam to simulate the detailing deficiency of the Turkish construction practice before the establishment of the modern seismic codes. To simulate the insufficient confinement details of the columns, the stirrup spacing of the columns was equal to the smaller dimension of the column section (100 mm). The 100 mm \times 150 mm beam was cast with a 450-mm wide, 55-mm thick slab. A 70-mm transverse reinforcement spacing was

used for the beams. The RC beam-column joint had only one column stirrup extending into the joint. The yield strength of the 4-mm and 8-mm diameter reinforcement bars was determined as 270 and 330 MPa, respectively. The target 28-day cylinder compression strength was 8 MPa to simulate the existing deficient structures with low concrete strength determined in field investigations [21-23].

A constant gravity load of 62 kN was applied by placing steel blocks on the RC frame (see Figure 1(c)). This gravity resulted in the axial load ratio (i.e. ratio of gravity load to axial load carrying capacity) for the RC column was roughly 20% for all specimens. Cyclic lateral loading was introduced by controlling the drift ratio (DR) as in Figure 1 (d).

Figure 1: a) Analyzed building floor view, b) Analyzed 4-story frame, c) Beam and column section.

The ISF was composed of rigidly connected beams and columns. The ISFs were implemented after constant gravity load was applied on the RC frame to simulate actual retrofit conditions. The application procedure was as flows; firstly, anchor holes were drilled into the

column face and bottom side of the RC beams. Then, these wholes were cleaned up by air blowing, brushing and air blowing (Figure 1 (b)). Next, epoxy primer was injected into these holes and the anchor rods were inserted and left for curing. In the second stage, a thin layer (about 3 mm) repair putty was applied on the RC member on all surfaces that contact the ISF (Figure 1). Before the epoxy cured, the anchor rods were tightened to fasten the individual steel members to the RC frame. Finally, the steel beams were welded to the steel column. The diameter of the anchor rods and holes were 6 mm and 8 mm, respectively. The anchors were embedded 120 mm into the RC beam and columns.

2.1 TEST RESULTS

Figure 2 shows the hysteretic response obtained from both specimens [20]. Specimens SP1 and SP2 developed a lateral stiffness (the peak positive and negative loading points during the first cycle ($\pm 0.5\%$ DR)) of 2.48 and 12.68 kN/mm, respectively. The lateral strength of the specimens SP1 and SP2 were 13.7 and 118.9 kN.

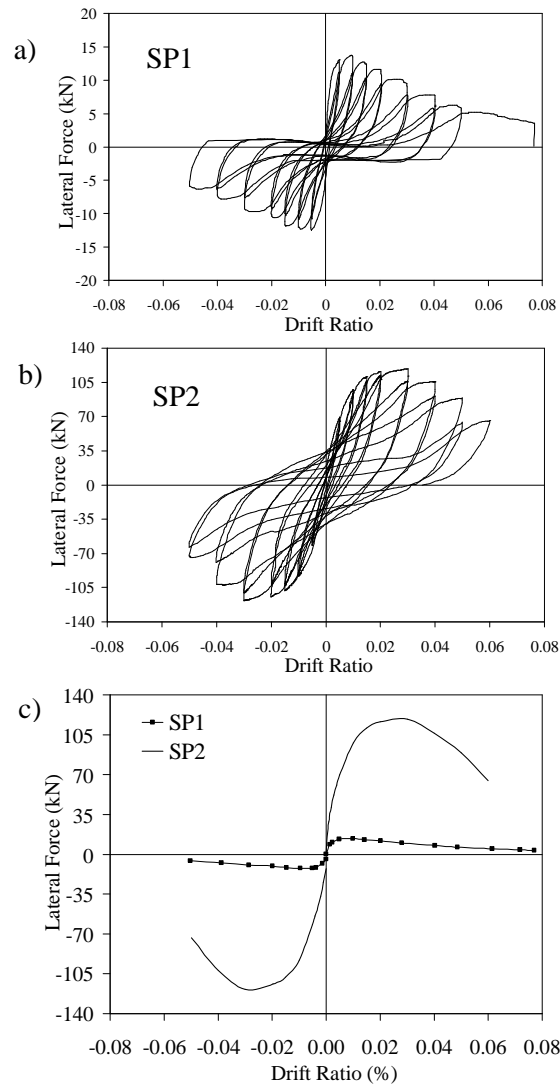

Figure 2: a) Cyclic response of the reference frame, b) Cyclic response of the strengthened frame, c) Envelope response of the frames.

Plastic hinges were first observed at the bases for the reference frame (specimen SP1). A plastic mechanism was formed at a drift ratio DR slightly higher than $\pm 2\%$. Upon further lateral displacements, pinching behavior and severe stiffness degradation was observed. Specimen SP2 was designed to develop composite action in the beam and two columns. Cracks in the concrete widened during each loading excursion that produced tension in the concrete portion of the composite section. The specimen SP2 failed due to fracture of the welded beam-to-column connection that initiated at $\pm 3\%$ DR. These test results indicated that the ISF retrofitting increased the lateral strength, stiffness and energy dissipation capacity of the deficient RC frame significantly.

2.2 ANALYTICAL STUDY OF THE TEST FRAME

The test frame, specimen SP2, was analyzed by using nonlinear static pushover procedure in order to determine plastic rotations at the ends of the beam and columns. Firstly, moment rotation relations were derived from sections indicated in Figure 1(b). The composite column and beam members had two moment curvature relation whether bending directions is positive or negative. When the composite section was under positive bending, the steel member (I-80 for beam and I140 for column) was under tension but the concrete was under compression. At the negative bending direction, this case was vice verse. Hence, two different moment curvature relations were developed for both composite column and beam. The moment curvature relation was converted into moment rotation relation. The plastic hinge length was assumed as half of the section height (TEC 2007).

Mander confined concrete model was used for columns and beam [24]. Longitudinal bar buckling was modeled by employing the backbone curve of Dhakal and Maekawa [25]. P- Δ effect was incorporated into the analytical model. SAP2000 [26] was used for the nonlinear static analysis. The analytical model was designed by using exact section dimensions and material properties (Figure 3).

Figure 3: Analytical model of the specimen SP2.

In the TEC-2007, the moment rotation relation can be designed as elastic perfectly plastic behavior. Hence, after yielding, no hardening was used to model the moment rotation behavior (Figure 3). The performance of the member in the procedure suggested in TEC 2007 depends on the reinforcement bar and concrete strain (Figure 4). The following equations were defined for three performance levels in TEC-2007; immediate occupancy (IO), life safety (LS) and collapse prevention (CP) performance levels.

IO performance level;

$$(\epsilon_{cu})_{IO} = 0.0035$$

$$(\epsilon_s)_{IO} = 0.010$$

LS performance level;

$$(\epsilon_{cg})_{LS} = 0.0035 + 0.01(\rho_s / \rho_{sm}) \leq 0.0135$$

$$(\epsilon_s)_{LS} = 0.040$$

CP performance level;

$$(\epsilon_{cg})_{CP} = 0.004 + 0.014(\rho_s / \rho_{sm}) \leq 0.018$$

$$(\epsilon_s)_{CP} = 0.060$$

Where,

ϵ_{cu} ; concrete strain at the top fiber

ϵ_{cg} ; concrete strain at the top fiber of the confined concrete

ϵ_s ; Reinforcement bar strain

ρ_s ; available volumetric ratio of the stirrup of the member

ρ_{sm} ; volumetric ratio of the stirrup of the member calculated by utilizing the TEC-2007

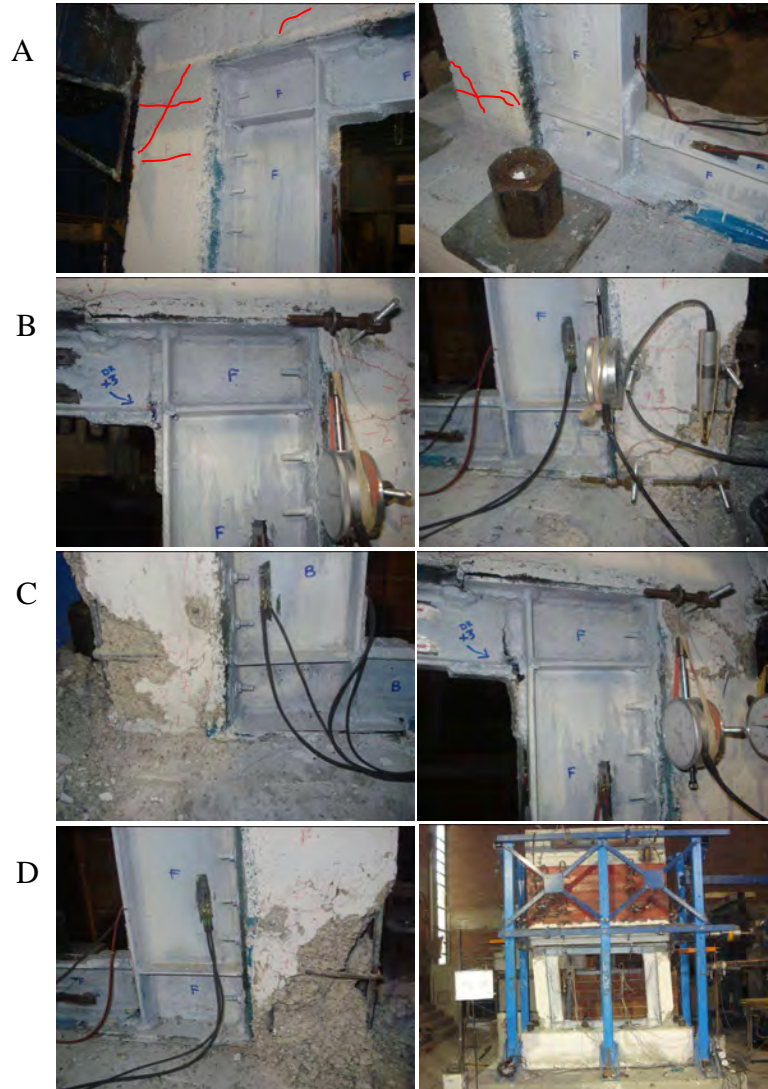

Figure 4: Strain at the cross section of the RC member.

Figure 5 indicates the static pushover curve of the test frame (specimen SP2). This figure also indicated the performance of the columns and beam in term of drift ratio. IO, LS and CP were determined by the method suggested in TEC 2007. Each performance levels indicated in Figure 5 exceeded the suggested strain limits at the bottom and top of the columns. Furthermore, at the end of each performance levels, the damage observed during the test are also seen in Figure 5. The interstory drift ratio (IDR) limits suggested in TEC 2007 are marked on this figure at 1, 3 and 4% DR. The average DR of the each three performance levels are about 1.0, 2.5 and 3.5 %, respectively.

3 CASE STUDY

In this section, the performance based design of existing five story RC building located in the Istanbul is presented. The building is a reinforced concrete frame structure with rigid shear wall surrounding the basement (Figure 6). Within this study, a performance

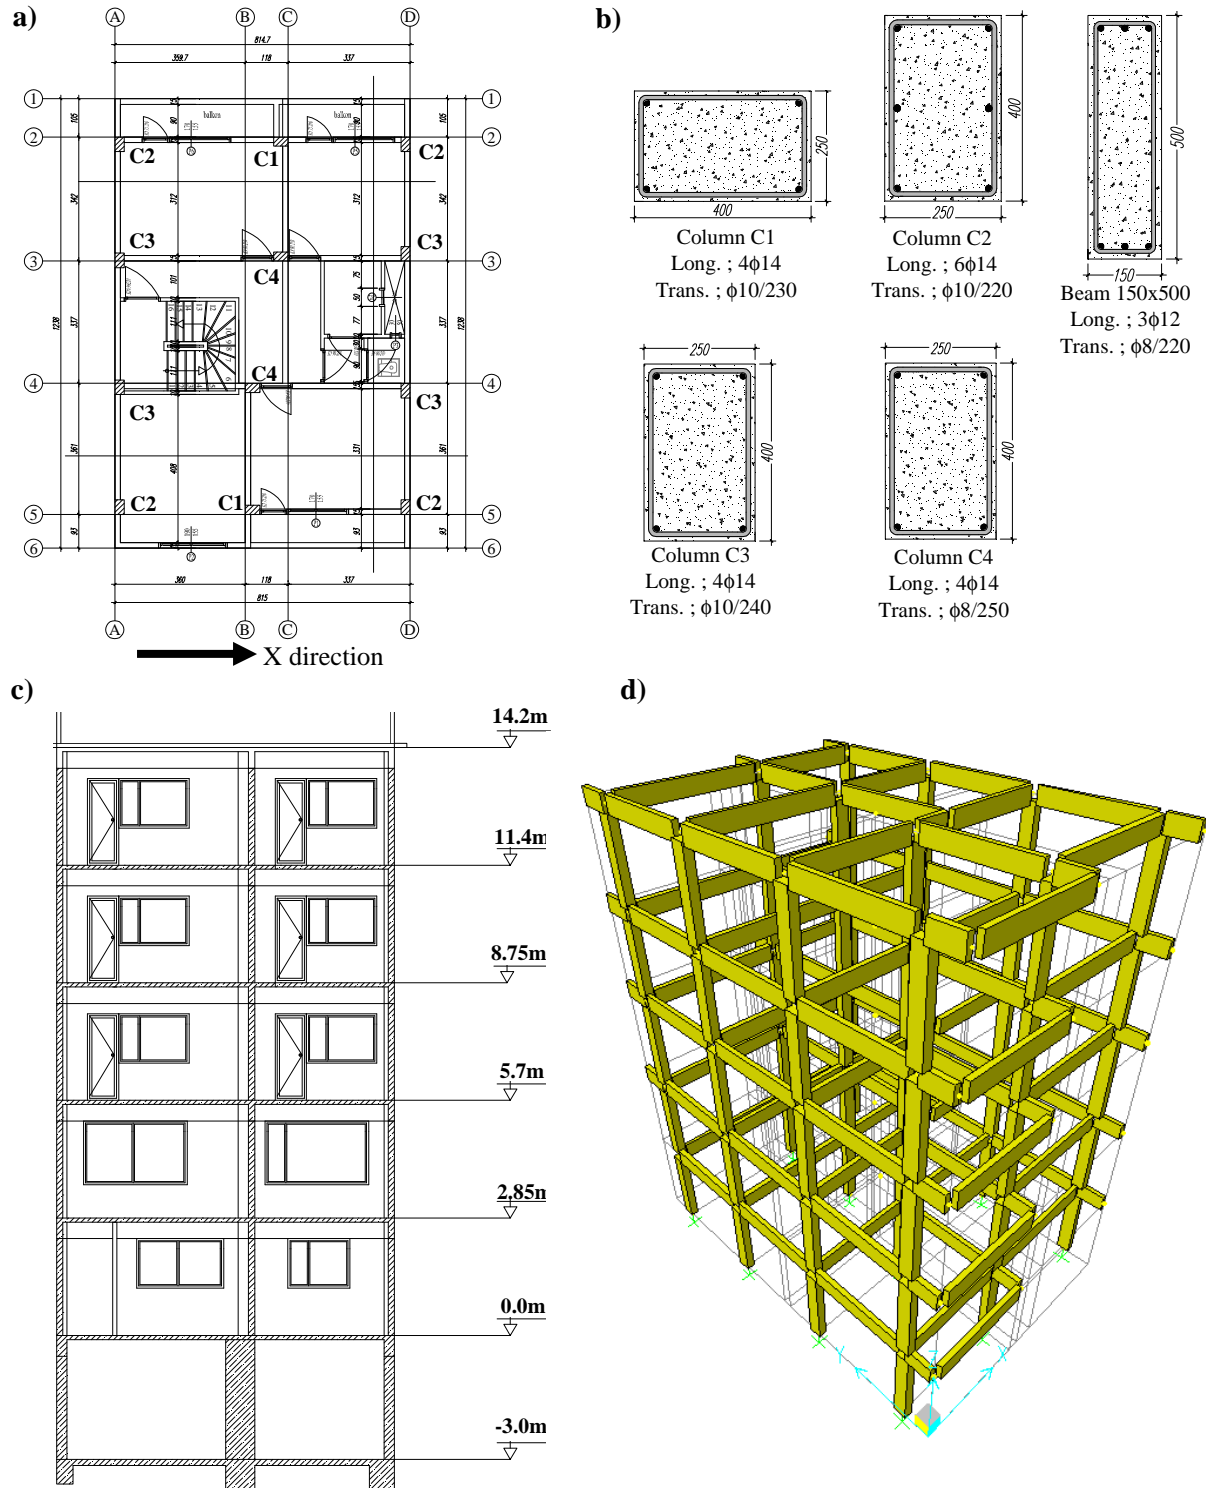

Figure 6: Five story building a) Plan view, b) column and beam dimensions, c) front view of the building, e) analytical model of the building (SAP2000).

evaluation method based on nonlinear pushover analysis is carried out using structural data. The strengthening of the building based on the methodology described previously from the test data is performed. Figure 6 indicates the plan view of the building. Uniaxial compressive strength and modulus of elasticity (calculated from [27]) are 8 MPa (close to test frame) and 13435 MPa, respectively. The yield strength of reinforcing steel was found as 220 MPa. The dimensions of the building in the x and y direction are 8.75 m and 12.23 m, respectively. The columns and beam dimensions are 250x400 and 150x500 mm, respectively. The orientation and also size of the beams and columns are shown in Figure 6. The stirrups spacing of the columns and beam are about 220 mm with a clear cover of 20 mm. It is important to mention that the stirrup spacing of columns and beams does not satisfy the current code TEC-2007 [19]. Furthermore, the in-situ concrete strength is lower than the code specified minimum. The steel grade of the longitudinal and transverse reinforcement is S220 whose yield strength is 220 MPa.

3.1 STRENGTHENED BUILDING WITH ISF

The strengthened technique was applied to enhance the lateral load resisting capacity of the direction only. Figure 7 indicates the strengthened bays of the building. There were two strengthened cases namely ISF 1 and ISF 2. The difference between them is; the ISF2 had additional strengthened bays, axis 3-3 and axis 4-4, at the first and second story. The steel members to build composite columns and beams are I-400 and 13mm-thick-steel plate (Figure 7). The yield strength of the both steel members was taken as 235 MPa.

3.2 PERFORMANCE OF THE BUILDING WITH AND WITHOUT ISF

Nonlinear static pushover analyses were conducted in order to estimate displacement capacity of the building for the required evaluation techniques. The 3D computer model of the building was generated using SAP2000 [26] from the original drawings of the building (Figure 6). All the joints on each floor were constrained in order to model the diaphragm effect. Moment-rotation properties derived from sectional analyses with the plastic hinge length (taken equal to half the member depth in the direction of loading as suggested by TEC 2007) idealization were assigned to the beam and column ends (similar to given moment rotation as seen in Figure 3). Axial force-moment yield surfaces obtained from interaction diagrams were used for column plastic hinge regions. Load distributions proportion to story mass and first mode amplitude were used for pushover analysis for x direction. Prior to conducting the pushover analyses, gravity loads and 30% of the live load on the structure were applied. The displacement-controlled pushover analysis was then performed to obtain performance point of the building and plastic deformations (rotations) of the members. After performing the pushover analysis and obtaining the capacity curve, the performance points of the building in x direction was calculated using method namely single degree of freedom (SDOF) approach employing the Duzce ground motion (DGM) (Figure 7). Pushover curve was converted into the acceleration displacement response spectrum (ADRS), Figure 8, by using Equation 1:

$$S_a = \frac{V_b}{\alpha_1 W} \text{ and } S_d = \frac{\Delta r}{\Gamma_1 \phi_{r,1}} \quad (1)$$

where W is the total weight of the MDOF structure, Vb is the base shear, Δr is the roof displacement of the MDOF structure, α1 is the modal mass coefficient for the first mode (first fundamental mode), and Γ1 is the modal participation factor for the first fundamental mode.

$\phi_{r,1}$ is the amplitude of the first fundamental mode at the roof, S_a is spectral acceleration, and S_d is the spectral displacement.

Figure 7: a) and b) Strengthened building with ISF1 and ISF2, c) frame view of the axis 2-2, d) Section of the composite members.

Figure 7: Duzce ground motion

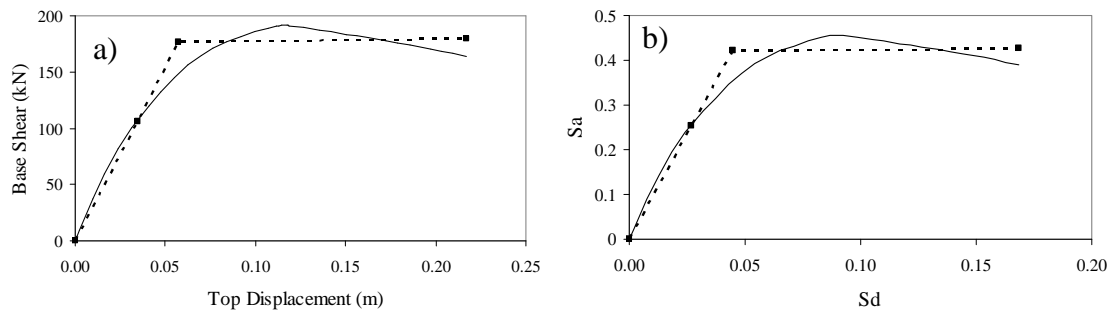

Figure 8: a) Pushover curve of the building, b) ADRS of the building.

For the SDOF approach, the linearization was performed based on the procedure given in FEMA 353 [29] (Figure 8). The mass of the building is taken as the mass corresponding to the governing x modes and 5% critical damping is assumed. Using the bilinear idealization with elastic unloading a SDOF analysis is conducted using the DGM to obtain the top displacement (performance point).

Figure 9: Pushover curve of the buildings, building with ISF1 and ISF2.

The performance points according to DGM are shown on the pushover curves in Figure 9. It can be observed that the building experiences an overall drift ratio of about 2.4 % in the x direction prior to retrofit.

A member by member evaluation is then performed to determine the damage level of the members. The number of columns and beams at different performance levels are presented in Table 1. This evaluation indicated that 100% and 36% of the first story columns and beams of the deficient building with any ISFs were at the total collapse (TC) performance level for x directions, respectively. This results indicates that this deficient building needs to be retrofitted.

Upon retrofitting, the number of the columns which were in the TC performance level decreased. Although 33% of the first story columns of the building implemented ISF 1 was within the TC performance level, this condition did not satisfy the performance level of the residential building suggested in TEC 2007. Finally, the desired performance level of the deficient building retrofitted with ISF2 was obtained by increasing numbers of retrofitted bays.

Table 1: Performance levels of the members.

Figure 10: IDR of the building at the performance points.

The IDR profiles for x directions obtained from pushover analysis at performance points of DGM are shown in Figure 10. It can be observed that highest IDR, which was about 4.7 % in

the x direction, occurred in the first story level of the building without any ISF retrofit. Upon retrofit the IDR reduced to about 1.4% for the x directions. It should be noted that the observed drift ratio is in good agreement with those limits proposed in the TEC 2007 (Figure 10). This result shows that the ISF retrofit scheme was successful in controlling drift deformations and reducing the demands in the columns. As a results, the ISF retrofit design presented above was found to be successful in LS performance level of the building by reducing the deformation demands on the RC columns and controlling the drift deformations. In addition, above results clearly indicates that a retrofit technique needs to increase lateral stiffness and strength aside from increasing global ductility capacity (if any member base retrofitting technique is not used) when ductility capacity of the existing columns and beams are insufficient.

4 CONCLUSION

The test results indicated that the ISF increased the lateral strength, stiffness and energy dissipation capacity of the deficient RC frames. The analytical study of the test frame simulated the behavior of the test frame successfully. The test frame load-deformation and damage observed during the test was correlated by the proposed performance levels suggested in TEC 2007. It was observed that the performance levels defined in TEC 2007 can be utilized conservatively to evaluate the frame retrofitted with ISF. Based on the data gained from the test and analytical results of the test frame, a case study consisted of a real existing residential building before and after ISF retrofit was evaluated by utilizing procedures suggested by the TEC 2007 under imposed DGM demand. It was observed that although seismically deficient five story RC building did not satisfy the performance levels of a residential building acceptance criterion with respect to TEC 20007, it was adequate after retrofitting with ISF. As a result, the ISF can be considered as a rapid, safe and practical retrofitting technique.

5 AKNOWLEDGE

The research discussed in this paper was conducted at Middle East Technical University (METU)-Structural Mechanics Laboratory. Funding provided by TÜBİTAK (project no: 106M493) is greatly appreciated.

Keywords: Sliding, Rigid Body, Friction, Seismic Isolation.

Abstract. *An experimental and numerical investigation is presented that studies the sliding response of a rigid body when subjected to horizontal dynamic and earthquake excitations. For this purpose, a steel block mock-up of a rigid body has been constructed and tested at the shaking table of Aristotle University. The dynamic excitations were based on either sinusoidal motions of various amplitudes and frequencies or simulated earthquake excitations based on actual recordings of prototype earthquake ground motions. The experimental results have shown that when sliding of this rigid block is permitted then its peak acceleration response is moderately amplified, provided that the excitation frequency is not close to the resonant frequency range of the block-spring dynamic system. This is particularly true for earthquake excitations and for relatively flexible spring-links thus achieving in this way a type of seismic isolation for the rigid block. A computer software was developed in order to numerically simulate this dynamic sliding response. The numerical results obtained through this specially developed computer software are next compared with the corresponding experimental measurements. The numerically predicted rigid block acceleration response is in good agreement, in all examined cases, with the measured values. The numerically predicted rigid body sliding displacement response also exhibits in numerous cases good agreement with the measured values. However, significant deviation between predicted and measured rigid body sliding displacement amplitudes were also observed. Despite these limitations of the predicted results it is believed that the developed software, although it deals with a complex problem in a relatively simple way, it can be useful in the preliminary design of structural systems with sliding capability at their support.*

1 INTRODUCTION

This paper presents results from an experimental and numerical investigation that deals with the sliding response of a rigid body when subjected to horizontal dynamic and earthquake excitations. The layout of this problem is shown in figure 1, where a rigid body (figure 1, designated with light color) is initially resting on a platform (figure 1, designated with dark color) that can move in a prescribed way in one horizontal direction, thus subjecting the rigid body to horizontal dynamic and earthquake excitations. The contact area between the rigid body and the moving platform is a horizontal plane having a friction coefficient μ (μ_{st} , the static coefficient of friction and μ_d , the dynamic coefficient of friction). Moreover, the rigid body of mass m is connected with the moving platform with an elastic spring having stiffness K and with a damper having a damping coefficient C . The motion of the moving platform is defined by the displacement vector $U(t)$ with respect to an motionless coordinate system x, y whereas the corresponding displacement vector of the rigid body is $X(t)$. The velocity and acceleration vectors of the rigid body and the moving platform are $\dot{X}(t)$ $\ddot{X}(t)$ and $\dot{U}(t)$ $\ddot{U}(t)$, respectively. The sliding displacement between the rigid body and the supporting moving platform is $U(t)-X(t)$. The following are the forces (figure 1) that arise in this rigid body – moving platform dynamic system [1].

F_{ine} = The inertia force, F_{spr} = The spring force, F_{damp} = The damping force

$F_{fr} = \mu_d m g$ = The friction force during sliding

$F_{fr} = \mu_{st} m g$ = The friction force when no sliding occurs

Figure 1. Layout of the problem

This particular problem appears to be of interest either in predicting the dynamic and earthquake response of relatively very stiff objects (rigid) that simply rest on horizontal floors or the behavior of stiff structures that incorporate a sliding surface as means of protection against dynamic or earthquake excitations.

2 EXPERIMENTAL INVESTIGATION

For this purpose, a special mock-up has been constructed that represents physically the previously stated problem (figure 1). It consisted of a steel rigid block rectangular in shape with dimensions 430mm x 430mm in plan and a height either 205mm or 410mm (upper part of figure 2); This block was simply resting on a steel moving platform (lower part of figure 2) and it was restrained to all other directions so that it could move only in the longitudinal horizontal direction. The mass of this sliding rigid block was either 124kg or 248kg. The various important physical parameters for this block sliding response are measured [6], [7], such as the coefficient of friction at the contact surface between the block and the moving

platform and the stiffness of the elastic spring as will be shown in the following sections 2.1. and 2.2. No viscous damper was introduced at this part of the experimental investigation.

Figure 2. Experimental set-up

2.1 Measuring the coefficient of friction

A special series of tests were performed in order to define the coefficient of friction of the contact surface between the sliding block and the moving platform. This surface was machined in a special way so that full contact conditions could be ensured between the sliding block and the moving platform. Moreover, this contact surface has been lubricated throughout all the experimental sequences [6], [8], [9]. Figure 3 depicts the friction force versus sliding displacement diagram when the mass of the sliding block was equal to 284kg (by placing 36kg extra mass on top of the rigid block). The frequency of the cycling displacements during these tests was varied from 0.1Hz to 1.0Hz. The values for the coefficient of friction found from these tests are listed below. A total number of 10 tests were performed.

Figure 3. Test for measuring the friction coefficient

When the rigid block mass was equal to 124kg the values of the friction coefficient were:

$$\mu_{st} = 0.165 \quad \mu_d = 0.153$$

When the rigid block mass was equal to 284kg the values of the friction coefficient were:

$$\mu_{st} = 0.158 \quad \mu_d = 0.136$$

2.2 Measuring the stiffness of the spring

Another series of tests were conducted in order to accurately measure the stiffness K of the spring that was employed to link the rigid block to the moving platform, as indicated in figure 1. Two types of springs were tested; the first was a spring that was certified for its properties whereas the second one was not certified. The loading arrangement which is depicted in figure 4 was employed during these tests whereby the force applied on the spring was measured together with the resulting spring displacement. Figure 5a shows the resulting

certified spring response during such a test whereby no pre-stressing force was applied at the spring. In figures 5b and 5c the resulting response is depicted when a pre-stressing force is applied through a special for this purpose system attached to either the certified or the non-certified spring, respectively. As was done for measuring the coefficient of friction, during the tests for measuring the spring stiffness the frequency of the cycling displacement was varied from 0.1Hz to 1.0Hz.

Figure 4. Test for measuring the spring stiffness

Figure 5a. The certified spring load-displacement response with no pre-stress

Figure 5b. The certified spring load-displacement response with pre-stress

Figure 5c. The non-certified spring load-displacement response with pre-stress

The stiffness of the certified spring with no pre-stress, as was estimated from the load-displacement response of these tests (figure 5a), had an average value $K=128.6$ KN/m.

The stiffness of the certified spring with pre-stress, as was estimated from the load-displacement response of these tests (figure 5b), had an average value $K=143$ KN/m.

The stiffness of the non-certified spring with pre-stress, as was estimated from the load-displacement response of these tests (figure 5b), had an average value $K=19.4$ KN/m.

2.3 Measuring the sliding response of the rigid block

Figure 6 depicts the experimental arrangement, whereby a number of displacement and acceleration sensors were used to monitor the sliding response of the rigid block and the actual motion of the moving platform [6], [7], [8], [9]. The force of the spring link was also monitored. The dynamic excitations of the moving platform were based on sinusoidal motions of various amplitudes and frequencies. The earthquake excitations of the moving platform were laboratory simulations based on actual recordings of prototype earthquake ground motions. The non-certified as well as the certified spring was used in a number of tests with sinusoidal or simulated earthquake excitations. In addition, a number of tests were

also conducted whereby there was no spring link between the rigid block and the moving platform.

Figure 6. Experimental arrangement for measuring the sliding response of the rigid block.

3 EXPERIMENTAL RESULTS

Selective experimental results are presented in the next sections whereby the rigid block is linked to the moving platform either with the non-certified or with the certified spring or with no spring at all. The moving platform is subjected to either sinusoidal motions, in the frequency range from 0.5Hz to 4Hz, or to simulated earthquake excitations based on the prototype Kern Country 1953 prototype earthquake horizontal acceleration recording (HTaft0407.int). The non-certified spring with a pre-stressing force is used in section 3.1. The results that are presented in this section are for a test that used a sinusoidal motion of 1.5Hz for the moving platform. The certified spring with no pre-stressing force is used in section 3.2. The results that are presented in this section are for a test that used a sinusoidal motion of 3.0Hz for the moving platform whereas in section 3.3. the certified spring with no pre-stress is again employed but this time the above named simulated earthquake motion is utilized. Finally, in sections 3.4. and 3.5. there is no spring linking the rigid block with the moving platform; a sinusoidal motion of 1.5Hz is employed in section 3.4. whereas the above named simulated earthquake motion is utilized in section 3.5.

3.1 Sinusoidal excitation 1.5Hz with non-certified spring (with pre-stress)

The presented results include the acceleration response (m/sec^2) of the moving platform and of the sliding rigid block (figure 7a) whereas the displacement (mm) of the moving platform and the spring is depicted in figures 7b and 7d respectively. Figures 7c and 7e depict the force that develops at the spring (KN) as well as the force-displacement response of this spring. Finally figure 7f depicts the sliding displacement of the rigid block relatively to the moving platform. Obviously, this sliding displacement must be theoretically equal to the spring displacement; this practically materializes in the used experimental set-up as can be seen by comparing the displacement response of figures 7f and 7d. Moreover, it can be seen that the non-certified spring force-displacement response with pre-stress measured individually (figure 5c) is in good agreement with that measured during the sliding response of the rigid body that mobilizes the response of the spring (figure 7e)

Fig. 7d. Displacement of the spring

Fig. 7e. Force-displacement response of the spring

Fig. 7f. Sliding displacement of the rigid block relative to the moving platform

3.2 Sinusoidal excitation 3.5Hz with certified spring (no pre-stress)

Again, the presented results include the acceleration response (m/sec^2) of the moving platform and of the sliding rigid block in figure 8a whereas the displacement (mm) of the moving platform and the spring is depicted in figures 8b and 8d respectively. Figures 8c and 8e depict the force that develops at the spring (kN) as well as the force-displacement response of this spring. Moreover, it can be seen that the certified spring response with no pre-stress measured during the sliding response of the rigid body that mobilizes the response of the spring (figure 8e) is in good agreement with that measured individually (figure 5a).

3.3 Simulated earthquake excitation with certified spring.

The results of two tests are presented here, both conducted with the certified spring; they are Test 002 (with small pre-stress, figures 9a to 9e) and Test 004 (with no pre-stress, figures 10a to 10e). Again, the presented results include the acceleration response of the moving platform and of the sliding rigid block in figures 9a (small pre-stress) or in figure 10a (no pre-stress). The displacement of the moving platform is depicted in figures 9b and the spring is depicted in figures 9b (small pre-stress) or in figure 10b (no pre-stress). Figures 9d and 10d depict the displacement of the spring, which coincides with the sliding displacement of the rigid block, whereas figures 9c and 10c depict the corresponding spring force. The force-displacement response of this certified spring is depicted in figures 9e and 10e, for either the small pre-stress or the no-pre-stress case, respectively. These force displacement response curves can be compared again with figures 5b and 5a, whereby a relatively good agreement can again be observed. Moreover, it can be seen that due to sliding the maximum acceleration response that develops at the rigid block is much smaller than the maximum

acceleration response of the moving platform (figures 9a and 10a). However, this reduction in the acceleration response of the rigid block is accompanied with considerable sliding displacement response of the rigid block that attains a maximum value equal to 3.65mm for Test 002 and to 14mm for Test 004.

3.4 Sinusoidal excitation 1.5Hz without spring link.

In this section as well as in the next section 3.5 the rigid block is simply resting on the moving platform having removed the spring that linked during the previous experiments the rigid block with the moving platform. In the present section the platform is moving in a horizontal sinusoidal motion of 1.5Hz.

Fig. 11a. Acceleration response of the moving platform and of the sliding block

Fig. 11b. Displacement of the moving platform, Test 005, 14-1-2008

Fig. 11c. Force that was measured at the actuator

Fig. 11d. Sliding displacement of the rigid block

The acceleration response of the moving platform and of the sliding rigid block is depicted in figure 11a whereas the displacement of the moving platform and the sliding displacement of the rigid block is depicted in figures 11b and 11d respectively. Figure 11c depicts the force that develops at the actuator during this experiment. In this case of free sliding, the maximum rigid block acceleration response is theoretically equal to $\mu_d \cdot g$, which is approximately confirmed by the measured response (if it processed with the proper low-pass filter). It is interesting to note that, in the absence of the spring link, the sliding displacement response of the rigid block develops relatively large values (30mm); moreover, there is a cumulative sliding displacement that appears as an offset from the initial zero displacement condition. This may be attributed to manufacturing tolerances whereby the contact surface between the rigid block and the moving platform deviates from the ideal horizontal plane. This deviation, which was beyond the means of our laboratory checking capabilities, may be also present in actual in-situ applications. The presence of the spring during the previous sinusoidal tests (section 3.1. and 3.2.) has as a result the reduction of the maximum sliding displacement values and the symmetric sliding with respect to the initial zero displacement condition (no cumulative sliding, see figures 7f and 8d). As was observed in all the previously depicted experiments the acceleration response of the rigid block is smaller than that of the moving platform.

3.5 Simulated earthquake excitation without spring link.

Again, the rigid block is simply resting on the moving platform having removed the spring-link. This time, the moving platform is subjected to a simulated earthquake excitation based on the prototype Kern County 1953 prototype earthquake horizontal acceleration recording (HTaft0407.int).

Fig. 12a. Acceleration response of the moving platform and of the sliding block

Fig. 12b. Displacement of the moving platform, Test 014, 14-1-2008

Fig. 12c. Force that was measured at the actuator

Fig. 12d. Sliding displacement of the rigid block relative to the moving platform

As before, the presented results include the acceleration response of the moving platform and of the sliding rigid block in figure 12a whereas the displacement of the moving platform and the spring is depicted in figures 12b and 12d, respectively. It can be seen that, due to sliding of the block without the spring link, the maximum rigid block acceleration response is much smaller than the maximum moving platform acceleration response (figure 12a). It is again interesting to note that in the absence of the spring link, the sliding displacement response of the rigid block develops relatively large values (30mm), as was also observed in section 3.4; moreover, there is again a cumulative sliding displacement that appears as an offset from the initial zero displacement condition. As mentioned in the previous section, this may be attributed to manufacturing tolerances whereby the contact surface between the rigid block and the moving platform deviates from the ideal horizontal plane. The sliding displacement response of the rigid block without the spring develops maximum sliding almost 30mm (figure 12d) which is twice as much as the sliding response of the rigid block linked to the moving platform with the certified spring and subjected to the simulated earthquake motion of HTaft0407.int (15mm, figure 10d, section 3.3).

4 NUMERICAL INVESTIGATION

The basic conditions, which are given below, are governing the sliding of the rigid body that is linked with a spring (K) and a damper (C) to a moving platform when it is subjected to horizontal $\ddot{U}(t)$ and vertical $\ddot{V}(t)$ acceleration. This represents the most general two dimensional rigid body sliding set-up [1], [2], [3], [4], [5].

Starting from an initial condition of no motion, in order for the rigid body to start sliding the platform acceleration $\ddot{U}(t)$ must exceed the value given by the following inequality (1)

$$|\ddot{U}(t)| > \mu_{st} \cdot g \cdot \left(1 + \frac{\ddot{V}(t)}{g}\right) \quad (1)$$

In this case, the rigid body acceleration will be given by the following relationship (2):

$$\ddot{X}(t) = \mu_d \cdot g \cdot \left(1 + \frac{\ddot{V}(t)}{g}\right) \cdot [\text{sign}(\dot{U}(t) - \dot{X}(t))] + \frac{K}{m} \cdot (U(t) - X(t)) + \frac{C}{m} \cdot (\dot{U}(t) - \dot{X}(t)) \quad (2)$$

When the rigid body is sliding it will be checked for reattachment to the moving platform by examining the absolute value of its relative velocity $|\dot{U}(t) - \dot{X}(t)|$, e.g. the relative velocity of the rigid body to the moving platform. If the value of the relative velocity becomes equal to zero and inequality (3) holds the rigid body will keep sliding.

$$\text{If } |\dot{U}(t) - \dot{X}(t)| = 0 \text{ and } \left| \ddot{U}(t) - \frac{K}{m} \cdot (U(t) - X(t)) \right| > \mu_{st} \cdot g \cdot \left(1 + \frac{\ddot{V}(t)}{g}\right) \quad (3)$$

If the value of the relative velocity becomes equal to zero and inequality (4) holds the rigid body is reattached to the moving platform

$$\text{If } |\dot{U}(t) - \dot{X}(t)| = 0 \text{ and } \left| \ddot{U}(t) - \frac{K}{m} \cdot (U(t) - X(t)) \right| \leq \mu_{st} \cdot g \cdot \left(1 + \frac{\ddot{V}(t)}{g}\right) \quad (4)$$

The above conditions were included in a computer software (namely *block* and *blockr*) that used a time step-by-step integration procedure incorporating an iteration scheme to reach acceptable limits of convergence. In this step-by-step integration procedure the following

simple relationships (5) and (6) were used for defining the velocity and displacement at a time t_i for the rigid body.

$$\dot{X}(t_i) = \dot{X}(t_{i-1}) + (\ddot{X}(t_{i-1}) + \ddot{X}(t_i)) \cdot \frac{\Delta t}{2} \quad (5)$$

$$X(t_i) = X(t_{i-1}) + (\dot{X}(t_{i-1}) + \dot{X}(t_i)) \cdot \frac{\Delta t}{2} \quad (6)$$

This computer software was next validated by numerically simulating the dynamic sliding response of the tested rigid block and by comparing the measured in the laboratory response, as briefly presented and discussed in sections 3.1. to 3.5 with the corresponding numerical predictions. In this numerical simulation all the important physical parameters of the problem at hand, such as the friction coefficients, the spring stiffness, the rigid body mass and the moving platform motion, were given as input to this computer software with values that were found from the laboratory measurements. The numerical results that describe the sliding response of the rigid block, obtained through this software, are next compared with the corresponding test results in the following sections 4.1. to 4.5.

4.1 Comparison of numerical predictions with the response measured during the test employing sinusoidal excitation 1.5Hz with non-certified spring (with pre-stress)

Figure 13a,b depicts a comparison of the predicted by the block software acceleration response of the rigid block with the corresponding measured response during this test when the moving platform is subjected to a sinusoidal motion of 1.5Hz. Apart from the platform motion that is input to the software the rest of the input parameters, are listed in figures 13a,b such as the static (μ_{st}) and dynamic coefficient (μ_d) of friction, the mass of the rigid block (M) and the stiffness of the spring.

block (no-prestress)

Input parameters

$\mu_{st} = .32$, $\mu_d = .27$
 K (N/m) = 20500
 M (kg) = 248
 DtF (sec) = .005
 Dt (sec) = .001
 $TIME$ (sec) = 14.995

Fig. 13a.

Fig. 13b block (no-prestress) K (N/m) = 20500

Fig. 13c blockr (pre-stress) $K1$ (N/m) = 58000
 $K2$ (N/m) = 21500

Figure 13d. Block sliding displacement response (Test 005 29-11-2007)

The stiffness of the spring is denoted as K when no pre-stress is present and $K1/K2$ when the spring is pre-stress and this is taken into account in the software (blockr). Figure 13a represents this measured and predicted rigid block acceleration response for the whole duration of the performed experiment whereas figure 13b and 13c represent time windows of this response between 4 and 7 seconds of the total time history. For predicting the rigid block acceleration response the spring pre-stress was initially ignored (figure 13b) and then it was taken into account (figure 13c). In the same figure the measured acceleration of the moving platform is also plotted together with the input platform acceleration used by the software.

As can be seen in figure 13b a relatively good agreement is obtained between predicted and measured rigid block acceleration response which is further improved when the spring pre-stress is included in the software (figure 13c). In figure 13d, the predicted sliding displacement response of the rigid block is compared with the corresponding measured response for the same test. As can be seen, the predicted sliding displacement response is significantly larger than the one measured in the laboratory.

4.2 Comparison of numerical predictions with the response measured during the test employing sinusoidal excitation 3.5Hz with certified spring (no pre-stress)

The comparison between predicted and measured rigid block acceleration response is presented in figures 14a,b as was done in the previous section whereas the predicted rigid block sliding response is presented in figure 14c.

block (no-prestress)

Input parameters

$\mu_{st} = .15$
 $\mu_d = .145$
 $K \text{ (N/m)} = 100000$
 $M \text{ (kg)} = 248$
 $DtF \text{ (sec)} = .005$
 $Dt \text{ (sec)} = .0005$
 $TIME \text{ (sec)} = 10.005$

Fig.14a. Acceleration response of moving platform and of the sliding rigid block (Test 011, 19-12-2007)

Fig. 14b Acceleration response of moving platform and of the sliding rigid block (Test 011, 19-12-2007)

Figure 14c. Rigid block sliding displacement response (Test 011, 19-12-2007)

As can be seen in figures 14a,b good agreement is obtained between predicted and measured rigid block acceleration response. In figure 14c, the predicted sliding displacement response of the rigid block is compared with the corresponding measured response for the same test. As can be seen, this time very good agreement is obtained between the predicted rigid block sliding displacement response and the one measured in the laboratory.

4.3 Comparison of numerical predictions with the response measured during the test employing simulated earthquake excitation with non-certified spring (with pre-stress)

Input parameters

$\mu_{st} = .15$
 $\mu_d = .13$
 $K \text{ (N/m)} = 123000$
 $M \text{ (kg)} = 248$
 $DtF \text{ (sec)} = .005$
 $Dt \text{ (sec)} = .001$
 $TIME \text{ (sec)} = 5.495$

Fig. 15a. Acceleration response of moving platform and of the sliding rigid block (Test 002, 21-12-2007)

Fig. 15b. Acceleration response of moving platform and of the sliding rigid block (Test 002, 21-12-2007)

Fig. 15c. Sliding displacement response of rigid block (Test 002, 21-12-2007)

The comparison between predicted and measured rigid block acceleration response is presented in figures 15a,b as was done in the previous sections, whereas the predicted rigid block sliding displacement response is presented in figure 15c. The rigid block is linked to

the moving platform with the non-certified spring (with pre-stress). This time the excitation is a simulated earthquake motion (see section 3.3). As can be seen, good agreement is obtained between predicted and measured rigid block acceleration response. The predicted rigid block sliding displacement response correlates reasonably well with the one measured in the laboratory in the time domain. However, the predicted sliding displacement response, in terms of amplitude, is significantly larger than the one measured in the laboratory.

The measured response is again compared with the one predicted by the software in figures 16a,b,c for a simulated earthquake test (Test 004, 21-12-2007), which is more intense than the one used before (Test 002, 21-12-2007). This time, the good agreement between observed and predicted rigid block response can be seen for both the acceleration (figures 16a,b) as well as the sliding displacement response (figure 16c)

Fig. 16a. Acceleration response of moving platform and of the sliding rigid block (Test 004, 21-12-2007)

Fig. 16b. Acceleration response of moving platform and of the sliding rigid block (Test 004, 21-12-2007)

Fig. 16c. Sliding displacement response of rigid block (Test 004, 21-12-2007)

4.4 Comparison of numerical and measured response during the test employing Sinusoidal excitation 1.5Hz without spring

The comparison between predicted and measured rigid block acceleration response is presented in figures 17a,b as was done in the previous sections whereas the predicted rigid block sliding response is presented in figure 17c. The rigid block is resting this time to the moving platform without any spring link attachment, which was used in the previous sections (4.1 to 4.3). The excitation of the moving platform is initially sinusoidal 1.5Hz. As can be seen, good agreement is obtained between predicted and measured rigid block acceleration response. The predicted rigid block sliding displacement response correlates reasonably well with the one measured in the laboratory in the time domain. However, the predicted sliding displacement response, in terms of amplitude, is significantly larger than the one measured in the laboratory. It is interesting to note that the cumulative sliding displacement, which

appears as an offset from the initial zero displacement condition in the measurements, is not predicted by the software. This partly confirms the explanation given in section 3.4. that this measured cumulative (offset) sliding displacement response may be attributed to manufacturing tolerances whereby the contact surface between the rigid block and the moving platform deviates from the ideal horizontal plane.

Input parameters

$\mu_{st} = .15$
 $\mu_d = .14$
 $K \text{ (N/m)} = 0$
 $M \text{ (kg)} = 248$
 $DtF \text{ (sec)} = .005$
 $Dt \text{ (sec)} = .001$
 $TIME \text{ (sec)} = 10.845$

Fig. 17a. Acceleration response of moving platform and of the sliding rigid block (Test 005, 14-1-2008)

Fig. 17b. Acceleration response of moving platform and of the sliding rigid block (Test 005, 14-1-2008)

Fig. 17c. Sliding displacement response of rigid block (Test 005, 14-1-2008)

4.5 Comparison of numerical predictions with the response measured during the test employing simulated earthquake excitation without spring

Input parameters

$\mu_{st} = .15$
 $\mu_d = .14$
 $K \text{ (N/m)} = 0$
 $M \text{ (kg)} = 248$
 $DtF \text{ (sec)} = .005$
 $Dt \text{ (sec)} = .001$
 $TIME \text{ (sec)} = 15.725$

Fig. 18a. Acceleration response of moving platform and of the sliding rigid block (Test 014, 14-1-2008)

Fig. 18b. Acceleration response of moving platform and of the sliding rigid block (Test 014, 14-1-2008)

Fig. 18c. Sliding displacement response of rigid block (Test 014, 14-1-2008)

The comparison between predicted and measured rigid block acceleration response is presented in figures 18a,b as was done in the previous sections whereas the predicted rigid block sliding response is presented in figure 18c. The rigid block is resting, as in section 4.4., to the moving platform without any link employing any spring attachment; however, this time a simulated earthquake excitation is used. As can be seen, good agreement is obtained between predicted and measured rigid block acceleration response. The predicted rigid block sliding displacement response correlates reasonably well with the one measured in the laboratory in the time domain as well as in terms of maximum amplitude. It is again interesting to note that, there is a cumulative sliding displacement that appears as an offset from the initial zero displacement condition in the predicted response that is much larger than the one observed during the experiment. This observation contradicts the explanation, which was given before in section 4.4., that this measured cumulative (offset) sliding displacement response may be attributed to manufacturing tolerances whereby the contact surface between the rigid block and the moving platform deviates from the ideal horizontal plane. As an alternative explanation, these differences between predicted and measured rigid block cumulative (offset) sliding displacements may also be attributed to the integration scheme which was used by the computer software. This alternative explanation needs verification.

In figure 19, the ratio of the acceleration response spectral values based on the rigid block acceleration response over the corresponding acceleration spectral values based on the platform acceleration is plotted in the period range from 0 to 2 seconds. This is done for test 14 (14-1-2008) whereby the rigid block was subjected to a simulated earthquake motion, as is shown in figures 19a,b,c. The relevant spectral ratio values are for 5% damping and correspond to both the predicted and the observed block acceleration response.

Figure 19. Ratio of response spectral values

As can be seen in this figure, these response spectral ratio values are, as expected, smaller than 1, which indicates the influence of sliding in reducing the rigid block acceleration response, as means of seismic isolation.

4.6 Comparison of numerical predictions with the response measured during a sweep test in the frequency domain.

In this section, a final comparison is performed between measured and predicted rigid block acceleration response. The developed software is utilized to perform a series of numerical solutions whereby the same rigid block with the same mass, spring stiffness and friction coefficients is used by subjecting it to a series of distinct sinusoidal excitations of the moving platform keeping the peak acceleration amplitude constant but varying the frequency of the excitation (numerical sweep test). The ratio of the maximum rigid block acceleration response over the peak acceleration of the moving platform from each numerical solution is plotted in figure 20 against the frequency of the corresponding excitation. This is done simulating three distinct physical problems representing the following:

- The tested during the experimental sequence rigid block with the certified spring ($\mu_{st}=0.15$ $\mu_d=0.14$, $M=248\text{kg}$, $K=100000\text{N/m}$ no pre-stress), presented in sections 3.1. to 3.5.
- The tested during the experimental sequence rigid block with the certified spring ($\mu_{st}=0.15$ $\mu_d=0.14$, $K=20000\text{N/m}$ no pre-stress), presented in sections 3.1. to 3.5.
- The tested during the experimental sequence rigid block with the certified spring ($\mu_{st}=0.15$ $\mu_d=0.14$, $K=2000\text{N/m}$ no pre-stress), presented in sections 3.1. to 3.5. This simulates a case whereby the spring link between the rigid block and the moving platform is very flexible, towards approximating a case whereby there is no spring link.

The resulting numerical values are plotted in figure 20 with solid lines whereas the corresponding experimental values are also plotted in the same figure with the dotted lines that connect the measured values (squares) at distinct frequencies during specific experiments. The following observations can be made based on the results presented in this figure.

Figure 20. Comparison of measured and predicted rigid body acceleration response

a. As expected, the presence of the spring introduces an amplification in the rigid block acceleration response with amplification ratio values less than two (2), except when the frequency of the excitation is close to the resonant frequency of the spring-block dynamic system. It must be pointed out that in the examined cases apart from the friction there is absence of any other damping mechanism; moreover, the friction coefficients were measured to have relatively small values (section 2.1). The absence of any other damping mechanism apart from the friction, with small values of the coefficients of friction, can also explain the

large amplification values when the excitation frequency becomes close to the resonant frequency [1].

b. When, the value of the spring stiffness is relatively small, the amplification of the rigid body acceleration response is smaller than one (<1) in the frequency range of many practical applications in the seismic design.(for frequencies larger than 0.5Hz, or for periods smaller than 2 seconds), thus introducing in this way the well known seismic isolation of such a rigid block, which is obtained by many such sliding devices.

c. The comparison between the measured results and the predicted values in this plot exhibit relatively good agreement, especially when this comparison is done in frequencies that are not close to the resonant frequency range.

d. In the tested case whereby there is no spring between the rigid block and the moving platform the response amplification value is smaller than one (<1) in a more extended frequency range.

5 CONCLUSIONS

1. An extensive experimental sequence has been performed studying the sliding response of a rigid block linked with a spring, having a wide variety of stiffness values, to a moving platform and being subjected to sinusoidal and simulated earthquake excitations. There was no other damping mechanism apart from the friction between sliding block and moving platform with relatively low values of the coefficient of friction. The experimental results have shown that when sliding of this rigid block is permitted then its peak acceleration response is moderately amplified, provided that the excitation frequency is not close to the resonant frequency range of the block-spring dynamic system. This is particularly true for earthquake excitations and for relatively flexible spring-links thus achieving in this way a type of seismic isolation for the rigid block.

2. This sliding response of the rigid block is accompanied by sliding displacements that can be of relatively large amplitude, when the stiffness of the spring that links the rigid block with the moving platform is relatively low. This sliding displacement response is accompanied by a cumulative sliding displacement, which may result in a permanent sliding displacement of considerable amplitude at the end of the excitation. The amplitude of the sliding displacement response decreases with the increase of the spring stiffness, when the excitation is not close to the resonant frequency of the spring-block dynamic system.

3. A computer software was developed in order to predict this rigid block sliding response. The numerical predictions were validated by comparing them to a large number of experimental measurements. As can be seen from this comparison, the numerical predictions confirm all the behavioral observations of the studied phenomenon, as they were recorded during this extensive experimental sequence.

4. The numerically predicted rigid block acceleration response is in good agreement with the measured values for all examined cases of spring stiffness and for both the sinusoidal as well as the simulated earthquake excitation of the moving platform.

5. The numerically predicted rigid block sliding displacement response exhibited in some cases good agreement with the measured values. However, in some other cases the deviation between predicted and measured rigid body sliding displacement response values were significant (of the order of 100%). It is interesting to note the cumulative sliding displacements that appear as an offset from the initial zero displacement condition; this is successfully reproduced by the predicted response only in some cases. Possible explanations that are given for this are manufacturing tolerances, whereby the contact surface between the rigid block and

the moving platform deviates from the ideal horizontal plane, as well as the integration scheme that is included in the computer software.

6. Despite the limitations of the predicted results it is believed that the developed software, although it deals with a complex problem in a relatively simple way, it can be useful in the preliminary design stages of structural systems with the sliding capability at their support.

Keywords: Infill Walls, RC Frames, Nonlinear Time History Analyses.

Abstract. *This study investigates the possible adverse effects of the infill walls on the seismic response of the deficient reinforced concrete structures. It is shown herein that neglecting the presence of infill walls may not always a safe design approach. First the modeling approach is verified against available pseudo dynamic test results. Afterwards, the response of a 4-story 3-bay RC frame was examined with and without infill wall schemes. 7.14 magnitudes 1999 Duzce Earthquake was applied as the ground motion record in the nonlinear time history analyses. In order to simulate failure of infill walls accurately, element removal algorithm was employed in the middle bay of RC frame with strut and tie model. Analysis results indicated that, including infill walls with element removal algorithm led unsafe results in terms of inter-story drift ratio in first story and rotations at the critical plastic hinge location. As a result, neglecting infill wall contribution to the lateral stiffness and strength is not always a conservative design approach.*

1 INTRODUCTION

Numerical simulations have been playing an important role on both design and assessment processes of the building structures. Infill walls are usually neglected in numerical approaches due to their limited effects on the lateral strength and stiffness of the system. Including infill walls also increases the complexity of the nonlinear numerical models which is not desired for time history analyses. There are several studies that investigate the lateral load resisting systems consisting unreinforced infill members. Behavior of masonry-infilled non-ductile reinforced concrete frames was studied in several studies [1]. [2] developed a three-strut model for concrete masonry-infilled steel frames. [3] performed one-story and five story structural systems that have deficient columns and infill walls with unreinforced masonry. An analytical formulation that implements automated removal of collapsed elements during an on-going simulation was proposed [3].

This study deals with numerical simulation of RC frames with infill walls by employing strut and tie model and element removal algorithm. First, validation of the proposed algorithm is presented by comparing simulation results with pseudo dynamic test results. Afterwards, a case study is presented to demonstrate the expected effects of including infill walls and their failure.

2 NUMERICAL VALIDATION

2.1 TEST FRAME

In order to gain confidence on the applied simulation algorithm simulation technique that will be described later in the paper, results were validated against recently obtained pseudo dynamic test data. A two story-three bay RC frame was constructed and tested in that study. Figure 1 indicates the frame dimensions and test setup. This RC frame was tested by utilizing pseudo dynamic test procedures. The details of the test frame and test results are available in elsewhere [4].

The north-south component of the 1999 Duzce earthquake as seen in Figure 2 was used for the pseudo dynamic test. This figure also shows the spectral acceleration vs. time plot of the Duzce earthquake and spectrum defined in Turkish Earthquake Code (TEC 2007) [5] and the fundamental period the analyzed frames. It can be observed that spectrum of the Duzce ground motion is expected to cause more demand in the constant acceleration region while being relatively close to the code specified spectrum.

2.2 NUMERICAL MODELING

Nonlinear time history analysis (NTHS) of test structure were performed by utilizing Opensees Simulation Platform [6] to observe the ability of estimating the dynamic response of a analyzed frame. Although general modeling approach of the test frame was mentioned in this study, compressive data about test frame and test data are available in elsewhere [4].

In order to compare the effect of infill walls on analyzed frame two NTHAs were conducted; frame with and without infill walls. Bare frame analysis was conducted without adding any new structural component to the system. On the other hand, frame with infill wall was analyzed with the diagonal strut model with the element removal algorithm. It was assumed that infill wall had a width of 150 mm (110 mm brick, 40 mm mortar). Compressive strength of the mortar was taken as 14 MPa.

Force based fiber frame elements were used to model beams and columns. The material model used for concrete (Concrete01) follows the rules of the confined and unconfined concrete models proposed by [7] with plastic offset rules [8]. Due to welding of longitudinal rein-

forcements to the foundation in the column ends, bond-slip was not observed at test frame. Hence, reinforcing steel was modeled using a bilinear elasto-plastic model (Steel 02) with a kinematic hardening slope of 1%. The infill walls were modeled using compression only truss elements connected to the diagonal nodes of the boundary frame.

Frame	Concrete Compressive Strength (Mpa)	Longitudinal Reinforcement Yield Strength (MPa)	Transverse Reinforcement Yield Strength (MPa)
Analyzed Frame	9.0	220	220
Test Frame	7.4	330	290

Table 1: Mechanical properties of the materials.

Figure 3: Infill wall layout and analytical model of the test frame.

The material properties and relevant equations from ASCE/SEI-41 guidelines [9] were employed. In this way it was possible to observe the success of estimating the natural period of the test structure with these stiffness values. Effective strut area for the infill walls was calculated according to ASCE/SEI-41 guidelines and found as 0.025 and 0.021 m² for the first and second stories using the following equations:

$$a = 0.175(\lambda_1 \times h_{col})^{-0.4} r_{inf} \quad (1)$$

$$\lambda_1 = \left[\frac{E_{ms}(t_{in} + t_p) \sin 2\theta}{4E_c I_c h_{in}} \right]^{1/4} \quad (2)$$

Above, h_{col} is the column height, r_{inf} is the diagonal length of infill panel, θ is the angle whose tangent is the infill height to length ratio, E_c and E_{ms} are the modulus of elasticity of concrete and the plaster-infill composite and t_{in} and t_p are the thicknesses of brick units and the plaster. The modulus of elasticity of the plaster-brick composite, E_{sm} , was computed as 10000 MPa from Binici and Ozcebe 2006 [10]:

$$E_{ms} = \frac{E_{in}t_{in} + E_mt_p}{t_{st}} \quad (3)$$

where E_{in} and E_m are the modulus of elasticity of the infill wall and mortar/plaster, and t_{in} and t_m are the thickness of the infill wall and mortar. Accordingly, E_{in} was taken as 7700MPa ($550F_m$) based on ASCE/SEI-41 recommendations and t_u was calculated as 16200 MPa ($4700\sqrt{F_c}$) using ACI 318-05 [11] equation.

The observations made during the test showed that diagonal cracks formed in the central region of the infill in both directions. Later these cracks extended in a step pattern indicating the failure of bed joints along the diagonal. Consequently, compressive strength of the strut (F_{cm}) was computed from ASCE/SEI-41 assuming that bed-joint shear strength governs the strength of the diagonal strut either in the form of a diagonal crack or a single horizontal bed joint by using equations:

$$V_{ss} = f_{mv}L(t_{in} + t_p) \quad (4)$$

$$f_{cm} = V_{ss}/(a \cos \theta) \quad (5)$$

in which V_{ss} is the total shear resistance along the wall length, L is the length of the infill wall, f_{mv} is the shear strength of bed mortar/plaster mix which was taken from ASCE/SEI-41 as 0.25 MPa for masonry in good condition. Popovics equation [12] was employed for the compressive stress-strain behavior of the infill struts (Concrete 04) as suggested by [13]. The strain at peak compressive strength and diagonal strut failure were taken as 0.002 and 0.004, respectively.

Although the infill diagonal strut fails in one direction in the numerical simulations, the strut in the opposite direction at the first story had still significant capacity and stiffness. Hence the frame could not deform in the opposite direction upon failure of only one diagonal strut. In order to overcome this modeling error, element removal algorithm as suggested by [3] was adopted. When the failure strain of the diagonal strut is exceeded in one direction, the struts in both directions are removed from the model. Upon element removal, internal forces were redistributed to achieve an equilibrium state at failure time. In this way, failure of the strut in one direction results in complete failure of the infill wall.

Nodes were constrained to act as rigid diaphragms for all stories. Lumped mass approach with a Rayleigh critical damping of 5% was utilized during the analyses by also incorporating the second order nonlinear geometric effects. The details of modeling and the properties of effective truss model are given in Figure 3. The NTHA results of the test frame indicate that the proposed model of the infill wall was able to capture the load deformation behavior (Figure 4) in a fairly accurate manner. It can be observed that inclusion of the element removal algorithm is necessary in order to capture the damage state of the test frame at the verge of collapse.

Figure 4: NTHA results of the test frame

3 CASE STUDY

3.1 FOUR STORY-THREE BAY RC FRAME

An exterior frame of a deficient existing 4-story RC building was analyzed with and without infill strut model to reflect the importance of infill modeling and element removal algorithm. The first floor plan view of this building is indicated in Figure 5. The evaluated 4-story 3-bay frame is given in Figure 5 where the complete details of the analyzed building are available elsewhere [14]. The frame had 250x400 mm columns which were oriented in their strong axis for B-axis and their weak axis for A, C and D-axes. All the beam dimensions were 150x500 mm. Interior bay of the frame (B-C axes) were used for installing infill walls as truss members. Table 1 indicates the mechanical properties of the materials. Accordingly, uniaxial compressive strength of the concrete was 9 MPa and the yield strength of reinforcing steel was 220 MPa. Stirrup spacing was 260 mm for beams and 280 mm for columns with a clear cover of 25 mm. Beams, columns and further structural details are given in Figure 5.

3.2 NUMERICAL MODEL OF FOUR STORY-THREE BAY RC FRAME

The modeling approach of the case study was similar to that of test frame. It was assumed that infill wall had a width of 150 mm (110 mm brick, 40 mm mortar) which is same as width of beams in analyzed structure. Effective strut area for the infill walls was calculated according to ASCE/SEI-41 guidelines and found as 0.042 m^2 . Compressive strength of the mortar and the elastic section modulus of the infill wall were taken as 14 MPa and 10000 MPa, respectively. The analytical model is shown in Figure 6.

3.3 ANALYSIS RESULTS OF THE FOUR STORY-THREE BAY FRAME

The NTHA results of the frames with and without infill walls are presented in Figure 7. For the analysis of the test frame with infill walls, the element removal algorithm was incorporated. The structure excluding the presence of infill walls exhibited a peak first-story drift ratio (DR) of about 3.6%. However, the structure with infill walls experienced more than 8% DR upon automatically removing the wall struts from the system. Structure with infill walls suffered higher DRs than the structure without infill walls and finally it collapsed under the extreme first-story DR demands. Effect of soft-story formation could be seen more clearly in Figure 8.

Figure 5: a) Analyzed building floor view, b) Analyzed 4-story frame, c) Beam and column section.

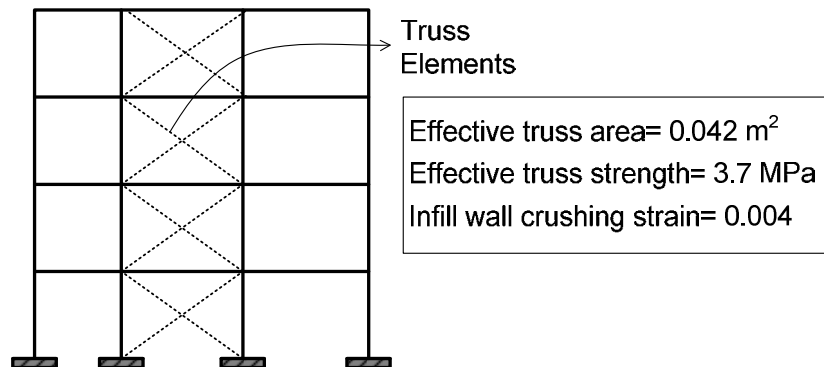

Figure 6: Infill wall layout and analytical model of the test and 4 story-3story frames.

According to results structure without infill walls satisfied inter story drift ratio (IDR) limits of TEC 2007 for the collapse prevention (CP) limit state and remained in the high damage region. Results reveal that neglecting infill walls for design purposes may not ensure designer to stay on the safe side for all the cases. The main difference between the results of two frames is the sudden collapse of the infill wall and change of dynamic properties of the test frame during the ground motion. The infill walls, although beneficial and control inter story drift deformations at low deformation demands, provide significant amplification of deformations (1st story in this example) when sudden collapse of the infill wall occurs. The estimation of deformations when infill walls are neglected may not necessarily be on the safe side for design purposes.

Figure 7: Comparison of simulation results with and w/o infill walls.

Figure 8: Comparison of inter-story DR with and w/o infill walls.

Base shear versus top story DR responses are given in Figure 9. Results show that incorporating infill walls to the system increased both the stiffness and the lateral load capacity of the frame significantly. However, after crushing of first story infill wall, this capacity dropped to the same level that was observed on the results of the bare frame. Therefore, capacity enhancement of infill walls to the system is not accountable at large deformation demands. The presence of an element removal algorithm clearly imposes more demand on the RC members than the case without the infill walls.

Figure 9: Base shear versus top-story DR with and w/o infill walls.

Performance evaluation of the both frames led to similar results for the first story (Figure 10). For the case without infill walls 75% of the columns passed beyond CP performance limit at first story. However, for the case with infill walls, all the first story columns of the test frame passed beyond CP performance limit as expected. Incorporating infill walls in the NTHA also changed the response on the upper stories. Frame without infill wall mainly experienced damage at the interior columns of first and second stories and exterior beams of first story. Violation of CP performance limit was observed for these beams. For the case with infill walls, formation of soft story oriented the distribution of damage to first story and prevented upper stories experiencing any significant damage. Both of the systems did not satisfy the overall performance criteria of TEC 2007 and found to be in collapse region.

Figure 10: Performance evaluation of RC frame members with and w/o infill walls.

4 CONCLUSIONS

For assessment purposes, contribution of infill walls may be included to have a better estimation of displacement demands. Results showed that ASCE-SEI-41 recommendations for strut modeling may lead to satisfactory estimation along with the use of element removal algorithm. The formation of a soft story mechanism was found to be better simulated with the

use of such a removal algorithm. Performance evaluation of the 4 story-3 bay frame showed that after failure of the infill wall, all the first story columns passed the CP limit state and sustained heavy damage due to excessive IDR levels. As a result, for design purposes neglecting infill walls may not always lead to safe design or assessment results.

5 ACKNOWLEDGE

The research discussed in this paper was conducted at Middle East Technical University (METU)-Structural Mechanics Laboratory. Funding provided by TÜBİTAK (project no: 106M493) is greatly appreciated.

Keywords: Seismic response, wave propagation, inhomogeneous soil, transfer function, equivalent homogeneous soil

Abstract. *Equivalent homogeneous soils are investigated as simplified approximations of continuously inhomogeneous soils. The examined system comprises of an inhomogeneous surface layer over a homogeneous one of higher stiffness. Five alternative definitions are adopted for the representative shear wave velocity (V_{hom}) in the inhomogeneous layer: (i) V_{hom1} at the base of the inhomogeneous layer (ii) V_{hom2} in the middle of the inhomogeneous layer (iii) V_{hom3} equal to the mean shear wave velocity within the inhomogeneous layer (iv) V_{hom4} providing equal travel time from base to surface between homogeneous and inhomogeneous soil and (v) V_{hom5} corresponding to an equivalent homogeneous soil having the same fundamental frequency as the inhomogeneous profile. Seismic response between inhomogeneous and equivalent homogeneous soils is compared by means of exact analytical solutions for single- and two-layer inhomogeneous soils. Fundamental frequencies and resonant peak amplitudes are examined, as affected by salient model parameters such as inhomogeneity factor, surface-to-base shear wave velocity ratio in the inhomogeneous layer, shear wave velocity contrast between the inhomogeneous and the homogeneous layer and relative layer thickness. It is observed that resonant frequencies of a smoothly-to-moderately inhomogeneous soil may be adequately captured by an equivalent homogeneous soil of either equal shear wave propagation velocity at the mid depth of the inhomogeneous layer, or of equal mean shear wave velocity within the whole layer. On the contrary, resonant amplitudes of a moderately-to-strongly inhomogeneous soil may be significantly underestimated or overestimated when an equivalent homogeneous soil is adopted, especially at higher resonances. The response of inhomogeneous soils with vanishing shear wave velocity near soil surface is explored.*

1 INTRODUCTION

Based on a detailed in-situ investigation of dynamic properties of soft deposits, Towhata [1] demonstrated analytically that shear wave propagation velocity may vary continuously with depth even for complex stratifications involving different soil materials. Utilizing a one-dimensional model of inhomogeneous soils with zero or finite stiffness at the surface, the above author showed analytically the possibility of higher amounts of seismic energy reaching the ground surface with respect to soils with discontinuous variation in shear modulus. Continuously inhomogeneous soils have been studied for different types of soil inhomogeneity or of seismic waves in multiple directions providing closed-form solutions for natural frequencies, modal shapes and amplification functions. Following the early work of Ambraseys [2] and Seed and Idriss [3], Dobry et al.[4] studied the dynamic response of inhomogeneous soils with shear wave propagation velocity of the form $V_s = c z^n$, z being depth and n a positive inhomogeneity coefficient, corresponding to zero shear modulus at ground surface. A special case of the above equation, corresponding to $n = 2/3$, was adopted by Travasarou and Gazetas [5] as part of an investigation of seismic response of soft marine clay sediments verifying analytically that exceedingly large amplification of seismic motion may occur on the free surface. The effect of rate and type of heterogeneity on the seismic response of heterogeneous soils with shear wave velocity increasing from a non-zero value at the free surface has been examined by Ambraseys [2], Toki & Cherri [6], Schreyer [7] and Gazetas [8]. More recently, Parashakis [9] and Semblat and Pecker [10] extended the aforementioned models to obtain analytical solutions of the wave equation for a heterogeneous soil with shear wave velocity increasing with depth according to a generalized power law.

On the other hand, according to most modern seismic codes [11-13], site classification is based on the average shear wave propagation velocity within the top 30 metres (i.e. $V_{s,30}$) of the soil profile. The above regulations essentially refer to a homogeneous or inhomogeneous profile without strong gradients in shear wave propagation velocity with depth. However, in case of a moderately-to-strongly inhomogeneous soil, the choice of a pertinent, “representative” shear wave velocity is not straightforward especially when thick and soft soil deposits are encountered. In this case, conventional analyses based on discretizing soil in a multi-layer system with constant properties within each layer, may underestimate soil amplification with respect to the actual response of a continuously inhomogeneous medium, depending primarily on frequency content of input motion [1].

In light of the above considerations, “equivalent” homogenous soils are investigated as simplified approximations of continuously inhomogeneous soils. The investigation focuses on layered inhomogeneous soils as an extension of a previous research effort by the authors referring to single-layer systems [14]. The examined system comprises of a surficial inhomogeneous zone followed by a homogeneous layer on rigid base. A generalized parabolic function is adopted to describe the shear wave propagation velocity in the inhomogeneous layer, allowing modeling of inhomogeneous soils having vanishing values of shear modulus at ground surface. The problem is treated analytically by implementing closed-form solutions derived both for single- and two-layer inhomogeneous soil deposits in terms of base-to-surface transfer functions [9, 15, 16]. Seismic response between inhomogeneous and equivalent homogeneous soils is compared by means of fundamental frequencies and resonant amplitudes ratios, as affected by governing model parameters such as layer thickness, surface-to-base shear wave velocity ratio in the inhomogeneous layer, impedance contrast between surface and base layer and rate of inhomogeneity. The dependence of near-surface shear strains for inhomogeneous soils with very small surface-to-base shear wave velocity ratios is investigated by means of asymptotic analyses.

2 PROBLEM DEFINITION

A continuously inhomogeneous viscoelastic soil zone of thickness H over a rigid base (Fig.1a) is considered as a basis of the layered inhomogeneous soil examined. Soil mass density, ρ , and hysteretic damping ratio, ζ , are considered constant with depth. Shear wave propagation velocity is assumed to increase with depth according to the generalized power law function:

$$V_s(z) = V_H \left[b + (1-b) \frac{z}{H} \right]^n \quad (1)$$

where b is defined as a function of the shear wave velocity at the surface (V_o) and base (V_H) of the inhomogeneous soil layer [i.e. $b=(V_o/V_H)^{1/n}$], n is a dimensionless inhomogeneity factor varying in the common range of 0 to 1 ([9], [17], [18]) and z stands for the vertical coordinate (depth) measured from ground surface. For small values of the inhomogeneity factor n , Eq.1 simplifies to a uniform distribution while values of n close to unity correspond to linear increase in shear wave velocity with depth.

The single-layer system is extended to account for the presence of an underlying homogeneous layer of thickness (h_b) and shear wave propagation velocity (V_b) forming a generalized two-layer inhomogeneous soil with bounded shear wave velocity at large depths (Fig.1b). In this manner, a wide set of soil types can be modeled encompassing different soil properties between the inhomogeneous and the homogeneous layer.

Seismic response of layered inhomogeneous soils is compared to different equivalent homogeneous cases. The latter are defined through a representative shear wave velocity V_{hom} in the inhomogeneous layer using the following definitions [14]:

- V_{hom1} , equal to the shear wave propagation velocity V_H at the base of the inhomogeneous layer:

$$V_{hom1} = V_H \quad (2)$$

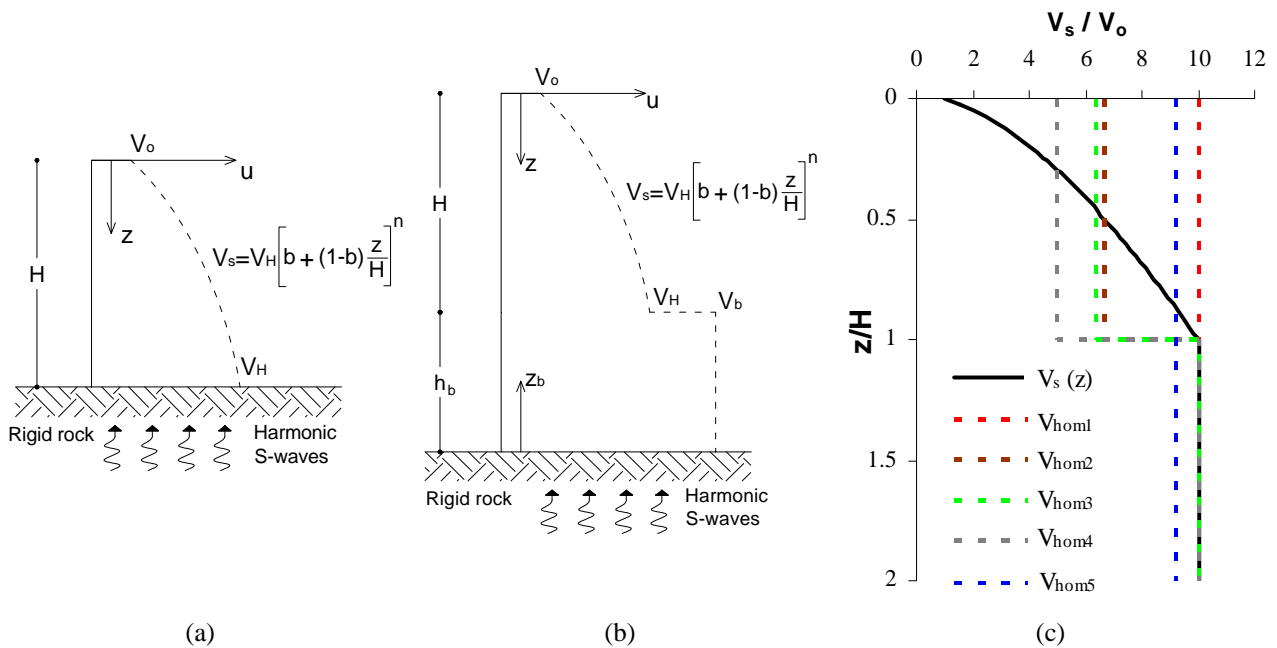

Figure 1. (a) Single inhomogeneous layer over rigid rock (b) Inhomogeneous surface layer over a homogeneous layer (c) Comparison of a two-layer inhomogeneous soil to the shear wave velocities of five equivalent homogeneous profiles ($V_o/V_H = 0.1$, $V_b/V_H=1$, $h_b/H=1$, $n=0.6$)

representing an always-stiffer soil with respect to the actual one

- V_{hom2} , equal to the shear wave propagation velocity at the mid depth of the inhomogeneous layer [8]:

$$V_{hom2} = V_s(H/2) \quad (3)$$

pertaining to an elementary yet potentially useful solution.

- V_{hom3} , equal to the mean shear wave propagation velocity within the inhomogeneous layer:

$$V_{hom3} = \frac{1}{H} \int_0^H V_s(z) dz \quad (4)$$

where $V_s(z)$ is given by Eq.1.

- V_{hom4} , providing equal base to surface travel times between homogeneous and inhomogeneous soil [19]

$$V_{hom4} = H \left[\int_0^H \frac{1}{V_s(z)} dz \right]^{-1} \quad (5)$$

- V_{hom5} , corresponding to an equivalent homogeneous soil having the same fundamental frequency as the inhomogeneous profile

$$V_{hom5} = f_{1Inhom} 4H \quad (6)$$

Alternatively, V_{hom5} may be viewed as the shear wave propagation velocity in the inhomogeneous soil corresponding to the “equivalent” depth (z_{eq}) proposed by Dobry et al. [20]. The two-layer equivalent homogeneous soils are compared to the inhomogeneous case in Fig. 1c based on the above V_{hom} profiles and the generalized parabola $V_s(z)$ in Eq.1. In this graph, the model parameters n , V_o/V_H , V_b/V_H and h_b/H were selected at 0.6, 0.1, 1 and 1 respectively. The deviation observed among the shear wave velocity profiles of the equivalent homogeneous soils is due to the small surface-to-base shear wave velocity ratio (V_o/V_H). Naturally, larger V_o/V_H ratios correspond to a smoother variation of $V_s(z)$ leading to comparable V_{hom} profiles.

The input motion is imposed at the base of the system in the form of a harmonic horizontal displacement, $u = u_o \exp(i\omega t)$, ω being the cyclic excitation frequency, generating vertically propagating S waves.

3 ANALYTICAL SOLUTION

Starting from the following ordinary differential equation:

$$\frac{d}{dz} \left[G(z) \frac{du}{dz} \right] + \rho \omega^2 u = 0 \quad (7)$$

which describes one-dimensional shear waves under harmonic oscillations in a soil layer with constant mass density ρ and variable shear modulus $G(z)$, it can be shown [14-16] that the displacement field of an inhomogeneous layer such as that described in Eq.1 is given by:

$$u(z) = \frac{C_1 \left(b + q \frac{z}{z_r} \right)^\mu}{N_{\nu+1} (\lambda b^{\ell/2})} \left\{ J_\nu \left[\lambda \left(b + q \frac{z}{z_r} \right)^{\ell/2} \right] N_{\nu+1} [\lambda b^{\ell/2}] - J_{\nu+1} [\lambda b^{\ell/2}] N_\nu \left[\lambda \left(b + q \frac{z}{z_r} \right)^{\ell/2} \right] \right\} \quad (8)$$

where $q=1-b$, C_I is an integration constant determined from the boundary conditions, $J_\nu(\)$ and $N_\nu(\)$ denote the Bessel functions of the first and second kind and order ν , respectively, and $\ell = 2(1-n)$ is a dimensionless parameter representing the step of the associated power series solutions [21]. Parameters μ and ν are obtained from the asymptotic convergence of the solution close to zero, as $\mu=(1-2n)/2$ and $\nu=(2n-1)/2(1-n)$, while the asymptotic behavior of the solution at infinity requires $\lambda = 2k_r z_r / \ell q$, k_r and z_r being a reference wave number ($=\omega/V_r$) and a reference depth.

By definition, the base-to-surface transfer function is expressed as [22, 23]:

$$F(\omega) \equiv \frac{u(0)}{u(H)} \quad (9)$$

where $u(0)$ and $u(H)$ stand for the horizontal soil displacement at the free surface and the base of the single-layer system, computed from Eq.8 by setting $z=0$ and $z=H$, respectively. After some algebra, Eq.9 yields:

$$F(\omega) = \frac{2b^{\mu-\ell/2}}{\pi\lambda} \left[J_{\nu+1}(\lambda b^{\ell/2}) N_\nu(\lambda) - J_\nu(\lambda) N_{\nu+1}(\lambda b^{\ell/2}) \right]^{-1} \quad (10)$$

Referring to the two-layer inhomogeneous soil, the base-to-surface transfer function is defined in the same spirit as in Eq. 9:

$$F(\omega) \equiv \frac{u(0)}{u_b(0)} \quad (11)$$

where $u_b(0)$ denotes the soil displacement at base level ($z_b=0$). The response of the underlying homogeneous layer is given by the function [22, 23]:

$$u_b(z_b) = A_1 \sin(k_b z_b) + A_2 \cos(k_b z_b) \quad (12)$$

where A_1 and A_2 represent the amplitudes of the waves travelling upward and downward in the layer, respectively, and $k_b (= \omega / V_b)$ is the corresponding wave number. Upon enforcing the continuity of shear stresses and displacements at the base of the system and the interface of the surface and the base layer:

$$\begin{aligned} u_b(0) &= u_o \\ u_b(h_b) &= u(H) \\ \tau_b(h_b) &= -\tau(H) \end{aligned} \quad (13)$$

by means of Eqs. 8 and 12 yield the following solution for the base-to-surface transfer function in Eq.11:

$$\begin{aligned} F(\omega) = & \left[\frac{2(1-n)(1-b)\rho_b}{\pi b^{1/2} H} \right] \left\{ k_H \rho_b \left[J_\nu(\theta_H) N_{\nu+1}(\theta_o) - J_{\nu+1}(\theta_o) N_\nu(\theta_H) \right] \cos(k_b h_b) - \right. \\ & \left. - k_b \rho_H \left[J_{\nu+1}(\theta_H) N_{\nu+1}(\theta_o) - J_{\nu+1}(\theta_o) N_{\nu+1}(\theta_H) \right] \sin(k_b h_b) \right\}^{-1} \end{aligned} \quad (14)$$

where $\theta_o = \lambda b^{\ell/2}$, $\theta_H = \lambda (b + qH / z_r)^{\ell/2}$; ρ_H and ρ_b stand for soil mass density of the inhomogeneous and the homogeneous layer, respectively, and $k_H (= \omega/V_H)$, $k_b (= \omega/V_b)$ the corresponding wave numbers. Material damping can be accounted for in the above solutions by replacing the real wave numbers with the complex counterparts $k_H^* (= \omega/V_H^*)$ and $k_b^* (= \omega/V_b^*)$, respectively. Further details on the analytical derivations of Eqs.10 and 14 can be found in references [9] and [14].

Figure 2. Base-to-surface transfer functions of two-layer inhomogeneous soil for (a) $V_b/V_H=1$ (b) $V_b/V_H=2$ (c) $V_b/V_H=3$. In all graphs $V_o/V_H=0.1$, $h_b/H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

Figure 3. Base-to-surface transfer functions of two-layer inhomogeneous soil for (a) $V_b/V_H=1$ (b) $V_b/V_H=2$ (c) $V_b/V_H=3$. In all graphs $V_o/V_H=0.75$, $h_b/H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

4 HARMONIC RESPONSE OF THE TWO-LAYER INHOMOGENEOUS SOIL

Analytical base-to-surface transfer functions obtained for the two-layer inhomogeneous soil by means of Eq.14 are plotted in Fig.2 referring to the combined effect of inhomogeneity factor n and shear wave velocity ratio (V_b/V_H) at the interface of the inhomogeneous and the homogeneous layer, with the abscissa normalized by the fundamental frequency of the soil, f_{1soil} . Shear wave velocity ratio V_o/V_H at the surface and the base of the inhomogeneous layer was set at 0.1 corresponding to strong gradients in shear wave velocity with depth. For this range of soil inhomogeneity, increasing the inhomogeneity factor n amplifies response and shifts higher mode resonances to lower frequencies [15, 16], especially for large shear wave velocity contrast (i.e large V_b/V_H ratios) between the surface and the base layer (Fig.2c). Of particular interest is the strong amplification observed at higher modes, indicating reduced soil damping effects, contrary to the response of a piece-wise homogeneous two-layer soil, where the role of higher soil modes progressively diminishes.

On the contrary, for higher surface-to-base wave velocity ratio (V_o/V_H) corresponding to a mild variation of shear wave propagation velocity within the surface inhomogeneous layer, the harmonic response of the two-layer inhomogeneous soil resembles that of the homogeneous case ($n=0.01$). This is clearly demonstrated in Fig.3 where Eq.14 is computed for a V_o/V_H ratio of 0.75 providing comparable base-to-surface transfer functions. Note that the only difference between the results shown in Fig.2 and Fig.3 is the value of V_o/V_H ratio. The above behavior was found to exist regardless of thickness (h_b) of the underlying homogeneous layer. The effect of the latter is explored in Fig. 4 for a two-layer inhomogeneous soil described by three layer thickness values (h_b/H) and a V_o/V_H ratio of 0.1. It is observed that as the inhomogeneity factor n approaches 1, deeper soil deposits tend to respond at lower frequencies with larger peak amplitudes (Figs. 4b-4c). However, the effect of both relative layer thickness and inhomogeneity factor is minimized with increasing V_o/V_H ratio, as shown in Figure 5 where base-to-surface transfer functions are computed for a higher V_o/V_H ratio (0.75).

Figure 4. Base-to-surface transfer functions of two-layer inhomogeneous soil for (a) $h_b/H=1$ (b) $h_b/H=2$ (c) $h_b/H=3$. In all graphs $V_o/V_H=0.1$, $V_b/V_H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

Figure 5. Base-to-surface transfer functions of two-layer inhomogeneous soil for (a) $h_b/H=1$ (b) $h_b/H=2$ (c) $h_b/H=3$. In all graphs $V_o/V_H=0.75$, $V_b/V_H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

Conclusively, the harmonic response of the generalized two-layer inhomogeneous system under investigation is primarily controlled by V_o/V_H ratio corresponding to a critical measure of soil inhomogeneity. Similar observations have been reported by Rovithis et al [14] referring to the single-layer system (Fig.1a) based on Eq.10.

5 COMPARISON WITH “EQUIVALENT” HOMOGENEOUS SOIL

The response of the inhomogeneous two-layer system was compared to the equivalent homogeneous soils in terms of natural frequencies and resonant peak amplitudes. Recall in this regard that for a homogeneous viscoelastic two-layer soil, base-to-surface transfer function is given by the expression [22]:

$$F(\omega) = [\cos(q_{hom}H) \cos(q_b h_b) - I_R \sin(q_{hom}H) \sin(q_b h_b)]^{-1} \quad (15)$$

where $q_{hom}(=\omega/V_{hom})$ and $q_b(=\omega/V_b)$ stand for the wave numbers of the surface and the base layer, respectively, and $I_R(=\rho_b V_b / \rho_H V_{hom})$ is the impedance contrast between the two layers.

Resonant frequencies and peak amplitudes ratios between equivalent homogeneous and inhomogeneous soils were obtained by means of Eqs.14 and 15 for each representative shear wave propagation velocity V_{hom} according to Eqs 2-6. For the purpose of this parametric investigation both (V_b/V_H) and (h_b/H) ratios were consecutively set at 1, 2 and 3.

Ratio of the fundamental frequency of the equivalent homogeneous profile to the first natural frequency of the inhomogeneous soil (f_{1hom}/f_{1Inhom}) is plotted in Fig.6 against the inhomogeneity factor n for the examined V_o/V_H ratios. In all graphs, V_{hom} is defined by Eq.2 (i.e $V_{hom}=V_H$) and V_b/V_H is equal to 3. Each plot corresponds to a different h_b/H ratio; 1, 2 and 3 respectively. Naturally, the use of V_H as the equivalent shear wave propagation velocity of the inhomogeneous layer results in a stiffer soil, leading to frequency ratios above unity especially for moderately-to-strongly inhomogeneous soils (small V_o/V_H ratios and large inhomogeneity factors n). However, larger h_b/H values referring to deeper soil deposits lead to lower f_{1hom}/f_{1Inhom} ratios (Fig. 6b-6c), indicating a prevailing contribution of the underlain homogeneous layer to the overall response.

Figure 6. Ratio of fundamental frequency of the equivalent homogeneous soil (f_{1hom}) to first natural frequency of the inhomogeneous soil (f_{1inhom}) as function of inhomogeneity factor n : (a) $h_b/H=1$ (b) $h_b/H=2$ (c) $h_b/H=3$. In all plots, $V_{hom}=V_{hom1}$, $V_b/V_H=3$, $\rho_b/\rho_H=1$, $\xi=0.05$

Resonant frequencies of a smoothly-to-moderately inhomogeneous soil (i.e. $V_o/V_H > 0.25$) are well-predicted by an equivalent homogeneous soil with a surface layer of either equal shear wave propagation velocity at the mid depth of the inhomogeneous layer (Eq.3), or of equal mean wave propagation velocity within the whole layer (Eq.4). Figures 7a-7c show f_{1hom}/f_{1inhom} ratios computed by means of Eq.3 for various h_b/H and V_b/V_H ratios. Similar results obtained from Eq.4 are plotted in Figs. 7d-7f referring to the second natural frequency of the deposit (i.e. f_{2hom}/f_{2inhom}). In all cases, frequency ratios are close to unity indicating a good approximation of the resonant frequencies of the inhomogeneous soil. The latter should be correlated with the continuous nature of the generalized parabola adopted to describe the wave propagation velocity in the inhomogeneous layer. Insignificant deviations from the exact solution are observed for low V_o/V_H ratios ($V_o/V_H=0.1$) leading to slightly overestimated frequencies with increasing inhomogeneity factor n , especially at high resonances (Figs. 7d-7f).

On the contrary, when the equivalent homogeneous soil is defined through Eq.5 ($V_{hom}=V_{hom4}$) the actual fundamental frequency of the inhomogeneous deposit is underestimated. Fig.8 shows the corresponding f_{1hom}/f_{1inhom} ratios for three values of shear wave velocity contrast at the interface of the inhomogeneous and the homogeneous layer. It is observed

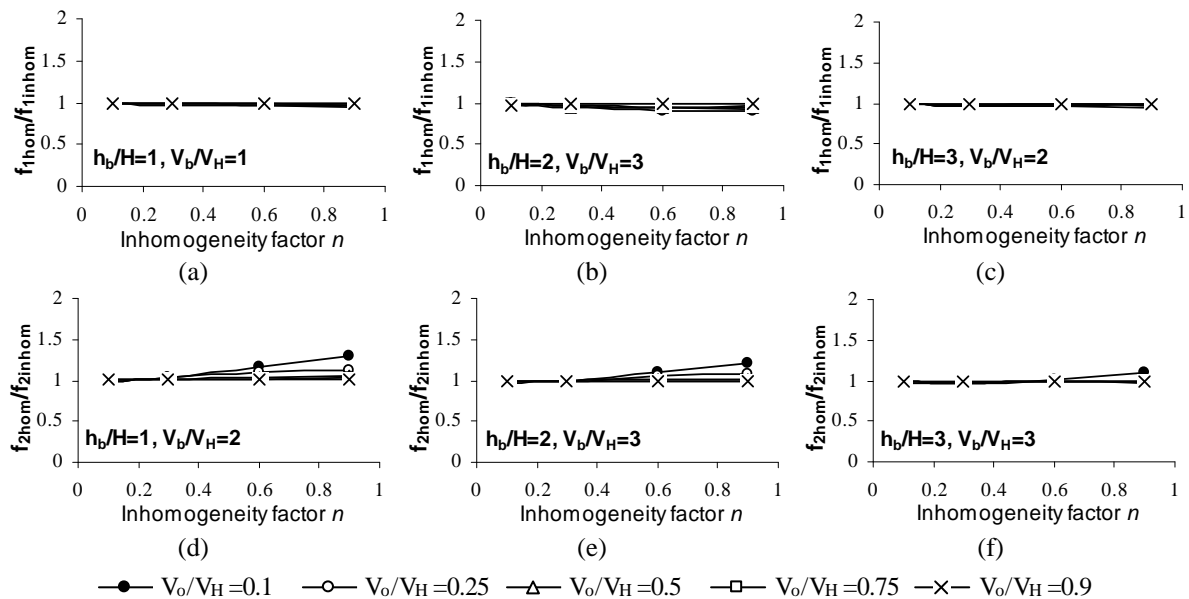

Figure 7. (a-c) f_{1hom}/f_{1inhom} ratios as function of inhomogeneity factor n : $V_{hom}=V_{hom2}$ (d-f) f_{2hom}/f_{2inhom} ratios as function of inhomogeneity factor n : $V_{hom}=V_{hom3}$. In all plots $\rho_b/\rho_H=1$, $\xi=0.05$

Figure 8. f_{1hom}/f_{1inhom} ratios as function of inhomogeneity factor n : (a) $V_b/V_H=1$ (b) $V_b/V_H=2$ (c) $V_b/V_H=3$. In all plots, $V_{hom}=V_{hom4}$, $h_b/H=1$, $\rho_b/\rho_H=1$, $\xi=0.05$

Figure 9. f_{3hom}/f_{3inhom} ratios as function of inhomogeneity factor n : (a) $V_b/V_H=1$ (b) $V_b/V_H=2$ (c) $V_b/V_H=3$. In all plots, $V_{hom}=V_{hom5}$, $h_b/H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

that indeed the fundamental frequency ratio is lower than 1 especially for large V_b/V_H ratios (Fig.8b-8c). Similar trends can be seen in Fig. 9 where f_{3hom}/f_{3inhom} ratios referring to the third natural frequency of a two-layer homogeneous soil having the same fundamental frequency as the inhomogeneous one are plotted by means of Eq.6 ($V_{hom}=V_{hom5}$).

Further comparisons between continuously inhomogeneous and equivalent homogeneous soils were performed, relating peak resonant amplitudes of base-to-surface transfer functions. Resonant amplitude ratios (A_{hom}/A_{inhom}) defined in the same spirit as the resonant frequency ratios are plotted in Fig. 10 corresponding to the first natural frequency (i.e. A_{1hom}/A_{1inhom}) of a two-layer system with (V_b/V_H) and (h_b/H) ratio of 3 and 2, respectively. Each plot in Fig.10 corresponds to a different equivalent homogeneous soil based on Eqs 2-6. Linear hysteretic damping was taken at 0.05 for both inhomogeneous and equivalent homogeneous cases. The same results are shown in Fig.11 for the second natural frequency of the deposit (A_{2hom}/A_{2inhom}). It is observed that the replacement of a continuously inhomogeneous soil with an equivalent homogeneous may lead to substantial overestimated or underestimated resonant amplitudes depending on the value of V_{hom} . Note, for example, that for a strongly inhomogeneous soil (i.e. $V_o/V_H = 0.1$, $n = 0.9$), A_{1hom}/A_{1inhom} ratio based on Eq.5 can be about 0.6 (Fig.10d), which suggests an underestimation of the actual resonant amplitude while Eq.6 yields a value of 1.7 (Fig.10e) overestimating strongly the amplitude of the fundamental resonance. The above deviation becomes larger at higher resonances. For example, A_{2hom}/A_{2inhom} ratios may vary in the range 0.4 (Fig.11a) to 4.5 (Fig.11e) depending on the approach followed to define V_{hom} . Thereby, the replacement of a continuously inhomogeneous soil layer with an equivalent homogeneous one in terms of peak resonant amplitudes may be valid only for a sufficiently smooth variation of shear wave velocity with depth. The latter was observed independently of V_b/V_H ratio, h_b/H ratio and V_{hom} .

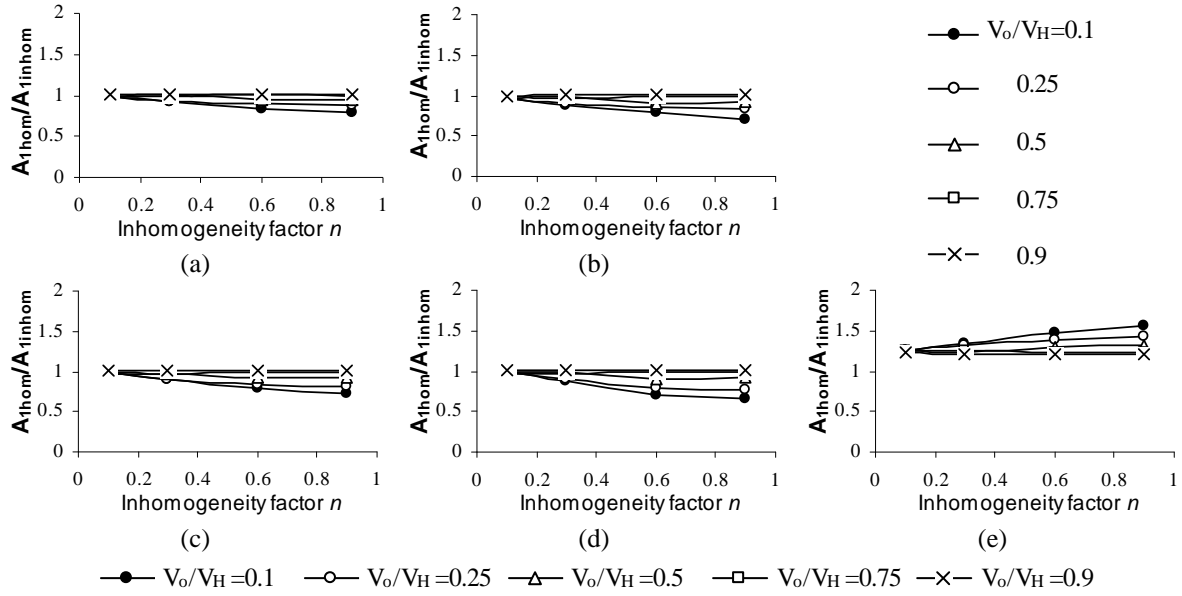

Figure 10. Resonant amplitude ratios (A_{1hom}/A_{1inhom}) corresponding to the first natural frequency of the system as function of inhomogeneity factor n : (a) $V_{hom}=V_{hom1}$ (b) $V_{hom}=V_{hom2}$ (c) $V_{hom}=V_{hom3}$ (d) $V_{hom}=V_{hom4}$ (e) $V_{hom}=V_{hom5}$. In all plots, $V_b/V_H=3$, $h_b/H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

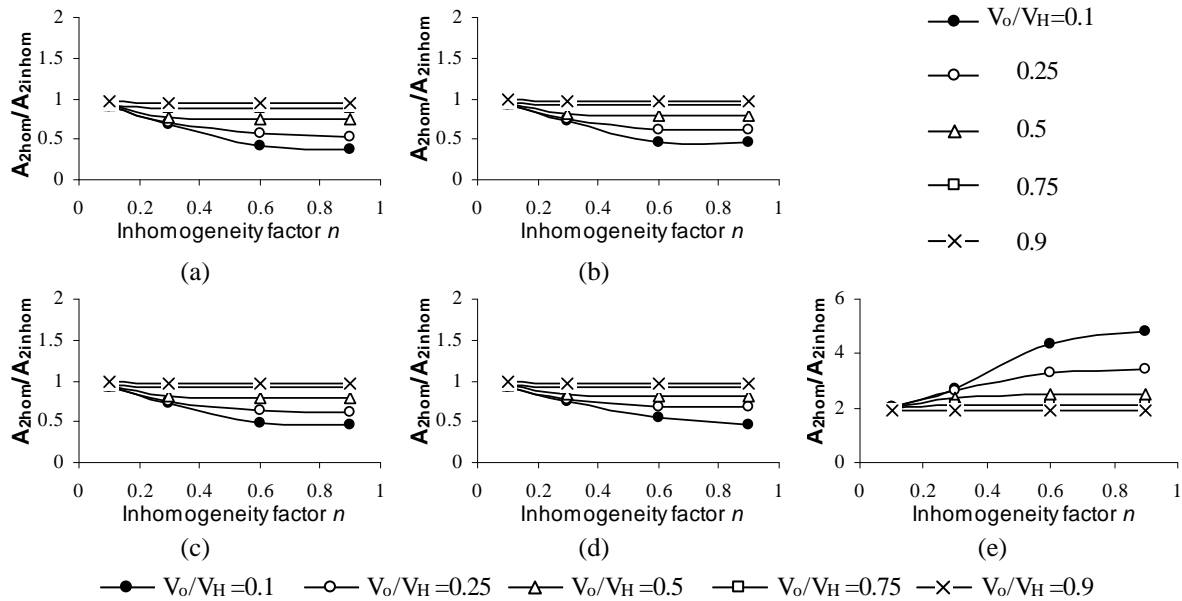

Figure 11. Resonant amplitude ratios (A_{2hom}/A_{2inhom}) corresponding to the second natural frequency of the system as function of inhomogeneity factor n : (a) $V_{hom}=V_{hom1}$ (b) $V_{hom}=V_{hom2}$ (c) $V_{hom}=V_{hom3}$ (d) $V_{hom}=V_{hom4}$ (e) $V_{hom}=V_{hom5}$. In all plots, $V_b/V_H=3$, $h_b/H=2$, $\rho_b/\rho_H=1$, $\xi=0.05$

6 INHOMOGENEOUS SOIL WITH VANISHING STIFFNESS AT SOIL SURFACE

For an inhomogeneous soil layer having zero stiffness at the free surface ($b=0$), it can be shown [14-16] that shear strain $\gamma(z)$ in the soil is given by:

$$\gamma(z) = -\frac{\omega^2 H}{V_H^2} \left(\frac{z}{H} \right)^{-2n} C_1 z^{1/2} J_\nu(\lambda b^{\ell/2}) \quad (16)$$

where $\nu = l/2(1-n)$, $\ell = 2(1-n)$ and $\mu = l/2$.

For values of z close to zero the term $z^{1/2} J_\nu(\lambda b^{\ell/2})$ becomes asymptotically equal to [24]:

$$z^{1/2} J_\nu(\lambda b^{\ell/2}) \sim z^{1/2} \frac{1}{\Gamma(1+\nu)} \left(\frac{\lambda z^{\ell/2}}{2} \right)^\nu \quad (17)$$

where $\Gamma(\cdot)$ is the Gamma function. Accordingly the solution in Eq.16 takes the form:

$$\gamma(z) = -\frac{\omega^2 H}{V_H^2} \left(\frac{z}{H} \right)^{-2n} C_1 z^{1/2} \frac{1}{\Gamma(1+\nu)} \left(\frac{\lambda z^{\ell/2}}{2} \right)^\nu \quad (18)$$

which for small z 's yields the expression (recall that $\nu\ell = 2(1-n)/2(1-n) = 1$ in this solution):

$$z^{-2n+1/2+\nu\ell/2} = z^{-2n+1/2+1/2} = z^{1-2n} \quad (19)$$

indicating that for $n > 1/2$ the exponent $(1-2n)$ becomes negative and, thereby, the magnitude of shear strain becomes infinite, regardless of frequency and excitation amplitude and despite the fact that the corresponding shear stress is zero. On the contrary, for $n < 1/2$ the exponent is positive and shear strain is zero at the ground surface. Therefore, strain amplitude at the surface can be either zero or infinite, depending on the value of the inhomogeneity factor, but never finite. These findings are in agreement with those obtained in [5] for $n=2/3$.

However, as real soils inherently possess a finite amount of stiffness at the surface, the behavior of the solution at very small V_0/V_H ratios is investigated in Fig.12, for a single inhomogeneous layer described by four inhomogeneity factors. Damping ratio, ξ , was set at 0.05 in this graph. Strong amplification is evident at higher mode resonances, as V_0/V_H and n tend to 0 and 1, respectively. This suggests that strong amplification will develop even for finite surface stiffness (under zero shear strain), which will merely get maximized at the theoretical

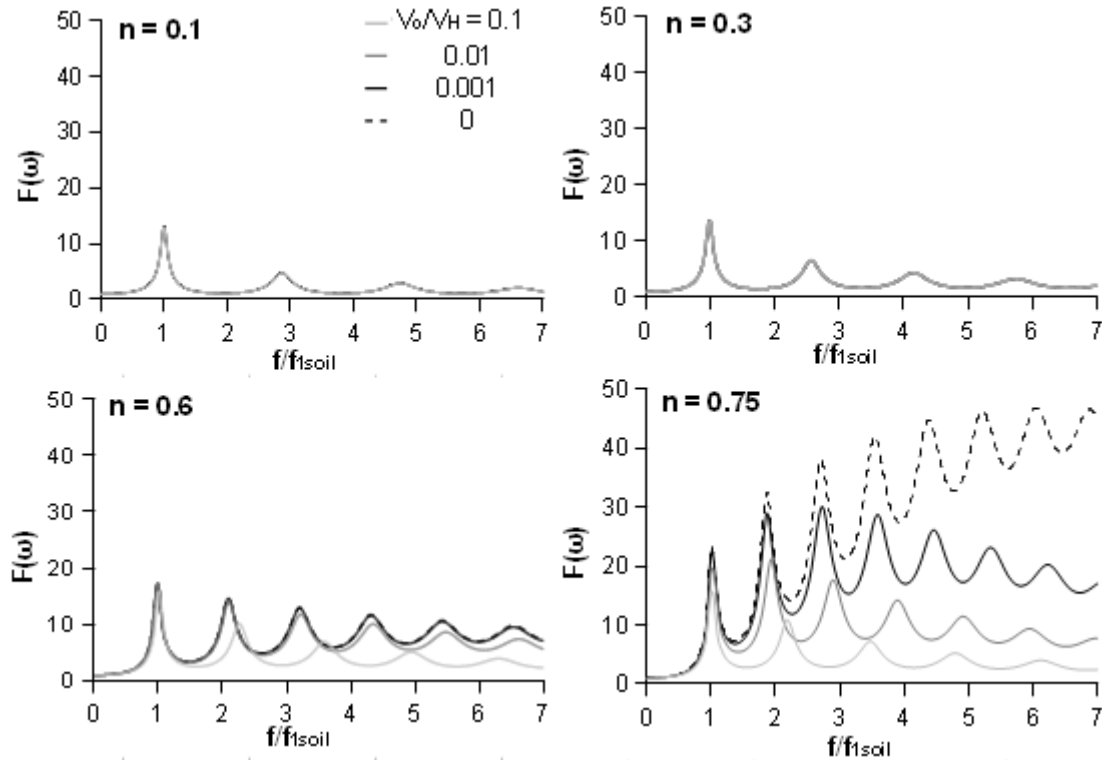

Figure 12. Effect of inhomogeneity factor n on base-to-surface transfer functions for a single inhomogeneous layer having V_0/V_H ratio of 0.1, 0.01, 0.001 and 0. In all plots, $\xi = 0.05$

limit $V_o/V_H=0$. An explanation is that the strong amplification is associated with transition phenomena (i.e., accumulation of wave energy in areas of progressively smaller elastic modulus near the surface leading to an increase in wave amplitude) as opposed to reflection phenomena associated with development of resonance in the layer.

7 CONCLUSIONS

Equivalent homogeneous soils were examined as simplified approximations of layered continuously inhomogeneous soils implementing alternative definitions for the representative shear wave propagation velocity. The investigation focused on resonant frequencies and peak resonant amplitudes, as affected by salient model parameters. The special case of an inhomogeneous soil having zero stiffness at the surface was explored as to the variation of shear strain with depth.

The harmonic response of a two-layer strongly inhomogeneous soil ($V_o/V_H = 0.1$) is amplified with increasing inhomogeneity factor n shifting higher mode resonance to lower frequencies. The above effect is more pronounced for deeper soil deposits with large shear wave velocity contrast between the surface and the base layer. Comparison of resonant frequencies and amplitudes between two-layer inhomogeneous and equivalent homogeneous soils revealed that the response of a smoothly-to-moderately inhomogeneous soil in terms of resonant frequencies may be adequately captured by an equivalent homogeneous soil with a surface layer of either equal shear wave propagation velocity at the mid depth of the inhomogeneous deposit, or of equal mean wave propagation velocity within the whole layer. For moderately-to-strongly inhomogeneous soil ($V_o/V_H < 0.5$ and inhomogeneity factor $n > 0.3$) the above equivalent homogeneous approximations remain a promising solution given that deep soil deposits ($h_b/H > 2$) are encountered. On the contrary, resonant amplitudes of a moderately-to-strongly inhomogeneous soil may be significantly overestimated or underestimated when an equivalent homogeneous soil approach is adopted, especially at higher resonances. For the special case of inhomogeneous soils with vanishing shear wave velocity at the free surface ($V_o/V_H = 0$), near-surface shear strain may be either zero (for $n < 0.5$) or infinite (for $n > 0.5$) but never finite. Strong amplification will develop even for finite surface stiffness (under zero shear strain) which will get maximized at the theoretical limit $V_o/V_H = 0$. From a practical viewpoint, a V_o/V_H ratio of less than 0.1 combined with an inhomogeneity factor n of over 0.5 will suffice to trigger this effect.

Keywords: Lightweight, Joints, Glue.

Abstract. *Lightweight timber structures have many advantages, but high-demand acoustic quality is hard to achieve due to the relatively poor insulation through the junctions, especially in the low frequency range (20 Hz-200 Hz) where the weight (mass per unit of area) of a construction is an important parameter for the air-borne insulation properties [1]. Increasing the mass would improve the insulation but this would go against the main advantage of lightweight constructions. Impact sound from a walking person is the most common sound insulation problem for these kinds of structures, where the footsteps produce a high-degree of noise disturbance. Similar investigations of junctions have been done before [2]. The aim of this particular investigation, however, is to show how glue modifies the sound transmission through the joints in a wooden floor. Theory shows that coupling occurs in a joint either along a line or at individual points depending on the distance between the screws or nails with regard to the bending wavelength [3], [4]. When a viscous elastic material as glue is inserted in between the parts of the joint, the behavior will change and it is therefore important to be studied. To achieve this aim, two structures were built. The first one constituted of two squared plates of dimension 0.6 m x 0.6 m, each one of them fixed onto one beam 4.5 m wide and 22 cm high, by means of equidistant screws. A second set-up was built too, but this time only a single 1.2 m x 0.6 m plate was fixed onto the beam. The same structures were built again a second time, but this time glue was applied around the screws on the contact surfaces.*

1 INTRODUCTION

Lightweight timber structures have many advantages, but high-demand acoustic quality is hard to achieve due to the relatively poor insulation through the junctions, especially in the low frequency range (20 Hz-200 Hz) where the weight (mass per unit of area) of a construction is an important parameter for the air-borne insulation properties [1]. Increasing the mass would improve the insulation but this would go against the main advantage of lightweight constructions. Impact sound from a walking person is the most common sound insulation problem for these kinds of structures, where the footsteps produce a high-degree of noise disturbance. Similar investigations of junctions have been done before [2]. The aim of this particular investigation, however, is to show how glue modifies the sound transmission through the joints in a wooden floor. Theory shows that coupling occurs in a joint either along a line or at individual points depending on the distance between the screws or nails with regard to the bending wavelength [3], [4]. When a viscous elastic material as glue is inserted in between the parts of the joint, the behavior will change and it is therefore important to study this latter. To achieve this aim, two structures were built. The first one constituted of two squared plates of dimension 0.6 m x 0.6 m, each one of them fixed onto one beam 4.5 m wide and 22 cm high, by means of equidistant screws. A second set-up was built but this time only a single 1.2 m x 0.6 m plate was fixed onto the beam. The same structures were built a second time, but this time glue was applied around the screws on the contact surfaces.

2 TEST MODELS

2.1 Geometry

A total number of four mockups were built. The first one was constituted of two squared plates of dimension 0.6 m x 0.6 m, each one of them fixed onto one beam, 4.5 cm wide and 22 cm high, by means of equidistant screws. A second set-up was built this time consisting only of a single 1.2 m x 0.6 m plate fixed onto an identical beam. The same structures were built a second time, but this time glue was applied around the screws on the contact surfaces.

Figure 1: Set-ups.

The distance between the screws connecting the chipboard plates to the bearing beam, following the recommendations of manufacturers, was set to 25 cm in the case of a single plate and 12.5 cm in the case of two plates. The last screws were placed with a distance of 5 cm from the edges in both cases. Both types of connections are realistic and can therefore be found in real timber lightweight structures.

2.2 Materials

The properties of the materials used are listed in Table 1, where E is the Modulus of Elasticity, ν the Poisson's ratio, d the damping coefficient, ρ the mass density and G is the shear modulus.

Spruce Beam		Chipboard		Screws	
E_1	$8.5 \cdot 10^9$ Pa	E_t	$3 \cdot 10^9$ Pa	E	$2.1 \cdot 10^{11}$ Pa
$E_2=E_3$	$3.5 \cdot 10^8$ Pa	ν	0.3	ν	0.3
$\nu_{12}=\nu_{13}$	0.25	ρ	767 kg/m^3	ρ	7800 kg/m^3
ν_{13}	0.3	d	0.055	d	0.02
$G_{12}=G_{13}$	$7 \cdot 10^8$ Pa				
G_{23}	$5 \cdot 10^7$ Pa				
ρ	432 kg/m^3				
d	0.025				

Table 1: Properties of the different materials used.

Those properties were obtained from the manufacturers who provided the materials. The glue used was ordinary commercial PVAc glue commonly used in real constructions.

3 WAVE PROPAGATION

3.1 Bending Waves

Bending waves are likely to be excited in bodies or structures where one or two dimensions are becoming small compared to the wavelength at an actual frequency, i.e. it is the dominant type of wave in construction elements (beams, plates...). If the plates of the floor structure are sufficiently thin, the shear wave propagation can be ignored and the acoustic wave propagation that leads to sound radiation are only the bending waves [5].

According to [7], the wave equation for a bending wave propagating along the x-axis has the following expression for the displacement η in the z-direction (orthogonal to the surface):

$$\eta(x,t) = [\eta_+ e^{(-ik_B x)} + \eta_- e^{(ik_B x)} + \eta_{\eta_-} e^{(-k_B x)} + \eta_{\eta_+} e^{(k_B x)}] e^{i\omega t} \quad (1)$$

where η_+ , η_- , η_{η_-} and η_{η_+} are constants. While the first two terms within the brackets correspond to travelling waves (sinusoidal harmonic waves), the third and forth terms define the so-called evanescent waves (near field vibration waves which decrease exponentially in both the positive and negative directions of the x-axis). Since our excitation consists on short impacts, only evanescent waves will be considered.

4 MEASUREMENT PROCEDURE

In order to measure the vibrations as accurately as possible, the set-ups were hung from the ceiling, suspended to soft rubber springs. The resonance frequency of those springs was calculated beforehand assuring that it is sufficiently low and lower than the lowest eigenfrequency for the structure so that no effect from them is caught in the measurements.

The structure was excited with a hammer producing a sound impact. Nine different excitation points were considered. Dual-axis accelerometers (*iMEMS ADXL203* and *ADXL202E*) were fixed on the structure to record the vibrations. The acquisition software used was *Spectrum SBench 6.1*. The measurement disposition can be seen in Figure 2.

Figure 2: Measurement disposition.

The overall transmission rate in the floor structure depends on discontinuities present in the structure in addition to other factors such as the location of the internal stiffness, the dimension of the standard chipboard plates used in the construction, the thickness of the beam and the distance between the screws [5].

5 RESULTS

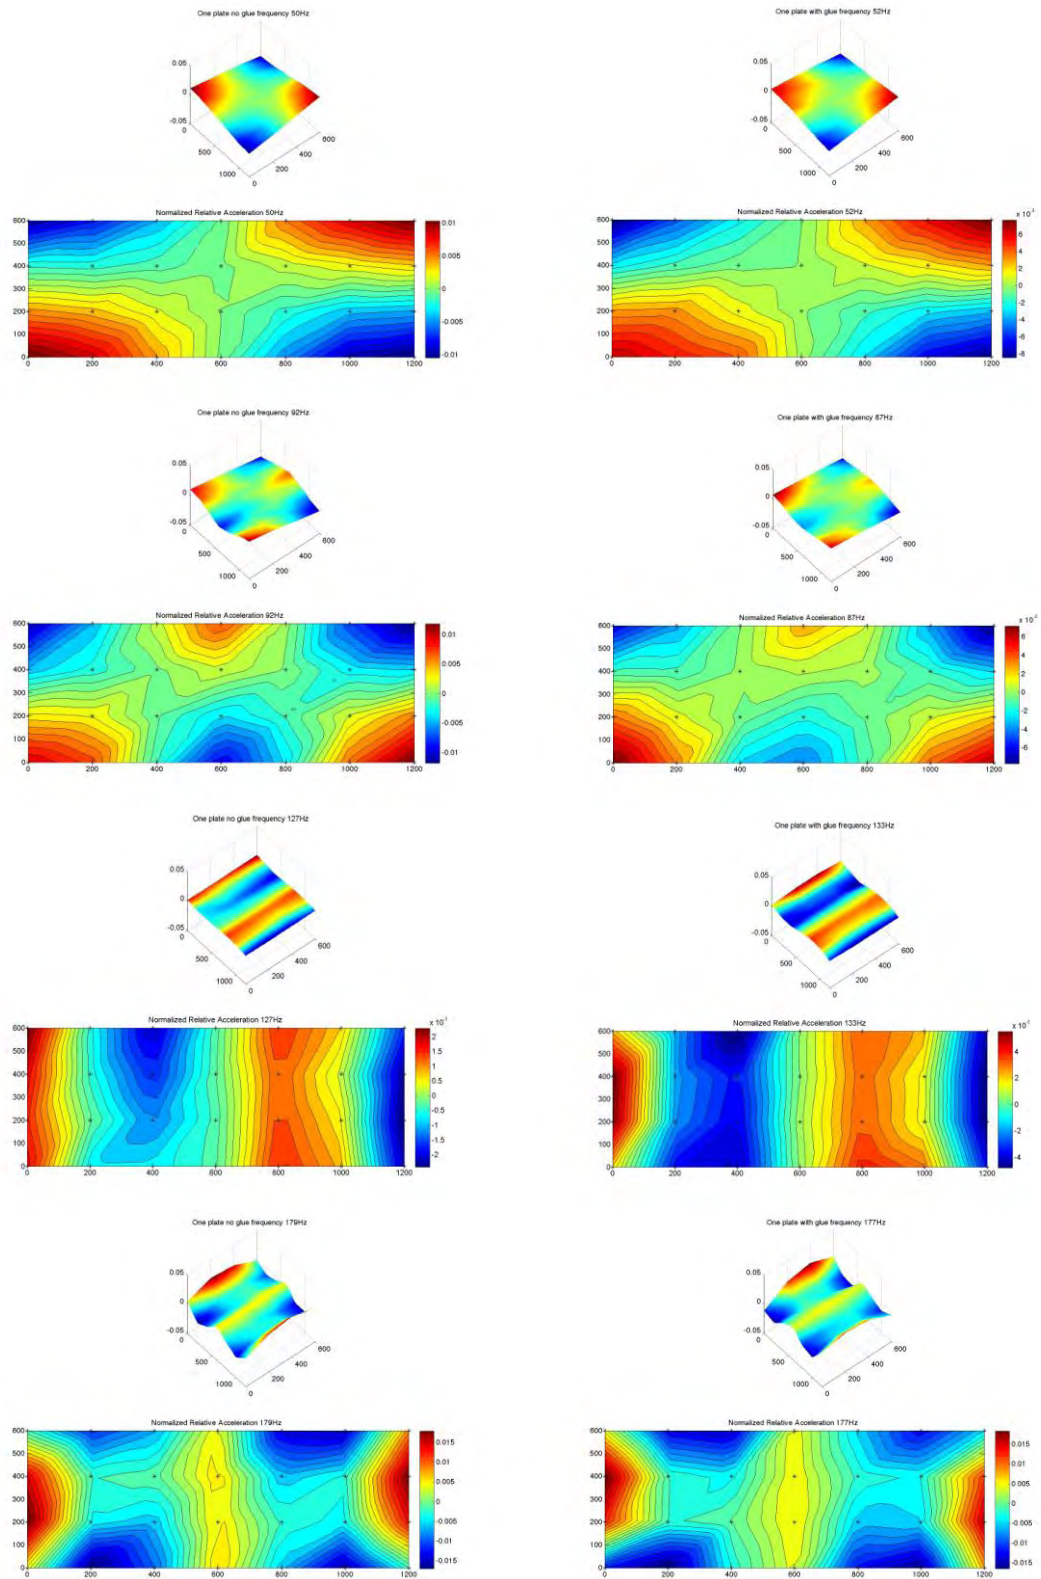

In order to present the results in a general fashion, the data acquired by the accelerometers was scaled with the force applied. As previously mentioned, the structure was excited at nine different locations. As a modal analysis is to be performed, it is not desired that the results are influenced by the excitation point. Thus, an average was carried out over all the excitation points according to [6].

In order to compare the behavior of both set-ups, the modal analysis previously mentioned was used to investigate the influence of the use of glue in the junctions.

5.1 Single-plate Set-up

In Figure 3, the normalized relative acceleration plots corresponding to different eigenmodes are presented. In the left column, the non-glue case is shown while the right column corresponds to the glued case.

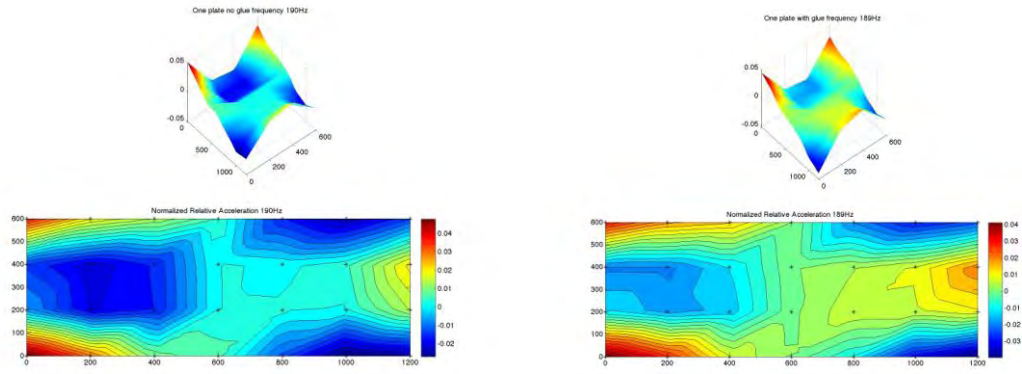

Figure 3: Comparison of modes of vibration. In the left hand side, six modes for the single non-glued plate are presented while the correspondent modes for the plate with glue are listed in the right column.

It can be observed that the glue does not have that much of an influence in the modal shapes or the frequencies they occur at, since their values are quite similar in both cases. Just a slight damping effect can be observed.

All the modes can be easily identified. The influence of the glue is visible in a reduction of the frequencies for the eigenmodes, especially for the frequencies within the higher part of the observed frequency range, particularly for the torsional modes (f_3 , and f_6). Note that the magnitudes of the accelerations are quite low due to the scaling with the force and the fact that the hammer blows were quite soft. Table 2 summarizes the eigenfrequencies.

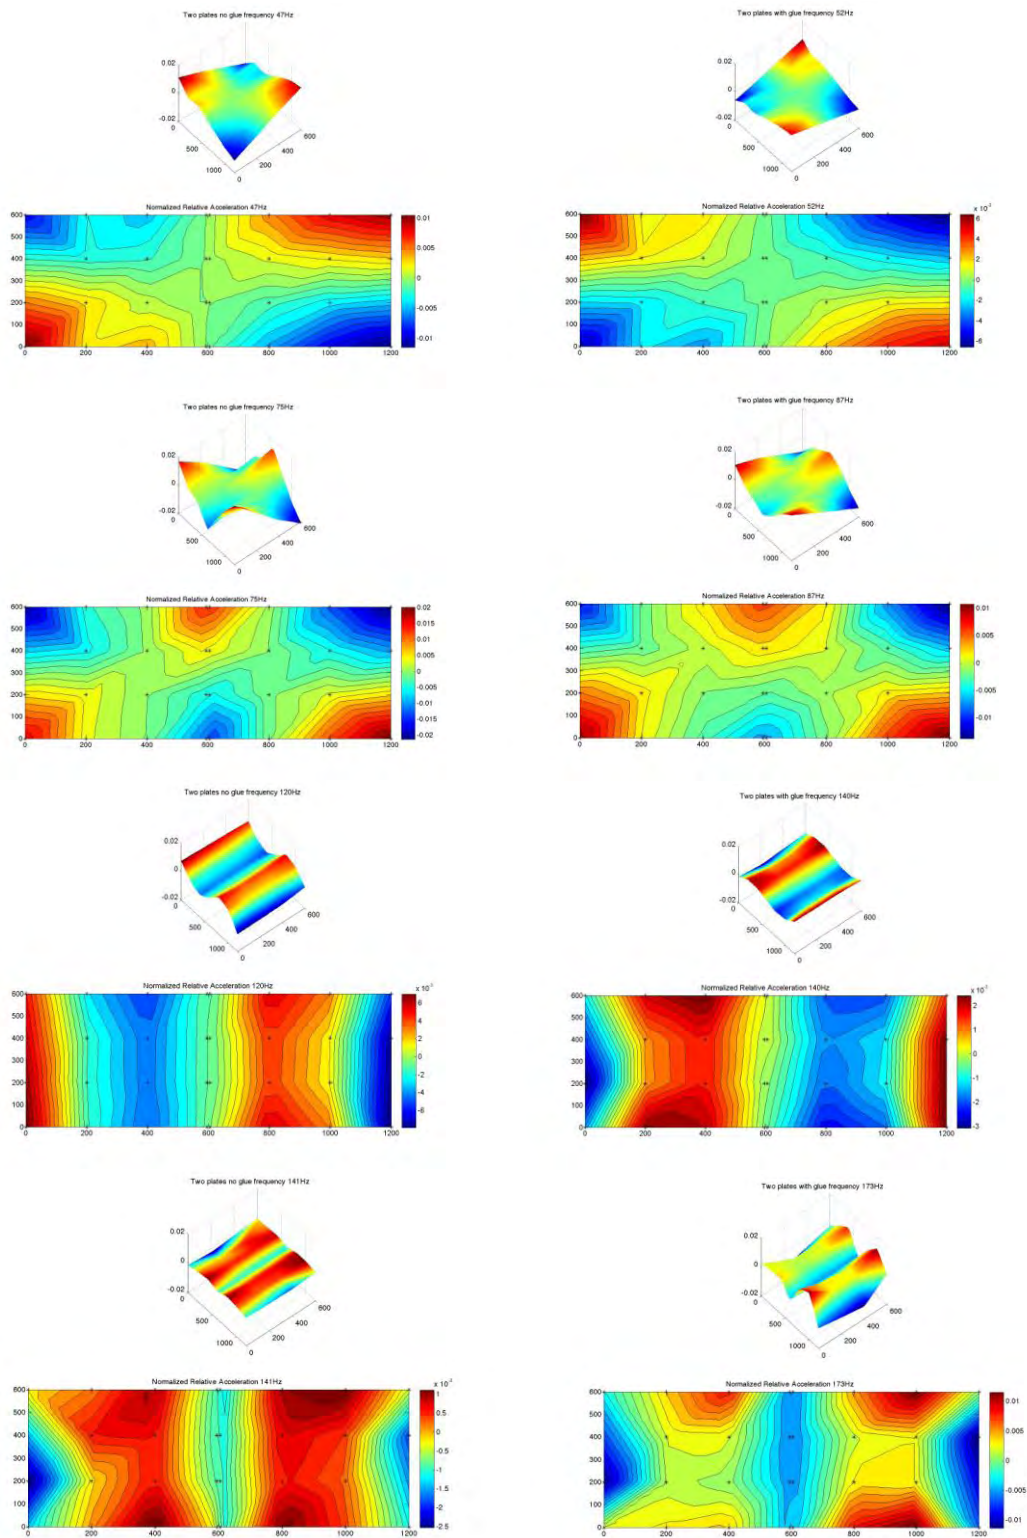

One plate no glue		One plate with glue	
f_1	36 Hz	f_1	33 Hz
f_2	50 Hz	f_2	52 Hz
f_3	92 Hz	f_3	87 Hz
f_4	127 Hz	f_4	133 Hz
f_5	179 Hz	f_5	177 Hz
f_6	190 Hz	f_6	189 Hz

Table 2: Eigenfrequencies for the single plate case.

5.2 Two plates Set-up

In Figure 4, the normalized relative acceleration plots corresponding to different eigenmodes are presented. In the left column, the non-glue case is shown while the right column corresponds to the glued case.

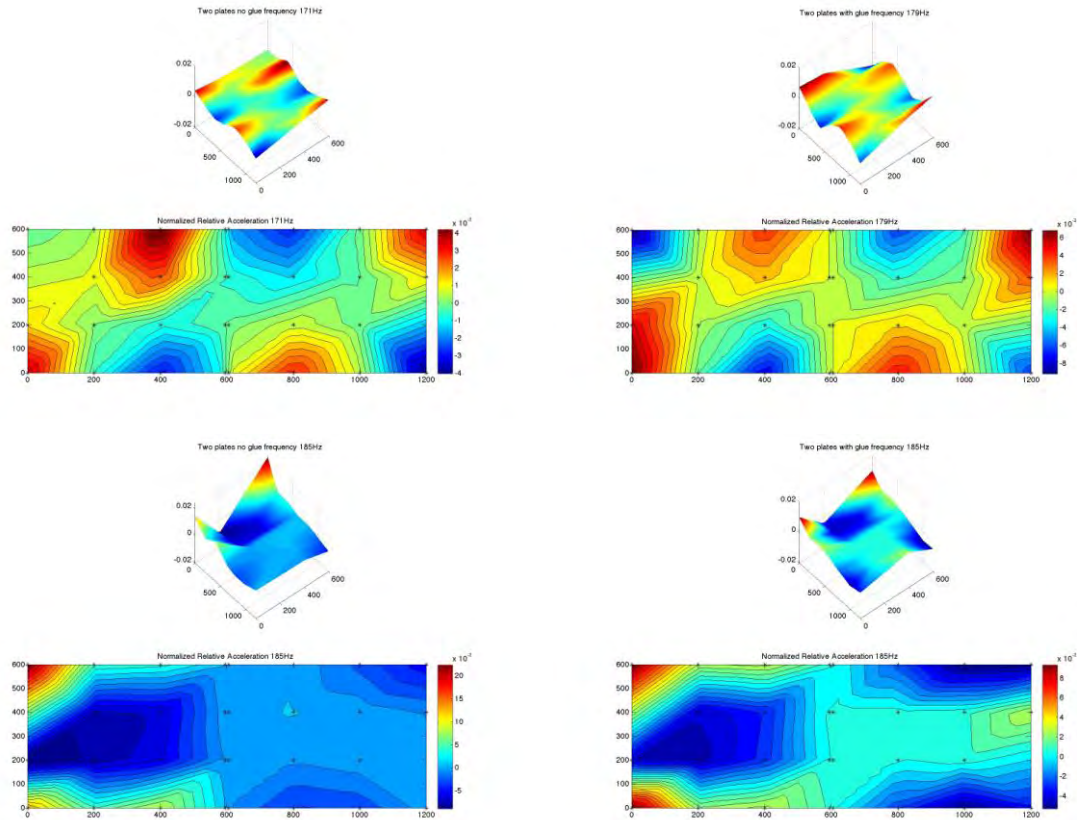

Figure 4: Comparison of modes of vibration. In the left hand side, seven modes for the single non-glued plate are presented while the modes for the plate with glue are listed in the right column.

The non-glued case is, as expected in advance, softer and thus the eigenfrequencies are lower than in the glued case for the correspondent mode (see Table 3). Again, the magnitudes of the accelerations are quite low due to the scaling with the force and the fact that the hammer blows were quite soft. Likewise, the modal shapes can be also easily identified. Table 3 summarizes the eigenfrequencies for each case.

Two plates no glue		Two plates with glue	
f_1	17 Hz	f_1	33 Hz
f_2	47 Hz	f_2	52 Hz
f_3	75 Hz	f_3	87 Hz
f_4	120 Hz	f_4	140 Hz
f_5	141 Hz	f_5	173 Hz
f_6	171 Hz	f_6	179 Hz
f_7	185 Hz	f_7	185 Hz

Table 3: Eigenfrequencies for the two-plate case.

Table 4 compares both glued cases. Note the similarity between them due to the use of glue, which seems to force the two plates to behave as a single plate.

One plate with glue		Two plates with glue	
f_1	33 Hz	f_1	33 Hz
f_2	52 Hz	f_2	52 Hz
f_3	87 Hz	f_3	87 Hz
f_4	133 Hz	f_4	140 Hz
f_5	177 Hz	f_5	173 Hz
	Not found	f_6	179 Hz
f_6	189 Hz	f_7	185 Hz

Table 4: Eigenfrequencies for the glued cases.

6 CONCLUSIONS

In this study, the influence of the use of glue in lightweight junctions has been investigated through measurements on set-ups. The conclusions that can be made are:

- It can be observed that in the single plate case, the glue did not have much of an influence. The slight differences observed may be due to the anisotropy of the spruce beam and its different properties in the different set-ups. This can be the result of, for instance, knots or also because of the damping properties of the glue.
- In the two-plate case it was noticed that the glue plays an important role since it stiffens the junction by pulling both plates together. Due to that, the non-glued case is, as expected, much softer and its eigenfrequencies therefore lower.
- It has been shown that the glue plays a double role within the joints. In the vertical layer when keeping together both plates it acts as a stiffener while in the horizontal layer (on top of the beam) it acts as a dampener. Further work is needed to study both behaviors of the glue.
- The previous conclusion can be validated comparing both cases with glue (Table 4). Note the similarities between both of them. The glue in the vertical layer (two-plate case) stiffens the junction letting them behave almost as a single plate glued onto a beam (the eigenfrequencies in both cases are almost identical).
- Further investigations about the double role of the glue are needed in order to obtain a better understanding of its behavior. Moreover, accurate models for simulation may be developed as a prediction tool for comparison. Likewise, the types of junctions studied could also be identified within a larger real structure and compared with the set-ups studied by similar measurement techniques.

Keyword: Retaining wall, lateral earth pressure, pseudo dynamic, limit equilibrium approach

Abstract. *The distribution of seismic earth pressures on rigid retaining walls is an important task in design. On the basis of the limit equilibrium approach and limit state analysis, this paper presents a solution to compute the seismic earth pressure on the back of a retaining wall. For this purpose, the equilibrium of forces acting on an element of the failed wedge is considered and the earth pressure on the wall is obtained using a mathematical procedure. In this study, the effects of both horizontal and vertical components of earthquake are taken into account using a pseudo-dynamic approach. The effect of phase differences in both shear and primary waves travelling through the backfill due to seismic excitation are also considered by entering the finite shear and primary wave velocities in the analysis. The results are provided in tabular and graphical non-dimensional forms and compared with pseudo-static method to highlight the realistic non-linearity of the seismic pressure distribution.*

1 INTRODUCTION

Estimation of the seismic earth pressure is an important topic of research for safe design of retainings wall in the seismic areas. It is common in practice that the seismic accelerations in both horizontal and vertical directions are considered in terms of equivalent static forces, the so called pseudo-static accelerations. Using the pseudo-static approach, several researchers have developed various methods to determine the seismic earth pressure on rigid retaining walls. These have been started from pioneering work performed by Okabe (1926) and Mononobe & Matsuo (1929), commonly known as Mononobe-Okabe (MO) method. The MO method was modified and simplified by Seed and Whitman. The MO method is attractive due to its simplicity since engineers are familiar with the Coulomb method. The MO method basically employs only force equilibrium and thus is not capable of determining other information such as the location of the resultant force or variation of earth pressure distribution along the wall. Moreover, the pseudo static approaches, do not, in essence, incorporate time dependent effect of applied earthquake load and effect of shear and primary waves.

Steedman and Zeng (1990) considered a harmonic sinusoidal term for horizontal seismic acceleration and studied the effect of phase change and finite shear wave velocity in analysis of retaining walls. They found that the finite shear wave velocity does not have significant influence on the magnitude of the total thrust on the wall. However, it has significant effect on the pressure distribution.

Choudhury and Nimbalkar (2006) have incorporated the effect of vertical seismic acceleration due to vertically propagating primary waves through the backfill soil. They have studied the effect of various parameters such as wall friction angle (δ) and soil friction angle (ϕ) on lateral earth pressures.

In earlier pseudo dynamic approaches, the seismic earth pressure distribution was obtained by differentiating the total active thrust. The static earth pressure and the dynamic earth pressure acting on the retaining wall could be obtained separately. In this manner, the static earth pressure distribution becomes a linear function of depth. However many experimental results show that the distribution of static active earth pressure on the face of a rough wall depends on the mode of wall movement and the distribution of active earth pressure on a rigid wall is nonlinear (Tsagareli, 1965; Sherif and Fang, 1984). Therefore, assuming linear earth pressure distribution on walls in static condition in these methods is questionable.

Recently, two methods were developed to present mathematical solutions for computing the distribution of lateral earth pressures in static (Wang, 2000) and seismic (Ghazavi and Safarzadeh, 2003) conditions. However, these solutions are crude and need further improvement.

The present study develops a new method for determination of magnitude, distribution and the height of point of application of total active thrust on rigid retaining walls in seismic condition. It also incorporates the effects of both horizontal and vertical seismic excitations. Moreover, the effects of seismic load on lateral earth pressure are investigated using pseudo-dynamic approach.

2 BASIC EQUATION OF ANALYTICAL METHOD:

There are some assumptions required to determine the seismic active earth pressure. As shown in Fig. 1, a fixed base vertical rigid retaining wall with H height is considered. The backfill is assumed to be homogenous, dry, and cohesionless. The failure surface is also assumed to be planar (Fig. 2). Considering analytical model for propagating waves through the backfill soil in the horizontal and vertical directions, the effect of horizontal and vertical seismic acceleration are investigated.

Figure 1. Model for Wave Propagation in Backfill Soil

Fig. 2 shows a failure plane inclined at an angle α with respect to the horizontal direction. An element with a thickness of dy at depth y from the ground surface is considered.

Figure 2. Soil Failed Wedge and Element of Soil Backfill

If the base of the wall is subjected to harmonic horizontal seismic acceleration ($\mathbf{a}_h = \mathbf{k}_h \cdot \mathbf{g}$) and harmonic vertical seismic acceleration ($\mathbf{a}_v = \mathbf{k}_v \cdot \mathbf{g}$), the accelerations at any depth z and time t from the wall top can be expressed as:

$$a_h(z, t) = a_h \sin\left(\omega\left(t - \frac{H - y}{V_s}\right)\right) \quad (1)$$

$$a_v(z, t) = a_v \sin\left(\omega\left(t - \frac{H - y}{V_p}\right)\right) \quad (2)$$

where \mathbf{H} = height of the wall, V_p, V_s = wave velocities in the horizontal and vertical directions, respectively, and $\mathbf{a}_h, \mathbf{a}_v$ = amplitude of acceleration in the horizontal and vertical directions, respectively. The horizontal and vertical seismic accelerations acting on the soil wedge as described in Eqs. (1) and (2) are not constants but dependent on time and phase difference in shear and primary waves propagating vertically through the backfill. This is normally proposed in pseudo-dynamic analysis of retaining walls.

3 DETERMINATION OF LATERAL EARTH PRESSURE

In the following sections the lateral static and seismic earth pressure determine separately then the total active earth pressure is obtained by add these two separate parts.

3.1 Determination of static lateral earth pressure

Consider as element of soil wedge with a thickness of $d\mathbf{y}$ at depth y from the ground surface (Fig.2). The forces exerted on this element are due to the vertical pressure σ_y on the top of the element, the vertical reaction $\sigma_y + d\sigma_y$ on the bottom of the element, the normal reaction σ_x of the retaining wall, the shear τ_x between the backfill and the back of the retaining wall, the normal reaction σ_r of the rest of the soil, the shear stress τ_r between the sliding wedge and the rest of the backfill. Fig. 3 shows the stresses and forces exerted on an arbitrary element of the backfill soil.

Figure 3. Forces and Stresses on an Element of Backfill

The equilibrium of horizontal forces on the element (Fig. 3) results in:

$$\sigma_x + \tau_r \cot \alpha - \sigma_r = 0 \quad (3)$$

Considering cohesionless backfill and assuming a full mobilization of shear forces along the failure plane gives:

$$\tau_x = \sigma_x \tan \delta \quad (4)$$

$$\tau_r = \sigma_r \tan \varphi \quad (5)$$

The horizontal earth pressure acting on the wall (σ_x) is equal to:

$$\sigma_x = K \sigma_y \quad (6)$$

where **K** is the lateral pressure coefficient.

Applying equilibrium condition to the vertical forces on the element (Fig. 3) results in:

$$\begin{aligned} \sigma_y(H - y) \cot \alpha + dW - (\sigma_y + d\sigma_y)(H - y - dy) \\ \times \cot \alpha - \tau_x dy - \tau_r \frac{r}{\sin \alpha} \sin \alpha - \sigma_r \times \frac{dy}{\sin \alpha} \cos \alpha = 0 \end{aligned} \quad (7)$$

With more simplifications, Eq. (7) may be converted to:

$$\frac{\sigma_y}{dy} = \gamma + \frac{1}{(H - y)} [\sigma_y - \sigma_r - (\tau_r + \tau_x) \tan \alpha] \quad (8)$$

$$\frac{\sigma_y}{dy} = [1 - ak] \frac{\sigma_y}{H - y} + \gamma \quad (9)$$

where:

$$a = \frac{\cos(\alpha - \varphi - \delta) \tan \alpha}{\sin(\alpha - \varphi) \cos \delta}$$

Eq. (9) is basic for computing the seismic lateral earth pressure on the wall and its solution is expressed as:

$$\sigma_y = \frac{A}{k} [H - y]^{ak-1} + \gamma \frac{H - y}{ak - 2} \quad (10)$$

where:

$$A = \left(\frac{\gamma K H^{2-aK}}{2 - aK} \right) \quad (11)$$

From Fig. 2, it is seen that the boundary condition is ($\sigma_{y=0} = 0$). Thus the following solution for the lateral earth pressure on the wall is obtained:

$$\sigma_{asx} = K \times H \left[\frac{1 - \frac{y}{H} - \left(1 - \frac{y}{H}\right)^{aK-1} \gamma}{ak - 2} \right] \quad (12)$$

The lateral active earth pressure is obtained from:

$$\sigma_{as} = \sqrt{\sigma_x^2 + \tau_x^2} = \sqrt{\sigma_x^2 + \sigma_x^2 \tan^2 \delta} = \frac{\sigma_{asx}}{\cos \delta} \quad (13)$$

3.1.1 Determination of lateral earth pressure coefficient (K)

The lateral earth pressure coefficient, K , has a significant influence on the pressure distribution in seismic condition. Evaluation of this is a very important issue, which must be treated carefully. This paper proposed a method to determination of the lateral earth pressure coefficient, K . By using of moment equilibrium of each element of soil an attempt to determination of lateral earth pressure coefficient is made. The moment equilibrium of forces about point **b** in Fig. 3 gives:

$$\tau_x \times l \times dy - dW \times \frac{l}{2} + d\sigma_y \times \frac{l^2}{2} = 0 \quad (14)$$

where l is the length of upper side of element and given by:

$$l = \gamma \times l \times dy = \cot \alpha (H - y) \quad (15)$$

Substituting Eq. (4) and (5) into Eq. (14) and omitting the differential terms of the second order gives:

$$\frac{d\sigma_y}{dy} = \gamma - \frac{2 \tan \varphi}{l} K \sigma_y \quad (16)$$

Equating Eq. (16) and Eq. (9) gives:

$$[1 - ak] \frac{\sigma_y}{H - y} + \gamma = \gamma - \frac{2 \tan \varphi}{l} K \sigma_y \quad (17)$$

More simplification gives:

$$[1 - ak] = -2 \tan \varphi \cot \alpha K \quad (18)$$

The lateral earth pressure coefficient is given by:

$$K = \frac{1}{(a - 2 \tan \varphi \tan \alpha)} \quad (19)$$

3.2 Determination of seismic lateral earth pressure

Similar to the pseudo-dynamic approach which considers finite shear wave velocity within the backfill material (Steedman and Zeng, 1990), it is also assumed that the backfill shear modulus (G) is constant with the depth. Only the phase and not the magnitude of accelerations are varying along the depth of the wall within backfill.

Figure 4. Analytical Model Considered for Computation of Seismic Part of Active Earth Pressure.

The mass of an element of wedge at depth z is

$$m = \frac{dW}{g} = \frac{\gamma}{g} \times l \times dz \quad (20)$$

The inertial force acting on a soil element is:

$$q_h = m \cdot a_h(z, t) \quad (21)$$

Consider the shear wave velocity, $V_s = \left(\frac{G}{\rho}\right)^{1/2}$, where, ρ is the density of the backfill material and primary wave velocity, $V_p = \left[\frac{G(2-2\nu)}{\rho(1-2\nu)}\right]^{1/2}$, where ν is the Poisson's ratio of the backfill are assumed to act within the soil media due to earthquake loading. For most geological materials, $\frac{V_p}{V_s} = 1.87$ (Das, 1993).

The period of lateral shaking, $T = \frac{2\pi}{\omega} = \frac{4H}{V_s}$, where ω is the angular frequency is considered in the analysis.

By substituting Eq. (1) into Eq. (22), the total horizontal inertial force acting within the failure zone can be expressed as:

$$Q_h(t) = \int_0^H m(z) \cdot a_h(z, t) dz = \frac{\lambda \gamma a_h}{4\pi^2 g \tan \alpha} (2\pi H \cos \omega \xi + \lambda (\sin \omega \xi - \sin \omega t)) \quad (22)$$

where

$$\xi = t - \frac{H}{V_s}$$

$$\lambda = TV_s$$

By substituting Eq. (2) into Eq. (23), the total vertical inertial force acting within the failure zone can be expressed as:

$$Q_v(t) = \int_0^H m(z) \cdot a_v(z, t) dz = \frac{\eta \gamma a_v}{4\pi^2 g \tan \alpha} (2\pi H \cos \omega \psi + \eta (\sin \omega \psi - \sin \omega t)) \quad (23)$$

where

$$\psi = t - \frac{H}{V_p}$$

$$\eta = TV_p$$

The total seismic active thrust $\mathbf{P}_{ad}(\mathbf{t})$ can be obtained by resolving the forces on the wedge and considering the equilibrium of the forces. Hence $\mathbf{P}_{ad}(\mathbf{t})$ can be expressed as:

$$P_{ad} = \frac{Q_h \cos(\alpha - \varphi) - Q_v \sin(\alpha - \varphi)}{\cos(\alpha - \alpha + \varphi)} \quad (24)$$

The seismic portion of active earth pressure distribution can be obtained from:

$$\sigma_{ad} = \frac{\partial P_{ad}(z)}{\partial z} = \frac{\cos(\alpha - \varphi) k_h \gamma z}{\cos(\delta - \alpha + \varphi) \tan \alpha} \sin \omega(t - \frac{z}{V_s}) - \frac{\cos(\alpha - \varphi) k_v \gamma z}{\cos(\delta - \alpha + \varphi) \tan \alpha} \sin \omega(t - \frac{z}{V_p}) \quad (25)$$

4 DETERMINATION OF TOTAL LATERAL EARTH PRESSURE AND RESULTANT THRUST

The total lateral earth pressure is obtained by adding static and seismic portions of active earth pressure. Thus, the total earth pressure can be express as:

$$\sigma_{ae} = \sigma_s + \sigma_d \quad (26)$$

where

$$\sigma_s = \frac{\gamma H}{(a - 2 \tan \varphi \tan \alpha) \cos \delta} \left[\frac{1 - \frac{y}{H} - \left(1 - \frac{y}{H}\right)^{\frac{a}{(a - 2 \tan \varphi \tan \alpha)} - 1}}{\frac{a}{(a - 2 \tan \varphi \tan \alpha)} - 2} \right] \quad (27)$$

$$\sigma_d = \frac{\cos(\alpha - \varphi) \gamma y}{\cos(\delta - \alpha + \varphi) \tan \alpha} (k_h \sin \omega(t - \frac{y}{V_s}) - k_v \sin \omega(t - \frac{y}{V_p})) \quad (28)$$

The total lateral active thrust is obtained by integrating static and seismic earth pressures. This gives:

$$P_{ae} = P_{as} + P_{ad} = \int_0^H \sigma_{ae} dy + \int_0^H \sigma_{ad} dy \quad (29)$$

Substituting static and seismic thrust in Eq. (29) gives:

$$P_{ae} = \frac{1}{2} \gamma H^2 \frac{\sin(\alpha - \varphi) \cot \alpha}{\cos(\alpha - \varphi - \delta)} + \left(\frac{T}{2H\pi^2 \tan \alpha} \right) \times \frac{(k_h V_s \cos(\alpha - \varphi) m_1 - k_v V_p \sin(\alpha - \varphi) m_2)}{\cos(\delta + \varphi - \alpha)} \quad (30)$$

where

$$m_1 = 2\pi \cos 2\pi \left(\frac{t}{T} - \frac{H}{TV_s} \right) + \frac{TV_s}{H} [\sin 2\pi \left(\frac{t}{T} - \frac{H}{TV_s} \right) - \sin 2\pi \frac{t}{T}]$$

$$m_2 = 2\pi \cos 2\pi \left(\frac{t}{T} - \frac{H}{TV_p} \right) + \frac{TV_p}{H} [\sin 2\pi \left(\frac{t}{T} - \frac{H}{TV_p} \right) - \sin 2\pi \frac{t}{T}]$$

The maximum value of P_{ae} is obtained by maximizing P_{ae} with respect to t and α

5 HEIGHT OF APPLICATION OF RESULTANT EARTH PRESSURE

The locations of the resultant of earth pressures on retaining wall in static and seismic conditions are determined using the Coulomb and MO methods for static and seismic conditions, respectively. In both methods, a linear distribution of earth pressures on the wall is assumed and thus the location of the total thrust is exact. In the MO method, Eq. (31) is normally used to obtain H_{ae} (Seed and Withman, 1970):

$$H_{ae} = \frac{P_a \left(\frac{H}{3} \right) + \Delta P_{ae} (0.6H)}{P_{ae}} \quad (31)$$

where $\Delta P_{ae} = P_{ae} - P_a$

For curvilinear distribution earth pressure presented in this paper, the height of the application of the resultant earth pressure can be determined using the following procedure. The resultant moment of the pressure about the wall bottom can be obtained from:

$$M_{ae} = \int_0^L (H - y) \sigma_{ae} dl \quad (32)$$

The height H_{ae} of application of the resultant pressure is:

$$H_{ae} = \frac{M_{ae}}{P_{ae} \cos \delta} \quad (33)$$

6 RESULTS AND DISCUSSION:

In this section, an example for a rigid retaining wall with a height of 5 m is considered. All necessary parameters are given in Fig. 5. As seen, the earth pressure distribution is non-linear and its maximum does not occur at the wall bottom.

Moreover the earth pressure decrease to zero at the bottom of wall in static condition but zero earth pressure does not occur at the bottom of wall in seismic condition.

For better comparison of result the distribution of earth pressure by assuming linear distribution of earth pressure in static condition is shown in Fig. 5. As observed, by making this assumption, the maximum earth pressure occurs at the wall bottom.

Figure 5. Distribution of Horizontal Earth Pressure on Retaining Wall for

$$\varphi = 33^\circ, \delta = 16^\circ, k_v = 0, V_s = 100 \frac{m}{s}, H = 5 m, T = 0.2s, \frac{H}{\lambda} = 0.167, \frac{H}{\eta} = 0.09, \beta = 90^\circ, \gamma = 18 \frac{kN}{m^3}$$

As shown in Fig. 5, due to changes of lateral earth pressure with time and angle of slip surface (α), the distribution shown makes the total lateral thrust maximum. Hence the distribution of lateral earth pressure nonlinearly comes close to triangular. However, if the maximum overturning is taken into consideration, the distribution of earth pressure becomes close to parabolic variation (Fig. 6). Therefore, in the design of retaining wall, both distributions of lateral earth pressure should be taken into account.

Figure 6. Distribution of Horizontal Earth Pressure on Retaining Wall for $\varphi = 33^\circ, \delta = 16^\circ, k_v = 0, V_s = 100 \frac{m}{s}, H = 5 m, T = 0.2s, \frac{H}{\lambda} = 0.167, \frac{H}{\eta} = 0.09, \beta = 90^\circ, \gamma = 18 \frac{kN}{m^3}$

7 CONCLUSIONS:

This paper has proposed a pseudo-dynamic method by considering the time effect and phase change in shear and primary waves propagating in the backfill behind the rigid retaining wall. The seismic and static total thrust, the location of the thrust and distribution of lateral earth pressures due to static and seismic loading on rigid retaining walls have been presented using a closed form solution. The differential equation governing an arbitrary element at a given depth along the wall height has been derived and solved explicitly using appropriate boundary conditions. The seismic earth pressure distributions, the total thrust on the wall, and the location of the thrust have then been determined. The present study considers both static and seismic earth pressure distributions in a nonlinear manner. Parametric studies were performed to show how the earth pressure is distributed on a rigid retaining wall. The general superiority of the current solution is that the value of lateral earth pressure coefficient, K , is more accurate and lacks any simplifying assumptions. It has also been demonstrated that K is the most important parameter which influences the non-linear pressure distribution. It has also been found that due to changes of the lateral earth pressure with time and angle of slip surface (α), a certain distribution gives the maximum total lateral thrust. If the wall overturning is critical, a parabolic distribution of earth pressures offer the maximum moment. In general, in the design of retaining walls, both distributions of lateral earth pressures should be taken into account.

Keywords: Waves, Wave Basis, Finite Elements, Dispersion Equation, Axially Moving Beam.

Abstract. *One approach to the numerical analysis of complex waveguides is the Wave Finite Element (WFE) method. In this method conventional Finite Elements (FEs) are used to discretise a small segment of a waveguide. The FE model of just this small part of the structure is post-processed using periodicity conditions, and an eigenproblem is then solved to predict dispersion characteristics and wavemodes. Once the wave characteristics are predicted, free vibration and response of the structure as a whole can be modelled in terms of these waves. This paper presents an extension of the method to moving one-dimensional waveguides. In particular an axially moving beam is considered. The FE formulation of a moving beam element is developed and the WFE method is applied to find the wave properties of such a beam. Natural frequency are obtained using the Phase Closure Principle and the Dynamic Stiffness Matrix, both formulated in terms of wavemodes and dispersion relation obtained from the WFE eigenproblem. The analytical equation of transverse motion of the travelling beam is also solved in terms of propagating and decaying waves, and the frequency equation is obtained using the phase closure principle. Numerical results are shown.*

1 INTRODUCTION

The research on the dynamics of moving media has had a renewed interest in the last few decade giving rise to large scientific production. There are a number of applications which involve moving structures and fluids, and the necessity to improve their performance has motivated the development of numerical and analytical methods to investigate the dynamics of mechanical models involving transport of mass. Studies on the dynamics of axially moving structures have been made by several authors, and many original and interesting studies have been produced. To cite just a few, the works [1, 2, 3, 4] can be listed.

In this paper the dynamics of a travelling one-dimensional waveguides is investigated using a Wave Finite Element method [5, 6]. The method is an FE post-processing technique for obtaining numerical prediction of wave characteristics. The method involves conventional FE analysis of a small segment of the structure. Typically this consists of just a single finite element, or a stack of elements meshed through the cross-section. The FE matrices of this segment are then post-processed using periodicity conditions, resulting in an eigenproblem, whose solutions yield the dispersion curves, frequency evolution of the wavenumber, and wavemodes. Once the dispersion characteristics are known, existing wave propagation methods can be applied to take into account boundary conditions, calculate natural frequencies, forced response or determine the systems stability [7].

An axially moving beam, modelled using the classical linear theory, is studied in the present paper. The FE element formulation of a linear moving beam element is derived following [8], and application of the WFE method is briefly described. Free vibrations of the moving beam are predicted using the Phase Closure Principle [9] and the Dynamic Stiffness Matrix [10] formulated in terms of wavemodes. These are applied once the wave characteristics are known from the WFE model. An analytical wave approach is also presented to show some characteristics of the elastic waves propagating in such a beam. Numerical results are shown and the accuracy of the proposed approach is discussed. The theory used in this paper is linear, therefore results are consistent with ‘low’ axial velocity and small deformation. However, this linear model well approximates the behaviour of many real cases, and it can be helpful for predicting instability region, where nonlinear terms become significant [11]. It must be pointed out that wave propagation in a travelling beam were also investigated by Chakraborty and Mallik in [12], and a Dynamic Stiffness Formulation of a moving beam was given by Banerjee and Gunawardana [13]. Both these works involve an analytical formulation of the equation of motion, while the present work concerns the application of a numerical technique based on FE analysis.

Although for the case of a moving beam there are no practical advantages in calculating dispersion curves and natural frequencies using the proposed method, this work shows that the WFE method can provide results for moving waveguides. This is of particular interest in more complicated cases where analytical formulation of the problem can be difficult and computational cost using standard numerical approaches can be very large.

2 EQUATION OF MOTION AND FE FORMULATION OF A MOVING BEAM ELEMENT

A prismatic axially moving beam is considered. The beam is modelled using an Eulero–Bernoulli beam with constant mass per unit length ρ and constant flexural rigidity EI . The beam moves with axial speed $v(t)$, and its transverse displacement, measured by a stationary observer, is denoted by $y(x, t)$, figure 1. External excitation are not taken into account.

Figure 1: Schematic model of an axially moving beam.

Time differentiation of the displacement yields

$$\begin{aligned}\frac{dy}{dt} &= \frac{\partial y}{\partial t} + v \frac{\partial y}{\partial x}; \\ \frac{d^2 y}{dt^2} &= \frac{\partial^2 y}{\partial t^2} + 2v \frac{\partial^2 y}{\partial x \partial t} + v^2 \frac{\partial^2 y}{\partial x^2} + \frac{\partial v}{\partial t} \frac{\partial y}{\partial x}.\end{aligned}\quad (1)$$

Accordingly, the analytical equation of transverse motion is

$$EI \frac{\partial^4 y}{\partial x^4} + \rho \left(\frac{\partial^2 y}{\partial t^2} + 2v \frac{\partial^2 y}{\partial x \partial t} + v^2 \frac{\partial^2 y}{\partial x^2} + \frac{\partial v}{\partial t} \frac{\partial y}{\partial x} \right) = 0. \quad (2)$$

In order to apply the WFE approach, a small segment of length L is taken and discretised using FE elements. Therefore a moving beam FE element is developed. The kinetic and potential energy of the element are

$$\begin{aligned}T &= \frac{1}{2} \rho \int_0^L \left(\frac{\partial^2 y}{\partial t^2} + 2v \frac{\partial^2 y}{\partial x \partial t} + v^2 \frac{\partial^2 y}{\partial x^2} \right) dx; \\ V &= \frac{1}{2} EI \int_0^L \left(\frac{\partial^2 y}{\partial x^2} \right)^2 dx.\end{aligned}\quad (3)$$

The transverse displacement of the beam element is modelled by standard cubic shape function $N(x)$ [14] and nodal displacements \mathbf{q} , that is

$$y = N(x)\mathbf{q}. \quad (4)$$

Substituting this equation in (3), the Lagrangian of the moving element is given by [8]

$$L = \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{M} \dot{\mathbf{q}} + \frac{1}{2} \mathbf{q}^T \mathbf{K}_1 \mathbf{q} - \frac{1}{2} \mathbf{q}^T \mathbf{K}_2 \mathbf{q} + \frac{1}{2} \mathbf{q}^T \mathbf{C}_1 \dot{\mathbf{q}} + \frac{1}{2} \dot{\mathbf{q}}^T \mathbf{C}_2 \mathbf{q}, \quad (5)$$

with

$$\begin{aligned}\mathbf{M} &= \rho \int_0^L \mathbf{N}^T \mathbf{N} dx; \quad \mathbf{K}_1 = \rho v^2 \int_0^L \mathbf{N}'^T \mathbf{N}' dx; \quad \mathbf{K}_2 = EI \int_0^L \mathbf{N}''^T \mathbf{N}'' dx; \\ \mathbf{C}_1 &= \rho v \int_0^L \mathbf{N}'^T \mathbf{N} dx; \quad \mathbf{C}_2 = \rho v \int_0^L \mathbf{N}^T \mathbf{N}' dx,\end{aligned}\quad (6)$$

where $'$ denotes differentiation with respect to x . The FE equation of motion can be obtained using Euler-Lagrangian equations. Therefore the FE equations of motion of a moving beam element are

$$\mathbf{M} \ddot{\mathbf{q}} + (\mathbf{C}_2 - \mathbf{C}_2^T) \dot{\mathbf{q}} + (\dot{\mathbf{C}}_2 - \mathbf{K}_2 + \mathbf{K}_1) \mathbf{q} = \mathbf{f}, \quad (7)$$

where \mathbf{f} are nodal forces.

Although in this section a general formulation considering time dependent velocity is given, in the following sections a constant axial velocity is assumed, that is $\frac{\partial v}{\partial t} = 0$ in equation (2) and $\dot{\mathbf{C}}_2 = \mathbf{0}$ in equation (7).

3 WAVE MOTION AND FREE VIBRATION

In this section the dynamics of the travelling beam is described using a wave approach. Solution of equation (2) are written in terms of harmonic waves $y(x, t) = Ae^{i(\omega t - kx)}$ which, substituted into (2), gives the dispersion relation between wavenumbers and frequencies:

$$a^2 k^4 - v^2 k^2 + 2v\omega k - \omega^2 = 0, \quad (8)$$

where $a = \sqrt{\frac{EI}{\rho}}$. The roots of this equation are

$$\begin{aligned} k_d &= -\frac{1}{2}\frac{v}{a} + \frac{1}{2}\sqrt{\frac{v^2}{a^2} + 4\frac{\omega^2}{a^2}}; & k_u &= \frac{1}{2}\frac{v}{a} + \frac{1}{2}\sqrt{\frac{v^2}{a^2} + 4\frac{\omega^2}{a^2}}; \\ k_{de} &= \frac{1}{2}\sqrt{4\frac{\omega^2}{a^2} - \frac{v^2}{a^2}} + i\frac{1}{2}\frac{v}{a}; & k_{ue} &= \frac{1}{2}\sqrt{4\frac{\omega^2}{a^2} - \frac{v^2}{a^2}} - i\frac{1}{2}\frac{v}{a}, \end{aligned} \quad (9)$$

and the solution of the homogeneous equation (2) can be written as a linear combination of these four flexural waves

$$y(x, t) = A_d e^{-ik_d x} e^{i\omega t} + A_u e^{ik_u x} e^{i\omega t} + A_{de} e^{-k_{de} x} e^{i\omega t} + A_{ue} e^{k_{ue} x} e^{i\omega t}. \quad (10)$$

For $0 < v < 2\sqrt{\omega a}$ solutions k_{de} and k_{ue} represent attenuating waves, therefore equations (9) represent one positive-going and one negative-going propagating waves, k_d and k_u respectively, and one positive-going and one negative-going decaying waves, k_{de} and k_{ue} respectively. On the other side, for $v > 2\sqrt{\omega a}$ solutions k_{de} and k_{ue} are real numbers representing two positive-going propagating waves. Hence, when $v > 2\sqrt{\omega a}$ there are four propagating waves, three positive-going waves, k_d , k_{de} and k_{ue} , and one negative-going wave, k_u . However, $v_g = 2\sqrt{\omega a}$ is the group velocity of a disturbance propagating in the beam, and it is expected that instability occurs when the axial velocity is faster than the energy velocity in the medium considered. Moreover, the axial speed is often much smaller than the speed of any travelling disturbance in the beam. Therefore the inequality $0 < v < 2\sqrt{\omega a}$ is assumed in the present paper.

Using the same formalism proposed in [9], the wave amplitude of the positive and negative going waves is given by $\mathbf{A}^+ = [A_d, A_{de}]^T$ and $\mathbf{A}^- = [A_u, A_{ue}]^T$, while the transfer matrices \mathbf{F}^+ and \mathbf{F}^- describe the propagation from one point to another through appropriate wavenumber

$$\mathbf{F}^+(x) = \begin{bmatrix} e^{-ik_d x} & 0 \\ 0 & e^{-k_{de} x} \end{bmatrix}, \quad \mathbf{F}^-(x) = \begin{bmatrix} e^{ik_u x} & 0 \\ 0 & e^{k_{ue} x} \end{bmatrix}. \quad (11)$$

To evaluate the free vibration, the interaction of both propagating and decaying waves with discontinuities is considered, and wave amplitudes and phases after reflection and transmission are arranged in reflection and transmission matrices. The elements of these matrices are obtained imposing equilibrium conditions [9]. In this paper we consider boundary conditions at the ends of the beam $A(x = 0)$ and $B(x = L_{tot})$, where L_{tot} is the total length of the beam, and the reflection matrices at the boundaries are denoted by \mathbf{R}_A and \mathbf{R}_B .

The wave amplitudes at each ends of the beam are denoted by \mathbf{A}^+ , \mathbf{A}^- , \mathbf{B}^+ and \mathbf{B}^- . If the incident waves impinging upon the right end at $A(x = 0)$ are the negative-going waves \mathbf{A}^- , then reflected waves have amplitude $\mathbf{A}^+ = \mathbf{R}_A \mathbf{A}^-$. Similarly if the incident waves impinging upon the left end are the positive-going waves of amplitude \mathbf{B}^+ , reflected waves are $\mathbf{B}^- = \mathbf{R}_B \mathbf{B}^+$. Considering the wave reflection matrices and using the transfer matrices, the following relations can be written

$$\mathbf{A}^+ = \mathbf{R}_A \mathbf{A}^-; \quad \mathbf{B}^- = \mathbf{R}_B \mathbf{B}^+; \quad \mathbf{B}^+ = \mathbf{F}^+(L_{tot}) \mathbf{A}^+; \quad \mathbf{A}^- = \mathbf{F}^-(-L_{tot}) \mathbf{B}^-. \quad (12)$$

Combing equations in (12), the characteristic equation is obtained

$$[\mathbf{R}_A \mathbf{F}^-(-L) \mathbf{R}_A \mathbf{F}^+(L) - \mathbf{I}] \mathbf{A}^+ = 0. \quad (13)$$

For non trivial solution, the determinant of the coefficients \mathbf{A}^+ must be zero, that is

$$|\det (\mathbf{R}_A \mathbf{F}^-(-L_{tot}) \mathbf{R}_A \mathbf{F}^+(L_{tot}) - \mathbf{I})| = 0. \quad (14)$$

Solutions of equations (14) and (13) give the natural frequencies and natural modes.

4 WAVE FINITE ELEMENT MODEL

In this section the WFE approach is briefly described. The FE equation of motion (7) of the moving beam element is considered with $\dot{\mathbf{C}}_2 = \mathbf{0}$. Assuming time harmonic behaviour, the equation of motion is

$$(-\omega^2 \mathbf{M} + i\omega \mathbf{C}_{eq} + \mathbf{K}_{eq}) \mathbf{q} = \mathbf{f}, \quad (15)$$

where $\mathbf{C}_{eq} = \mathbf{C}_2 - \mathbf{C}_2^T$ and $\mathbf{K}_{eq} = \mathbf{K}_2 - \mathbf{K}_1$.

Figure 2: WFE model and node numbering.

The nodal degrees of freedom (DOFs) \mathbf{q} and the nodal forces \mathbf{f} are partitioned into left and right, figure 2, that is

$$\mathbf{q} = [\mathbf{q}_L^T \quad \mathbf{q}_R^T]^T; \quad (16)$$

T denoting the transpose, with a similar expression for the nodal forces \mathbf{f} . Under the passage of a wave the nodal DOFs are related by periodicity conditions [15]

$$\mathbf{q}_R = \lambda \mathbf{q}_L, \quad (17)$$

where $\lambda = e^{-ikL}$ and k is the wavenumber, while equilibrium at left side of the segment implies

$$[\mathbf{I} \quad \lambda^{-1} \mathbf{I}] \mathbf{f} = \mathbf{0}. \quad (18)$$

By substituting equation (17) in equation (15), and premultiplying both sides of equation (15) by the matrix in equation (18), the equation of free wave motion takes the form

$$[\overline{\mathbf{K}}_{eq}(kL) - \omega^2 \overline{\mathbf{M}}(kL) + i\omega \overline{\mathbf{C}}_{eq}(kL)] \mathbf{q}_L = \mathbf{0}. \quad (19)$$

Solutions of equation (19) yield the dispersion curves and the wavemode shapes. This involves solving a quadratic polynomial eigenvalue problem, which is recast as the standard linear eigenvalue problem [5, 6]. Associated with eigenvalues, viz. wavenumbers, are eigenvectors Φ_{qj} , which represent wavemodes, and vectors

$$\Phi_{fj} = [\overline{\mathbf{K}}_{eq}(kL) - \omega^2 \overline{\mathbf{M}}(kL) + i\omega \overline{\mathbf{C}}_{eq}(kL)] \Phi_{qj}. \quad (20)$$

These can be partitioned into positive-going and negative-going waves, which are denoted by $(\lambda_j^+, \Phi_{qj}^+, \Phi_{fj}^+)$ and $(\lambda_j^-, \Phi_{qj}^-, \Phi_{fj}^-)$ respectively. Positive going waves are typically characterised by [7]

$$|\lambda_j^+| \leq 1; \quad \text{Real}[i\omega \mathbf{f}_L \mathbf{q}_L] < 0 \quad \text{if} \quad |\lambda_j^+| = 1. \quad (21)$$

Note that if there are n degrees of freedom for node L and R , then there are $2n$ eigenvalues and the eigenvectors matrix Φ_q and Φ_f are $n \times 2n$.

5 FREE VIBRATION USING WFE DISPERSION RELATION AND WAVEMODES

Free vibration and dynamic response can be obtained using wave-based methods, in particular when the analysis focus on disturbance propagation [7]. In this section natural frequencies are predicted using wavemodes and dispersion curves obtained from the WFE eigenproblem (19). In the following it is assumed that nodal forces and displacements are described in terms of wave amplitudes \mathbf{A} using wavemodes as a basis, that is

$$\mathbf{q}_L = \Phi_q \mathbf{A}; \quad \mathbf{f}_L = \Phi_f \mathbf{A}. \quad (22)$$

In practise displacements are often expanded onto a reduced basis and only $m < 2n$ pairs of waves - positive and negative going waves - are retained, so that Φ_q and Φ_f are $n \times m$ matrices and λ is an array of size m [7]. Although there is not a rigorous criterium, this reduced basis is supposed to include all the wavemodes which mostly contributes to the structure response. Typically all the propagating waves are retained together with the attenuating and evanescent waves which either decay not very rapidly with distance or are becoming propagating in the frequency band of interest.

5.1 Dynamic Stiffness Formulation

The dynamic stiffness matrix [10] of the beam is developed using wavemodes and dispersion curves, and subsequently used to investigate free vibration characteristics. If $N = L_{tot}/L$, where L_{tot} is the total length of the beam and N is typically an entire number, the total displacement at $A(x = 0)$ and $B(x = NL)$ can be expanded as

$$\mathbf{Q} = \begin{bmatrix} \mathbf{q}(0) \\ \mathbf{q}(NL) \end{bmatrix} = \begin{bmatrix} \Phi_q \\ \Phi_q \wedge^N \end{bmatrix} \mathbf{A} = \mathbf{D}_q \mathbf{A}. \quad (23)$$

In equation (23) the diagonal matrix $\wedge = \text{diag}(\lambda_1, \dots, \lambda_m)$ contains the WFE eigenvalues, and the matrix \mathbf{D}_q is a rectangular $2n \times m$ matrix. A similar expression is given for nodal forces

$$\mathbf{F} = \begin{bmatrix} \mathbf{f}(0) \\ \mathbf{f}(NL) \end{bmatrix} = \begin{bmatrix} \Phi_f \\ \Phi_f \wedge^N \end{bmatrix} \mathbf{A} = \mathbf{D}_f \mathbf{A}. \quad (24)$$

Since wavemodes are assumed to be linearly independent, the matrix \mathbf{D}_q is a full column rank matrix, i.e. $\text{rank}(\mathbf{D}_q) = m$, and the left pseudoinverse \mathbf{D}_q^\dagger can be calculated. Hence the wave amplitude can be obtained from

$$\mathbf{A} = \mathbf{D}_q^\dagger \mathbf{Q}. \quad (25)$$

Substituting equation (25) in equation (24) yields

$$\mathbf{F} = \mathbf{D}_f \mathbf{D}_q^\dagger \mathbf{Q} = \bar{\mathbf{D}} \mathbf{Q}, \quad (26)$$

where $\bar{\mathbf{D}}$ is the dynamic stiffness matrix. Once the dynamic stiffness matrix is obtained, free vibration are calculated in the usual way as it is done in the FE method. In particular resonances occur when $|\det(\bar{\mathbf{D}}')| = 0$, where $\bar{\mathbf{D}}'$ is obtained from $\bar{\mathbf{D}}$ after applying boundary conditions. A numerical procedure is used in the present work. Therefore the determinant is evaluated numerically for each frequency, and resonances occur when $|\det(\bar{\mathbf{D}}')|$ shows stationary values. It is of worth to point out that the present formulation can also be used to evaluated the forced response of the structure.

5.2 Phase Closure Principle

Following section 3, consider a beam with some boundary conditions at the end $A(x = 0)$ and $B(x = L_{tot})$. Again wave amplitudes at each end are denoted by \mathbf{A}^+ , \mathbf{A}^- , \mathbf{B}^+ and \mathbf{B}^- and the boundary conditions have reflection matrices \mathbf{R}_A and \mathbf{R}_B . According to [7], the boundary conditions can be written as $\mathbf{E}\mathbf{q} + \mathbf{G}\mathbf{f} = \mathbf{0}$. Complicated boundary conditions can be easily introduced using this formulation. Since displacements and forces can be expanded as $\mathbf{q} = \Phi_q^+ \mathbf{A}^+ + \Phi_q^- \mathbf{A}^-$ and $\mathbf{f} = \Phi_f^+ \mathbf{A}^+ + \Phi_f^- \mathbf{A}^-$, reflection matrices are

$$\begin{aligned} \mathbf{R}_B &= -(\mathbf{E}_B \Phi_f^- + \mathbf{G}_B \Phi_q^-)^\dagger (\mathbf{E}_B \Phi_f^+ + \mathbf{G}_B \Phi_q^+); \\ \mathbf{R}_A &= -(\mathbf{E}_A \Phi_f^+ + \mathbf{G}_A \Phi_q^+)^\dagger (\mathbf{E}_A \Phi_f^- + \mathbf{G}_A \Phi_q^-). \end{aligned} \quad (27)$$

Equation (12) can be rewritten as $\mathbf{B}^+ = [\wedge^+]^N \mathbf{A}^+$, $\mathbf{A}^- = [\wedge^-]^N \mathbf{B}^-$, $\mathbf{B}^- = \mathbf{R}_B \mathbf{B}^+$ and $\mathbf{A}^+ = \mathbf{R}_A \mathbf{A}^-$, which solved give

$$[\mathbf{R}_A [\wedge^-]^N \mathbf{R}_B [\wedge^+]^N - \mathbf{I}] \mathbf{A}^+ = \mathbf{0}, \quad (28)$$

where $[\wedge^+] = \text{diag}(\lambda_1^+, \dots, \lambda_m^+)$ and $[\wedge^-] = \text{diag}(\lambda_1^-, \dots, \lambda_m^-)$ correspond to positive-going and negative-going waves. Therefore natural frequencies occur when

$$|\det(\mathbf{R}_A [\wedge^-]^N \mathbf{R}_B [\wedge^+]^N - \mathbf{I})| \quad (29)$$

shows stationary values.

6 NUMERICAL EXAMPLE

In this section a numerical example is presented and WFE results are compared with those obtained using the wave approach described in section 3. The beam considered is an aluminum beam with cross section $h = 0.002\text{m}$. The element length for the WFE formulation is $L = 0.001\text{m}$. Figure 3 shows the complex dispersion curves obtained from equations (9) and (19), where $\Omega = L^2 \omega / a$ is the non-dimensional frequency. It can be noticed that results agree very well. Table 1–3 show natural frequencies of the beam predicted for different values of the axial velocity. The beam is simply supported, and its total length is $L_{tot} = 0.4\text{m}$. Results obtained from equations (14), (26), and (28) are compared. It can be noticed that equation (28) gives more accurate results with respect to equation (26). Hence the Phase Closure Principle seems to be preferable for WFE application. Accuracy of the numerical WFE results increases with frequency. This is perhaps due to the short length of the FE element. It can also be noticed that natural frequencies decrease when the axial velocity increases. Divergence instability in

fact occurs at a critical moving speed [11], where the linear theory breaks down. However, far from the critical speed, which for the present case is quite high, the method proposed offers a powerful alternative to analytical approaches, in particular for more complicated cases, such as pipe conveying fluid, which will be the subject of further analysis. Moreover, the linear theory can be the first step in the analysis to provide useful information for a more refined nonlinear investigation.

It is of worth noting that, for a simply supported beam, a closed form approximate frequency neglecting evanescent waves in (14) is

$$\omega = \frac{n^2 \pi^2}{L^2} a - \frac{v^2}{4a}. \quad (30)$$

Accuracy of equation (30) is related to the rate of decay of evanescent waves k_{de} and k_{ue} , thus it is expected that equation (30) is more accurate for higher frequency and low axial speed.

7 CONCLUSIONS

In the present paper the dynamics of a travelling one-dimensional waveguide was studied using a Wave Finite Element method. In particular an axially moving beam, modelled using the classical linear theory, was considered. The FE formulation of a moving beam element was developed, and a brief description of the WFE method was given. Natural frequencies were then calculated using the Dynamic Stiffness Matrix and the Phase Closure Principle, both formulated in terms of wave characteristics obtained from the WFE eigenproblem. An analytical wave approach was also presented to show some characteristics of the elastic waves propagating in such a beam. Numerical examples were shown. Results were compared with those obtained using the analytical approach, showing the accuracy of the proposed technique, in particular at higher frequency.

Abstract. *In modern constructions, thin-layer coats are often used as protecting or strengthening elements. Deformations of such constructions may cause significant stresses on the interface between the base and the coat because of the difference in their physical-mechanical properties, which leads to the destruction or delamination of the cover. Of special interest is strength analysis under dynamical or vibrational impacts because of the possibility of localizing oscillations in a neighborhood of the initial inhomogeneities (such as inclusions, defects, construction elements, etc.). In this paper, on the example of the delamination of a string from an elastic substrate, the possibility of localizing oscillations on a delamination defect is demonstrated and the effect of this localization on the growth of the delamination zone is analyzed. A simplified setting of the problem is considered. The possibility of localizing oscillations on a delamination defect is demonstrated and an approximate analytical solution is constructed, which takes into account only the first symmetric form of oscillations describing the development of the initial delamination. A numerical modeling of the problem is performed, and the results of modeling are compared with the approximate analytical solution.*

1 INTRODUCTION

In modern constructions, thin-layer coats are often used as protecting or strengthening elements. Deformations of such constructions may cause significant stresses on the interface between the base and the coat because of the difference in their physical-mechanical properties, which leads to the destruction or delamination of the cover. Delamination of multilayer constructions under static and dynamic (shock) loads have an extensive bibliography. We mention the fundamental works [1-8]. The impact of static or shock loads on the emergence and development of delamination in multilayer constructions has been studied fairly well, but much less is known about destructions of this type under nonstationary (vibrational) loads. The interest in the latter is caused by the fact that even small variable actions may cause the localization of oscillations in a neighborhood of inhomogeneities (such as inclusions, defects, construction elements, etc.) [9] and lead to the emergence and growth of defects, which strongly affects the reliability and functionality of the whole construction.

An example of such coated constructions in which delamination destructions are observed is the blades of a wind turbine, which are becoming increasingly popular because of the interest in alternative energy sources. In recent years, the increase in the power of wind turbines has enhanced requirements to rotor blades.

During the operation of the rotor, the top coat of a blade, which is a thin film, may detach on some part of its length. To estimate the functionality of the construction, it is important to know the further scenario of the behavior of such a film with a detached fragment. Such defects may appear and grow for several reasons, which include wind loads and stationary oscillations arising in blades during their operation.

This paper studies the possibility of oscillation localization near delaminations from cracks and the impact of localization on the growth of the defects. We suggest a model for analyzing conditions under which a delamination zone grows or ceases to grow.

2 STATEMENT OF THE PROBLEM

Taking into account the fact that the thickness of a thin-layer coat is usually much less than the characteristic size of the substrate, in the first approximation, we replace a coat attached to a substrate by a film on an elastic substrate.

The main purpose of this paper is to show that, if an elastic substrate has an inhomogeneity (the coefficient of the elastic substrate vanishes for some part of the film length), then, under a non-stationary harmonic load, some part of the propagating wave energy is localized near the inhomogeneity. Depending on the parameters of the film and the elastic substrate, various scenarios of the film behavior are possible: the length delamination zone may increase unlimitedly, or it may cease to grow at some time.

Note that if there are only propagating waves in the film, then the wave processes only insignificantly affect the behavior of the delamination zone, because the excited wave process rapidly fades out. The situation changes if the waves in the film-waveguide localize near the defect. As is known, in the absence of dissipation, localized oscillations of certain frequencies may not attenuate for an infinitely long time [9], thereby substantially affecting the behavior of the delamination zone. The existence of standing waves localized near the delamination zone means that the corresponding spectral problem has not only continuous but also discrete spectrum of eigenfrequencies.

This paper considers the simplest mathematical model for the behavior of such a film under the action of a transverse non-stationary harmonic load. The film is attached to an elastic Win-

Figure 1: A scheme of film delamination

kler foundation, which models an element of a blade. In the framework of this model, the birth of a delamination is not studied; it is assumed that, at initial moment of time, a film fragment of length $2l_0$ is torn away from the elastic substrate.

We assume that the delamination emerges not near the blade boundaries, which is confirmed by in-situ observations. The tension of the detached part of the film differs from the tension of the film on the elastic substrate, and when the detached part oscillates, the interaction between the film and the elastic substrate has the character of a one-sided contact, and the interaction of the film with the substrate has a relay characteristic. These two factors significantly complicate constructing a solution; for this reason, at the present stage of modeling, we assume that tension is constant over the entire film and the detached part does not interact with the elastic substrate. Vibro-impact loads in the delamination zone and a variable tension of the film will be taken into account at the next modeling stage.

As the simplest model we consider the following case, in which the problem under consideration reduces to a one-dimensional problem: the delamination zone is contained in the domain $-l_0 < x < l_0$, $-\infty < y < \infty$, and the force is applied along the line $x = x_p$, $-\infty < y < \infty$. In this case, the problem reduces to the problem about oscillations of a string on an elastic substrate with variable stiffness $k[x, l(t)]$: namely, stiffness vanishes on the detached part of the string, and on remaining part of the string, it equals k_0 . The equation describing the displacement of a string on an elastic substrate under a load applied at a point $x = x_p$ has the form

$$\begin{aligned} \rho u_{tt} - T u_{xx} + k[x, l(t)]u &= -P(x, t), \quad -\infty < x < \infty, \\ u, u_x &\rightarrow 0 \quad |x| \rightarrow \infty \end{aligned} \quad (1)$$

Here, ρ is the specific density of the string, u is the vertical displacement of the string, T is the tension of the unperturbed string, and $P(t)\delta(x - x_p)$ is the exciting force. We assume that, at the initial moment of time $t = 0$, there is a film fragment of length $2l_0$ detached from the elastic substrate. For the delamination criterion we take the following deformation criterion: when the displacement of at least one end of the detached part attains a critical value Δ , the delamination zone grows with rate β (see Fig. 1). The equation describing the growth of the delamination zone has the form [8]

$$\frac{dl}{dt} = \beta \left\{ H[u(x, t)|_{x=l_-(t)} - \Delta] + H[u(x, t)|_{x=l_+(t)} - \Delta] \right\} \quad (2)$$

Here, $l_-(t)$ is the coordinate of the left end of the detached fragment, $l_+(t)$ is the coordinate of the right end of the detached fragment, $2l(t) = l_- + l_+$ is the length of the detached fragment, $u(x, t)$ is the displacement of the string point with coordinate x at a moment t , H is the Heaviside function, β is the coefficient determining the growth rate of the delamination, and Δ is the critical displacement, under which the film separates from the elastic substrate.

Under certain conditions, oscillations may localize on the initial delamination fragment of length $2l_0$ (see [9]), and the amplitude of oscillations at the endpoints of the delamination zone may surpass the critical displacement value Δ at some moment of time, which leads to the growth of the delamination zone. The increase in the length of the detached film fragment, in turn, affects the localization of oscillations near the defect, so that the passage to other forms of localized oscillations may occur. Therefore, we must solve the system of equations (1) and (2) under the initial conditions

$$l|_{t=0} = l_0; \quad u, u_t|_{t=0} = 0 \quad (3)$$

and the following boundary conditions for any fixed t :

$$u, u_x \rightarrow 0 \quad |x| \rightarrow \infty \quad (4)$$

Thus, we have obtained a connected problem about non-stationary oscillations of a string on an elastic substrate and the growth of the zone of the delamination of a part of this string from an elastic substrate, which is described by the system of equations (1)-(4).

3 STEADY-STATE OSCILLATIONS OF A STRING. LOCALIZED MODES

First, consider the case where the length of the delamination domain is constant: $2l = 2l_0$. The corresponding spectral problem $u(x, t) = v(x)e^{i\omega t}$ takes the form

$$\begin{aligned} T v_{xx} - [k(x) - \rho \omega^2] v &= 0, \quad -\infty < x < \infty, \\ v, v_x &\rightarrow 0 \quad |x| \rightarrow \infty \end{aligned} \quad (5)$$

Here, ω is the frequency and $k = k_0[H(x + l_0) - H(x - l_0)]$. The specific density of the string is assumed to be constant. We denote the sound speed in the string by $c = \sqrt{T/\rho}$ and the cut-off frequency by $\omega_b = \sqrt{k_0/\rho}$.

This spectral problem is a special case of the problem about oscillations of a string with a distributed elastic-mass inclusion, which was considered in detail in [9]. It was shown that problem (5) has not only continuous spectrum of oscillation eigenfrequencies, which begins with the cut-off frequency ω_b , but also discrete spectrum, which goes before the cut-off frequency consists of finitely many eigenfrequencies. The eigenforms of oscillations corresponding to the discrete spectrum, known as localized (trapped) modes, are localized near the inclusion and do not carry energy away to infinity.

The symmetric localized modes corresponding to the eigenfrequencies ω_{sn} , which are determined by the dispersion relation

$$\tan \frac{l_0}{c} \omega = \frac{\sqrt{\omega_b^2 - \omega^2}}{\omega}, \quad (6)$$

have the form

$$v_i^s = \begin{cases} \cos \gamma_1 x, & |x| < l_0, \\ \cos \gamma_1 l_0 e^{-\gamma_0 |x-l_0|}, & |x| > l_0 \end{cases} \quad (7)$$

where $\gamma_1 = \omega/c$ and $\gamma_0 = \sqrt{\omega_b^2 - \omega^2}/c$.

Figure 2: The eigenfrequencies.

The antisymmetric localized modes are determined by the spectrum of frequencies determined from the dispersion relation

$$\tan \frac{l_0}{c} \omega = -\frac{\omega}{\sqrt{\omega_b^2 - \omega^2}} \quad (8)$$

and have the form

$$v_i^a = \begin{cases} \sin \gamma_1 l_0 e^{-\gamma_0 |x-l_0|}, & x > l_0 \\ \sin \gamma_1 x, & |x| < l_0, \\ -\sin \gamma_1 l_0 e^{\gamma_0 |x+l_0|}, & x < -l_0. \end{cases} \quad (9)$$

The scheme of the determination of the roots of the frequency equations (6) and (8) is shown in Fig.2. The abscissas of the intersection points of the curves determining the right- and left-hand sides of the frequency equations give the required eigenfrequencies, provided that the parameter values ω_b , c , and l_0 are known. Note that the first eigenfrequency corresponds to a symmetric localized mode, the second corresponds to an antisymmetric mode, etc. The number of eigenfrequencies before the cut-off frequency is determined by the parameters of the waveguide and the length of the delamination zone.

The eigenfunctions corresponding to frequencies $\omega > \omega_b$ from the continuous spectrum (we call them traveling modes) are determined in [9].

It can be shown that the localized modes (7)-(9) and traveling modes are orthogonal in the sense of generalized functions [10].

4 THE NON-STATIONARY PROBLEM: EXPANSION IN EIGENFORMS

As above, we assume that the length of the delamination zone is constant and equals $2l_0$. Let $v_i(x)$ denote the localized modes (eigenfunctions) corresponding to the discrete eigenfrequencies ω_i ($i = 1, 2, \dots, N$), and let $v_\omega(x)$ be the traveling modes (eigenfunctions) corresponding to frequencies from the continuous spectrum.

Then we seek a solution of (1) in the form of an expansion in the eigenfunctions of the

spectral problem (5) [10]

$$u(x, t) = \sum_{i=1}^N v_i(x) q_i(t) + \int_{\omega_b}^{\infty} v_{\omega}(x) q_{\omega}(t) d\omega. \quad (10)$$

where $q_i(t)$ and $q_{\omega}(t)$ are unknown functions so-called generalized coordinates.

Substituting (10) into (1), multiplying by eigenfunctions, integrating with respect to x , and applying the dispersion relations (6) and (8), we obtain

$$\ddot{q}_i + \omega_i^2 q_i = \frac{Q_i(t)}{M_i}, \quad q_i, \dot{q}_i|_{t=0} = 0, \quad i = 1, 2, \dots, N \quad (11)$$

$$\ddot{q}_{\omega} + \omega^2 q_{\omega} = \frac{Q_{\omega}(t)}{M_{\omega}}, \quad q_{\omega}, \dot{q}_{\omega}|_{t=0} = 0. \quad (12)$$

Here, Q_i are generalized forces acting on the forms from the discrete spectrum, the Q_{ω} are generalized forces acting on the forms from the continuous spectrum, and the M_i and M_{ω} are generalized masses, which are determined as follows:

$$Q_i = \int_{-\infty}^{\infty} v_i(x) P(x, t) dx, \quad M_i = \frac{1}{c^2} \int_{-\infty}^{\infty} v_i^2(x) dx$$

$$Q_{\omega} = \int_{-\infty}^{\infty} v_{\omega}(x) P(x, t) dx, \quad M_{\omega} = \frac{1}{c^2} \int_{-\infty}^{\infty} v_{\omega}^2(x) dx$$

Solving the system of equations (11)-(12), we obtain the following expression for the string deflection:

$$u(x, t) = \sum_{i=1}^N \frac{v_i(x)}{M_i \omega_i} \int_0^t \sin \omega_i(t - \tau) Q_i(\tau) d\tau + \int_{\omega_b}^{\infty} \frac{v_{\omega}(x)}{M_{\omega} \omega} \int_0^t \sin \omega(t - \tau) Q_{\omega}(\tau) d\tau d\omega. \quad (13)$$

Thus, we have obtained a solution of Eq.(1) in the form of an expansion in localized and traveling modes for the string with a distributed inclusion. Using the Riemann-Lebesgue lemma, we can show that the integral determining the expansion in the continuous spectrum in formula (13) tends to zero as $t \rightarrow \infty$, and for large t , the solution of problem (1) is determined only by localized forms of oscillations:

$$u(x, t) \rightarrow \sum_{i=1}^N \frac{v_i(x)}{M_i \omega_i} \int_0^t \sin \omega_i(t - \tau) Q_i(\tau) d\tau \quad \text{for } t \rightarrow \infty. \quad (14)$$

Thus, an external action leads to the localization of waves in the film delamination zone, and in the absence of dissipation in the system, these localized waves may exist infinitely long.

5 FILM DELAMINATION

After the localization of oscillations on a defect of fixed length is analyzed, we proceed to study the initial problem (1)-(4) on film delamination, that is, on the growth of the initial delamination zone.

Suppose that, at the initial moment of time, the length of the zone of film delamination from the substrate equals $2l_0$. We assume that the value l_0 is such that there exists a unique eigenfrequency $\omega_0 < \omega_b$, which determines a symmetric eigenform according to (7). Then we seek a solution of the initial problem (1)-(4) in the form

$$u(x, t) = v_0(x) q_0(t). \quad (15)$$

Remark. In expansion (10) only the first term corresponding to a localized mode is retained; thus, the transition processes related to the propagation of traveling waves are not taken into account.

Thanks to the existence of the first symmetric form of oscillations, we can assume that $l_+ = l_-$ and write Eq.(2), which describes the growth of the delamination zone, in the form

$$\frac{dl}{dt} = \beta H[u(x, t)|_{x=l(t)} - \Delta]. \quad (16)$$

The length of the delamination zone varies in time, and now the symmetric form $v_0(x, l)$ depends on time and is defined on a variable interval, namely,

$$v_0(x, l) = \cos \lambda x H(l - x) + \cos \lambda l e^{-\gamma(x-l)} H(x - l), \quad 0 < x < \infty,$$

where $\lambda = \omega_0/c$. Substituting (15) into the equation (1) for string oscillations, multiplying the obtained equation by $v_0(x, l)$, and integrating the result with respect to x , we arrive at a fairly complicated nonlinear equation with respect to $q_0(t)$ and $l(t)$. Discarding nonlinear terms, we obtain the following equation for the generalized coordinate $q_0(t)$:

$$\ddot{q}_0 + \omega^2(l)q_0 = \frac{Q_0(t)}{M_0}, \quad q_0, \dot{q}_0|_{t=0} = 0,$$

where

$$\omega^2(l) = \left[2\omega_b^2 \int_l^{+\infty} v_0^2 dx + c^2 \int_{-\infty}^{+\infty} v_{0x}^2 dx \right] / \int_{-\infty}^{+\infty} v_0^2 dx.$$

We assume that $\lambda \tilde{l} = \omega_0[l(t) - l_0]/c \ll 1$. It is easy to show that, in this case, we have

$$\omega^2(l) = \omega_0^2 + o[(\lambda \tilde{l})^2], \quad \tilde{l} = l(t) - l_0.$$

Replacing $\omega(l)$ by ω_0 in the last equation, we reduce the initial problem to the system of equations

$$\ddot{q}_0 + \omega_0^2 q_0 = \frac{Q_0(t)}{M_0}, \quad q_0, \dot{q}_0|_{t=0} = 0, \quad (17)$$

$$\frac{dl}{dt} = \beta H[v_0(l, \omega_0)q_0(t) - \Delta], \quad l(t)|_{t=0} = l_0. \quad (18)$$

First, consider the simplest example of an external action, namely, the oscillations initiated by an impulse exciting force $P(t) = P_0 \delta(t)$. In this case, the generalized force is

$$Q_0(t) = P_0 \cos \lambda l e^{-\gamma_0(x_p-l)} \delta(t).$$

The generalized mass does not depend on the exciting force and has the form

$$M_0(t) = \rho[l + \sin 2\lambda l/2\lambda + \cos \lambda l/\gamma_0].$$

Thus, Eq. (17) can be rewritten in the form

$$q_0(t) = \frac{P_0 e^{-\gamma_0(x_p-l)}}{M_0 \omega_0} \cos \lambda l \sin \omega_0 t \quad (19)$$

Substituting (19) into (18), we obtain

$$\frac{dl}{dt} = \beta H \left[\frac{P_0 \varepsilon \cos^2 \lambda l}{M_0(l) \omega_0} \sin \omega_0 t - \Delta \right], \quad l(t)|_{t=0} = l_0 \quad (20)$$

where $\varepsilon = e^{-\gamma_0(x_p-l)}$. We assume that the force is applied so that $\varepsilon < 1$. We seek an approximate solution to Eq.(20). Since $|\sin \omega_0 t| \leq 1$, it follows from (20) that a necessary condition for the growth of the delamination zone has the form

$$\frac{P_0 \varepsilon \cos^2 \lambda l}{M_0(l) \omega_0} > \Delta. \quad (21)$$

If l_0 is such that condition (21) is violated (the amplitude of string oscillations does not attain the critical value), then the delamination zone cannot grow. If the initial conditions are such that inequality (21) holds, then the delamination zone begins to linearly grow at rate β at the moment $t = t_1$, which can be approximately determined from the expression

$$\sin \omega_0 t = \frac{\Delta \omega_0 M_0(l_0)}{P_0 \varepsilon \cos^2 \lambda l_0}$$

and

$$l(t) = l_0 + \beta t H(t - t_1).$$

The length of the delamination zone increases until time $t = t_2$, at which the argument of the Heaviside function (20) vanishes. The growth of the delamination zone resumes at time $t = t_3$, which can be found from the expression

$$\sin \omega_0 t = \frac{\Delta \omega_0 M_0(l_2)}{P_0 \varepsilon \cos^2 \lambda l_2}.$$

Such a step growth of the delamination zone continues until $l(t)$ reaches a certain critical value. Indeed, as the length of the delamination zone decreases, the amplitude of string oscillations decreases; thus, there exists a moment of time t_k and the corresponding length $l = l_k$ for which condition (20) ceases to hold, and the growth of the delamination zone stops.

A similar picture is observed in the case where the exciting force is harmonic, in which this force has the form $P(t) = P_0 \sin \nu t$, where ν denotes frequency. In this case, Eq. (17) has the approximate solution

$$q_0(t) = P_0 \varepsilon \int_0^t \frac{\cos \lambda l(\tau)}{M_0(\tau)} \sin \nu(t - \tau) \sin \omega_0 \tau d\tau. \quad (22)$$

As well as in the case of impulse load, it can be proved that the moments of time t_i determining the growth periods of the delamination zone, can be found from the equation

$$q_0(t) \cos \lambda l = \Delta$$

Thus, the approximate analytic solution of the problem constructed on the basis of only the symmetric eigenform (7) describes the step growth of the delamination zone, and the growth rate is determined by the value of the parameter β . An analysis of Eq.(18), which describes the

Figure 3: The behavior of the boundary of the delamination zone.

growth of the delamination zone, shows that various modes of growth are possible, which are determined by the behavior of the argument of the Heaviside function in (18).

A numerical modeling of the initial problem (1)-(4) was performed. Motion was excited by a harmonic force. Results of the numerical modeling of the growth of the delamination zone for the parameter values $\beta = 0.2, 0.1, 0.05$ and $\Delta = 2 \cdot 10^{-6}$ are shown in Fig.3.

An analysis of numerical results demonstrates the possibility of the localization of oscillations near a delamination defect under certain loads and problem parameter values and of the following three cases of the delamination development: (i) the absence of growth of the delamination zone for large values of the critical displacement Δ , provided that the amplitude of the displacements does not attain the critical value; (ii) the growth of the delamination zone up to a certain size, after which the growth stops (see Fig.3); (iii) for very small Δ , the growth of the delamination zone is virtually unbounded. Thus, the numerical solution of the system of equations (1)-(4) well agrees qualitatively with the approximate analytic solution.

6 CONCLUSIONS

The delamination of thin-layer elements caused by dynamic or vibrational loads, which is observed during the exploitation of real-life constructions, leads to the destruction of these constructions. Therefore, problems related to determining reasons for such destructions are of great practical interest. In this paper, for the example of the delamination of a string from an elastic substrate, the possibility of the localization of oscillations near a delamination defect was demonstrated and the impact of this localization on the growth of the delamination zone was analyzed. The problem considered here is only the first approximation of a fairly complicated problem. A simplified setting of the problem under consideration was suggested. In constructing an approximated analytic solution, only the first symmetric form of oscillations was taken into account. In the future, non-symmetric forms and the transformation of oscillations as the delamination zone grows must be taken into account. The simplest criterion for the growth of the delamination zone was chosen, which does not take into account the real rheology near the

boundaries of the delamination zone. It is quite natural to consider the generalization of the obtained results to the case of the delamination of a two-dimensional film, a bar, and a thin plate.

However, even the simplified model makes it possible to explain the destructions observed in constructions with thin-layer coats under comparatively mild loads, which are caused by the localization of oscillations near various defects.

Abstract. *In the present paper, a finite-element model of a double-plate panel is implemented to investigate the transmission of sound through a simple lightweight structure. A numerical study is performed of the following three coupling configurations: 1) Structure-borne sound via plate-stud-plate structures without air inclusions; 2) transmission via the plate-stud-plate structure including the internal acoustic medium; 3) transmission via plate-air-plate connections in a double-leaf panel with no structural coupling between the two plates. A fully coupled analysis is performed in which solid finite elements are adopted for the structure, whereas the acoustic medium is discretized into fluid continuum elements. The computations are carried out in frequency domain in the low frequency range and the load acts as a diffuse sound field on one side of the panel.*

1 INTRODUCTION

Lightweight building techniques are currently progressing faster than the development of prediction tools for the acoustic behavior of such structures. In order to ensure that the increasing demands to sound insulation between dwellings are being accommodated, reliable prediction tools are needed at an early stage of the building design. For a variety of simple structures, analytical solutions have been established [9], and for heavy structures, statistical energy analysis (SEA) [15, 7, 6, 13] has in general been found to provide a reliable prediction of noise transmission. However, SEA has limited validity for lightweight structures such as wooden floor and wall panels.

Fahy and Gardonio [13] describe the transmission of sound through bounded partitions from a wave point-of-view, but when it comes to bounded double-leaf partitions the transmission behavior becomes too complicated for analytical approaches. Therefore, the wave propagation problems have to be numerically analyzed using a method depending of the frequency region considered. The conventional finite element method (FEM) [2] can be used, especially for low-frequency problems where the considered elements can be considered short compared with the wavelength. However, the frequency range of interest for wave propagation problems is often such that FEM analysis seems to be quite difficult due to the requirement of small element sizes to match the wavelength which implies huge unmanageable data sets. Therefore, instead of FEM for high-frequency analysis, where the elements are long compared to a wavelength, the so-called energy methods such as SEA and energy finite element method (EFEM) [3, 17, 4, 18] are well established methods. Another energy based method is the European standard EN 12354 [1], which is widely used to predict sound transmission in buildings. However, as with SEA, EN 12354 is based on assumptions which are typically not fulfilled by lightweight building structures. Therefore, predictions of sound transmission in such structures using EN 12354 may be imprecise [16].

Currently there is an increasing focus on the transmission of low frequency noise, as sources like road and air traffic or even home theater subwoofers become part of everyday life for many people. Recently, research has been presented where sound transmission in the low frequency range through lightweight structures has been predicted with numerical methods [5, 12, 10]. The results from these papers indicates that FEM tools can give reliable results for prediction of sound transmission loss, however more investigations have to be performed in this field where the influence of different modeling strategies will be considered. The construction of a lightweight structure is fairly complex and many variables belonging to material models, junction types and coupling phenomena between structure and acoustic medium have to be modeled in a proper way. Although basic theories are well established, modeling transmission through simple structural elements is not straightforward as numerous of the mentioned variables need to be considered. Some of the modeling difficulties are well known, but only a limited number of applications have been evaluated. Ongoing research is concerned with the loss factors in the different types of couplings that occur in lightweight structures including both different types of beams [8, 14] as well as line coupling versus point coupling [13, 8, 14]. The goal of the present paper is to obtain a greater knowledge on the coupling between fluid and structure using FEM tools for the prediction of sound transmission in lightweight building structures. The method of investigations will primarily be based on a numerical investigation using available elements in the commercial FEM software package ABAQUS [11]. The following Section 2 presents the double panel lightweight wall element and different modeling scenarios and finally results are given and discussed in Section 3 and 4.

Flanking noise in a similar panel structure is analysed in a companion paper by Gandalal, Dickow, Andersen and Sorokin.

2 PROBLEM DESCRIPTION

Lightweight wall and floor constructions are often made from panel structures with plates on stud (or joist) frames. In such a panel, the frames may be either single or double-stud frames with or without different porous and elastic layers included to reduce the transmission of sound and vibration through the panel. In the case of single-stud frames there is direct structural coupling from one side of the panel to the other. In the present study the subject of investigation is a single-stud double-plate panel without porous or elastic layers, see Figure 1. The goal of this preliminary study is to investigate the effect of the air inclusions in the model while at the same time gaining experience regarding how to model such structures for future investigations.

2.1 Numerical model

The panel consists of two plates mounted on a frame structure with a total of six cavities, see Figure 1. The stud dimensions are 50 mm by 60 mm and the plate thickness is 20 mm. The total wall dimension is 3350 mm (w) by 2600 mm (h) by 100 mm (d). The studs are placed 550 mm part (center-to-center). Homogeneous and isotropic materials are assumed. The material properties are:

- Timber (plate and studs): Young's modulus 14 GPa, Poisson Ratio 0.35, density 500 kg/m³. Damping is set to 1% of the stiffness.
- Air: Bulk modulus 141360 Pa, density 1.2 kg/m³.

The damping is applied as structural damping, i.e. the damping forces are assumed proportional to the forces caused by stressing of the structure. This simulates the effects of friction in the timber.

The panel is modeled in the commercial FEM package ABAQUS using solid continuum finite elements for the structure and fluid continuum elements for the air inclusions in the fi-

Figure 1: Overall geometry of the double-plate wall panel. The structure consists of two plates tied to a stud frame. A specification of the panel is given in Section 2.1

nite cavities. 20-node brick elements with quadratic spatial interpolation of the displacement are adopted with a mesh size of 5 cm. The mesh is designed such that the nodes constituting the plate mesh align with the nodes on the frame structure. All structural contact points are connected using tie constraints in x , y , and z -directions. As three-dimensional solid continuum elements have no rotational degrees of freedom, only displacements are considered. The coupling between the structure and the acoustic medium in the cavities is handled by tie constraints as well. The boundaries are clamped, i.e. all nodes on the top, bottom and side surfaces of the structure are rigid. Three different scenarios are investigated:

1. Structure-borne sound via plate-stud-plate structures without air inclusions,
2. transmission via the plate-stud-plate structure including the internal acoustic medium,
3. plate-air-plate transmission when there is no structural connection between the two plates.

In the latter case, half of the studs are tied to one plate, while the other half are tied to the other. Thus, the total mass of the panel is unchanged while the stiffness is of course reduced significantly. Furthermore the size of the cavities is unchanged compared with cases 1 and 2. When calculating the eigenfrequencies of the panel, a fourth case is investigated; similar to case 3 but without the structural-acoustical coupling. This is done to see how the coupling affects the modes related to the finite air-filled cavities inside the panel.

2.2 Excitation

If a concentrated load (point force) is applied directly to the panel, the position of the excitation is likely to be located in a nodal line of one or more of the structural modes of the panel. Therefore, as the present paper is dealing with transmission of sound through the entire panel, a diffuse field excitation model has been utilized. In ABAQUS, a diffuse field loading condition may be approximated by a number of deterministic incident plane waves coming from angles distributed over a hemisphere encapsulating the loaded surface. The number of incident plane waves used for the approximation is given by N^2 , where N is called the number of seeds.

Figure 2: The structure is excited by a diffuse field in the source room. The investigated output quantity in the receiving room is the translational surface acceleration, normal to the plane of the plate, expressed as the root-mean-square (spatial average) acceleration. Here a_z^j is the magnitude of the acceleration (z -direction) of the j th node on the plate surface.

2.3 Response

Preferably, the model should include an acoustic medium inside the receiving room such that the sound pressure could be used to find the transmission loss of the structure. However, due to the computational complexity associated with such a model, this is not included yet. Instead, the investigated output quantity in the receiving room, $\langle a_z \rangle_{\text{RMS}}$, is the translational surface acceleration, normal to the plane of the plate, expressed as the spatial root-mean-square acceleration. This is depicted in Figure 2.

3 RESULTS

3.1 Modal analysis

Eigenfrequencies of the four different configurations, i.e. 1) without air inclusions, 2) with air inclusions, 3) without structural coupling and 4) without any coupling, have been found using the Lanczos algorithm implemented in ABAQUS. In the cases without structural coupling between sending and receiving room, half of the ribs are connected to one plate, while the other half are connected to the other plate. The results are shown in Figure 3. A comparison of calculated eigenfrequencies in the case of using shell elements for the plates instead of solid continuum elements is shown in Figure 4.

Figure 3: Eigenfrequencies of the four different configurations: 1) without air inclusions, 2) with air inclusions, 3) without structural coupling and 4) without any coupling between the two plates. Groups of air-modes in the fully coupled case are indicated by arrows.

Figure 4: Eigenfrequencies with and without air when the plates are modeled using shell elements and solid continuum elements respectively.

By inspecting curves for cases 1) and 2) in Figure 3 it is clearly seen that the air inclusions provide a number of modes occurring in groups of six. Such a group is found between the 2nd and 3rd structural modes and the modeshapes of these are shown in Figure 6. Figure 5 shows the modeshape of the 2nd and 3rd structural modes.

Figure 5: Modeshapes showing the second and third structural modes.

Figure 6: A group of modes provided by the air inclusions.

3.2 Frequency response

The frequency response of the panel has been investigated in the range 50-250 Hz with a 1 Hz resolution. The panel is excited by a diffuse field on one side and the response is considered on the opposite side. First, a comparison between responses of the structure (without air inclusions) when using respectively 10, 30 and 40 seeds is performed. The result is shown in Figure 7.

Figure 7: Spatial RMS acceleration of the receiving room plate surface as a function of frequency. The excitation of the sending room is a diffuse field simulated using 10, 30 and 40 seeds, i.e. using respectively 100, 900 and 1600 incident plane waves in ABAQUS. The calculations are performed without air inclusions in the model.

Next, using 30 seeds for diffuse field simulation in ABAQUS, the frequency responses with and without air inclusions are compared in Figure 8. The bottom part of the figure shows the difference between the two curves in the upper part. Finally, Figure 9 shows the response in the case of no structural coupling between the two plates in the panel structure.

Figure 8: The effect of including the air inside the structure. The structure is excited by simulating a diffuse field using 30 seeds in ABAQUS. The bottom figure shows the difference between the two curves in the top figure.

Figure 9: Spatial RMS acceleration of the receiving room plate surface as a function of frequency when there is no structural coupling in the model. The structure is excited by simulating a diffuse field using 30 seeds in ABAQUS.

4 DISCUSSION

As the presented results only represent the preliminary steps of a larger research project on sound transmission through lightweight building structures, focus has been on the basic details of how such structures are modeled for research purposes. Here, solid continuum elements have been adopted for the structure rather than elements based on simplified theory like that of shells and beams. For the considered frequency range, however, shell elements are expected to yield similar results as the wavelengths are large compared with the thickness of the panel. For the eigenfrequencies this is confirmed by looking at Figure 4, where it is seen that the difference is a slight frequency shift in the structural modes due to the shell elements having fewer degrees of freedom.

4.1 Modal analysis

By looking at Figure 3 and comparing the two curves with and without air inclusions in the cavities, it is seen that more modes appear within the considered frequency region when the air is included. Furthermore, the (structural) modes of the calculation without air appear in the calculation with air (the curves take a step up at the same frequencies). What is interesting, is the observation that the extra modes in the calculation with air inclusions are grouped together very closely in bunches of six. Based on this observation the actual modeshapes of such a group have been investigated. Figure 5 shows the second and third structural modes while Figure 6 shows the (air-related) modes in between the two. These modes (one for each cavity) differ slightly from each other in frequency due to the different positions of the air inclusions in the structure to which they are coupled.

Next, the eigenfrequencies in the case of no structural coupling between the two sides of the panel are considered. The curve (Figure 3) does not show the same groups of air related modes, which is rather unexpected as the air inclusions are identical to the other cases. This result may be explained by the fact that the coupling between the structure and the air becomes relatively stronger). Thus, movement of the air will be affected much more by the two structurally independent plates coupled to either side of the air cavities and vice versa. In order to verify this hypothesis, a fourth case have been considered, in which there is still no structural coupling between the plates, but furthermore the air is not coupled to the structural parts either. It is seen that the air related modes now appear in groups as expected.

4.2 Diffuse field excitation

A convergence study of the number of seeds needed in ABAQUS to adequately approximate a diffuse field has been done. The results show (see Figure 7) that for the given structure convergence seems to be fairly good when using 30 seeds for the approximation. Similar results are seen when examining the model including air inside the cavities.

4.3 Frequency response

The frequency response for the panel with air inclusions is compared to the panel without air inclusions in Figure 8. It is seen that the two configurations yield nearly identical results for the given frequency region. The peaks located at the first three structural modes of the panel are slightly lower in frequency when the air is included. This is due to the added mass of the air. Aside from this, only a very small difference is seen around 135 Hz where a group of air-related modes occurs. From an overall perspective the air inclusions do not show significant behavior in this frequency range.

When examining the response of the uncoupled case (see Figure 9), more peaks are seen as more modes are present. The overall acceleration level is quite similar to the coupled case. This does not quite match the expectations as the main transmission path is now broken. However, the calculations are for a constructed case where the enclosed volumes of air are still rather small having relatively (to the properties of air) rigid boundaries. Because of this, the air inclusions show a spring like behavior. At low frequencies the displacement is relatively large, meaning that the stiffness of the air enclosures becomes significant, resulting in the observed behavior.

5 CONCLUSION

Using a finite element approach, the effect of including an acoustic medium in the cavities of a double-plate single-stud lightweight wall/floor panel has been examined in the low frequency range. It is seen, that the air inclusions contribute to the mode count of the panel as they provide groups of modes related to the pressure field in the cavities. These modes, however, have very little effect on the frequency response when exciting the panel using an approximated diffuse sound field. The significance of the air-to-structure couplings depends strongly on the stiffness of the structure and it is expected, that the effect of the air-inclusions will be more pronounced for a limp structure. In the case of no structural coupling the sound transmission surely depends on the air-inclusions, as these constitute the only transmission path between the two plates.

Furthermore, it has been shown, that when shell elements are used rather than solid continuum elements for modeling the plates, the panel becomes slightly stiffer due to the reduced degrees of freedom. However, the same modes occur – only shifted slightly in frequency.

It has been demonstrated that for the model at hand a diffuse field approximation in ABAQUS converges and that using 30 seeds gives reasonably good results.

The present paper merely presents the introductory steps in a larger research project on sound transmission in lightweight building structures. Along the line of the model presented here, future work includes adding a sound field in the receiving room in order to predict the transmission loss, making a more efficient diffuse field excitation, investigate elastic couplings between plate/stud, investigating screw connections and other coupling properties. The greater goal being a better understanding of the different parameters affecting the sound transmission of such structures. This understanding is needed in order to develop a simplified prediction tool like [1] to be used with lightweight building structures.

Keywords: Lightweight panel structure, flanking noise, periodic stiffening, finite element method.

Abstract: *The present analysis focuses on flanking noise transmission within a two-wall structure of finite size. The walls are lightweight panel structures, each consisting of two plates with internal ribs. A finite-element model is utilized, assuming that the studs are fully fixed to the plates. Further, the air enclosed in the cavities within the structure is taken into consideration, whereas the external air has been disregarded. A fully coupled analysis is performed in which solid finite elements are adopted for the structure, whereas the acoustic medium within the panel is discretized into fluid continuum elements. The computations are carried out in frequency domain in the range below 500 Hz and the load acts as a concentrated force on one side of one of the panels. The responses of the same panel as well as the adjacent wall are studied.*

The position of the load relative to the stiffeners is important. Hence, analyses are carried out for different positions of the load. It has been found that the ribs have a significant impact, not only on the flanking noise but also on the direct radiation of sound from the wall on which the external force has been placed. Furthermore, the response changes when the air inside the wall panels is disregarded.

1 INTRODUCTION

Noise transmission within building structures is one of the main concerns in current time. For heavy structures, e.g. concrete buildings, statistical energy analysis (SEA) has been found to provide a reliable framework for prediction on noise transmission [1]. For example, Nightingale [5] found that a full wave SEA model of the junction produced useful results regarding the transmission of vibrational energy via flanking junctions from the point of excitation on a finite periodic rib-stiffened plates using SEA. However, SEA has limited validity for lightweight structures such as wooden floors with joists spanning in one direction or double-plate panel walls with vertical ribs [2, 12]. The periodic nature of the stiffening provides a nonhomogeneous modal density due to the formation of stop bands. Thus the vibrations are not diffuse and the number of modes in certain frequency bands may be limited. Hence, other methods of analysis must be employed.

As an alternative to SEA, the finite-element method (FEM) can be used [17] to describe flanking transmission in dwellings. Numerical simulations can reduce the cost of experiments and may also improve the design of sound insulation. However, modelling of lightweight structures is complicated, since such structures contain various materials and junctions as well as a relatively strong coupling to the acoustic medium compared to heavier structures such as concrete walls and decks. Furthermore, the FEM has limitations when it comes to the high-frequency range. Small elements must be employed in order to obtain an adequate discretization of the waves propagating in the structure and the acoustic medium. This results in a huge number of degrees of freedom, leading to long computation times.

Some research has been done in which sound transmission in the low-frequency range through lightweight structures has been predicted with numerical methods [6, 7, 14]. For example, Motoki [9] investigated sound radiation from a double-leaf structure under point force excitation, applying the load on a lightweight interior leaf connected to a massive exterior leaf. It was deduced that redesigning the interior leaf does not provide a significant reduction of the radiated sound power. In order to reduce the sound radiation, it is required to take damping mechanisms into account, e.g. acoustical damping.

Currently, there is also an increasing interest in periodic structures for better sound insulation. By a theoretical study, Takahashi [3] found that the spacing between ribs and the stiffness of the connector as well as the use of thick rigid materials all have a significant importance regarding the minimization of sound radiation from periodically connected infinite double-plate structures.

The current paper focuses on flanking noise transmission between two adjacent walls forming an L-shape with a rigid connection at the joint. The analyses concern the dynamic response to point-force excitation with the load applied at different positions on the source wall. The walls are identical, and with reference to the work by Hongisto [16] it is expected that flanking noise transmission can be very strong. Hence, a study is made of the energy transmission at various frequencies within the low-frequency range below 500 Hz. The findings of the paper indicate that the FEM can be applied to predict flanking noise in lightweight building structures with periodic stiffening.

Since flanking noise is the main consideration, the acoustic medium in the adjacent room is not modelled. However, the influence of including the air enclosed within the cavities inside the panel has been examined. The distribution of energy between the structure and the air has been analysed. The commercial code ABAQUS has been employed to model the double-plate panel structure using elements available in the ABAQUS/Standard library [19]. Material damping was introduced in the structure, whereas no damping was assumed in the air. For comparison, an analysis was performed in which the structural damping has been disregarded.

The aim of the paper is to get a better understanding of flanking-noise behaviour within two adjacent panels having couplings between the internal acoustic medium and the structure. Section 2 represents the model of the double-panel lightweight wall structures, whereas the results are discussed in Section 3 and concluding remarks are given in Section 4. Direct transmission of noise through a similar panel structure is analysed in a companion paper by Dickow, Domadiya, Andersen and Kirkegaard.

2 PROBLEM DESCRIPTION

Lightweight structures are usually constructed in panels with plates on stud or joist frames. To reduce the transmission of sound, frames are usually designed with single or double studs or constructed with layers of foam or another viscoelastic material. In the present case, single-stud double-plate panels have been considered. The structure consists of two identical panels forming an L-shape such that there is a direct structural coupling between the two panels. Furthermore, the plates are directly attached to the frame with no inclusion of elastic or viscoelastic layers. The aim of the study is to investigate the flanking noise transmission between the two walls under different circumstances. Thus, analyses are carried out with and without inclusion of the acoustic medium enclosed in the cavities within the panels. Further, different positions of a point force on one of the panels have been considered (see Figure 1), and the influence of structural damping is investigated.

Figure 1: Complete geometry of two-wall structure.

2.1 Geometry and materials

The structure consists of two panels which are identical in sense of materials and geometry. Each panel consists of two plates mounted on a frame structure with six acoustic cavities (see Figure 1). The stud dimensions are 50 mm by 60 mm and the plate thickness is 20 mm. The total wall dimensions are 3350 mm (width) by 2600 mm (height) by 100 mm (thickness). The

studs are placed with a distance of 550 mm (centre-to-centre). Homogeneous and isotropic materials are assumed. The material properties are:

- Timber (plates and frame): Young's modulus 14 GPa, Poisson ratio 0.35, mass density 550 kg/m³. Damping is set to 1% of the stiffness (frequency-independent structural damping).
- Air (acoustic cavities): Bulk modulus 141,360 Pa, mass density 1.2 kg/m³. No damping is introduced in the air inclusions.

It should be noted that the external air has not been included into the computational model, i.e. the acoustic medium surrounding the walls has been disregarded. Introduction of the surrounding air has an anticipated effect of reducing the Eigen frequencies of the structure due to the added-mass effect, and at the same time damping will occur due to radiation of sound.

2.2 Computational model

The panel is modelled in the commercial FEM package ABAQUS using solid continuum finite elements for the structure and fluid continuum elements for the air inclusions in the finite cavities. 20-node brick elements with quadratic spatial interpolation of the displacement (structure) and pressure (acoustic medium) are adopted with a mesh size of 50 mm. The mesh size has been chosen based on the wavelengths of waves propagating in the model at the higher frequency of interest—in this case 500 Hz.

The mesh is generated in such a way that nodes constituting the plate mesh align with the nodes on the frame structure. All structural contact points are connected using tie constraints in the x , y and z directions. Three-dimensional solid continuum elements have no rotational degrees of freedom, i.e. only displacements are considered. However, due to the local piecewise second-order interpolation of the displacements, the model adequately describes bending in the plates with a single element over the thickness direction.

The fluid–structure coupling is generated by using tie constraints within ABAQUS [19]. The two walls are connected by a column with cross-sectional dimensions of 100 mm by 100 mm and consisting of the same material as the remaining structure. Finally, the panels are fixed along the entire outer edge, i.e. at the top and bottom of the walls as well as the ends of the two adjacent panels.

2.3 Method of analysis

Two analyses have been performed on the present lightweight structure: 1) Modal analysis; 2) analysis of the steady state response to point excitation. In the modal analysis, the real Eigen frequencies were determined with and without air inclusions inside the panel structure. The Lanczos solver implemented in ABAQUS was applied in order to account for the structure–fluid coupling. In case of the steady state response to point excitation, direct steady state analysis was performed. Currently, mode-based analysis in ABAQUS does not support simultaneous modelling of fluid–structure coupling and structural damping. The steady state response analysis has been done under five different specifications of the model and load:

1. Transmission from wall 1 to wall 2 with air inclusions (load position 1),
2. Transmission from wall 1 to wall 2 without air inclusions (load position 1),
3. Transmission from wall 1 to wall 2 with air inclusions (load position 2),
4. Transmission from wall 1 to wall 2 with air inclusions (load position 3),
5. Energy deviation on receiving wall with and without damping (load position 1).

The three different load positions are considered in order to quantify the influence of the load position on the transmission to the adjacent wall, i.e. the flanking noise transmission. Material damping is introduced within the two panels, but as indicated by item 5 above, a comparison is made with an alternative model without structural damping. In addition to the total transmitted energy, the relative distribution of energy between the structure and the enclosed acoustic medium is also investigated at wall 2 for the three different loading positions.

3 RESULTS AND DISCUSSION

3.1 Eigen modes and Eigen frequencies

The undamped Eigen modes and corresponding Eigen frequencies of two panel structures with and without air inclusions were extracted using ABAQUS. Figure 2 shows the accumulated number of modes occurring below a given frequency in the interval 0 to 500 Hz. In the case with no internal air inclusions, only structural modes are present, and below approximately 420 Hz the modal density is low with the first mode occurring at approximately 95 Hz (see Figure 3). Beyond 420 Hz, the modal density increases significantly due to local modes of resonance in the plate fields between the studs.

When the air inclusions inside the panel are introduced into the computational model, Figure 2 shows that the number of modes increases dramatically. The first modes occur at about 67 Hz. However, these are not structural modes but modes related to resonance of the air in the cavities inside the panel. These “bubble modes” appear in bunches of 12 since there are 12 cavities in the structure. Due to the coupling between the structure and the acoustic medium, some spreading is present in the Eigen frequencies related to a bunch of “bubble modes”. However, since the coupling is weak in the present case at low frequencies, the frequencies are closely spaced as indicated by Figure 2 and the first two subfigures of Figure 4. With the inclusion of the air, the first structural mode in the panel structure is reduced from 95 Hz to about 80 Hz as an effect of the added mass (see Figure 2). A similar observation can be made for the subsequent structural modes up to about 340 Hz. At higher frequencies, there is a rapid increase in the number of modes, i.e. a higher modal density, within the panel. Further, a clear distinction between structural modes and “bubble modes” cannot be made, thus indicating a higher degree of structure–fluid coupling at higher frequencies.

Figure 2: Eigen frequencies within whole panel with and without air inclusions.

Figure 3: Structural modes at different frequencies in the model without air inclusions.

Figure 4: “Bubble modes” generated due to resonance in the air inclusions.

3.2 Steady state response to point excitation

The steady state response of the panel structure to point excitation on one of the walls (the *source wall*) has been analysed for three different positions of the load (see Figure 1). The focus of the analyses has been put on the *receiver wall* in order to study the flanking noise transmission. Furthermore, for load position 1 (at the centre of the source wall), the energy transferred to the receiver wall was determined with and without the air inclusions in the two panels, and computations were made with and without structural damping.

Figure 5: Kinetic energy per load cycle in whole model for the three different load positions.

Figure 5 shows a comparison of the kinetic energy per load cycle (absolute values) in the whole model for load positions 1, 2 and 3 and at 55 frequencies in the interval from 60 Hz to 500 Hz. It is noted that the models include the air inside the cavities as well as structural damping corresponding to 1% of the stiffness. At lower frequencies, peaks occur in the response near the structural Eigen frequencies. The point forces placed at load positions 1 and 2 provide nearly the same magnitude of response. With reference to Figures 1 and 3 this can be explained by the fact that the two loads act at positions leading to a similar strength of the excitation of the source panel within the first few structural modes of vibration. The analyses show that the peaks near 80 Hz and 200 Hz are slightly more pronounced for load position 1 compared to the two other load positions. This can be explained by the fact that a load applied to the centre of the source wall provides a stronger excitation of the first and third structural mode than a load applied near one of the ends of the panel. By contrast, the load applied at the centre of the source wall (i.e. at load position 1) acts near a node of the second mode, leading to a smaller response than observed for load positions 2 and 3.

For an excitation near 67 Hz it is expected that the load will induce strong vibrations in the “bubble modes”. This is not visible in Figure 5, which can be explained by the coarse frequency spacing combined with the fact that the “bubble modes” are weakly damped and almost uncoupled from the structural modes at lower frequencies. Hence, unless the “bubble modes” are excited very close to their resonance frequencies, they are not excited at all.

At higher frequencies, load positions 1 and 2 provide a significantly lower energy level than observed for load position 3—especially beyond 360 Hz. This can be explained by the longer distance from the load to the main part of the structure leading to a longer transmission path. Hence, the effect of structural damping is stronger. Moreover, the periodicity introduced by the ribs has an influence at the higher frequencies.

The kinetic energy transferred to the receiver wall with and without structural damping is presented in Figure 6 for load position 1. The structural behaviour with and without damping is almost identical in the low frequency range, but there is a reduction in the level of energy for frequencies beyond 260 Hz when damping is included, in particular near the resonance frequencies. If a higher frequency resolution is adopted, the peaks will go to infinity in the case without damping. At the higher frequencies, i.e. 400 to 500 Hz, the modal density is relatively higher than observed at lower frequencies. Hence, the influence of the structural damping is visible for all frequencies in the range.

Figure 6: Energy transferred to the receiving wall with and without structural damping for load position 1.

Another interesting observation can be made regarding the response at frequencies above 350 Hz, where the modal density becomes higher. Thus, the total amount of kinetic energy transferred to the receiving panel may be similar for a number of frequencies in this interval. However, the local distribution of the energy over the receiving panel can be very different. This is illustrated in Figure 8 which shows the distribution of the kinetic energy at three different frequencies for the panel without air and with the point force placed at load position 1. At the frequency 394 Hz the main part of the energy is concentrated in the half of the receiver wall that is closer to the joint with the source wall. However, as the frequency is gradually increased to 410 Hz, the energy is transferred to the other end of the receiver wall.

Figure 7: Response at three different frequencies for the panel without air and load position 1. The shades of grey indicate the magnitude of kinetic energy per unit volume (darker shades correspond to more energy).

Figure 8 shows the kinetic energy transferred to the receiver wall with and without air inclusions for load position 1. An increase of the energy due to the inclusion of the air within the cavities is seen at almost all frequencies. Finally, Figure 9 shows the relative distribution of energy between the air and the structure in the receiver wall for all three different load positions. It is observed that the structure generally carries the main part of the energy in all three cases. The energy contained in the air is 1–3 orders of magnitude smaller, which corresponds well to the fact that the mass of the air is less than 1% of the structural mass. However, a strong fluid–structure coupling is seen for load positions 1, 2 and 3, respectively, at the frequencies 200 Hz, 140 Hz and 340 Hz. Here, some of the “bubble modes” are excited.

Figure 8: Energy transferred to the receiving wall with and without air inclusions for load position 1.

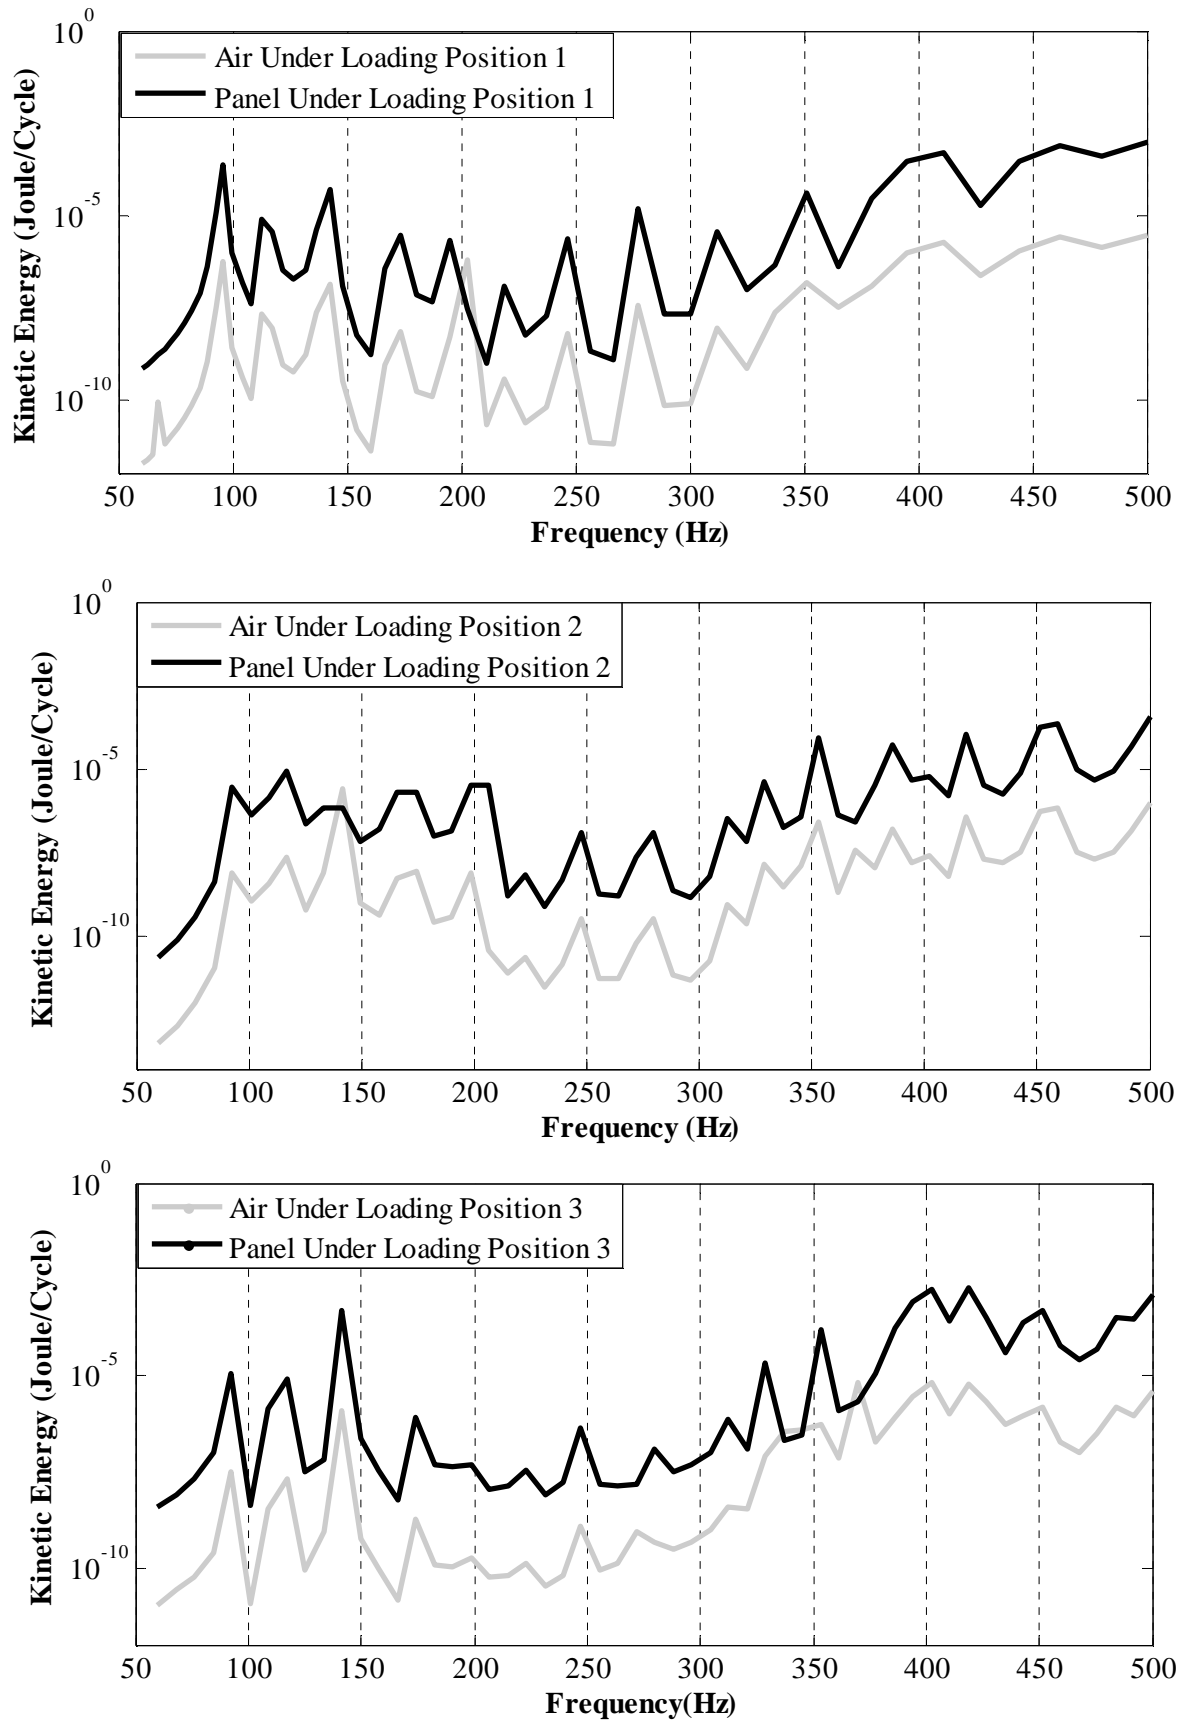

Figure 9: Distribution of energy between air and panel at receiver wall for three different load positions.

4 CONCLUDING REMARKS

Flanking transmission between two double-plate single-stud lightweight panels has been analysed under different conditions in the frequency range below 500 Hz. Slight differences have been observed in the Eigen frequencies depending on whether the air inside the cavities within the panels has been included or not. For example, the first structural mode with and without air inclusions occurs at 80 Hz and 95 Hz, respectively. The kinetic energy per load cycle within the whole structure was extracted for three different positions of a point force acting on one of the panels. It was observed that the energy level is highly influenced by the load position, especially at higher frequencies. Material damping as well as periodic stiffening may contribute to a decrease of the transmission when the load is applied on the source panel at a greater distance away from the receiver panel.

It is also seen that the energy present in the receiver wall is slightly increased when air is included within the panel structure. The structure still carries the main part of the energy and in most situations the coupling between the structure and the fluid is weak. Due to resonance of the air inside the cavities, “bubble modes” exist, but due to the weak coupling with the structure at lower frequencies, excitation of these modes will not lead to a significant excitation of the structure and vice versa. However, for certain combinations of the load position and the excitation frequency, a significant part of the energy is transferred to the air inside the receiver panel. At frequencies beyond 350 Hz the modal density becomes much higher than observed at lower frequencies and the structural and acoustic modes become mixed, indicating a stronger fluid–structure coupling with increasing frequency.

The present paper is a result of preliminary research in a larger research project on mitigation of flanking transmission in lightweight building structures. Future work involves a closer investigation of the influence of periodicity in the stiffening of lightweight structures. Further, the energy dissipation at junctions will be examined, and a sound field will be introduced in the adjacent room in order to predict the flanking noise behaviour of the structure. Comparisons will be made between panels with unidirectional ribs and with two sets of orthogonal stiffeners. The aim is to predict flanking noise behaviour via joints or as direct transmission between adjacent rooms.

Keywords: Bending Wave, Dispersion Relation, Finite Products, Beam, Timoshenko Theory.

Abstract. *This paper shows that conventional Timoshenko theory for bending waves is a member of a two-parameter family $(m; n)$ of approximations to the exact equations of linear elasticity. Higher members of the family are shown to represent the exact dispersion relation with extraordinary accuracy; in particular, an arbitrary number of branches can be captured accurately over their entire length, i.e. up to arbitrarily high frequencies and wavenumbers. The theory admits a rational accuracy analysis, and resolves certain controversies about the validity of higher-branch approximations. The paper demonstrates conclusively that Timoshenko theory is a completely rational theory, thus ending decades of doubt on the matter. The standard Euler-Bernoulli theory is a lower member of the two-parameter family. Especially useful is Timoshenko $(1; 2)$ theory, which extends conventional Timoshenko $(0; 1)$ theory by capturing the first four branches of the exact dispersion relation rather than merely the first two.*

1 INTRODUCTION

In the hierarchy of bending-wave theories for plates and beams, the first and simplest theory is Euler-Bernoulli theory, valid at the lowest frequencies and wave numbers; next comes Timoshenko theory, with or without various correction factors, valid to higher frequencies and wavenumbers; and finally comes exact linear theory, based on the full equations of linear elasticity, valid to any frequency and wavenumber for which linear theory still holds. The aim of this paper is to fill the very large gap between these last two theories, but use only polynomials. The gap is worth filling, because the dispersion relations obtained from exact linear theory are transcendental (when they can be obtained analytically at all), i.e. do not have the simple polynomial form of the earlier two theories, and engineers concerned with bending waves have overwhelmingly preferred the simplicity of polynomial theories

We shall fill the gap by means of a hierarchy of Timoshenko-type theories, in which the simplicity and accuracy of Timoshenko-type polynomial dispersion relations are maintained at very high frequencies and wavenumbers. At first sight, the quest for such dispersion relations would appear to be a hopeless undertaking. One reason is that the conventional Timoshenko dispersion relation is invariably derived from a kinematic hypothesis about the shape of frequencies. Another reason is that any truncated Taylor-series expansion of an exact dispersion relation must likewise fail at higher frequencies, because of the known finite radius of convergence of such an expansion. Thus strategies based on more elaborate kinematic hypotheses, or on ever-longer Taylor-series truncations, can at best succeed in a limited range of frequency and wavenumber.

The fundamental idea of this paper is to separate completely the derivation of a Timoshenko-type dispersion relation from any dependence on a kinematic hypothesis or a Taylor-series approximation. Instead, we use two families of finite-product polynomials, namely ‘sine-based’ polynomials S_m of degree m , and ‘cosine-based’ polynomials C_n of degree n . These polynomials are products of factors corresponding to a specified finite number of roots of a sine or cosine function. The roots correspond to the cut-on frequencies of different types of modes. The result is a two-parameter family (m, n) of polynomial approximations to the exact dispersion relation, of which the member $(m, n) = (0, 1)$ is a conventional Timoshenko approximation.

If an analytical expression is available for the exact dispersion relation, the method is trivial to implement: for any (m, n) , the corresponding finite-product approximation may be written down; and numerical computation of all of its roots, real or complex, is instantaneous on any computer, because of the universal availability and reliability of software for calculating the roots of polynomials. If, instead of an analytical expression, a numerical code is available for calculating the dispersion relation, the method may be implemented by first computing the cut-on frequencies of the low-order modes; these frequencies are then used to determine the appropriate finite-product polynomials.

In this paper, we implement the method in complete detail for the canonical problem of the subject, namely bending waves in a planar elastic layer, for which exact linear theory leads to the Rayleigh-Lamb dispersion relation. The numerical accuracy of the approximations obtained can be displayed explicitly in plots comparing the exact and approximate dispersion relations. It reveals the almost incredible accuracy of the above polynomials in representing the exact dispersion relation for small values of (m, n) . Particularly accurate approximations are obtained when $n = m+1$. Hence a sequence of approximations is obtained which may be referred to as the Timoshenko $(0, 1)$ dispersion relation, the Timoshenko $(1, 2)$ dispersion relation, etc. This family of approximations approaches the exact Rayleigh-Lamb dispersion relation arbitrarily closely at arbitrarily high frequencies and wave numbers. The structure of these approximations, together with a detailed account of their numerical accuracy, is fully presented. The fact that such approximations can exist at all is far from obvious, but was demonstrated by Chapman & Sorokin [1]. Especially useful is the Timoshenko $(1, 2)$ disper-

sion relation, which offers a massive extension of the range of validity of conventional Timoshenko (0, 1) dispersion relation, and provides ample accuracy for practically all anti-symmetric plate waves and vibrations of engineering interest.

2 TERMINOLOGY

We use the term Timoshenko-type theory for any theory or approach which leads to a polynomial dispersion relation of a certain type (specified explicitly) which generalises the conventional Timoshenko dispersion relation to a higher order polynomial. It must be emphasized that the type of theory refers only to how the dispersion relation is derived from physical principles and approximations, not to the final form of the dispersion relation itself. In every case, the dispersion relation is of the same form, namely a member of a specific two-parameter family of dispersion relations labelled by the parameters (m, n) . This codified scheme brings unity to what would otherwise be a ‘zoo’ of approximate methods. Two main aspects of the paper are, first, the demonstration that established approximations fit within the scheme, and second, that, when applied to slightly higher (m, n) than hitherto, the scheme gives new approximations displaying an extraordinary increase in accuracy and scope at almost no cost. Our use of the terms Timoshenko theory and Timoshenko dispersion relation is an extension of their familiar use, but is entirely logical in describing the results obtained in the paper.

One might wonder why such a simple method as ours has not been exploited already. The answer lies in Runge’s phenomenon, namely the fact that the polynomials S_m and C_n do not represent the underlying sine and cosines accurately on account of the high-amplitude oscillations which the polynomials display away from the centre of their range. Such oscillations are known to anyone who has tried polynomial interpolation with an equally spaced set of grid points. The crucial fact underlying this paper is that, in a homogeneous linear combination of products of sines and cosines, Runge’s phenomenon cancels out almost exactly if an appropriate choice is made of the number of factors in the sine-based and cosine-based polynomials. With such a choice, inaccuracy in the individual representations of the sines and cosines does not lead to inaccuracy in the resulting approximation to the dispersion relation. In this context the term homogeneous means that in every term of the exact dispersion relation the number of sines or cosines multiplied together is the same; for the Rayleigh-Lamb dispersion relation, this number is two.

The cancelling out of Runge’s phenomenon answers a long-standing objection to Timoshenko theory from devotees of ‘rational mechanics’. It has repeatedly been claimed that Timoshenko theory is ‘just an engineering approximation’, and in particular that the excellent performance of the Timoshenko dispersion relation in capturing the first thickness-shear branch near cut-on is spurious. Indeed, it has been stated that Timoshenko theory is a ‘low-frequency theory trying to be a high-frequency theory’. The key point, emphasized in this paper, is that the Timoshenko dispersion relation can be derived by a method independent of a kinematic hypothesis or a Taylor-series truncation. This method shows that the Timoshenko dispersion relation is an early member of a sequence of approximations which, because of the cancelling-out of Runge’s phenomenon, approaches the exact dispersion relation at high frequencies and wavenumbers with extraordinary rapidity. Accordingly, Timoshenko theory is completely rational. A mathematically rigorous justification of the above assertions is given in [1] for waves in a planar layer.

3 FINITE-PRODUCT TIMOSHENKO THEORY

The key idea in finite-product Timoshenko theory for a planar layer is to start with the exact dispersion relation of Rayleigh-Lamb theory, and immediately replace the sine and cosine terms by finite-product polynomials, chosen to have the same roots as the original sines and cosines in a

finite region. After this step has been taken, all calculations are performed with polynomials, and the original transcendental dispersion relation is not used again, unless accuracy analysis is required. The lengths of the finite regions are at the choice of the investigator: the longer the regions, the higher is the polynomial order of the finite-product dispersion relation, and the greater is its region of accuracy in the frequency-wavenumber plane. This region of accuracy increases rapidly with polynomial order, and may be made arbitrarily large. In this sense, finite-product Timoshenko theory fills completely the gap between conventional Timoshenko theory and Rayleigh-Lamb theory, referred to in the Introduction.

The exact Rayleigh-Lamb dispersion relation for this problem is (see [2]):

$$L_3^4 S_1 C_2 + K^2 L_2^2 C_1 S_2 = 0. \quad (1)$$

Here $S_i \equiv S(L_i^2/4)$, $C_i \equiv C(L_i^2/4)$, $L_i^2 = \Omega_i^2 - K^2$, $i = 1, 2$ and $L_3^2 = \frac{1}{2}\Omega_2^2 - K^2$. Furthermore,

$$(K, \Omega_1, \Omega_2) = \left(kh, \frac{\omega h}{c_1}, \frac{\omega h}{c_2} \right) \text{ with conventional notations for velocities of P- and S-waves.}$$

The functions S and C are defined by $S(s^2) = s^{-1} \sin(s)$ and $C(s^2) = \cos(s)$. The use of S and C , rather than sine and cosine, helps avoid square roots in equations, where the square roots ultimately cancel out in pairs, and so maintains polynomial form. We define the finite products as follows:

$$S_{mi} = \prod_{m'=1}^m \left(1 - \frac{L_i^2}{4(m'\pi)^2} \right), \quad C_{ni} = \prod_{n'=1}^n \left(1 - \frac{L_i^2}{(2n'-1)^2 \pi^2} \right), \quad i = 1, 2 \quad (2)$$

If $m = 0$ or $n = 0$, the value of the corresponding finite product is defined as 1. Then the equation (1) is approximated by:

$$L_3^4 S_{m1} C_{n2} + K^2 L_2^2 C_{n1} S_{m2} = 0 \quad (3)$$

Although equation (3) is of simple form, it is divisible by $L_1^2 - L_2^2$. We introduce

$$I_{mn} = 4 \frac{S_{m1} C_{n2} - C_{n1} S_{m2}}{L_1^2 - L_2^2} \quad (4)$$

Then equation (3) becomes $(\Omega_B = \frac{\omega h}{c_B}, c_B^2 = \frac{c_2^2(c_1^2 - c_2^2)}{3c_1^2})$

$$-\frac{1}{3} \Omega_B^2 S_{m1} C_{n2} = K^2 L_2^2 I_{mn} \quad (5)$$

Equations (3) and (5) give the cut-on frequencies of the first m thickness-stretch modes and the first n thickness-shear modes. The reason is that these equations are satisfied if $K = 0$ and either $S_{m1} = 0$ or $C_{n2} = 0$. This is the motivation for using the finite-product method, since the exact Rayleigh-Lamb dispersion relation (1) is satisfied if $K = 0$ and either $S(L_1^2/4) = 0$ or $C(L_2^2/4) = 0$. The finite-product approximations (3) and (5) agree with the exact dispersion relation on a grid of points in the (K, Ω) plane, for which the above cut-on points form the boundary; details of the grid are given in [1].

The simplest way to introduce correction factors is to replace the term L_2^2 on the right-hand side of equation (5) by the quantity $L_{2\gamma\delta}^2$ defined by $L_2^2 = \gamma\Omega_2^2 - \delta K^2$:

$$-\frac{1}{3}\Omega_B^2 S_{m1} C_{n2} = K^2 L_{2\gamma\delta}^2 I_{mn} \quad (6)$$

At this stage, the values of γ and δ are arbitrary. The replacement of L_2^2 by $L_{2\gamma\delta}^2$ is not made in any other term, thus C_{n2} and I_{mn} contain L_2^2 not $L_{2\gamma\delta}^2$. Hence, the grid is preserved.

4 TIMOSHENKO (0,1) THEORY

The finite product theory, presented above for arbitrary m and n , will now be analyzed in detail for $(m,n) = (0,1)$. In this case, the reduced equation (6) becomes:

$$\Omega_B^2 = \frac{1}{\pi^2} \Omega_B^2 \Omega_2^2 - \frac{1}{\pi^2} \left(12\gamma + \frac{c_2^2}{c_B^2} \right) \Omega_2^2 K^2 + \frac{12\delta}{\pi^2} K^4 \quad (7)$$

For equation (7), to recover the Bernoulli-Euler limit $\Omega_B^2 = K^4$, we must take $\delta = \frac{\pi^2}{12}$.

Further analysis shows that γ is a re-parametrization of the standard stiffness correction factor κ via the relation

$$\gamma = \frac{\pi^2}{12\kappa} - \frac{c_2^2}{12c_B^2} (1 - \kappa) \quad (8)$$

For the conventional Timoshenko dispersion relation with $\kappa = \frac{\pi^2}{12}$, this formula gives

$$\gamma = 1 - \frac{c_2^2}{12c_B^2} \left(1 - \frac{\pi^2}{12} \right) \quad (9)$$

In all these formulas, $\frac{c_2^2}{3c_B^2} = \frac{c_1^2}{c_1^2 - c_2^2}$ for both plane strain and plane stress.

5 TIMOSHENKO (1,2) THEORY

Then $(m,n) = (1,2)$, the definitions give: $S_{mi} = 1 - \frac{L_i^2}{4\pi^2}$, $C_{mi} = \left(1 - \frac{L_i^2}{\pi^2} \right) \left(1 - \frac{L_i^2}{9\pi^2} \right)$, $i = 1, 2$.

Hence $I_{mn} = \frac{31}{9\pi^2} \left[1 - \frac{4}{31\pi^2} (L_1^2 + L_2^2) + \frac{4}{31\pi^2} L_1^2 L_2^2 \right]$. In the reduced equation (7), we must take $\delta = \frac{3\pi^2}{31}$ to recover the Bernoulli-Euler limit $\Omega_B^2 = K^4$. Then the reduced equation becomes

$$\Omega_B^2 \left(1 - \frac{L_1^2}{4\pi^2} \right) \left(1 - \frac{L_2^2}{\pi^2} \right) \left(1 - \frac{L_2^2}{9\pi^2} \right) = -K^2 \left(\frac{31\gamma}{\pi^2} \Omega_2^2 - K^2 \right) \left[1 - \frac{4}{31\pi^2} (L_1^2 + L_2^2) + \frac{4}{31\pi^2} L_1^2 L_2^2 \right] \quad (10)$$

This simple equation has a truly extraordinary range of numerical accuracy.

6 TIMOSHENKO (M, N) THEORY

We have seen that for the finite-product equation (7) or (10) to recover the Bernoulli-Euler limit $\Omega_B^2 = K^4$, the correction factor $\delta = \frac{3\pi^2}{31}$ must take value $\frac{\pi^2}{12}$ when $(m, n) = (0, 1)$ and the value $\frac{3\pi^2}{31}$ when $(m, n) = (1, 2)$. These are examples of the general result that, for arbitrary (m, n) , the value of the correction factor is $\delta = \frac{1}{3(c_{n1} - s_{m1})}$, where $s_{m1} = \frac{1}{\pi^2} \sum_{m'=1}^m \frac{1}{m'^2}$ and $c_{n1} = \frac{4}{\pi^2} \sum_{n'=1}^n \frac{1}{(2n'-1)^2}$. Thus δ is always a rational multiple of π^2 . For example, the next value in the sequence above is $\delta = \frac{300\pi^2}{3019}$ for $(m, n) = (2, 3)$. Since $s_{m1} \rightarrow \frac{1}{6}$ as $m \rightarrow \infty$, and $c_{n1} \rightarrow \frac{1}{2}$ as $n \rightarrow \infty$, it follows that $\delta \rightarrow 1$ as m and n increase. The above results are consequences of series expansions

$$S_m = \prod_{m'=1}^m \left(1 - \frac{s}{(m'\pi)^2} \right) = 1 - s_{m1}s + s_{m2}s^2 - s_{m3}s^3 + \dots \quad (11)$$

$$C_{ni} = \prod_{n'=1}^n \left(1 - \frac{4c}{(2n'-1)^2\pi^2} \right) = 1 - c_{n1}c + c_{n2}c^2 - c_{n3}c^3 + \dots \quad (12)$$

$$I_{mn} = c_{n1} - s_{m1} - (c_{n2} - s_{m2})(s + c) + (c_{n3} - s_{m3})(s^2 + cs + c^2) + (s_{m1}c_{n2} - s_{m2}c_{n1})sc + \dots \quad (13)$$

Expansion of the products in equations (11-12) gives $s_{m1} = \frac{1}{\pi^2} \sum_{m'=1}^m \frac{1}{m'^2}$ and $c_{n1} = \frac{4}{\pi^2} \sum_{n'=1}^n \frac{1}{(2n'-1)^2}$ (see above). Then substitution of equations (11-13), with appropriate arguments, into the finite-product equation (6) determines the correction factor as $\delta = \frac{1}{3(c_{n1} - s_{m1})}$.

7 BOUNDARY CONDITIONS

We have considered the planar elastic layer as a waveguide, i.e. as having indefinite length. For more general problems, boundary conditions at the ends must be included. The question then arises of solving a complete boundary-value problem if the Timoshenko (m, n) dispersion relation is to be used. Within the approach of this paper, this would be tackled by first formulating the problem with the exact equations of linear elasticity (either directly or using Hamilton's principle with the exact Lagrangian), and then using the Timoshenko (m, n) field structure to reduce the problem to finite-dimensional modal form. This is an important direction for further work.

8 CONCLUSIONS

The method just described provides an incentive to re-examine certain classical problems for which analytical dispersion relations have been derived, but for which reasonable polynomial approximations have not been found. For example, the exact dispersion relation for elastic waves in a cylindrical shell contains many combinations of Bessel functions, quite beyond the range of analysis ‘by hand’. Yet the finite-product method can be applied, yielding a family of polynomial approximations readily obtained with a symbolic mathematical software package. A theoretical task would be to relate the families of approximations arising in such problems to the wave-hierarchy theories of Whitham [3].

ON THE POTENTIAL OF LOCAL RESONATORS TO OBTAIN LOW-FREQUENCY BAND GAPS IN PERIODIC LIGHTWEIGHT STRUCTURES

Keywords: local resonators, band gap, vibro-acoustic insulation, lightweight structures

Abstract. *Periodic structures, such as honeycomb core panels, combine excellent mechanical properties with a low mass, making them attractive for application in transport and machine design. However, the high stiffness to mass ratio of these lightweight panels may result in unsatisfactory dynamic behavior in that it may impair the panels' ability to reduce noise and vibration levels. Their noise and vibration properties can be improved by the application of band gaps, i.e. zones with no free wave propagation. As indicated by Brillouin, periodic structures can exhibit band gap behavior, which in the case of sandwich panels could lead to frequency zones of reduced sound radiation or improved sound transmission loss. Band gaps are commonly the result of interference of traveling waves on the unit cell level, which implies that the lower limit of band gap zones is set by the length scale of the unit cell. However, band gaps can also be obtained by the addition of local resonators. These local resonance band gaps can be freely tuned in a low-frequency zone, independent of the unit cell scale length, making them an appealing engineering tool to improve the dynamic behavior of periodic lightweight structures. By means of numerical models the potential of local resonance band gaps for lightweight periodic panels is shown and compared with interference based band gaps.*

1 INTRODUCTION

For the improvement of vibro-acoustic attenuation a variety of methods exists. Conventional methods rely on the acoustic mass law or the addition of an absorptive layer. The first method results in heavy materials. The second method leads to thick materials, since to be efficient, the thickness of the absorptive layer should be in the same order of magnitude as the acoustic wave length. Often both methods are unsatisfactory to improve the low-frequency vibro-acoustic response of lightweight applications.

The noise and vibration properties of periodic structures can be improved by the application of band gaps, i.e. zones with no free wave propagation. As indicated by Brillouin [1], periodic structures can exhibit such band gap behavior. These gaps result in frequency zones of attenuated structural response. The question arises whether the band gap behavior can be exploited to produce sandwich panels with reduced sound radiation or improved sound transmission loss.

The understanding of periodicity in material crystals and the resulting energy band gaps has led to a high number of applications in solid state physics, such as ‘photonic crystals’. Recently quite some research has been performed to transfer these concepts to elastodynamics. Often these band gaps are obtained by incorporating a periodic distribution of wave scatters distributed in a matrix material. These ‘phononic crystals’ show attenuation of elastic waves in certain frequency bands, although often outside the audible frequency range. Recently, band gaps are actively pursued in order to obtain better structural dynamic behavior in periodic engineering systems such as truss core structures, stiffened plates and cylindrical shells [2, 3, 4].

In solid state physics, there are two theoretical approaches to the understanding of band gaps [5]. The first approach is based on Bragg scattering: zones with destructive interference between reflected and transmitted waves and hence high reflection and low transmission [6]. A second approach utilizes the tight-binding approach, starting from individual atoms/molecules, consisting of well-defined discrete electronic states. Where the first approach is dependent on the wavelength and relies strongly on periodicity, the second approach has as key element the discrete electronic states in individual atoms/molecules and the existence of local modes or local resonances.

The main physical principle behind the band gaps in aforementioned applications is the interference of traveling waves on the unit cell level. This implies that the frequency zone of the band gap is linked to the length scale of the unit cell which is a major drawback to obtain low frequency band gaps. Examples of applications based on the second approach are more scarce, although this method is equally well applicable to elastodynamics problems. In recent literature, examples of this second approach show a huge potential for vibro-acoustic problems [7, 8]. The decoupling of band gap frequency and unit cell length scale opens up the possibility of low frequency vibro-acoustic attenuation, beating the mass law.

This paper compares both methods of band gap creation with respect to vibro-acoustic attenuation. Mainly two characteristics are investigated: strength of vibro-acoustic attenuation and ease of manipulation of the band gap frequencies. Since band gaps show up as zones with no free wave propagation in infinite structures, only infinite structures are investigated. The first section elaborates on the modeling techniques used. The second section provides a one

dimensional example to illustrates the difference in attenuation factors. In a third section, a two dimensional example is used to compare band gap frequencies.

2 MODEL OF PERIODIC STRUCTURES

2.1 Bloch's theorem

Figure 1: Schematic presentation of an infinite periodic structure (left). The shaded rectangle (right) represents a unit cell of the structure. Each point p in the structure can be expressed with respect to a corresponding point u in the unit cell.

Figure 1 represents a schematic view of a two-dimensional periodic structure. The structure is built as a repetition of the unit cell in two directions (\mathbf{d}_1 and \mathbf{d}_2), with \mathbf{d}_1 and \mathbf{d}_2 basis-vectors of the unit cell with length L_1 and L_2 , respectively. Since the structure is periodic, each point p in the structure can be expressed with respect to a corresponding point u in the unit cell, translated n_1 cells along \mathbf{d}_1 and n_2 times along \mathbf{d}_2 (Fig. 1):

$$\mathbf{r}_p = \mathbf{r}_u + n_1 \mathbf{d}_1 + n_2 \mathbf{d}_2 \quad (1)$$

The theorem of Bloch (eq. 4) states that the response of a two-dimensional periodic system can be expressed in terms of the response of a reference unit cell, and an exponential term defining amplitude and phase change as the wave propagates from one cell to the next [1, 9]. The proportionate change in wave amplitude occurring when transitioning from one cell to the next, is independent of the cell location within the periodic system.

$$u(\mathbf{r}_p, \omega) = u_{ref}[\mathbf{r}_u, \omega] \cdot e^{\mathbf{k} \cdot (n_1 \mathbf{d}_1 + n_2 \mathbf{d}_2)} \quad (2)$$

The amplitude and phase change is determined by the wave vector \mathbf{k} , which is a general term expressing the amplitude decay and phase change of a wave per meter. In practice the wave vectors are expressed in terms of the length of the unit cell:

$$\boldsymbol{\mu} = \mathbf{k} \cdot \mathbf{d} \quad (3)$$

The propagation vector $\boldsymbol{\mu}$ (eq. 3) expresses the complex phase shift when moving across a cell in the \mathbf{d}_1 \mathbf{d}_2 -direction. With this notation the Bloch theorem is rewritten as:

$$u(\mathbf{r}_p, \omega) = u_{ref}[\mathbf{r}_u, \omega] \cdot e^{\boldsymbol{\mu} \cdot \mathbf{n}} \quad (4)$$

Where \mathbf{n} is a vector indicating the amount of cells moved in the \mathbf{d}_1 - and \mathbf{d}_2 -direction with respect to the unit cell.

2.2 Modelling the unit cell

Since the response of the entire structure is characterized by the response of the unit cell, a model of the unit cell suffices to investigate the wave propagation in the entire structure.

The finite element approach is chosen to model the unit cell [10, 11]. The equation of motion for harmonic motion is written in the usual matrix form:

$$(\mathbf{K} - \omega^2 \mathbf{M})\mathbf{q} = \mathbf{f} \quad (5)$$

with \mathbf{K} the stiffness matrix, \mathbf{M} the mass matrix, \mathbf{q} the generalized displacements, \mathbf{f} the generalized forces and ω the angular frequency.

The equation of motion (Eq. 5) can be reduced by taking the boundary condition of the unit cell into account. The Bloch theorem states that the displacements and the forces are scaled with a factor e^{μ_1} and e^{μ_2} when moving from one cell to the next in the \mathbf{d}_1 - resp. \mathbf{d}_2 -direction. Demanding compatible displacements and force balance at the boundaries of the unit cell, a reduction matrix \mathbf{R} in terms of the wave vector $\boldsymbol{\mu}$ can be derived [12].

$$\begin{aligned} (\mathbf{K} - \omega^2 \mathbf{M})\mathbf{q} &= \mathbf{f} \\ \mathbf{R}^{*T}(\mathbf{K} - \omega^2 \mathbf{M})\mathbf{R}\mathbf{q}^{(red)} &= \mathbf{R}^{*T}\mathbf{f} \end{aligned} \quad (6)$$

Under the assumption of no internal forces, the reduced force vector ($\mathbf{R}^{*T}\mathbf{f}$) equals the zero vector and the equation of motion (eq. 5) reduces to an eigenvalue problem (eq. 7) in terms of the reduced stiffness and mass matrices $\mathbf{K}^{(red)} = \mathbf{R}^{*T}\mathbf{K}\mathbf{R}$ and $\mathbf{M}^{(red)} = \mathbf{R}^{*T}\mathbf{M}\mathbf{R}$.

$$(\mathbf{K}^{(red)} - \omega^2 \mathbf{M}^{(red)})\mathbf{q}^{(red)} = \mathbf{0} \quad (7)$$

In this paper two approaches are used to solve this eigenvalue problem.

Direct approach In one-dimensional problems only propagation in one direction exists: the propagation vector $\boldsymbol{\mu}$ reduces to a complex scalar μ . For each frequency the eigenvalue problem can be rewritten in a polynomial form in terms of e^μ which can be solved for [13]. Stop bands are frequency zones where free wave propagation is inhibited and thus the propagation constant has a real part. Inspection of the propagation constant results therefore in the identification of stop bands.

Inverse approach Assuming free wave propagation, the propagation vector is strictly imaginary $\boldsymbol{\mu} = i\epsilon$. Solving Eq. 7 for the frequency ω as a function of imaginary propagation vector ϵ , the frequencies of free wave propagation are found. In the case of imaginary propagation constants, the matrix $(\mathbf{K}^{(red)} - \omega^2 \mathbf{M}^{(red)})$ is Hermitian and the solutions for ω are always real [12].

Considering the advantage of obtaining complex propagation constants, the first method will be applied to gain insight in the difference in attenuation factors between interference based and local resonance based band gaps. The second method will be used to investigate the manipulation of band gap frequencies for structures with two-dimensional periodicity.

2.3 Irreducible Brillouin contour

To obtain the pass and stop bands with the inverse approach, eq. 7 needs to be solved for every possible combination of purely imaginary propagation constants $\mu_1 = i\epsilon_1$ and $\mu_2 = i\epsilon_2$. The solved frequencies make up a surface in the wave domain (ϵ_1, ϵ_2) , the so called dispersion surface $\omega = f(\epsilon_1, \epsilon_2)$. This dispersion surface yields the frequencies for which wave propagation without attenuation is possible. The frequencies which are not a solution of the eigenvalue problem, are frequencies where only attenuated wave propagation is possible and thus these frequencies belong to stop bands.

Since the analyzed structure is periodic, also the dispersion surface will be periodic and hence not the entire wave domain must be investigated. A periodic zone in the wave domain is called a Brillouin zone, and only the first Brillouin zone needs to be examined [1, 6]. Exploiting the symmetry of the unit cell, the first Brillouin zone can be further reduced to an irreducible Brillouin zone which is the smallest zone in the wave space that comprehends all information [2, 14].

A further reduction in computational cost can be achieved by limiting the variation of the wave vector along the contour of the irreducible Brillouin zone. The maxima and minima of each dispersion surface can be found on this boundary. The resulting dispersion curves contain sufficient information for the calculation of band gaps. Although this procedure is widely accepted in literature, according to the authors, no rigorous proof of this is available, but also no counterexamples can be found.

In this paper, the unit cell will be limited to a symmetric rectangular unit cell. As a result in the (ϵ_1, ϵ_2) domain only the contour with corner points $(0, 0)$, $(0, \pi)$, (π, π) , $(0, 0)$ needs to be investigated [2].

3 ATTENUATION FACTOR

To drastically improve the vibro-acoustic behavior, a strong vibro-acoustic attenuation is required. The propagation vector μ is a measure of vibro-acoustic attenuation: a larger real part, yields stronger attenuation. To compare attenuation factors for both interference and local resonance band gaps, the direct approach of solving eq. 5 is followed.

An infinite Euler-Bernoulli beam serves as a test case: this example is easy to grasp while computationally non demanding. Periodicity is introduced by the addition of a point mass or a spring-mass system. Table 1 summarizes the material characteristics and cross section dimensions of the infinite beam.

Name	Symbol	Value
Young's modulus	E	210 GPa
Density	ρ	$7800 \frac{kg}{m^3}$
Poisson's ratio	ν	0.3
Cross sectional area	A	$1 * 10^{-4} m^2$
Second moment of inertia (bending)	I	$8.33 * 10^{-10} m^4$

Table 1: Material characteristics and dimensions of the infinite beam used in the examples.

3.1 Interference band gap

Interference results from the combination of reflected and transmitted waves. A point mass without rotational inertia is added repeatedly every distance L to the infinite beam to introduce scatterers for reflection. Figure 2 shows the unit cell of the infinite beam. The added mass is 20% of the mass of the unit cell.

Figure 2: Unit cell of an infinite Euler-Bernoulli beam with a periodic point mass.

Since the band gap is due to interference, the frequency of the band gap is linked to standing wave behavior. The first standing waves will occur for a frequency where the unit cell length (L) equals half a structural wavelength. This condition is mathematically equivalent to claiming that the phase shift across the unit cell ϵ equals π . For an infinite Euler-Bernoulli beam, this frequency for bending equals to:

$$f_{\frac{\lambda}{2}} = \frac{\pi}{2L^2} \sqrt{\frac{EI}{\rho A}}. \quad (8)$$

This frequency $f_{\frac{\lambda}{2}}$ is used to make the frequency in the results dimensionless and independent of the periodicity length.

Figure 3: Dispersion curves for an infinite Euler-Bernoulli beam with a periodic point mass. The frequency zone without strictly imaginary wave propagation constant μ indicates a band gap.

Figure 3 shows the calculated propagation constants for a frequency range 0 to $1.5f_{\frac{\lambda}{2}}$. The solutions for both the right and left running waves are shown. Two different wave types are found. The first wave type (dashed lines) has a purely real wavenumber, expressing a damped exponential decay. The second wave type (full and dash-dotted line) starts as a free propagating

wave with increasing phase shift for increasing frequency. This trend stops as the phase shift ϵ across the unit cell becomes π (dimensionless frequency 0.85). Between dimensionless frequency 0.85 and 1 the imaginary part of the propagation constant μ remains constant and the real part differs from zero. In this frequency zone, no free wave propagation is possible and a band gap is found. For higher frequencies the wave transitions again to a free propagating wave.

3.2 Local resonance band gap

The existence of a local resonance in the unit cell can also lead to a band gap. A periodic repetition of a spring-mass system is added to the infinite Euler Bernoulli beam to simulate this behavior. Figure 4 shows the unit cell. The added mass is 20% of the mass of the unit cell, the stiffness is chosen such that the resonance of the spring-mass system equals $0.5f_{\frac{\lambda}{2}}$.

Figure 4: Unit cell of an infinite Euler-Bernoulli beam with a spring-mass periodically attached.

Figure 5: Dispersion curves for an infinite Euler-Bernoulli beam with a periodic spring-mass system. The resonance frequency of the spring-mass system is $0.5f_{\frac{\lambda}{2}}$. The frequency zone without strictly imaginary wave propagation constant μ indicates a band gap.

The propagation constants for a frequency range 0 to $1.5f_{\frac{\lambda}{2}}$ are shown in Fig. 5. For frequencies lower than the resonance frequency, the system is very similar to the beam with periodic masses: a free propagating wave (full and dash-dotted line) and a damped wave (dashed lines) are found. In the zone close to the resonance frequency the behavior changes drastically: both wave types have complex propagating constants and a band gap opens up from dimensionless frequency 0.47 to 0.55.

The local resonance band gap is smaller than the interference band gap (Fig.3), but shows very

strong attenuation. For higher frequencies the wave types correspond again with the previous example.

It can be noticed that from dimensionless frequency 1 up to 1.065 a second band gap opens up, although this band gap has a very low attenuation. This band gap is linked to standing wave behavior and can be explained as scattering due to the impedance of the resonator.

3.3 Comparison

For the same mass addition, the local resonance band gap shows a stronger attenuation, while the interference band gap opens up a larger band gap. The position of the band gap due to interference is linked to the standing wave behavior of the unit cell, whereas for the local resonance the band gap frequencies depend on the resonance frequency of the mass-spring system. The manipulation of band gap frequencies will be investigated in more detail in the next section.

4 BAND GAP FREQUENCIES

To improve vibro-acoustic behavior, it is crucial to be able to control the band gap frequencies. Attenuation in a certain frequency region often suffices to improve the vibro-acoustic behavior of a system drastically.

An infinite steel plate serves as a test case. Periodicity is again introduced by the addition of a point mass or a spring-mass system. Table 2 summarizes the material characteristics and dimensions.

Name	Symbol	Value
Young's modulus	E	210 GPa
Density	ρ	$7800 \frac{kg}{m^3}$
Poisson's ratio	ν	0.3
Thickness	t	1mm

Table 2: Material characteristics and dimensions of the infinite plate used in the examples.

Only the dispersion curves linked to out-of-plate motion of the plate will be examined. The in-plane modes of the plate are decoupled from the out-of-plane modes for flat plates and can be omitted from a vibro-acoustic point of view.

4.1 Interference band gap

To investigate interference band gaps, a point mass without rotational inertia is added periodically in two dimensions. The length of repetition in x and y direction is the same, so that the unit cell (Fig. 6) is symmetrical and square. The mass of the point mass is 20% of the mass of the unit cell.

The interference band gap will be linked to the standing wave behavior of the plate, however, now standing waves in different directions are possible. The first standing wave in y direction occurs when the wave length in y direction equals double the length of the unit cell (L). For the

Figure 6: Square unit cell of an infinite plate with a periodic point mass.

x direction the same frequency is found due to symmetry. The first standing wave in diagonal direction occurs when the projected wavelength in both x and y direction equal double the unit cell length, hence when the diagonal wavelength equals $\sqrt{2}L$. These conditions are mathematically equivalent to claiming that the phase shift across the unit cell (ϵ_x, ϵ_y) is equal to $(0, \pi)$ for a wave in y direction and equal to (π, π) for the diagonal wave. It is worth pointing out that these are two of the three corner points of the irreducible Brillouin contour.

For an infinite plate with plane stress assumption the relationship between frequency and wavelength for bending waves is given by:

$$f = \frac{2\pi}{\lambda^2} \sqrt{\frac{t^2 E}{12(1 - \nu^2)\rho}}. \quad (9)$$

The frequency for which the wavelength λ equals two times the unit cell length is used to make the frequency in the results dimensionless. Hence for the first standing wave in y direction the dimensionless frequency will be 1, for the first diagonal standing wave the dimensionless frequency will be 2.

Figure 7: Dispersion curves for an infinite plate with a point mass repeated periodically in two dimensions. The dispersion curves are calculated along the contour of the irreducible Brillouin Contour: O,A,B,O $\mapsto (0, 0), (0, \pi), (\pi, \pi), (0, 0)$. The added mass is 20% of the unit cell mass.

Figure 7 shows the dispersion curves obtained with the inverse approach. For each frequency there is a corresponding point in the wave domain, and thus direction, for which free

wave propagation is possible. Point A corresponds with propagation constants $(0, \pi)$ and a partial band gap from dimensionless frequency 0.84 to 1 is noticeable. For point B, corresponding with propagation constants (π, π) a partial band gap from dimensionless frequency 1.45 to 2 is found. Interference causes band gaps for waves in a certain direction in the frequency region corresponding to the standing wave in that direction, but these band gaps are not large enough to create a band gap across the entire wave domain.

Figure 8 shows the dispersion curves for an added periodic point mass of 80% of the unit cell. The partial band gap clearly comprises a broader frequency range and the partial band gaps are large enough to result in a complete band gap of $0.07f_{\frac{\lambda}{2}}$.

Figure 8: Dispersion curves for an infinite plate with a point mass repeated periodically in two dimensions. The dispersion curves are calculated along the contour of the irreducible Brillouin Contour. The added mass is 80% of the unit cell mass.

4.2 Local resonance band gap

Local resonance band gaps are achieved by the addition of a mass-spring system in the same manner as the point mass in the previous example. Figure 9 shows the unit cell. The mass is 20% of the mass of the unit cell, the stiffness is chosen so that the resonance of the unit cell is at a dimensionless frequency of 0.5.

Figure 9: Unit cell of an infinite plate with a spring-mass system periodically attached.

The dispersion diagram (Fig. 10) shows a band gap from a dimensionless frequency of 0.48 up to 0.54. In a frequency region around the resonance frequency of the spring-mass

system, no free wave propagation is possible. The original dispersion curve is pulled down to frequencies below the resonance of the spring-mass system. Above the resonance frequency a new dispersion curve appears. The pulled down dispersion curve relates to in phase movement of plate and resonator; the new dispersion curve contains modes where resonator and plate move out-of-phase.

Figure 10: Dispersion curves for an infinite plate with a spring-mass system added periodically in two dimensions. The dispersion curves are calculated along the contour of the irreducible Brillouin Contour: $O, A, B, O \mapsto (0, 0), (0, \pi), (\pi, \pi), (0, 0)$. The added mass is 20% of the unit cell mass. The resonance frequency of the spring-system is $0.5f_{\frac{\lambda}{2}}$.

Figure 11 shows the link between band gap width and added mass of the local resonator. The stiffness of spring-mass system is changed in function of the mass addition so that the dimensionless resonance frequency is kept at 0.5. Increasing the mass of the local resonator leads to a larger band gap. Although the lower limit of the band gap is pushed down a little, the higher limit of the band gap is affected the most. This agrees with the statement that the lower limit of the band gap is strongly linked to the local resonator resonance, while the upper limit is more influenced by the interaction of the resonator and the plate [15].

Figure 11: Relationship between frequencies of free wave propagation for an infinite plate with a spring-mass system added periodically in two dimensions and the mass of the spring-mass system. The spring stiffness is adjusted as function of the added mass to keep the resonance frequency fixed at a $0.5f_{\frac{\lambda}{2}}$.

Figure 12 shows the link between band gap and resonance frequency of the local resonator. The mass of the local resonator is kept at 20% of the plate mass and the stiffness is changed to

change the resonance frequency. For the different resonance frequencies band gaps are calculated, which are represented as white gaps in Fig. 12. Up to a dimensionless frequency of 1, the resulting band gap is always centered at the resonance frequency of the local resonator. For higher frequencies no band gap is found.

Figure 12: Relationship between frequencies of free wave propagation for an infinite plate with a spring-mass system added periodically in two dimensions and the resonance frequency of spring-mass system. The added mass of the local resonator is 20% of the plate mass.

The upper frequency of the highest band gap obtained is linked to standing wave behavior. Figure 13 shows the dispersion diagram for a spring-mass system with a dimensionless resonance frequency of 1.5. A free propagation wave at a dimensional frequency of 1.5 is found for the point with imaginary propagation constants $(0.72\pi, \pi)$, indicated with a black circle in Fig. 13. This correlates with a standing wave in y-direction and traveling wave in x-direction. In the corresponding wave motion all the spring-mass systems are in nodal points and hence not excited. For frequencies higher than the first standing wave frequency, it will always be possible to have traveling waves for which the mass-spring systems are in nodal positions: the dimensionless frequency of 1 is thus the upper-limit for local resonance band-gaps.

Figure 13: Dispersion curve for an infinite plate with a spring-mass system added periodically in two dimensions. The dispersion curves are calculated along the contour of the irreducible Brillouin Contour: $O, A, B, O \mapsto (0, 0), (0, \pi), (\pi, \pi), (0, 0)$. The added mass is 20% of the unit cell mass. The resonance frequency of the spring-mass system is $1.5f_{\frac{\lambda}{2}}$. The black circle indicates the point $(0.72\pi, \pi)$ and dimensionless frequency 1.5.

Figures 14 is the result of a comparable analysis as Fig. 12 but with an added relative

mass of 80%. It is clear that once again no band gaps show up for frequencies higher than a dimensionless frequency 1. Although, this time spring-mass-systems with a dimensionless resonance frequency higher than 1 still result in band gaps. For these resonance frequencies however, the link between resonance frequency and band gap frequency is lost. The resulting band gap is not a purely local resonance band gap: due to the relative large added mass and the resonance frequency in the vicinity of the standing wave frequency, the large impedance of the spring-mass-system at the standing wave frequency will lead to an interference based band gap.

Figure 14: Relationship between frequencies of free wave propagation for an infinite plate with a spring-mass system added periodically in two dimensions and the resonance frequency of spring-mass system. The added mass of the local resonator is 80% of the plate mass.

4.3 Comparison

Although interference is a method of creating band gaps, these band gaps are not guaranteed for two dimensional topologies and can only be formed at frequencies corresponding with standing waves across the unit cell. Local resonance based resonators create a band gap at the frequency of the local resonator although this band gap is only guaranteed for frequencies lower than the first standing wave frequency of the unit cell.

For spring-mass-systems with a high impedance at the standing wave frequency, a combination of local resonance based band gaps and interference band gaps is possible.

5 CONCLUSIONS

This paper shows the potential of band gaps to suppress wave motion in certain frequency ranges. Band gaps can be created due to interference or by the addition of a local resonators in each unit cell.

Interference band gaps are linked to standing wave behavior and are not guaranteed. This explains why, although a lot of panels are periodic, band gaps are not often encountered: either the band gap frequency is too high or a complete band gap is not found.

The periodic introduction of a local resonator introduces a band gap at the resonance frequency of the local resonator. This is the case as long as the resonance frequency of the local resonator is below the first standing wave frequency in the unit cell.

In general the local resonance band gap shows stronger vibro-acoustic attenuation and the frequencies of the band gap are easier to manipulate. In conclusion, local resonance band gaps

seem to have a high potential to improve the vibro-acoustic behavior of periodic lightweight structures in the low-frequency region.

Keywords: Machinery Foundation, Design Optimization, Forced Vibration, Vibration Isolation.

Abstract. *This paper deals with the problem of optimum design of a foundation for rotating machinery on a storey of a building with a view to minimize the level of standing-wave vibration in the building. The foundation is usually designed as a base plate for the machinery, with some resilient mounts fixed to the bottom of the base plate and supported by the floor of the storey in order to provide a suitable level of vibration isolation of the building. Due to variable service speeds and the existence of non-balanced masses, the rotating machinery may be considered a source that within a given range of excitation frequencies excites forced vibration of the foundation, and thereby the floors and walls, etc., of the building. The transmission of such vibrations through the building may result in undesirable sound emission and unsatisfactory comfort conditions for the people in dwellings and offices of the building. To remedy this, the objective of this work is to develop and implement a method of design optimization to determine optimum stiffness values of resilient mounts subject to constraints on availability of physical properties of material to be used. The design objective is chosen as minimization of the power transmitted from the machine to the floor of the building where the foundation for the rotating machinery is mounted. At the current stage of our project, this problem is only carried out for a given, quite simplified model of a building. However, for this building model, the design and performance of the optimized machinery foundation will be illustrated and discussed using several numerical examples. In the next stage of our work, a multi-material, parameterized building model will be developed with detailed dimensions and connections of components, and the current problem will be extended to encompass simultaneous design optimization of both the building and the foundation for the rotating machinery in order to minimize the level of standing-wave vibration in the building.*

1 INTRODUCTION

Rotating machinery in buildings is usually applied in central heating and ventilation systems, and larger machinery of this type including a pump is normally mounted on a foundation, which is usually designed as a base plate for the machinery with some resilient mounts fixed to the bottom of the base plate and supported by the floor of the storey. Due to variable service speeds and the existence of non-balanced masses, the rotating machinery may be considered a source that within a given range of excitation frequencies excites forced vibration of the foundation, and thereby the floors and walls, etc., of the building. The transmission of such vibrations through the building may result in undesirable sound emission and unsatisfactory comfort conditions for the people in dwellings and offices of the building. Aside from that, vibrations increase safety hazards in machinery, buildings and installations. The primary goals of vibration insulation are to restrict the detrimental effects of vibrations on people to within reasonable limits, and to protect sensitive apparatus and safety systems from excessive stresses from vibrations.

Problems of design optimization of machinery foundations against vibration have been mainly studied from two aspects:

1. Free vibration design, also termed as frequency design. This aims at keeping the operating frequency as far away as possible from the eigenfrequencies of the machinery mounting system by adjusting the mounting system in order to avoid resonance. It is usually realized by maximization of the fundamental eigenfrequency or frequency gaps between two consecutive eigenfrequencies of the machinery mounting system.
2. Forced vibration design. The machinery mounting system is assumed to be subjected to a time-varying unbalanced mechanical loading, and this system will be designed by minimizing a chosen cost function describing the level of vibration response or transmission.

The problem of forced vibration design optimization of the installation systems of machinery in buildings has been extensively researched under the assumption of a rigid supporting structure [1-3]. The design based on a rigid supporting structure model is reasonable for the installation of machinery in many real engineering situations. However, this rigid support based model may not be appropriate for the problem studied in the present paper where the machinery is to be installed on a relatively flexible floor of the storey in a lightweight building. Based on a flexible support model, Ashrafiuon [4] studied design optimization of aircraft engine-mount systems for vibration isolation, and Xie et al [5] considered optimization of the mounting system for microelectronics manufacturing equipment using the receptance matrix method. In these works, minimization of the transmitted force from the vibrating machine to the receiver is chosen as the design objective. In the work [6] it was suggested to choose the power flow as the cost function because it combines both forces and velocities in a single concept. Furthermore, the transmitted power from the unbalanced machine to the floor is closely related to the structural noise emission from the floor. Power flow is considered to be a more reasonable measure of the vibratory state in vibro-acoustic modeling. The power flow from a vibrating machine to different flexible receivers through resilient mounts is presented in the works [6-9].

When rotating machinery is to be mounted on building floors rather than directly on a soil foundation, suitable resilient mounts should be provided as vibration isolation elements under the machine with a view to reduce the transmission of vibration.

The design optimization of machinery mounting systems is studied in this paper. The system consists of a rotating, unbalanced machine as vibration source, a mounting system as isolator, and a flexible floor as receiver. By assuming a simple time harmonic excitation

generated within the machine by its operating mechanisms, it is convenient to characterize the individual sub-structures by their complex mobilities evaluated at the interfaces of contiguous sub-structures. The mobility is defined as the ratio of the complex amplitudes of the velocities and forces at any interface for a given frequency [10]. The physical quantities, such as velocities, forces and moments at the interfaces, are solved in terms of the mobility matrices of sub-structures.

A generalized mathematical model of mobility power flow is developed in this paper for evaluation of the response of the total system subjected to a given external excitation. In this model, the machine is modeled as a rigid mass subjected to a harmonically time-varying force. The base plate is assumed to be rigidly connected with the machine, and included in the modeling of the machine. The mounting system of the machine is designed as some resilient supports fixed to the bottom of the machine and supported by the floor of the storey in order to provide a suitable level of vibration isolation of the floor. The flexible floor is modeled as an elastic uniform plate, and the driving point and transfer mobilities of the plate are adopted in the model. The degrees of freedom associated with flexural vibration of the supporting structure are of main interest because the flexural wave motion is usually dominating the sound radiation compared with the in-plane wave motion.

The objective of minimizing vibration transmission is realized by sizing optimization of the stiffness coefficients of the resilient mounts. The design objective is chosen as minimization of the power flow transmitted to the building floor through the resilient mounts at the excitation frequency of the machinery. The design and performance of the optimized machinery foundation will be illustrated and discussed using several numerical examples.

The rest of this paper is organized as follows. First, a generalized mathematical model of mobility power flow is developed in this paper. The formulation of minimization of transmitted power flow is presented in Section 3. Section 4 presents a simplified parametric example only considering the vertical flexural motion, and a generalized optimization example with more degrees of freedom. In Section 5, a shape optimization problem of a pad that is placed on a flexible floor to support a resilient mount, is presented. Finally, observations and conclusions are drawn based on the optimization results.

2 A GENERAL MOBILITY FORMULATION OF THE MACHINERY MOUNTING SYSTEM

A general model with a rotating, unbalanced machine as vibration source, a mounting system as isolator, and a flexible floor as receiver, is developed for analysis and optimization of vibration transmission, see the model in Figure 1. The machine is modeled as a rigid body subjected to a harmonically time-varying force. The mounting system of the machine is designed as some resilient supports fixed to the bottom of the machine and supported by the floor of the storey in order to provide a suitable level of vibration isolation of the floor. The flexible floor is modeled as an elastic uniform plate, and the driving point and transfer mobilities [11] of the plate are adopted in the model. Figure 1 gives a representation of a vibratory rigid body resiliently mounted on a four-edge simply supported plate via multiple resilient mounts. The forces and velocities at the interface of the contiguous sub-systems are shown in Figure 2, where the arrows define the positive directions of the forces and velocities.

Figure 1: A machine mounted to a flexible floor via multiple resilient mounts

Figure 2: Description of forces and velocities between three sub-systems: source, resilient mounts and receiver

2.1 Rigid body

A local coordinate system $x_o y_o z_o$, cf. Figure 1, is adopted with origin in the center of gravity of the machine. It is assumed that the machine is excited by a generalized concentrated force vector \mathbf{F}^s with three force and three moment components acting at the center of gravity. The corresponding generalized velocity vector at the center of gravity is denoted as \mathbf{V}^s .

$$\mathbf{F}^s = \{F_1^s, F_2^s, F_3^s, F_4^s, F_5^s, F_6^s\}^T \quad (1)$$

$$\mathbf{V}^s = \{V_1^s, V_2^s, V_3^s, V_4^s, V_5^s, V_6^s\}^T \quad (2)$$

where the superscript T represents the transpose of a matrix or vector.

A number of resilient mounts are assumed to be attached to the bottom of the machine, and the generalized output force and velocity vectors from the rigid body to the resilient mounts at the n junctions are assembled in the vectors

$$\mathbf{F}^a = \{\mathbf{F}^{a1} \quad \mathbf{F}^{a2} \quad \dots \quad \mathbf{F}^{an}\}^T, \quad \mathbf{V}^a = \{\mathbf{V}^{a1} \quad \mathbf{V}^{a2} \quad \dots \quad \mathbf{V}^{an}\}^T \quad (3)$$

Correspondingly, the generalized force and velocity vectors acting at the j -th resilient mount by the machine are \mathbf{F}^{bj} and \mathbf{V}^{bj} , and each of them includes six components, respectively.

The dynamics governing equation of the rigid body [12] can be written in terms of the mobility matrices,

$$\begin{Bmatrix} \mathbf{V}^s \\ \mathbf{V}^a \end{Bmatrix} = \begin{bmatrix} \mathbf{M}_{11}^s & \mathbf{M}_{12}^s \\ \mathbf{M}_{21}^s & \mathbf{M}_{22}^s \end{bmatrix} \begin{Bmatrix} \mathbf{F}^s \\ \mathbf{F}^a \end{Bmatrix} \quad (4)$$

where $\mathbf{M}_{11}^s = \frac{1}{i\omega} \mathbf{J}^{-1}$, $\mathbf{M}_{12}^s = \frac{1}{i\omega} \mathbf{J}^{-1} \mathbf{R}$, $\mathbf{M}_{21}^s = \frac{1}{i\omega} \mathbf{R}^T \mathbf{J}^{-1}$, $\mathbf{M}_{22}^s = \frac{1}{i\omega} \mathbf{R}^T \mathbf{J}^{-1} \mathbf{R}$. The symbol ω is the excitation frequency, i represents the imaginary unit, $i = \sqrt{-1}$, \mathbf{R} represents the location matrix of the resilient mounting junctions with respect to the center of gravity of the machine, and \mathbf{J} is the general mass matrix. The time dependent term $\exp(i\omega t)$ is omitted in the remainder.

2.2 Resilient mounts

The resilient mounts are used as vibration isolators for minimizing vibration transmission from the machine to the building floor. At the mounting junctions on the plate, the generalized force and velocity vectors at the bottom ends of the resilient mounts, see Figure 2, are assembled in the vectors

$$\mathbf{F}^c = \{\mathbf{F}^{c1} \quad \mathbf{F}^{c2} \quad \dots \quad \mathbf{F}^{cn}\}^T, \quad \mathbf{V}^c = \{\mathbf{V}^{c1} \quad \mathbf{V}^{c2} \quad \dots \quad \mathbf{V}^{cn}\}^T \quad (5)$$

The relation between the velocity vectors and force vectors at the two ends of the j -th resilient mount is given by using the four-pole equation [13, 14],

$$\begin{Bmatrix} \mathbf{F}^{bj} \\ \mathbf{V}^{bj} \end{Bmatrix} = \begin{bmatrix} \mathbf{diag}(\mathbf{T}_{11}^j) & \mathbf{diag}(\mathbf{T}_{12}^j) \\ \mathbf{diag}(\mathbf{T}_{21}^j) & \mathbf{diag}(\mathbf{T}_{22}^j) \end{bmatrix} \begin{Bmatrix} \mathbf{F}^{cj} \\ \mathbf{V}^{cj} \end{Bmatrix} \quad (6)$$

where $\mathbf{diag}(\mathbf{T}_{pq}^j)$, $p, q = 1, 2$, means the diagonal transmission sub-matrix of the j -th resilient mount.

For generality, in this study, each resilient mount is modelled as six lumped stiffness components with negligible mass, where three components with translational stiffness and three with rotational stiffness are assumed without coupling between the different stiffness components. For example, the p -th component of the j -th resilient mount is described by the following four-pole equation

$$\begin{Bmatrix} F_p^{bj} \\ V_p^{bj} \end{Bmatrix} = \begin{bmatrix} -1 & 0 \\ -\frac{i\omega}{\mu_p^j} & 1 \end{bmatrix} \begin{Bmatrix} F_p^{cj} \\ V_p^{cj} \end{Bmatrix} \quad (7)$$

where F_p^{bj} denotes the p -th ($p = 1, \dots, 6$) component of the generalized force at the j -th resilient mount, and μ_p^j denotes the stiffness coefficient of the p -th stiffness component in the j -th resilient mount.

For all resilient mounts, the transmission matrix equation is obtained as

$$\begin{Bmatrix} \mathbf{F}^b \\ \mathbf{V}^b \end{Bmatrix} = \begin{bmatrix} \mathbf{T}^{11} & \mathbf{T}^{12} \\ \mathbf{T}^{21} & \mathbf{T}^{22} \end{bmatrix} \begin{Bmatrix} \mathbf{F}^c \\ \mathbf{V}^c \end{Bmatrix} \quad (8)$$

The conditions for force equilibrium and motion compatibility at the junctions can be written as

$$\mathbf{F}^a = -\mathbf{F}^b, \mathbf{V}^a = \mathbf{V}^b, \mathbf{F}^c = -\mathbf{F}^d, \mathbf{V}^c = \mathbf{V}^d \quad (9)$$

2.3 The supporting floor

The supporting floor is modeled as a thin, elastic uniform plate. When there are no significant reflections from the boundaries or from discontinuities within the receiver, an infinite, uniform plate model may be assumed. Otherwise, a finite plate with suitable boundary conditions should be considered. The supporting plate floor is excited by the force and moment components at the bottom of each resilient mount. The force and velocity vectors at the plate mounting points, see Figure 2, are assembled in the vectors

$$\mathbf{F}^d = \{\mathbf{F}^{d1} \quad \mathbf{F}^{d2} \quad \dots \quad \mathbf{F}^{dn}\}^T, \mathbf{V}^d = \{\mathbf{V}^{d1} \quad \mathbf{V}^{d2} \quad \dots \quad \mathbf{V}^{dn}\}^T \quad (10)$$

The force vector at each resilient mount junction $j = 1, \dots, n$ includes six components,

$$\mathbf{F}^{dj} = \{F_1^{dj}, F_2^{dj}, F_3^{dj}, F_4^{dj}, F_5^{dj}, F_6^{dj}\}^T \quad (11)$$

Accordingly, the velocity vector at each resilient mount junction $j = 1, \dots, n$ includes three translation components and three rotational components, i.e.,

$$\mathbf{V}^{dj} = \{V_1^{dj}, V_2^{dj}, V_3^{dj}, V_4^{dj}, V_5^{dj}, V_6^{dj}\}^T \quad (12)$$

The mobility equation of the plate can be now written as follows [11, 15-18], where $[\mathbf{Y}]$ is the mobility matrix,

$$\begin{Bmatrix} \mathbf{V}^{d1} \\ \mathbf{V}^{d2} \\ \vdots \\ \mathbf{V}^{dn} \end{Bmatrix} = \begin{bmatrix} \mathbf{y}^{d11} & \mathbf{y}^{d12} & \dots & \mathbf{y}^{d1n} \\ \mathbf{y}^{d21} & \mathbf{y}^{d22} & \dots & \mathbf{y}^{d2n} \\ \dots & & & \vdots \\ \mathbf{y}^{dn1} & \mathbf{y}^{dn2} & \dots & \mathbf{y}^{dnn} \end{bmatrix} \begin{Bmatrix} \mathbf{F}^{d1} \\ \mathbf{F}^{d2} \\ \vdots \\ \mathbf{F}^{dn} \end{Bmatrix} = [\mathbf{Y}] \begin{Bmatrix} \mathbf{F}^{d1} \\ \mathbf{F}^{d2} \\ \vdots \\ \mathbf{F}^{dn} \end{Bmatrix} \quad (13)$$

Since the flexural vibration dominates the noise emission of the building floor, only the out-of-plane flexural wave will be taken into account. Thus, the in-plane shear and longitudinal motions induced by in-plane forces, and drilling motion of the plate induced by twisting moment are neglected. The out-of-plane flexural waves are induced by the out-of-plane force and the in-plane moment components. For example, the mobility sub-matrix \mathbf{y}^{d21} can be written as

$$\mathbf{y}^{d21} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & y_{wF_z}^{21} & y_{wM_x}^{21} & y_{wM_y}^{21} & 0 \\ 0 & 0 & y_{\theta_x F_z}^{21} & y_{\theta_x M_x}^{21} & y_{\theta_x M_y}^{21} & 0 \\ 0 & 0 & y_{\theta_y F_z}^{21} & y_{\theta_y M_x}^{21} & y_{\theta_y M_y}^{21} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (14)$$

where the mobility term $y_{wF_z}^{21}$ relates an out-of-plane translational velocity V_z^{d2} at the junction no.2 to an out-of-plane force excitation F_z^{d1} at junction no.1, where the latter junction is the excitation point, and the former junction is the response point.

The mobility representation is a useful tool to describe the dynamic properties of the supporting floor. For a realistic complicated floor, force and moment mobilities at the mounting junctions can be measured by experiments. For some simple infinite and finite structures, the mobility matrices can be derived analytically. The mobility formulations for an elastic uniform plate with simply supported edges and an infinite plate can be found in, e.g., Refs. [10, 11, 15].

2.4 Power flow

The time averaged power flow transmitted from the machine to the building floor can be expressed as

$$\Pi = \frac{1}{2} \text{Re} \left[(\mathbf{F}^d)^* \mathbf{V}^d \right] = \frac{1}{2} \text{Re} \left[(\mathbf{F}^d)^* \mathbf{Y} \mathbf{F}^d \right] \quad (15)$$

where the symbol $()^*$ represents conjugate transpose of a matrix or vector.

The transmitted force \mathbf{F}^d can be solved from Eqs. (4), (8) and (13) by applying the conditions of force equilibrium and motion compatibility in Eq. (9). For brevity, the somewhat lengthy derivation is omitted here, as the same result can be found in Ref. [14]. Thus one gets the following expression for the transmitted force \mathbf{F}^d ,

$$\mathbf{F}^d = \left(-\mathbf{T}^{21} - \mathbf{M}_{22}^s \mathbf{T}^{11} + \mathbf{T}^{22} \mathbf{Y} + \mathbf{M}_{22}^s \mathbf{T}^{12} \mathbf{Y} \right)^{-1} \mathbf{M}_{21}^s \mathbf{F}^s \quad (16)$$

In order to avoid excessive vibration of the machine, a suitable constraint on the velocity \mathbf{V}^s of the rigid body may be applied. Thus, the velocity \mathbf{V}^s is sometimes of interest in design optimization of machinery mounting system. The expression for the velocity \mathbf{V}^s given in Eq. (17) is obtained by solving Eqs. (4), (8) and (13) with the conditions of force equilibrium and motion compatibility in Eq. (9),

$$\mathbf{V}^s = \mathbf{M}_{11}^s \mathbf{F}^s + \mathbf{M}_{12}^s \left(\mathbf{T}^{11} - \mathbf{T}^{12} \mathbf{Y} \right) \mathbf{F}^d \quad (17)$$

3 OPTIMIZATION FORMULATION FOR MINIMIZATION OF POWER TRANSMISSION

3.1 Optimization formulation

The problem of design optimization of the rotating machinery mounting system with the objective of minimizing the total power flow transmitted from the machine to the building floor via several resilient mounts, can be formulated as

$$\begin{aligned} \min_{\mu} \left\{ \Pi = \frac{1}{2} (\mathbf{F}^d)^* \operatorname{Re} \{ \mathbf{Y} \} \mathbf{F}^d \right\} \\ \text{s.t. Given constraints} \\ \mu_{\min} \leq \mu_i \leq \mu_{\max}, i = 1, \dots, n^{dv} \end{aligned} \quad (18)$$

The present work aims to realize this objective by optimizing stiffness coefficients μ_i of resilient mounts in a given range between μ_{\min} and μ_{\max} . The lower and upper limits of the stiffness coefficients are usually determined by physical properties of the resilient mounts. A reasonable lower limit is important for satisfying requirements on the static displacement of the machine, or the motion during starting and stopping stages. It is well-known that the stiffness of resilient mounts is normally frequency dependent. However, for simplicity the stiffness will be assumed to be independent of frequency in the following.

In the expression for the total transmitted power Π in (18), \mathbf{F}^d denotes the vector of amplitudes of the loading vector acting on the plate with the excitation frequency ω . The given constraints are specified by physical and geometrical requirements on mounting systems. The symbol n^{dv} denotes the number of design variables.

3.2 Design sensitivity analysis

The sensitivity of the objective function Π in Eq. (18) with respect to the design variable μ_k can be derived as

$$\frac{\partial \Pi}{\partial \mu_k} = \frac{1}{2} \frac{\partial \left(\operatorname{Re} \left\{ [\mathbf{F}^d]^* [\mathbf{Y}] [\mathbf{F}^d] \right\} \right)}{\partial \mu_k} = \operatorname{Re} \left\{ [\mathbf{F}^d]^* [\mathbf{Y}] \frac{\partial [\mathbf{F}^d]}{\partial \mu_k} \right\}, k = 1, \dots, n^{dv} \quad (19)$$

where the symmetric characteristics of the mobility matrix $[\mathbf{Y}]$ have been used.

In order to derive the sensitivity of the transmitted force $\frac{\partial \mathbf{F}^d}{\partial \mu_k}$ with respect to the design variables, Eq. (16) is rewritten as

$$(-\mathbf{T}^{21} - \mathbf{M}_{22}^s \mathbf{T}^{11} + \mathbf{T}^{22} \mathbf{Y} + \mathbf{M}_{22}^s \mathbf{T}^{12} \mathbf{Y}) \mathbf{F}^d = \mathbf{M}_{21}^s \mathbf{F}^s \quad (20)$$

By differentiating both sides of Eq. (20) with respect to the design variable μ_k , considering the condition that only \mathbf{T}^{21} is dependent on design variables among the mobility matrices of the machine, resilient mounts and the floor plate, and assuming that the generalized excitation force \mathbf{F}^s generated by the rotating unbalanced machine is design independent, $\frac{\partial \mathbf{F}^d}{\partial \mu_k}$ can be obtained as

$$\frac{\partial \mathbf{F}^d}{\partial \mu_k} = (-\mathbf{T}^{21} - \mathbf{M}_{22}^s \mathbf{T}^{11} + \mathbf{T}^{22} \mathbf{Y} + \mathbf{M}_{22}^s \mathbf{T}^{12} \mathbf{Y})^{-1} \frac{\partial \mathbf{T}^{21}}{\partial \mu_k} \mathbf{F}^d, k = 1, \dots, n^{dv} \quad (21)$$

The accuracy of analytical sensitivities has been validated by overall finite difference sensitivity calculations. With these sensitivity results, the design problem (18) may be solved by a mathematical programming method, e.g., MMA by Svanberg [19].

4 NUMERICAL EXAMPLES

4.1 A simplified parametric example

First, a simple special case of the vibratory system shown in Figure 1 is considered. Here, four identical resilient mounts are placed symmetrically with respect to the machine, and mounted on a flexible floor, which is assumed to be an infinite elastic plate of constant thickness. This simplification leads to an equivalent system of the resilient mounts as shown in Figure 3, which consists of four separate sets of a spring of stiffness μ and a mass m^s equal to $m/4$, where the symbol m represents the total mass of the machine. The dynamic governing equation is simplified correspondingly, i.e., the forces acting on all four mounting points are assumed to be the same, that is, $F^0/4$, where F^0 denotes the vertical excitation force acting on the machine. A similar simplified model using a finite four-edge simply supported plate as the receiver is studied in [20].

Figure 3: A simplified modeling for the machine connected to a flexible floor via four symmetrically placed mounts

From the vibration equation of a system with a single degree of freedom, see, e.g. [21], the force F_j transmitted from the mass m^s to the floor via the j -th spring is obtained from [11, 20]

$$F_j = \frac{F_0}{4} \frac{1}{1 - \frac{m\omega^2}{4\mu} + i\omega \frac{m}{4} Y_j} \quad (22)$$

where μ is the stiffness of the spring.

Since only the out-of-plane force excitation on the plate is considered, the mobility matrix of the plate in Eq. (13) can be simplified. By the concept of effective point mobility Y_j as a space averaged effective mobility over all excitation points [22], Y_j can be expressed as $Y_j = Y_{j1} + Y_{j2} + Y_{j3} + Y_{j4}$ for $j=1, 2, 3$, and 4 . The symbol Y_{jk} is the general mobility element from the excitation point k to the response point j , where Y_{jk} with $k = j$ is the driving point mobility, while Y_{jk} with $k \neq j$ denotes the transfer mobility. The effective mobility represents the ratio of the total velocity due to all applied forces to the force acting at the point j . It can be calculated that the effective point mobility of an infinite plate Y_j ($j=1, 2, 3, 4$) are same,

i.e., $Y_1 = Y_2 = Y_3 = Y_4$. The driving point and transfer mobilities of an infinite plate can be found in, e.g., [11, 15].

The velocity V_0 of the machine is calculated based on the same assumption

$$V_0 = \frac{F_0}{4} \frac{\frac{\mu}{i\omega} + \frac{1}{Y_1}}{\left(\frac{\mu}{i\omega} + \frac{1}{Y_1}\right)\left(\frac{\mu}{i\omega} + i\omega \frac{m}{4}\right) - \left(\frac{\mu}{i\omega}\right)^2} \quad (23)$$

Thus, from Eq. (15) the time averaged power $P = \Pi$ transmitted from the machine to the floor can be rewritten as

$$P = 2 \operatorname{Re}(Y_1) \left| \frac{F_0}{4} \right|^2 \left| \frac{1}{1 - \frac{m\omega^2}{4\mu} + i\omega \frac{m}{4} Y_1} \right|^2 \quad (24)$$

As a reference to evaluate the effect of the spring isolator, the power flow P^{ws} from the machine to the building floor without spring isolators is given in Eq. (25) below. The modeling without isolation is obtained by removing the spring isolators from Figure 3, and we find that the power P^{ws} transmitted from the machine to the floor without spring isolators is given by

$$P^{ws} = 2 \operatorname{Re}(Y_1) \left| \frac{F_0}{4} \right|^2 \left| \frac{1}{1 + i\omega \frac{m}{4} Y_1} \right|^2 \quad (25)$$

The velocity V_0^{ws} of the machine without spring isolators is calculated as

$$V_0^{ws} = \frac{F_0}{4} \frac{Y_1}{i \frac{m}{4} \omega Y_1 + 1} \quad (26)$$

Assuming four springs with the same stiffness coefficient, the dependence of transmitted power P in Eq. (24) on the stiffness coefficient μ will be studied for different excitation frequency and mass values of the machine. In this section, no damping is assumed for the springs and the plate.

For a rigid building floor, the velocity at the mounting junction on the plate is zero, $V_1 = 0$, thus the transmitted power $P = 0$. If the stiffness of the spring is reasonably selected to make the resonance frequency $\omega_0 = \sqrt{\frac{\mu}{m/4}}$ of the mass-spring system to be located far from the excitation frequency ω , the transmitted force $|F_i|$ on the floor is relatively small.

When a flexible floor is considered, the mobility of the plate must be taken in account, and the velocity of the mounting point on the plate $V_1 \neq 0$. Thus we should pay attention to the transmitted power P , the velocity V_1 and force F_1 .

When the bending stiffness of the plate is quite large, the corresponding mobility Y_1 is very small. The conclusion is similar to the case of a rigid floor above. The transmitted power P , shown in Figure 4 (a), and force F_1 are very large only in the vicinity of resonance, and in other cases both of them are generally small. In this example, the given circular excitation frequency ω is 50 rad/s.

A suitably flexible plate of thickness 0.2 made of a material with Young's modulus 2×10^9 , Poisson's ratio 0.3 and mass density 840, is studied here. SI units are assumed. Transmitted powers for different mass values of machine and excitation frequencies are presented in Figure 4 (b). For a specified excitation frequency and a given stiffness coefficient, it is seen that when the mass of the machine increases, then the transmitted power decreases. Actually, an inertia concrete block is sometimes placed at the bottom of machine to increase the mass of the vibrating rigid body. The extra inertia block can be deemed beneficial for reduction of transmitted power when an infinite plate is the receiver, in which case no resonant behavior can occur. Though infinite structures do not exist in reality, the assumption of infinite structures is applicable in many circumstances where there are no significant reflections from discontinuities or boundaries within the receiver [6].

The only peak of each curve in Figure 4 (b) comes from the resonance of the spring-rigid body system. Obviously, the peak will move to the right when the mass of the machine is increased, and the maximum value at the peak also decreases significantly. If the mass of the machine is the same, then the value of the transmitted power at the peak point is reduced for a higher value of the excitation frequency. This can be explained from Eq. (24) where the term $\omega m^s Y_1$ in the denominator increases with increasing excitation frequency, which can be approximately considered as increasing the effect of damping.

Compared with the power flow P^{ws} from the machine to the building floor without spring isolators, it is found that if a very soft spring is provided under the machine, the transmitted power to the floor will be considerably reduced, but it may cause significant vibration velocity of the machine, see Figure 5. If a machine is rigidly bolted to the floor in the infinite plate case, then the vibratory movement of the machine may be reduced, but the transmitted power to the floor will be relatively large. Thus, some compromise must be made between the two requirements, and motivates optimization.

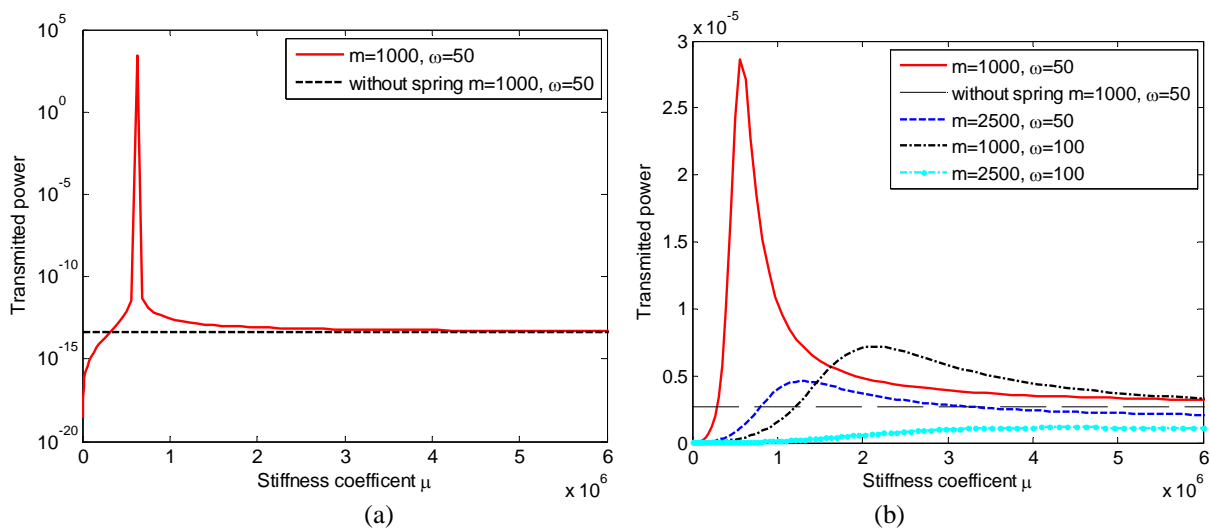

Figure 4: Transmitted power for different masses of machine and excitation frequencies: (a) very stiff floor plate, (b) relatively flexible floor plate

Figure 5: Velocity of machine for different masses of machine and excitation frequencies

4.2 Optimization of the mounting system of a machine with six degrees of freedom subjected to generalized excitation forces

The model shown in Figure 1 is considered for minimizing the power flow. It is now assumed that a machine with six degrees of freedom is excited by a concentrated force vector \mathbf{F}^s acting at its center of gravity. The receiver is modeled as a four-edge simply supported finite plate of uniform thickness 0.1, which is made of the same material as in the previous example. A loss factor $\eta = 0.005$ is introduced for the material.

The stiffness coefficients of four resilient mounts are chosen as design variables, i.e. we have $n^{dv} = 24$ when considering the stiffness components in every direction to be design variables.

The lower and upper limits μ_{\min} and μ_{\max} of the stiffness coefficients are given as 10^2 and 10^5 , respectively. The units of stiffness coefficients of translational and rotational stiffness components are N/m and Nm/rad. First, a vertical excitation force $\mathbf{F}^s = \{0, 0, 1000, 0, 0, 0\}^T$ is considered. The initial values of all design variables are taken to be 5×10^4 , which provides a convenient reference for evaluation and discussion of the vibration reduction by optimization. At the same time, the power flow without resilient mounts is calculated as a reference to evaluate the effect of the isolator. When considering vertical force excitation, the design objective is independent on the stiffness components in the directions of the in-plane and twisting motions. However, the rotational stiffness with respect to the x and y directions and the vertical translational stiffness will influence the transmitted power.

Excitation frequency ω	Power flow		
	Initial design	Optimized design	Design without resilient mounts
10	1.2134	0.0997	1.3508
20	0.0712	0.0075	0.0776
50	0.2660	5.1457e-005	0.8417
100	0.0312	5.6883e-005	0.0617

Table 1: Optimized result for the case with an excitation force in the z direction, only

As stated in Table 1, it is found that, in comparison with the initial design and design without resilient mounts, the optimization has reduced the power flow significantly for four different excitation frequencies, $\omega = 10, 20, 50, 100$.

Next, an excitation force $\mathbf{F}^s = 1/\sqrt{2} \{1000, 0, 1000, 0, 0, 0\}^T$ with a different direction but the same magnitude as above, is considered. When simultaneously considering the vertical and horizontal (in the x direction) force excitations, the design objective depends on the vertical translational stiffness, the rotational stiffnesses with respect to the x and y directions, and the horizontal stiffness with respect to the x direction. The same initial design is used.

Excitation frequency ω	Power flow		
	Initial design	Optimized design	Design without resilient mounts
10	0.8528	0.0499	0.7780
20	3.7194	0.0038	2.1498
50	0.1334	2.5622e-05	0.4561
100	0.0157	2.8445e-05	0.0353

Table 2: Optimized result for case with excitation forces in both the x and z directions

The results shown in Table 2 for this case also illustrate that substantial reduction of the power flow can be achieved for the excitation frequencies considered. When the excitation frequency ω is taken to be 10 or 20, the design without resilient mounts gives relatively lower values of the power flow compared with those of the initial design. This implies that an inappropriately chosen isolator may increase the vibration transmission. The important conclusion that can be drawn from the results reported in Tables 1 and 2 is that design optimization is extremely useful for the best possible selection of an isolator.

5 SHAPE OPTIMIZATION OF A SUPPORTING PAD PLACED ON A FLEXIBLE FLOOR FOR A RESILIENT MOUNT

This section deals with the shape optimization of a rotationally symmetric pad (see Figure 6) which, as illustrated in Figure 7, transfers a vertical force F from a resilient mount to a distributed pressure loading $-f(x)$ on a flexible wooden floor. One- and two-parameter analytical expressions for the distributed pressure loading are derived in Brunskog and Hammer [23] for the problem of pressing a rigid, plane indenter a small uniform distance into the plane surface of an elastic body. For simplicity and in order to apply the result from [23], we shall model the wooden floor as an infinite, isotropic, elastic plate as considered in Section 4.1. Moreover, we assume that the Young's modulus of the pad is large relative to that of the plate, and that the radius r_b of the pad is sufficiently small such that the introduction of the pad does not change the force equilibrium condition $\mathbf{F}^c = -\mathbf{F}^d$ and the motion compatibility condition $\mathbf{V}^c = \mathbf{V}^d$ in Eq. (9).

Figure 6: Schematic figure of a rotationally symmetric supporting pad for a resilient mount

The pad is assumed to be a circular truncated cone with a slant boundary subject to design. Due to rotational symmetry of the pad, the design problem can be formulated as a shape optimization problem of the curved part of the plane radial section of the pad shown in Figure 7, where the y axis is oriented along the center line, and x indicates the radial direction. The design boundary is defined by Spline curves evaluated in terms of the positions of the given points a and b and three master nodes, i.e., node 1, 2 and 3 shown in Figure 7. The coordinates of the master nodes are chosen as design variables. The design domain is meshed by a number of 4-node axisymmetric finite elements.

Figure 7: The axisymmetric planar design domain with three master nodes on the design boundary

All dimensions of the design domain are normalized by the radius r_b of the plane bottom surface, i.e., $r_t = \lambda_t r_b$, $h_l = \lambda_l r_b$, $h_r = \lambda_r r_b$.

The shape optimization problem is formulated as

$$\begin{aligned} \min_{\mathbf{x}} C &= \mathbf{P}^T \mathbf{U} \\ \text{s.t. } V &\leq \bar{V} \\ \mathbf{x}_L &\leq \mathbf{x} \leq \mathbf{x}_U \end{aligned} \quad (27)$$

where C is the static compliance of the structure. Assuming the point c of action of the force F to be fixed, the compliance C is defined as the scalar product of the nodal force vector \mathbf{P} and the vector \mathbf{U} of nodal displacements in the y direction at the bottom surface of the pad. Moreover, V denotes the volume of the axisymmetric structure, \bar{V} is the given upper limit on the volume, and \mathbf{x}_L and \mathbf{x}_U denote allowable lower and upper limits of the design variables which are the coordinates of three master nodes on the design boundary. The upper limit of the volume is prescribed as $\bar{V} = 0.51$ which corresponds to 75% of the volume of the circular truncated cone formed by 360° rotation of the area a-b-c-d-e along the y axis when $r_b = 1$.

The design variable vector \mathbf{x} is expressed as

$$\mathbf{x} = \{x_1 \quad x_2 \quad x_3 \quad y_1 \quad y_2 \quad y_3\}^T \quad (28)$$

where subscripts 1, 2 and 3 represent node numbers of master nodes on the design boundary.

A numerical example is presented here with the dimensions of design domain taken to be $r_b = 1$, $r_i = 0.1r_b$, $h_l = 0.5r_b$, $h_r = 0.05r_b$. The pressure function is adopted from the paper [23] in the form

$$f(x) = \frac{c}{\sqrt{1-x^2+\varepsilon}}, \quad c = 1.59 \times 10^4 \quad (29)$$

where a small value $\varepsilon = 10^{-6}$ is introduced for avoiding singularity when x equals r_b at the outer edge, and the integral of pressure over the circular bottom surface is obtained as

$$F = 2\pi \int_0^{r_b=1} f(x) x dx = 10^5 \quad (30)$$

The lower and upper limits of design variables are chosen as $0.7 \leq x_1 \leq 1.0$, $0.4 \leq x_2 \leq 0.7$, $0 \leq x_3 \leq 0.4$, $h_b = 0.05 \leq y_1 \leq 0.2$, $0.2 \leq y_2 \leq 0.35$, and $0.35 \leq y_3 \leq 0.5 = h_l$. The initial and final designs are compared in Figure 8. The values of the design variables, volume and compliance of initial and optimized designs are given in Table 3. As a result of the shape optimization, the compliance is reduced from 51.73 to 49.16.

	Initial design	Optimized design
x_1	0.80	0.80
x_2	0.50	0.51
x_3	0.20	0.17
y_1	0.10	0.10
y_2	0.20	0.22
y_3	0.40	0.38
C	51.73	49.16
V	0.50	0.51

Table 3: Comparison of initial and final designs ($\bar{V} = 0.51$)

Figure 8: Radial sections of initial and optimized pad designs

6 CONCLUSIONS

The problem of optimization of the machinery mounting system in a lightweight building is studied in this paper. A general mobility equation is developed for the system consisting of source, isolator and receiver of vibration by assembling the mobility matrices of each sub-system. The objective of minimizing vibration transmission is realized by sizing optimization of stiffness coefficients of resilient mounts. In comparison with designs without resilient mounts, designs with optimized isolators can provide significant reduction of the power flow.

Shape optimization of a supporting pad for a resilient mount is also studied. Such a pad may be used for transferring a vertical force from a resilient mount to a distributed pressure loading on a flexible floor. Artificial modeling of the resilient mounts and the floor of the building is adopted in this study. Work on more practical modeling of resilient mounts and building structures is in progress.

Abstract. *Structural health monitoring of pipelines by guided waves is a technique under continuous development. It proved a relevant efficiency in defects detection in pipes. The analysis of reflections from cracks provides guidance to defects sizing. A guided wave technique capable of screening long lengths of pipes has been developed in our laboratory. The wave finite element method, adapted for the case of hollow cylinders as waveguide, was used to calculate reflection coefficients from different rectangular notches sizes and some singularities located in industrial pipeline. The numerical simulations were established while varying the excitation frequency. The aim of this work is to create a database for the identification and approximation of defects sizes detected in an industrial installation subject of experimental tests. The results were compared to usual finite element simulations in order to validate the technique. Good agreement was found between the results. Thus, the database can be used to size approximately the founded defects.*

1 INTRODUCTION

The technique of defect detection by guided-waves is the solution that becomes more and more widespread in the non-destructive testing field. This technique allows the scanning of long-distance pipeline from a single position through the use of guided-waves propagation along the tested pipes and facilitates the defect detection. Torsional mode has shown relevant advantages in defect detection in pipes [1, 2]. These found damages need to be dimensioned in order to be classified depending on its severity. The reflection and transmission of the wave through defects gives good information about its sizes. Indeed, guided wave reflection and transmission depends on the defect size and shape, as well as the incident wave type and frequency. Since the near field is complex due to the presence of defects, analytical model can not readily be used to describe the near field effect that accounts for the energy redistribution of the scattered wave modes. Structural waveguides usually consist of many local features, such as welding, ribs, curved members, supports and others. They could also largely destroy the original wave form and evoke spurious echoes.

Wave propagation in waveguides has been studied for a long time as far as the question of propagation through periodic structures was addressed [3, 4]. The Wave Finite Element Method (WFEM) was employed for the low and midfrequency description of coupled structures and the analysis of wave propagation through a notch was studied [5]. Other studies consider the applicability of the WFEM and study the guided elastic wave propagation in cylindrical pipes with local inhomogeneities [6]. The intact and damaged curved structures was also treated to determine their response to incident waves [7].

In this paper, we present firstly the basis of the WFEM. This latter was then used to construct a database of reflection coefficients from a rectangular notch in pipe with three dimensions : depth, axial and circumferential extents. The chosen mode was the torsion and calculations was made in the frequency range $[5 - 15]kHz$.

2 WAVE FINITE ELEMENT METHOD

In this section, we present the basis of the WFEM that was used to construct a database of reflection coefficients from defects and features in the pipe. A hybrid WFE/FE method was employed for the scattered field calculation [6].

By using axisymmetric elements, WFE method for the 1-D wave propagation problem is employed to extract the wave numbers and mode shapes for axisymmetric modes (longitudinal modes $L(0, m)$ and torsional modes $T(0, m)$). Those eigenmodes are then superposed to form a scattering equation by connecting with FE formulation of the pipe segment with inhomogeneities. The dynamic reduction technique, component modal synthesis (CMS) is combined to formulate a numerically efficient scattering equation when dealing with the complex substructure models. This reduction technique fully takes into account the fact that the pipelines usually have some standard local features, and also allows various types of 3-D defects to be considered with ease.

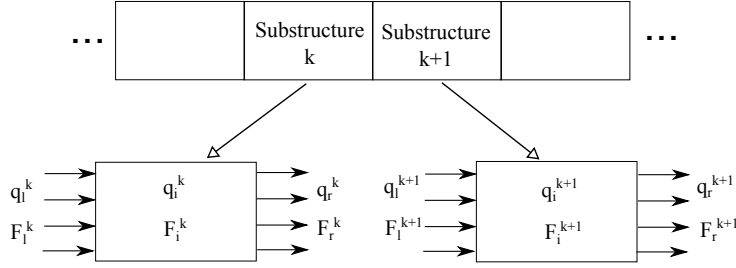

Figure 1: Structure discretized to identical cells

2.1 Finite element description

The structure can be discretized to identical cells as is shown in figure 1. The general FE formulation of a typical cell for the 1-D wave propagation in the pipe can be written as

$$\begin{bmatrix} \mathbf{D}_{ll} & \mathbf{D}_{li} & \mathbf{D}_{lr} \\ \mathbf{D}_{il} & \mathbf{D}_{ii} & \mathbf{D}_{ir} \\ \mathbf{D}_{rl} & \mathbf{D}_{ri} & \mathbf{D}_{rr} \end{bmatrix} \begin{Bmatrix} \mathbf{q}_l \\ \mathbf{q}_i \\ \mathbf{q}_r \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_l \\ \mathbf{F}_i \\ \mathbf{F}_r \end{Bmatrix}, \quad (1)$$

where $[\mathbf{D}]$ is the structure dynamic stiffness matrix, subscripts l , r and i denote the left, right and interior components, respectively. Assume that no external force be applied at interior dofs, eq.1 is condensed as

$$\begin{bmatrix} \mathbf{S}_{ll} & \mathbf{S}_{lr} \\ \mathbf{S}_{rl} & \mathbf{S}_{rr} \end{bmatrix} \begin{Bmatrix} \mathbf{q}_l \\ \mathbf{q}_r \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_l \\ \mathbf{F}_r \end{Bmatrix}, \quad (2)$$

where

$$\begin{aligned} \mathbf{S}_{ll} &= \mathbf{D}_{ll} - \mathbf{D}_{li}\mathbf{D}_{ii}^{-1}\mathbf{D}_{il}; & \mathbf{S}_{lr} &= \mathbf{D}_{lr} - \mathbf{D}_{li}\mathbf{D}_{ii}^{-1}\mathbf{D}_{ir}; \\ \mathbf{S}_{rl} &= \mathbf{D}_{rl} - \mathbf{D}_{ri}\mathbf{D}_{ii}^{-1}\mathbf{D}_{il}; & \mathbf{S}_{rr} &= \mathbf{D}_{rr} - \mathbf{D}_{ri}\mathbf{D}_{ii}^{-1}\mathbf{D}_{ir}. \end{aligned}$$

To describe the wave motion, eigensolution need to be decomposed to positive and negative going wave modes for the computational purpose. These modes include both the propagating and non-propagating modes. Through the eigensolutions, the non-reflecting boundaries are described by the incident wave mode bases

$$\mathbf{q}_r = [\mathbf{q}^+] \mathbf{A}^+, \quad \mathbf{F}_r = -[\mathbf{F}^+] \mathbf{A}^+. \quad (3)$$

Substitution into Equation 2 yields

$$\{(\mathbf{S}_{rl}\mathbf{S}_{ll}^{-1}\mathbf{S}_{lr} - \mathbf{S}_{rr})[\mathbf{q}^+] - [\mathbf{F}^+]\} \mathbf{A}^+ = \mathbf{S}_{rl}\mathbf{S}_{ll}^{-1}\mathbf{F}_l. \quad (4)$$

From Equation 4, the excited wave modes can be calculated for a given excitation. The wave field is thus represented fully by the incident wave modes.

The eigenmodes in the structural waveguide that come from the spectral solutions of WFE method can be superposed to describe the wave field. Those eigenmodes travel independently and do not interfere with one another. A set of wave modes can be traveling at the same time in the waveguides, thus the motion at any point therein is simply regarded as the sum of the motion of various modes. The incident, reflected and transmission waves can be expressed as

$$\mathbf{q}^{inc} = [\mathbf{q}^+] \Lambda^+ \mathbf{A}^{inc}, \quad \mathbf{q}^{ref} = [\mathbf{q}^-] \Lambda^- \mathbf{A}^{ref}, \quad \mathbf{q}^{tra} = [\mathbf{q}^+] \Lambda^+ \mathbf{A}^{tra}, \quad (5)$$

where \mathbf{q}^{inc} and \mathbf{q}^{tra} are formed of the same bases, $[\mathbf{q}^+]$ and $[\mathbf{q}^-]$ are normalized N by N_r matrices, \mathbf{A}^{inc} , \mathbf{A}^{ref} and \mathbf{A}^{tra} denote the amplitudes of the corresponding waves, Λ^+ and Λ^- are diagonal matrices relating respectively to the positive and negative going waves, which are given as

$$\Lambda^\pm = \text{diag} \{ e^{\pm j k_i x} \}, (i = 1, 2, \dots, N_r). \quad (6)$$

Analogically, we can obtain the expressions of \mathbf{F}^{inc} , \mathbf{F}^{ref} and \mathbf{F}^{tra} :

$$\mathbf{F}^{inc} = [\mathbf{F}^+] \Lambda^+ \mathbf{A}^{inc}, \quad \mathbf{F}^{ref} = [\mathbf{F}^-] \Lambda^- \mathbf{A}^{ref}, \quad \mathbf{F}^{tra} = [\mathbf{F}^+] \Lambda^+ \mathbf{A}^{tra}, \quad (7)$$

where the force vectors are also eigenvectors or obtained from the displacement vectors.

2.2 Wave propagation in an infinite structural waveguide with a local defect

Consider an infinitely long structure with the local inhomogeneities which are due to the geometry or material variation. A monochromatic incident wave, which comprises a single or multiple wave modes, is assumed to be generated at $x - \infty$ and travel in the positive $x - \infty$ direction. Scattering phenomenon emerges when the incident wave impinges on those inhomogeneities as is shown in figure 2.

Figure 2: Waves propagation through damaged coupling structure.

The resultant wave field consists of the incident and scattered components (both reflection and transmission). The modeling of damaged cell is similar to that of typical one for modes extraction except that additional interior dofs might be included. The coupling condition is governed by the dynamics equation of coupling structures that can be condensed as

$$\begin{bmatrix} \mathbf{S}_{ll}^c & \mathbf{S}_{lr}^c \\ \mathbf{S}_{rl}^c & \mathbf{S}_{rr}^c \end{bmatrix} \begin{Bmatrix} \mathbf{q}_l^c \\ \mathbf{q}_r^c \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_l^c \\ \mathbf{F}_r^c \end{Bmatrix}. \quad (8)$$

Considering the couple conditions

$$\mathbf{q}_l^c = [\mathbf{q}^+] \mathbf{A}^{inc} + [\mathbf{q}^-] \mathbf{A}^{ref}, \quad \mathbf{q}_r^c = [\mathbf{q}^+] \mathbf{A}^{tra}, \quad (9)$$

and

$$\mathbf{F}_l^c = [\mathbf{F}^+] \mathbf{A}^{inc} + [\mathbf{F}^-] \mathbf{A}^{ref}, \quad \mathbf{F}_r^c = [\mathbf{F}^+] \mathbf{A}^{tra}, \quad (10)$$

the governing equations for the scattering problem can be obtained from eq. 7 :

$$\begin{bmatrix} \mathbf{S}_{ll}^c [\mathbf{q}^-] - [\mathbf{F}^-] & \mathbf{S}_{lr}^c [\mathbf{q}^+] \\ \mathbf{S}_{rl}^c [\mathbf{q}^-] & \mathbf{S}_{rr}^c [\mathbf{q}^+] + [\mathbf{F}^+] \end{bmatrix} \begin{Bmatrix} \mathbf{A}^{ref} \\ \mathbf{A}^{tra} \end{Bmatrix} = \begin{bmatrix} [\mathbf{F}^+] - \mathbf{S}_{ll}^c [\mathbf{q}^+] \\ -\mathbf{S}_{rl}^c [\mathbf{q}^+] \end{bmatrix} \{ \mathbf{A}^{inc} \}, \quad (11)$$

Given a single or a set of incident modes as the input in Equation 10, scattered modes (reflection and transmission) acting as the output can be obtained. Numerically, the base number N_r is suggested to be frequency dependent, which can be implemented by a routine to include those slightly evanescent wave modes into the bases.

To numerically describe the wave mode scattering, the reflection and transmission coefficients are defined by the solution of response from Equation 11:

$$\mathbf{R}_i = \frac{\mathbf{A}_i^{ref}}{\mathbf{A}_i^{inc}}, \quad \mathbf{T}_i = \frac{\mathbf{A}_i^{tra}}{\mathbf{A}_i^{inc}} \quad (12)$$

where $i = 1, 2, \dots, Nr$. It should be mentioned that the coefficients depend not only on the defects, but also on the normalization method of eigenmodes and the size of intact part of waveguide that included for the reduction of high order near-field modes. The change of the phase of the coefficient with the frequency is partially owing to the size of intact part of waveguide in coupling structure model.

3 NUMERICAL IMPLEMENTATIONS

Guided wave techniques have two main objectives: defect localization and defect sizing. The location of the defect can be easily evaluated from the reflection of a well tuned wave packet. Practically, the time frequency analysis or denoise processing of the obtained testing signal is necessary. The sizing of the defects is much more difficult, because the reflection or transmission signal depends not only the defect size or shape, but also the mode type and frequency, potential mode conversion, and the attenuation due to dissipation, leakage or geometry. However, the wave-defect interaction analysis will help to find out which type of modes are sensitive to a given type of defects. Generally, the numerical wave-defect interaction analysis will provide a reference of the sizing in the practical test, at least to some extent.

3.1 Methodology

To construct the database of reflection coefficients, a numerical finite element model of a pipe-damaged section was created. The defect is a rectangular notch with three-dimensional variables: depth, axial and circumferential extents (figure 3). These parameters can describe most of defects types that can be encountered such as (notchs, corrosion, metal loss ...). The pipe is steel with a density $\rho = 7800 kg.m^{-3}$, a Young modulus $E = 2.10^{11} Pa$ and a Poisson's ratio $\nu = 0.3$. The outer diameter is $168mm$ and the thickness of the pipe wall is $11mm$. Reflection coefficients calculation was made depending on the frequency in the range $[5 - 15]kHz$. This latter corresponds practically to the signal frequency by which the pipe under test was excited. The torsion mode was considered in the calculation process. In fact, the inspection system use this mode to generate guided waves for the defect detection.

Figure 3: Damaged pipe with defect dimensions.

The waveguide 1 is a pipe section connected to the waveguide 2 which is a coupling structure with defect and it is in turn connected to waveguide 3 similar to the 1st one (see figure 4). Several iterations conduct us to obtain a database that contain reflection coefficients as a function of four variables : a , b , c and f , respectively, axial, depth, circumferential extents and frequency.

Figure 4: Finite element models of waveguides : (a) Waveguide 1 and 3, (b) Waveguide 2

3.2 Numerical results and interpretations

Figure 5 shows the reflection coefficients variation with frequency for different defect sizes. These curves prove the dependence of reflection coefficients with the excitation frequency. Generally speaking, these coefficients increase with the frequency. Figure 6 shows the reflection coefficients variation with axial, circumferential and depth defect extents at 10kHz for different sizes. These curves demonstrate the increase of the reflection coefficients with the defect sizes. The database constructed by a large diversity of defect sizes let us to plot the 3-D curves showing the evolution of reflection coefficients with two chosen variables from the defect dimensions (a, b or c) at a given frequency. In figure 7 we can see 3-D graphs of the reflection coefficients variation with defect sizes at 10kHz. It is clear that the reflection monotonically increases with axial extent at constant depth and vice versa, it also increases with circumferential extent at constant axial extent and vice versa.

Figure 8 shows color maps of the 3-D reflection plot in figure 7. The lines are isolines of constant reflection coefficient as described by the color bar. From these isolines we can observe that the reflection coefficient obtained for example at a certain depth and axial extent is also obtained at smaller depth and larger axial extent.

4 CONCLUSIONS

In this study, the Wave Finite Element Method was used to calculate the reflection coefficients from a rectangular notch, with varying dimensions, located in a pipe excited by torsional mode. The database created will serve for the sizing of defects detected by an experimental inspection system. Results show the increase of the reflection coefficients with the defect sizes and its dependence on the frequency. The reflection coefficients generally have nonlinear relationship with defects size of transverse size except at some frequencies. This means the choice of central frequency is crucial for the accurate estimation of the damage severity.

Keywords: meshless methods, generalized finite difference method, moving least squares, seismic waves, perfectly matched layer.

Abstract. *The interior of the Earth is heterogeneous with different material and may have complex geometry. The free surface can also be uneven. Therefore, the use of a meshless method with the possibility of using an irregular grid-point distribution can be of interest for modelling this kind of problem.*

This paper shows the application of Generalized Finite Difference Method (GFDM) to the problem of seismic wave propagation in 2-D. To use this method in unbounded domains one must truncate the computational grid-point avoiding reflection from the edges. Perfectly Matched Layers (PML) absorbing boundary condition has then been included in the numerical model proposed in this work.

1 Introduction

During recent years, meshless methods have emerged as a class of effective numerical methods which are capable of avoiding the difficulties encountered in conventional computational mesh based methods. Considerable research in computational mechanics has been devoted to the development of meshless methods. In these methods, the domain of interest is discretized by a scattered set of points.

An important path in the evolution of meshless methods has been the development of the Generalized Finite Difference Method (GFDM), also called Meshless Finite Difference Method (MFDM). The bases of the GFD were published in the early seventies. The idea of using an eight node star and weighting functions to obtain finite difference formulae for irregular meshes, was first put forward by [9] using moving least squares (MLS) interpolation and an advanced version of the GFDM was given by [12]. [1] reported that the solution of the generalized finite difference method depends on the number of nodes in the cloud, the relative coordinates of the nodes with respect to the star node, and on the weight function employed.

An h-adaptive method in GFDM is described in [2], [4] and [5].

In this paper, this meshless method is applied to seismic wave propagation. The GFDM is a robust numerical method applicable to structurally complex media. Due to its relative accuracy and computational efficiency it is the dominant method in modeling earthquake motion [10] and [11]. The perfectly matched layer (PML) absorbing boundary performs more efficiently and more accurately than most traditional or differential equation-based absorbing boundaries ([6], [7], [13] and [8]).

The paper is organized as follows. Section 1 is an introduction. Section 2 describes the GFDM obtaining the explicit generalized differences schemes for the seismic waves propagation. In Section 3 a stability condition is obtained. In Section 4 the grid dispersion relations is derived. In Section 5 are analyzed the relations between irregularity of cloud of nodes, the step of time and star-dispersion. In Section 6 an PML is defined in 2-D. In Section 7 some numerical results are included. Finally, in Section 8 some conclusions are given.

2 Explicit Generalized Differences Schemes for the seismic waves propagation problem for a perfectly elastic, homogeneous and isotropic medium

2.1 Equation of motion

The equations of motion for a perfectly elastic, homogeneous, isotropic medium in 2-D are

$$\begin{cases} \frac{\partial^2 U_x(x, y, t)}{\partial t^2} = \alpha^2 \frac{\partial^2 U_x(x, y, t)}{\partial x^2} + \beta^2 \frac{\partial^2 U_x(x, y, t)}{\partial y^2} + (\alpha^2 - \beta^2) \frac{\partial^2 U_y(x, y, t)}{\partial x \partial y} \\ \frac{\partial^2 U_y(x, y, t)}{\partial t^2} = \beta^2 \frac{\partial^2 U_y(x, y, t)}{\partial x^2} + \alpha^2 \frac{\partial^2 U_y(x, y, t)}{\partial y^2} + (\alpha^2 - \beta^2) \frac{\partial^2 U_x(x, y, t)}{\partial x \partial y} \end{cases} \quad (1)$$

with the initial conditions

$$U_x(x, y, 0) = f_1(x, y); U_y(x, y, 0) = f_2(x, y) \\ \frac{\partial U_x(x, y, 0)}{\partial t} = f_3(x, y); \frac{\partial U_y(x, y, 0)}{\partial t} = f_4(x, y) \quad (2)$$

and the boundary condition

$$\begin{cases} a_1 U_x(x_0, y_0, t) + b_1 \frac{\partial U_x(x_0, y_0, t)}{\partial n} = g_1(t) \\ a_2 U_y(x_0, y_0, t) + b_2 \frac{\partial U_y(x_0, y_0, t)}{\partial n} = g_2(t) \end{cases} \quad en \quad \Gamma \quad (3)$$

where $f_1(x, y)$, $f_2(x, y)$, $f_3(x, y)$, $f_4(x, y)$, $g_1(t)$ y $g_2(t)$ are showed functions,

$$\alpha = \sqrt{\frac{\lambda + 2\mu}{\rho}}, \quad \beta = \sqrt{\frac{\mu}{\rho}}$$

ρ is the density, λ and μ are Lamé elastic coefficients and Γ is the boundary of Ω .

2.2 A GFDM Explicit Scheme

The aim is to obtain explicit linear expressions for the approximation of partial derivatives in the points of the domain. First of all, an irregular grid or cloud of points is generated in the domain $\Omega \cup \Gamma$. On defining the central node with a set of nodes surrounding that node, the star then refers to a group of established nodes in relation to a central node. Every node in the domain has an associated star assigned to it.

This scheme uses the central-difference form for the time derivative

$$\frac{\partial^2 U_x(x_0, y_0, n\Delta t)}{\partial t^2} = \frac{u_{x,0}^{n+1} - 2u_{x,0}^n + u_{x,0}^{n-1}}{(\Delta t)^2}; \quad \frac{\partial^2 U_y(x_0, y_0, n\Delta t)}{\partial t^2} = \frac{u_{y,0}^{n+1} - 2u_{y,0}^n + u_{y,0}^{n-1}}{(\Delta t)^2} \quad (4)$$

Following [1], [2] and [4], the explicit difference formulae for the spatial derivatives are obtained,

$$\begin{aligned} \frac{\partial^2 U_x(x_0, y_0, n\Delta t)}{\partial x^2} &= -m_0 u_{x,0}^n + \sum_{j=1}^N m_j u_{x,j}^n; & \frac{\partial^2 U_y(x_0, y_0, n\Delta t)}{\partial x^2} &= -m_0 u_{y,0}^n + \sum_{j=1}^N m_j u_{y,j}^n \\ \frac{\partial^2 U_x(x_0, y_0, n\Delta t)}{\partial y^2} &= -\eta_0 u_{x,0}^n + \sum_{j=1}^N \eta_j u_{x,j}^n; & \frac{\partial^2 U_y(x_0, y_0, n\Delta t)}{\partial y^2} &= -\eta_0 u_{y,0}^n + \sum_{j=1}^N \eta_j u_{y,j}^n \\ \frac{\partial^2 U_x(x_0, y_0, n\Delta t)}{\partial x \partial y} &= -\zeta_0 u_{x,0}^n + \sum_{j=1}^N \zeta_j u_{x,j}^n; & \frac{\partial^2 U_y(x_0, y_0, n\Delta t)}{\partial x \partial y} &= -\zeta_0 u_{y,0}^n + \sum_{j=1}^N \zeta_j u_{y,j}^n \end{aligned} \quad (5)$$

where N is the number of nodes in the star whose central node has the coordinates (x_0, y_0) (in this work $N = 8$ and the are selected by using the four quadrants criteria ([?])).

m_0, η_0, ζ_0 are the coefficients that multiply the approximate values of the functions U and V at the central node for the time $n\Delta t$ (u_0^n and v_0^n respectively) in the generalized finite difference explicit expressions for the space derivatives.

m_j, η_j, ζ_j are the coefficients that multiply the approximate values of the functions U and V at the rest of the star nodes for the time $n\Delta t$ (u_j^n and v_j^n respectively) in the generalized finite difference explicit expressions for the space derivatives.

The replacement in Eq. 1 of the explicit expressions obtained for the partial derivatives leads to

$$\left\{ \begin{array}{l} u_{x,0}^{n+1} = 2u_{x,0}^n - u_{x,0}^{n-1} + (\Delta t)^2 [\alpha^2 (-m_0 u_{x,0}^n + \sum_{j=1}^N m_j u_{x,j}^n) + \beta^2 (-\eta_0 u_{x,0}^n + \sum_{j=1}^N \eta_j u_{x,j}^n) \\ \quad + (\alpha^2 - \beta^2) (-\zeta_0 u_{y,0}^n + \sum_{j=1}^N \zeta_j u_{y,j}^n)] \\ u_{y,0}^{n+1} = 2u_{y,0}^n - u_{y,0}^{n-1} + (\Delta t)^2 [\beta^2 (-m_0 u_{y,0}^n + \sum_{j=1}^N m_j u_{y,j}^n) + \alpha^2 (-\eta_0 u_{y,0}^n + \sum_{j=1}^N \eta_j u_{y,j}^n) \\ \quad + (\alpha^2 - \beta^2) (-\zeta_0 u_{x,0}^n + \sum_{j=1}^N \zeta_j u_{x,j}^n)] \end{array} \right. \quad (6)$$

3 Stability Criterion

For the stability analysis the first idea is to make a harmonic decomposition of the approximated solution at grid points and at a given time level (n). Then we can write the finite difference approximation in the nodes of the star at time n , as

$$u_0^n = A\xi^n e^{i\mathbf{k}^T \mathbf{x}_0}; \quad u_j^n = A\xi^n e^{i\mathbf{k}^T \mathbf{x}_j}; \quad v_0^n = B\xi^n e^{i\mathbf{k}^T \mathbf{x}_0}; \quad v_j^n = B\xi^n e^{i\mathbf{k}^T \mathbf{x}_j} \quad (7)$$

where \mathbf{x}_0 is the position vector of the central node of the star, $\mathbf{x}_j, j = 1, \dots, N$ are the position vectors of the rest of the nodes in the star and \mathbf{h}_j are the relative position vectors of the nodes in the star in respect to the central node whose coordinates are $h_{jx} = x_j - x_0, h_{jy} = y_j - y_0$. ξ is the amplification factor whose value will determine the stability condition, w is the angular frequency in the grid.

$$\mathbf{x}_j = \mathbf{x}_0 + \mathbf{h}_j; \quad \xi = e^{-iw\Delta t}$$

\mathbf{k} (fig. 1) is the column vector of the wave numbers

$$\mathbf{k} = \begin{Bmatrix} k_x \\ k_y \end{Bmatrix} = k \begin{Bmatrix} \cos \varphi \\ \sin \varphi \end{Bmatrix}$$

Then we can write the stability condition as: $\|\xi\| \leq 1$.

Figure 1: Irregular star (9 nodes)

The wavenumber \vec{k}

Including 7 into 6, cancelation of $\xi^n e^{i\nu^T \mathbf{x}_0}$, leads to

$$\begin{aligned}
 A\xi &= 2A - \frac{A}{\xi} + (\Delta t)^2 [\alpha^2 (-Am_0 + A \sum_1^N m_j e^{i\mathbf{k}^T \mathbf{h}_j}) + \beta^2 (-A\eta_0 + A \sum_1^N \eta_j e^{i\mathbf{k}^T \mathbf{h}_j}) + \\
 &\quad (\alpha^2 - \beta^2)(-B\zeta_0 + B \sum_1^N \zeta_j e^{i\mathbf{k}^T \mathbf{h}_j})] \\
 B\xi &= 2B - \frac{B}{\xi} + (\Delta t)^2 [\beta^2 (-Bm_0 + B \sum_1^N m_j e^{i\mathbf{k}^T \mathbf{h}_j}) + \alpha^2 (-B\eta_0 + B \sum_1^N \eta_j e^{i\mathbf{k}^T \mathbf{h}_j}) + \\
 &\quad (\alpha^2 - \beta^2)(-A\zeta_0 + A \sum_1^N \zeta_j e^{i\mathbf{k}^T \mathbf{h}_j})] \quad (8)
 \end{aligned}$$

where

$$m_0 = \sum_1^N m_j; \quad \eta_0 = \sum_1^N \eta_j; \quad \zeta_0 = \sum_1^N \zeta_j \quad (9)$$

Including 9 into 8, the system of equations is obtained

$$\begin{aligned}
 A[\xi - 2 + \frac{1}{\xi} + (\Delta t)^2 \alpha^2 \sum_1^N m_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j}) + (\Delta t)^2 \beta^2 \sum_1^N \eta_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j})] \\
 + B(\Delta t)^2 (\alpha^2 - \beta^2) \sum_1^N \zeta_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j}) = 0 \\
 A(\Delta t)^2 (\alpha^2 - \beta^2) \sum_1^N \zeta_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j}) + B[\xi - 2 + \frac{1}{\xi} + (\Delta t)^2 \beta^2 \sum_1^N m_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j}) \\
 + (\Delta t)^2 \alpha^2 \sum_1^N \eta_j (1 - e^{i\mathbf{k}^T \mathbf{h}_j})] = 0 \quad (10)
 \end{aligned}$$

B can be obtained from the second equation and included into the first, then operating with the real and imaginary parts of conditions obtained, and canceling with conservative criteria, the condition for stability of star is obtained.

$$\Delta t < \sqrt{\frac{4}{(\alpha^2 + \beta^2)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}]}} \quad (11)$$

4 Star dispersion

4.1 Star-dispersion relations for the P and S waves

The real part of the condition obtained from Eq. 10 leads to

$$\omega = \frac{1}{\Delta t} \arccos \Phi \quad (12)$$

where

$$\Phi = 1 - \frac{(\Delta t)^2}{4}((\alpha^2 + \beta^2)(a_1 + a_3) + ((\alpha^2 + \beta^2)^2(a_1 + a_3)^2 + 4[(\alpha^2 - \beta^2)^2(a_5^2 - a_6^2) + (\alpha^2 a_2 + \beta^2 a_4)(\beta^2 a_2 + \alpha^2 a_4) - (\alpha^2 a_1 + \beta^2 a_3)(\beta^2 a_1 + \alpha^2 a_3)])^{\frac{1}{2}})$$
(13)

with

$$\begin{aligned} a_1 &= \sum_1^N m_j (1 - \cos \mathbf{k}^T \mathbf{h}_j) \Rightarrow \frac{\partial a_1}{\partial k} = a_{1,k} = \sum_1^N m_j d \sin kd \\ a_2 &= \sum_1^N m_j \sin \mathbf{k}^T \mathbf{h}_j \Rightarrow \frac{\partial a_2}{\partial k} = a_{2,k} = \sum_1^N m_j d \cos kd \\ a_3 &= \sum_1^N \eta_j (1 - \cos \mathbf{k}^T \mathbf{h}_j) \Rightarrow \frac{\partial a_3}{\partial k} = a_{3,k} = \sum_1^N \eta_j d \sin kd \\ a_4 &= \sum_1^N \eta_j \sin \mathbf{k}^T \mathbf{h}_j \Rightarrow \frac{\partial a_4}{\partial k} = a_{4,k} = \sum_1^N \eta_j d \cos kd \\ a_5 &= \sum_1^N \zeta_j (1 - \cos \mathbf{k}^T \mathbf{h}_j) \Rightarrow \frac{\partial a_5}{\partial k} = a_{5,k} = \sum_1^N \zeta_j d \sin kd \\ a_6 &= \sum_1^N \zeta_j \sin \mathbf{k}^T \mathbf{h}_j \Rightarrow \frac{\partial a_6}{\partial k} = a_{6,k} = \sum_1^N \zeta_j d \cos kd \end{aligned}$$
(14)

and

$$\mathbf{k}^T \mathbf{h}_j = k(h_{jx} \cos \varphi + h_{jy} \sin \varphi) = kd$$

Is known that

$$\omega = 2\pi \frac{c^{grid}}{\lambda^{grid}}$$
(15)

where c^{grid} and λ^{grid} are the phase velocity (α^{grid} or β^{grid}) and the wavelength (λ_P^{grid} or λ_S^{grid}) in the star respectively.

Defining the relations:

$$s = \frac{2}{\lambda_S^{grid} \sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}]}}$$
(16)

$$s_P = \frac{2}{\lambda_P^{grid} \sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}]}}$$
(17)

$$p = \frac{\beta \Delta t \sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}]}{2}$$
(18)

$$r = \frac{\alpha}{\beta}$$
(19)

$$s_P = \frac{s}{r} \quad (20)$$

Substituting Eqs. 12, 17, 18 and 20 into Eq. 15, the star-dispersion relations for P and S waves are obtained:

$$\frac{\alpha^{grid}}{\alpha} = \frac{\arccos \Phi}{2\pi sp} \quad (21)$$

$$\frac{\beta^{grid}}{\beta} = \frac{\arccos \Phi}{2\pi sp} \quad (22)$$

4.2 Star-dispersion for group velocity

By definition the group velocity is the derivative of w (see Eq.12) with respect to k , thus

$$\alpha_{group}^{grid} = \frac{\partial w}{\partial k} = \frac{\Delta t}{4} \frac{\beta^2 \Upsilon}{\sqrt{1 - \Phi^2}} \quad (23)$$

where

$$\begin{aligned} \Upsilon = & (r^2 + 1)(a_{1,k} + a_{3,k}) + \frac{1}{2}[2(r^2 + 1)^2(a_1 + a_3)(a_{1,k} + a_{3,k}) + \\ & 4[2(r^2 - 1)^2(a_5 a_{5,k} - a_6 a_{6,k}) + (r^2 a_{2,k} + a_{4,k})(a_2 + r^2 a_4) + \\ & (r^2 a_2 + a_4)(a_{2,k} + r^2 a_{4,k}) - (r^2 a_{1,k} + a_{3,k})(a_1 + r^2 a_3) - \\ & (r^2 a_1 + a_3)(a_{1,k} + r^2 a_{3,k})]] \times [(r^2 + 1)^2(a_1 + a_3)^2 + \\ & 4[(r^2 - 1)^2(a_5^2 - a_6^2) + (r^2 a_2 + a_4)(a_2 + r^2 a_4) - (r^2 a_1 + a_3)(a_1 + r^2 a_3)]]^{-\frac{1}{2}} \end{aligned} \quad (24)$$

Defining

$$\begin{aligned} F = & (r^2 + 1)(a_1 + a_3) + [(r^2 + 1)^2(a_1 + a_3)^2 + \\ & 4[(r^2 - 1)^2(a_5^2 - a_6^2) + (r^2 a_2 + a_4)(a_2 + r^2 a_4) - (r^2 a_1 + a_3)(a_1 + r^2 a_3)]]^{-\frac{1}{2}} \end{aligned} \quad (25)$$

and substituting Eqs. 18 and 25 into Eq. 23, the star-dispersion for waves P and S are

$$\frac{\alpha_{group}^{grid}}{\alpha} = \frac{1}{2\sqrt{2}r} \frac{\Upsilon}{\sqrt{F - \left(\frac{pF}{\sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}] \sqrt{2}}} \right)^2}} \quad (26)$$

$$\frac{\beta_{group}^{grid}}{\beta} = \frac{1}{2\sqrt{2}} \frac{\Upsilon}{\sqrt{F - \left(\frac{pF}{\sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}] \sqrt{2}}} \right)^2}} \quad (27)$$

5 Irregularity of the star (IIS) and dispersion

In this section we are going to define the index of irregularity of a star (IIS) and also the index of irregularity of a cloud of nodes (IIC).

The coefficients m_0, η_0, ζ_0 are functions of: a) the number of nodes in the star, b) the coordinates of each star node referred to the central node of the star and c) the weighting function (see references [1, 4]). If the number of nodes by star is fixed, in this case 9 ($N = 8$), and the weighting function

$$w(h_{jx}, h_{jy}) = \frac{1}{(\sqrt{h_{jx}^2 + h_{jy}^2})^3} \quad (28)$$

the expression

$$\frac{1}{\sqrt{(r^2 + 1)[(|m_0| + |\eta_0|) + \sqrt{(m_0 + \eta_0)^2 + \zeta_0^2}]}} \quad (29)$$

is function of the coordinates of each node of star referred to its central node.

The coefficients m_0, η_0, ζ_0 , are functions of $\frac{1}{h_{jx}^2 + h_{jy}^2}$.

Denoting τ_l a the average of the distances between of the nodes of the star l and its central node and denoting τ the average of the τ_l values in the stars of the mesh, then

$$\mathbf{h}_j = \tau \begin{Bmatrix} \overline{h_{jx}} \\ \overline{h_{jy}} \end{Bmatrix} \quad (30)$$

$$\overline{m_0} = m_0 \tau^2; \quad \overline{\eta_0} = \eta_0 \tau^2; \quad \overline{\zeta_0} = \zeta_0 \tau^2 \quad (31)$$

The stability criterion can be rewritten

$$\Delta t < \frac{2\tau}{\beta \sqrt{(r^2 + 1)} \sqrt{(|\overline{m_0}| + |\overline{\eta_0}|) + \sqrt{(\overline{m_0} + \overline{\eta_0})^2 + \overline{\zeta_0}^2}}} \quad (32)$$

For the regular mesh case, the inequality 32 is

$$\Delta t < \frac{\tau}{\beta \sqrt{r^2 + 1}} \frac{2(\sqrt{2} - 1)\sqrt{3}}{\sqrt{5}} \quad (33)$$

Multiplying the right-hand side of inequality 35 by the factor

$$\frac{\sqrt{5}(\sqrt{2} + 1)}{\sqrt{3(|\overline{m_0}| + |\overline{\eta_0}|) + \sqrt{(\overline{m_0} + \overline{\eta_0})^2 + \overline{\zeta_0}^2}}} \quad (34)$$

the inequality 32 is obtained.

For each one of the stars of the cloud of nodes, we define the IIS for a star with central node in (x_0, y_0) as Eq. 34

$$IIS_{(x_0, y_0)} = \frac{\sqrt{5}(\sqrt{2} + 1)}{\sqrt{3(|\overline{m_0}| + |\overline{\eta_0}|) + \sqrt{(\overline{m_0} + \overline{\eta_0})^2 + \overline{\zeta_0}^2}}} \quad (35)$$

that takes the value of one in the case of a regular mesh and $0 < IIS \leq 1$

If the index IIS decreases, then absolute values of $\overline{m_0}$, $\overline{\eta_0}$, $\overline{\zeta_0}$ increases and then according with 33, Δt decreases and star dispersion increases (see 21, 22, 26 and 27).

The irregularity index of a cloud of nodes (IIC) is defined as the minimum of all the IIS of the stars of a cloud of nodes

$$IIC = \min\{IIS_{(x_z, y_z)}/z = 1, \dots, NT\} \quad (36)$$

where NT is the total number of nodes of the domain.

6 Recursive Equations

6.1 Recursive equations with PML in x-direction.

For computational convenience, we split the second order equations of motion (1) into five coupled first order equations by introducing the new field variables γ_{xx} , γ_{xy} , γ_{yy}

$$\left\{ \begin{array}{l} \rho \frac{\partial U_x(x, y, t)}{\partial t} = \frac{\partial \gamma_{xx}(x, y, t)}{\partial x} + \frac{\partial \gamma_{xy}(x, y, t)}{\partial y} \\ \rho \frac{\partial U_y(x, y, t)}{\partial t} = \frac{\partial \gamma_{xy}(x, y, t)}{\partial x} + \frac{\partial \gamma_{yy}(x, y, t)}{\partial y} \\ \frac{\partial \gamma_{xx}(x, y, t)}{\partial t} = (\lambda + 2\mu) \frac{\partial U_x(x, y, t)}{\partial x} + \lambda \frac{\partial U_y(x, y, t)}{\partial y} \\ \frac{\partial \gamma_{xy}(x, y, t)}{\partial t} = \mu \frac{\partial U_x(x, y, t)}{\partial y} + \mu \frac{\partial U_y(x, y, t)}{\partial x} \\ \frac{\partial \gamma_{yy}(x, y, t)}{\partial t} = \lambda \frac{\partial U_x(x, y, t)}{\partial x} + (\lambda + 2\mu) \frac{\partial U_y(x, y, t)}{\partial y} \end{array} \right. \quad (37)$$

We shall make two simplifications, we shall assume that the space far from the region of interest is homogeneous, linear and time invariant. Then, under these assumptions, the radiating solution in infinite space must be (superposition of plane waves):

$$\omega(\mathbf{x}, t) = \mathbf{W}(\mathbf{x}, t) e^{i(\boldsymbol{\kappa} \cdot \mathbf{x} - \omega t)} \quad (38)$$

As w is an analytic function of \mathbf{x} , then we can analytically continue it, evaluating the solution at complex values of \mathbf{x} . Then, the solution is not changed in the region of interest and the reflections are avoided.

$$\left\{ \begin{array}{l} U_x(x, y, t) = u_x(x, y) e^{-i\omega t} \Rightarrow \dot{U}_x(x, y, t) = -i\omega u_x(x, y) e^{-i\omega t} = -i\omega U_x(x, y, t) \\ U_y(x, y, t) = u_y(x, y) e^{-i\omega t} \Rightarrow \dot{U}_y(x, y, t) = -i\omega u_y(x, y) e^{-i\omega t} = -i\omega U_y(x, y, t) \\ \gamma_{xx}(x, y, t) = \Gamma_{xx}(x, y) e^{-i\omega t} \Rightarrow \dot{\gamma}_{xx}(x, y, t) = -i\omega \Gamma_{xx}(x, y) e^{-i\omega t} = -i\omega \gamma_{xx}(x, y, t) \\ \gamma_{xy}(x, y, t) = \Gamma_{xy}(x, y) e^{-i\omega t} \Rightarrow \dot{\gamma}_{xy}(x, y, t) = -i\omega \Gamma_{xy}(x, y) e^{-i\omega t} = -i\omega \gamma_{xy}(x, y, t) \\ \gamma_{yy}(x, y, t) = \Gamma_{yy}(x, y) e^{-i\omega t} \Rightarrow \dot{\gamma}_{yy}(x, y, t) = -i\omega \Gamma_{yy}(x, y) e^{-i\omega t} = -i\omega \gamma_{yy}(x, y, t) \end{array} \right. \quad (39)$$

Thus, we have a complex coordinate

$$\tilde{x} = x + if \quad (40)$$

As this complex coordinate is inconvenient, we have a change variables in this region (PML)

$$\partial \tilde{x} = (1 + i \frac{df}{dx}) \partial x \quad (41)$$

In order to have an attenuation rate in the PML independent of frequency (ω), we have

$$\frac{df}{dx} = \frac{\delta_x(x)}{\omega} \quad (42)$$

where ω is the angular frequency and δ_x is some function of x .

PML x-dir can be conceptually assumed up by a single transformation of the original equation. Then wherever an x derivative appears in the wave equations, it is replaced in the form

$$\frac{\partial}{\partial x} \rightarrow \frac{1}{1 + i \frac{\delta_x(x)}{\omega}} \frac{\partial}{\partial x} \quad (43)$$

The equations are frequency-dependent, and to avoid it a solution is to use an auxiliary differential equation (ADE) approach in the implementation of PML. The following equations are obtained

$$\left\{ \begin{array}{l} \frac{\partial U_x(x, y, t)}{\partial t} = \frac{1}{\rho} \left[\frac{\partial \gamma_{xx}(x, y, t)}{\partial x} + \frac{\partial \gamma_{xy}(x, y, t)}{\partial y} \right] + \psi_1(x, y, t) - \delta_x U_x(x, y, t) \\ \frac{\partial U_y(x, y, t)}{\partial t} = \frac{1}{\rho} \left[\frac{\partial \gamma_{xy}(x, y, t)}{\partial x} + \frac{\partial \gamma_{yy}(x, y, t)}{\partial y} \right] + \psi_2(x, y, t) - \delta_x U_y(x, y, t) \\ \frac{\partial \gamma_{xx}(x, y, t)}{\partial t} = (\lambda + 2\mu) \frac{\partial U_x(x, y, t)}{\partial x} + \lambda \frac{\partial U_y(x, y, t)}{\partial y} + \psi_3(x, y, t) - \delta_x \gamma_{xx}(x, y, t) \\ \frac{\partial \gamma_{xy}(x, y, t)}{\partial t} = \mu \frac{\partial U_x(x, y, t)}{\partial y} + \mu \frac{\partial U_y(x, y, t)}{\partial x} + \psi_4(x, y, t) - \delta_x \gamma_{xy}(x, y, t) \\ \frac{\partial \gamma_{yy}(x, y, t)}{\partial t} = \lambda \frac{\partial U_x(x, y, t)}{\partial x} + (\lambda + 2\mu) \frac{\partial U_y(x, y, t)}{\partial y} + \psi_5(x, y, t) - \delta_x \gamma_{yy}(x, y, t) \\ \frac{\partial \psi_1(x, y, t)}{\partial t} = \frac{\delta_x}{\rho} \frac{\partial \gamma_{xy}(x, y, t)}{\partial y} \\ \frac{\partial \psi_2(x, y, t)}{\partial t} = \frac{\delta_x}{\rho} \frac{\partial \gamma_{yy}(x, y, t)}{\partial y} \\ \frac{\partial \psi_3(x, y, t)}{\partial t} = \lambda \delta_x \frac{\partial U_y(x, y, t)}{\partial y} \\ \frac{\partial \psi_4(x, y, t)}{\partial t} = \mu \delta_x \frac{\partial U_x(x, y, t)}{\partial y} \\ \frac{\partial \psi_5(x, y, t)}{\partial t} = (\lambda + 2\mu) \delta_x \frac{\partial U_y(x, y, t)}{\partial y} \end{array} \right. \quad (44)$$

Where the five last equations 46 are ADE approach and the new field variables

$$\left\{ \begin{array}{l} \psi_1(x, y, t) = \frac{1}{\rho} i \frac{\delta_x}{\omega} \frac{\partial \gamma_{xy}(x, y, t)}{\partial y} \\ \psi_2(x, y, t) = \frac{1}{\rho} i \frac{\delta_x}{\omega} \frac{\partial \gamma_{yy}(x, y, t)}{\partial y} \\ \psi_3(x, y, t) = i \lambda \frac{\delta_x}{\omega} \frac{\partial U_y(x, y, t)}{\partial y} \\ \psi_4(x, y, t) = i \mu \frac{\delta_x}{\omega} \frac{\partial U_x(x, y, t)}{\partial y} \\ \psi_5(x, y, t) = i (\lambda + 2\mu) \frac{\delta_x}{\omega} \frac{\partial U_y(x, y, t)}{\partial y} \end{array} \right. \quad (45)$$

6.1.1 An scheme in GDFM for elastic part

Following [1], [2] and [4], the explicit difference formulae for the spatial derivatives of a function are obtained,

$$\frac{\partial U_x(x_0, y_0, n\Delta t)}{\partial x} = -m_{1,0}u_{x,0}^n + \sum_{j=1}^N m_{1,j}u_{x,j}^n; \quad \frac{\partial U_x(x_0, y_0, n\Delta t)}{\partial y} = -m_{2,0}u_{x,0}^n + \sum_{j=1}^N m_{2,j}u_{x,j}^n \quad (46)$$

and similarly for first spatial derivatives of the functions: $U_y, \gamma_{xx}, \gamma_{xy}, \gamma_{yy}, \psi_1, \psi_2, \psi_3, \psi_4, \psi_5$. Substituting Eq. 46 into Eq. 37 the an scheme in GFDM for elastic part are obtained

$$\left\{ \begin{array}{l} u_{x,0}^{n+1} = u_{x,0}^n + \frac{\Delta t}{\rho} [-m_{1,0}\gamma_{xx,0}^n + \sum_{j=1}^N m_{1,j}\gamma_{xx,j}^n - m_{2,0}\gamma_{xy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{xy,j}^n] \\ u_{y,0}^{n+1} = u_{y,0}^n + \frac{\Delta t}{\rho} [-m_{1,0}\gamma_{xy,0}^n + \sum_{j=1}^N m_{1,j}\gamma_{xy,j}^n - m_{2,0}\gamma_{yy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{yy,j}^n] \\ \gamma_{xx,0}^{n+1} = \gamma_{xx,0}^n + \Delta t [(\lambda + 2\mu)(-m_{1,0}u_{x,0}^n + \sum_{j=1}^N m_{1,j}u_{x,j}^n) \\ + \lambda(-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n)] \\ \gamma_{xy,0}^{n+1} = \gamma_{xy,0}^n + \Delta t [\mu(-m_{2,0}u_{x,0}^n + \sum_{j=1}^N m_{2,j}u_{x,j}^n) \\ + \mu(-m_{1,0}u_{y,0}^n + \sum_{j=1}^N m_{1,j}u_{y,j}^n)] \\ \gamma_{yy,0}^{n+1} = \gamma_{yy,0}^n + \Delta t [\lambda(-m_{1,0}u_{x,0}^n + \sum_{j=1}^N m_{1,j}u_{x,j}^n) \\ + (\lambda + 2\mu)(-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n)] \end{array} \right. \quad (47)$$

6.1.2 An scheme in GDFM for PML part

Substituting Eq. 46 into Eq. 44 the an scheme in GFDM for PML part are obtained

$$\left\{ \begin{array}{l}
 u_{x,0}^{n+1} = u_{x,0}^n + \frac{\Delta t}{\rho} [-m_{1,0}\gamma_{xx,0}^n + \sum_{j=1}^N m_{1,j}\gamma_{xx,j}^n - \\
 m_{2,0}\gamma_{xy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{xy,j}^n] + \Delta t[\psi_{1,0}^n - \delta_x u_{x,0}^n] \\
 u_{y,0}^{n+1} = u_{y,0}^n + \frac{\Delta t}{\rho} [-m_{1,0}\gamma_{xy,0}^n + \sum_{j=1}^N m_{1,j}\gamma_{xy,j}^n - \\
 m_{2,0}\gamma_{yy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{yy,j}^n] + \Delta t[\psi_{2,0}^n - \delta_x u_{y,0}^n] \\
 \gamma_{xx,0}^{n+1} = \gamma_{xx,0}^n + \Delta t[(\lambda + 2\mu)(-m_{1,0}u_{x,0}^n + \sum_{j=1}^N m_{1,j}u_{x,j}^n) + \\
 \lambda(-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n)] + \Delta t[\psi_{3,0}^n - \delta_x \gamma_{xx,0}^n] \\
 \gamma_{xy,0}^{n+1} = \gamma_{xy,0}^n + \Delta t[\mu(-m_{2,0}u_{x,0}^n + \sum_{j=1}^N m_{2,j}u_{x,j}^n) + \\
 \mu(-m_{1,0}u_{y,0}^n + \sum_{j=1}^N m_{1,j}u_{y,j}^n)] + \Delta t[\psi_{4,0}^n - \delta_x \gamma_{xy,0}^n] \\
 \gamma_{yy,0}^{n+1} = \gamma_{yy,0}^n + \Delta t[\lambda(-m_{1,0}u_{x,0}^n + \sum_{j=1}^N m_{1,j}u_{x,j}^n) + \\
 (\lambda + 2\mu)(-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n)] + \Delta t[\psi_{5,0}^n - \delta_x \gamma_{yy,0}^n] \\
 \psi_{1,0}^{n+1} = \psi_{1,0}^n + \frac{\Delta t}{\rho} \delta_x [-m_{2,0}\gamma_{xy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{xy,j}^n] \\
 \psi_{2,0}^{n+1} = \psi_{2,0}^n + \frac{\Delta t}{\rho} \delta_x [-m_{2,0}\gamma_{yy,0}^n + \sum_{j=1}^N m_{2,j}\gamma_{yy,j}^n] \\
 \psi_{3,0}^{n+1} = \psi_{3,0}^n + \lambda \Delta t \delta_x [-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n] \\
 \psi_{4,0}^{n+1} = \psi_{4,0}^n + \mu \Delta t \delta_x [-m_{2,0}u_{x,0}^n + \sum_{j=1}^N m_{2,j}u_{x,j}^n] \\
 \psi_{5,0}^{n+1} = \psi_{5,0}^n + (\lambda + 2\mu) \Delta t \delta_x [-m_{2,0}u_{y,0}^n + \sum_{j=1}^N m_{2,j}u_{y,j}^n]
 \end{array} \right. \quad (48)$$

6.2 Recursive equations with PML in x-direction and y-direction.

In this case

$$\begin{cases} \frac{\partial}{\partial x} \rightarrow \frac{\partial}{\partial x} (1 + i \frac{\delta}{\omega})^{-1} \\ \frac{\partial}{\partial y} \rightarrow \frac{\partial}{\partial y} (1 + i \frac{\delta}{\omega})^{-1} \end{cases} \quad (49)$$

We obtain

$$\begin{cases} \frac{\partial U_x(x, y, t)}{\partial t} = \frac{1}{\rho} \left[\frac{\partial \gamma_{xx}(x, y, t)}{\partial x} + \frac{\partial \gamma_{xy}(x, y, t)}{\partial y} \right] - \delta U_x(x, y, t) \\ \frac{\partial U_y(x, y, t)}{\partial t} = \frac{1}{\rho} \left[\frac{\partial \gamma_{xy}(x, y, t)}{\partial x} + \frac{\partial \gamma_{yy}(x, y, t)}{\partial y} \right] - \delta U_y(x, y, t) \\ \frac{\partial \gamma_{xx}(x, y, t)}{\partial t} = (\lambda + 2\mu) \frac{\partial U_x(x, y, t)}{\partial x} + \lambda \frac{\partial U_y(x, y, t)}{\partial y} - \delta \gamma_{xx}(x, y, t) \\ \frac{\partial \gamma_{xy}(x, y, t)}{\partial t} = \mu \frac{\partial U_x(x, y, t)}{\partial y} + \mu \frac{\partial U_y(x, y, t)}{\partial x} - \delta \gamma_{xy}(x, y, t) \\ \frac{\partial \gamma_{yy}(x, y, t)}{\partial t} = \lambda \frac{\partial U_x(x, y, t)}{\partial x} + (\lambda + 2\mu) \frac{\partial U_y(x, y, t)}{\partial y} - \delta \gamma_{yy}(x, y, t) \end{cases} \quad (50)$$

6.2.1 An scheme in GDFM for elastic part

The equations of the elastic part is given by Eq. 47

6.2.2 An scheme in GDFM for PML part

Substituting Eq. 46 into Eq. 50 the an scheme in GFDM for PML part are obtained

$$\begin{cases} u_{x,0}^{n+1} = u_{x,0}^n + \frac{\Delta t}{\rho} [-m_{1,0} \gamma_{xx,0}^n + \sum_{j=1}^N m_{1,j} \gamma_{xx,j}^n - \\ m_{2,0} \gamma_{xy,0}^n + \sum_{j=1}^N m_{2,j} \gamma_{xy,j}^n] - \Delta t \delta u_{x,0}^n \\ u_{y,0}^{n+1} = u_{y,0}^n + \frac{\Delta t}{\rho} [-m_{1,0} \gamma_{xy,0}^n + \sum_{j=1}^N m_{1,j} \gamma_{xy,j}^n - \\ m_{2,0} \gamma_{yy,0}^n + \sum_{j=1}^N m_{2,j} \gamma_{yy,j}^n] - \Delta t \delta u_{y,0}^n \\ \gamma_{xx,0}^{n+1} = \gamma_{xx,0}^n + \Delta t [(\lambda + 2\mu)(-m_{1,0} u_{x,0}^n + \sum_{j=1}^N m_{1,j} u_{x,j}^n) + \\ \lambda(-m_{2,0} u_{y,0}^n + \sum_{j=1}^N m_{2,j} u_{y,j}^n)] - \Delta t \delta \gamma_{xx,0}^n \\ \gamma_{xy,0}^{n+1} = \gamma_{xy,0}^n + \Delta t [\mu(-m_{2,0} u_{x,0}^n + \sum_{j=1}^N m_{2,j} u_{x,j}^n) + \\ \mu(-m_{1,0} u_{y,0}^n + \sum_{j=1}^N m_{1,j} u_{y,j}^n)] - \Delta t \delta \gamma_{xy,0}^n \\ \gamma_{yy,0}^{n+1} = \gamma_{yy,0}^n + \Delta t [\lambda(-m_{1,0} u_{x,0}^n + \sum_{j=1}^N m_{1,j} u_{x,j}^n) + \\ (\lambda + 2\mu)(-m_{2,0} u_{y,0}^n + \sum_{j=1}^N m_{2,j} u_{y,j}^n)] - \Delta t \delta \gamma_{yy,0}^n \end{cases} \quad (51)$$

7 Numerical Results

7.1 GFDM with known boundary conditions

Let us solve the Eq. 1, in $\Omega = [0, 2] \times [0, 1] \subset \mathbf{R}^2$, with Dirichlet boundary conditions

$$\begin{cases} U_x(0, y, t) = 0 & \forall y \in [0, 1] \\ U_x(1, y, t) = \sin 2 \sin y \cos(\sqrt{2}\beta t) & \forall y \in [0, 1] \\ U_x(x, 0, t) = 0 & \forall x \in [0, 1] \\ U_x(x, 1, t) = \sin x \sin 2 \cos(\sqrt{2}\beta t) & \forall x \in [0, 1] \end{cases}$$

$$\begin{cases} U_y(0, y, t) = 0 & \forall y \in [0, 1] \\ U_y(1, y, t) = \cos 2 \cos y \cos(\sqrt{2}\beta t) & \forall y \in [0, 1] \\ U_y(x, 0, t) = 0 & \forall x \in [0, 1] \\ U_y(x, 1, t) = \cos x \cos 2 \cos(\sqrt{2}\beta t) & \forall x \in [0, 1] \end{cases} \quad (52)$$

and initial conditions

$$U_x(x, y, 0) = \sin x \sin y; U_y(x, y, 0) = \cos x \cos y; \quad \frac{\partial U_x(x, y, 0)}{\partial t} = 0; \frac{\partial U_y(x, y, 0)}{\partial t} = 0 \quad (53)$$

using a regular mesh (see Fig. 3 with 861 nodes) and irregular meshes (see Figs. 4 and 5) with 861 nodes. The analytical solutions (see Fig. 6) is

$$U_x(x, y, t) = \cos(\sqrt{2}\beta t) \sin x \sin y; \quad U_y(x, y, t) = \cos(\sqrt{2}\beta t) \cos x \cos y \quad (54)$$

The weighting function is given by Eq. 29 and the criterion for the selection of star nodes is the quadrant criterion (see references [1, 4, 5]). The global error is evaluated for each time increment, in the last time step considered, using the following formula

$$Global \quad error = \frac{\sqrt{\frac{\sum_{j=1}^{NT} (sol(j) - exac(j))^2}{NT}}}{|exac_{max}|} \times 100 \quad (55)$$

where $sol(j)$ is the GFDM solution at the node j $exac(j)$ is the exact value of the solution at the node j , $exac_{max}$ is the maximum value of the exact solution in the cloud of nodes considered and NT is the total number of nodes of the domain.

Table 1 shows the global error, with $\Delta t = 0.0005$, for value of $\alpha = 1$ and $\beta = 0.5$, in the regular mesh (see Fig. 3) with $n = 500$.

Table 2 shows the values of the global error for several values of Δt , using the irregular mesh with 861 nodes (see Fig. 4), with $n = 500$ and $IIC = 0.9072$.

Table 3 shows the values of the global error for several values of Δt , using the irregular mesh with 861 nodes (see Fig. 5), with $n = 500$ and $IIC = 0.8312$.

Table 1: The global errors with $\alpha = 1; \beta = 0.5$

N of Nodes	Global Error U_x	Global Error U_y
861	0.0004222	0.0004712

Figure 6: Exact solution U_x without PML.

Table 2: Influence of the Δt in the global error with $\alpha = 1; \beta = 0.5; n = 500; IIC = 0.9072$

Δt	Global Error U_x	Global Error U_y
0.005	0.004105	0.004326
0.001	0.0017170	0.001374
0.0005	0.000662	0.000669

Table 3: Influence of the Δt in the global error with $\alpha = 1; \beta = 0.5; n = 500; IIC = 0.8312$

Δt	Global Error U_x	Global Error U_y
0.005	0.005234	0.005321
0.001	0.001983	0.002110
0.0005	0.000821	0.000840

7.2 GFDM with PML

Let us solve the Eq. 1, in $\Omega = [0, 2] \times [0, 1] \subset \mathbf{R}^2$, with homogeneous the Dirichlet boundary conditions and the initial conditions are given by Eq. 53, using the regular mesh with 861 nodes (see Fig. 6) used in subsection 7.1, the analytical solutions is given by Eq. 54. The weighting function is given by Eq. 28 and the criterion for the selection of star nodes is the quadrant criterion.

Figure 8 shows the graphic the approximated solution of u_x , after 100 time steps, with PML in x-direction and y-direction for $1.4 \leq x \leq 2$ and $0.6 \leq y \leq 1$ (see Fig. 7).

Figure 10 shows the graphic the approximated solution of u_x , after 100 time steps, with PML

Figure 7: Regular mesh with PML region. Figure 8: Approximated solution U_x with PML.

in x-direction and y-direction for $\leq x \leq 0.6$ and $0 \leq y \leq 0.2$, $0.8 \leq y \leq 1$ (see Fig. 9).

Figure 9: Regular mesh with PML region. Figure 10: Approximated solution U_x with PML.

8 Conclusions

This paper shows a scheme in generalized finite differences, for seismic wave propagation in 2-D. The von Neumann stability criterion has been expressed as a function of the coefficients of the star equation and the velocity ratio.

The investigated star dispersion has been related with the irregularity of the star using the irregularity indicator of the mesh. The use of irregular meshes, adjusted to the geometry of the problem, may create high dispersion in certain stars which is related to high values of the irregularity index of the mesh (IIC). In this case the mesh can be redefined by an adaptive process ([2]) until a mesh whit suitable dispersion and irregularity index values is obtained.

The formulation of the PML is compatible with GFDM and numerical results confirm that PML has an extraordinary performance in absorbing outgoing waves.

Abstract. *This paper shows the application of Generalized Finite Difference Method (GFDM) to dynamic analysis of beams and plates. The use of a meshless method with the possibility of using an irregular grid-point distribution can be of interest for modeling this problem.*

1 INTRODUCTION

The Generalized finite difference method (GFDM) is evolved from classical finite difference method (FDM). GFDM can be applied over general or irregular clouds of points [7]. The basic idea is to use moving least squares (MLS) approximation to obtain explicit difference formulae which can be included in the partial differential equations [9]. Benito, Ureña and Gavete have made interesting contributions to the development of this method [1, 2, 6, 4, 5, 12]. The paper [3] shows the application of the GFDM in solving parabolic and hyperbolic equations. This paper describes how the GFDM can be applied for solving dynamic analysis problems of plates [10, 11, 13].

The paper is organized as follows. Section 1 is the introduction. Section 2 describes the explicit generalized finite difference schemes. In section 3 is studied the von Neumann stability. In Section 4 is analyzed the relation between stability and irregularity of a cloud of nodes. In Section 5 some applications of the GFDM for solving problems of dynamic analysis are included. Finally, in Section 6 some conclusions are given.

2 EXPLICIT GENERALIZED FINITE DIFFERENCE SCHEMES

2.1 Vibrations of simple beam

Let us consider the problem governed by the following partial differential equation (pde)

$$\frac{\partial^2 U(x, t)}{\partial t^2} + A_1 \frac{\partial^4 U(x, t)}{\partial x^4} = F_1(x, t) \quad x \in (0, L), \quad t > 0 \quad (1)$$

with boundary conditions at the ends of the beam of length L for each particular case and initial conditions

$$U(x, 0) = 0; \quad \frac{\partial U(x, t)}{\partial t} \Big|_{(x, 0)} = F_2(x) \quad (2)$$

where F_1 and F_2 are two known smooth functions, the constant A_1 depends of the material and geometry of the beam.

Firstly, we use the explicit difference formulae for the values of partial derivatives in the space variable. The intention is to obtain explicit linear expressions for the approximation of partial derivatives in the points of the domain.

First of all, an irregular grid or cloud of points is generated in the domain. On defining the composition central node with a set of N points surrounding it (henceforth referred as nodes), the star then refers to the group of established nodes in relation to a central node. Each node in the domain have an associated star assigned [1, 5, 7, 9].

If u_0 is an approximation of fourth-order for the value of the function at the central node (U_0) of the star, with coordinate x_0 and u_j is an approximation of fourth-order for the value of the function at the rest of nodes, of coordinates x_j with $j = 1, \dots, N$, then, according to the Taylor series expansion

$$U_j = U_0 + h_j \frac{\partial U_0}{\partial x} + \frac{h_j^2}{2} \frac{\partial^2 U_0}{\partial x^2} + \frac{h_j^3}{6} \frac{\partial^3 U_0}{\partial x^3} + \frac{h_j^4}{24} \frac{\partial^4 U_0}{\partial x^4} + \dots \quad (3)$$

where $h_j = x_j - x_0$.

If in equation 3 the terms over fourth order are ignored. It is then possible to define the function $B_4(u)$ as in [1, 3, 4, 5, 7, 9]

$$B_4(u) = \sum_{j=1}^N \left[(u_0 - u_j + h_j \frac{\partial u_0}{\partial x} + \frac{h_j^2}{2} \frac{\partial^2 u_0}{\partial x^2} + \frac{h_j^3}{6} \frac{\partial^3 u_0}{\partial x^3} + \frac{h_j^4}{24} \frac{\partial^4 u_0}{\partial x^4}) w(h_j) \right]^2 \quad (4)$$

where $w(h_j)$ is the denominated weighting function.

If the norm 4 is minimized with respect to the partial derivatives the linear equations system is obtained

$$\mathbf{A}_4 \mathbf{D}_{u_4} = \mathbf{b}_4 \quad (5)$$

where

$$\mathbf{A}_4 = \begin{pmatrix} \sum_{j=1}^N h_j^2 w^2 & \sum_{j=1}^N \frac{h_j^3}{2} w^2 & \sum_{j=1}^N \frac{h_j^4}{6} w^2 & \sum_{j=1}^N \frac{h_j^5}{24} w^2 \\ & \sum_{j=1}^N \frac{h_j^4}{4} w^2 & \sum_{j=1}^N \frac{h_j^5}{12} w^2 & \sum_{j=1}^N \frac{h_j^6}{48} w^2 \\ & & \sum_{j=1}^N \frac{h_j^6}{36} w^2 & \sum_{j=1}^N \frac{h_j^7}{144} w^2 \\ & SYM & & \sum_{j=1}^N \frac{h_j^8}{576} w^2 \end{pmatrix} \quad (6)$$

and

$$\mathbf{D}_{u_4} = \left\{ \frac{\partial u_0}{\partial x} \quad \frac{\partial^2 u_0}{\partial x^2} \quad \frac{\partial^3 u_0}{\partial x^3} \quad \frac{\partial^4 u_0}{\partial x^4} \right\}^T \quad (7)$$

$$\mathbf{b}_4 = \left\{ \begin{array}{l} \sum_{j=1}^N (-u_0 + u_j) h_j w^2 \\ \sum_{j=1}^N (-u_0 + u_j) \frac{h_j^2}{2} w^2 \\ \sum_{j=1}^N (-u_0 + u_j) \frac{h_j^3}{6} w^2 \\ \sum_{j=1}^N (-u_0 + u_j) \frac{h_j^4}{24} w^2 \end{array} \right\} \quad (8)$$

and solving system 5 the explicit difference formulae are obtained as in [2]. On including the explicit expressions for the values of the partial derivatives the star equation is obtained

$$\frac{\partial^4 U(x, t)}{\partial x^4} \Big|_{(x_0, n)} = \eta_0 u_0 + \sum_{j=1}^N \eta_j u_j \quad (9)$$

with

$$\eta_0 + \sum_{j=1}^N \eta_j = 0 \quad (10)$$

Secondly, we shall use an explicit formula for the part of the equation 1 that depends on time. This explicit formula can be used to solve the Cauchy initial value problem. This method involves only one grid point at the advanced time level. The second derivative with respect to time is approached by

$$\frac{\partial^2 U}{\partial t^2} \Big|_{(x_0, y_0, n)} = \frac{u_0^{n+1} - 2u_0^n + u_0^{n-1}}{(\Delta t)^2} \quad (11)$$

If the equations 9 and 11 are substituted in equation 1 the following recursive relationship is obtained

$$u_0^{n+1} = 2u_0^n - u_0^{n-1} - A_1^2(\Delta t)^2[\eta_0 u_0^n + \sum_{j=1}^N \eta_j u_j^n] + F_1(x_0, n) \quad (12)$$

The first derivative with respect to the time is approached by the central difference formula

$$\frac{\partial U}{\partial t}|_{x,0} = \frac{u_0^1 - u_0^{-1}}{2\Delta t} = F_2(x_0) \Rightarrow u_0^{-1} = u_0^1 - 2\Delta t F_2(x_0) \quad (13)$$

If equation 13 is substituted in equation 12 and taking into account initials conditions (2), the following equation is obtained

$$u_0^1 = \Delta t F_2(x_0) + \frac{F_1(x_0, 0)}{2} \quad (14)$$

The equation 14 relates the value of the function at the central node of the star, at time $n = 1$, with the values $F_1(x_0, 0)$ and the initial conditions $F(x_0)$.

2.2 Vibrations of plates

Let us to consider the problem governed by

$$\frac{\partial^2 U(x, y, t)}{\partial t^2} + A_2^2 \left[\frac{\partial^4 U(x, y, t)}{\partial x^4} + 2 \frac{\partial^4 U(x, y, t)}{\partial x^2 \partial y^2} + \frac{\partial^4 U(x, y, t)}{\partial y^4} \right] = G_1(x, y, t) \\ (x, y) \in (0, L) \times (0, L), \quad t > 0 \quad (15)$$

with boundary conditions at the edges of the plate $[0, L] \times [0, L]$ for each particular case and initial conditions

$$U(x, y, 0) = 0; \quad \frac{\partial U(x, y, t)}{\partial t}|_{(x,y,0)} = G_2(x, y) \quad (16)$$

where G_1 and G_2 are two known smooth functions, the constant A_2 depends of the material and geometry of the plate.

In a similar way that the one used in the subsection previous. If u_0 is an approximation of fourth-order for the value of the function at the central node (U_0) of the star, with coordinates (x_0, y_0) and u_j is an approximation of fourth-order for the value of the function at the rest of nodes, of coordinates (x_j, y_j) with $j = 1, \dots, N$, then, according to the Taylor series expansion

$$U_j = U_0 + h_j \frac{\partial U_0}{\partial x} + k_j \frac{\partial U_0}{\partial y} + \frac{h_j^2}{2} \frac{\partial^2 U_0}{\partial x^2} + \frac{k_j^2}{2} \frac{\partial^2 U_0}{\partial y^2} + h_j k_j \frac{\partial^2 U_0}{\partial x \partial y} + \\ + \frac{h_j^3}{6} \frac{\partial^3 U_0}{\partial x^3} + \frac{k_j^3}{6} \frac{\partial^3 U_0}{\partial y^3} + \frac{h_j^2 k_j}{2} \frac{\partial^3 U_0}{\partial x^2 \partial y} + \frac{h_j k_j^2}{2} \frac{\partial^3 U_0}{\partial x \partial y^2} + \frac{h_j^4}{24} \frac{\partial^4 U_0}{\partial x^4} + \frac{k_j^4}{24} \frac{\partial^4 U_0}{\partial y^4} + \\ + \frac{h_j^3 k_j}{6} \frac{\partial^4 U_0}{\partial x^3 \partial y} + \frac{h_j^2 k_j^2}{4} \frac{\partial^4 U_0}{\partial x^2 \partial y^2} + \frac{h_j k_j^3}{6} \frac{\partial^4 U_0}{\partial x \partial y^3} + \dots \quad (17)$$

where $h_j = x_j - x_0$; $k_j = y_j - y_0$.

If in equation 17 the terms over fourth order are ignored. It is then possible to define the function

$$B_{14}(u) = \sum_{j=1}^N \left[(u_0 - u_j + h_j \frac{\partial u_0}{\partial x} + k_j \frac{\partial u_0}{\partial y} + \frac{h_j^2}{2} \frac{\partial^2 u_0}{\partial x^2} + \frac{k_j^2}{2} \frac{\partial^2 u_0}{\partial y^2} + h_j k_j \frac{\partial^2 u_0}{\partial x \partial y} + \right. \\ \left. + \frac{h_j^3}{6} \frac{\partial^3 u_0}{\partial x^3} + \frac{k_j^3}{6} \frac{\partial^3 u_0}{\partial y^3} + \frac{h_j^2 k_j}{2} \frac{\partial^3 u_0}{\partial x^2 \partial y} + \frac{h_j k_j^2}{2} \frac{\partial^3 u_0}{\partial x \partial y^2} + \frac{h_j^4}{24} \frac{\partial^4 u_0}{\partial x^4} + \frac{k_j^4}{24} \frac{\partial^4 u_0}{\partial y^4} + \right. \\ \left. + \frac{h_j^3 k_j}{6} \frac{\partial^4 u_0}{\partial x^3 \partial y} + \frac{h_j^2 k_j^2}{4} \frac{\partial^4 u_0}{\partial x^2 \partial y^2} + \frac{h_j k_j^3}{6} \frac{\partial^4 u_0}{\partial x \partial y^3} \right) w(h_j, k_j) \Big]^2 \quad (18)$$

where $w(h_j, k_j)$ is the denominated weighting function.

If the norm 18 is minimized with respect to the partial derivatives the linear equation system is obtained

$$A_{14} D_{u_{14}} = b_{14} \quad (19)$$

where A_{14} , $D_{u_{14}}$ and b_{14} can be obtained in a similar way that the one used in the expressions 6, 7 and 8, and solving system the explicit difference formulae are obtained. On including the explicit expressions for the values of the partial derivatives the star equation is obtained

$$\left[\frac{\partial^4 U(x, y, t)}{\partial x^4} + 2 \frac{\partial^4 U(x, y, t)}{\partial x^2 \partial^2} + \frac{\partial^4 U(x, y, t)}{\partial y^4} \right]_{(x_0, y_0, n)} = \mu_0 u_0 + \sum_{j=1}^N \mu_j u_j \quad (20)$$

with

$$\mu_0 + \sum_{j=1}^N \mu_j = 0 \quad (21)$$

If the equations 9 and 20 are substituted in equation 15 the following recursive relationship is obtained

$$u_0^{n+1} = 2u_0^n - u_0^{n-1} - A_2^2(\Delta t)^2 [\mu_0 u_0^n + \sum_{j=1}^N \mu_j u_j^n] + G_1(x_0, y_0, n) \quad (22)$$

Using a similar process for to obtain the equation 14 the following equation is obtained

$$u_0^1 = \Delta t G_2(x_0, y_0) + \frac{G_1(x_0, y_0, 0)}{2} \quad (23)$$

The expressions 12 and 22 relates the value of the function at the central node of star, at time step $n + 1$, with the values of the functions in the nodes of the star at time step n .

3 CONVERGENCE

According to Lax's equivalence theorem, if the consistency condition is satisfied, stability is the necessary and sufficient condition for convergence. In this section we study firstly the truncation error of the equations 1 and 14, and secondly consistency and stability.

3.1 Truncation error

As it is well known, the truncation errors for second order time derivative (TEt) is given as follows:

$$\frac{\partial^2 U(\mathbf{x}, t)}{\partial t^2} = \frac{u_0^{t+\Delta t} - 2u_0^t + u_0^{t-\Delta t}}{(\Delta t)^2} - \frac{(\Delta t)^2}{12} \frac{\partial^4 U(\mathbf{x}, t_1)}{\partial t^4} + \Theta((\Delta t)^4), t < t_1 < t + \Delta t \quad (24)$$

$$(TE_t) = -\frac{(\Delta t)^2}{12} \frac{\partial^4 U(\mathbf{x}, t_1)}{\partial t^4} + \Theta((\Delta t)^4), t < t_1 < t + \Delta t \quad (25)$$

In order to obtain the truncation error for space derivatives, Taylor's series expansion including higher order derivatives is used and then higher order functions $B_p^*[u]$, $p = 4, 14$ are obtained. The expressions of $B_p[u]$, $p = 4, 14$ are similar to the ones given in 4 and 18, but incorporating now higher order derivatives. If the new norms $B_p^*[u]$, $p = 4, 14$ are minimized with respect to the partial derivatives until the fourth order, the following linear equation systems are obtained:

$$\mathbf{A}_p \mathbf{D}_{u_p} = \mathbf{b}_p^* \quad (26)$$

where \mathbf{A}_p , \mathbf{D}_{u_p} and \mathbf{b}_p with $(p = 4, 14)$ are as previously calculated in 6, 7, 8 for $p = 4$ and similarly for $p = 14$, and \mathbf{b}_p^* can be split in two parts as follows

$$\mathbf{b}_p^* = \mathbf{b}_p + \mathbf{b}_p^{**} \quad (27)$$

where the new terms \mathbf{b}_p^{**} correspond to the new higher order derivatives incorporated in the Taylor's series expansion to extend the functions from $B_p[u]$, $p = 4, 14$ to $B_p^*[u]$, $p = 4, 14$.

Then a better approximation of the partial derivatives can be obtained using the inverse matrix \mathbf{A}_p^{-1}

$$\mathbf{D}_{u_p} = \mathbf{A}_p^{-1} \mathbf{b}_p + \mathbf{A}_p^{-1} \mathbf{b}_p^{**} \quad (28)$$

In the equation 28 the expression $\mathbf{A}_p^{-1} \mathbf{b}_p$ is the approximation used in the GFDM (see [3] and [12]) and then the truncation errors for spatial derivatives are given by

$$TE_{x_p} = \mathbf{A}_p^{-1} \mathbf{b}_p^{**} \quad (29)$$

We develop only the truncation error corresponding to $p = 4$ case. The other truncation error for $p = 14$ case can be obtained in a similar way that the one used in $p = 4$ case.

$$B_4^*(u) = \sum_{j=1}^N [(U_0 - U_j + h_j \frac{\partial U_0}{\partial x} + \frac{h_j^2}{2!} \frac{\partial^2 U_0}{\partial x^2} + \frac{h_j^3}{3!} \frac{\partial^3 U_0}{\partial x^3} + \frac{h_j^4}{4!} \frac{\partial^4 U_0}{\partial x^4} + \frac{h_j^5}{5!} \frac{\partial^5 U_0}{\partial x^5} + \frac{h_j^6}{6!} \frac{\partial^6 U_0}{\partial x^6} + \dots) w(h_j)]^2 \quad (30)$$

If the function 29 is minimized with respect partial derivatives up to the fourth order, the following linear equations system is defined

$$\mathbf{A}_4 \mathbf{D}_{u_4} = \left(\sum_{j=1}^N \Xi h_j \quad \sum_{j=1}^N \Xi \frac{h_j^2}{2!} \quad \sum_{j=1}^N \Xi \frac{h_j^3}{3!} \quad \sum_{j=1}^N \Xi \frac{h_j^4}{4!} \right)^T \quad (31)$$

where

$$\Xi = [-U_0 + U_j - \frac{h_j^5}{5!} \frac{\partial^5 U_0}{\partial x^5} - \frac{h_j^6}{6!} \frac{\partial^6 U_0}{\partial x^6} - \dots] w(h_j)^2 \quad (32)$$

with $N \geq 4$, and then

$$TE_{x_4} = -\frac{1}{A_1^2} \mathbf{A}_4^{-1} \times \left(\sum_{j=1}^N \Upsilon h_j \quad \sum_{j=1}^N \Upsilon \frac{h_j^2}{2!} \quad \sum_{j=1}^N \Upsilon \frac{h_j^3}{3!} \quad \sum_{j=1}^N \Upsilon \frac{h_j^4}{4!} \right)^T \quad (33)$$

where

$$\Upsilon = -[\frac{h_j^5}{5!} \frac{\partial^5 U_0}{\partial x^5} + \frac{h_j^6}{6!} \frac{\partial^6 U_0}{\partial x^6} + \dots] w(h_j)^2 \quad (34)$$

and operating

$$TE_{x_4} = \frac{1}{A_1^2} [\sum_{j=1}^N \Psi_{1,j} \frac{\partial^5 U}{\partial x^5} + \Psi_{2,j} \frac{\partial^6 U}{\partial x^6} + \dots] + \Theta(h_j) \quad (35)$$

where $\Psi_{1,j}(h_j)$ and $\Psi_{2,j}(h_j)$ are homogeneous rational functions of order two and $\Theta(h_j)$ is a series of third- and higher-order functions.

The expression 35 is the truncation error for spatial derivatives.

Taking into account that the total truncation errors (TTE) is given by

$$TTE = TE_t + TE_{x_4} \quad (36)$$

where TE_t and TE_{x_4} are given by 25 and 35 respectively.

3.2 Consistency

By considering bounded derivatives in 36

$$\lim_{(\Delta t, h_j) \rightarrow (0,0)} TTE \rightarrow 0 \quad (37)$$

Then, the truncation error condition given in 37 shows the consistency of the approximation.

3.3 Stability criterion

For the difference schemes, the von Neumann condition is sufficient as well as necessary for stability [8]. "Boundary conditions are neglected by the von Neumann method which applies in theory only to pure initial value problems with periodic initial data. It does however provide necessary conditions for stability of constant coefficient problems regardless of the type of boundary condition".

For the stability analysis the first idea is to make a harmonic decomposition of the approximated solution at grid points and at a given time level n . Then we can write the finite difference approximation in the nodes of the star at time n , as

$$u_0^n = \xi^n e^{i\nu^T \mathbf{x}_0}; \quad u_j^n = \xi^n e^{i\nu^T \mathbf{x}_j} \quad (38)$$

where ξ is the amplification factor,

$$\mathbf{x}_j = \mathbf{x}_0 + \mathbf{h}_j; \quad \xi = e^{-i\omega \Delta t}$$

$\boldsymbol{\nu}$ is the column vector of the wave numbers

$$\boldsymbol{\nu} = \begin{Bmatrix} \nu_x \\ \nu_y \end{Bmatrix}$$

then we can write the stability condition as: $\|\xi\| \leq 1$.

Including the equation 38 into the equation 12 or 22, cancelation of $\xi^n e^{i\boldsymbol{\nu}^T \mathbf{x}_0}$, leads to

$$\xi = 2 + \frac{1}{\xi} - (\Delta t)^2 A^2 (m_0 + \sum_1^N m_j e^{i\boldsymbol{\nu}^T \mathbf{h}_j}) \quad (39)$$

where A is the constant A_1 or A_2 respectively and m_0, m_j are the coefficients η_0, η_j or μ_0, μ_j . Using the equations 10 or 21 and after some calculus we obtain the quadratic equation

$$\xi^2 - \xi [2 + A^2 (\Delta t)^2 (\sum_1^N m_j (1 - \cos \boldsymbol{\nu}^T \mathbf{h}_j) - i \sum_1^N m_j \sin \boldsymbol{\nu}^T \mathbf{h}_j)] + 1 = 0 \quad (40)$$

Hence the values of ξ are

$$\xi = b \pm \sqrt{b^2 - 1} \quad (41)$$

where

$$b = 1 + \frac{A^2 (\Delta t)^2}{2} \sum_1^N m_j (1 - \cos \boldsymbol{\nu}^T \mathbf{h}_j) - i \frac{A^2 (\Delta t)^2}{2} \sum_1^N m_j \sin \boldsymbol{\nu}^T \mathbf{h}_j \quad (42)$$

If we consider now the condition for stability, we obtain

$$\|b \pm \sqrt{b^2 - 1}\| \leq 1 \quad (43)$$

Operating with the equations 42 and 43, canceling with conservative criteria, the condition for stability of star is obtained as

$$\Delta t \leq \frac{1}{4A\sqrt{|m_0|}} \quad (44)$$

4 IRREGULARITY OF THE STAR (IIS) AND STABILITY

In this section we are going to define the index of irregularity of a star (IIS) and also the index of irregularity of a cloud of nodes (IIC).

The coefficient m_0 is function of:

- The number of nodes in the star
- The coordinates of each star node referred to the central node of the star
- The weighting function (see references [1, 4])

If the number of nodes by star and the weighting function are fixed, then the equation 44 is function of the coordinates of each node of star referred to its central node.

Denoting τ_0 as the average of the distances between of the nodes of the star and its central node with coordinates (x_0, y_0) and denoting τ the average of the τ_0 values in the stars of the cloud of nodes, then

$$\overline{m_0} = m_0 \tau^4 \quad (45)$$

The stability criterion can be rewritten as

$$\Delta t < \frac{\tau^2}{4A\sqrt{|\overline{m}_0|}} \quad (46)$$

For the regular mesh case, the inequality 44 is for the cases of one and two dimensions as follows

$$\begin{cases} \Delta t < \frac{\sqrt{2}\tau^2}{18A\sqrt{3}} & \text{if } N = 4 \\ \Delta t < \frac{9\tau^2}{A\sqrt{13}[3(1+\sqrt{2})+2\sqrt{5}]^2} & \text{if } N = 24 \end{cases} \quad (47)$$

Multiplying the right-hand side of inequalities 47, respectively, by the factors

$$\begin{cases} \frac{9\sqrt{3}}{2\sqrt{2|\overline{m}_0|}} & \text{if } N = 4 \\ \frac{\sqrt{13}[3(1+\sqrt{2})+2\sqrt{5}]^2}{36\sqrt{|\overline{m}_0|}} & \text{if } N = 24 \end{cases} \quad (48)$$

the inequality 46 is obtained.

For each one of the stars of the cloud of nodes, we define the IIS for a star with central node in (x_0, y_0) as Eq. 48

$$\begin{cases} IIS_{x_0} = \frac{9\sqrt{3}}{2\sqrt{2|\overline{m}_0|}} & \text{if } N = 4 \\ IIS_{(x_0, y_0)} = \frac{\sqrt{13}[3(1+\sqrt{2})+2\sqrt{5}]^2}{36\sqrt{|\overline{m}_0|}} & \text{if } N = 24 \end{cases} \quad (49)$$

that takes the value of one in the case of a regular mesh and $0 < IIS \leq 1$

If the index IIS decreases, then absolute values of \overline{m}_0 increases and then according with 43, Δt decreases.

The irregularity index of a cloud of nodes (IIC) is defined as the minimum of all the IIS of the stars of a cloud of nodes.

5 NUMERICAL RESULTS

In this section we present different numerical results.

5.1 Transverse vibrations of a simply supported beam

In this section, the weighting function used is

$$\Omega(h_j) = \frac{1}{(\sqrt{h_j^2})^3} \quad (50)$$

The global exact error can be calculated as

$$Global \quad exact \quad error = \sqrt{\frac{\sum_{i=1}^{NT} e_i^2}{NT}} \quad (51)$$

Figure 1: regular and irregular mesh

Figure 2: irregular meshes

where NT is the number of nodes in the domain and e_i is the exact error in the node i .
Let us solve the pde

$$\frac{\partial^2 U(x, t)}{\partial t^2} + \frac{1}{\pi^4} \frac{\partial^4 U(x, t)}{\partial x^4} = 0 \quad x \in (0, 1), \quad t > 0 \quad (52)$$

with boundary conditions

$$\begin{cases} U(0, t) = U(1, t) = 0 \\ \frac{\partial^2 U(x, t)}{\partial x^2} \big|_{(0, t)} = \frac{\partial^2 U(x, t)}{\partial x^2} \big|_{(1, t)} = 0, \end{cases} \quad (53)$$

and initial conditions

$$U(x, 0) = 0; \quad \frac{\partial U(x, t)}{\partial t} \big|_{(x, 0)} = \sin(\pi x) \quad (54)$$

The exact solution is

$$U(x, t) = \sin(\pi x) \sin t \quad (55)$$

Table 1 shows the results of the global error, using a regular mesh of 21 nodes (figure 1), for several values of Δt .

Δt	Global error	IIC	Global error
0.005	0.00276	0.96	0.00107
0.002	0.00109	0.78	0.00295
0.001	0.00017	0.62	0.00534
0.0005	0.00002	0.46	0.00903

Table 1: Influence of Δt in the global error.

Table 2: Influence of irregularity of mesh in the global error

Table 2 shows the results of global error with $\Delta t = 0.001$ for several irregular meshes of 21 nodes (figures 1 and 2). We have established a measure of the irregularity of the nodes distribution in the domain. For this purpose we have assigned to every node in the domain a value that corresponds with the average of the distances from it to the rest of its star nodes. Then, the index of irregularity (IIC) is defined as the standard deviation of these values.

Figure 3 shows the approximated solution of the equations 52, 53 and 54 in the last time step ($n = 1000$) with $\Delta t = 0.005$.

As new initial conditions let us assume that due to impact an initial velocity is given to a point of the beam at the distance $x = 0.5$ from the left-hand support, which give the initial conditions

$$U(x, 0) = 0; \quad \begin{cases} \frac{\partial U(x, t)}{\partial t} \big|_{(x, 0)} = 1 & \text{if } x = 0.5 \\ \frac{\partial U(x, t)}{\partial t} \big|_{(x, 0)} = 0 & \text{if } x \neq 0.5 \end{cases} \quad (56)$$

Figure 3: Approximated solution in the last time step ($\Delta t = 0.005$)

Figure 4: Approximated solution with $n=100$ Approximated solution with $n=200$

The exact solution in this case is given by

$$U(x, t) = 2(\sin(\pi x) \sin(t) - \frac{1}{9} \sin(3\pi x) \sin(9t) + \frac{1}{25} \sin(5\pi x) \sin(25t) - \dots) \quad (57)$$

Table 3 shows the results of the global error, using a regular mesh of 21 nodes (figure 1) and $\Delta t = 0.001$, when we increases the number of time steps (n).

Figures 4 and 5 shows the approximated solution of the equation 52 with the initial conditions

n	Global error
100	0.001628
200	0.001700
500	0.001816
1000	0.002252

Table 3: Variation of global error versus the number of time steps.

56 in the last time step for $n = 100$, $n = 200$, $n = 500$ and $n = 1000$ respectively.

5.2 Forced vibrations of a simply supported beam

In this section, the weighting function used is 50 and the global error is calculated by 51
The pde is given by

$$\frac{\partial^2 U(x, t)}{\partial t^2} + \frac{1}{\pi^4} \frac{\partial^4 U(x, t)}{\partial x^4} = 15 \sin(2\pi x) \sin t \quad x \in (0, 1), \quad t > 0 \quad (58)$$

with boundary conditions

$$\begin{cases} U(0, t) = U(1, t) = 0 \\ \frac{\partial^2 U(x, t)}{\partial x^2} \big|_{(0, t)} = \frac{\partial^2 U(x, t)}{\partial x^2} \big|_{(1, t)} = 0, \end{cases} \quad (59)$$

Figure 5: Approximated solution with $n=500$ Approximated solution with $n=1000$

Figure 6: Approximated solution in the last step ($\Delta t = 0.005$)

and initial conditions

$$U(x, 0) = 0; \quad \frac{\partial U(x, t)}{\partial t} \Big|_{(x, 0)} = \sin(\pi x) + \sin(2\pi x) \quad (60)$$

The exact solution for this case is given by

$$U(x, t) = (\sin(\pi x) + \sin(2\pi x)) \sin t \quad (61)$$

Table 4 shows the results of the global error, using a regular mesh of 21 nodes (figure 1) for several values of Δt .

Table 5 shows the results of global error with $\Delta t = 0.001$ for several irregular meshes of 21 nodes (figures 1 and 2).

Figure 6 shows the approximated solution of the equation 57 in the last time step ($n = 1000$)

Δt	Global error	IIC	Global error
0.005	0.01025	0.96	0.00744

6 CONCLUSIONS

The use of the generalized finite difference method using irregular clouds of points is an interesting way of solving partial differential equations. The extension of the generalized finite difference to the explicit solution of some dynamic analysis problems has been developed.

The von Neumann stability criterion has been expressed in function of the coefficients of the

star equation for irregular cloud of nodes.

The index of irregularity of a clouds of nodes (IIC) is given and, also, its relation with the stability. As it is shown in the numerical results, a decrease in the value of the time step, always below the stability limits, leads to a decrease of the global error.

Keywords: Smoothed Particle Hydrodynamics, non-cohesive sediment, reservoir flushing, underwater explosion, experimental validation.

Abstract. *This work shows an application of the Smoothed Particle Hydrodynamics (SPH) for the numerical modeling of engineering problems involving rapid evolution over time, high strain and gradients, heterogeneity, deformable contours and the presence of mobile material interfaces.*

Following a Lagrangian approach the continuum is discretized by means of a finite number of material particles carrying physical properties and moving according to Newton's equations of the classical physics. Spatial derivatives of a variable at a point are approximated by using the information on the neighboring particles based on the kernel approximation.

This paper recalls the basics of the method along with some numerical aspects concerning boundaries treatment, time integration scheme etc.; furthermore some details are provided about the recent improvements carried out for SPH simulations of: a) non-cohesive sediment flushing by rapid water discharge in an hydropower reservoir, b) underwater explosion for bottom sediment resuspension in an artificial reservoir.

Numerical examples are illustrated and discussed concerning 2D and 3D test cases carried out with the aim of investigating the basic features of both sediment dynamics and gas explosion: obtained results shows that the SPH method can be applied to model the relevant engineering aspects of the considered problems and can be a helpful tool for future design applications in the field of hydropower reservoir management.

1 INTRODUCTION

The key idea at the base of a meshfree method is to obtain a discretization of the continuum through a set of arbitrarily distributed nodes (or particles) that lack of a connective mesh and can adapt to possible topological and geometrical changes.

With respect to traditional grid-based approaches, a meshless method allows tracing the deformation undergone by the material without excessive degradation of numerical results (owing to conflicts between mesh and physical compatibility) and high computational effort (e.g. adaptive mesh refinement).

When the nodes assumes a physical meaning (i.e. they represent material particles carrying physical properties such as mass, momentum etc.) is said a meshfree particle method and follows, in general, a Lagrangian approach.

Among the different meshfree particle methods the Smoothed Particle Hydrodynamics (SPH) was originally developed as a probabilistic model for simulating astrophysical problems [1, 2]. It was later modified as a deterministic meshfree particle method and applied to continuum solid and fluid mechanics [3, 4] because the kinematics and dynamics of the liquid particles, responding to Newton's Equations of the classical physics, could be described in analogy with the simulation of the collective movement of astrophysical particles at large scale.

According to standard SPH, a continuous physical quantity $A(\mathbf{x})$, defined on the domain Ω as a function of the position vector \mathbf{x} , and its spatial derivatives at the i -th material point are approximated by using the information on the neighboring particles based on the kernel estimate.

This procedure adopts a kernel function $W(r, h)$, which is continuous, non-zero and depends on the modulus of the relative position $r = |\mathbf{x}_i - \mathbf{x}_j|$ of the neighboring j -th particle falling within a circular space (spherical in 3D problems) with radius $2h$, where h is generally referred to as the smoothing length (Fig.1).

Figure 1: Typical representation of particle discretization and kernel function.

The SPH approximation of the field function $A(\mathbf{x})$ originates from the concept of integral representation:

$$A(\mathbf{x}) = \int_{\Omega} \delta(\mathbf{x} - \mathbf{x}') A(\mathbf{x}') d\Omega_{\mathbf{x}'} \quad (1)$$

In Eq.1 the Dirac delta function δ is replaced by the kernel function leading to the kernel approximation:

$$\langle A(\mathbf{x}) \rangle = \int_{\Omega} W(r, h) A(\mathbf{x}') d\Omega_{\mathbf{x}'} \quad (2)$$

The discrete form of the Eq.2, for the set of material particles representing the discretized continuum, can be obtained by the so called particle approximation:

$$\langle A(\mathbf{x}_i) \rangle = \sum_{j=1}^N \frac{m_j}{\rho_j} A(\mathbf{x}_j) W(r_{ij}, h) \quad (3)$$

The summation in Eq.3 is extended over the N -neighboring particles, having volume $\Delta V_j = m_j / \rho_j$, falling within the compact support (or influence domain) Ω_i of the i -th particle.

In a similar fashion it can be demonstrated that the particle approximation of the function derivative can be obtained by shifting the differential operation on the kernel; two alternative expressions are commonly adopted in fluid mechanics [5, 6]:

$$\begin{aligned} \langle \nabla \cdot A(\mathbf{x}_i) \rangle &= \frac{1}{\rho_i} \sum_{j=1}^N m_j [A(\mathbf{x}_j) - A(\mathbf{x}_i)] \cdot \nabla W(r_{ij}, h) \\ \langle \nabla \cdot A(\mathbf{x}_i) \rangle &= \rho_i \sum_{j=1}^N m_j \left[\frac{A(\mathbf{x}_j)}{\rho_j^2} + \frac{A(\mathbf{x}_i)}{\rho_i^2} \right] \cdot \nabla W(r_{ij}, h) \end{aligned} \quad (4)$$

Applying the SPH interpolation, the Lagrangian form of the Navier-Stokes equations for a weakly compressible viscous fluid can be transformed into a system of ordinary differential equations that, by adopting the equations (4) and replacing $W(r_{ij}, h)$ with W_{ij} , are written as:

$$\begin{aligned} \left\langle \frac{D\rho}{Dt} \right\rangle_i &= - \sum_{j=1}^N m_j (\mathbf{u}_j - \mathbf{u}_i) \cdot \nabla W_{ij} \\ \left\langle \frac{D\mathbf{u}}{Dt} \right\rangle_i &= - \sum_{j=1}^N m_j \left(\frac{p_i}{\rho_i^2} + \frac{p_j}{\rho_j^2} + \Pi_{ij} \right) \nabla W_{ij} + \mathbf{g} \\ &\quad + \sum_{j=1}^{N_i} \frac{m_j}{\rho_i \rho_j} \frac{4\mu_i \mu_j}{\mu_i + \mu_j} \frac{\mathbf{x}_{ij} \cdot \nabla W_{ij}}{\mathbf{x}_{ij}^2 + 0.01h^2} \mathbf{u}_{ij} \end{aligned} \quad (5)$$

The additional term Π_{ij} in Eq.5 is the so called Monaghan artificial viscosity [4] introduced for numeric stability:

$$\Pi_{ij} = \begin{cases} \frac{-\alpha_M (c_{si} + c_{sj})}{\rho_i + \rho_j} \phi_{ij} + \frac{2\beta_M}{\rho_i + \rho_j} \phi_{ij}^2 & \text{if } \mathbf{u}_{ij} \cdot \mathbf{x}_{ij} < 0 \\ 0 & \text{if } \mathbf{u}_{ij} \cdot \mathbf{x}_{ij} > 0 \end{cases} \quad \phi_{ij} = \frac{h \mathbf{u}_{ij} \cdot \mathbf{x}_{ij}}{\mathbf{x}_{ij}^2 + (0.1h)^2} \quad (6)$$

There are several advantages that can be obtained from such an approach: representation of the evolution of both free-surfaces, moving-interfaces and breaking becomes more simple to face with [7]; treatment of large deformation and shock problems becomes a relatively easier task [8]; the particle tracking along with the relevant field variables can be obtained by numerical solution of the discretized set of governing equations in Lagrangian form [9].

2 NUMERICAL ASPECTS

The solution strategy of a meshfree particle method follows a pattern similar to a grid-based method.

The computational domain is divided into a finite number of particles, followed by the numerical discretization of the system of partial differential equations according to the procedure described in the previous section; the resulting ordinary differential equations are solved through any stable time-stepping algorithm [10]: here a first order explicit numerical scheme is used and a cubic spline function is adopted for kernel representation [8].

The obtained velocity field allows one to update the particle position \mathbf{x} and to compute the density field by means of the continuity equation (1); the pressure p_i at each point is then calculated through the equation of state for a weakly compressible fluid and then smoothed out:

$$p_i = p_{0i} + \frac{\varepsilon}{\rho} (\rho_i - \rho_{0i})$$

$$p_i^{smth} = p_i + \mathcal{G}_p \frac{\sum_{j=1}^N (p_j - p_i) \Delta V_j W_{ij}}{\sum_{j=1}^N \Delta V_j W_{ij}} \quad (7)$$

Solid boundaries are treated by means of the semi-analytic technique [8]. Each portion of the solid contour contributing to the mass and momentum equations of the generic i -th particle is replaced by a fluid region extending beyond the boundary and treated as a material continuum with uniform velocity ($\mathbf{u}_b = \mathbf{u}_i$), and hydrostatic pressure distribution (Fig.2).

Figure 2: Schematic of boundary treatment (2D case).

A typical term for boundary contribution in the balance equations is:

$$C_1 \int_{\alpha} C_2 J_n(\vartheta, \varphi) d\alpha$$

$$\text{with: } C_1 = f(\rho_i, \mathbf{u}_i, \mathbf{u}_b, \nu) \quad C_2 = f(\nabla r) \quad J_n(\vartheta, \varphi) = \int_{r_b(\vartheta, \varphi)}^{2h} \frac{dW}{dr} r^n dr \quad (8)$$

In Eq.8 $\alpha = f(\vartheta, \varphi)$ denotes the solid angle under which the i -th particle sees the portion of the solid boundary intersected by its sphere of influence and the integrals J_n ($n=1, 2, 3$) depends on the boundary's geometry and can be computed analytically.

3 MODELING NON-COHESIVE SEDIMENT FLUSHING

This Section illustrates some details concerning the SPH modeling of fluid-sediment coupled dynamics in flushing problems induced by rapidly varied water flows.

Figure 3: Sketch of the bottom sediment.

In a typical situation schematized by Fig.3, the solid grains can be: *a*) at or very close to the fluid-sediment interface and thus exposed to the hydrodynamic bottom shear or *b*) hidden by the overlaying solid particles.

3.1 Exposed grains

In the first condition the erosion of a single grain is evaluated by means of a failure criterion which is based on the Shields theory and defines a critical threshold that triggers the motion of the solid particle.

The critical bottom shear for an horizontal bed $\tau_{b\ cr,0}$ is evaluated through the Shields parameter ϑ_{cr} which can be computed as a function of the grain Reynolds number Re_* :

$$\vartheta_{cr} \equiv \frac{\tau_{b\ cr,0}}{(\rho^s - \rho) g d} = f(Re_* \equiv u_* d_{50} / \nu) \quad (9)$$

The erosion of the grain occurs only if the critical bottom shear is exceeded by the hydrodynamic bottom shear:

$$\tau_b = \rho u_*^2 \quad (10)$$

From equations (9) and (10) follows that the friction velocity u_* should be evaluated for determining particle erosion: this is obtained from the computed fluid velocity u^l at a given position z close to the water-sediment interface and assuming a logarithmic velocity profile:

$$u^l(z) = \frac{u_*}{\kappa} \ln\left(\frac{z}{z_0}\right) \quad (11)$$

An iterative procedure should be applied since the characteristic bed roughness z_0 is a function of the friction velocity in turn.

Additional corrective coefficients should be introduced in order to account for a reduction of $\tau_{b\ cr,0}$ owing to both longitudinal and transverse bed slope [11].

If a solid particle is eroded it is considered as a viscous fluid whose kinematics and dynamics responds to the governing equations (5); elsewhere is treated as explained in the following point.

3.2 Hidden grains

In the second condition granular particles are treated as part of the boundary and excluded from the computation of the velocity and density fields; their total pressure (p_i^{tot}) is imposed according to the lithostatic condition and then included in the pressure smoothing of the fluid particles:

$$\begin{aligned} p_i^{ls} &= \zeta_i^{ws} g \rho + p_i^l + \frac{(u_i^l)^2}{2} \rho \\ p_i^{tot} &= p_i^{ls} + \zeta_i^s g \rho^s \end{aligned} \quad (13)$$

Equations (13) imply that the total pressure at the i -th particle inside the solid matrix can be evaluated only if ζ_i^s and ζ_i^{ws} are known: this means that the local fluid-sediment interface needs to be identified at each time step. Such task is accomplished, with a relatively reduced effort, within the algorithm for the neighboring particle search: the spatial domain is divided into squared columns with base length of $2h$ and, for each column, the highest solid and the lowest fluid particles are stored and adopted for imposing the total lithostatic pressure at every time step.

4 MODELING GAS EXPLOSION

The explosion process of a high explosive (HE) material is characterized by a violent oxidation involving a chemical compound and an oxidizer; since the internal energy of the products is lower than the one of the reactants, a great amount of heat (say reaction heat) is quickly released [12].

Even if such a phenomenon develops at very high speed of reaction, in the early phase it is characterized by two distinct inhomogeneous zones: a detonation-produced explosive gas and a non-oxidized explosive; between them a very thin layer exists which represents the front of a reacting shock wave (detonation wave) advancing with a characteristic velocity U .

Anyway in several applications the detonation speed can be assumed indefinitely high and the HE charge completely transformed into gaseous products; their expansion can be analyzed by considering the Euler equation for an inviscid fluid and assuming adiabatic process [6, 13].

As a result the viscous contribution at the right hand side of the linear momentum Eq.5 is neglected, and a balance equation for the gas internal energy is introduced:

$$\left\langle \frac{De}{Dt} \right\rangle_i = \frac{1}{2} \sum_{j=1}^N m_j \left(\frac{p_i}{\rho_i^2} + \frac{p_j}{\rho_j^2} + \Pi_{ij} \right) (\mathbf{u}_i - \mathbf{u}_j) \cdot \nabla W_{ij} \quad (14)$$

The state equation given by eq.15 is used for adiabatic transformation.

$$p_i = (\gamma - 1) \rho_i e_i \quad (15)$$

The kernel function adopted in subsequent analyses is a quintic spline [14], while the time integration is carried out through an explicit numerical scheme deriving from the symplectic algorithm [15].

5 NUMERICAL EXAMPLES

This section provides some numerical results concerning basic SPH simulations of both sediment flushing and gas explosion; the models previously described are adopted.

5.1 Sediment flushing

In the following are illustrated 2D and 3D numerical simulations of non-cohesive sediment flushing by a rapid water flow.

Figure 4: Longitudinal cross-section of the sediment flushing model.

The problem set up is schematized in Fig.4: it simplifies a more refined laboratory test [16] for the analysis of sediment erosion at the midsection of a long-narrow artificial reservoir induced by the opening of the bottom outlet for siltation control.

In order to moderate the computational time, the volume of both sediment and stored water has been lowered by reducing the longitudinal length of the tank toward its left-hand boundary; at the initial time the same water level as in the abovementioned experiment has been assumed, thus keeping the hydraulic head invariant.

The horizontal deposit of non-cohesive sediment is composed of uniform sand with median diameter $d_{50}=0.1$ mm, bed porosity $n=0.53$ and saturated unit volume density $\rho^s=1750$ kg/m³.

The longitudinal measures of the SPH model are shown in Fig.4; the transverse thickness of the 3D model is equal to 0.03m; the resulting total particles number (water plus sediment)

is 3300 and 9900 respectively in the 2D and 3D geometry (transverse thickness equal to 0.03 m); other relevant physical and numerical model parameters are summarized in Tab.1.

MODEL PARAMETERS		
h_0	interpart. distance	0.01 m
h	smoothing length	$1.25 h_0$
ρ_0	water ref. density	1000 kg/m^3
ρ^s	sediment ref. density	1750 kg/m^3
μ	water viscosity	$1.0\text{E-}3 \text{ Pa/s}$
μ^s	sediment viscosity	750 Pa/s
ε	water comp. modulus	$1.0\text{E-}6 \text{ kg/(m s}^2\text{)}$
ε^s	sediment comp. mod.	$1.75\text{E-}6 \text{ kg/(m s}^2\text{)}$
α_M	artificial viscosity	0.2
β_M	artificial viscosity	0.0
\mathcal{G}_p	pressure smoothing	0.2
d_{50}	median grain diameter	$1.0\text{E-}4 \text{ m}$
k_s	char. grain roughness	$3.0 d_{50}$

Table 1: Principal model parameters adopted for flushing computations.

At the initial time the sediment bed has a vertical thickness of 0.165 m; the water height is 0.8 m and it is discharged from the lower right-hand side of the tank at a constant flow rate of $q_0 = 7.9\text{E-}3 \text{ m}^3/\text{s}$ producing the scouring of the bottom sediment.

Figure 5: Comparison of eroded profile in 3D (left-hand) and 2D geometry at $t = 11.0 \text{ s}$.

Fig.5 shows a comparison of the eroded sediment profiles at time 11s; water particles are depicted in blue while the color of solid grains depends on their status: the red indicates fixed particles (both hidden and exposed) that are treated as a solid boundary and excluded from the computation, while the green color denotes eroded sediment transported as bed load; the latter are located in that zone where the velocity reaches the highest values (see Fig.6) and are confined within a distance of $2h$ from the water-sediment interface.

From Fig.5 can be seen a good qualitative agreement between 3D and 2D model: similar water free surface and eroded profile are obtained; in both cases the sediment slope is characterized by the presence of a sub-horizontal berm past the intake: this is consistent with

the velocity profile along the flow path during the transient phase and is confirmed by the experimental test during the early phase.

Figure 6: Pressure (left-hand) and velocity profile in 3D model.

Figure 6 displays pressure and velocity profiles obtained with the 3D geometry at $t = 9.00$ s: lithostatic pressure distribution in the fixed solid particles is visible; the velocity modulus is maximum around the intake.

5.2 Gas explosion

In the following are shown some numerical simulations of the expansion process of a HE gas; both the underwater and vacuum expansion of a circular-shaped charge are considered. As previously specified the detonation velocity U is assumed to be indefinitely high with respect to the gas kinematic: thus the explosive charge is assumed completely detonated.

Table 2 summarizes the relevant model parameters adopted in subsequent computations.

MODEL PARAMETERS		
h_0	interpart. distance	0.005 m
h	smoothing length	$1.3 h_0$
ρ_0	water ref. density	1000 kg/m^3
ρ_0^g	gas ref. density	1630 kg/m^3
e_0	spec. detonation energy	$4.29\text{E}+06 \text{ J/kg}$
c_s	speed of sound	$5.0\text{E}+4 \text{ m/s}$
α_M	artificial viscosity	0.2
β_M	artificial viscosity	10.0
\mathcal{V}_v	velocity smoothing	0.2
γ_W	water state equation	1.4 – 7.0
γ_G	gas state equation	1.4

Table 2: Principal model parameters adopted for gas explosion computations.

When considering the vacuum gas expansion, at the initial time 20 particles are placed in the radial direction while 60 particles are positioned along the tangential direction resulting in a total number of 1200. The particle position, velocity and pressure are depicted in Fig.7 at time intervals of $10\mu\text{s}$; axes labels are in meters.

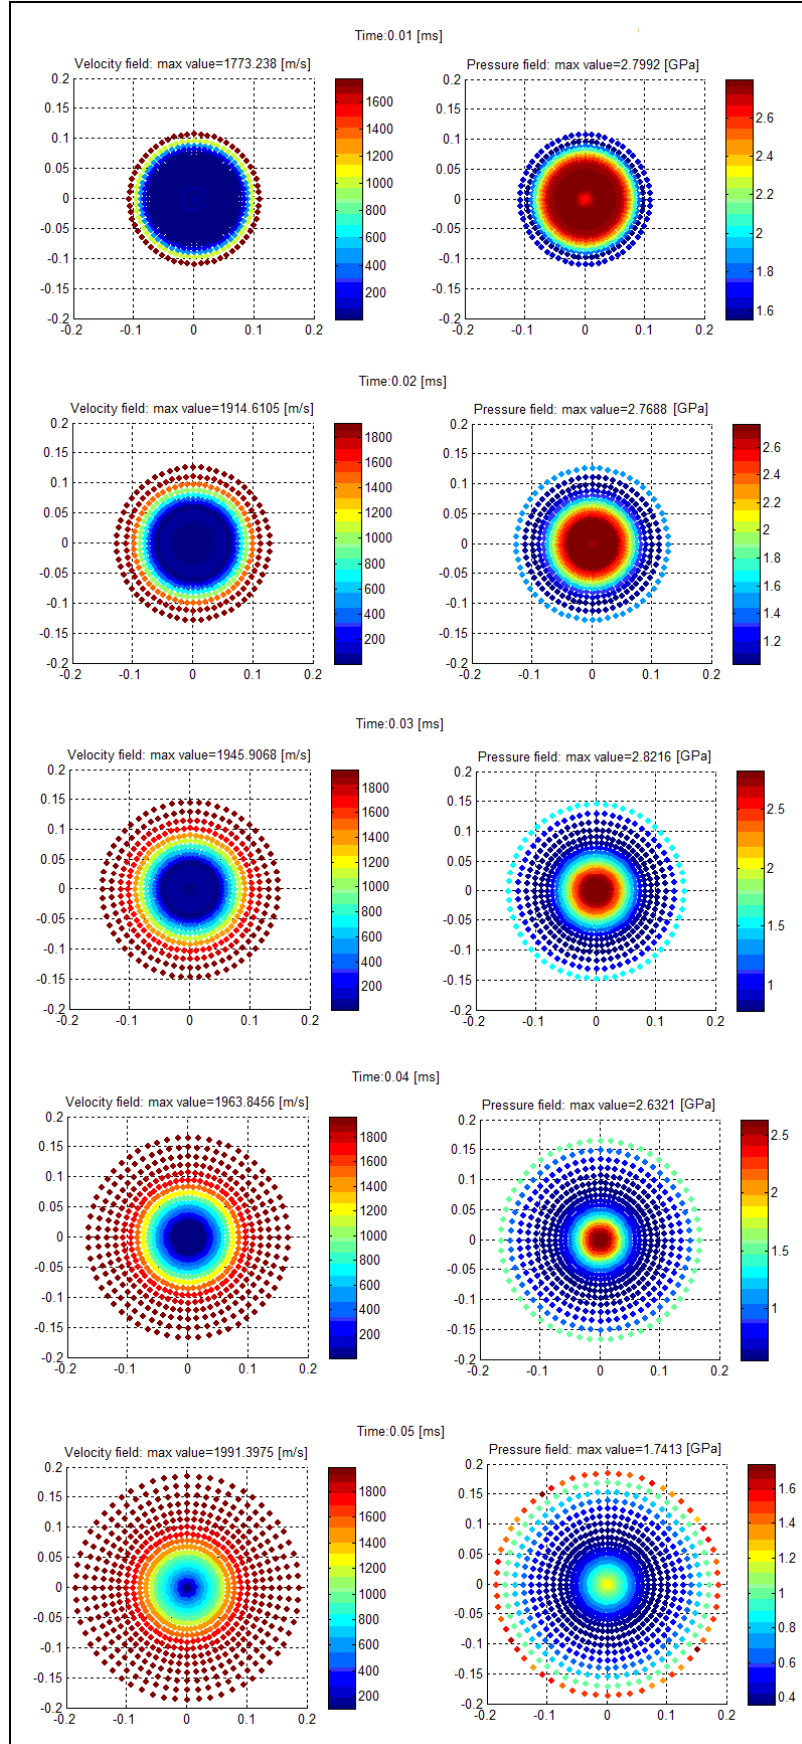

Figure 7: Expansion of detonated gas in vacuum; axes scale in meters.

The charge centre represents a singular point since no particle is placed on it and this explains the lower pressure.

The expansion process reflects theoretical expectation until $t=40\mu\text{s}$: past that time some irregularities in the pressure distribution at the outer boundary of the gaseous mass appear; such a fact should be connected with the lack of information owing to the low number of neighbors in the interaction domain of external particles.

Such non-physical behavior is however avoided if a surrounding medium is considered for confinement of the explosive charge.

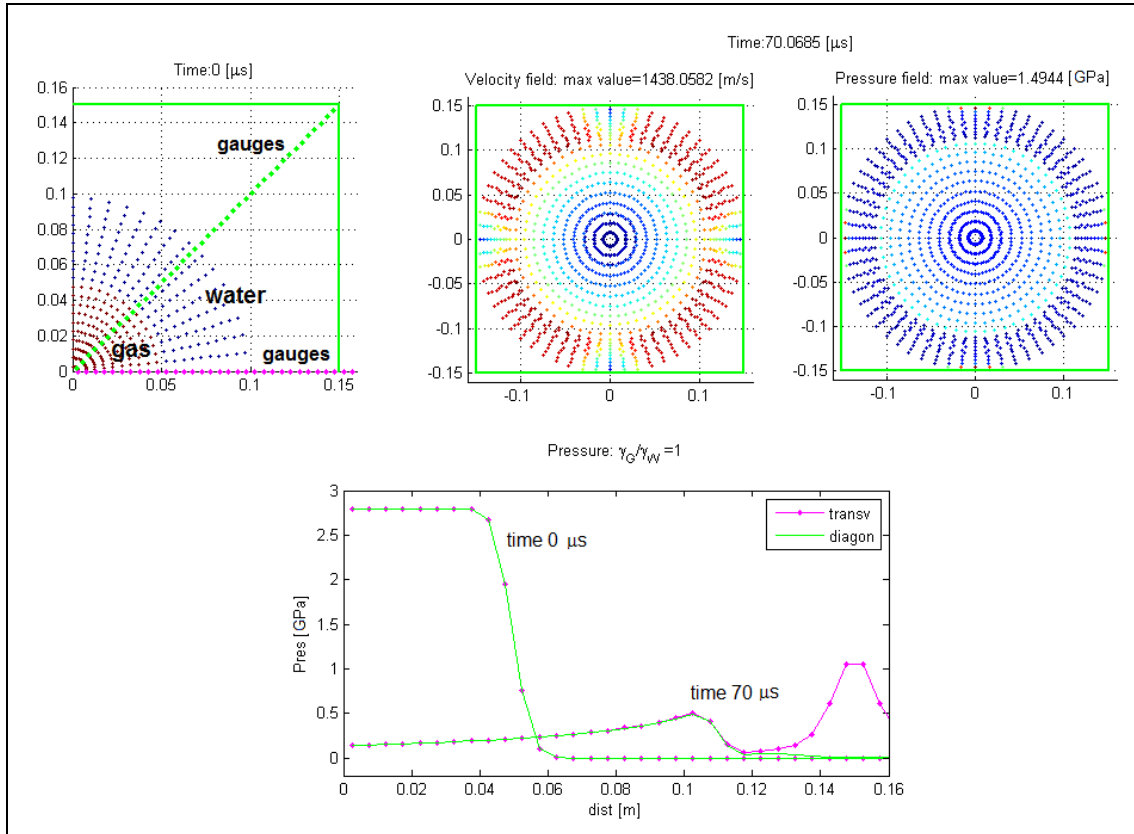

Figure 8: Expansion of detonated gas surrounded by a water crown into a rigid box; axes scale in meters.

Fig.8 shows the expansion of a circular charge surrounded by a water crown and confined in a rigid squared box with length of 0.30 m; the simulation is carried out considering the same compressibility modulus for both gas and water (i.e. $\gamma_G/\gamma_W = 1$).

The upper left-hand panel displays the initial configuration and the position of the gauges for pressure detection on the transversal and diagonal directions; continuous green line denotes the rigid box contour.

The central and right-hand upper panels show particles position, velocity modulus and pressure at time $t = 0.07$ ms when the water impacts with the box walls.

The lower panel shows pressure distribution at initial time ($t = 0.0$ ms) and at the impact time ($t = 0.07$ ms): in the latter a pressure wave is reflected by the box wall and propagates backward along the transversal direction with a peak of about 1 GPa.

The simulation ends at 0.2 ms: after the gas and water particles have completely expand occupying the whole box internal volume, symmetrical jets originates from both transversal and diagonal directions thus pumping the gas toward the box center and producing a contraction of its volume.

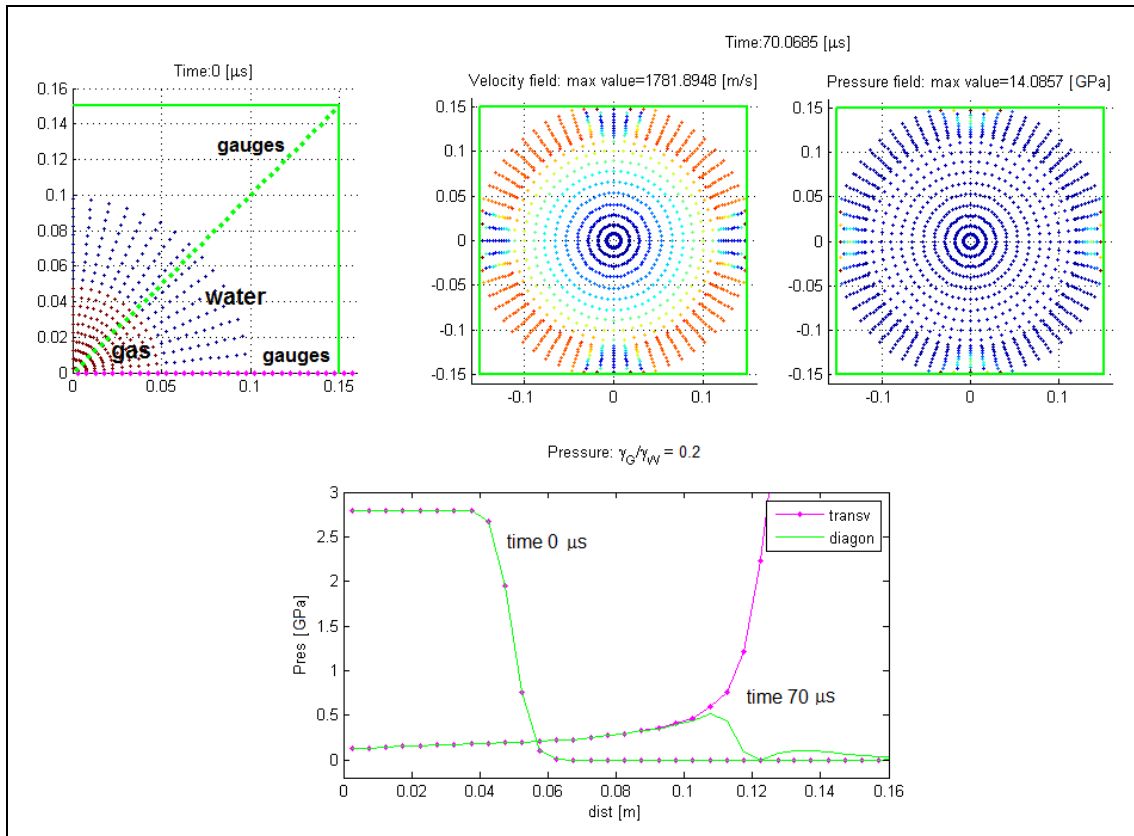

Figure 9: Expansion of detonated gas surrounded by a water crown into a rigid box; axes scale in meters.

Fig.9 shows the results obtained when increasing to 7.0 the value of the gamma water constant in the state equation (i.e. $\gamma_G/\gamma_W = 0.2$).

The particles dynamics is rather similar to that one described in the case $\gamma_G/\gamma_W = 1$: anyway now the water compressibility modulus is greater than the gas and this produces reflected pressure waves with higher peaks and celerity; the pulsation frequency of the gas expansion and contraction described in the previous analysis is also increased.

6 CONCLUSIONS

An advanced application of the Smoothed Particle Hydrodynamics method for the numerical modeling of rapid multiphase flow and underwater explosion problems have been illustrated in this paper.

The basic features of the numerical model adopted for simulating both non-cohesive sediment flushing and underwater expansion of a HE gas have been illustrated.

The proposed results have shown that the physics of the investigated problems can be simulated with an adequate degree of accuracy for engineering applications.

8 LIST OF SYMBOLS

A	physical field function (scalar or vector)
C_n	normalization factor for kernel functions
c_s	speed of sound
d_{50}	median sediment diameter
D/Dt	material derivative
e	internal energy
k_s	characteristic grain roughness height
h	smoothing length
h_0	initial interparticle distance
ΔV	particle volume
m	mass
n	dimension of the physical space
N	neighboring particles
p	pressure
p_0	reference pressure
$r_{ij}= \mathbf{x}_i-\mathbf{x}_j $	modulus of the relative distance vector
u_*	friction velocity
U	detonation wave characteristic velocity
∇r	radial unit vector
\mathbf{g}	gravitational acceleration vector
\mathbf{u}	velocity vector
\mathbf{u}_{ij}	relative velocity vector
\mathbf{u}_b	velocity vector of the solid boundary
\mathbf{x}	position vector
\mathbf{x}_{ij}	relative position vector
dV	elementary volume
α_M, β_M	constants of Monaghan artificial viscosity
δ	<i>Dirac</i> delta function
γ	state equation parameter
ε	fluid compressibility modulus
κ	Von Kàrmàn constant
φ, ϑ, r	spherical coordinates
μ	dynamic viscosity
ν	cinematic viscosity
Π	Monaghan artificial viscosity
ρ	density
ρ^s	sediment density
ρ^g	gas density
ρ_0	reference density
\mathcal{G}_{cr}	Shields parameter
θ_p	pressure smoothing coefficient
$\tau_{b\ cr,0}$	critical bottom shear stress (horizontal bed)
τ_b	hydrodynamic bottom shear
ζ^s	solid particle distance from the water-sediment interface
ζ^w	local draught of the water-sediment interface
ζ^{ws}	fluid particle distance from the water-sediment interface

W	kernel smoothing function
$d\Omega$	elementary volume of the continuum
Ω	spatial domain
Ω_i	compact support (or influence domain) of the i -th particle

Abstract. *Passive strategies based on the introduction of energy dissipating devices into the structures have received considerable attention in recent years. Within this framework, as reliable and cheap energy-dissipation devices, viscous fluid dampers have been largely used in seismic protection of industrial machines, technical equipments, buildings and bridges. Since the versatility of this passive protection system satisfactorily meets a wide range of requirements, a reliable identification of their nonlinear mechanical behavior is of outstanding importance. This paper focuses on the parametric identification of fractional derivative based models for nonlinear viscous dampers by means of non-classical methods, which are unconventional algorithms whose inner work is based on socially, physically and/or biologically inspired paradigms. Non-classical strategies are potentially powerful tools for solving complex identification problems because of their start-point independence, noise robustness and the capability in looking for the best solution in a global way. In contrast, it is important to highlight that they typically possess weak forms of convergence. For better assessing the correctness of some non-classical methods in parametric identification of viscous dampers, we perform a large comparative analysis which involve the following soft computing based techniques: a multi-species genetic algorithm, six standard differential evolution algorithms and four swarm intelligence based algorithms (including a chaotic particle swarm optimization algorithm). A numerical study is initially conducted in order to investigate the general reliability of these methods. Moreover, the paper also provides some results about the parametric identification of nonlinear viscous dampers by using experimental data. A critical review of the obtained evidences is given in order to provide useful guidelines for similar engineering applications.*

1 INTRODUCTION

Existing strategies for enhancing structural performances and safety against natural and manmade hazards can be grouped into three broad areas: base isolation, passive energy dissipation and active control. Passive energy dissipation systems can be realized by using a very wide range of materials and devices for enhancing damping, stiffness and strength. They can be used both for seismic hazard mitigation and for rehabilitation of aging or deficient structures. These devices generally operate on principles such as frictional sliding, yielding of metals, phase transformation in metals, deformation of viscoelastic solids or fluids and fluid orificing [1]. In this paper, the attention is focused on viscous damper devices whose most interesting features are: (i) low maintenance costs; (ii) usability for several severe earthquakes without damage; and (iii) forces exerted by the damper devices do not increase the stress in the structural system, being out of phase with the elastic forces. A viscous fluid damper typically consists of a piston within a damper housing filled with a compound of silicone or similar type of oil. Through a number of small orifices, the fluid pass from one side of the piston to the other: therefore, this device is able to dissipate energy through the movement of a piston in a highly viscous fluid based on the concept of fluid orificing [1]. Nowadays, a large number of civil engineering structures (buildings as well as bridges) is equipped with viscous fluid dampers in order to control seismic or wind induced motions and thermal expansions.

Since the applications of viscous dampers is growing very fast, their characteristics must be carefully investigated in order to provide a reliable support for designing an efficient protection strategy. Because of their inherent nonlinear behavior, condition assessment techniques require appropriate identification techniques. For instance, several identification approaches, both parametric and nonparametric, are compared in [2] by using real data carried out from full-scale nonlinear viscous dampers commonly used with large flexible bridges. About the parametric techniques, in [2] are explored the capability of the Adaptive Random Search: to this end, the authors solved an optimization problem in which the numerical values of the unknown model parameters were estimated by minimizing an objective function based on the normalized mean square error between the measured and identified damper responses. Since its weak form of convergence, the Adaptive Random Search belongs to the class of non-classical identification techniques [3], which are unconventional numerical identification methods mostly based on socially, physically and/or biologically inspired paradigms (i.e., ant colony based algorithms, artificial neural networks, differential evolution algorithms, genetic algorithms, genetic programming, particle swarm optimization algorithms, etc.).

This paper provides a comprehensive investigation about the parametric identification of viscous dampers via non-classical methods. To this end, we perform a large comparative analysis in which the following soft computing based techniques are examined: a special multi-species genetic algorithm, six standard differential evolution algorithms and four swarm intelligence based algorithms (including a chaotic particle swarm optimization algorithm). A numerical study is initially conducted in order to investigate the general reliability of these methods. Moreover, the paper also provides some results about the parametric identification of a full-scale nonlinear viscous damper by using experimental data. A critical review of the obtained evidences is given in order to provide useful guidelines for similar engineering applications.

2 PARAMETRIC IDENTIFICATION OF VISCOUS DAMPERS

The application of non-classical methods for the parametric identification of viscous dampers requires (i) the definition of an appropriate single-degree-of-freedom mechanical model and (ii) the formalization of the objective (or cost) function to be minimized.

2.1 Dynamic models

The damper effect is an output resistive force, therefore it acts in the opposite direction to that of the relative velocity between the ends of the damper device itself. The typical damping force ψ_d is:

$$\psi_d = C_\alpha \operatorname{sgn}[\dot{y}] |\dot{y}|^\alpha \quad (1)$$

where y is the displacement time-history (the time variable t is omitted for the sake of conciseness, the upper dots indicate the time-derivative). Moreover, $\operatorname{sgn}[\cdot]$ is the signum function, C_α is the damping coefficient and α is the damping law exponent. The value of α for seismic applications ranges between 0.10 and 0.50 (in this way the force rises very fast for small velocity values and becomes almost constant for large velocity values). Regarding the elastic force ψ_e , both linear and parabolic models were investigated in [4]:

$$\psi_e = K_1 y \quad (2)$$

$$\psi_e = K_2 y^2 + K_1 y + K_0 \quad (3)$$

in which K_1 is the elastic stiffness, K_2 and K_0 are two constants. In [4] is stated that the parabolic function reproduces the shape of the test cycles more precisely, but the linear one may be preferred because it is more simple and yields a comparable energy balance. By combining Eq. (1) and Eq. (2), the equation of motion of a fractional viscous damper system subjected to a time-varying force p is [4]:

$$M\ddot{y} + C_\alpha \operatorname{sgn}[\dot{y}] |\dot{y}|^\alpha + K_1 y = p \quad (4)$$

where M is the effective mass. If the parabolic model given by Eq. (3) is taken into account, then the equation of motion becomes [4]:

$$M\ddot{y} + C_\alpha \operatorname{sgn}[\dot{y}] |\dot{y}|^\alpha + (K_2 y^2 + K_1 y + K_0) = p \quad (5)$$

In [5] are considered a fraction viscous model and a linear one as follows:

$$M\ddot{y} + C_1 \dot{y} + C_\alpha \operatorname{sgn}[\dot{y}] |\dot{y}|^\alpha + K_1 y = p \quad (6)$$

where C_1 is the internal damping coefficient.

The system response can be determined as solution of the considered equation of the motion by using standard numerical time-marching techniques if the initial conditions and the values of the system parameters are known.

2.2 Parametric identification

The model parameters \mathbf{x} of the viscous damper are identified by solving the following single-objective optimization problem :

$$\begin{aligned} \min_{\mathbf{x}} \{ & f(\mathbf{x}) \} \\ \text{s.t. } & \mathbf{x}^l \leq \mathbf{x} \leq \mathbf{x}^u \end{aligned} \quad (7)$$

in which \mathbf{x}^l and \mathbf{x}^u are the lower and upper bounds of the system parameters, respectively.

The objective or cost function $f(\mathbf{x})$ is:

$$f(\mathbf{x}) = \frac{100}{S\sigma_y^2} \sum_{s=1}^S (y_s - y_s^*(\mathbf{x}))^2 \quad (8)$$

where y_s is the measured displacement, y_s^* is the computed displacement, S is the number of data points (s is a generic sample index) and σ_s^2 . The cost function in Eq. (8) coincides with that in [2] as the weight for the velocity-based addend is equal to zero. In fact, although the information regarding the velocity response may help the parametric identification, it introduces some additional complications. First, the velocity response is not typically measured, so that it needs to be calculated from the displacement response. Second, the weights of a mixed displacement-velocity cost function should be tuned for better matching the experimental data, and thus it requires preliminary user-supervised runs. On the other hand, the objective function in Eq. (8) can be directly used with experimental data without preliminary runs.

The Adaptive Random Search was used in [2] to solve a single-objective optimization problem as in Eq. (7) in order to identify the system parameter \mathbf{x} . In this paper, we perform comparative analyses involving differential evolution, particle swarm optimization and genetic algorithm.

3 IDENTIFICATION VIA DIFFERENTIAL EVOLUTION

Differential evolution algorithm (DEA) is a relatively recent stochastic, population-based global optimization method whose positive features are attracting the interest of several researches in the field of the applied sciences. Different from traditional evolutionary algorithms, this optimizer is completely self-organizing and requires few lines of code in most of the existing programming languages. Moreover, its functionality requires a small set of embedded control parameters, which makes it easy to use for non-experts.

3.1 Mutation operators

The standard version of the DEA [1] uses the differences between randomly selected individuals as the source of random variations for a third individual referred to as the target vector. Trial solutions are generated by adding weighted difference vectors to the target vector. This process is dubbed mutation operator: its main goal is to enable diversity in the current population as well as “to move” the individuals in such a way a better result is expected. By computing the differences between two individuals randomly chosen from the population, the algorithm estimates the gradient in that zone rather than in a single point of the search space. Let us consider ${}^k\mathbf{x}_i = \{x_{i1}, \dots, x_{ij}, \dots, x_{in}\}$ the i th individual (with $i=1, \dots, N$) at iteration k . The initial population ${}^0\mathbf{x}_i$ for $i=1, \dots, N$ is defined by generating randomly the collection of N solutions within the specified search space. During the iteration $k+1$, for each individual ${}^k\mathbf{x}_i$ a mutation vector ${}^{(k+1)}\mathbf{z}_i$ is computed by using one of the following alternatives:

$${}^{(k+1)}\mathbf{z}_i = {}^k\mathbf{x}_{r1} + F^1 ({}^k\mathbf{x}_{r2} - {}^k\mathbf{x}_{r3}) \quad (9)$$

$${}^{(k+1)}\mathbf{z}_i = {}^k\mathbf{x}_{best} + F^1 ({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2}) \quad (10)$$

$${}^{(k+1)}\mathbf{z}_i = {}^k\mathbf{x}_i + F^2 ({}^k\mathbf{x}_{best} - {}^k\mathbf{x}_i) + F^1 ({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2}) \quad (11)$$

$${}^{(k+1)}\mathbf{z}_i = {}^k\mathbf{x}_{best} + F^2 ({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2}) + F^1 ({}^k\mathbf{x}_{r3} - {}^k\mathbf{x}_{r4}) \quad (12)$$

$${}^{(k+1)}\mathbf{z}_i = {}^k\mathbf{x}_{r1} + F^2 ({}^k\mathbf{x}_{r2} - {}^k\mathbf{x}_{r3}) + F^1 ({}^k\mathbf{x}_{r4} - {}^k\mathbf{x}_{r5}) \quad (13)$$

where $r1, r2, r3$ and $r4$ denote integers randomly selected within the set $\{1, \dots, i-1, i+1, \dots, N\}$ such that $r1 \neq r2 \neq r3 \neq r4$. The individual ${}^k\mathbf{x}_{best}$ is the best performer in the population at iteration k . The coefficients F^1 and F^2 are the so-called mutation coefficients and they are real positive constants whose typical values are in the range $[0.40, 1.00]$, 0.50 in our numerical applications.

These parameters control the amplification level of the mutation (for this reason they are also dubbed “scale factors”).

3.2 Crossover operator

The crossover follows the mutation phase. For each mutated vector $^{(k+1)}\mathbf{z}_i$ a trial vector $^{(k+1)}\mathbf{u}_i$ (offspring) is generated by using the following so-called binomial crossover:

$$^{(k+1)}\mathbf{u}_{ij} = \begin{cases} ^{(k+1)}\mathbf{z}_{ij} & \text{if } q \leq p^c \text{ or } j = \text{randint}(1, n) \\ ^k\mathbf{x}_{ij} & \text{otherwise} \end{cases} \quad (14)$$

where q is a random number generated by using the uniform probability density function in the range $[0,1]$. The parameter p^c is the probability of crossover and it takes values between 0 and 1 (usually, 0.50). Moreover, $\text{randint}(1, n)$ is an integer randomly selected within the set $\{1, \dots, n\}$ and it is adopted to ensure that at least one parameter is taken into account for constructing the vector $^{(k+1)}\mathbf{u}_i$.

3.3 Selection operator

An opportune strategy is needed to ensure the feasibility of the obtained solutions in Eq. (14), that means the fulfillment of both lower and upper bounds of the search space: in this paper, if a vector out-of-range is obtained, then its projection on the prescribed interval is considered (so-called projection scheme). Subsequently, the selection operator is performed by means of a very simple one-to-one competition scheme between $^{(k+1)}\mathbf{u}_i$ and $^{(k+1)}\mathbf{x}_i$ as follows:

$$^{(k+1)}\mathbf{x}_i = \begin{cases} ^{(k+1)}\mathbf{u}_i & \text{if } f(^{(k+1)}\mathbf{u}_i) < f(^{(k+1)}\mathbf{x}_i) \\ ^k\mathbf{x}_i & \text{otherwise} \end{cases} \quad (15)$$

Therefore the winner $^{(k+1)}\mathbf{x}_i$ in the selection stage is the best performer between the parent individual $^k\mathbf{x}_i$ and its trial one $^{(k+1)}\mathbf{u}_i$. The output of this operator is a new population for the next generation, unless a stopping criteria has not been fulfilled. In this study, we will stop the evolutionary search once a maximum number of iterations L is achieved.

3.4 An adaptive mutation operator

In [7] is presented a mutation operator in which only one control parameter is required and the mutation coefficients are adaptive. The mutation operator proposed in [7] deals with the following revised version of Eq. (11):

$$^{(k+1)}\mathbf{z}_i = ^k\mathbf{x}_i + ^kF_{r3,i} \left(^k\mathbf{x}_{r3} - ^k\mathbf{x}_i \right) + ^kF_{r1,r2} \left(^k\mathbf{x}_{r1} - ^k\mathbf{x}_{r2} \right) \text{ if } k \leq \kappa L \quad (16)$$

and

$$^{(k+1)}\mathbf{z}_i = ^k\mathbf{x}_{r1} + ^kF_{best,i} \left(^k\mathbf{x}_{best} - ^k\mathbf{x}_i \right) + ^kF_{r1,r2} \left(^k\mathbf{x}_{r1} - ^k\mathbf{x}_{r2} \right) \text{ if } k > \kappa L \quad (17)$$

where κ is the only one control parameter. The adaptive mutation coefficients in Eq. (16) and in Eq. (17) are calculated as follows:

$$^kF_{r3,i} = \max \left\{ \left| \frac{f(^k\mathbf{x}_{r3}) - f(^k\mathbf{x}_i)}{^kf_{\max} - ^kf_{\min}} \right|, 0.5 \right\} \quad (18)$$

$${}^k F_{r1,r2} = \begin{cases} \max \left\{ \left| \frac{f({}^k \mathbf{x}_{r1}) - f({}^k \mathbf{x}_{r2})}{{}^k f_{\max} - {}^k f_{\min}} \right|, 0.5 \right\} & \text{if } k \leq \kappa L \\ \left| \frac{f({}^k \mathbf{x}_{r1}) - f({}^k \mathbf{x}_{r2})}{{}^k f_{\max} - {}^k f_{\min}} \right| & \text{if } k > \kappa L \end{cases} \quad (19)$$

$${}^k F_{best,i} = \left| \frac{{}^k f_{\min} - f({}^k \mathbf{x}_i)}{{}^k f_{\max} - {}^k f_{\min}} \right| \quad (20)$$

in which:

$$\begin{aligned} {}^k f_{\min} &= \min_{i=1,\dots,N} \{f({}^k \mathbf{x}_i)\} \\ {}^k f_{\max} &= \max_{i=1,\dots,N} \{f({}^k \mathbf{x}_i)\} \end{aligned} \quad (21)$$

Taking into account this operator, the mutation occurs in two distinct ways. The first one takes place when $k \leq \kappa L$ and its goal is to help the exploration of the search space. In this effort, the weighted difference vectors in Eq. (16) only involves randomly selected individuals and the mutation coefficients are forced to be greater than 0.5, see Eq. (18) and the first equality in Eq. (19). Once $k > \kappa L$, the mutation scheme proposed in Eq. (19) is performed. In this case, the current best individual ${}^k \mathbf{x}_{best}$ is taken into account. Substantially, the goal of this alternative scheme is to keep track of the current best performer within the population. Moreover, an improved exploitation can be achieved by removing the lower bounds for the adopted mutation coefficients (therefore numerical values less than 0.50 are accepted at this time). However, there is not rigid separation between exploration and exploitation because the numerical values of the scale factors are dynamically adjusted during the evolutionary search (adaptive property): for instance, if the exploration of the search space is not concluded for $k \leq \kappa L$ then the numerical values of the mutation remain sensibly large and the global recognition is not penalized. Our numerical analyses – on both mathematical and engineering problems – demonstrate that a good value for κ (the only parameter of the proposed mutation operator) should be selected within 0.40 and 0.60, $\kappa=0.50$ in this paper.

3.5 A free-parameter crossover operator

The binomial scheme in Eq. (14) was replaced in [7] with the following one:

$${}^{(k+1)} \mathbf{u}_i = {}^{(k+1)} \mathbf{q}_i \times {}^k \mathbf{x}_i - (1 - {}^{(k+1)} \mathbf{q}_i) \times {}^{(k+1)} \mathbf{z}_i \quad (22)$$

where ${}^{(k+1)} \mathbf{q}_i$ is a vector whose n components are random numbers generated by using the uniform probability density functions in the range $[0,1]$. Moreover, $\mathbf{1} = \{1_1, \dots, 1_j, \dots, 1_n\}$. The results of the binomial crossover in Eq. (14) are vertex points of the hypercube defined by ${}^{(k+1)} \mathbf{z}_i$ and ${}^{(k+1)} \mathbf{x}_i$. Similarly, these vertex points are possible solutions of the crossover operator presented in Eq. (22) when ${}^{(k+1)} q_{ij} \rightarrow 0$ or ${}^{(k+1)} q_{ij} \rightarrow 1$ for each $j=1, \dots, n$. Additionally, this crossover operator allows the exploration of the inner space bounded by this hypercube. It is evident that the probability of reproduction is not required for performing the proposed crossover, and thus Eq. (22) is a free-parameter operator.

4 IDENTIFICATION VIA PARTICLE SWARM OPTIMIZATION

Based on the swarm intelligence theory, two different categories of optimizers can be formulated:

- Particle swarm optimization algorithms (PSOAs) in which is assumed that a Newtonian dynamic regulates the movement of the particles. Therefore, position and velocity can be determined simultaneously.
- Quantum-behaved particle swarm optimization algorithms (Q-PSOAs) in which the Newtonian hypothesis is rejected. In this case, the classical mechanic is replaced with the quantum mechanics in which the term “trajectory” is meaningless [8].

The first class of PSOAs is the object of investigation in this paper.

4.1 General model

The i th particle (with $i=1,\dots,N$) at iteration k has two attributes, that are its velocity ${}^k\mathbf{v}_i = \{{}^k\mathbf{v}_{i1}, \dots, {}^k\mathbf{v}_{ij}, \dots, {}^k\mathbf{v}_{in}\}$ and position ${}^k\mathbf{x}_i = \{{}^k\mathbf{x}_{i1}, \dots, {}^k\mathbf{x}_{ij}, \dots, {}^k\mathbf{x}_{in}\}$. To protect the cohesion of the swarm the velocity ${}^k\mathbf{v}_{ij}$ is forced to be (in absolute value) less than a maximum velocity v_j^{\max} with $\mathbf{v}^{\max} = \{v_1^{\max}, \dots, v_j^{\max}, \dots, v_n^{\max}\}$. Typically, it is assumed $\mathbf{v}^{\max} = \gamma(\mathbf{x}^u - \mathbf{x}^l)/\tau$ (the time factor $\tau = 1$ is introduced to assign a physical meaning to the formula) but there is not sufficient degree of uniformity about γ whose numerical value can vary in a large interval (usually its value is 0.50). The initial positions ${}^0\mathbf{x}_i$ for $i=1,\dots,N$ are defined by generating randomly the collection of N solutions within the assigned search space. Moreover, ${}^0\mathbf{v}_{ij}$ is randomly generated using an uniform distribution between $-v_j^{\max}$ and $+v_j^{\max}$. At iteration $k+1$ the velocity ${}^{(k+1)}\mathbf{v}_i$ and the position ${}^{(k+1)}\mathbf{x}_i$ are evaluated as follows [9]:

$${}^{(k+1)}\mathbf{v}_i = w^k \mathbf{v}_i + c_1 {}^{(k+1)}\mathbf{r}_{i1} \times ({}^k\mathbf{x}_i^{Pb} - {}^k\mathbf{x}_i) + c_2 {}^{(k+1)}\mathbf{r}_{i2} \times ({}^k\mathbf{x}^{Gb} - {}^k\mathbf{x}_i) \quad (23)$$

$${}^{(k+1)}\mathbf{x}_i = {}^k\mathbf{x}_i + \tau {}^{(k+1)}\mathbf{v}_i \quad (\tau = 1) \quad (24)$$

in which w is the inertia weight whereas c_1 and c_2 are the so-called acceleration factors (they are called cognitive and social parameter, respectively). In Eq. (23), ${}^{(k+1)}\mathbf{r}_{i1}$ and ${}^{(k+1)}\mathbf{r}_{i2}$ are vectors whose n terms are random numbers uniformly distributed between zero and one, the symbol \times denotes the term-by-term multiplication. The superscripts on the left and the subscripts on the right denote that a different couple of random vectors is needed for each particle at any iteration. The symbol ${}^k\mathbf{x}_i^{Pb}$ denotes the best previous position of the i th particle (also known as *pbest*):

$${}^k\mathbf{x}_i^{Pb} = \begin{cases} {}^{(k-1)}\mathbf{x}_i^{Pb} & \text{if } f({}^k\mathbf{x}_i) > f({}^{(k-1)}\mathbf{x}_i^{Pb}) \\ {}^k\mathbf{x}_i & \text{otherwise} \end{cases} \quad (25)$$

given that ${}^0\mathbf{x}_i^{Pb} = {}^0\mathbf{x}_i$. According to the adopted definition for ${}^k\mathbf{x}^{Gb}$, there are two versions of PSOAs. If ${}^k\mathbf{x}^{Gb}$ is the best position among all the particles in the swarm (also known as *gbest*) such a version is called global PSOA (and the swarm is said to be fully informed or fully connected). On the other hand, if ${}^k\mathbf{x}^{Gb}$ is evaluated on a smaller number of adjacent particles (also known as *lbest*, ${}^k\mathbf{x}^{Lb}$) we have a local PSOA. In this paper, we will consider that all particles share information with each other about the best performer of the swarm, so that

$${}^k\mathbf{x}^{Gb} = \arg \min_{i=1,\dots,N} \{f({}^k\mathbf{x}_i^{Pb})\} \quad (26)$$

The check on the maximum admissible velocity for each particle i is performed at iteration k in the following manner:

$${}^k v_{ij} = \begin{cases} \text{sgn} \left[{}^k v_{ij} \right] v_j^{\max} & \text{if } |{}^k v_{ij}| > |v_j^{\max}| \\ {}^k v_{ij} & \text{otherwise} \end{cases} \quad \forall j = 1, \dots, n \quad (27)$$

Another check is needed to verify that the particle is within the feasible search space:

$$\left({}^k x_{ij}, {}^k v_{ij} \right) = \begin{cases} \left({}^k x_{ij}, {}^k v_{ij} \right) & \text{if } x_j^l \leq {}^k x_j \leq x_j^u \\ \left({}^k x_{ij} = x_j^l, {}^k v_{ij} = 0 \right) & \text{if } {}^k x_j < x_j^l \quad \forall j = 1, \dots, n \\ \left({}^k x_{ij} = x_j^u, {}^k v_{ij} = 0 \right) & \text{otherwise} \end{cases} \quad (28)$$

In Eq. (28), the unfeasible particle's velocity is fixed to zero for the next iteration to avoid considering any points outside the search space.

A typical operator (called “craziness operator”) is performed to increase the direction diversity in the swarm. Specifically, the adopted version for the craziness operator works on the particle's velocity only. Assigned a probability of craziness P_{cr} , the particle's velocity in Eq. (27) is replaced as follows:

$$\text{if } r \leq P_{cr} \rightarrow {}^{(k+1)} v_{ij} \sim U \left(-v_j^{\max}, v_j^{\max} \right) \quad \forall j = 1, \dots, n \quad (29)$$

in which r is a uniform random number between 0 and 1, $U(\cdot)$ is the uniform probability density function. Once the particle's velocity is assigned by means of Eq. (29), a new position ${}^{(k+1)} \mathbf{x}_i$ is calculated for the particle by including this result in Eq. (24). A high value for P_{cr} results in (ineffective) pure random search, therefore its value should be less than 0.1 (0.05 in this study). Following iteratively this simple set of instructions, the swarm is expected to “fly” toward the global optimum of the problem. In our studies, the routine is stopped once a maximum number of iterations L is achieved.

4.2 Inertia weight and acceleration factors

The constriction factor χ is alternative to the use of the static inertia weight, initially proposed by [10] to replace the \mathbf{v}^{\max} clamping. The constriction model describes the way of choosing w , c_1 and c_2 as follows:

$$\begin{aligned} {}^{(k+1)} \mathbf{v}_i &= \chi \left[{}^k \mathbf{v}_i + c_1 {}^{(k+1)} \mathbf{r}_{i1} \times \left({}^k \mathbf{x}_i^{Pb} - {}^k \mathbf{x}_i \right) + c_2 {}^{(k+1)} \mathbf{r}_{i2} \times \left({}^k \mathbf{x}_i^{Gb} - {}^k \mathbf{x}_i \right) \right] \\ \chi &= \frac{2}{2 - \varphi - \sqrt{\varphi^2 - 4\varphi}} \\ \varphi &= c_1 + c_2 \geq 4 \end{aligned} \quad (30)$$

The new particle's position is computed as indicated in Eq. (24). Very typical values for this model are $c_1=c_2=2.05$, that is $\chi=0.73$.

The model given by Eq. (23) can be modified by assuming both inertia weight and acceleration factors as dynamic parameters, that is: $w={}^k w$, $c_1={}^k c_1$, $c_2={}^k c_2$. In [11] is proposed a linearly decreasing inertia weight:

$${}^k w = \left({}^0 w - {}^L w \right) \frac{L - k}{L} + {}^L w \quad (31)$$

where 0w and Lw are the initial and final values of the inertia weight (typically 0.9 and 0.4 respectively). Similarly, in [12] are proposed linearly iteration-dependent models for the acceleration factors:

$$\begin{aligned} {}^k c_1 &= \left({}^0 c_1 - {}^L c_1 \right) \frac{L-k}{L} + {}^L c_1 \\ {}^k c_2 &= \left({}^0 c_2 - {}^L c_2 \right) \frac{L-k}{L} + {}^L c_2 \end{aligned} \quad (32)$$

In several papers, ${}^k c_1$ changes from 2.5 to 0.5 and ${}^k c_2$ from 0.5 to 2.5.

4.3 Chaotic particle swarm optimization

One of the major drawbacks of the PSOA is its premature convergence, especially for search spaces with several local optima. In order to overcome this problem, some researchers proposed to introduce chaotic maps with certainty, ergodicity and pseudo-randomness property into PSOA so as to improve the global convergence [13]. Moreover, in [8] and [14] is stated that – due to the non-repetition of chaos – chaos-based optimization algorithms can carry out overall searches at higher speeds than stochastic ergodic searches that depend on probabilities. The ways in which the chaos entries into PSOAs are different but in this study we consider the most diffused one: in detail, we assume that chaotic maps are adopted to select the numerical values for the parameters of the particle's velocity in Eq. (23). Different numerical studies have been conducted for choosing the better chaotic maps. Looking for a synthesis of the documented results, we assume that the inertia weight is updated by adopting the logistic map [13]:

$${}^{(k+1)}\tilde{w} = \lambda {}^k \tilde{w} (1 - {}^k \tilde{w}) \quad \text{with } {}^k \tilde{w} \in (0,1) \quad (33)$$

where λ is assumed equal to 4 to obtain ergodicity in $(0,1)$. The upper symbol \sim indicates that the corresponding quantity is evaluated by means of an opportune chaotic map. In our applications, the adopted value of the chaotic inertia weight are scaled within the interval $[0.40, 0.90]$. About the acceleration factors, in [14] is proposed the use of the Zaslavskii map:

$${}^{(k+1)}\zeta_1 = \text{mod} \left[{}^k \zeta_1 + \nu + \delta {}^{(k+1)}\zeta_2, 1 \right] \quad (34)$$

$${}^{(k+1)}\zeta_2 = \cos(2\pi {}^k \zeta_1) + e^{-\rho} {}^k \zeta_2 \quad (35)$$

in which $\text{mod}[\cdot]$ is the modulus (signed remainder after division). The use of Zaslavskii map has been theoretically justified in [14] for virtue of its ergodicity and unpredictability, since a strange attractor with large Lyapunov exponent can be found for $\nu=400$, $\rho=3$ and $\delta=12.6695$ (in this case, ${}^k \zeta_2 \in [-1.0512, 1.0512]$). Therefore, in [14] is stated that a Zaslavskii map-based chaotic PSOA should be more capable of escaping from local optima than random search. In our applications, both chaotic acceleration factors are functions based on the results of Eq. (35), but final values are scaled within the interval $[0.50, 2.50]$.

4.4 Passive congregation

The dynamic of natural swarms can be modeled by taking into account two grouping forms [15]:

- Aggregation, that is a grouping by environmental forces. Two types of aggregation forms can be identified. The passive aggregation is a passive grouping due to physical phenom-

ena (i.e., transport caused by water currents) whereas the active aggregation is a grouping by attractive resources (i.e., food or space within the environment);

- Congregation, that is a grouping by social forces (it depends on the group itself and not on the environment). Also in this case two different forms of congregation can be analyzed. The passive congregation is the attraction between members of the group without the existence of observable social behaviors and therefore it looks as a random phenomenon. On the other hand, the social congregation happens under active information transfer, so that the behavior of the group depends on the relations among the members of the group.

It has been pointed out in [15] that the third addend of the standard PSOA in Eq. (23) models an active aggregation rather than a passive congregation because ${}^k\mathbf{x}_{Gb}$ can be regarded (using a biologic metaphor) as “the place with most food”. Therefore, the standard model in Eq. (23) does not incorporate a congregation form. Starting from this consideration, in [15] is proposed a new rule for updating the particle’s velocity: by including a passive congregation term the information sharing within the swarm may be improved and the recognition of the search space as well. Accounting for the passive congregation, the particle’s velocity is updated as follows [15]:

$${}^{(k+1)}\mathbf{v}_i = w {}^k\mathbf{v}_i + c_1 {}^{(k+1)}\mathbf{r}_{i1} \times ({}^k\mathbf{x}_i^{Pb} - {}^k\mathbf{x}_i) + c_2 {}^{(k+1)}\mathbf{r}_{i2} \times ({}^k\mathbf{x}_{Gb} - {}^k\mathbf{x}_i) + c_3 {}^{(k+1)}\mathbf{r}_{i3} \times ({}^k\mathbf{x}_{rand} - {}^k\mathbf{x}_i) \quad (36)$$

in which ${}^k\mathbf{x}_{rand}$ is a particle selected randomly from the swarm, ${}^{(k+1)}\mathbf{r}_{3i}$ is a vector whose terms are random numbers uniformly distributed between zero and one and c_3 is another acceleration factor (called passive congregation coefficient, a constant positive real value). The adopted (constant) numerical values for the control parameters in Eq. (36) are taken from [15].

5 IDENTIFICATION VIA GENETIC ALGORITHM

Genetic algorithms are well known non-classical techniques for parametric identification: during a succession of generations, these methods generate new points in the admissible search space by applying operators on the current solutions set and “statistically” moving toward more optimal places in virtue of the Darwinian strife for survival. A detailed state-of-the-art review about genetic algorithm based mechanical system identification can be found in [16].

A modified real-coded genetic algorithm [17] for parametric identification of mechanical system is considered in this paper. The algorithm – whose acronym is MGAR – utilizes several subpopulations and a migration operator with a ring topology is periodically performed to allow the interaction between them. For each subpopulation, a specialized medley of recent genetic operators (crossover and mutation) has been adopted and is briefly discussed. The final algorithm includes an operator based on the auto-adaptive asexual reproduction of the best individual in the current subpopulation. This latter was introduced to avoid a long stagnation at the start of the evolutionary process due to insufficient exploration as well as to attempt an improved local exploration around the current best solution at the end of the search. The original algorithm included a search space reduction technique, but it is not considered in this paper because of the small number of unknown parameters to be identified. This algorithm was successfully adopted for nonlinear [17] and large linear system identification [18]. The interested reader can refer to [17] and [18] for more information about it and the adopted numerical values for the embedded control parameters.

6 NUMERICAL RESULTS

A large numerical investigation is conducted to assess the performances of the above presented non-classical identification techniques for parametric identification of a nonlinear viscous damper subject to various dynamic loads (harmonic and earthquake loading). The effect of the noise contamination in the reference response is also studied.

6.1 Problem data and non-classical identification methods under investigation

A list of the considered non-classical identification methods is given in Tab. 1.

Algorithm	Short description
DEA01	A DEA whose mutation operator is given by Eq. (9) and with binomial crossover as in Eq. (14)
DEA02	A DEA whose mutation operator is given by Eq. (10) and with binomial crossover as in Eq. (14)
DEA03	A DEA whose mutation operator is given by Eq. (11) and with binomial crossover as in Eq. (14)
DEA04	A DEA whose mutation operator is given by Eq. (12) and with binomial crossover as in Eq. (14)
DEA05	A DEA whose mutation operator is given by Eq. (13) and with binomial crossover as in Eq. (14)
DEA06	A DEA with adaptive mutation – as in Eq. (16) and Eq. (17) – and a free-parameter crossover given by Eq. (22), see [7]
PSOA01	A PSOA whose velocity model is Eq. (23), with inertia weight as in Eq. (31), social and cognitive factors as in Eq. (32)
PSOA02	A PSOA in which the velocity updating rule (based on the use of the constriction factor) is given by Eq. (30)
PSOA03	A PSOA based on the use of chaotic maps (so-called chaotic PSOA) for both inertia weight and acceleration factors
PSOA04	A PSOA with passive congregation in which the velocity updating rule is given by Eq. (36)
MGAR	A modified multi-species real-coded genetic algorithm with specialized operators for each subpopulation, see [17] and [18]

Table 1: List of non-classical identification methods under investigation.

The parametric identification of the viscous damper is performed by solving the optimization problem in Eq. (7) whose cost function is given in Eq. (8). For this numerical investigation, the adopted mechanical model is that in Eq. (6) and the numerical values of the involved parameters are taken from [5]: $M=1000$, $C_1=100$, $C_\alpha=400$, $K_1=1000$ and $\alpha=0.20$. The set of parameters to be identified is $\mathbf{x}=\{M, C_1, K_1, C_\alpha, \alpha\}$ and \mathbf{x}^* is its true real value. Lower and upper bounds are, $\mathbf{x}^l=0.10\mathbf{x}^*$ and $\mathbf{x}^u=2.00\mathbf{x}^*$, respectively. The population size and the maximum number of iterations are $N=50$ and $L=400$, respectively.

6.2 Nonlinear viscous damper subject to harmonic base motion

The viscous damper is subject to harmonic base motion:

$$p(t) = -Ma_g^{\max} \sin(\Omega t) \quad (37)$$

in which $a_g^{\max}=0.25g$ (g is the gravity acceleration) and Ω is given in Tab. 2 as function of the natural frequency of the system, that is $\omega = \sqrt{(K_1/M)}$.

Initial velocity and initial displacement are both equal to zero. The total number of samples is $S = 2000$. Unit of measures are arbitrary but consistent.

Load case	Ω/ω
L1	1.00
L2	0.50
L3	2.00

Table 2: Load cases.

Mean results over thirty distinct runs (that is, with different initial populations) are presented in Fig. 1 (for M), Fig. 2 (for C_1), Fig. 3 (for K_1), Fig. 4 (for C_a) and Fig. 5 (for α). The black horizontal solid line denotes the true parameter value.

A general overview of the obtained results leads to the following considerations:

- Non-classical identification methods provide an effective way for the parametric identification of nonlinear viscous dampers subject to harmonic-type dynamic loading, because the final errors are acceptable for practical applications.
- The load case L1 causes the most critical situation for the parametric identification of nonlinear viscous dampers. This may be imputable to the use of harmonic excitation whose frequency coincides with that of the viscous damper.
- The DEA06 and MGAR are the best competitor for this numerical application because the identified parametric values are very close to the exact solution. Their performance in the parametric identification are strongly better than the others for the load case L1.

Figure 1: Identification results for M .

However, it was observed that all non-classical methods can achieve the exact solution of the identification problem by increasing the number of objective function evaluations. In this perspective, DEA06 and MGAR are more competitive than the others from a computational standpoint.

A more detailed inspection of the plotted results may provide further practical information. For instance, it appears that DEAs and PSOA's lead to comparable final results. There are no significant differences within the standard DEAs. On the other hand, the chaotic PSOA (labeled as PSOA03 in Tab. 01) is slightly better than the others.

Figure 2: Identification results for C_I .

Figure 3: Identification results for K_I .

The most critical parameters to be identified is C_a : as it can be seen in Fig. 4, its numerical value for the load case L1 is approximately identified by the most of the investigated techniques (not so good results are obtained by using DEA01, DEA05, PSOA01, PSOA02 and PSOA04). For the most critical loading condition (L1), it is observed that (i) the identified values of M , C_1 and K_1 (mean values over thirty runs) are greater than the exact ones whereas (ii) the identified values of C_a (mean values over thirty runs) are lower than the exact ones.

Figure 4: Identification results for C_a .Figure 5: Identification results for α .

Some samples of the convergence histories for DEA06 are shown in Fig. 6 (for load case L1), Fig. 7 (for load case L2) and Fig. 8 (for load case L3). As above, the black horizontal solid line denotes the true parameter value. The objective function shows a small number of stagnations (number of iterations without improvements). This means that the exploration phase of the evolutionary search for DEA06 is very efficient.

Figure 6: A sample of the convergence histories for DEA06 (load case L1).

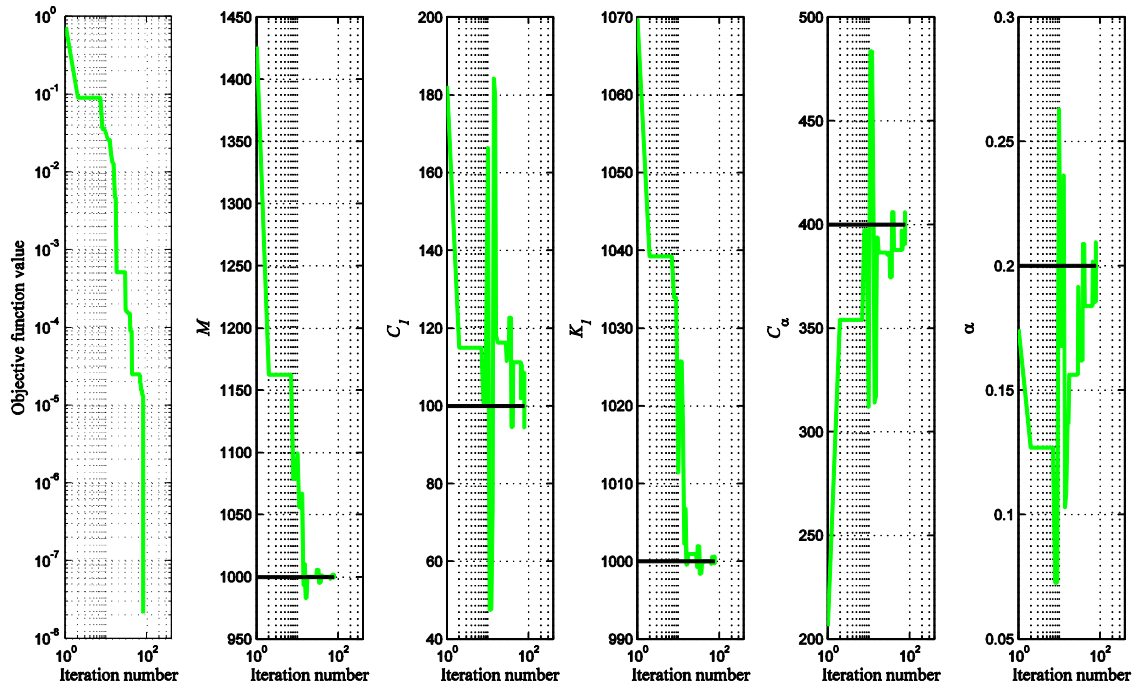

Figure 7: A sample of the convergence histories for DEA06 (load case L2).

Figure 8: A sample of the convergence histories for DEA06 (load case L3).

Convergence histories of the model parameters confirm the effectiveness of DEA06 in parametric identification of the nonlinear viscous damper because a quasi exact results is achieved once 200÷300 iterations are completed. As a consequence, the total elaboration time can be reduced without jeopardizing the correctness of the identification process.

6.3 Nonlinear viscous damper subject to earthquake motion

The same nonlinear viscous dampers was identified under, both, white random noise and earthquake excitation. Using the non-classical methods under investigation (as they are listed in Tab. 1), all the model parameters were exactly identified (i.e., to four decimal digits). It has been observed that the final accuracy is slightly better than the obtained one for harmonic loading. It is an expected results, because the efficiency of the identification depends on the information contained in the input-output data: in this sense, harmonic loads with a low frequencies content are a limited excitation source. Herein, only results for a viscous damper subject to a real earthquake record are shown. Thus, the dynamic load is:

$$p(t) = -Ma_g(t) \quad (38)$$

in which a_g is the adopted earthquake record (for this numerical application, the El Centro earthquake is considered). Moreover, in order to study the detrimental effect of the noise contamination, a noisy reference system response is taken into account. A uniform-type noise was considered with a noise-to-signal-ratio (NSR) equal to 15%. The obtained noisy signal has not been subject to de-noising.

The results – summarized in Fig. 9 – demonstrate that DEA06 is relatively insensitive to moderate noise levels. The noise robustness of non-classical identification methods is well known in the current literature and it depends on the implicit parallelism in such numerical techniques [7][17]. Comparing the identification results by using a noise-free (solid lines in Fig. 9) and a noisy reference response, it is observed that:

- Because of the noise contamination, the minimum value of the objective function in Eq. (8) is not equal to zero. The final minimum value of the objective function under noisy signals may be very far from the ideal one (that is, equal to zero).
- The role of the exploration phase increases as the NSR value grows. In fact, the convergence histories toward the optimal solutions using noise-free data are faster than those for a NSR=15%. It is observed that the initial parts of the evolutionary search are more irregular when using a noisy system response, thus highlighting the importance of the exploration stage.

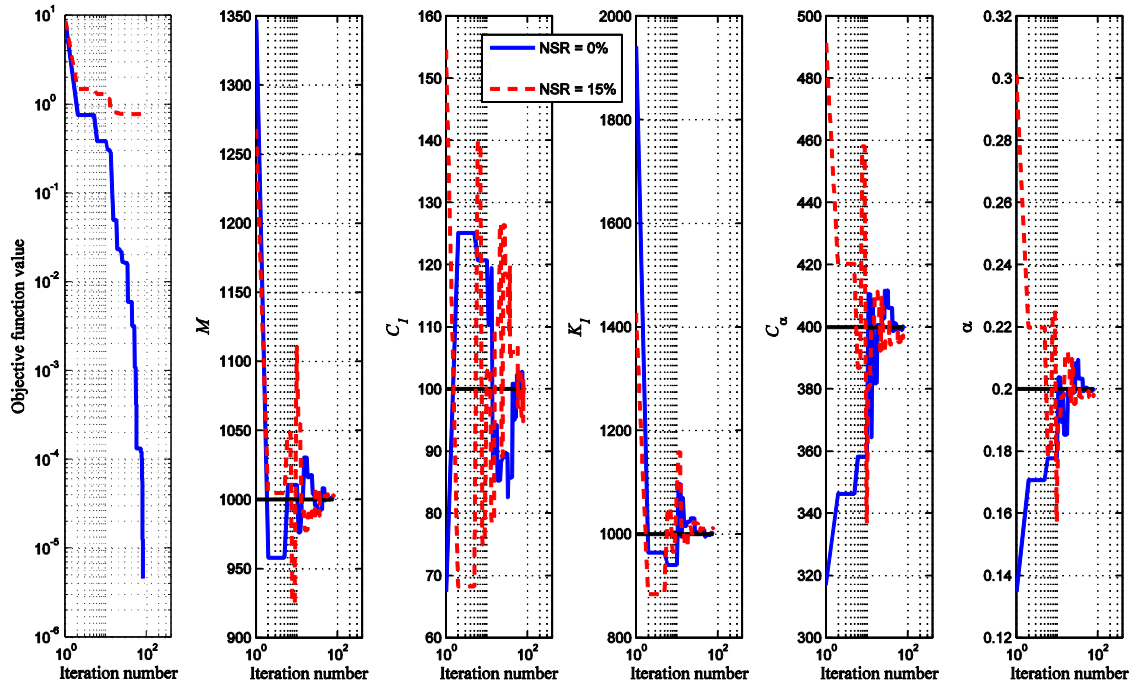

Figure 9: Convergence histories for DEA06 using free-noise and noisy reference response.

7 EXPERIMENTAL RESULTS

The synthesis of the conducted numerical studies provide positive evidences about the reliability of the investigated non-classical identification techniques for parametric identification of nonlinear viscous dampers. Moreover, useful aspects regarding the computational efficiency and the robustness against the instrumental noise were addressed. Nonetheless, the real viscous damper response may be more complicated and neglected nonlinearities can be relevant. Therefore it is essential to assess the applicability of these methods by using experimental data. To this end, some experimental tests were performed on a full-scale nonlinear viscous damper.

Abstract. *In this study multi-objective optimization of structural frames is investigated. Two different materials, reinforced concrete and reinforced engineered cementitious composites (ECC), with different response characteristics are used to model the frames. ECC is characterized by high tensile strength and ductility, high energy absorption and reduced crack widths when compared to conventional concrete. However, the material is more expensive than conventional concrete. Therefore, in order to quantify the potential benefits that could be obtained by replacing concrete with ECC, the structural performance is evaluated for the whole-life-cycle of the structure. The results of the optimization problem are presented in Pareto-optimal form which is preferred by decision makers due to the provided flexibility in selecting the solution alternatives. The option of replacing the conventional material, concrete, with a high performance alternative, ECC, is investigated in an optimization framework with the ultimate goal of higher safety, increased sustainability and improved performance.*

1 INTRODUCTION

Optimal and sustainable design of structures has become an important issue in the recent years. Through the use of optimization techniques, it is possible to reduce the material usage, hence environmental impacts, and concurrently prevent failures by better understanding the structural behavior at different limit states. This paper investigates the use of a high-performance material, engineered cementitious composites (ECC), to reduce the life-cycle cost (LCC) of concrete frames and improve the structural performance at different limit states.

ECC is a fiber-reinforced high-performance material introduced as a replacement for concrete by Li and co-workers [1-4]. ECC differs from other types of high-performance cementitious materials in that the microstructures are optimized using micromechanical models to achieve ultra-high ductility, with crack widths limited to below 100 μ m and ultimate tensile strain capacity as high as 5 percent [5]. The improved performance of ECC comes with an increased cost and reduced greenness. The ECC mixtures are less environmental friendly and cost 1.5-3.3 times more than concrete. However, the seismic structural performance of ECC evaluated in terms of stiffness, strength, ductility and energy absorption capacity is significantly higher [6]. Therefore, the material has to be utilized in the most efficient way to reduce the LCC, increase sustainability through less material usage and extended lifetime, and improve safety through higher performance. This is best investigated by defining an optimization problem that includes structural response in addition to initial and whole-life-cycle costs as the primary objectives.

In the following, a multi-objective optimization problem is formulated taking into account the structural performance, and the initial and whole life-cycle costs. In order to utilize the ECC material in the most efficient way, the critical (potential plastic hinge) locations of the structural frames, i.e. beam-column connections and bases of the columns are deployed with ECC and for the rest of the structure conventional concrete is used. Here, these are referred as multi-material (MM) frames. To assess the performance of this intervention strategy, the results are compared to those of the frames made of concrete only and ECC only.

The ground motions that are used for inelastic dynamic time history analysis of the structural frames are derived by probabilistic seismic hazard analysis (PSHA) at a selected site. This computationally intensive inelastic dynamic time history analysis is employed so as to accurately obtain the earthquake demand and to distinguish the response of reinforced concrete (RC) and ECC frames from that of MM frames. The structural capacity is evaluated by pushover analysis and local response measures, strains in longitudinal reinforcement and matrix (concrete or ECC), are used to define the limit states. The optimal solutions in the search space are found by a Taboo search algorithm which is shown to be very efficient in solving combinatorial problems. The results are presented in Pareto-optimal form to provide flexibility in selecting the alternative solutions and to compare the performance of different frames in the objective function space.

2 SEISMIC HAZARD AND EARTHQUAKE GROUND MOTIONS

2.1 Definition of the seismic hazard

In this study uniform hazard spectra (UHS) obtained from PSHA are used to characterize the seismic hazard for a selected site. The UHS used here are based on the developments by U.S. Geological Survey (USGS) on 2008 national seismic hazard mapping [7].

A site at the intersection of 2nd and Market Streets in San Francisco, CA (with coordinates 37° 47' 21.58'' N, 122° 24' 04.77'' W) is selected and the seismic hazard is consistently de-

rived. The sources of seismicity contributing to the hazard at the selected site are shown in Figure 1(a). The governing faults for the selected site are the San Andreas, the San Gregorio and the Hayward faults. The source-to-site distance varies between 11 km to 25 km depending on the fault. The soil conditions might significantly alter the characteristics of the ground motions at a site, therefore, the soil conditions are also taken into account in the development of UHS. The soil at the selected site is determined as D on the NEHRP [8] scale with a shear wave velocity in the range from 180 m/sec to 360 m/sec.

Site specific hazard curve for peak ground acceleration (PGA), and UHS for three different return periods (i.e. 75, 475, and 2475 years) are calculated as shown in Figure 3(a) and (b), respectively. These return periods correspond to three structural limit states: immediate occupancy (IO), life safety (LS) and collapse prevention (CP), respectively.

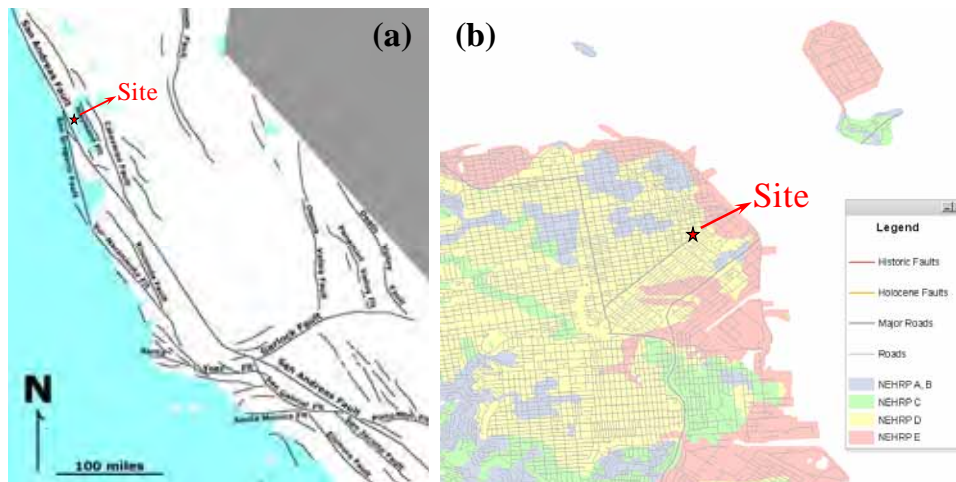

Figure 1: (a) Sources of seismicity [9], and (b) soil profile at the selected site [10].

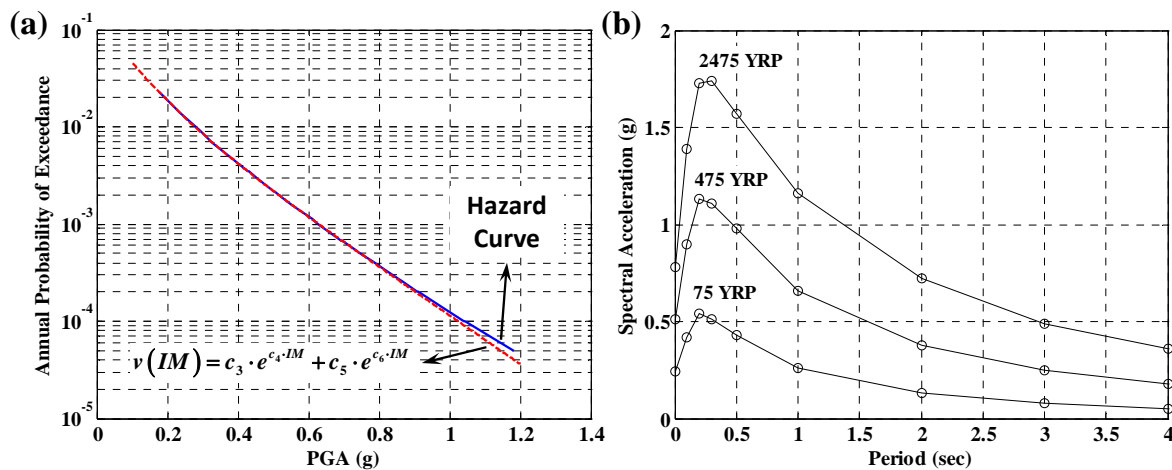

Figure 2: (a) PGA hazard curve, and (b) UHS at different return periods (YRP stands for years return period).

2.2 Selection and spectrum matching of the earthquake ground motions

The disaggregation is performed in order to determine the relative contribution of seismic sources to hazard at a particular location. As a result of the disaggregation calculations the significant parameters, i.e. magnitude, distance, and PGA that characterize the seismic hazard are determined. These values together with the soil conditions and UHS control the selection of earthquake time histories that are used for seismic design and assessment purposes.

The PEER NGA database [11] is utilized to select seven earthquake recordings are for each of the three return periods. The following criteria are used for selecting the records: (1) earthquakes having similar mechanisms to those which are pertinent to the faults affecting the site, (2) magnitudes within ± 1 with the governing magnitude for the considered return period, (3) shear wave velocity of the recording station within the range from 180 m/sec to 360 m/sec, and (4) the acceleration spectrum of the earthquake time history matching as closely as possible the UHS associated with the considered return period.

Spectrum matching is utilized to make the selected ground motions compatible with the UHS at different return periods. For this purpose the RSPMatch software [12] is utilized. The relevant period range for the structural frames considered in this study is from 0-1 sec (see Section 3.1). Therefore, in order not to introduce unrealistic low frequency oscillations in the spectrum compatible ground motions, when target spectra are defined the original spectra of the records are retained for periods longer than 1 sec, and UHS are used for periods shorter than 1 sec. The response spectra, and the acceleration time history before and after spectrum matching of an example record for 475 years return period are shown in Figure 3(a) and (b), respectively.

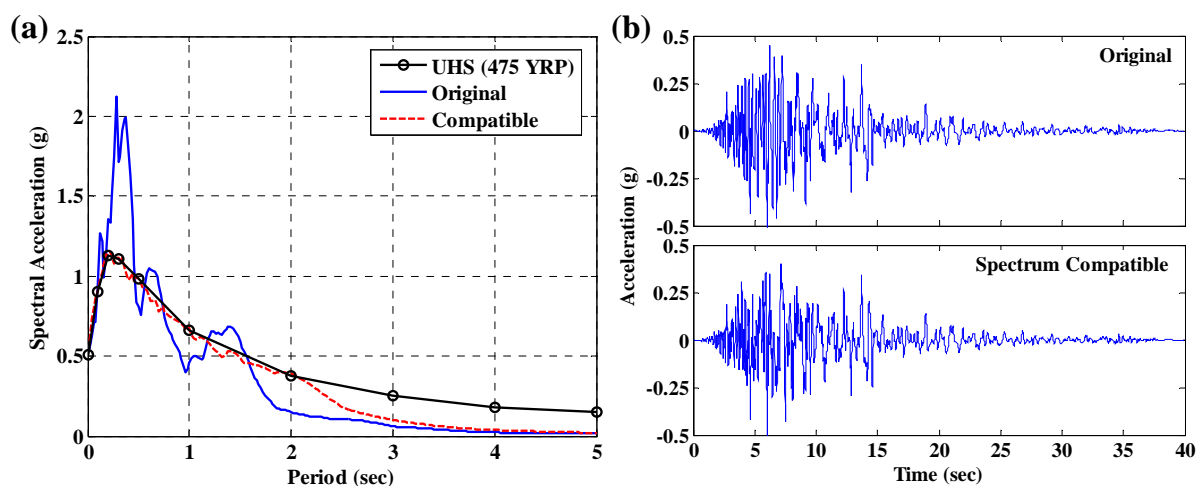

Figure 3: (a) UHS, and response spectrum, and (b) acceleration time history of the selected record, before and after spectrum matching for the 475 years return period.

3 DESCRIPTION OF THE MULTI-OBJECTIVE OPTIMIZATION PROBLEM

3.1 Structural frames

The frame considered for structural optimization is illustrated in Figure 4. The critical locations, i.e. beam-column connections and the column bases are made of ECC, while the rest of the frame is concrete. One tenth of the members' length on each side is assumed to be the critical regions. As mentioned earlier RC only and ECC only frames are also considered for comparison purposes. Seven design variables are defined for the optimization problem as given in Table 1, alongside the minimum and maximum values and increments. The combination of these design variables results in 30,000 cases which constitute the search space for each frame type.

The initial cost of the frames considers only the material costs. The unit prices for concrete and steel are assumed to \$0.13/liters and \$0.66/kg, respectively. It is assumed that the struc-

tural members are properly designed to prevent shear failure and the amount shear reinforcement is calculated following a capacity design approach. First, the moment capacity of the sections are calculated and increased by 20 percent to account for overstrength. Then, the shear force that produces the moment capacity is evaluated and the required shear reinforcement is calculated according to ACI-318 [13]. The cost of shear reinforcement is also included in the initial cost of the frames. It is demonstrated through experimental studies that the shear reinforcement can be eliminated for flexural ECC members [6]. Therefore, no shear reinforcement is added to sections where ECC is used. Labor costs are not considered in this study.

Figure 4: The considered structural frame for optimization.

	Minimum	Maximum	Increment
Column Reinforcement Ratio	1.0%	2.5%	0.50%
Beam Reinforcement Ratio	0.5%	2.0%	0.50%
Width of Exterior Columns (mm)	660.4	863.9	50.8
Width of Interior Columns (mm)	711.2	914.4	50.8
Width of Columns (mm)	457.2	660.4	50.8
Depth of Beams (mm)	508	711.2	50.8
Depth of Beams (mm)	406.4	508	50.8

Table 1: Design variables and ranges for the considered structural frames.

3.2 Evaluation of structural capacity and earthquake demand

Structural capacity is evaluated by pushover analysis. The frames described in Section 3.1 are modeled using fiber-based finite element analysis software ZEUS NL [14] which includes a validated constitutive model for ECC [6]. The three structural limit states, IO, LS and CP that correspond to the three return periods, 75, 475 and 2475 years are determined from the pushover analysis using local response measures, i.e. strains in concrete and longitudinal reinforcement. Based on previous research on testing of steel reinforcement and concrete [15], the occurrence of IO and LS limit states are defined as the reaching or exceeding 0.5 and 5 percent strain, respectively, in the reinforcing steel of any of the columns or beams. The occurrence CP limit state is defined as reaching or exceeding 10 percent strain in reinforcing steel or 1 percent compressive strain in core concrete in any of the columns or beams.

In order to establish the mean values for the limit states to be used in the LCC model, 50 cases are selected randomly from the 30,000 combinations. Pushover analyses of the RC, MM and ECC frames are conducted and the limit states are found in terms of interstory drift.

The selected cases are also utilized to quantify the dispersion in earthquake demand due to variability in the ground motion which is a critical parameter for LCC calculation. Each of the previously mentioned 50 cases is subjected seven ground motions (using inelastic dynamic time history analysis) for each return period. A lognormal distribution is fitted to the earthquake demand at each return period and for each frame type to obtain the dispersion values (β_D in Section 3.3). It is seen that the dispersion in earthquake demand increases for increasing hazard level (return period). 0.25, 0.35 and 0.45 are used as to describe the dispersion in earthquake demand at return periods of 75, 475 and 2475 years, respectively.

3.3 Derivation of the life-cycle cost model

The LCC of a structure (due to post earthquake repair) is a critical parameter for structural engineers and decision makers such as owners. Therefore, it is important to include the LCC as one of the objectives in optimal seismic design of structures. The expected LCC of a structure is calculated as [16]

$$E[C_{LC}(t)] = C_0 + \frac{(1 - e^{-\lambda t})}{\lambda} \sum_{i=1}^N C_i P_i \quad (1)$$

where C_0 is the initial construction cost, t is the service life of the structure (here taken as 75 years), λ is the constant discount rate per year that converts costs due to hazard that occurs in the future into present value (taken as 1 percent), N is the total number of limit-states considered (here equal to 3), P_i is the probability that the structure will be in the i^{th} damage state given the earthquake occurrence, and C_i is the corresponding cost as a fraction of the initial cost of the structure. P_i is given by

$$P_i = P(\Delta_D > \Delta_{C,i}) - P(\Delta_D > \Delta_{C,i+1}) \quad (2)$$

where Δ_D is the earthquake demand and $\Delta_{C,i}$ is the structural capacity, in terms of drift ratio, defining the i^{th} damage state as described in Section 3.2. The probability of demand being greater than capacity is evaluated as

$$P(\Delta_D > \Delta_{C,i}) = \int_0^{\infty} P(\Delta_D > \Delta_{C,i} | IM = im) \left| \frac{dv(IM)}{dIM} \right| dIM \quad (3)$$

where the first term inside the integral is the conditional probability of demand being greater than the capacity given the ground motion intensity, IM . This term is also known as the fragility function. The second term is the slope of the mean annual rate of exceedance of the ground motion intensity. The hazard curve defined as $v(IM)$ in Eqn. (3), where IM is PGA for this study, is shown in Figure 2(a). The conditional probability of demand being greater than the capacity is

$$P(\Delta_D > \Delta_{C,i} | IM = im) = \int_0^{\infty} P(\Delta_D > \delta | IM = im) f_C(\delta) d\delta \quad (4)$$

where δ is the variable of integration and f_C is the probability density function for structural capacity. This formulation assumes that the demand and the capacity are independent of each other. Structural capacity is assumed to be lognormally distributed with $\Delta_{C,i}$ and β_C that are, respectively, the mean and the standard deviation of the corresponding normal distribution. $\Delta_{C,i}$ is evaluated as described in Section 3.2 for RC, MM and ECC frames. The structural de-

mand is also assumed to follow a lognormal distribution and the probability of demand exceeding a certain value, δ , is given by

$$P(\Delta_D > \delta \mid IM = im) = 1 - \Phi \left[\frac{\ln(\delta) - \lambda_{D|IM=im}}{\beta_D} \right] \quad (5)$$

where $\Phi[\cdot]$ is the standard normal cumulative distribution, λ_D is the natural logarithm of the mean of the earthquake demand as a function of the ground motion intensity, and β_D is the standard deviation of the corresponding normal distribution of the earthquake demand. Although, β_C and β_D are dependent on ground motion intensity, in most studies they are taken as constants due to lack of information. The uncertainty in capacity (here represented with β_C) due to sources such as modelling error, lack of knowledge and variation in material properties was investigated in several studies [17]. In this study it is assumed to be equal to 0.35 taking previous research as a reference [17]. The dispersion in earthquake demand (here represented with β_D) due to variability in ground motions is evaluated here as described in Section 3.2. The mean of earthquake demand, μ_D , as a continuous function of the ground motion intensity is described using

$$\mu_D(IM) = c_1 \cdot IM^2 \quad (6)$$

where the constant c_1 is determined by curve fitting to the three data points that match the PGA of the ground motions records at return periods 75, 475 and 2475 years with the earthquake demand evaluated using inelastic dynamic analysis.

The hazard curve shown in Figure 2(a) is also described in the mathematical form

$$v(IM) = c_3 \cdot e^{c_4 \cdot IM} + c_5 \cdot e^{c_6 \cdot IM} \quad (7)$$

where c_3 through c_6 are constant to be determined from curve fitting. The results of the curve fitting using the functional form described by Eqn. (7) to the PGA hazard curve at the selected site is shown in Figure 2(a).

With the above described formulation each term in Eqn. (3) is represented as an analytical function of the ground motion intensity, IM . Thus, using numerical integration the desired probabilities of Eqn. (2) can easily be calculated. The LCC is evaluated through Eqn. (1).

4 TABOO SEARCH ALGORITHM

As described earlier the optimization problem is reduced to a combinatorial one due to discrete nature of the design variables. Taboo search (TS) algorithm which is known to be very efficient in solving combinatorial problems is used here.

To describe the modified TS algorithm used here, first, it is required to make the following definitions. The taboo list includes points in the design space for which the objective functions are evaluated for. Since inelastic dynamic time history analysis is computationally costly, this list is used to avoid multiple runs with the same combination of design variables. That is, a point in the taboo list is not evaluated again. The Pareto list includes the points that are not dominated by other points within the set for which the evaluation of objective functions is performed (i.e. the taboo list). The seed list includes the points around which optimal solutions are looked for. The latter are called as the neighboring points and they are basically the adjacent elements of the multidimensional array, that defines the decision (or design) variables, around the given seed point. The modified TS algorithm works as follows:

- Start with the minimum cost combination evaluate the objective function and add this point into taboo, seed and Pareto lists. Use this point as the initial seed point.
- Find the neighboring points around the current seed. Here the number of neighboring points is chosen equal to the number of design variables and selected randomly amongst all the adjacent elements of the multidimensional array that defines the design variables.
- Evaluate the objective function for all the neighboring points and add these into taboo list.
- Find the Pareto-front using the set of points for which the objective function is evaluated and update the Pareto list as the current Pareto-front.
- Amongst the neighboring points for the current iteration choose the one that is on the Pareto-front and minimizes the cost function as the next seed point and add this point into the seed list. If there is no point which satisfies these conditions choose randomly one of the points from the Pareto list amongst the ones that are not already in the seed list.
- Check if the predetermined maximum number of objective function evaluations is exceeded; if yes stop, if not go to Step b.

5 RESULTS AND DISCUSSION

As an example of how the TS algorithm conducts the search within the search space, in Figure 5(a), the results for initial cost vs. maximum interstory drift for the MM frame at 2475 years return period is shown. It is seen that the TS algorithm is very efficient in narrowing down the search space to the points that are close to the Pareto-front, which is shown with solid line with circle marks. In Figure 5(b), the Pareto-fronts at the three hazard levels are compared for the MM frame. These results are very useful for decision makers. It allows the decision maker, whether it is the owner or the engineer, to choose among the set of optimal solutions depending on the requirements of the project. As an example, if the requirement of the project is that the maximum interstory drift under the 2475 years return period earthquake is less than four percent, one can easily find the least cost solution. Later on, if the requirement of the project changes and it becomes necessary to limit the maximum interstory drift to three percent, no additional analysis will be required to find the optimal solution.

Figure 5: (a) Initial cost vs. maximum interstory drift for the MM frame at 2475 years return period, (b) Pareto-fronts for different return periods – MM frame.

As shown in Figure 6(a), in terms of total cost, the MM frame performs slightly better than RC frame due to reduced repair cost resulting from the increase in structural capacity as described in Section 3.2. However, as mentioned in Section 3.1, for simplicity in calculation of the initial cost, the workmanship costs are not included, and the initial cost is solely based on the material cost. In other words, the reduction in workmanship costs due to reduction in reinforcement detailing and prevention of congestion problems that result from the elimination of shear reinforcement is not taken into account. Furthermore ECC material is proven to be more durable than conventional concrete due to reduced crack widths with a distributed cracking pattern which increases the lifetime of the buildings [18, 19]. MM frame performs better when this additional information is taken into account. It is seen in Figure 6(a) that with the ECC frame the maximum interstory drift could be lowered to levels which cannot be achieved with the RC or MM frames. The Pareto-fronts for repair vs. initial cost for the three frames are compared in Figure 6(b). It is seen that the repair cost of the ECC frame is significantly less compared to RC frame for similar initial costs. The repair cost of the ECC frame is higher as it is based on the higher initial material cost.

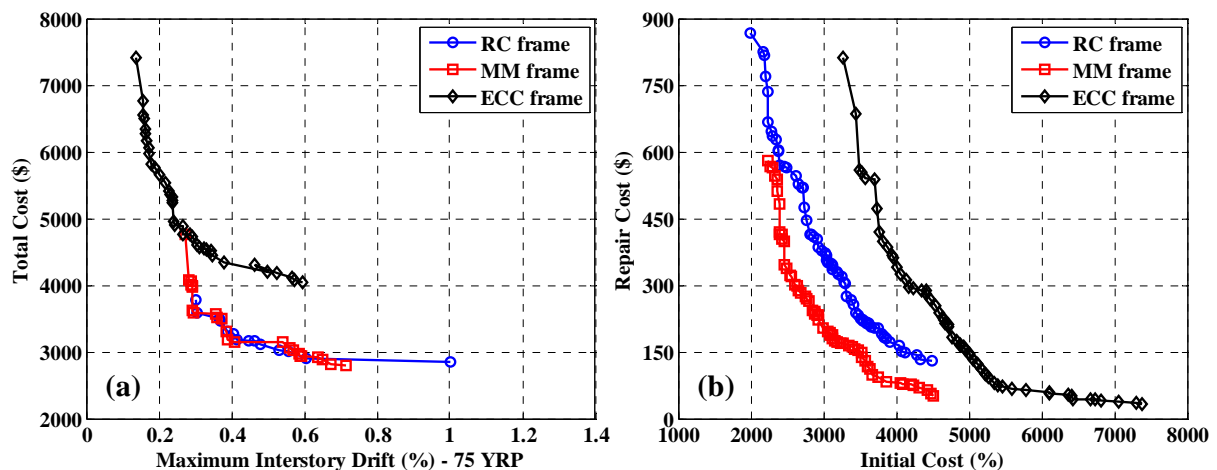

Figure 6: Pareto fronts for the three frames (a) total (life-cycle) cost vs. maximum interstory drift at 75 years return period, (b) repair cost vs. initial cost.

The seismic LCC analysis poses significant challenges to researchers. There are various parameters that have direct effect on the LCC results. Most importantly, for the formulation provided in this paper, the constants C_i in Eqn. (1) which define the cost of repair for the i^{th} damage state as a fraction of the initial cost have strong influence on the LCC. It is not straightforward to determine damage states for structures and the associated cost for repair. Furthermore, based on the adopted definitions, the limit state threshold values may vary significantly which affects the failure probabilities. Eqn. (4) assumes that the structural capacity is independent of earthquake demand which is another simplification that is usually adopted. Finally, the evaluation of workmanship cost is difficult as it is dependent on various parameters, above all the cost of labor at the location of construction. These are the most important assumptions of this study that warrant further investigation in the future studies.

6 CONCLUSIONS

The use of engineered cementitious composite (ECC) materials for improving the seismic design of buildings in terms of safety, economy and sustainability, is investigated through a multi-objective optimization problem. The objectives are selected as the structural performance, initial and the life-cycle cost (LCC). Three types of structural frames are considered:

made from reinforced concrete (RC) and reinforced ECC only, and a multi-material (MM) frame where the ECC is only used at the beam-column connections and at the bases of the columns. It is observed that, although the earthquake demand is significantly reduced in the case of ECC frame, the gain is not justified due to increased initial cost. On the other hand, the structural capacity of the MM frame is significantly higher which results in reduced repair hence LCC. If the additional benefits such as the reduction in workmanships costs and increased in life-time with enhanced ECC material durability are taken into account, the MM frame come forward as the most optimal solution to achieve the multiple objectives of the problem.

Abstract. *Viscoelastic (VE) dampers are now among preferable energy dissipation devices used for passive seismic response control. It is the aim of this paper to find the optimal damper placement and to determine the optimal parameters of dampers. The dynamic behavior of VE dampers, as described by the fractional Maxwell rheological model, is written in the form of a fractional differential equation. Fractional models have an ability to correctly describe the behavior of VE materials and dampers using a small number of model parameters. The equation of motion for the structure considered is expressed in the state space. The structure is subjected to a base acceleration. For the harmonic external forces the displacement response of the structure is determined. Solving the equation of motion yields an input-output relationship with the matrix frequency response function. The objective function, which we minimize, is the weighted sum of amplitudes of the transfer functions of interstorey drifts, evaluated at the fundamental, natural frequency of the frame with the dampers. The solution is obtained using the sequential optimization method and the particle swarm optimization method (PSO). The results obtained by both methods are compared.*

1 INTRODUCTION

Viscoelastic dampers are successfully applied to reduce excessive vibrations of buildings caused by winds and earthquakes. Incorporation of the VE dampers into a structure leads to a significant reduction of undesirable vibrations, see Soong [1]. A number of applications of VE dampers in civil engineering are listed in [2]. The dampers' behavior depends mainly on the rheological properties of the VE material the dampers are made of and their geometric parameters. In the past, several rheological models were proposed to describe the dynamic behavior of VE materials and dampers. Both the classic and the so-called fractional-derivative models of dampers are available. In the classic approach, mechanical models consisting of springs and dashpots are used to describe the rheological properties of VE dampers [3]. A good description of the VE dampers requires mechanical models consisting of a set of appropriately connected springs and dashpots. In this approach, the rheological properties of VE dampers are described using the fractional calculus and the fractional mechanical models. The fractional calculus has received considerable attention and has been used in modeling the rheological behavior of VE materials [4] and dampers [5]. The fractional models have an ability to correctly describe the behavior of VE materials and dampers using a small number of model parameters. A single equation is enough to describe the VE damper dynamics, which is an important advantage of the discussed model. However, in this case, the VE damper equation of motion is the fractional differential equation. The dynamic analysis of frame or building structures with dampers is presented in many papers [6, 7], where the fractional-derivative rheological model is used to model the dampers' behavior.

In this paper, planar frame structures with VE dampers mounted on them are considered. The VE dampers are modeled using the three-parameter fractional rheological Maxwell model. The structures are treated as linear elastic systems. The equations of motion of the whole system (structure with dampers) are written in terms of both physical and state-space variables. The proposed approach to the state space formulation is new. This is the main advantage of the proposed formulation, which does not require matrices with huge dimensions. However, the resulting matrix equation of motion is a fractional differential equation.

It is aim of the present paper to find the optimal placements of the dampers and to determine their optimal parameters. The objective function, which we minimize, is the weighted sum of amplitudes of the transfer functions of interstorey drifts, evaluated at the fundamental, natural frequency of a frame with dampers. The optimality criterion is expressed by the vector consisting of the values of the above mentioned transfer functions of the interstorey drifts.

The solution to the considered optimization problem is arrived at using the sequential optimization method and the particle swarm optimization method (PSO), which is based on the study of social behavior in a self-organized population system [8, 9]. Numerical tests carried out for a multi-storey building structure modeled as a shear plane frame with VE dampers mounted on it show that the presented methods are simple and efficient.

2 THE RHEOLOGICAL MODEL OF DAMPER

In this paper, the fractional Maxwell model is used to represent the rheological properties of VE dampers. The considered model consists of a fractional dashpot with the constants: c_i , α_i ($0 < \alpha_i \leq 1$) and a spring of the stiffness k_i . The equations of motion for the Maxwell model could be written using the so-called relative internal variable v_i (see Figure 1). The above-mentioned equations of motion for the damper are as follows:

$$\begin{aligned} u_i &= c_i D_t^{\alpha_i} (x_i - v_i) \\ u_i &= k_i v_i \end{aligned} \quad (1)$$

where u_i is the damper force and x_i is the relative damper displacement. Moreover, $D_t^{\alpha_i}(\bullet)$ denotes the Riemann-Liouville fractional derivative of the order α_i with respect to time, t .

Figure 1: Rheological model of fractional Maxwell damper

The equation of motion of the classical Maxwell models could be obtained after substituting $\alpha_i = 1$ into Equations (1).

3 EQUATIONS OF MOTION

The frame with VE dampers is treated as the elastic linear system, which could be modeled as the shear frame. The mass of the system is lumped at the level of storeys.

3.1 The equations of motion expressed in physical coordinates

The equation of motion of the whole system (structure with dampers) can be written as follows:

$$\mathbf{M}_s \ddot{\mathbf{q}}_s(t) + \mathbf{C}_s \dot{\mathbf{q}}_s(t) + \mathbf{K}_s \mathbf{q}_s(t) = \mathbf{s}(t) + \mathbf{p}(t) \quad (2)$$

where the symbols \mathbf{M}_s , \mathbf{C}_s and \mathbf{K}_s denote the mass, the damping, and the stiffness ($n \times n$) matrices, respectively. Moreover, $\mathbf{q}_s(t) = \text{col}(q_{s,1}, \dots, q_{s,j}, \dots, q_{s,n})$ and $\mathbf{p}(t) = \text{col}(p_1, \dots, p_j, \dots, p_n)$ denote the vector of displacements of the structure and the vector of excitation forces, respectively. The $\mathbf{s}(t) = \text{col}(s_1, s_2, \dots, s_n)$ vector is the ($n \times 1$) vector of interaction forces between the frame and the dampers [10].

For the Maxwell model of dampers, the vector of interactive forces $\mathbf{s}(t)$ is treated as a sum of two vectors, i.e., $\mathbf{s}(t) = \mathbf{s}_1(t) + \mathbf{s}_2(t)$. The vector $\mathbf{s}_1(t)$ contains interactive forces which are reactions of the elastic part of the Maxwell dampers to the frame, while the vector $\mathbf{s}_2(t)$ contains interactive forces which are reactions of the dashpot part of the dampers. It is assumed that the dashpot part of the Maxwell model is joined with the upper storey while the elastic part is joined with the lower storey. Moreover, the brace stiffness could be taken into account in the stiffness parameter of the Maxwell model. If a structure with only one damper, denoted as the damper number i , mounted between two successive storeys, j and $j+1$, is considered then the vectors $\mathbf{s}_1(t)$ and $\mathbf{s}_2(t)$ could be written in the following form:

$$\begin{aligned} \mathbf{s}_1(t) &\equiv \mathbf{s}_{1i}(t) = \text{col}(0, \dots, s_j = u_i, \dots, 0) = \tilde{\mathbf{e}}_i u_i(t) \\ \mathbf{s}_2(t) &\equiv \mathbf{s}_{2i}(t) = \text{col}(0, \dots, s_{j+1} = -u_i, \dots, 0) = \hat{\mathbf{e}}_i u_i(t) \end{aligned} \quad (3)$$

where $\tilde{\mathbf{e}}_i = \text{col}(0, \dots, \tilde{e}_j = 1, \tilde{e}_{j+1} = 0, \dots, 0)$, $\hat{\mathbf{e}}_i = \text{col}(0, \dots, \hat{e}_j = 0, \hat{e}_{j+1} = -1, \dots, 0)$.

Taking into account that $q_{s,j}(t) = \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t)$ and $q_{s,j+1}(t) = -\hat{\mathbf{e}}_i^T \mathbf{q}_s(t)$, the damping force $u_i(t)$ of the Maxwell damper could be shown in two equivalent forms:

$$\begin{aligned} u_i(t) &= k_i(v_i(t) - q_{s,j}(t)) = k_i v_i(t) - k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) \\ u_i(t) &= c_i(D_t^{\alpha_i} q_{s,j+1}(t) - D_t^{\alpha_i} v_i(t)) = -c_i D_t^{\alpha_i} v_i(t) - c_i \hat{\mathbf{e}}_i^T D_t^{\alpha_i} \mathbf{q}_s(t) \end{aligned} \quad (4)$$

and the interaction force vectors $\mathbf{s}_{1,i}(t)$ and $\mathbf{s}_{2,i}(t)$ are given by:

$$\begin{aligned} \mathbf{s}_1^{(i)}(t) &= \tilde{\mathbf{e}}_i k_i v_i(t) - \tilde{\mathbf{e}}_i k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) = \tilde{\mathbf{e}}_i k_i \mathbf{h}_i^T \mathbf{q}_r(t) - \tilde{\mathbf{e}}_i k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) \\ \mathbf{s}_2^{(i)}(t) &= -\hat{\mathbf{e}}_i c_i D_t^{\alpha_i} v_i(t) - \hat{\mathbf{e}}_i c_i \hat{\mathbf{e}}_i^T D_t^{\alpha_i} \mathbf{q}_s(t) = -\hat{\mathbf{e}}_i c_i \mathbf{h}_i^T D_t^{\alpha_i} \mathbf{q}_r(t) - \hat{\mathbf{e}}_i c_i \hat{\mathbf{e}}_i^T D_t^{\alpha_i} \mathbf{q}_s(t) \end{aligned} \quad (5)$$

where the vector of internal variables $\mathbf{q}_r(t) = \text{col}(v_1(t), \dots, v_i(t), \dots, v_m(t))$ and the vector $\mathbf{h}_i = \text{col}(0, \dots, h_i = 1, \dots, 0)$ have the dimension $(m \times 1)$. Moreover, from the equilibrium condition of the internal node of the Maxwell model of damper we obtain:

$$-c_i D_t^{\alpha_i} q_{s,j+1}(t) + c_i D_t^{\alpha_i} v_i(t) - k_i q_{s,j}(t) + k_i v_i(t) = 0 \quad (6)$$

In the matrix notation, Equation (6) for $i = 1, 2, \dots, m$, may be rewritten in the form:

$$c_i \hat{\mathbf{e}}_i^T D_t^{\alpha_i} \mathbf{q}_s(t) + c_i \mathbf{h}_i^T D_t^{\alpha_i} \mathbf{q}_r(t) - k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) + k_i \mathbf{h}_i^T \mathbf{q}_r(t) = 0 \quad (7)$$

When m dampers are present in the frame, and all the fractional parameters are equal, (i.e., $\alpha_i = \alpha = \text{const.}$) then the interaction force vectors are:

$$\begin{aligned} \mathbf{s}_1(t) &= \sum_{i=1}^m \tilde{\mathbf{e}}_i k_i \mathbf{h}_i^T \mathbf{q}_r(t) - \sum_{i=1}^m \tilde{\mathbf{e}}_i k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) \\ \mathbf{s}_2(t) &= -\sum_{i=1}^m \hat{\mathbf{e}}_i c_i \mathbf{h}_i^T D_t^{\alpha} \mathbf{q}_r(t) - \sum_{i=1}^m \hat{\mathbf{e}}_i c_i \hat{\mathbf{e}}_i^T D_t^{\alpha} \mathbf{q}_s(t) \end{aligned} \quad (8)$$

After pre-multiplying Equation (7) by \mathbf{h}_i and summing up all equations with respect to i , we have:

$$\sum_{i=1}^m \mathbf{h}_i c_i \hat{\mathbf{e}}_i^T D_t^{\alpha} \mathbf{q}_s(t) + \sum_{i=1}^m \mathbf{h}_i c_i \mathbf{h}_i^T D_t^{\alpha} \mathbf{q}_r(t) - \sum_{i=1}^m \mathbf{h}_i k_i \tilde{\mathbf{e}}_i^T \mathbf{q}_s(t) + \sum_{i=1}^m \mathbf{h}_i k_i \mathbf{h}_i^T \mathbf{q}_r(t) = 0 \quad (9)$$

Taking into account that $\mathbf{s}(t) = \mathbf{s}_1(t) + \mathbf{s}_2(t)$ and substituting Equations (8) into (2) we obtain the following equation of motion for the frame with the Maxwell dampers:

$$\begin{aligned} \mathbf{M}_s D_t^2 \mathbf{q}_s(t) + \mathbf{C}_s D_t^1 \mathbf{q}_s(t) + \mathbf{C}_{ss}^d D_t^{\alpha} \mathbf{q}_s(t) + (\mathbf{K}_s + \mathbf{K}_{ss}^d) \mathbf{q}_s(t) + \\ + \mathbf{C}_{sr}^d D_t^{\alpha} \mathbf{q}_r(t) - \mathbf{K}_{sr}^d \mathbf{q}_r(t) = \mathbf{p}(t) \end{aligned} \quad (10)$$

Equation (9) could be rewritten in the form:

$$\mathbf{C}_{rs}^d D_t^{\alpha} \mathbf{q}_s(t) + \mathbf{C}_{rr}^d D_t^{\alpha} \mathbf{q}_r(t) - \mathbf{K}_{rs}^d \mathbf{q}_s(t) + \mathbf{K}_{rr}^d \mathbf{q}_r(t) = 0 \quad (11)$$

The following symbols

$$\mathbf{C}_{ss}^d = \sum_{i=1}^m \hat{\mathbf{e}}_i c_i \hat{\mathbf{e}}_i^T, \quad \mathbf{C}_{sr}^d = \sum_{i=1}^m \hat{\mathbf{e}}_i c_i \mathbf{h}_i^T, \quad \mathbf{C}_{rs}^d = \sum_{i=1}^m \mathbf{h}_i c_i \hat{\mathbf{e}}_i^T = (\mathbf{C}_{sr}^d)^T, \quad \mathbf{C}_{rr}^d = \sum_{i=1}^m \mathbf{h}_i c_i \mathbf{h}_i^T,$$

$$\mathbf{K}_{rs}^d = \sum_{i=1}^m \mathbf{h}_i k_i \tilde{\mathbf{e}}_i^T = (\mathbf{K}_{sr}^d)^T, \quad \mathbf{K}_{rr}^d = \sum_{i=1}^m \mathbf{h}_i k_i \mathbf{h}_i^T, \quad \mathbf{K}_{sr}^d = \sum_{i=1}^m \tilde{\mathbf{e}}_i k_i \mathbf{h}_i^T, \quad \mathbf{K}_{ss}^d = \sum_{i=1}^m \tilde{\mathbf{e}}_i k_i \tilde{\mathbf{e}}_i^T,$$

were introduced in Equations (10) and (11). The system of fractional differential Equations (10) and (11) constitute a set of equations from which the dynamic response of the structure with the Maxwell dampers can be determined.

3.2 The equations of motion expressed in the state space

In many cases it is very convenient to use the equation of motion expressed in the state space. In the case of frames with the Maxwell dampers the vector of state variables and the vectors of state variables' derivatives are defined as:

$$\begin{aligned} \mathbf{z}(t) &= \text{col}(\mathbf{q}_r(t), \mathbf{q}_s(t), D_t^1 \mathbf{q}_s(t)) \\ D_t^1 \mathbf{z}(t) &= \text{col}(D_t^1 \mathbf{q}_r(t), D_t^1 \mathbf{q}_s(t), D_t^2 \mathbf{q}_s(t)) \\ D_t^\alpha \mathbf{z}(t) &= \text{col}(D_t^\alpha \mathbf{q}_r(t), D_t^\alpha \mathbf{q}_s(t), D_t^{\alpha+1} \mathbf{q}_s(t)) \end{aligned} \quad (12)$$

Moreover, when the following additional matrix equation:

$$\mathbf{M}_s D_t^1 \mathbf{q}_s(t) - \mathbf{M}_s D_t^1 \mathbf{q}_s(t) = \mathbf{0} \quad (13)$$

is appended to the Equation (10) and (11) a set of equations is obtained which could be rewritten using the state variables defined above. The resulting matrix equation is in the form:

$$\mathbf{A} D_t^1 \mathbf{z}(t) + \mathbf{A}_1 D_t^\alpha \mathbf{z}(t) + \mathbf{B} \mathbf{z}(t) = \tilde{\mathbf{p}}(t) \quad (14)$$

where

$$\mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_s & \mathbf{M}_s \\ \mathbf{0} & \mathbf{M}_s & \mathbf{0} \end{bmatrix}, \quad \mathbf{A}_1 = \begin{bmatrix} \mathbf{C}_{rr}^d & \mathbf{C}_{rs}^d & \mathbf{0} \\ \mathbf{C}_{sr}^d & \mathbf{C}_{ss}^d & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{K}_{rr}^d & -\mathbf{K}_{rs}^d & \mathbf{0} \\ -\mathbf{K}_{sr}^d & \mathbf{K}_s + \mathbf{K}_{ss}^d & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & -\mathbf{M}_s \end{bmatrix}, \quad \tilde{\mathbf{p}}(t) = \begin{bmatrix} \mathbf{0} \\ \mathbf{p}(t) \\ \mathbf{0} \end{bmatrix}$$

The above approach to the state space formulation is new. In comparison with previous ones, such as those given in [11, 12], matrices with huge dimensions were not required which is the main advantage of the proposed formula. Moreover, all of the matrices appearing in Equation (14) are symmetrical.

4 DYNAMIC ANALYSIS

4.1 Dynamic characteristics of structures

Applying the Laplace transform, taking into account that $\tilde{\mathbf{p}}(t) = \mathbf{0}$:

$$\mathcal{L}[\mathbf{z}(t)] = \mathbf{Z}, \quad \mathcal{L}[D_t^\alpha \mathbf{z}(t)] = s^\alpha \mathbf{Z}, \quad \mathcal{L}[D_t^1 \mathbf{z}(t)] = s \mathbf{Z}, \quad (15)$$

the equation of motion (14) can be written as

$$(s\mathbf{A} + s^\alpha \mathbf{A}_1 + \mathbf{B})\mathbf{Z} = \mathbf{0}, \quad (16)$$

Equation (16) constitutes a non-linear eigenproblem which can be solved using the continuation method. The solution to the considered non-linear equation could be shown as a curve in the configuration space, i.e., the s, \mathbf{Z} space. The first point in this curve is obtained for $\alpha = 1$, in this case Equation (16) expresses the linear eigenvalue problem. Next, the solution to the

eigenproblem (16) for the chosen value of $\alpha \in (0, 1)$ is investigated. The incremental-iteration method, presented in detail in [10], is used. Usually, one incremental step and three or four iterations are enough to reach the solution for the final value of the fractional parameter. The continuation method enables the eigenvalues s_i to be determined.

The dynamic behavior of a frame with viscoelastic dampers is characterized by the natural frequency ω_i and the non-dimensional damping parameter γ_i . Similarly to viscous damping, the above-mentioned properties are defined as follows:

$$\omega_i^2 = \mu_i^2 + \eta_i^2, \quad \gamma_i = -\mu_i / \omega_i, \quad (17)$$

where $\mu_i = \text{Re}(s_i)$, $\eta_i = \text{Im}(s_i)$.

4.2 Frequency response functions

In this section we investigate the steady state harmonic responses of structures governed by Equations (14). For the harmonic external forces described by:

$$\mathbf{p}(t) = \mathbf{P} \exp(i\lambda t), \quad (18)$$

where $i = \sqrt{-1}$, λ is the frequency of excitation, the displacement response of the structure can be expressed as:

$$\mathbf{q}_s(t) = \mathbf{Q}_s(\lambda) \exp(i\lambda t). \quad (19)$$

If relationships (18) and (19) are substituted into the equation of motion (14), written in the state space, the following equation is obtained:

$$\mathbf{Q}_s(\lambda) = \tilde{\mathbf{H}}(\lambda) \tilde{\mathbf{P}}, \quad (20)$$

where:

$$\tilde{\mathbf{H}}(\lambda) = [i\lambda \mathbf{A} + (i\lambda)^\alpha \mathbf{A}_1 + \mathbf{B}]^{-1}. \quad (21)$$

When the structure is subjected to a base acceleration $\ddot{u}_g(t)$, the excitation vector is written as $\mathbf{p}(t) = -\mathbf{M} \mathbf{r} \ddot{u}_g(t)$, where $\mathbf{r} = \text{col}\{1, 1, \dots, 1\}$. For the harmonic external forces, $\ddot{u}_g(t) = \ddot{U}_g \exp(i\lambda t)$. The displacement response of the structure is given by relationship (19) and $\mathbf{Q}_s(\lambda)$ is determined from:

$$\mathbf{Q}_s(\lambda) = \mathbf{H}(\lambda) \ddot{U}_g. \quad (22)$$

where the vector $\mathbf{H}(\lambda) = -\tilde{\mathbf{H}}(\lambda) \mathbf{M} \mathbf{r}$ will be called the vector of frequency transfer functions of displacements.

5 OPTIMIZATION PROBLEM

It is the aim of this paper to find the optimal dampers' placements and to determine the optimal parameters of the dampers k_{di} and c_{di} . The objective function, which is minimized, is the weighted sum of amplitudes of the transfer functions of interstorey drifts, $h_i(\lambda)$, evaluated at the fundamental, natural frequency ($\lambda = \omega_1$) of the frame with the dampers. The optimality criteria may be described as follows:

$$F = \mathbf{w}^T \mathbf{h}(\omega_1). \quad (23)$$

where the vector $\mathbf{h}(\omega_1) = \text{col}(h_1(\omega_1), h_2(\omega_1), \dots, h_n(\omega_1))$ consists of the values of the above mentioned amplitudes of transfer functions of interstorey drifts, $\mathbf{w} = \text{col}(w_1, w_2, \dots, w_n)$ is the vector of weight coefficients, and n stands for the number of the structure's degrees of freedom.

The considered optimization problem is subjected to some constraints. We assume that the sum of damping coefficients and the sum of stiffness parameters are known and constant. Moreover, the values of the parameters of damping, $c_{d,i}$, and stiffness, $k_{d,i}$, for every damper must be non-negative. The above constraints are written as:

$$\sum_{i=1}^m c_{d,i} = C_d, \quad \sum_{i=1}^m k_{d,i} = K_d, \quad c_{d,i} \geq c_{\min}, \quad k_{d,i} \geq k_{\min}. \quad (24)$$

where c_{\min}, k_{\min} represent the assumed low-value positive numbers ($c_{\min} = 1.0 N \text{ sec}^\alpha / m$ was chosen in our example).

The vector $\mathbf{H}_d(\lambda)$ of the frequency transfer functions of interstorey drifts can be calculated from the following formula:

$$\mathbf{H}_d(\lambda) = \mathbf{T} \mathbf{H}(\lambda), \quad (25)$$

where the transformation matrix is:

$$\mathbf{T} = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 & 0 & 0 \\ -1 & 1 & 0 & \dots & 0 & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 0 & -1 & 1 \end{bmatrix}. \quad (26)$$

The solution is obtained using the sequential optimization method and the particle swarm optimization method (PSO). In the first case, for every possible location of one damper the values of the objective function are calculated. The right fixed location of the damper is the position for which the minimum value of the objective function is obtained. When the first damper's location is determined the procedure is repeated until all locations are found for the dampers. However, there is no proof for the solution's convergence although many examples show that this method is simple and efficient in many engineering applications (for instance [13]).

The PSO algorithm which is based on the study of social behavior in a self-organized population system (i.e., ant colonies, fish schools), searches a space by adjusting the trajectories of so-called particles. In the considered optimization problem, the vector of the i -th particle's position \mathbf{p}_i consists of damping coefficients of dampers currently mounted on the structure, i.e., $\mathbf{p}_i = \text{col}(c_{d,1}^{(i)}, c_{d,2}^{(i)}, \dots, c_{d,n}^{(i)})$. The dimension of the vector \mathbf{p}_i is equal to the number of building storeys. Moreover, to reduce the number of elements of the particle position vector and because of technological requirements for the damper, the stiffness parameter of the damper is calculated assuming that the ratio $c_{d,i} / k_{d,i}$ is given and will not change during iteration.

A population of particles is initialized with random positions and velocities [9]. Taking into account the best positions of the particles at subsequent iteration $k+1$, the algorithm adjusts the behavior of the particles by the following rules:

$$\begin{aligned}\mathbf{v}_i(k+1) &= w(k)\mathbf{v}_i(k) + \frac{c_1}{\Delta t} \mathbf{R}_1(k)(\mathbf{b}_i(k) - \mathbf{p}_i(k)) + \frac{c_2}{\Delta t} \mathbf{R}_2(k)(\mathbf{g}_i(k) - \mathbf{p}_i(k)) \\ \mathbf{p}_i(k+1) &= \mathbf{p}_i(k) + \mathbf{v}_i(k+1)\Delta t\end{aligned}\quad (27)$$

where $\Delta t = 1$, $\mathbf{p}_i(k)$ is the position of i -th particle at k -th iteration, $\mathbf{v}_i(k)$ is the corresponding velocity vector; $\mathbf{b}_i(k)$ and $\mathbf{g}_i(k)$ stand for the best position found by the particle i and the best position in the particle's neighbourhood achieved so far, respectively; $\mathbf{R}_1(k)$, $\mathbf{R}_2(k)$ are the diagonal matrices of independent random numbers uniformly distributed in the range $(0, 1)$; $w(k)$ is the inertia factor providing balance between exploration and exploitation, c_1 is the individuality constant, and c_2 is the sociality constant. To speed up convergence, the inertia weight could be linearly reduced. A new velocity, which moves the particle in the direction of a potentially better solution, is calculated based on its previous value, and the particle location at which the best fitness so far has been achieved.

The initial values of the elements $v_{i,j}(0)$ of the velocity vector $\mathbf{v}_i(0)$ are calculated from the following formula:

$$v_{i,j} = r_3 C_d \varepsilon_0, \quad (28)$$

where r_3 is the random number taken from the range $(0, 1)$ and ε_0 is a constant ($\varepsilon_0 = 0.05$ is assumed). The initial values of the elements of the vector $\mathbf{p}_i(0)$ are determined from the following relationship:

$$c_{d,i}(0) = \frac{\tilde{r}_i C_d}{\sum_{j=1}^m \tilde{r}_j}, \quad (29)$$

where \tilde{r}_i is a random number taken from the range $(0, 1)$. The above choices assure that all assumed initial approximations of dampers parameters, i.e., vectors $\mathbf{p}_i(0)$ and $\mathbf{v}_i(0)$ fulfill the optimization constraints (24).

An important part of the PSO algorithm is the way of handling the constraints introduced in the optimization problem. Here, the following very simple procedure is used to fulfill the constraints (24):

- if non-admissible values $c_{d,i}(k+1) < 0$ result from the relationship (27) then $c_{d,i}(k+1) = c_{\min}$ is artificially introduced,
- in order to fulfill the constraint (27.1), elements of the vector $\mathbf{p}_i(k+1)$ are normalized in such a way that:

$$\tilde{c}_{d,i} = \frac{c_{d,i}}{\sum_{j=1}^m c_{d,j}} C_d \quad (30)$$

The PSO procedure is ceased if the change of the objective function is sufficiently small, i.e., when:

$$|F(k+1) - F(k)| \leq \varepsilon_1 F(k+1) \quad (31)$$

where ε_1 is an assumed low-value number.

6 NUMERICAL TEST

In the numerical example, a ten-storey building structure modeled as a shear plane frame with VE dampers mounted on it is investigated. The bending rigidity of columns varies in sequence, for every two storeys: $k_1 = k_2 = 68710.0 \text{ kN/m}$, $k_3 = k_4 = 54010.0 \text{ kN/m}$, $k_5 = k_6 = 42170.0 \text{ kN/m}$, $k_7 = k_8 = 28660.0 \text{ kN/m}$, $k_9 = k_{10} = 16450.0 \text{ kN/m}$, but the mass value is the same for every floor: $m_s = 2.07Mg$. The structure's damping ratios corresponding to the stiffness of the storeys are: $c_1 = c_2 = 4.76 \text{ kN sec/m}$, $c_3 = c_4 = 3.73 \text{ kN sec/m}$, $c_5 = c_6 = 2.91 \text{ kN sec/m}$, $c_7 = c_8 = 1.98 \text{ kN sec/m}$, $c_9 = c_{10} = 1.44 \text{ kN sec/m}$ (data taken from [13]).

Firstly, the calculations were carried out for a frame without dampers (see Figure 2a), only the damping properties of structure were taken into account.

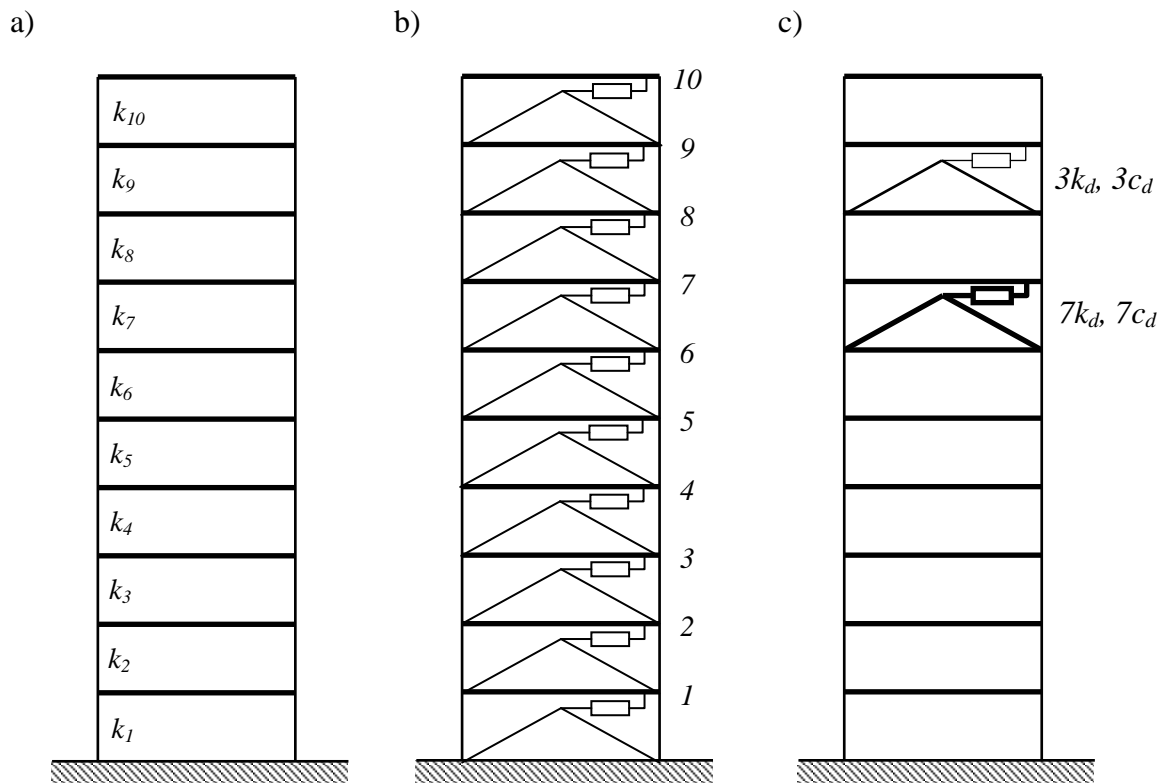

Figure 2: Diagram of a 10-storey frame with different distributions of dampers

The solution to Equation (16), where $\mathbf{A}_1 = \mathbf{0}$ and $\mathbf{K}_{rr}^d = \mathbf{K}_{sr}^d = \mathbf{K}_{rs}^d = \mathbf{K}_{ss}^d = 0$, leads to the eigenvalues s_i which enable determination of the dynamic properties of the structure described by Equation (17). The results, the natural frequencies of the structure and the values of non-dimensional damping factor are presented in Table 1.

Next, the authors investigated a structure with one damper mounted on every storey (see Figure 2b). The assumed value of the sum of the damping coefficients and the sum of the stiffness parameters are: $C_d = 500 \text{ kN sec}^\alpha / m$, and $K_d = 25000 \text{ kNm}^2$, respectively. If damp-

ers are uniformly distributed within a structure, the data for every single damper are: $k_d = 2500 \text{ kNm}^2$, $c_d = 50 \text{ kN sec}^\alpha / \text{m}$, $\tau_d = c_d / k_d = 0.02$. The values of fractional parameters for all dampers are identical, i.e., $\alpha = 0.6$. Using the suggested procedure, the dynamic properties of the considered system were computed (see Table 1).

A first solution to the optimization problem is obtained using the sequential optimization method. For every possible location of one damper, the values of fundamental frequency are calculated (see Figure 3).

Modal number	No dampers		Dampers's distribution			
			uniform		optimal	
	ω_i	γ_i	ω_i	γ_i	ω_i	γ_i

Table 1: Natural frequencies ω_i and non-dimensional damping factors γ_i

Next, the objective function is evaluated for the frame, taking into account every possible position of the damper. The results are presented in Figure 4. It was assumed that the values of the weight coefficients w_i in Equation (23) are equal to one.

Figure 3: Non-dimensional damping factors versus first damper's position

The correct fixed location of the first damper is at the seventh storey, for which the minimum value of the objective function is obtained. When the first damper's location is deter-

mined the procedure is repeated until all locations for the dampers are found. The optimal locations of ten successive dampers are found to be: seven at the seventh storey and three at the ninth storey (see also Figure 2c). The dynamic properties of structures with optimally distributed dampers are shown in Table 1.

It can be noted that the non-dimensional damping ratio of the first mode of vibration is greater (by about 28%), compared with the same ratio for the structure with uniformly distributed dampers. Moreover, the damping ratios of the third, fourth, fifth, seventh, ninth, and tenth modes of vibration are smaller.

Figure 4: Objective function versus first damper's position

In the second approach, the PSO method is applied. In Equation (27), we define the values of coefficients $c_1 = c_2 = 2$ and the declining value of the inertia factor; starting with $w = 0.9$, it decreased by 0.005 at every step of iteration. A population of ten particles was initialized with random positions. The coordinates of every particle position describe the current distribution of damping properties on the frame. On every storey, the value of the damping coefficient must be non-negative and smaller than the assumed constant value $C_d = 500 \text{ kN sec}^\alpha / m$ (i.e., $c_{\min} \leq c_{d,i} \leq C_d$). The stiffness parameters of the dampers are calculated from the value of the ratio $c_{d,i} / k_{d,i}$ which is equal to 0.02 and constant for every damper.

Changes of the best value of the objective function during the iteration process are presented in Figure 5. The solution to the optimization problem, i.e., the optimal distribution of VE dampers obtained with the help of both optimization methods is shown in Table 2.

The objective function, the weighted sum of amplitudes of the transfer functions of interstorey drifts is: $F_0 = 1.7053$, $F_U = 0.3739$, $F_S = 0.2759$ for the frame without dampers, for uniformly distributed dampers, and for the optimal solution obtained by the sequential and PSO methods, respectively.

It can be concluded that results obtained by both methods yield similar dampers' distributions on the frame. Differences between the optimal values of damping coefficients obtained as the result of optimization procedures are partially affected by an incremental way of distribution of damping coefficients in the sequential optimization method. Moreover, in the PSO method the values of the damping $c_{d,i}$ parameters of every damper must be non-negative.

7 CONCLUDING REMARKS

In this paper, frame structures with viscoelastic dampers mounted on them are considered. Viscoelastic dampers are modeled using a three-parameter, fractional rheological Maxwell model which more precisely describes the VE damper's properties, compared with the classical one. The resulting matrix equation of motion is the fractional differential equation. The problem of optimal distribution of VE dampers modeled by the fractional rheological Maxwell model is solved for the first time. The considered optimization problem is solved by minimization of the objective function which is the weighted sum of amplitudes of the transfer functions of interstorey drifts. The sequential optimization method and the particle swarm optimization method are used to successfully solve the optimization problem. Examples of numerical calculations were shown. The presented results demonstrate the effectiveness and applicability of the proposed approach.

Keywords: Structural optimization, constrained optimization, evolution algorithms, selection criteria

Abstract. *Optimization is a central aspect of structural engineering, but its practical application hasn't been supported by mathematical and numerical tools because of inner strong non-linear aspects involved. Moreover during last few decades Evolutionary Algorithms (EAs) gives new interest and horizons in this specific topic, thanks to their strong capacity in treatment of these problems more efficiently than standard methods. But a common criticism to EAs is lack of efficiency and robustness in handling constraints, mainly because they were originally developed for unconstraint problems only. For this reason during past decade hybrid algorithms combining evolutionary computation and constraint-handling techniques have shown to be effective in this specific area. Moreover still now this is a crucial point for practical applications in structural optimization. In this paper a Normalized Domination Selection-based (NDS) rule is proposed to solve constrained-handling optimization problems using a modified version of proposed Differential Evolution algorithm (NDS - DEa). The strategy developed doesn't requires any additional parameter, increasing the appeal for a simple implementation in many real problems by structural designer without a specific knowledge in the field. Mainly it is based on a domination criteria in selection phase. Actually a common way for constrained handling is introducing a specific role for selection step, so that all other phase of EA aren't modified; in this way DE flow chart scheme doesn't present any modification from a standard unconstrained one. Anyway the specific constrained selection scheme plays an important role in solution search efficiency, certainly more than in unconstrained cases. Unconstrained selection is based only on comparing individuals OF values, but in constrained one it seemed somewhat different and complicated. The more simple, common and intuitive way for approaching this phase is the penalty function, where OF values are reduced for those individuals don't satisfying constraints disqualifies (unfeasible individuals). It is immediate (and well known in literature) that depending on penalty low adopted, a more drastic or permissive surviving of unfeasible solutions happened. But this is a central point in this problems, because of in many cases indeed real optimal solutions lies*

just on one constraints, so that its correct evaluation needs of specific research around the boundary, not only in the feasible space. to develop this strategy the domination concept is related to the specific selection that has to be implemented. If in a unconstrained contest it means simply that the domination coincide with the OF ranking, in the constrained contest the question has to be properly treated. In fact there are three possible scenarios:

- *both two individuals are feasible -> selection based on rank*
- *both two individuals are unfeasible -> selection of the feasible one*
- *one is feasible and the other is unfeasible -> selection of less unfeasible*

Moreover the last case presents same some ambiguity because in general there are many constraints with different scales, so that it is impossible to rank correctly to different unfeasible individuals. For this reason a normalized criteria is here proposed and analyzed with different cross over methodology. A comparative analysis using different test cases is performed.

1 INTRODUCTION

Optimization techniques play an important role in many scientific, economical, social and many other problems, the very purpose of which is to find the best way to do something or alternatively to help decision makers to derive the maximum benefit from limited available resources. A common way in many cases has been using past experiences in similar conditions or extending indications from comparable situations. These approaches will not lead in general to the best solution, but the shortcomings of indirect design can be overcome by adopting a direct or optimal design procedure.

An optimization problem or an optimal design procedure consists in finding a maximum or a minimum function problem under some constraint conditions. To deal with this class of problems many different approaches are possible in theory and many heuristic intelligent algorithms have been developed for different classes of optimization problems.

Within the framework of the soft computing methodologies, an incredible number of non-conventional paradigms has been explored in order to create efficient and user-friendly optimizers. Nowadays, a wide variety of biological, social and physical metaphors has been analyzed and tested. Evolutionary Algorithms EAs are stochastic search methods that mimic the metaphor of natural biological evolution and/or the social behavior of species. EAs are ubiquitous nowadays, having been effectively applied to several problems from different domains, including optimization, automatic programming, machine learning, operations research, bioinformatics, and social systems. Usually grouped under the term Evolutionary Computation or Evolutionary Algorithms, one can find the domains of Genetic Algorithms, Evolution Strategies, Evolutionary Programming and Genetic Programming.

These are stochastic search and optimization heuristics derived from the classic evolution theory, which are implemented on computers in the majority of cases. The basic idea is that if only those individuals of a population reproduce, which meet a certain selection criteria, and the other individuals of the population die, the population will converge to those individuals that best meet the selection criteria. If imperfect reproduction is added, the population can begin to explore the search space and will move to individuals that have an increased selection probability and that inherit this property to their descendants. These population dynamics follow the basic rule of the Darwinist evolution theory, which can be described in short as the “survival of the fittest”. To solve optimization problems with an evolutionary heuristic the individuals of a population have to represent a possible solution of a given problem and the selection probability is set proportional to the quality of the represented solution.

The interest toward this class of optimizers is continuously attracting consensus, substantially because the objective function and constraints are not required to be differentiable, continuous or even explicit. In effect, no preliminary assumptions or *a priori* information are needed for solving constrained optimization problems by means of EAs.

In these author knowledge, at the moment, there isn't a unique accepted classification of different EAs proposed in literature, so that a possible non exhaustive one is proposed in the following, where similar techniques differ in the implementation details and in the nature of the particular applied problem.

- **Genetic algorithm:** *This is the most popular (and older) type of EA. One seeks the solution of a problem in the form of strings of numbers (traditionally binary, although the best representations are usually those that reflect something about the problem being solved), by applying operators such as recombination and mutation (sometimes one, sometimes both). This type of EA is often used in optimization problems;*
- **Genetic programming:** *Here the solutions are in the form of computer programs, and their fitness is determined by their ability to solve a computational problem.*

- **Evolutionary programming:** Like genetic programming, only the structure of the program is fixed and its numerical parameters are allowed to evolve;
- **Evolution strategy** - This works with vectors of real numbers as representations of solutions, and typically uses self-adaptive mutation rates;
- **Differential evolution:** It is based on vector differences and it is therefore primarily suited for numerical optimization problems.
- **Particle swarm optimization:** This is based on the ideas of animal flocking behavior and it is also primarily suited for numerical optimization problems.
- **Ant colony optimization:** This is based on the ideas of ant foraging by pheromone communication to form paths. It is primarily suited for combinatorial optimization problems.
- **Invasive weed optimization algorithm:** It is based on the ideas of weed colony behavior in searching and finding a suitable place for growth and reproduction.
- **Harmony search:** Based on the ideas of musicians' behavior in searching for better harmonies. This algorithm is suitable for combinatorial optimization as well as parameter optimization.
- **Gaussian adaptation:** This is based on information theory. Used for maximization of manufacturing yield, mean fitness or average information. See for instance Entropy in thermodynamics and information theory.

Among these approaches one of the more promising one is the Differential Evolution algorithm (DEa): this can be defined a recent stochastic, population-based global optimization method and was proposed about a decade ago [10][11]. The algorithm is based on the use of a special crossover-mutation operator, based on the linear combination of three different individuals and one subject-to-replacement parent. The selection process is performed via deterministic tournament selection between the parent and the child created by it. It is immediate noting that the general structure of the DEa shares similar features with other evolutionary algorithms like GAs. For instance, both optimizers adopt the same terminology to define the key elements of the algorithm (i.e. a collection of solutions is called “population”, each solution is called “individual” and each iteration is called “generation”) and incorporate operators (like mutation, crossover and selection scheme) that work in similar manners. Nonetheless, it is different in handling distance and direction information to move from the population at the current generation toward the next one because it has constructive cooperation between individuals: in this sense, it behaves like Particle Swarm Optimization algorithms (PSOs). Another interesting feature of DEa deals with the selection operator that performs very well and sometimes it is more efficient and faster than other population based algorithms, because of the one-to-one competition scheme. In more general terms, its fashion can be imputable to two positive features; firstly, the DEs provides more simple operators in comparison to the most advanced GAs. Moreover, it requires only few embedded control parameters (typically the total number of control parameters is less than the adopted ones for GAs and PSOs), so that the parameter tuning stage is less time consuming and maybe more practical for non-experts in the field of soft computing techniques.

All attractive features of EAs are in opposition to some criticisms. For instance, EAs suffer the lack of well posed theories about their convergence and a larger computational time is typically required. Moreover, in their original formulation they were limited to unconstrained problems and do not include a method to incorporate feasibility information into the fitness function. In effect, many real-world optimization problems in science and engineering involve a number of constraints which the optimal solution must satisfy. Actually, due to constraints, the feasible space might be reduced to some portion, sometimes very narrow if compared with

the overall search space. Sometimes simply finding feasible solutions itself could be a daunting challenge for some specific practical problems.

As it is known, the ultimate goal of constrained optimization problem is to find the feasible optimal solution. To achieve this goal in EAs, it is required that more feasible individuals are involved in the evolution process. However, on the other hand, some infeasible individuals may carry some information, sometime important, for the final solution than their feasible counterparts in some generations. Hence, these two aspects lead to a contradiction in constrained evolutionary optimization. To address this contradiction, the main challenge is to handle the constraints and to optimize the objective function simultaneously. One possible way is to determinate the tradeoff between the constraint violations and the objective function.

This has triggered a considerable amount of researches and a wide variety of approaches have been suggested in the last few years to incorporate constraints into the fitness function of an evolutionary algorithm. The most popular approach is the use of (mainly exterior) penalty function [12] where the aim is to decrease the fitness of infeasible solutions in order to favor the selection of feasible solutions. Several alternative constraint-handling techniques have been proposed [9].

Actually it is generally accepted that performance of an algorithm largely depends on the underlying mechanism of constraint handling. Motivated by this fact, a number of constraint-handling techniques have been proposed for evolutionary algorithms, and over last few years several methods have been proposed.

These methods have been grouped by different authors into the following categories [1][2][4]:

- *Methods based on preserving the feasibility of solutions. The idea behind the method is based on specialized operators which transform feasible parents into feasible offspring. The method assumes linear constraints only and a feasible starting point or feasible initial population.*
- *Methods based on penalty functions. Many evolutionary algorithms incorporate a constraint-handling method based on the concept of exterior penalty functions which penalize infeasible solutions. These methods differ in important details, such as how the penalty function is designed and applied to infeasible solutions.*
- *Methods which make a clear distinction between feasible and infeasible solutions. There are a few methods which emphasize the distinction between feasible and infeasible solutions in the search space. One of those methods distinguishes between feasible and infeasible individuals: for any feasible individual \mathbf{x} and any infeasible individual \mathbf{y} : $f(\mathbf{x}) < f(\mathbf{y})$, i.e. any feasible solution is better than any infeasible one.*
- *Other hybrid methods. These methods combine evolutionary computation techniques with deterministic procedures for numerical optimization problems. Most constrained problems can be handled by the penalty function method. A measure of the constraint violation is often useful when handling constraints.*

According to the no free lunch theorem, it is impossible for a single constraint handling technique to outperform all other techniques on every problem. In other words, depending on several factors such as the ratio between feasible search space and the whole search space, multimodality of the problem, the chosen EA and global exploration/local exploitation stages of the search process, different constraint handling techniques can be effective on different problems and during different stages of the search process.

The most used techniques incorporate constraints into the fitness function, such as in penalty functions approach, but they usually eliminate all unfeasible individuals. On the other hand it is particularly important to maintain diversity in the population and to be able to keep solu-

tions both inside and outside the feasible region. In fact, several studies have shown that, despite their popularity, traditional (external) penalty functions, even when used with dynamic penalty factors, tend to have difficulties to deal with highly constrained search spaces and with problems in which the constraints are active in the optimum. In these situations infeasible individuals may carry more important information for the final solution than their feasible counterparts in some generations. Hence, these two aspects lead to a contradiction in constrained evolutionary optimization. The use of (exterior) penalty functions is one of the most popular methods to deal with constrained search spaces when using Constrained optimization Evolution Algorithms (COEAs).

For these reasons an efficient and adequate constraint-handling technique is a key element in the design of competitive COEAs to solve complex optimization problems. In this way, this subject deserves special research efforts, with the main aim of proposing approaches able to prevent a too fast convergence without an adequate global (feasible and unfeasible space) re-search process. Some recent proposes in this way investigated modification of what is generally known as the *Constraint Domination Selection (CDS) rule*.

This methodology was initially proposed by Deb [3] as a modification of Powell and Skolnick method which gives a dynamic penalty to each element so that at each generation the best unfeasible element has a rank that is better than the worst unfeasible one. The Deb's method uses a tournament selection operator, where two solutions are compared. In this method, any feasible solution is preferred to any infeasible solution; among two feasible solutions, the one having a better objective function value is preferred and among two infeasible solutions, the one having smaller constraint violation is preferred. Moreover all these method are static application of a *Constraint Domination Selection (CDS) rule*, that practically prefers feasible solutions to unfeasible ones. Finally this was implemented on different types of Evolution Strategies in which the results were very promising [7][6]

The main motivation of this work was to increase this selection criteria to better perform constrained optimization by correctly using selection criteria with specific crossover operators. Standard differential evolution algorithms in unconstrained Optimum Design

The feature of the optimal design is that it consists of only logical decisions in a mathematical way, setting out constraints, and minimizes or maximizes an objective function, that is generally either cost, benefit or a generic merit function. Many of the methods give rise to local minimum/maximum. This, however, depends on the mathematical nature of the optimization problem, that generally can be described as follows:

Find the best vector $\mathbf{x} \in \Omega$ that minimizes $f(\mathbf{x})$ (1)

Satisfying the following constraints

$$g_i(\mathbf{x}) \leq 0 \quad i = 1, 2, \dots, n_g \quad (2)$$

$$h_j(\mathbf{x}) = 0 \quad j = 1, 2, \dots, n_h \quad (3)$$

in which $\mathbf{x} = \{x_1, \dots, x_j, \dots, x_n\}$ is a vector whose components are real numbers, $f(\mathbf{x})$ is the objective function (OF) to be minimized and Ω is a box-type search space. For instance, if $[x_j^l, x_j^u]$ is the admissible interval for the j^{th} variable (x_j^l and x_j^u are its lower and the upper bounds, respectively), then:

$$\Omega = [x_1^l, x_1^u] \otimes [x_2^l, x_2^u] \dots \otimes [x_j^l, x_j^u] \otimes \dots \otimes [x_n^l, x_n^u] \subseteq \mathbb{R} \quad (4)$$

where the symbol \otimes denotes the Cartesian product between intervals.

The constraints of the optimization problems can be both inequalities $g_i(\mathbf{x})$ or equalities $h_i(\mathbf{x})$. Without loss of generality, all equalities can be converted into inequalities using the transformation $|h_j(\mathbf{x})| - \varepsilon \leq 0$, $j = 1, 2, \dots, n_h$, where ε is a tolerance parameter.

Therefore, in the following we will refer only to inequalities-based constraints, e.g. $g_p(\mathbf{x}) \leq 0$ with $p = 1, \dots, n_g, n_g+1, \dots, n_g+n_h$.

A solution \mathbf{x} is regarded as *feasible* if:

$$\sum_{k=1}^{n_p} \max(0, g_k(\mathbf{x})) \leq 0 \quad (5)$$

otherwise it is called as *unfeasible*.

A general optimization problem can be formulated as a typical minimization problem in the form

$$\min_{\mathbf{x}} \{f(\mathbf{x})\} \quad (6)$$

$$\text{s.t. } \mathbf{x}^l \leq \mathbf{x} \leq \mathbf{x}^u$$

in which $\mathbf{x} = \{x_1, \dots, x_j, \dots, x_n\}$ is the design vector (for example the collection of n system parameters to be identified), $\mathbf{x}^l = \{x_1^l, \dots, x_j^l, \dots, x_n^l\}$ and $\mathbf{x}^u = \{x_1^u, \dots, x_j^u, \dots, x_n^u\}$ are its lower and upper bounds, respectively. The shape of the objective function may have many local optima and high complex topology, therefore, when preliminary information are not available it may not always be convex. In these circumstances special optimizers have to be used.

In the following it is illustrated the state of the art of DEa for problems in form (6).

Differential evolution is a simple but powerful population-based stochastic search technique for solving global optimization problem which is characterized by simplicity, effectiveness and robustness. Its main idea is to construct at each generation, for each element of the population a mutant vector. This mutant vector is constructed through a specific mutation operation based on adding differences between randomly selected elements of the population to another element. The original DE algorithm is described in the following briefly. The main variation introduced for constrained problems is in selection process, where use of CDS gives to algorithms for unconstrained problem a natural extension for constrained ones. Moreover the CDS is also applied to evaluation of “best” individual over the entire population. This because some proposed DE algorithm present a mutation that take into account information about the “best” individual over the entire population. In this case a “direction” to escape from constrained space is available at each iteration.

The general structure of a DE is typically for evolutionary algorithms, the particularity of the algorithm being related with the mutation and crossover operators. By combining different mutation and crossover operators various schemes have been developed. In literature different DE schemes are denoted using the convention DE/a/b/c where a denotes the way of constructing the mutant vector, b denoted the number of differences in the construction of the mutant vector and, finally, c denotes the crossover type.

The working of DEa depends on the manipulation and the efficiency of three main operators: mutation, crossover and selection.

2 MUTATION

The main idea of DEa is to construct at each generation for each element of the population a mutation vector. The mutant vector is constructed through a specific mutation operation based on adding differences between randomly selected element of the population to another element.

DEa uses the differences between two randomly selected individuals as the source of random variations for a third individual referred to as the *target vector*. *Trial solutions* are generated by adding weighted difference vectors to the target vector. This process is referred to as the mutation operator: its main goal is to enable diversity in the current population as well as to direct the individuals in such a way a better result is expected. By computing the differences between two individuals randomly chosen from the population, the algorithm estimates the gradient in that zone rather than in a point. Let consider ${}^k\mathbf{x}_i = \{x_{i1}, \dots, x_{ij}, \dots, x_{in}\}$ the i^{th} individual (for $i = 1, \dots, N$) at iteration k . The initial population ${}^0\mathbf{x}_i$ for $i = 1, \dots, N$ is defined by generating pseudo-randomly the collection of N solutions within the specified search space. In this study the Latin Hypercube Sampling (LHS) technique has been iteratively used to generate the best initial population with minimum correlation between samples [8]. At iteration $k+1$, for each individual ${}^k\mathbf{x}_i$ a mutation vector ${}^{(k+1)}\mathbf{v}_i$ is computed by means of one of the following alternatives:

$$\text{rand /1/bin} \quad {}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_{r1} + F^1 \left({}^k\mathbf{x}_{r2} - {}^k\mathbf{x}_{r3} \right) \quad (7)$$

$$\text{best /1/bin} \quad {}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_{best} + F^1 \left({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2} \right) \quad (8)$$

$$\text{current-to-best /1/bin} \quad {}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_i + F^2 \left({}^k\mathbf{x}_{best} - {}^k\mathbf{x}_i \right) + F^1 \left({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2} \right) \quad (9)$$

$$\text{best /2/bin} \quad {}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_{best} + F^2 \left({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2} \right) + F^1 \left({}^k\mathbf{x}_{r3} - {}^k\mathbf{x}_{r4} \right) \quad (10)$$

$$\text{rand /2/bin} \quad {}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_{r1} + F^2 \left({}^k\mathbf{x}_{r2} - {}^k\mathbf{x}_{r3} \right) + F^1 \left({}^k\mathbf{x}_{r4} - {}^k\mathbf{x}_{r5} \right) \quad (11)$$

Two new possible mutation strategy candidates are thus here reported to evaluate their effectiveness in

rand /1/bin (based on tournament selection)

$${}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_i + {}^kF_{r3,i} \left({}^k\mathbf{x}_{r3} - {}^k\mathbf{x}_i \right) + {}^kF_{r1,r2} \left({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2} \right) \quad (12)$$

if $k \leq 0.5L$

rand/1/bin (based on attraction-repulsion paradigm)

$${}^{(k+1)}\mathbf{v}_i = {}^k\mathbf{x}_{r1} + {}^kF_{best,i} \left({}^k\mathbf{x}_{best} - {}^k\mathbf{x}_i \right) + {}^kF_{r1,r2} \left({}^k\mathbf{x}_{r1} - {}^k\mathbf{x}_{r2} \right) \quad (13)$$

if $k > 0.5L$

The mutation coefficients in (12) and in (13) are calculated as follows:

$${}^kF_{r3,i} = \max \left\{ \left| \frac{f({}^k\mathbf{x}_{r3}) - f({}^k\mathbf{x}_i)}{{}^kf_{\max} - {}^kf_{\min}} \right|, 0.5 \right\} \quad (14)$$

$${}^kF_{r1,r2} = \begin{cases} \max \left\{ \left| \frac{f({}^k\mathbf{x}_{r1}) - f({}^k\mathbf{x}_{r2})}{{}^kf_{\max} - {}^kf_{\min}} \right|, 0.5 \right\} & \text{if } k \leq 0.5L \\ \left| \frac{f({}^k\mathbf{x}_{r1}) - f({}^k\mathbf{x}_{r2})}{{}^kf_{\max} - {}^kf_{\min}} \right| & \text{if } k > 0.5L \end{cases} \quad (15)$$

$${}^k F_{best,i} = \left| \frac{{}^k f_{min} - f({}^k \mathbf{x}_i)}{{}^k f_{max} - {}^k f_{min}} \right| \quad (16)$$

in which

$${}^k f_{min} = \min_{i=1,\dots,N} \{f({}^k \mathbf{x}_i)\} \quad {}^k f_{max} = \max_{i=1,\dots,N} \{f({}^k \mathbf{x}_i)\} \quad (17)$$

From Equation (7) to Equation (11) $r1$, $r2$, $r3$ and $r4$ denote integers randomly selected within the set $\{1, \dots, i-1, i+1, \dots, N\}$ and $r1 \neq r2 \neq r3 \neq r4$. The individual ${}^k \mathbf{x}_{best}$ is the best performer in the population at the iteration k . The coefficients F^1 and F^2 are the so-called mutation coefficients and they are real positive constants. These parameters control the amplification level due to the mutation operator (for this reason they are also dubbed scale factors). Any alternative mutation operator leads to different versions of DEAs [10]: rand/1/bin, best/1/bin, current-to-best/1/bin, best/2/bin, rand/2/bin, respectively. Storn and Price shown that the usage of two difference vectors may improve the diversity of the population, especially when the population size is high enough.

As before stated, only mutation in (8), (9) and (10) are used in the following for constrained handling problems. This because they are specifically implemented with a “best” selection based on a CDS rule.

3 CROSSOVER

The perturbed individual ${}^{(k+1)}\mathbf{v}_i$ and the current population ${}^k \mathbf{x}_i$ are then subject to crossover operation. The crossover follows the mutation phase and for each mutated vector ${}^{(k+1)}\mathbf{v}_i$ a trial vector ${}^{(k+1)}\mathbf{u}_i$ (offspring) is generated by using the binomial crossover formalized in Equation (18).

$${}^{(k+1)}\mathbf{u}_{ij} = \begin{cases} {}^{(k+1)}\mathbf{v}_{ij} & \text{if } u \leq p^c \text{ for } j = \text{randint}(0, n) \\ {}^k \mathbf{x}_{ij} & \text{otherwise} \end{cases} \quad (18)$$

In Equation (18) u is a pseudo-random number generated by using the uniform probability density functions in the range $[0,1]$. The parameter p^c is the probability of crossover (or crossover ratio or probability of reproduction) and it takes values between 0 and 1 and it is set by the user. Moreover, $\text{randint}(0, n)$ is a pseudo-randomly integer selected within the set $\{1, \dots, j, \dots, n\}$: based on its realization, an additional condition is introduced to ensure that at least one parameter is taken into account for constructing the vector ${}^{(k+1)}\mathbf{u}_i$.

4 SELECTION

The selection operator in case of unconstrained problems employs a very simple one-to-one competition scheme between ${}^{(k+1)}\mathbf{u}_i$ and ${}^{(k+1)}\mathbf{x}_i$ as follows

$${}^{(k+1)}\mathbf{x}_i = \begin{cases} {}^{(k+1)}\mathbf{u}_i & \text{if } f({}^{(k+1)}\mathbf{u}_i) < f({}^{(k+1)}\mathbf{x}_i) \\ {}^k \mathbf{x}_i & \text{otherwise} \end{cases} \quad (19)$$

Therefore, the winner in the selection stage is the best performer between the parent individual and its trial one. The output of this operator is a new population for the next generation, if a stopping criteria has not been satisfied. Likely to the evolutionary algorithms, the required number of iterations L is not known a priori and therefore a stopping criterion is needed. In more general terms, the stopping criteria can be the same typically adopted for GAs, see for instance [8] and its references. In this study, we stop the search once a maximum number of iterations L is achieved.

A general way the most used way to deals with constraint handling problems consists in replacing standard selection criteria with one that considers not only performance (OF) of solution but feasibility too. In this sense, this selection criteria is obtained by operating a solutions ranking by a generalized domination concept between different individuals: given two solutions, namely $^{(k+1)}\mathbf{u}_i$ and $^{(k+1)}\mathbf{x}_i$ the concept of dominance can be introduced:

$$^{(k+1)}\mathbf{x}_i \succ ^{(k+1)}\mathbf{u}_i \quad (20)$$

that denotes that $^{(k+1)}\mathbf{u}_i$ is dominated by $^{(k+1)}\mathbf{x}_i$

In a constrained based selection the concept of domination must be expressed in a wider sense than those obtained considering simply the OF. Taking into account individuals feasibility, violation function for the i^{th} individual is evaluated by the violation function:

$$\Phi(^k\mathbf{x}_i) = \sum_{p=1}^{n_g+n_h} \max\{0, g_p(^k\mathbf{x}_i)\} \geq 0 \quad (21)$$

so that its value is zero if and only if all constrains are satisfied (the i^{th} individual lies in the feasible design variable space); differently (the i^{th} individual lies in the unfeasible design variable space) the violation function is a positive scalar number.

The selection method able to consider properly feasibility in dominance should be formulated in the following way:

$$^{(k+1)}\mathbf{x}_i \succ ^{(k+1)}\mathbf{u}_i \Leftrightarrow \left\{ \begin{array}{l} \left(f(^{(k+1)}\mathbf{x}_i) < f(^{(k+1)}\mathbf{u}_i) \right) \text{ and } \left(\Phi(^{(k+1)}\mathbf{x}_i) = 0 \right) \wedge \left(\Phi(^{(k+1)}\mathbf{u}_i) = 0 \right) \\ \text{or} \\ \left(\Phi(^{(k+1)}\mathbf{x}_i) = 0 \right) \text{ and } \left(\Phi(^{(k+1)}\mathbf{u}_i) > 0 \right) \\ \text{or} \\ \Phi(^{(k+1)}\mathbf{x}_i) < \Phi(^{(k+1)}\mathbf{u}_i) \end{array} \right. \quad (22)$$

These should be summarized in simply words by the following rule:

$^{(k+1)}\mathbf{x}_i$ dominates $^{(k+1)}\mathbf{u}_i$ if:

- ◆ $^{(k+1)}\mathbf{x}_i$ and $^{(k+1)}\mathbf{u}_i$ are both feasible solutions, and $^{(k+1)}\mathbf{x}_i$ has the minimum value of OF
- ◆ $^{(k+1)}\mathbf{x}_i$ is feasible and $^{(k+1)}\mathbf{u}_i$ is unfeasible
- ◆ $^{(k+1)}\mathbf{x}_i$ and $^{(k+1)}\mathbf{u}_i$ are both unfeasible solutions, and $^{(k+1)}\mathbf{x}_i$ has the minimum value of violation.

This domination criterion should be simply expressed in words as the rule that “feasible solutions survive to the infeasible in any cases”.

Moreover, selection scheme (20) based on (22) is well defined in cases 1 and 2. The first is nothing else than standard selection (both two individuals are feasible, so that the selection can’t deal with constraints. The second simply defines that when are compared two individuals that are one feasible and the other unfeasible, the feasible survives.

The third case presents some drawbacks because it is not so well defined as the first two. Actually, because of number of constraints involved in a optimization problem (usually greater than one) it is impossible to correctly ranking violation levels of unfeasible individuals by using directly the violation function presented in (21). To properly clarify this point, in a generic search space selecting between two unfeasible individuals, we have to prefer those more closer to the feasible space; unfortunately the violation function, as it has been obtained in (21) is not able to evaluate this distance, so that it isn’t able to ranking solutions according their distance to the feasible space because it is obtained simply adding violation levels of different constraints that are not homogeneous according their effective distance from the feasible

space. In simply words it means that, once two solutions are both unfeasible, it isn't possible evaluating correctly which of them is the "*less far*" from the feasible space boundary. This piece of information is needed in evolutionary search algorithms to properly select the best solution among a group of unfeasible ones. So that, the dominance based selection criterion for two unfeasible individuals is still an open question and there isn't a metric measure to evaluate what is the "*less worst*".

In order to overcome this limitation, modified versions of the standard rule are here proposed, to evaluate if and how they increase algorithm performance in convergence to a feasible space. This aspect is extremely important especially in engineering optimizations, where the necessity of a feasible solution is priority respect to those of a performance ones.

A first variation of standard Deb's Dominance Selection rule consists in using a normalization of violation function in (21). In this way, one scraps from the effective numerical value of the violated constraint, whose value should be very different regardless of the effective distance of individual from the admissible domain. The final goal in this manner is to obtain a ranking in which individuals nearest

to the admissible domain work better.

For this aim, each constraint violation is normalized according to:

$${}^k\chi_r^i = \frac{\max(0, {}^k g_r^i)}{g_r^{\max}} \quad (23)$$

where:

$$g_r^{\max} = \max_{j=1, n_p} ({}^k g_r^j) \quad (24)$$

being n_p the number of the population.

It is clear that ${}^k\chi_r^i \in [0,1]$ for all k considered, so that having a normalized weight for all constraints considered.

The violation function is thus defined as

$${}^k\Phi^i = \sum_{r=1}^{n_v} {}^k\chi_r^i \quad (25)$$

5 NUMERICAL ANALYSIS

The proposed domination-based selection schemes have been applied to eleven mathematical and three engineering benchmark optimization problems.

A complete presentation of these benchmark problems is given in Appendix. The optimization problems are solved fifty times by using the NDS_DE and the final results are recorded. The initial population is different for each run. The best, the worst, the mean value of the OF at hand as well as its standard deviation are calculated over the fifty simulated runs. For better understanding the inner work of the proposed selection schemes, the behaviors of an additional indicator is also analyzed.

With this aim, a measure of the difficulty of solving each test problem, a metric measure ρ (as suggested by Koziel and Michalewicz [4]) was introduced as the ratio of the feasible and total population number at each generation, so that considering the following set:

$${}^kS = \left\{ {}^k\mathbf{x}_i \in \Omega \mid g_p({}^k\mathbf{x}_i) \leq 0 \quad \forall p = 1, \dots, n_q + n_r \right\} \quad (26)$$

whose cardinality is denoted $\#({}^kS) \leq N$, the ratio ${}^k\rho$ is:

$${}^k\rho = \frac{\#({}^kS)}{N} \in [0,1] \quad (27)$$

whose value is 0 when no individual lies in feasible space, and is 1 when all of them are feasible. To properly measure the ratio between feasible and infeasible space dimension, in table 1 it is reported the value of ρ for the mathematical test functions here analyzed, using 10^6 individuals randomly generated [7].

Problem	N	Type of function	ρ	LI	NI	LE	NE
g01	13	<i>quadratic</i>	0,0003%	9	0	0	0
g02	20	<i>nonlinear</i>	99,9973%	2	0	0	0
g03	10	<i>nonlinear</i>	0,0026%	0	0	0	1
g04	5	<i>quadratic</i>	27,0079%	4	2	0	0
g05	4	<i>nonlinear</i>	0,0000%	2	0	0	3
g06	2	<i>nonlinear</i>	0,0057%	0	2	0	0
g07	10	<i>quadratic</i>	0,0000%	3	5	0	0
g08	2	<i>nonlinear</i>	0,8581%	0	2	0	0
g09	7	<i>nonlinear</i>	0,5199%	0	4	0	0
g10	8	<i>linear</i>	0,0020%	6	0	0	0
g11	2	<i>quadratic</i>	0,0973%	0	0	0	1

Table 1: Values of ρ (evaluated in a pure random way) for the 11 mathematical test problems chosen

The different values of ρ for each of the functions chosen are shown in Table 1, where n is the number of decision variables, LI is the number of linear inequalities, NI the number of nonlinear inequalities, LE is the number of linear equalities and NE is the number of nonlinear equalities.

A standard and a normalized domination-based selection scheme have been adopted and they are indicated in Table 2.

6 RESULTS ANALYSIS

This study takes into consideration designers basic rule that is to prefer a feasible but not economic solution to a more economic but unfeasible ones. This is an important point in structural and seismic design, where constraints violations usually are associated to an unacceptable low safety level. So that, differently from standard analysis to constrained optimization problems, in this research is analysed firstly the ability of algorithms to produce feasible solutions and only after is analysed their performances. In this research are analyzed 12 test functions from literatures [3].

Three main efficiency indicators are used to evaluate performances, with references to different selection criteria and cross over algorithms; the performance indicators are :

- *Objective Function*
- *Stagnation*
- *ratio between Unfeasible individuals and total population size ρ*

Due to random nature of DE, performances are evaluated as statistically over 100 independent runs, and in particular as:

- Best
- Worst

- Mean
- Standard Deviation

The first analysis is performed over a population of 50 individuals and a number of 300 generations. As first analyzed index the ratio between unfeasible and total population size ρ .

This ratio ρ is evaluated with reference to how many iterations are necessary to reach two different goals: the first is to have at least one feasible individual over all independent runs (figure 1) and the second is to have at least one feasible individuals over all independent runs. From a pragmatic point of view the first indication concerns performance while the second concerns robustness of algorithms with reference to ability to reach feasible solutions.

Smaller is number of generations needs to reach both to indicators, and greater is effectiveness of algorithms in reaching feasible solutions. If finally generations number is 300, than any feasible solution is reached at all.

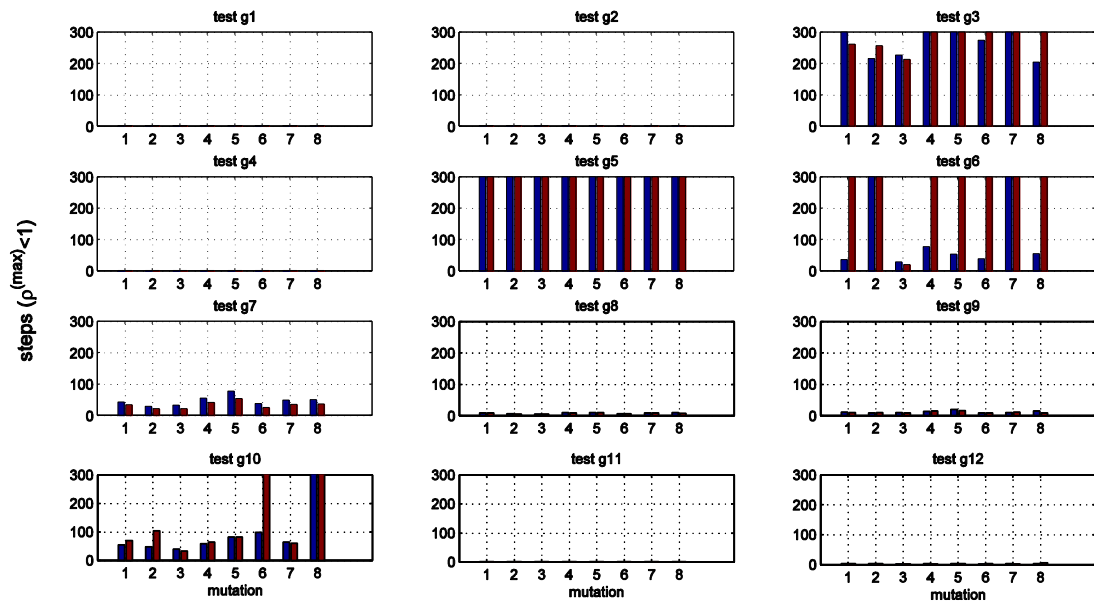

Figura 1: number of steps necessary to have that all runs gives at least one feasible solution. Mutation are those reported in table XX, while blu bars are for normalised approach, while red ones are for standard approach

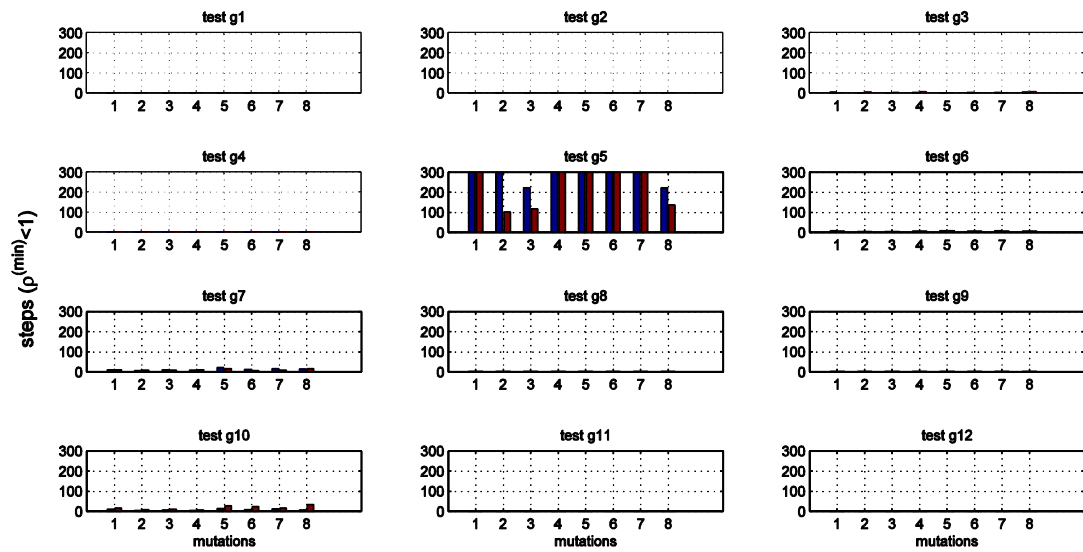

Figura 2: number of steps necessary to have that at least one runs presents a single feasible solution. Mutation are those reported in table XX, while blu bars are for normalised approach, while red ones are for standard approach

Mutation type	denomination	Equation reference
1	rand/1/bin	(7)
2	best/1/bin	(8)
3	current-to-best/1/bin	(9)
4	best/2/bin	(10)
5	rand/2/bin	(11)
6	Proposed 1	(12)
7	Proposed 2	(13)
8	Random (1-7)	(7) - (13)

Table 2: mutation type used in the analysis.

It is immediate that the function g5 is the more difficult to deal with. From figure 2 it appears that without any combination of cross over and selection criteria we have all independent runs with at all a single feasible solution. That means that the worst case is that after 300 generations we are not able to reach any feasible individual.

To better understand performances for ratios ρ are reported for each test function, for all considered combinations of cross over and selection criteria, that are Normalized (on the left) and Standard (on the right). Results are reported after 100, 200 and 300 generations (to evaluate efficiency under different number of generations) in best case (minimum value) in table 3 and worst case (maximum value) in table 4. When rho is equal to one means that no feasible solution are present, and when is equal to 0 means that all solutions are feasible.

table 4: ratio ρ , worst solutions over 100 independent runs

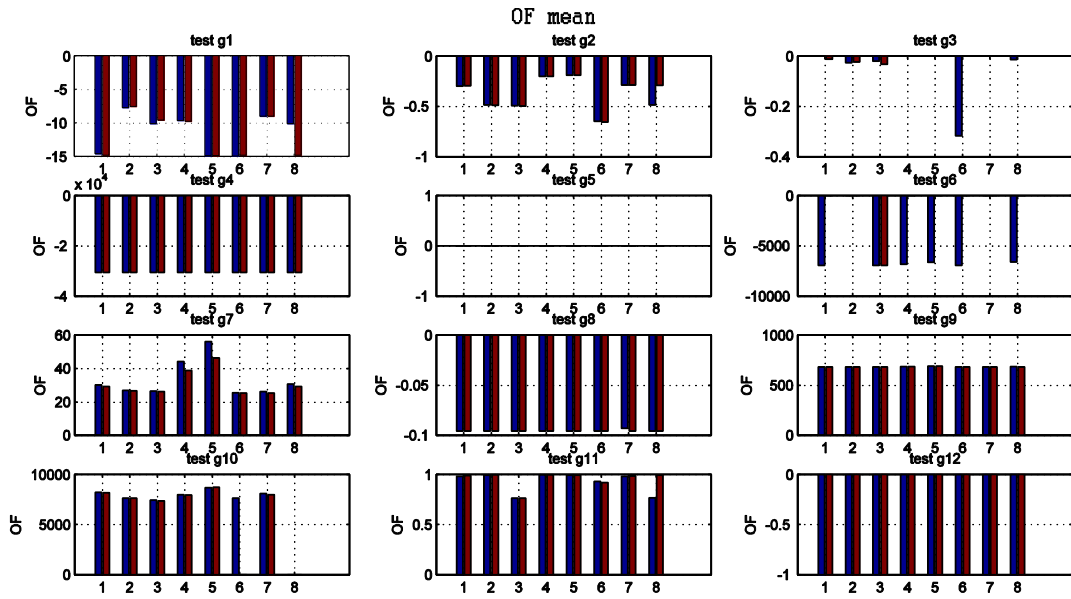

Figure 3: mean values of OF

Finally an aveluation of OF is reported in figure 3, where are reported

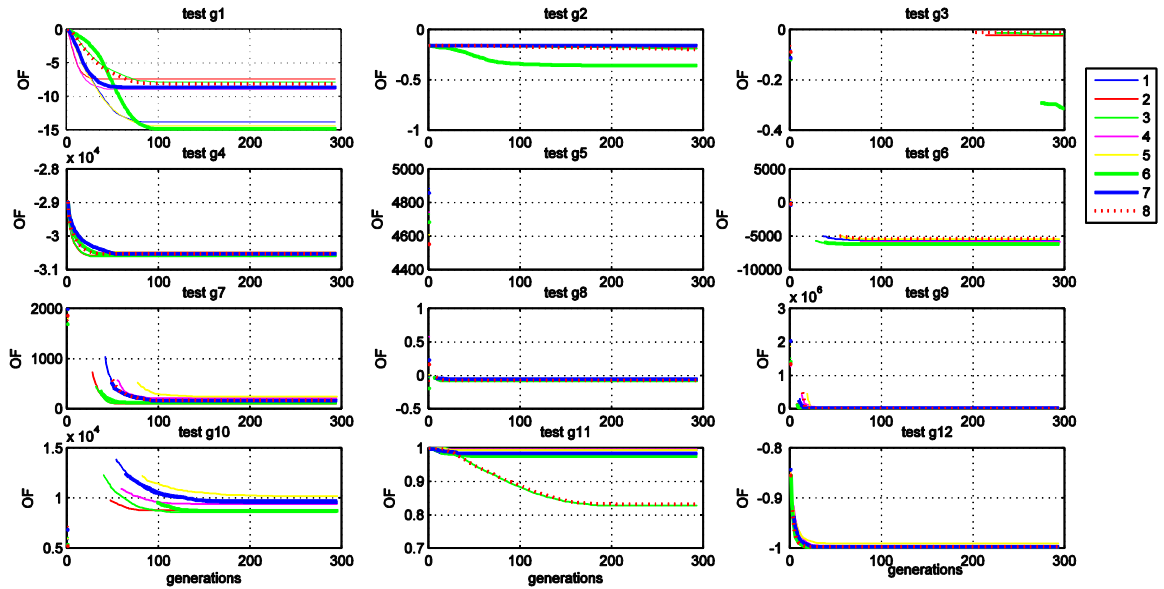

Figure 4: mean values of OF using a normalised selection criteria

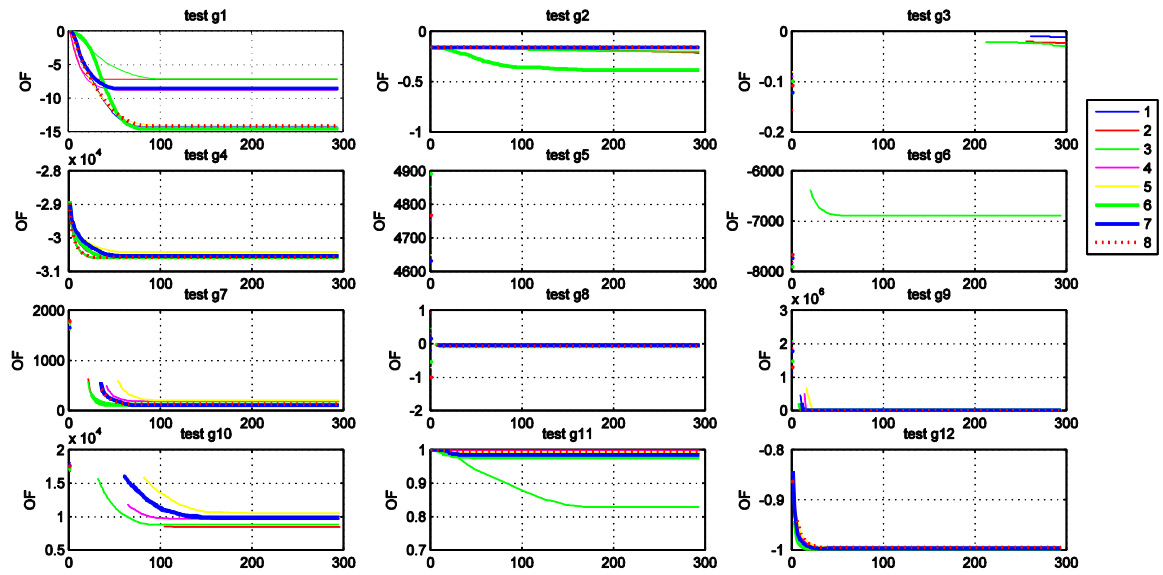

Figure 5: mean values of OF using a standard selection criteria

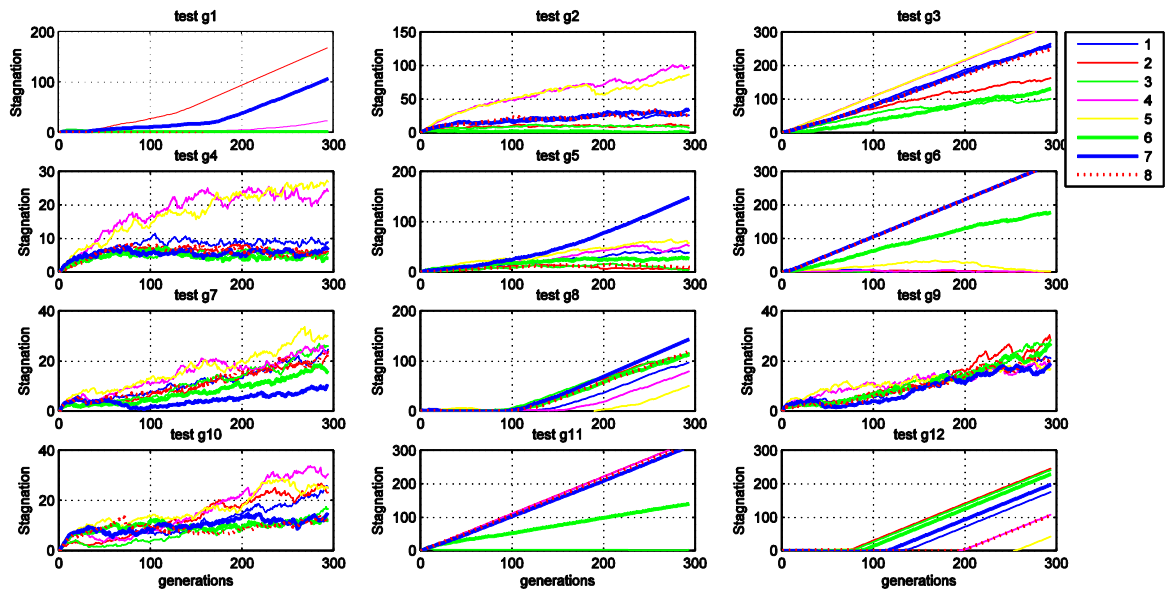

Figure 6: mean values of stagnations using a standard selection criteria

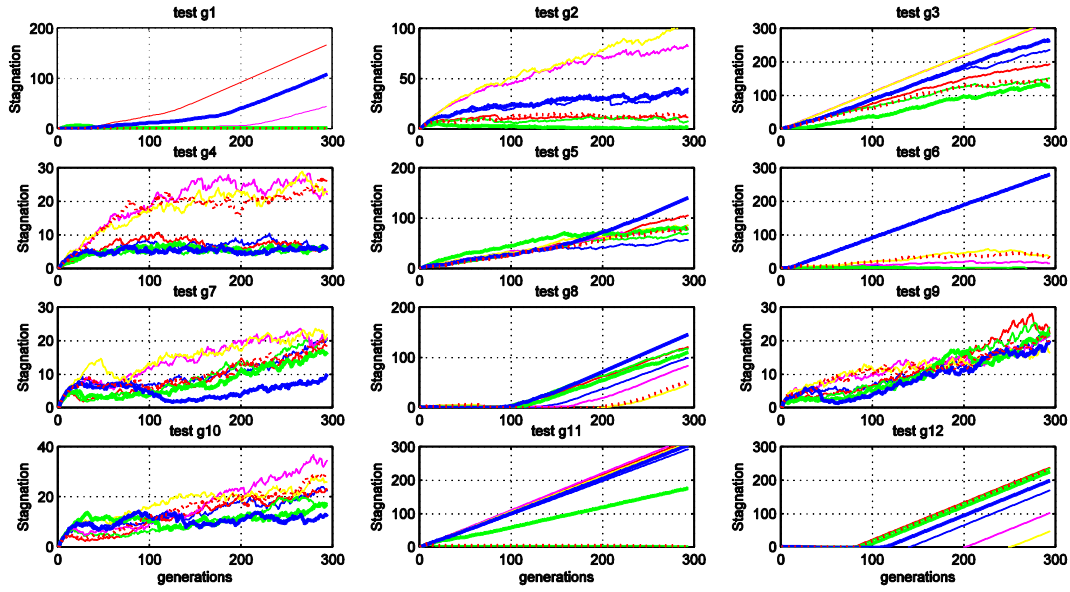

Figure 7 mean values of stagnations using a Normalized selection criteria

A deeper analysis of the two more difficult functions to be optimized - from the feasibility point of view - is thus developed. In details two more selection criteria have been used, in addition to the Standard - eq. (21) - and Normalized - eq. (25) - before considered.

In details the first one is a Normalized modified to take into consideration number of active violations in each selection, that means violation table search

$${}^k\Phi_m^i = n_a \left(1 + \sum_{r=1}^{n_v} {}^k\chi_r^i \right) \quad (28)$$

where n_a is the number of active constraints. Finally a complete different criteria is considered, based on the Kreisselmeier–Steinhsauser (KS) function that was first presented by G. Kreisselmeier and R. Steinhsauser in [5], that is in the following form:

$${}^k\Phi_{KS}^i = \ln \left(\sum_{r=1}^{n_v} e^{{}^k\chi_r^i} \right) \quad (29)$$

The selection used for a deep analysis of functions g3 and g5 are thus reported in table

Violation type	Denomination	Equation reference
Standard	A	(25)
Normalized	B	(21)
Normalized modified	C	(28)
Kreisselmeier–Steinhsauser	D	(29)

Table 5: mutation type used in the analysis.

In table 6 and 7 are reported results obtained for the four selection criteria. Are reported the results in terms of best, worst, mean and standard deviation of the OF, evaluated over 2000 generations using 100 independent runs. Results in terms of mean and standard deviation are reported only if all 100 independent runs produce at least a single feasible solution. As reported results of g5 presents only few positive results. In details considering this function's results (table 5) only mutation *current-to-best/1/bin* type - eq (9) - gives positive results (all indepen-

dent runs produce at least one feasible solution) associated with selection C and D. Moreover in tables 4 and 5 are reported the better four combinations in green, and the worsted four in red. The best one is thus underlined to be well recognizable from the others.

An interesting observation is done in terms of the worst results, that deals directly with robustness of the algorithms. In this since we should notice that the here proposed mutation criteria (eq 12) presents in all analyzed cases the best results, independently from the specific selection criteria used.

7 CONCLUSIONS

With the aim of better explore possibilities of Differential Evolutionary (DE) algorithms in solving structural and seismic optimization problems, a numerical analysis has been conducted over standard test functions with the aim of compare different DE strategies using combinations of selection criteria and cross over. The constrained nature of the problem has been approached by using a number of selection criteria able to take into consideration elements feasibility starting from the original Deb's proposal in this way. Main advantages of this technique is inner simplicity due to absence of additional parameters to be opportunely regulated by tray and error initial procedure. Tree variations of original Deb's one are pro-

posed, using each of them with different cross over criteria. Five are just proposed in literature, while 2 are here proposed to evaluate their performances in accordance with selection criteria. A first numerical analysis has been carried on a reduced number of generations (300) and using a small population size over 12 standard test functions. Algorithms performances in reaching feasible solutions has been evaluated over a set of 100 independent runs; best mean and worst conditions have been analyzed. Finally a deeper analysis has been evaluate over the two more problematic functions , using a more wide number of possible cross over - selection criteria . Using a greater number of generations (2000), results have been carried on using four selections and seven cross over different criteria (for 28 different DE). Results have indicated that results are strongly influenced by proper selection of those two DE elements, and that a modified Deb's selection criteria shows a general higher performance instead of the original one.

Keywords: fragility curves, seismically induced landslide displacements, RC buildings, foundation system, structural damage index, corrosion of reinforcement

Abstract. *The present study aims at the development of an efficient analytical methodology for the vulnerability assessment of RC buildings subjected to earthquake triggered slope movements. The vulnerability is defined through specific probabilistic fragility functions for specified limit states. The fragility curves are numerically estimated in terms of peak ground acceleration at the “seismic bedrock”, versus the probability of exceedance of each limit state, for the considered structure types. A two -step, uncoupled approach is performed. In the first step, the differential permanent displacements at the building’s foundation level are estimated using an adequate finite difference dynamic slope model. Properly selected and corrected acceleration time histories are applied at the base of the model to assess the building’s foundation response and the associated ground and foundation displacements are computed accordingly. Then, the calculated differential displacements are imposed to the fiber-based building model at the foundation level to assess the building’s response for different ground landslide displacements induced by the earthquake. Limit states are defined in terms of a threshold value of building’s material strain. Various sources of uncertainty concerning the capacity of the building, the deformation demand and the definition of limit states are considered in the analysis. The developed methodology is applied to both “low code” and “high code” RC frame buildings resting on shallow foundations with varying strength and stiffness characteristics (isolated footings, continuous foundation), standing near the crest of a relative slow moving soil slide. In case of the “low code” (usually old) RC buildings, the effect of corrosion of the reinforcement on the vulnerability estimation is also considered. The final goal of this research is to propose efficient fragility functions for a variety of RC building typologies.*

1 INTRODUCTION

Major landslide events occurred in Taiwan, California, Japan, Italy, China and elsewhere represent some of the most pronounced collateral hazards associated with earthquakes in terms of human losses and direct and indirect damage to the built environment. Seismically induced permanent ground deformation occurring as a result of landslides can adversely affect the likely performance of vulnerable engineering structures as it may account for a significant proportion of the total earthquake damage. Thus, predicting the expected performance of precarious slopes and affected facilities within the unstable area during or after an earthquake event, is of primary importance for design, urban planning, and for seismic hazard and risk studies.

Various methods of different complexity have been proposed to assess earthquake induced landslide hazards including the estimation of the probability of occurrence of a landslide and the slope permanent co-seismic displacement along a slip surface using Newmark-type displacement methods or advanced numerical approaches. However little work has been done on the quantification of the physical vulnerability of structures affected by earthquake triggered landslides. A major constraint to this may be considered the scarcity of accurate and reliable information on seismically induced landslide damage. HAZUS [1] multi-hazard loss estimation methodology may be considered an exception. Separate fragility curves, distinguishing between ground failure due to lateral spreading and ground failure due to ground settlement, and between shallow and deep foundations, were generated considering one combined Extensive/Complete damage state. However, the aforementioned methodology, exclusively based on expert judgment, involves a high degree of subjectivity and simplification as it does not account for the various landslide types and mechanisms, the soil type, the building typology, the stiffness of the foundation and the different damage states.

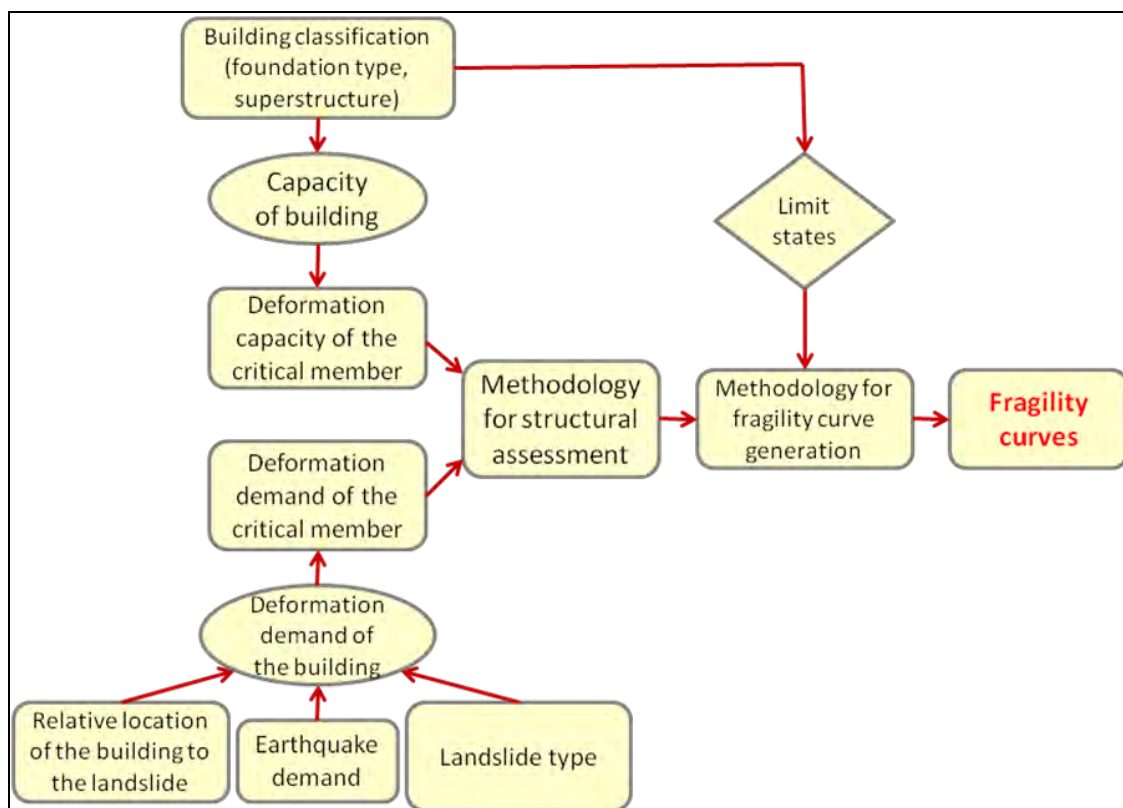

The present study, recognizing the need to improve the available background, aims at the proposition and quantification of an analytical procedure to assess the vulnerability of RC structures as a consequence of earthquake induced landslide displacements. The final goal of this research is to propose adequate fragility functions for a variety of RC building typologies.

2 METHODOLOGY

The proposed methodology [2], largely inspired from the seismic risk analysis, may be applied for the vulnerability assessment of RC buildings subjected to earthquake triggered relative slow moving soil slides. The proposed approach is principally based on a comprehensive set of numerical computations and statistical analysis. In terms of numerical simulation, a two-step uncoupled analysis is conducted. In the first step, the differential permanent displacements at the building's foundation level are estimated using the FLAC2D [3] finite difference dynamic slope model. The effect of ground shaking to the structure's response and the associated damages is not considered in the vulnerability of the building itself, which is assessed only for the differential movements due to slow moving seismically triggered landslides. Then, the computed differential displacements are applied as input to the building model at the foundation level, to assess the building's response for different differential ground landslide displacements induced by earthquake with progressively increased intensities. The numerical analysis of the building's response is performed through the fiber-based finite element code SEISMOSTRUCT [4]. Limit states are defined in terms of a threshold value of building's material strain.

The fragility curves are numerically estimated in terms of peak ground acceleration at the "seismic bedrock", (PGA) versus the probability of exceedance of each limit state considering various sources of uncertainty. The selection of the PGA against the differential displace-

ments value is a key point of the present method and it is explicitly related to the main parameter of any seismic hazard assessment.

The description of the methodological framework together with a simplified case study has already presented in [2]. In the present study an improved version of the methodology and the corresponding application is attempted, emphasizing at the variability on the earthquake ground motion and on the associated differential displacements, yielding a more descriptive characterization of the structural damage and considering buildings with different strength and stiffness characteristics and code design level. Some key points of the proposed framework are highlighted in the following paragraphs:

may lead to the complete destruction of any structure within their path, slow-moving slides also have adverse effects on affected facilities [5]. The damage caused by a slow moving landslide on a building is mainly attributed to the cumulative permanent (absolute or differential) displacement and it is concentrated within the unstable area. A relative slow moving soil slide that will produce tension cracks due to differential displacement to a RC building, exposed to the landslide hazard, is considered in this study.

The characteristics (amplitude, frequency content and duration) of the earthquake ground motion in relation to the soil dynamic properties and stratigraphy can significantly influence the derived deformation demand for the building. Material damping, the impedance contrast between sediments and the underlying bedrock, and the characteristics of incident wavefield are considered to represent the governing factors for site amplification/attenuation [6,7]. A fundamental period of the earthquake close to the natural period of the site can lead to resonance phenomena and, consequently, to an amplified energy content of the ground motion. Combining a low-frequency seismic input motion together with a resonance phenomenon in the low-frequency range, the slope failure potential assumes its highest values [8].

The position of the building with respect to the landslide area is a very important contributing factor in estimating vulnerability. Landslides triggered by earthquakes tend to be clustered near ridge crests and hill slope toes. Peng et al. [9] attributed this ridge-crest clustering to topographic effects, and the clustering at hill slope toes to dynamic pore-pressure changes in the water-saturated material of lower hill slopes. In this study, a building standing near the crest where the seismic ground motion due to topographic effects is generally amplified is considered [10,11].

For a landslide of given type, mechanism and intensity, the typology of the exposed structure is also a key factor in the vulnerability assessment methodology. Geometry, material properties, state of maintenance, code design level, soil conditions, foundation and structure details, number of floors etc. are among typical typological parameters which determine the capacity of the building to withstand the specified co-seismic landslide displacement. The response to permanent total and differential ground deformation depends primarily on the foundation type. A structure on a deep foundation (e.g. piles) compared to shallow foundations often experiences higher resistance ability and hence a lower vulnerability. For shallow foundations, the distinction is between rigid or flexible/unrestrained foundation systems. When the foundation system is rigid (e.g. continuous raft foundation), the building is expected rather to rotate as a rigid body and a failure mainly attributed to the loss of functionality of the structure is anticipated. In this case, the damage states are defined empirically, as there is limited structural demand to the members of the building (apart from possible $P-\Delta$ effects at larger rotations). On the contrary, when the foundation system is flexible (e.g. isolated footings), the various modes of differential deformation produce structural damage (e.g. cracks) to the building members [12,13] that can be estimated using an analytical procedure analogous to that of the response due to seismic ground motion.

When building response to ground failure comprises structural damage, damage states can be classified using the same schemes used for structural damage caused by ground shaking. Limit states are defined in terms of limit value of a component's strain based on damage observation from previous earthquake events, the existing knowledge related to earthquake damage levels, and published tolerances for non-earthquake related foundation deformations [14,12].

In the probabilistic approach proposed herein, the uncertainties related to the capacity of the building, the definition of the limit states and the deformation demand (differential permanent displacement) should be considered. The uncertainty in the displacement capacity is a

function of the material properties, geometric properties, and the yield strain of steel and post-yield strain capacities of the steel and concrete. The uncertainty in the demand includes all of the variability associated with the ground motion estimation plus the additional uncertainties associated with the landslide type and size, the relative position of the building to the landslide area, the variability in soil parameters and stratigraphy and the uncertainty within the assessment of ground deformations.

3 APPLICATION

3.1 Deformation demand- Numerical analysis

An application of the proposed methodology to an idealized case study is presented herein. To estimate the input differential displacements at the building's foundation level, we applied FLAC 2D finite difference dynamic model [3] (fig. 2) using an elastoplastic constitutive model with Mohr-Coulomb failure criterion and non associated plastic flow rule, able to simulate large deformations for slope stability assessments. A small amount of Rayleigh damping (1 to 3%) is assigned to account for the energy dissipation in the elastic range. The center frequency of the installed Rayleigh damping is selected to lie between the fundamental frequencies of the input acceleration time histories and the natural modes of the system. In the slope area, a fine grid discretization is adopted, whereas towards the lateral boundaries of the model, where the accuracy requirements loosen, the mesh is coarser. The slope height and inclination are 20m and 30° respectively. Free field absorbing boundaries are applied along the lateral boundaries while quiet (viscous) boundaries are applied along the bottom of the dynamic model to minimize the affect of reflected waves. In order to apply quiet boundary conditions along the same boundary as the dynamic input, the seismic motions must be input as stress loads combining with the quiet (absorbing) boundary condition. The soil type is selected to represent a homogenous dry sand corresponding to soil category C of EC8 [15]; its material, physical and dynamic properties are provided in Table 1.

A building is assumed to be located 3m from the slope crest. The building is modeled only by its foundation with a width of 6m (uncoupled approach). Two different foundation systems are considered (Table 2): isolated footings and a uniform loaded continuous slab foundation. In the first case, the foundation is simulated with concentrated loads at the footings' links. In the second case, the foundation system is modeled as a deformable elastic beam connected to the grid through appropriate frictional interface elements that can approximate the potential Coulomb sliding and/or tensile separation of the beam. The static factor of safety of the slope is calculated through a limit equilibrium method as $F_s=1.45$.

Prior to the dynamic simulations, a static analysis is carried out to establish the initial effective stress field throughout the model. The dynamic input motion consists of SV waves vertically propagating from the base. Six different earthquake records are used as excitation for the dynamic analysis: (i) Valnerina (Cascia-L), Italy, Ms=5.8 , 1979, (ii) Athens (Kypseli-L), Greece, Mw=5.9, 1999, (iii) Montenegro-[TRA (EW)], former Yugoslavia, Mw=6.9, 1979 and (iv) Northridge (Pacoima Dam -L), USA, Ms=6.7, 1994, (v) Campano Lucano (Sturno-L), Italy, Mw=6.9 , 1980 and (vi) Duzce (L), Turkey, Mw=7.2, 1999. They all refer to outcrop conditions. The selected records cover a wide range of seismic motions in terms of the seismotectonic environment, amplitude, frequency content and significant duration. Before applied along the base of the model, they are subjected to appropriate correction (baseline correction, filtering and tapering) to assure an accurate representation of wave

transmission through the model. Figure 3 presents the normalized elastic response spectra of the input motions together with the proposed elastic design spectrum of EC8 [15] for soil type A (rock).

Figure 3: Normalized average elastic response spectrum of the input motions in comparison with the corresponding elastic design spectrum for soil type A (rock) according to EC8.

The input accelerograms are scaled to five levels of peak ground acceleration (PGA=0.1, 0.3, 0.5, 0.7 and 0.9g) so as to assess the building response for different displacement magnitudes. This procedure will allow resulting in different damage states for the building and finally to be able to construct the corresponding vulnerability curves. Figure 4 presents the maximum values of differential displacements for the building with flexible and stiff foundation system derived from the dynamic analysis by applying the different scaled accelerograms. It is observed that the specific characteristics (frequency content and duration) of the seismic ground motions can significantly influence the magnitude of the computed differential displacement at the foundation level. Moreover, it is worth noticing that when the soil structure interaction is considered, the differential horizontal displacements at the beam foundation are practically zero and the total differential displacement vector for the building is generally decreased.

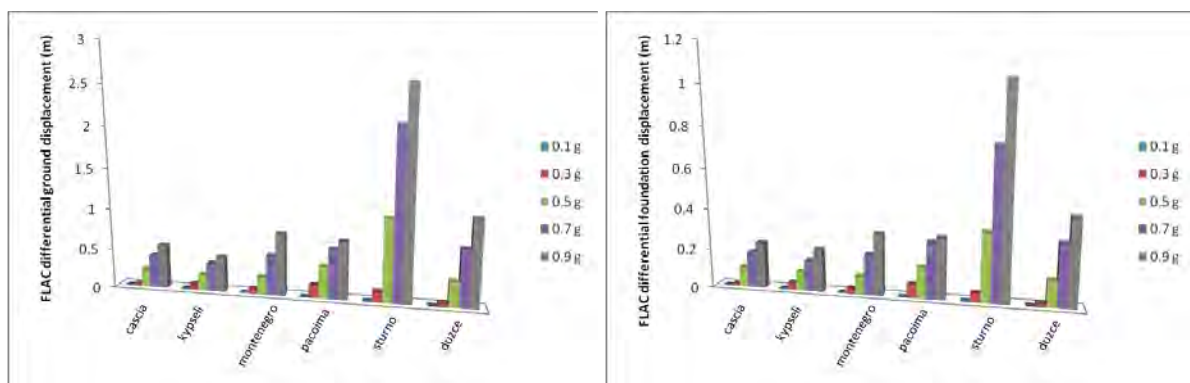

Figure 4: Maximum values of differential displacement vector for buildings with flexible and stiff foundation system

3.2 Comparison with simplified displacement methods

To validate the numerical results, they are compared, in terms of maximum permanent

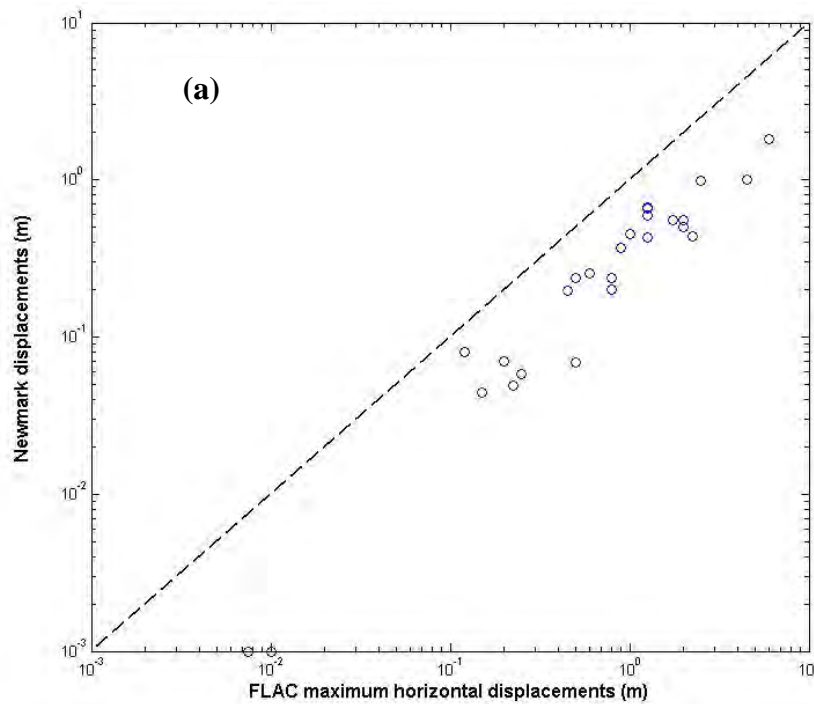

horizontal displacement, with the simplified Newmark-type displacement methods. The conventional Newmark rigid block model [16,17], as well as a recent improved version to account for the soil deformability using a coupled stick-slip deformable sliding block model [18], are used to calculate permanent displacements of the slide mass.

Bray and Travararou [18] displacement model captures the primary influence of the system's yield coefficient (k_y), its initial fundamental period (T_s), and the ground motion's spectral acceleration at a degraded period equal to $1.5T_s$. The input accelerograms applied to both methods are the scaled acceleration time histories recorded on rock multiplied by the site amplification factor $S=1.15$ (as proposed in EC8 for subsoil class C), in an effort to conservatively approximate the equivalent acceleration time histories acting on the potentially sliding mass. The yield coefficient, k_y , is computed by applying the following relationship, as proposed in [19]:

$$k_y = \tan(\varphi - \beta) + c / (\gamma \cdot H \cdot \cos 2\beta \cdot (1 + \tan \varphi \cdot \tan \beta)) \quad (1)$$

where φ = friction angle, c = cohesion, H = height of the critical sliding surface and β = slope angle.

The results of the above methods are summarized in figure 5 (a) and (b) respectively in comparison with the co-seismic numerical displacements calculated herein. The direct application of Newmark rigid block approach is found to underestimate the computed displacements. This can be regarded as relevant considering that Newmark's method treats the potential landslide block as a rigid mass (no internal deformation) that slides in a perfectly plastic manner on an inclined plane, which is not realistic in our case. The results of fully coupled stick-slip deformable sliding block model introduced by Bray and Travararou [18] are generally in good agreement with that of the dynamic analysis. In both cases, however, a large scatter on the predicted residual displacements is detected recognizing the need to adopt a fully probabilistic framework, as proposed in Bray and Travararou [18].

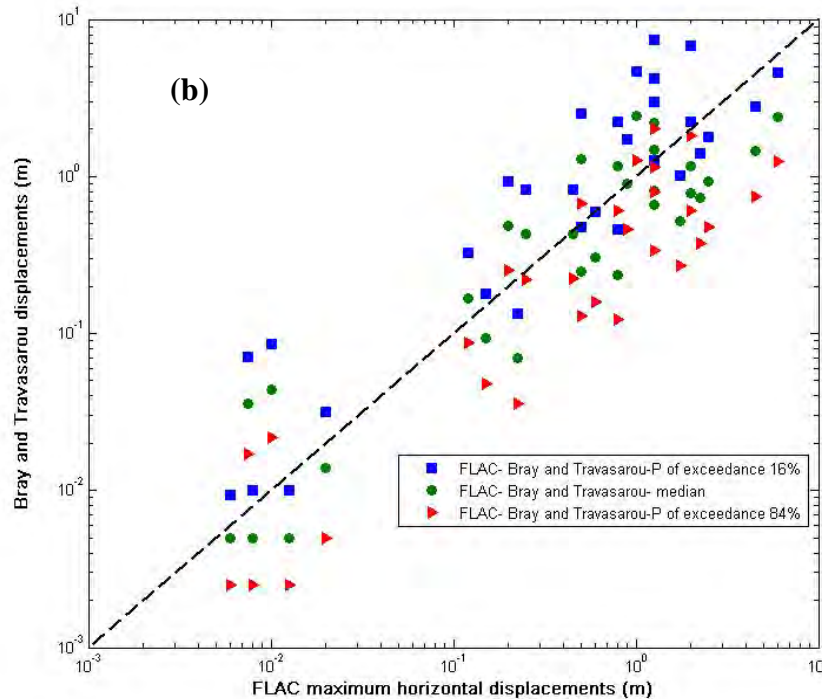

Figure 5: Comparison of Newmark [16] (a) and Bray and Travarasrou [18] (b) displacements with maximum horizontal displacement from 2D dynamic analyses.

3.3 Analysis of the building's response

The analyses of the buildings is conducted using the finite element code SeismoStruct [4], which is capable of calculating the large displacement behavior of space frames under static or dynamic loading, taking into account both geometric nonlinearities and material inelasticity. Both local (beam-column effect) and global (large displacements/rotations effects) sources of geometric nonlinearity are automatically taken into account. The spread of material inelasticity along the member length and across the section area is represented through the employment of a fiber-based modeling approach, implicit in the formulation of SeismoStruct's inelastic beam-column frame elements. Nonlinear static time-history analyses are performed for all numerical simulations. In particular, the differential permanent (ground or beam) displacement (versus time) curves, directly extracted from the FLAC dynamic analysis, are statically imposed at one of the RC frame supports.

The studied buildings are single bay-single storey RC bare frame structures that vary in their foundation system and design code level. Regarding the foundation system, buildings with flexible foundation system (isolated footings) and buildings with stiff but not completely rigid foundation system (continuous uniform loaded foundation of finite stiffness characteristics) are considered. Both “low code” and “high code” design buildings that differ in the strength and stiffness characteristics and the corresponding assigned limit strain levels are examined. The reference building's height and length are 3m and 6m respectively. All columns and beams have rectangular cross sections (0.40x 0.40m). The longitudinal reinforcement used is 8Φ14 ($A=0.00123\text{m}^2$) for all the cross sections considered.

The use of such simple structures is justified from the observation that the number of storeys and bays do not seem to comprise crucial parameters in the determination of the building's performance subjected to permanent ground displacements. The latter is also confirmed in [12] for the vulnerability assessment of RC buildings due to liquefaction induced ground

deformations. Hence, one bay-one storey RC structures despite their simplicity are found to be adequately representative of the performance of real low rise RC frame buildings.

The material properties assumed for the members of the reference RC buildings are described below. A uni-axial nonlinear constant confinement model (fig. 6 (a)) is used for the concrete material ($f_c=20\text{MPa}$, $f_t=2.1\text{MPa}$, strain at peak stress 0.002mm/mm , confinement factor 1.2), assuming a constant confining pressure throughout the entire stress-strain range [20]. For the reinforcement, a uni-axial bilinear stress-strain model with kinematic strain hardening (fig. 6(b)) is utilized ($f_y=400\text{MPa}$, $E=200\text{GPa}$, strain hardening parameter $\mu=0.005$). This simple model is characterized by easily identifiable calibrating parameters and by its computational efficiency.

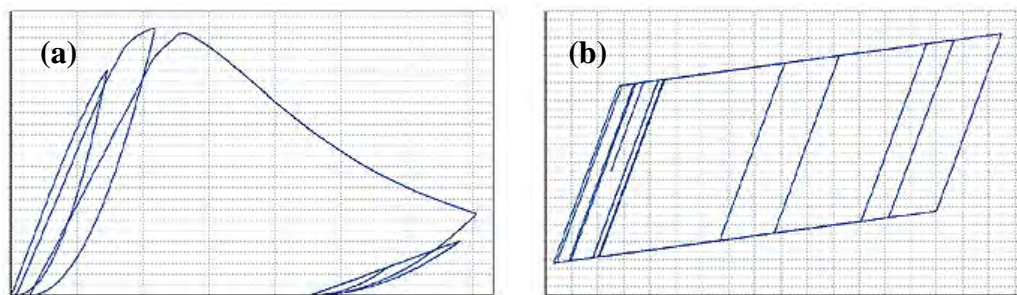

Figure 6: Stress-strain models for concrete (a) and steel (b).

A sensitivity analysis is performed for the reference building cases which allows for indentifying the influence of different parameters on the structural response and proposing a preliminary probabilistic framework of the damage estimation. The parameters selected to vary are: the yield strength of steel ($f_y=210, 400\text{ MPa}$ for “low code” and $400, 500\text{ MPa}$ for “high code”), the compressive ($f_c=16, 20\text{ MPa}$ for “low code” and $20, 30\text{ MPa}$ for “high code”) and tensile ($f_t=2.0, 2.1\text{ MPa}$ for “low code” and $2.1, 3.0\text{ MPa}$ for “high code”) strength of concrete, the reinforcement bar size ($\Phi 12, \Phi 14$ for “low code” and $\Phi 14, \Phi 16$ for “high code”) and the confinement factor ($1.0, 1.2$ for “low code” and $1.2, 1.3$ for “high code”) for progressively increasing levels of differential displacements extracted from the previous dynamic stress strain analysis for increasing level of input acceleration time histories. In case of the “low code” (usually old) RC buildings, the effect of corrosion of the reinforcement on the vulnerability estimation is also considered. The loss of area of steel due to corrosion of the RC elements is modeled as a reduction in longitudinal reinforcing bar cross sectional area compared to the elements in the initial nondegraded state. In this study, a 50% reduction of the area of reinforcing steel is assumed.

The deformed shapes of buildings with flexible foundation system are essentially the same irrespective of the variability in the strength parameters and the level of demand, observation that is in accordance with that of [12]. The same trend is observed to the buildings with stiff foundation (Fig. 7). In both building typologies, a column failure mechanism is detected (see also [21]). The reason is that the axial stiffness of the beams is generally much higher compared to the flexural stiffness of the columns. Moreover, in the case of buildings with flexible foundations, the applied differential displacement vector is mainly governed by the horizontal component that determines the deformation mode (fig. 7(a)). On the contrary, in buildings with stiff foundation system the applied displacements are practically vertical. Hence, it is concluded that the inclination of the applied differential permanent displacement constitutes a fundamental parameter in determining the deformed shape of the building when subjected to a

permanent displacement at the foundation level. It is worth noting that the deformed shape of building with flexible and stiff foundations and the associated computed displacements at the critical column are found to closely approximate the idealized response of a RC frame building subjected to liquefaction induced lateral movement (with an associated vertical component) and to vertical settlements respectively, as proposed in [12].

Figure 7: Deformed shapes for buildings with flexible (a) and stiff (b) foundations. The failure mechanism at the critical column is also shown.

3.4 Analytical fragility curves

We derived in this stage different sets of analytical fragility curves for low rise (single bay-single storey) RC buildings with varying stiffness of the foundation system and different code design level. Fragility curves for “low code” corroded RC buildings are also constructed. Each curve provides the conditional probability of exceeding a certain limit or damage state under a range of seismic induced landslide events of given type and intensity. The landslide intensity is expressed in this work in terms of peak ground acceleration at the seismic bedrock that is the initial trigger of the slow moving slide. This will result to permanent differential displacements at the foundation level.

The probabilistic nature of the problem is treated by accounting for the variability associated with the building capacity (yield strength of steel, compressive and tensile strength of concrete, reinforcement bar size, confining factor), as well as the variability in the demand, assuming different progressively increasing acceleration time histories that result in different permanent differential displacement magnitudes at the building’s foundation links. In order to identify the building performance (damage) state and to construct the corresponding fragility curves, a damage index (DI) is introduced describing the steel and concrete material strains. Within the context of a fibre-based modelling approach, such as that implemented in SeismoStruct, material strains do usually constitute the best parameter for identification of the performance state of a given structure [4]. In all cases analyzed (600 in total), the steel material strain (ϵ_s) yields more critical results. Thus, it was decided to adopt only this parameter as a damage index hereafter for simplicity reasons. In this way, it is possible to establish a relationship between the damage index (ϵ_s) and the input motion intensity in terms of the PGA values at the assumed seismic bedrock, for the different building typologies and consequently to assign a median value of PGA to each limit state. Figure 8 presents representative PGA - damage index curves for low rise, “high code” design RC frame buildings with stiff and flexible foundation system.

The next step is the definition of the damage or limit states. Based on the work of Crowley et al. [14], Bird et al. [12,13] and engineering judgment, 4 limit states (LS₁, LS₂, LS₃, LS₄) are defined. Considering that low code RC buildings are poorly constructed structures characterized by a low level of confinement, the limit steel strains needed to exceed post yield limit

states should have lower values compared to high code, properly constructed RC buildings. As a consequence, it was decided to adopt different limit state values for exceedance of extensive and complete damage for low and high code frame RC buildings. A qualitative description of each damage band for reinforced concrete frames is given in Table 3 while the limit state values finally adopted in quantitative terms are presented in Table 4. These concern exceedance of minor, moderate, extensive and complete damage of the building. The first limit state is specified as steel yielding that is the ratio between yield strength and modulus of elasticity of the steel material.

Figure 8: PGA–damage index relationships for 1-story-1-story “high code” RC frame buildings with stiff and flexible foundation system

Structural damage band	Description
None to slight	Linear elastic response, flexural or shear type hair-line cracks (<1.0 mm) in some members, no yielding in any critical section
Moderate	Member flexural strengths achieved, limited ductility developed, crack widths reach 1.0 mm, initiation of concrete spalling
Extensive	Significant repair required to building, wide flexural or shear cracks, buckling of longitudinal reinforcement may occur
Complete	Repair of building not feasible either physically or economically, demolition after earthquake required, could be due to shear failure of vertical elements or excessive displacement

Table 3: Structural damage state descriptions for RC frame buildings (after [14])

Limit state	Steel strain (ϵ_s) –low code	Steel strain (ϵ_s) – high code
LS1	Steel bar yielding	Steel bar yielding
LS2	0.0125	0.0125
LS3	0.025	0.04
LS4	0.045	0.06

Table.4. Definition of Limit states for “low” and “high” code design RC buildings

In order to construct the fragility relationships, appropriate cumulative distribution functions, as the ones proposed in HAZUS [1], that describe the fragility relationships have been generated. For structural damage, given peak ground acceleration PGA, the probability of exceeding a given limit state, SL_i, is modeled as:

$$f(PGA) = \Phi \left[\frac{1}{\beta_i} \ln \left(\frac{PGA}{PGA_i} \right) \right] \quad (2)$$

Where:

- Φ is the standard normal cumulative distribution function,
- \overline{PGA}_i is the median value of peak ground acceleration at which the building reaches the limit state, i,

β_i is the standard deviation of the natural logarithm of peak ground acceleration for limit state, i.

The median values of peak ground acceleration that correspond to each limit state can be defined for the threshold values of the aforementioned damage indexes as the values that corresponds to the 50% probability of exceeding each limit state. The standard deviation values [β] describe the total variability associated with each fragility curve. Three primary sources contribute to the total variability for any given damage state [1], namely the variability associated with the definition of the limit state value, the capacity of each structural type and the demand (seismic demand, landslide type, relative position of the structure to the landslide). Based on the work of Crowley et al [14], Bird et al [13] and HAZUS [1] prescriptions, the uncertainty in the definition of limit states, for all building types and limit states, is assumed to be equal to 0.4 while the variability of the capacity is assumed to be $\beta = 0.3$ for “low code” and $\beta = 0.25$ for “high code” buildings. The last source of uncertainty associated with the demand, is taken into consideration by calculating the variability in the results of numerical simulation carried out in FLAC 2D for the different input motions at each level of PGA applied at the base of the dynamic model. It should be mentioned that this variability is different for the two different building types. In particular, it is higher in the case of the buildings with flexible foundation system. The total uncertainty is estimated as the root of the sum of the squares of the component dispersions. The median (expressed in terms of peak ground acceleration PGA) and beta values of each limit state for the building with flexible and stiff foundation system are shown in Table 5.

Figures 9-11 illustrate the derived sets of fragility curves for the different building typologies, design code level and considering the effect of rebar corrosion for an assumed deterioration scenario in case of “low code” buildings. As expected, the building with stiff foundation system sustain less damage due to earthquake induced slow moving slides compared to the building with the flexible foundation system. More specifically, only minor and moderate damages are possible for the “high code” stiff buildings while minor, moderate and extensive damage are expected for “low code” stiff buildings for the specified levels of landslide intensity. Low code, poorly designed and constructed buildings are associated with a rapid transi-

tion from low levels of damage to collapse. This can be seen from the closeness of the four limit state curves and the steepness of their slopes. In contrast, well-designed buildings generally present a more ductile behavior, allowing for larger distinction between the curves. The consideration of corroded structural members in case of low code RC buildings reveals a significant increase in the system's vulnerability. This is more evident for buildings with flexible foundations and low levels of damage.

Foundation type	Design level	Median PGA (g)				β_i
		LS ₁ (g)	LS ₂ (g)	LS ₃ (g)	LS ₄ (g)	
Flexible	High	0.3	0.4	0.67	0.85	0.8
	Low	0.3	0.395	0.51	0.69	0.81
	Low_corroded	0.2	0.365	0.455	0.59	0.81
Stiff	High	0.36	0.55	>0.9		0.74
	Low	0.345	0.525	0.74	>0.9	0.76
	Low_corroded	0.25	0.5	0.71		0.76

Table 5: Parameters of fragility functions

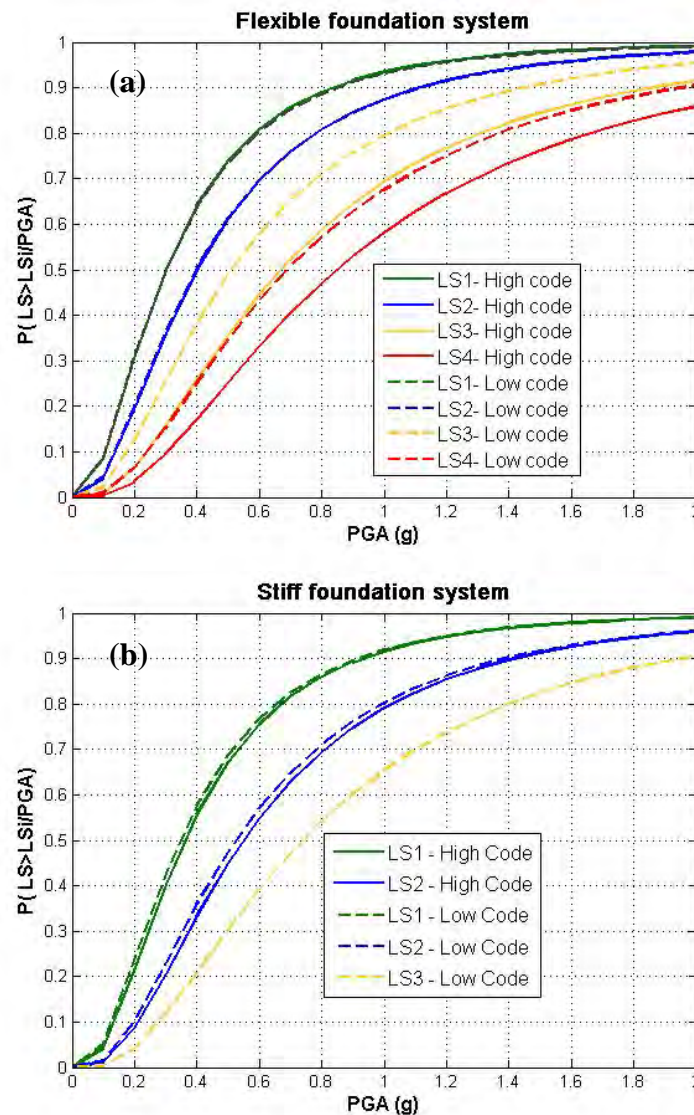

Figure 9: Fragility curves for low rise RC buildings with flexible (a) and stiff (b) foundation system

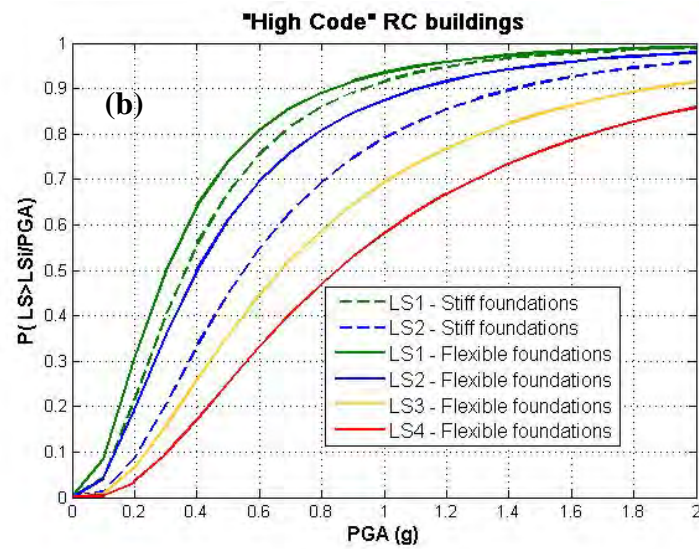

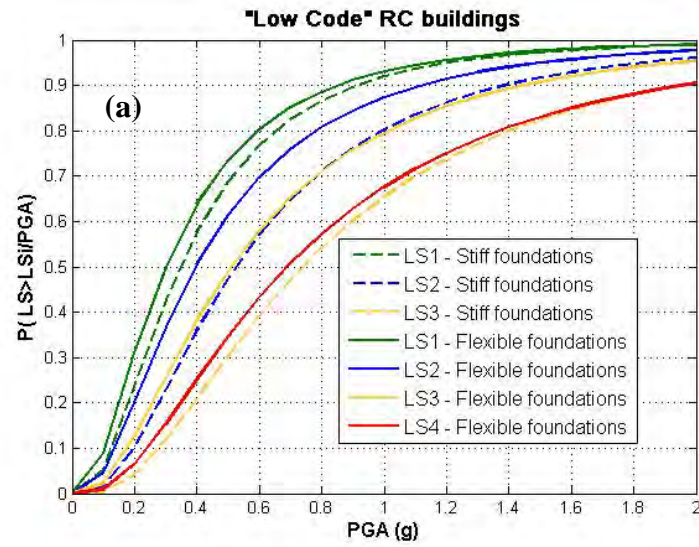

Figure 10: Fragility curves for low rise RC buildings, "low code" (a) and "high code" (b) design

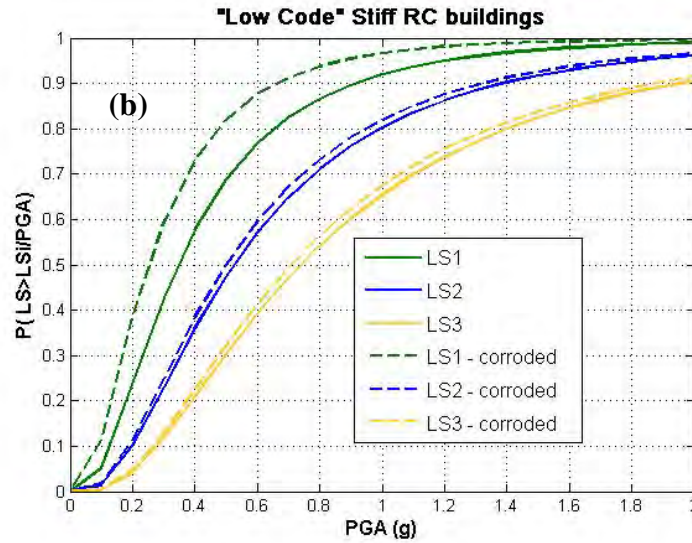

Figure 11: Fragility curves for low rise “low code” flexible (a) and stiff (b) RC buildings

It should be noticed that only the structural damage of the building members is considered in this study. The total damage (structural and non-structural) will be quite different (certainly larger) in case of the building with the stiff foundation as a considerable amount of damage may be attributed to the rotation of the whole building as a rigid body. In the latter, the damage can only be defined using empirical criteria and expert opinion [12]. Furthermore, it is worth pointing out that the complex issue of combined ground shaking and ground failure due to landslide is not taken into account in the evaluation of the building ‘s vulnerability. The authors are planning to include this in a future work. Finally, although the results are limited by some of the idealizations and assumptions of the analysis, they should provide a useful starting point in the vulnerability assessment of affected buildings standing near the crest of precarious slopes, providing the basis for more sophisticated numerical analysis for the particular governing conditions in selected real case studies.

4 CONCLUSIONS

An analytical-numerical methodology to estimate physical vulnerability of RC buildings subjected to co-seismic landslide displacements has been presented. The analysis results to the construction of fragility relationships for single bay-single story RC buildings that differ in the foundation system (isolated footing and continuous foundation) and code design level. For low code, usually old, structures the effect of corrosion of the reinforcement on the vulnerability estimation is also investigated. Various uncertainties, related to the capacity of the building, the deformation demand and the definition of limit states are considered in the analysis. It is observed that “high code” buildings with stiff foundation system are expected to suffer less structural damage compared to the other building typologies examined. The performance of “low code” RC structures is found to be degraded due to the consideration of corroded structural members, revealing a substantial increase in the vulnerability of buildings resting on flexible foundations. Finally the proposed fragility curves can be used to estimate the seismic risk and to design appropriate mitigation measures at building or aggregate scale.

Keywords: Nonlinear Dynamic Analysis, Near-Fault Ground Motions, Scaling Method, Seismic Demand, Collapse Capacity, Variability.

Abstract. *Assessment of the seismic performance of a structure often requires conducting nonlinear dynamic analyses under a set of ground motion records scaled to a specific level of intensity. Recent researches have demonstrated that pseudo spectral acceleration at the first mode period of vibration, $S_a(T_1)$, which is commonly used as the seismic intensity scaling index, may introduce a large scatter in the estimated seismic demands under near-fault pulse-like ground motions. Considering the need to provide more accurate estimation of seismic demands by using a smaller number of records, development of an improved scaling method that can reduce the variability in seismic demands becomes inevitable.*

In this paper, an improved intensity measure is developed based on the Root-Mean-Square (RMS) value of spectral responses, which is calculated over an appropriate period range. For this purpose, Incremental Dynamic Analyses (IDAs) are carried out for five generic frames of short to relatively long periods under 40 pulse-like earthquake records rotated to the fault-normal direction. Statistical study of the IDAs results is performed to determine the type of the response spectrum (i.e. pseudo acceleration, velocity or displacement) and the optimal period range for calculating the RMS value as the improved scaling method.

Statistical evaluation reveals that the RMS of pseudo spectral accelerations, $(S_a)_{rms}$, provides much superior results than RMS of spectral displacements, $(S_d)_{rms}$, and RMS of spectral velocities, $(S_v)_{rms}$. It is concluded that the optimal period range varies with the fundamental period of a structure, and that $(S_a)_{rms}$, if calculated over the optimal period range, can predict the seismic demands with the overall dispersions that are generally reduced by the relative amount of 14 percent with respect to those of $S_a(T_1)$. The newly proposed parameter can also reduce the dispersion in predicted collapse capacities of the frames by the relative amount of 24 percent compared to $S_a(T_1)$ on average.

1 INTRODUCTION

Performance Based Earthquake Engineering (PBEE) has received much attention in recent years as the new proficient method that can provide a quantitative basis in assessment of the seismic performance of structures. PBEE is a desirable concept and its implementation depends strongly on the ability to confidently estimate the probability that Engineering Demand Parameter (EDP), such as maximum storey drift, plastic hinge rotation and member force, exceeds a specific value. The probability that the EDP exceeds a specific value is a function of seismological random variables (such as magnitude and distance) and structural random variables (such as stiffness, strength, ductility and mass), and it is typically estimated through combining the results of Incremental Dynamic Analyses (IDAs) of a structure and seismic hazard analysis. In IDA, the intensity of each record is incremented after each inelastic dynamic analysis by using an intermediate quantity as the seismic intensity scaling index which is usually referred to as Intensity Measure (IM) [1].

The IM, as the seismic intensity scaling index, should represent those parameters of earthquake ground motions that strongly influence the structural responses, and it is required to introduce a small variability in EDP at any given IM level ($\sigma_{EDP|IM}$). A small variability is desirable because the standard error of sample mean of $\ln(EDP)$ for any specified IM level is equal to the ratio of the $\sigma_{EDP|IM}$ to the square root of n , where n is the number of earthquake records that have been sampled, and the sample mean of $\ln(EDP)$ is typically the first-order information used in quantifying the probabilistic seismic demand analysis [2].

Selecting the appropriate intensity measure for near-fault ground motions requires more accurate attention for special characteristics of this type of motions. In near-fault records influenced by forward directivity or fling step phenomena, most of the seismic energy from the rupture appears as a single coherent pulse-type motion. Ground motions having such a distinct pulse-like character generally arise at the beginning of the seismogram, and their effects tend to increase the long-period portion of the acceleration response spectrum. Studies have shown that for this type of motions, the maximum demand is a function of the ratio of the ground motion's pulse period, T_P , to the fundamental period of the structure [3]. With respect to this issue, the pseudo spectral acceleration measured at the first mode period of vibration, $S_a(T_1)$, which is commonly used as the IM in the performance-based earthquake engineering, cannot adequately predict the seismic demands imposed on structures by near-fault pulse-like ground motions [3], because it is not good representative for those parameters of near-fault earthquakes, such as pulse period, that affect the response of the structures.

The major shortcoming of $S_a(T_1)$, as the IM, is its inability in describing the effective frequency content of earthquakes at $T \neq T_1$. This weakness is more pronounced when pulse motions dominate the structural responses. The efficiency of $S_a(T_1)$ can be approximately improved by incorporating ε , shown to capture the average local spectral shape at T_1 , via a vector IM for ordinary earthquakes [4]. Nevertheless, pulse-like motions cannot be adequately characterized by the vector of $S_a(T_1)$ and ε , because their response spectra usually exhibit a sharp change, making it difficult to simply estimate spectral shape using $S_a(T_1)$ and local spectral shape at T_1 via epsilon [5, 6].

For near-fault earthquakes, Yang and Coworker have proposed intensity measures of Improved Effective Peak Acceleration (IEPA) for rigid systems, and Improved Effective Peak Velocity (IEPV) for medium to long period systems [7]. IEPA and IEPV have been respectively defined based on the average value of spectral accelerations and spectral velocities around their predominant peak. Whereas IEPA and IEPV have been developed based on the frequency characteristics of near-fault earthquakes, since these IMs are calculated over individual period ranges of records, and these period ranges are only defined based on the predo-

minant period of each response spectrum without any consideration of modal periods of a structure, they may introduce a large record to record variability [8]. It has been shown that the frequency content of earthquakes at a period range around the first mode period of a structure can describe the damaging effects of ground motions on the structure in a much better manner [8].

In this paper, an improved intensity measure is developed based on the Root-Mean-Square (RMS) value of spectral responses, calculated over an optimal period range, in order to reduce the variability in seismic demands under near-fault pulse-like ground motions. Based on the Incremental Dynamic Analyses (IDAs) of five frames of various heights under 40 near-fault pulse-like ground motions, it is shown that RMS of pseudo spectral accelerations, $(S_a)_{\text{rms}}$, provides much superior results than RMS of spectral velocities, $(S_v)_{\text{rms}}$, and RMS of spectral displacements, $(S_d)_{\text{rms}}$. All possible period ranges for calculating the RMS value are considered, and the optimal period range that can significantly reduce the overall variability in seismic demands obtained from IDAs is proposed. It is shown that the optimal period range is a function of the fundamental period of the structure, and that RMS of pseudo spectral accelerations, $(S_a)_{\text{rms}}$, calculated over the proposed period range, can considerably increase the accuracy of the seismic demand prediction with respect to $S_a(T_I)$.

2 STRUCTURAL SYSTEMS

Incremental dynamic analyses results of two-dimensional generic one-bay frames were used to develop the newly improved IM. The advantage of using the generic frames is that they do not represent a specific structure and thereby the results from analyses are not a function of a particular system. They are adequate to capture the global behavior of multi-bay frames and to evaluate the sensitivity of the results to various structural heights [9].

The generic frames used in this study consist of frames with number of stories, N , equal to 3, 6, 9, 12, 15 and the fundamental periods, T_1 , of $0.1N$. Seismic demands of these frames under near-fault ground motions were obtained using the Open System for Earthquake Engineering Simulation (OpenSees) [10]. The main characteristics of these models can be found in references 8 and 9. Non-linear behavior of the frames was modeled by using rotational springs at the beam ends and at the bottom of the first-storey columns. Peak oriented hysteretic model and the energy based deterioration model was used to represent the non-linear load-deformation behavior of abovementioned rotational springs [11].

3 NEAR-FAULT PULSE-LIKE GROUND MOTIONS DATABASE

Increasing number of recorded near-fault ground motions, with seismologists and engineers efforts, may do recognizing those characteristics of this type of motions that strongly affect the dynamic responses of structures [12-14]. These researches have been generally focused on the pulse motions contained in near-fault records due to forward directivity and the fling step effects.

Considering that the pulse motions in near-fault records strongly affect the dynamic responses of structures [15], a large variability in the seismic demands of structures under scaled pulse-type motions may be observed, unless an appropriate method is used to scale this type of ground motions. Therefore, this study focused on a database of 40 near-fault earthquake records compiled from records that exhibit intense velocity pulses. The database includes the acceleration time-histories of the 2003 Bam (Bam station), the 1998 Golbaft (Sirch station), the 1990 Rudbar (Abbar station), the 1978 Tabas (Tabas station) and the 1977 Naghan (Naghan station) Iranian near-fault pulse-like earthquakes that were taken from Iran strong motion network data bank [16]. Moreover, 35 near-fault records, having distinct velocity pulses, were

taken from PEER strong motion database and added to this database [17]. All ground motions have been recorded on stiff soil, very dense soil and rock based on the ASCE7-10 [18] site classification for all faulting styles. The earthquake magnitude, M_w , ranges from 6.2 to 7.2, and the closest distance to fault rupture ranges from 0.07 to 18.2 km.

Near-fault ground motions have orientation that is controlled by the geometry of the fault, and thereby it is necessary to treat them as a vector rather than scalar quantities [19]. In this paper, 40 near-fault ground motion records were rotated to the fault-normal and fault-parallel components using the transformations proposed by Somerville [19]. Owing to more severity of the fault-normal components relative to the fault-parallel components [14], the normal components of the records were used as the seismic input in this study. It is worth noting that the pulse period and the peak spectral velocity of the used fault-normal components respectively range from 0.45 to 8.93 (*sec*), and from 84 to 500 (*cm/sec*).

4 DEVELOPMENT OF AN IMPROVED SCALING METHOD

Intensity measures (IM) are intermediate quantities which describe earthquake strength in terms of parameters that can be strongly related to seismic demands of structures. The pseudo spectral acceleration at the first period of a structure, $S_a(T_1)$, which is commonly used as the IM, may not show satisfactory correlation with the seismic demands distribution, particularly under near-fault pulse-like ground motions [5, 6]. This brought about as a result of two flaws of $S_a(T_1)$; one flaw is that this parameter does not describe the frequency content of ground motions at higher modes of vibration; and the other one is that it does not account for inelastic lengthening of modal periods as a structure softens under stiffness degradation. When the input time history is a near-fault pulse, these shortcomings are accentuated due to the sharp change in spectral ordinates around the pulse period [5].

In this study, in an attempt to compensate for the shortcomings of $S_a(T_1)$, a new improved scaling parameter was developed on the basis of the root-mean-square (RMS) value of spectral responses over the period range of $[T_a, T_b]$ in accordance with the following equation:

$$(S_{res})_{rms} = \left[\frac{1}{n} \sum_{i=1}^n S_{res}^2(T_i) \right]^{0.5}, \quad T_a \leq T_i \leq T_b \quad (1)$$

$$T_{i+1} = T_i + \Delta T$$

In Equation 1, $S_{res}(T_i)$ is the spectral response at T_i , and ΔT is equal to 0.025 (*sec*) for the 3-storey frame and 0.05 (*sec*) for other frames.

In developing this new improved IM according to Equation 1, there are two important key issues that should be carefully accounted in order to achieve the minimum amount of variability in seismic demands; firstly, which type of response spectrum (i.e. pseudo acceleration, velocity or displacement) is more capable to be used for calculating the root-mean-square value. In other words, which one of the parameters of $(S_a)_{rms}$, $(S_v)_{rms}$ and $(S_d)_{rms}$ is more efficient; secondly, with respect to the first mode period of a structure, which period range is more appropriate to be used for calculating the RMS value as improved IM.

4.1 Evaluation of the efficiency of the $(S_a)_{rms}$, $(S_v)_{rms}$ and $(S_d)_{rms}$ as the IM

Incremental dynamic analyses (IDAs) of the genetic frames under the near-fault ground motions were employed to determine the type of the response spectrum and the period range that can be reliably used to calculate the RMS value according to Equation 1. IDAs for the peak maximum interstory drift ratio, IDR_{max} , of the 6-storey and 12-storey frames in terms of $S_a(T_1)$ as the IM, are shown in Figure 1. Each point in these figures corresponds to the IDR_{max}

Figure 1: IDAs results of the 6 and 12-storey frames in terms of $S_a(T_l)$

of the frame obtained from a nonlinear dynamic analysis under a record scaled to a specific level of intensity.

The variability in IDAs can be quantified in terms of Coefficient Of Variation (COV) of IM values corresponding to a specific level of response (conditioned on a specific value of IDR_{max}) which was characterized by $COV_{(IM|IDR_{max})}$. The average value of $COV_{(IM|IDR_{max})}$ on the interval $[0, IDR_c]$ was calculated as the mean COV of the IM values, where IDR_c is the individual drift ratio capacities of the frames.

To select the best type of response spectrum for development of the improve IM, all possible period ranges of $[T_a, T_b]$ were used to calculate each of the parameters of $(S_a)_{rms}$, $(S_d)_{rms}$ and $(S_v)_{rms}$ as the alternative for IM. For each one of these alternatives, and based on the IDAs of the frames, the mean COV was calculated. The minimum amount of mean COV that can be achieved by using each of the parameters of $(S_a)_{rms}$, $(S_d)_{rms}$ and $(S_v)_{rms}$ was determined, which is provided in Figure 2.

Figure 2 indicates that the efficiency of $(S_a)_{rms}$, $(S_v)_{rms}$ and $(S_d)_{rms}$ is approximately similar for the 9 and 12-storey frames; however, $(S_a)_{rms}$ becomes more capable as the number of stories decreases to 3 and 6 or as it increases to 15. Based on these observations, velocity-based improved intensity measures are only appropriate for the 9, 12 and 15- storey frames included in the relatively low to moderate frequency systems. Therefore, with respect to the efficiency of $(S_a)_{rms}$ for all ranges of structural height, the parameter of $(S_a)_{rms}$ is chosen as the best estimation of an earthquake strength.

4.2 Selection of the optimal period range in order to reduce the overall variability

Relation of the mean COV to the period range of $[T_a, T_b]$ over which the parameter of $(S_a)_{rms}$ has been calculated according to Equation 1, is respectively shown in Figures 3a and 3b for the 6 and 12- storey frames, for instance. In these figures, the abscissa represents the ratio of T_a to T_l and the ordinate represents the ratio of T_b to T_l , where T_a and T_b are the lower and upper limits of the period range of $[T_a, T_b]$, and T_l is the individual fundamental periods of the frames. The optimal period range, leading to the minimum mean COV, can be found from these figures, which strongly depends on the fundamental period of the frames as follows:

Optimal period range for short-period frames: Studying the relation of the mean COV to the period range for the 3 and 6-storey frames, which is presented in Figure 3a for the 6-storey frame as an example, reveals that the minimum scatter in the IDAs of short-period frames can be obtained by using the optimal period range of $[0.9T_l, 1.3T_l]$, among all period ranges. This implies that the period elongation effects in the seismic demand prediction of short-period

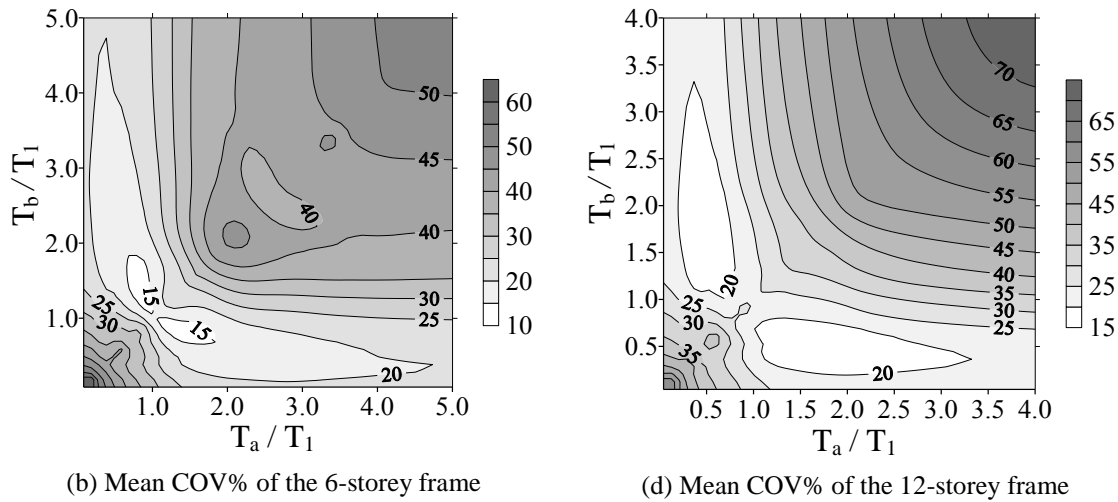

Figure 2: Minimum value of mean COV% in IDAs using $(S_a)_{rms}$, $(S_d)_{rms}$ and $(S_v)_{rms}$, calculated over the respective optimal period range

(b) Mean COV% of the 6-storey frame

(d) Mean COV% of the 12-storey frame

Figure 3: Mean COV% in IDAs results for $(S_a)_{rms}$ calculated over various period ranges of $[T_a, T_b]$

frames are significant, whereas the higher modes effects are insignificant.

Optimal period range for moderated to relatively long-period frames: Studying the results of the statistical evaluation shows that in addition to the effects of period elongation on the seismic demands of the 9, 12 and 15-storey frames, the effects of higher modes are also significant in these frames. Therefore, both higher modes effects and period elongation effects emerge in the optimal period range for these frames. Based on the mean COV values for the 9, 12 and 15-storey frames, which is presented in Figure 3b for 12-storey frame as an example, the minimum scatter in the IDAs of moderate to relatively long-period frames can be obtained by using the optimal period range of $[0.3T_1, 1.9T_1]$. It is worth nothing that considering the modal periods of the 9, 12 and 15-storey frames shows that the lower limit of the optimal period range (i.e. $0.3T_1$) is approximately equal to the average value of the T_2 and T_3 , where T_2 and T_3 are respectively the second and the third mode periods of the frame.

5 COMPARING THE EFFICIENCY OF $(S_A)_{RMS}$ AND $S_A(T_1)$

When performing IDAs of a structure under an ensemble of ground motions, a fraction of Ground Motions (GMs) will result in collapse of the structure at any given intensity level. Therefore, seismic demand prediction requires statistical response evaluation of the non collapse data (denoted NC) as well as the collapse data (denoted C) in accordance with the following equation [5]:

$$P[IDR_{max} > x | IM = im] = P[IDR_{max} > x | IM = im, NC] \cdot (1 - P_{C|IM=im}) + P_{C|IM=im} \quad (2)$$

where $P[IDR_{max} > x | IM = im, NC]$ is the probability of IDR_{max} exceeding a given level x at a given intensity level of im , for non-collapse data; and $P_{C|IM=im}$ is the probability of collapse at each im level. It should be mentioned that the collapse data (denoted C) was indicated by either non-convergence of dynamic analysis or excessive IDR_{max} demand in this study.

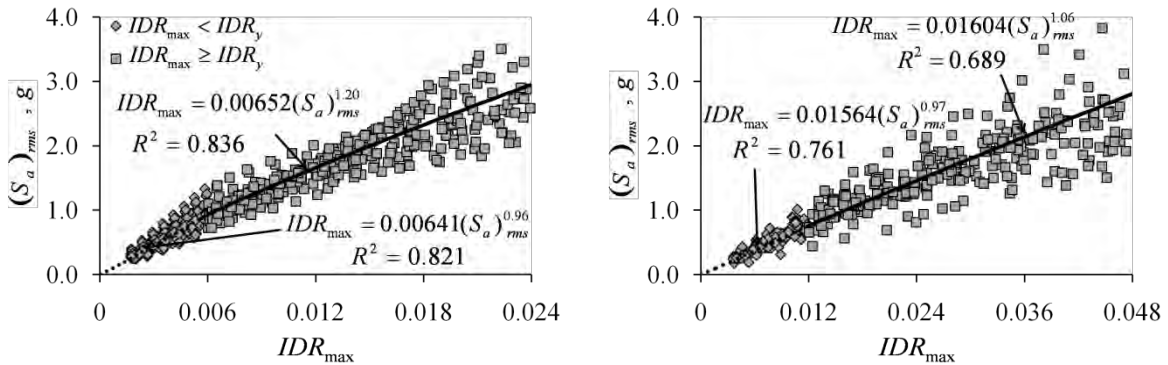

To improve the accuracy of seismic demand prediction in accordance with Equation 2, the improved IM should be able to reduce the variability in the non-collapse data as well as the collapse data, which will be discussed in the following for $S_a(T_I)$ and $(S_a)_{rms}$.

IDAs of short-period frames: Incremental dynamic analyses results of the 3 and 6-storey frames were adapted for the new improved IM of $(S_a)_{rms}$, calculated over the optimal period range of $[0.9T_I, 1.3T_I]$, in order to compare the efficiency of this new parameter with the commonly used parameter of $S_a(T_I)$. Non-collapse IDAs results of the 6-storey frame, presented in terms of $S_a(T_I)$ in Figure 1a, are provided in terms of $(S_a)_{rms}$ in Figure 4a as the example for IDAs of short-period frames. From comparing these figures, following observations can be made; for low levels of intensity at which the response is elastic the parameter of $(S_a)_{rms}$ results in more variability than $S_a(T_I)$. This follows the fact that linear responses of the short-period frames are dominated by the first mode of vibration. As the intensity of GMs is increased, period elongation effects become significant, and $(S_a)_{rms}$ provides more accurate estimation of responses. Using the optimal period range for calculating $(S_a)_{rms}$ made possible to significantly reduce the dispersions at large intensities so as not to substantially increase the scatter at low levels of intensity, and consequently the overall variability can be reduced.

Based on the non-collapse IDAs results (as shown in Figures 1a and 4a for the 6-storey frame), the overall variability was quantified in terms of dispersion of drift response conditioned on the ground motion intensity measure. For this purpose, dispersion was calculated according to the following equation as the standard deviation of the drift data from an average response curve obtained from regression analysis between drift and the seismic intensity:

$$\sigma_{IDR_{max}} = \left[\sum_{i=1}^n (IDR_{max,i} - \bar{IDR}_{max,i})^2 / (n - 1) \right]^{1/2} \quad (3)$$

In Equation 3, $IDR_{max,i}$ is the i th response obtained from a nonlinear dynamic analysis under a record scaled to a specific level of intensity, $\bar{IDR}_{max,i}$ is the average response obtained from regression curve at the same intensity for which $IDR_{max,i}$ was calculated, and n is the sample size of the non-collapse data at all levels of intensity (as an example for the 6-storey frame, n is the number of points in Figures 1a or 4a).

(a) IDAs results of the 6-storey frame

(b) IDAs results of the 12-storey frame

Figure 4: IDAs results of the 6 and 12-storey frames in terms of $(S_a)_{rms}$

Figure 5: (a) The ratio of the standard deviation to IDR_y for IDAs results of the frames based on $S_a(T_I)$ and $(S_a)_{rms}$, (b) COV% in the IM values leading to collapse for $S_a(T_I)$ and $(S_a)_{rms}$

Figure 5a provides the ratio of the standard deviation, which was calculated in accordance with Equation 3, to the individual yield drift ratios of frames (i.e. $\sigma_{IDR_{max}}/IDR_y$), for all frames and for $S_a(T_I)$ and $(S_a)_{rms}$. It can be seen that $(S_a)_{rms}$ can respectively reduce the $\sigma_{IDR_{max}}/IDR_y$ of the 3 and 6-storey frames from 0.42 and 0.40 for $S_a(T_I)$ to 0.35 and 0.33, and in so doing can improve the accuracy of the non-collapse seismic demand prediction (i.e. $P[IDR_{max} > x|IM = im, NC]$ in Equation 2).

While $(S_a)_{rms}$ reduces the overall dispersion, this reduction is most apparent at larger drifts, where the structure behaves nonlinearity. This implies that in addition to improvement of the accuracy in predicting the non-collapse seismic demand, $(S_a)_{rms}$ can increase the accuracy of collapse capacity prediction. The intensity (IM value) at which structural collapse is occurred under an earthquake record, is referred to as collapse capacity of the structure under the earthquake record. The considerable difference between the efficiency of $S_a(T_I)$ and $(S_a)_{rms}$ in collapse capacity prediction of the 3 and 6-storey frames, can be clearly observed in Figure 5b. From this figure, it can be observed that the COV in the IM values leading to collapse of the 3 and 6-storey frames were respectively reduced from 23.7 and 27.8 percent for $S_a(T_I)$ to 16.8 and 20.8 percent for $(S_a)_{rms}$. Therefore, the parameter of $(S_a)_{rms}$ can considerably improve the accuracy of the collapse prediction of the short-period frames (i.e. $P_{C|IM=im}$ in Equation 2).

IDAs of moderate to relatively long-period frames: Non-collapse IDA results of the 12-storey frame, presented in terms of $S_a(T_I)$ in Figure 1b, are provided in terms of $(S_a)_{rms}$ in Figure 4b as the example for the IDAs of moderate to relatively long-period frames. It should be mentioned that for these frames, $(S_a)_{rms}$ was calculated over the optimal period range of $[0.3T_I, 1.9T_I]$. From Figures 1b and 4b, it can be observed that R^2 factor, an indicator of how well the equation resulting from the regression analysis, is significantly increased from 0.474 for $S_a(T_I)$ to 0.761 for $(S_a)_{rms}$ at low levels of response ($IDR_{max} < IDR_y$), and from 0.551 for $S_a(T_I)$ to 0.689 for $(S_a)_{rms}$ at high levels of response ($IDR_{max} > IDR_y$), where IDR_y is the yield interstorey drift ratio of the frame.

The ratio of $\sigma_{IDR_{max}}/IDR_y$ was calculated according to Equation 3 for non-collapse IDAs results of the 9, 12 and 15-storey frames for $S_a(T_I)$ and $(S_a)_{rms}$, which is shown in Figure 5a. This figure demonstrates that $(S_a)_{rms}$ can considerably reduce the $\sigma_{IDR_{max}}/IDR_y$, and thereby can enhance the accuracy of the non-collapse seismic demand prediction. In addition to the ability in non-collapse seismic demand prediction, $(S_a)_{rms}$ can be efficiently employed in predicting the probability of collapse. The COV in collapse capacities of the 9, 12 and 15-storey frames for $S_a(T_I)$ and $(S_a)_{rms}$ are presented in Figure 5b. This figure implies that using $(S_a)_{rms}$

can respectively reduce the COV in collapse prediction of the 9, 12 and 15-storey frames from 32.1, 26.9 and 33.3 percent for $S_a(T_I)$ to 28.2, 21.4 and 23.0 percent. Reduction in the dispersion of non-collapse data as well as the collapse data in this way helps reducing the number of records necessary to predict the probability that seismic demand exceeds a given value, in accordance with Equation 2, within a specified confidence interval.

6 CONCLUSION

With the goal of developing an improved intensity measure (IM) for scaling near-fault pulse-like ground motions, the ability of root-mean-square (RMS) of spectral responses, calculated over the optimal period range, was considered in this study. The evaluation of RMS of spectral responses has led to the following conclusions:

1. It was concluded that root-mean-square of pseudo spectral accelerations, $(S_a)_{rms}$ generally provides much superior results with respect to those of spectral displacements, $(S_d)_{rms}$, and spectral velocities, $(S_v)_{rms}$.
2. Statistical evaluations of IDAs results of the 3 and 6-storey frames, short-period frames, revealed that calculating the $(S_a)_{rms}$ over the optimal period range of $[0.9T_I, 1.3T_I]$, compared to all possible period ranges, was led to the minimum overall variability in the predicted seismic demands. This illustrates the significance of period elongation effects in seismic demand prediction of short-period frames through incremental dynamic analyses.
3. Based on the statistical evaluation of IDAs results of the 9, 12 and 15-storey frames, moderated to relatively long-period frames, it was concluded that the minimum overall scatter in the IDAs results can be obtained by using the optimal period range of $[0.3T_I, 1.9T_I]$, among all possible period ranges. This indicated that both higher modes effects and period elongation effects are significantly important in seismic demand prediction of these frames in terms of $(S_a)_{rms}$.
4. The seismic intensity scaling index of $(S_a)_{rms}$, calculated over the optimal period, compared to $S_a(T_I)$ can considerably reduce the $\sigma_{IDR_{max}}/IDR_y$, the ratio of the standard deviation of non-collapse IDR_{max} demands to the individual yield IDR of the frames. By using $(S_a)_{rms}$, the ratio of $\sigma_{IDR_{max}}/IDR_y$ for the 3, 6, 9, 12 and 15-storey frames was respectively reduced by the relative amount of 16, 18, 10, 10 and 15 percent compared to those of $S_a(T_I)$.
5. The newly proposed IM can also reduce the dispersion in predicted collapse capacities of the frames by the relative amount of 24 percent compared to $S_a(T_I)$ on average.

Abstract. *Inelastic structural models used for performance-based design intrinsically dissipate a part of the total amount of the seismic energy imparted to the structure. To take into account the energy dissipation sources not considered in the structural model but that nevertheless exist, damping generally is added. Given an inelastic structural model, state-of-the-practice documents thus advocate to add a portion of damping that is consistent with the inelastic structural model used. The main purpose of this contribution is to investigate whether it is a priori straightforward for practitioners to consistently add damping or not. There is indeed no clear theoretical framework for adding damping. This investigation is based on a reinforced concrete moment-resisting frame tested on the shaking table of the École Polytechnique of Montreal. Numerical analyses were carried out with ten different combinations of inelastic structural models and added viscous damping models. The main conclusion of this investigation is that it is a complex task to add viscous damping in a way that is consistent with the capacity of the inelastic structural model to dissipate imparted seismic energy. In the context of RC moment-resisting frame structures in seismic loading, without considering any interaction with the surrounding environment, computing energy dissipation quantities can serve as an indicator for assessing the consistency looked for and appears as a paradigm for performance-based engineering.*

1 INTRODUCTION

The theoretical formalism we use to derive the set of equilibrium equations that governs the motion of a civil engineering structure in dynamic loading is inherited from the mathematical works achieved at the end of the 17th century and during the 18th. Mechanics was at that time a branch of mathematics and the development of infinitesimal calculus and variational calculus has been motivated by the need to rationally describe the world as human beings can perceive it. The world was in particular assumed to be perfect in the sense that it was conservative: no energy dissipation source was considered.

The first introduction of a source of energy dissipation in the formulation of a mechanical problem is attributed to Sir John William Strutt, better known as Lord Rayleigh. His analytical method, along with modal damping, is nowadays still widely used to model the damping phenomenon observed in the response of elastic mechanical systems. It is also common practice, *e.g.* in earthquake engineering, to introduce Rayleigh's damping in the simulation of inelastic systems. Although Lord Rayleigh himself mentioned that his theory lacks physical insight, it is suitable for correctly representing the behavior of a structure as far as i) it remains in its elastic range and ii) there is no need for a microscopic description of the internal mechanisms that generate damping.

When the assumption of elasticity is discarded, *e.g.* for performance-based engineering, there are two main reasons why an explicit description of internal mechanisms becomes necessary. First, internal mechanisms cause irreversible modifications in the structure that have to be accurately described to assess its performance level. For instance, strength and stiffness degradations of structural elements are key indicators to assess residual structural capacity. Second, they dissipate part of the imparted seismic energy and thus participate to the global damping characteristics observed in the structural response. It is however not realistic to explicitly model each internal energy dissipative mechanism, but the most important should be modeled.

Combining explicitly modeled energy dissipation sources with added viscous damping, such as Rayleigh's damping, is common practice in performance-based earthquake engineering [1]. This will be shown in the next section where we will first present the definitions we adopted for damping and finally introduce the concept of *consistent added damping*. As mentioned in recent building rules [2], the portion of added damping should be consistent with the inelastic structural model. As far as performance-based engineering is concerned, the main purpose of this contribution is to investigate whether it is *a priori* straightforward to consistently add damping or not. To this end, the third section is dedicated to the numerical modeling of a reinforced concrete moment-resisting frame tested on the shaking table of the École Polytechnique of Montreal [3]. Ten numerical simulations are carried out according to different combinations of inelastic structural models and Rayleigh's damping models. An analyses of the results is provided and its main conclusion, expressed in the context of RC moment-resisting frame in seismic loading, is that the proportion of seismic energy that is dissipated by the added viscous damping model E_D , even when associated to small critical damping ratios, can become preponderant with respect to the proportion of seismic energy that is dissipated by the inelastic structural model E_H . This sounds not physical. Modeling a portion of added damping that is consistent with a given inelastic structural model thus appears as a complex task. According to this conclusion, in this particular context of RC moment-resisting frame structure in seismic loading and without considering any interaction between the structure and its surrounding environment, computing the E_D/E_H ratio could *a posteriori* be used as an indicator of consistency.

2 CONSISTENT ADDED DAMPING

2.1 Definitions for damping

The definition of damping might somehow be ambiguous. The definition we adopted in this paper needs thus to be clarified. First, in [2], the following definitions are proposed:

- Inherent damping: damping due to inherent dissipation of energy by elements of the structure.
- Additional viscous damping: damping added in the simulation to take into account inherent energy dissipation sources not explicitly considered in the inelastic structural model.

In the numerical simulations, there are thus two sources of damping: damping that comes from the inelastic structural model and additional viscous damping.

Then, in [4], in the context of inelastic structural analysis, damping is defined as *“the portion of energy dissipation that is not captured in the hysteretic response of components that have been included in the model”*. According to this definition, it is also suggested in [4] to use *“un-modeled energy dissipation”* as a more appropriate terminology for damping.

In this contribution, we adopt the following definitions:

- Hysteretic damping: energy dissipation due to the inelastic response of the structural elements included in the model.
- Added damping: damping added in the simulation, for instance Rayleigh’s damping, to take into account energy dissipation sources not explicitly modeled in the inelastic structural model.

On the contrary to what is suggested in [4], we decided to also qualify the hysteretic energy dissipation as damping. Indeed, in experimental investigations, measured damping is due to all the energy dissipative phenomena; then, in the numerical simulations, hysteretic energy dissipation sources also participate to the damping characteristics of the structure. In what follows, all the energy dissipation sources, that is total damping, is thus split into an explicitly modeled part (hysteretic damping) and an additional part (added damping). This latter part is introduced in the simulations to take into account the energy dissipation sources not explicitly modeled in the inelastic structural model.

2.2 Some words on the state of the practice

Section 2.4 in [4] is a very useful and detailed presentation of damping in the buildings in the context of nonlinear structural analysis. We provide here a very short summary of it.

Experimental evidence concerning 1/3 to 1/2 scale reinforced concrete frame systems are presented. The critical damping ratios in the first mode versus level of damage measured from 7 shaking table tests are shown and it is concluded that:

- In the initial or undamaged condition, the critical damping ratio ranges from 1% to 3%.
- In structures that have undergone modest levels of shaking (less than 1% drift) and sustained slight damage (*i.e.* hairline cracking, minor spalling), damping values increase to about 4%.
- Following significant damage, damping increases beyond 5% up to a maximum measured value of 11% of critical.

Inelastic structural models cannot represent all the energy dissipation mechanisms involved in the measured damping. It is mentioned in [2] section 6.4.4 that *“most of the structural damping [should] be modeled directly in the analysis through hysteretic response of the structural components”*. And then, *“depending on the type and characteristics of the nonlinear model, additional viscous damping may be used to simulate the portion of energy dissipation arising from both structural and nonstructural components (e.g. cladding, partitions) that is not otherwise incorporated in the model”*.

Concerning now the choice of the critical damping ratios to be considered for adding viscous damping, the general principle to be appealed for is expressed in the following terms in [2] section 6.4.4: *“When used, viscous damping should be consistent with the inherent damping in the structure that is not already captured by the nonlinear hysteretic response that is directly simulated in the model”*. It is stated in [4] that *“many of the currently available guidelines on damping are intended for use with elastic dynamic analysis”*. Nevertheless, the value of 5% of critical damping is presented as common practice for nonlinear studies of low to mid-rise buildings. In [5], the dynamic behavior of steel-concrete composite structures is modeled and the authors conclude that the two critical damping ratios of 1% and 5% *“can be viewed as reasonable lower and upper bounds when energy dissipation due to material hysteretic behavior is already modeled explicitly”*. In works developed with the finite element computer program *Vector* [6], it is advocated not to add damping and thus to use the inelastic structural model as the sole source of seismic energy dissipation.

2.3 Adding viscous damping

The inelastic earthquake response of RC structures is computed according to the following discrete equations of motion:

$$\mathbf{M}\ddot{\mathbf{U}}(t) + \mathbf{C}(t)\dot{\mathbf{U}}(t) + \mathbf{R}(t) = \mathbf{F}^{sta} - \mathbf{M}\Delta\ddot{\mathbf{U}}_g(t) \quad (1)$$

where \mathbf{M} , $\mathbf{C}(t)$ are the mass and damping matrices and $\mathbf{R}(t)$ is the nonlinear restoring forces vector; \mathbf{F}^{sta} is the applied static forces, and $-\mathbf{M}\Delta\ddot{\mathbf{U}}_g(t)$ represents the applied seismic forces with Δ the matrix indicating the active dynamic degrees of freedom for directional mass and $\ddot{\mathbf{U}}_g(t)$ the applied ground acceleration.

There are several methods for introducing added viscous damping ($\mathbf{C}(t)\dot{\mathbf{U}}(t)$) in numerical simulations: the so-called Rayleigh's or Caughey's methods or modal damping. We only present here Rayleigh's methods that will be used for the numerical simulations presented in the next section:

$$\mathbf{C}_{[i]}(t) = (a_M\mathbf{M} + b_K\mathbf{K}_0)_{[1]} , (a_M\mathbf{M} + b_K\mathbf{K}_{tan}(t))_{[2]} \text{ or } (a_M(t)\mathbf{M} + b_K(t)\mathbf{K}_{tan}(t))_{[3]} \quad (2)$$

where \mathbf{K}_0 and $\mathbf{K}_{tan}(t)$ are the initial and tangent stiffness matrices. The coefficients a_M and b_K determine the critical damping ratio for two chosen structural frequencies.

Although all of these methods have clear significance and computational benefits in elastic simulations, they might be inappropriate in inelastic analyses and thus have to be handled with care. Several researchers presented seismic analyses of nonlinear structural systems using different damping models from Eqs. (2) [7, 8, 9, 10]. It was concluded that $\mathbf{C}_{[3]}(t)$ was the best model to maintain a constant value of added viscous damping throughout the analysis and avoid spurious internal damping forces. However, the update of parameters $a_M(t)$ and $b_K(t)$ with the progress of the solution is not practical from a computational aspect and damping models $\mathbf{C}_{[1]}$ or $\mathbf{C}_{[2]}(t)$ are generally preferred. The coefficients a_M and b_K are most often computed from

the initial dynamic properties of the structures, but pushover analysis (or other approximations) could also be used to predict the secant stiffness at the target ductility to estimate an elongated natural period of vibration in the computation of a_M and b_K .

The purpose of the following section is to investigate how far such commonly used added viscous Rayleigh's damping models can be considered as consistent with the hysteretic damping coming from the inelastic structural model. Then, to *a posteriori* quantify this consistency, an indicator based on energy quantities is suggested.

3 ENERGY AS AN INDICATOR OF CONSISTENCY FOR ADDED DAMPING

In this section, numerical inelastic seismic analyses of a RC moment-resisting frame tested on a shaking table are compared. Different computer programs available to practitioners and researchers are used to combine different RC inelastic and added viscous damping models, and to compare their relative amount of energy dissipated during the seismic time-history.

3.1 Description of the RC frame structure and ground motions

Figure 1: RC frame tested on a shaking table.

Fig. 1 shows the geometry and reinforcing steel of the half scale RC moment-resisting frame that was tested on a shaking table some years ago by Filiatrault *et al.* [3] at École Polytechnique of Montreal. The structure was designed according to the Canadian National Building Codes CNBC 1995 for a global displacement ductility demand $R = 2$. A detailed description of the frame is given in [3]. The two bays, two stories frame is 5 m wide, 3 m high with rectangular cross-sections of 15x16 cm and 14x15 cm for the 1st and 2nd floor beams, 17x13 cm and 18x13 cm for the external and internal columns. Resulting properties of RC are as follows: concrete Young's modulus 25,200 MPa, compressive strength 31 MPa and Poisson's ratio 0.17; the longitudinal steel Young's modulus 224,600 MPa with a yield strength 438 MPa and the

ultimate strength 601 MPa. Four inverted U shape concrete blocks attached in each span of the beams were used to simulate concentrated gravity loads from framing joints. The centers of gravity of the added masses were computed such that they coincide with the center of gravity of the beams. Service cracks were induced by the added masses. The total weight of the frame was 95 kN. The fundamental period was measured at 0.36 s in a free-vibration test with a first modal damping ratio of 3.3%. Mode 1 is preponderant.

The ground motion record that was selected for the test program corresponds to the N04W component of the accelerogram recorded in Olympia, Washington (April 13, 1949). Fig. 2 presents the feedback record measured on the shaking table during the test initially scaled to a peak ground acceleration $PGA = 0.21$ g, as well as the corresponding response spectrum.

Figure 2: Seismic input motion: (a) shaking table acceleration, (b) response spectrum (5% critical damping ratio).

The frame structure was designed according to the CNBC 1995. The structural response observed during the shaking table test, expressed in terms of displacements, shear forces and plastic hinges positions, is in accordance with the building code.

3.2 Structural models

It is well known that all the inelastic analyses do not provide identical results and it is not realistic to aim at modeling all the energy dissipative phenomena that can occur during seismic time-history. However, as mentioned in [11], there are *“phenomena that affect the behavior at or near collapse and that cannot be detected and evaluated by means of conventional elastic analysis techniques”*; among others, the author focuses on i) structure P-delta effects, ii) deterioration in strength and stiffness and, for moment-resisting frame structures, iii) the capacity design strong column–weak girder concept for which excessive plastic hinging in columns should be avoided. The inelastic structural models used thus have to be at least capable of reproducing these key issues.

The model developed with the computer program *Ruaumoko* [12] (Fig. 3a) is based on beam-column elements with plastic hinges lumped at the member ends. The Q-HYST degrading rule version of the modified Takeda model (Fig. 3b) was used to represent the inelastic moment-rotation behavior in plastic hinges. The backbone of the hysteretic curve was obtained from a plane section analysis program. At each node the connection was modeled using rigid end beam and column offsets (infinitely stiff zones whose length is equal to the depth of the adjacent

beam or column) and plastic hinges whose lengths are equal to half the height inside the stirrups. *Ruaumoko* allows using the damping models $C_{[1]}$ or $C_{[2]}(t)$ defined in Eqs. 2.

Figure 3: Ruaumoko lumped plasticity model: (a) geometry; (b) modified Takeda hysteretic model.

We also used the computer program *Perform3D* [13] allowing for the discretisation of the various frame cross-sections into fibers. A division of the sections into 6 concrete and steel layers for the columns and 8 layers for the beams was used. A 1D behavior law was associated to each material; Fig. 4a shows the stress-strain behavior of the concrete material models. The mesh is the same as in Fig. 3a. For the structural model referred to as *Perform3D_1*, unconfined concrete material was assigned to each concrete fiber and 5 numerical integration points (NIPs) per element were considered. For the structural model *Perform3D_2*, the concrete material was defined as confined concrete inside the stirrup and as unconfined outside (Fig. 4b), and only 2 NIPs per element were considered. Connections at each node were modeled by using rigid end beam and column offsets, that is, for *Perform3D* program, zones whose length is equal to the depth of the adjacent beam or column and whose stiffness is 10 times those of the element. In *Perform3D*, Rayleigh's damping models are not exactly defined as in Eqs. 2. We consequently define both $C_{[F1]}$ as a Rayleigh's damping model computed according to the initial stiffness, as for model $C_{[1]}$, and $C_{[F2]}$ as a Rayleigh's damping model computed according to the reduced stiffness associated to a global displacement ductility $R = 2$, in the spirit of model $C_{[2]}$. To this, the methodology is described in [13].

Figure 4: Perform3D fiber element model: (a) concrete model, (b) confined and unconfined fibers. Stiffness degradation is modeled and there is no strength in tension.

Degradations, and thus energy dissipation phenomena, were observed in the beam-column joints during the test. For more detailed structural models, rigid end zones should thus be replaced by inelastic connections.

3.3 Results analysis

The total weight of the structure P and the fundamental elastic period T^{ela} are first indicated in Tab. 1. *A posteriori*, with the experimental results at hand, the values obtained for T^{ela} can be validated as follows. Because of the dead load, there is significant initial damage in the structure and the experimental fundamental period that is initially measured ($T_{FV}^{ini,exp} = 0.36$ s) is longer than the elastic one. The elastic dynamic properties of the mock-up are thus not known. For *Perform3D*, we evaluate the initial fundamental period by weakly exciting the structure after the dead load has been applied, letting it return to rest in free vibrations and measuring T_{FV}^{ini} (mode 1 is predominant). Then, the maximum top-displacement d_{max} is indicated. The quantities E_T , E_D and E_H correspond to the total seismic energy dissipated by the numerical model, the energy dissipated by the added viscous damping model and by the inelastic structural model. Finally, the fundamental period T_{FV}^{fin} is computed when the structure returns to rest at the end of the seismic motion.

Table 1: Earthquake response analyses of a RC moment-resisting frame using different inelastic structural and added viscous damping models (excerpt of the results).

Our purpose here is to show that it is somehow difficult to *a priori* assess that an added damping model is consistent with the inelastic structural model. Indeed, even for Rayleigh's damping models defined with small critical damping ratios, E_D can become very larger than E_H . This sounds not acceptable for most of the performance-based analyses. One can hope that this non-realistic behavior would be avoided with a "good" inelastic structural model. However, there is *a priori* no reason not to check whether added damping is consistently modeled or not and the computation of the amounts of energy dissipated all along the seismic time-history seems to provide a pertinent indicator for this.

The following tendencies can be observed from Tab. 1:

- The $E_{H/D}/E_T$ ratio is affected by the choice of a structural model. 1) For the lumped plasticity models (*Ruaumoko*), hysteretic energy is preponderant, which is no more the case for the *Perform3D* fiber element models; this is illustrated in Fig. 5. 2) For *Perform3D* models, the assumptions made on the concrete behavior law also significantly affect the energy ratios.
- For a given computer program, the larger the E_H/E_T ratio is, the larger and closer to the experimental response is the maximum top-displacement. This observation supports some researchers' opinion, who advocate not to introduce added damping in inelastic simulations [6].
- For both *Ruaumoko* and *Perform3D* models, the energy repartition is not significantly affected by the choice of a Rayleigh's damping model of the $C_{[(F)1]}$ or $C_{[(F)2]}$ kind. Defining added viscous damping according to a reduced stiffness matrix with respect to the initial one nevertheless leads to a slight reduction of the E_D/E_T ratio.
- For both *Ruaumoko* and *Perform3D* models, the energy ratios are sensitive to $\xi_{1,2}$, the critical damping ratio attributed to modes 1 and 2.
- For all *Ruaumoko* models, the final fundamental structural frequency is roughly $T_{FV}^{fin} = 0.45$ s. This indicates that the global structural stiffness degradation is independent from the E_H/E_T ratio. On the contrary, for *Perform3D* models, there is a clear correlation between the amount of energy dissipated by the model and the degradation of the global stiffness. Considering *Perform3D* models only, the best approximation is obtained when there is almost no added damping.

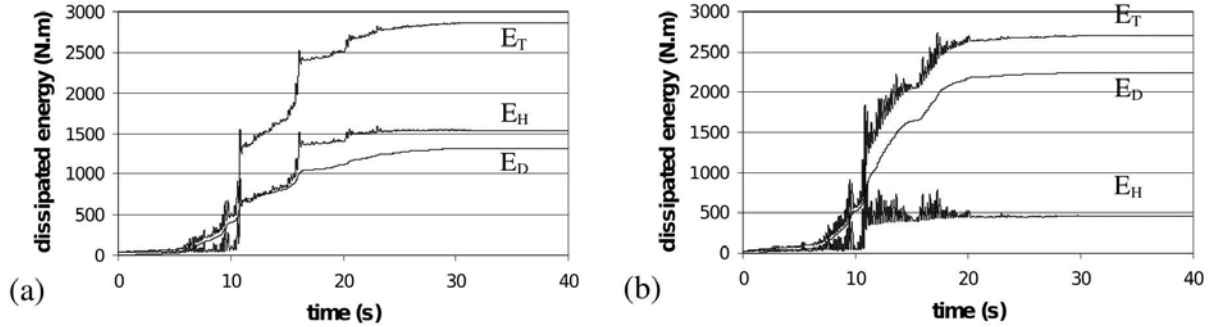

Figure 5: Energy dissipation sources: (a) *Ruaumoko* $C_{[1]}=3.3\%$, (b) *Perform3D.2* $C_{[F2]}=1.5\%$.

Besides, computing energy quantities allows to compare the relative importance of the inelastic mechanisms accounted for in the structural model. For instance, for detailed material constitutive models developed in the theoretical frameworks of continuum mechanics and thermodynamics with interval variables, it is often difficult, in the context of seismic inelastic time-history analysis, to assess whether enriching the model with new local mechanism is meaningful or not. However, for this kind of models, it is often straightforward to compute the energy dissipated by each local phenomenon such as plasticity or damage [14], and it is thus possible to quantify the relative importance of each local phenomena.

4 CONCLUSIONS

In the particular context of RC moment-resisting frame structure in seismic loading, and without considering any interaction between the structure and its surrounding environment:

- **Facts.** The seismic energy imparted to a structure is dissipated consequently to inelastic mechanisms, that are irreversible modifications, in the structure.
- **Issue.** Performance-based methods ideally require that the irreversible modifications in the structure are predicted. One of the main issues related to performance-based engineering thus is: how to model the energy dissipation mechanisms in the structure?
- **Methodological aspects.** The need for modeling internal energy dissipation provides methodological indications for the development of inelastic analyses. Energy dissipation in a structural numerical model should be mostly hysteretic to predict the internal modifications. However, it is not always satisfied for inelastic numerical simulations, even when added viscous damping is associated to a small critical damping ratio. Therefore, developments should be oriented towards both increasing the capacity of inelastic structural models to reproduce the physical mechanisms that dissipate the imparted energy and reducing the portion of added damping.
- **Results interpretation.** Results of inelastic time-history analyses can be better interpreted according to energetic quantities, which indicate whether the energy dissipation is, as expected, mostly hysteretic or not. In the case most of the energy is dissipated by added damping, it can be inferred that the numerical simulation failed to predict the internal modifications in the structure (strength and stiffness loss, drift, etc.). Elastic simulations are an extreme case: all the seismic energy is dissipated by added damping and, consequently, the structure after the earthquake is the same as before. Computing the portion of the total energy dissipated by a particular nonlinear mechanism during the seismic time-history would also allow to decide whether it is worth modeling this mechanism or not.

For these reasons, expressed in the context of RC frame structures in seismic loading, and without considering any interaction between the structure and its surrounding environment, modeling energy dissipation is a paradigm [15] for performance-based engineering.

Keywords: Pushover Analysis, Displacement Modification Method, Strain Energy, Equivalent Single Degree of Freedom System, Nonlinear Response History Analysis.

Abstract. *In this paper a new energy-based pushover procedure is presented in order to achieve an approximate estimation of structural performance under strong earthquakes. The steps of the proposed methodology are quite similar to those of the well-known displacement modification method. However, the determination of the characteristics of the equivalent single degree of freedom (E-SDOF) system is based on a different concept. Its main idea is to determine the E-SDOF system by equating the external work of the lateral loads acting on the multi degree of freedom (MDOF) system under consideration to the strain energy of the E-SDOF system. After a brief outline of the theoretical background, the sequence of the steps needed for the implementation of the proposed methodology along with the necessary equations are systematically presented. Finally, the accuracy of the proposed method is evaluated by an extensive parametric study which shows that, in general, it provides better results compared to those produced by other similar procedures.*

1 INTRODUCTION

In the last decades many research efforts have focused on developing simplified procedures for the approximate estimation of the inelastic performance of buildings under seismic excitation, in order to avoid the significant computational cost and the various inherent disadvantages of an accurate inelastic dynamic analysis. As a result of these efforts the idea of pushover analysis has been born. In the last decade a variety of more or less similar inelastic static pushover procedures have been developed, some of which have been already adopted by several seismic codes ([1], [2], [3], etc.).

Static Pushover Analysis, or Nonlinear Static Procedure (NSP) as it is denoted in seismic codes, seems to be a useful tool for engineering practice. Nevertheless, as it has already been stressed by many researchers (e.g., [4]), this procedure involves many shortcomings and can provide reasonable results only for low and medium rise planar systems. This is due to the fact that the determination of the structure's response is based on the assumption that the dynamic behavior depends only on a single elastic vibration mode. In addition, this elastic mode is supposed to remain constant despite the successive formation of plastic hinges during the seismic excitation. Also, the choice of roof displacement - as characteristic response quantity for the construction of the capacity curve - instead of any other displacement is arbitrary and it is doubtful whether the base shear-roof displacement curve is the most meaningful index of the nonlinear response of a structure, especially for irregular in height and asymmetric in plan systems. To overcome these shortcomings various modified pushover procedures have been proposed in the recent past (e.g., [5], [6], [7], [8]). Some of them [6], [7], [8] are based on the energy equivalence between the multi degree of freedom (MDOF) and the equivalent single degree of freedom (E-SDOF) systems (energy-based procedures). According to energy-based procedures, the strain energy of the structure or, equivalently, the work done by the external loads is considered to be the most representative index of its nonlinear response.

Hernandez-Montes et al. [6] suggested an energy-based formulation of pushover analysis which was motivated by the reversals in the higher mode capacity curves that were observed when applying Modal Pushover Analysis [5]. This method uses an energy-based displacement derived from the work done by the lateral loads to establish the capacity curve, instead of using the roof displacement. In each step of the pushover procedure, the work done by lateral loads associated with each mode is computed using an incremental formulation. The corresponding increment in the energy-based displacement is calculated by dividing the increment of work at each step by the base shear at that step. The incremental displacements are accumulated to obtain the energy-based displacement of the E-SDOF system. Thus, a modified capacity curve is plotted for each mode, which is used in lieu of the conventional pushover curve. These modified curves resemble traditional first mode pushover curves and do not exhibit the anomalies observed in higher mode curves.

Parducci et al. [7] proposed the determination of an equivalent energy-based displacement of the E-SDOF system. This displacement does not correspond to any actual point of the structural model, but it is a virtual value equalizing the work done by the lateral loads to the strain energy of the E-SDOF system. Then, the strain energy versus equivalent displacement diagram is plotted and - in combination with a pseudo-energy response spectrum - the performance point is determined. This point is used to estimate the response of the structure.

Earlier, Oliveto et al. [8] determined a displacement parameter based on power equivalence (which in finite terms translates into energy equivalence) between MDOF and E-SDOF systems. The properties of the E-SDOF system are then calculated as function of this energy-based displacement. Recently, this procedure was extended to include Modal Pushover Analysis [9].

The objective of the present paper is the formulation and preliminary evaluation of a new energy-based Nonlinear Static Procedure (NSP) for the approximate estimation of the seismic response of structures. The proposed procedure uses the strain energy which is considered as a more reliable index of the structural response than the base shear. This is due to the fact that the strain energy depends on the values of all forces acting to the structure as well as on the values of the displacements of all the system's degrees of freedom. The steps of the proposed methodology are quite similar to those of the well-known displacement modification method [1], [3]. However, the determination of the characteristics of the E-SDOF system is based on a different concept. Specifically, the definition of the E-SDOF system is based on the equalization of the external work of the lateral loads acting on the MDOF system under consideration to the strain energy of the E-SDOF system. In contrast to other energy-based procedures, the energy equivalence is used to derive a modified resisting force of the E-SDOF system, instead of an energy-based displacement. Thus, a modified capacity curve is plotted. As a first step, the procedure is formulated in a manner that takes into account only the predominant vibration mode and in its current form it can be rigorously applied to low and medium rise planar systems.

Firstly, the theoretical background and the assumptions of the proposed methodology are presented and briefly discussed. Secondly, both the sequence of the steps needed for the implementation of the proposed methodology along with the necessary equations are systematically presented. Finally, the accuracy of the proposed methodology is evaluated by an extensive parametric study. The paper closes with comments on results and conclusions. The whole investigation proved that the here proposed methodology gives, in general, better results as compared to other similar procedures.

2 THEORETICAL BACKGROUND

It is well known that the linear elastic response of a MDOF system can be decomposed to responses of SDOF systems, one for each elastic vibration mode (modal analysis). Although this concept lacks a theoretical basis in the inelastic range of behavior, it has been widely used by many researchers (e.g., [5]) in order to develop approximate, simplified nonlinear static procedures. It is obvious that this approach includes some fundamental assumptions. A major assumption is that the response of a MDOF system can be expressed as superposition of the responses of appropriate SDOF systems just like in the linear range. Of course, such an assumption violates the very logic of nonlinearity, as the superposition principle is not valid to nonlinear systems. However, it must be thought as a fundamental postulate, which constitutes the basis on which many simplified pushover procedures are built. Thus, each SDOF system corresponds to a vibration "mode" i with "modal" vector $\boldsymbol{\phi}_i$ (the quotation marks indicate that the application of the superposition principle is not strictly valid). The displacements \mathbf{u}_i and the inelastic resisting forces \mathbf{F}_{si} are supposed to be proportional to $\boldsymbol{\phi}_i$ and $\mathbf{M}\boldsymbol{\phi}_i$, respectively (where \mathbf{M} is the mass matrix of the system). Furthermore, "modal" vectors $\boldsymbol{\phi}_i$ are supposed to be constant, despite the successive development of plastic hinges.

Taking into account the aforementioned assumptions and applying well-known principles of structural dynamics the following conclusion is derived [10]: the nonlinear response of a MDOF system with N degrees of freedom subjected to an horizontal earthquake ground motion $\ddot{u}_g(t)$ can be expressed as superposition of the responses of N E-SDOF systems, each one corresponding to a vibration "mode" having mass equal to the effective modal mass M_i^* , displacement D_i which depends on the roof displacement u_{Ni} and inelastic resisting force equal to the "modal" base shear parallel to the direction of excitation V_i . Furthermore, the external work of "modal" forces \mathbf{F}_{si} on the differential displacements $d\mathbf{u}_i = v_i \boldsymbol{\phi}_i dD_i$ (where v_i is the

modal participation factor of mode i) is equal to the work of the resisting force (or the strain energy) of the corresponding E-SDOF system for the differential displacement dD_i .

Some basic equations correlating the properties of the “modal” E-SDOF systems to the properties of the MDOF system are derived and summarized in Table 1. However, these equations are derived on the basis of the aforementioned assumptions and cannot be valid all together at the same time when a pushover analysis is conducted. Thus, Modal Pushover Analysis [5] leaves out the 3rd equation and uses the two others to establish the “modal” E-SDOF systems. The conventional procedures adopted by codes follow a similar approach with some additional assumptions. More specifically, they take into account only the predominant vibration mode and permit modifications to the corresponding mode shape vector. The existing energy-based single or multimodal procedures keep the last two equations and determine the E-SDOF systems’ displacements on the basis of the energy equivalence between E-SDOF and MDOF system. On the contrary, the proposed method keeps the 1st and the 3rd equation and uses the energy equivalence to determine a modified resisting force of the E-SDOF systems.

MDOF system		E-SDOF systems
“modal” displacements $\mathbf{u}_i^T = \boldsymbol{\varphi}_i^T \mathbf{v}_i D_i$ (roof displacement u_{Ni})	\Rightarrow	displacement $D_i = u_{Ni} / v_i \varphi_{Ni}$ (1 st)
“modal” base shear V_i	\Rightarrow	resisting force $V_{SDOFi} = V_i$ (2 nd)
work of “modal” forces on the differential “modal” displacements $d\mathbf{u}_i^T = \boldsymbol{\varphi}_i^T \mathbf{v}_i dD_i$ $E(d\mathbf{u}_i)$	\Rightarrow	work of resisting force on the differential displacement dD_i $E(dD_i) = E(d\mathbf{u}_i)$ (3 rd)

Table 1: Definition of the E-SDOF systems.

3 THE PROPOSED METHODOLOGY

As a first step, the proposed methodology is formulated in a manner that takes into account only the predominant vibration mode in the excitation direction. Thus, in its current form, it is suitable for structural systems with small contributions of higher modes, such as low and medium rise planar frames. The steps needed for its implementation are as follows [10]:

- Step 1: Create the structural model.
- Step 2: Apply to the model a set of lateral incremental forces proportional to the vector $\mathbf{M}\boldsymbol{\varphi}_1$ of the fundamental elastic vibration mode 1 and determine the (strain energy)-(roof displacement) curve E_1 - u_{N1} . E_1 is equal to the work of the external forces and moments.
- Step 3: Divide the abscissas of the E_1 - u_{N1} diagram by the quantity $v_1\varphi_{N1} = u_{N1}/D_1$ and determine the (strain energy)-(displacement) diagram E_1 - D_1 of the E-SDOF system (Figure 1).
- Step 4: Calculate the work $\Delta E_{1,\lambda}$ (Figure 1) of the external forces in each of λ discrete intervals between the successive formation of plastic hinges. $dE_{1,\lambda}$, as part of $\Delta E_{1,\lambda}$ (Equation (1)), is considered to derive from Equation (2).

$$dE_{1,\lambda} = \Delta E_{1,\lambda} - V_{1,\lambda-1} (D_{1,\lambda} - D_{1,\lambda-1}) = \Delta E_{1,\lambda} - V_{1,\lambda-1} dD_{1,\lambda} \quad (1)$$

$$dE_{1,\lambda} = \frac{1}{2} k_{1,\lambda} dD_{1,\lambda}^2 \Rightarrow k_{1,\lambda} = 2 dE_{1,\lambda} / dD_{1,\lambda}^2 \quad (2)$$

where $k_{1,\lambda}$ is the stiffness of the E-SDOF system corresponding to mode 1 in the interval λ . The resisting force $V_{1,\lambda}$ is given by Equation (3):

$$V_{1,\lambda} = V_{1,\lambda-1} + k_{1,\lambda} dD_{1,\lambda} \quad (3)$$

For $\lambda = 1$ (i.e., when the first plastic hinge is created) the force $V_{1,1}$ is equal to the base shear parallel to the direction of excitation. By utilizing Equations (1), (2) and (3) for each interval, determine the (resisting force)-(displacement) diagram V_1 - D_1 of mode 1 (Figure 2).

Figure 1: (Strain energy)-(displacement) diagram E_1 - D_1 of the E-SDOF system.

Figure 2: (Resisting force)-(displacement) diagram V_1 - D_1 of the E-SDOF system.

- Step 5: Idealize V_1 - D_1 to a bilinear curve using one of the well known graphic procedures (e.g., [1], Section 3.3.3.2.5) and calculate the period T and the yield strength reduction factor R of the E-SDOF system corresponding to mode 1.
- Step 6: Calculate the target displacement and other response quantities of interest (drifts, plastic rotations, etc.) of mode 1, using one of the well known procedures of displacement modification (e.g., [1], Section 3.3.3.3.2 / [11], Section 10.4). If the procedure is applied for research purposes using recorded earthquake ground motions, it is recommended to estimate the inelastic displacement of the E-SDOF system by means of nonli-

near dynamic analysis, instead of using the relevant coefficients (e.g., C_1 in ASCE 41-06 and FEMA 440). This is due to the fact that the coefficient values given by codes are based on statistical processing of data with excessive deviations and, therefore, large inaccuracies might result [12].

- Step 7: Repeat steps 2 to 6 applying the incremental forces in the opposite direction. It is obvious that this step is necessary to apply only for asymmetric structures.

4 EVALUATION OF THE PROPOSED METHODOLOGY

In order to evaluate the accuracy of the proposed methodology an extensive parametric study is carried out. In particular, the methodology is applied to a series of 3-, 6-, 9- and 12-storey R/C planar frames (Figures 3 to 11). Each frame is characterized by a string symbol comprising one or two letter(s) and a number which indicates the number of its storeys. The meaning of the letter(s) is as follows:

- R – Regular frames.
- M – frames with irregular distribution of Mass along the height. (Odd and even storeys have different masses).
- S – frames with irregular distribution of Stiffness along the height. (Odd storeys have greater height).
- SS – frames with Soft Storey. (1st storey has greater height).

For each frame three sets of pushover analyses are performed: i) one based on the proposed methodology (PM), ii) a second based on a procedure similar to the existing energy-based methods, i.e. according to it the energy equivalence between MDOF and E-SDOF systems is achieved by modifying the displacements (EB) and iii) a third based on the conventional displacement modification procedure (CP). The only difference between the three applied pushover procedures is the determination of the V_1 - D_1 diagram (step 4), while the rest of the steps and assumptions are identical. V_1 - D_1 diagram affects the characteristics of the E-SDOF system (T and R) and as a consequence the estimation of the target displacement. Each set of analyses comprises 12 different accelerograms corresponding to strong earthquake motions recorded in Greece. The maximum response of the E-SDOF system is calculated by means of nonlinear dynamic analysis for each excitation. Then, the target roof displacement is either estimated by multiplication of the resulting response by the quantity $v_1\phi_{N1}$ (PM, CP) or obtained by the roof displacement – energy-based displacement correspondence (EB) [6].

Storey height: 3m - Bay width: 5m
 Restraints: columns fixed at base

Figure 11: Frame SS12.

The storey displacements and drifts of the frames under consideration are compared to those obtained by nonlinear response history analysis (NL-RHA), which is considered as the reference solution. In Figures 12 to 20 the mean errors for the 12 excitations (in relevance to the NL-RHA results) of storey displacements and drifts are shown. Notice that the positive sign (+) means that the response parameters obtained by NSPs are greater than those obtained by NL-RHA. Conversely, the negative sign (-) means that the response parameters are underestimated by NSPs. From Figures 12 to 20 becomes clear that the proposed concept for the determination of the E-SDOF system leads to more accurate estimation of the target roof displacement (only in the case of frame R12 EB gives a little lower mean error). Mean errors range from -1% to 17% for PM, from 1% to 45% for EB and from 5% to 52% for CP. Concerning the rest response quantities, the mean errors resulting from the PM are sufficiently smaller in most cases (80% and 73% of cases in relevance to CP and EB, respectively). All the three applied procedures fail to provide a reasonable estimation for drifts at the upper storeys of taller frames. Such failures have been observed in many similar investigations due to the higher mode effects (e.g., [12]).

5 CONCLUSIONS

A new energy-based Nonlinear Static Procedure (NSP) is formulated and evaluated in this paper. According to this procedure

- The properties of the E-SDOF system are determined by equating the external work of the lateral loads acting on the MDOF system under consideration to the strain energy of the E-SDOF system, and
- In contrast to other energy-based procedures, this energy equivalence is used to derive a modified resisting force of the E-SDOF system, instead of an energy-based displacement.

According to the results of an extensive parametric study the following conclusions can be drawn:

- The proposed method leads to a more accurate estimation of the target roof displacement.
- In most cases the values of other significant response parameters (e.g., displacements and drifts) are more accurate too.
- None of the three compared pushover procedures can provide reasonable estimations of drifts at upper storeys of tall buildings due to higher modes effects.

For the present, the proposed methodology can be rigorously applied to low and medium rise planar frame structures with rather small contributions of higher mode effects. However, it can be easily extended in a manner that allows its application to high rise planar frames with significant contributions of higher modes as well as to multi-storey asymmetric 3D-buildings.

Finally, it is worth noticing that the implementation of the proposed procedure in existing analysis software can be accomplished without particular difficulty.

Abstract. *Earthquake ground motion excitation can induce pounding in adjacent buildings with inadequate separation distance. This hazard is particularly relevant in densely inhabited metropolitan areas, due to the very limited space among buildings.*

Existing procedures for minimum separation distance are based on approximations of the peak relative horizontal displacement between adjacent buildings, and are characterized by unknown safety levels. The present study proposes a reliability-based procedure for assessing the level of safety corresponding to a given value of the separation distance between adjacent buildings exhibiting linear elastic behavior. The seismic input is modeled as a nonstationary random process, and the first-passage reliability problem corresponding to the pounding event is solved employing analytical techniques involving the determination of some specific statistics of the response processes. Comparison of computed analytical results with numerical simulation results are also shown, in order to validate the proposed methodology.

The proposed procedure is employed for evaluating the reliability of simplified design code formulae used to determine building separation distances. Furthermore, the capability of the proposed method to deal with complex systems is demonstrated by assessing the effectiveness of the use of viscous dampers, according to different retrofit schemes, in reducing the pounding probability of adjacent buildings modeled as multi-degree-of-freedom systems.

1 INTRODUCTION

Earthquake ground motion excitation can induce pounding in adjacent buildings with inadequate separation distance. The corresponding risk is particularly relevant in densely inhabited metropolitan areas, due to the need of maximizing the land use and the consequent limited separation distance between adjacent buildings.

The problem of seismic pounding has been investigated by several researchers in the last two decades. A significant number of early studies focused on the definition of simplified rules, such as the Double Difference Combination (DDC) rule, for determining the peak relative displacement response of adjacent buildings at the potential pounding locations [1],[2],[3]. A critical separation distance (CSD) was defined and set equal to the mean peak relative displacement between adjacent buildings, by neglecting the associated probability of pounding. In the same context, considerable research effort was devoted to the assessment of the accuracy of code rules (e.g., the absolute sum (ABS) and square-root-of-the-sums-squared (SRSS) rule) [4] in determining the mean peak relative displacement response (i.e., the CSD) of adjacent buildings [5].

More recent studies have adopted a probabilistic approach for the assessment of the seismic pounding risk. In Lin [6], a method was proposed to estimate the first two statistical moments of the random variables describing the peak relative displacement response between linear elastic structures subjected to stationary base excitation. In Lin and Weng [7], a numerical simulation approach was suggested to evaluate the pounding probability, over a 50-year design lifetime, of adjacent buildings separated by the code-specified CSD. The latter study considered both the uncertainty affecting the seismic input intensity (by using a proper hazard model) and the record-to-record variability (by using artificially generated spectrum-compatible ground acceleration time histories as input loading). The buildings were modeled as multi-degree of freedom systems with inelastic behavior and deterministic properties. In Hong et al. [8], a procedure was developed to assess the fractiles of the CSD between linear elastic systems with deterministic and uncertain structural properties subjected to stationary base excitation. The previous study was later extended by Wang and Hong [9] to include non-stationary seismic input.

Despite the numerous studies available in the literature on seismic pounding, to the best of the authors' knowledge, a reliability-based methodology for the evaluation of the safety levels associated with specified CSDs is still needed. In addition, the gradual progress of seismic design codes from a prescriptive to a performance-based design philosophy generates a significant need for new advanced, accurate, and computationally efficient reliability-based methodologies for the assessment and mitigation of seismic pounding risk.

This paper presents a fully probabilistic methodology for assessing the seismic pounding risk between adjacent buildings with linear behavior. This methodology is consistent with and can be easily incorporated into a performance-based earthquake engineering (PBEE) approach such as the Pacific Earthquake Engineering Research center (PEER) framework [10],[11]. The presented methodology considers the uncertainty affecting both the seismic input (i.e., site hazard and record-to-record variability) and the parameters used to describe the structural systems of interest (i.e., material properties, geometry, and damping properties). The seismic input is modeled as a nonstationary random process. The seismic pounding risk is computed from the solution of a first-passage reliability problem. While the approach proposed is general, the methodology presented here is specialized to linear elastic systems subjected to Gaussian loading. Under these assumptions, approximate analytical solutions and efficient simulation techniques can be used to solve the relevant first-passage reliability problem. Thus, this methodology is appropriate for structural systems that remain in their linear elastic beha-

rior range before pounding (which is a very common condition for low values of the CSDs and, thus, high seismic pounding risk), although it can be extended to account for nonlinear behavior of the considered structural systems.

2 PBEE FRAMEWORK FOR SEISMIC POUNDING RISK ASSESSMENT

The PEER PBEE framework is a general probabilistic methodology, based on the total probability theorem, for risk assessment and design of structures subjected to seismic hazard [10],[11]. The PEER PBEE methodology involves four probabilistic analysis components: (1) probabilistic seismic hazard analysis (PSHA), (2) probabilistic seismic demand analysis (PSDA), (3) probabilistic seismic capacity analysis (PSCA), and (4) probabilistic seismic loss analysis (PSLA). PSHA provides the probabilistic description of an appropriate ground motion intensity measure (IM), usually expressed as mean annual frequency (MAF) $v_{IM}(im)$ of exceedance of a specific value im . PSDA provides the statistical description of structural response parameters of interest, usually referred to as engineering demand parameters ($EDPs$), conditional to the value of the seismic intensity IM . PSCA consists in computing the probability of exceeding a specified physical limit-state, defined by structure-specific damage measures (DMs), and conditional to the values of the $EDPs$. Finally, PSLA provides the probabilistic description of a decision variable (DV), which is a measurable attribute of a specific structural performance and can be defined in terms of cost/benefit for the users and/or the society.

The reliability-based procedure developed in this paper consists in computing the mean annual frequency (MAF) of pounding, v_p , between two adjacent buildings. This procedure is a specialization for the seismic pounding problem of the first three steps of the general PEER PBEE framework (i.e., PSLA is out of the scope of this paper). It is noteworthy that the proposed approach is conceptually very different from the computation of the CSD, which does not explicitly provide the probability of pounding associated with a given separation distance. The computation of the MAF of pounding can be expressed as

$$v_p = \int \int_{edp \, im} G_{DM|EDP}(dm|edp) \cdot dG_{EDP|IM}(edp|im) \cdot |dv_{IM}(im)| \quad (1)$$

in which, $G_{DM|EDP}(dm|edp)$ = cumulative probability function of variable DM conditional to $EDP = edp$, and $G_{EDP|IM}(edp|im)$ = cumulative probability function of variable EDP conditional to $IM = im$, where upper case symbols indicate random variables and lower case symbols denote specific values assumed by the corresponding random variable. The IM must be selected so that it can be readily related to the stochastic description of an appropriate random process model for the input ground motion. This selection must also account for sufficiency and efficiency of the IM in describing the effects of the ground motion excitation on the structural response [12]. However, an exhaustive selection of appropriate IMs for different types of structures and structural performances is outside the scope of this paper.

The maximum value $U_{rel,max}$ of the relative distance $U_{rel}(t)$ between the adjacent buildings observed during the seismic event (i.e., for $t \in [0, t_{max}]$, with t = time and t_{max} = duration of the seismic event) is assumed here as EDP . The probabilistic distribution of $U_{rel,max}$ reflects the record-to-record variability of the ground motions expected to occur at the site for a given intensity, as well as the effects of the uncertainty in the parameters used to describe the structural model. Finally, the pounding event is assumed as the controlling limit-state in PSCA, by using the following limit-state function, g :

$$g = \Xi - U_{rel,max} \quad (2)$$

in which Ξ = random variable describing the building separation distance, and the pounding event corresponds to $g \leq 0$. Thus, $G_{EDP|IM}(epd|im) = P[U_{rel,max} \geq u | IM = im]$ and $G_{DM|EDP}(dm|edp) = P[g < 0 | U_{rel,max} = u]$. An important intermediate result of the procedure is the convolution of PSCA and PSDA, also called fragility analysis, which yields a fragility curve. Fragility curves describe the probability $P_{p|IM}$ of pounding conditional on the seismic intensity, i.e.,

$$P_{p|IM} = \int_{edp} G_{DM|EDP}(dm|edp) \cdot dG_{EDP|IM}(edp|im) \quad (3)$$

The MAF of pounding, ν_p , can be used to compute the MAF of exceeding a specified value of DV , e.g., the MAF of repair cost due to pounding damage. The computation of the latter quantity requires the definition of a realistic loss model, based on appropriate structural response models (e.g., dynamic impact between adjacent systems) and damage models (e.g., damage produced by floor-to-floor and floor-to-column pounding). Structural response and damage models involve the definition of other $EDPs$ and DMs , respectively, in addition to those already employed in this paper for assessing the pounding risk. Several structural response and damage models available in the literature could be employed to define an appropriate loss model [13],[14],[15],[16].

In addition, ν_p can be directly used to determine the pounding risk, $P_p(t_L)$, for a given structure over its design life (t_L = design lifetime, e.g., 50 years). Assuming that the occurrence of a pounding event can be described by a Poisson process and that the buildings are immediately restored to their original condition after pounding occurs, $P_p(t_L)$ can be easily computed as

$$P_p(t_L) = 1 - e^{-\nu_p \cdot t_L} \quad (4)$$

3 SEISMIC POUNDING RISK ASSESSMENT METHODOLOGY

Fragility analysis is the most computationally challenging component of the probabilistic PBEE framework. A simple and general approach for fragility analysis in seismic pounding assessment is provided by Monte Carlo simulation (MCS) [5],[7]. For any given value of IM , MCS-based fragility analysis requires (1) the definition of a set of ground motions that are selected from an appropriate database of real records or generated from an appropriate random process, (2) the sampling of the structural parameters that define the structural systems and of their separation distances, (3) the numerical simulation of the structural response for each ground motion time history and each set of structural parameters and separation distances, and (4) the evaluation of $P_{p|IM}$ as the ratio between the number of failures and the number of samples. However, the computational cost associated with MCS can be very high and even prohibitive when small failure probabilities need to be estimated by numerically simulating the time history response of complex multi-degree-of-freedom (MDOF) systems.

In this paper, an efficient combination of analytical and simulation techniques is proposed for the calculation of $P_{p|IM}$ under the assumptions of linear elastic behavior for the buildings and of Gaussian input ground motion. The methodology is described first for linear elastic

systems with deterministic structural properties and separation distance, and then generalized to stochastic linear systems.

It is noteworthy that, for low values of the building separation distance ξ , the buildings are expected to behave elastically before pounding occurs, while the assumption of linear behavior of the buildings before pounding becomes less realistic for larger values of ξ . If the buildings are expected to enter their nonlinear behavior before pounding, the methodology described in the remainder of this paper needs to be extended to nonlinear systems, e.g., by using statistical linearization techniques [17] or subset simulation [18]. This extension is out of the scope of this paper.

3.1 Linear systems with deterministic structural properties

The computation of the conditional failure probability $P_{p|IM}$ can be expressed in the form of a single-barrier first-passage reliability problem as [5],[9]

$$P_{p|IM} = P \left\{ \max_{0 \leq t \leq t_{\max}} [U_{rel}(t)] \geq \xi \mid IM = im \right\} \quad (5)$$

in which $U_{rel}(t) = U_A(t) - U_B(t)$, $U_A(t)$ and $U_B(t)$ = displacement response of the adjacent buildings A and B at the (most likely) pounding location, and ξ = deterministic value of the building separation distance (Fig. 1).

Fig. 1. Geometric description of the pounding problem between adjacent buildings.

Under the hypotheses of deterministic linear elastic systems subjected to Gaussian loading processes and deterministic threshold, several analytical approximations of $P_{p|IM}$ exist in the literature [19],[20],[21],[22]. These analytical approximations require computing the following statistics of the relative displacement process $U_{rel}(t)$ for a given $IM = im$: $\sigma_{U_{rel}}^2(t)$ = variance of $U_{rel}(t)$, $\sigma_{\dot{U}_{rel}}^2(t)$ = variance of the relative velocity process $\dot{U}_{rel}(t)$, $\rho_{U_{rel}\dot{U}_{rel}}(t)$ = correlation coefficient between $U_{rel}(t)$ and $\dot{U}_{rel}(t)$, $\omega_{c,U_{rel}}(t)$ = time-variant central frequency of $U_{rel}(t)$, and $q_{U_{rel}}(t)$ = bandwidth parameter of $U_{rel}(t)$. These statistics can be obtained from the spectral characteristics of order zero to two of process $U_{rel}(t)$ [23],[24],[25].

Following the methodology described in Barbato and Conte [24], a state-space formulation of the equations of motion for the two buildings is employed to compute exactly and in closed-form the required spectral characteristics. The seismic input is modeled as a time-modulated Gaussian colored noise process. For this specific input ground motion process, the

spectral characteristics of the displacement processes (and of any response process obtained as a linear combination of the displacement processes) are available in exact closed-form for SDOF systems and both classically and non-classically damped MDOF systems [25].

The equations of motion for the linear system constituted by two non-connected adjacent buildings can be expressed as follows:

$$\mathbf{m} \cdot \ddot{\mathbf{U}}(t) + \mathbf{c} \cdot \dot{\mathbf{U}}(t) + \mathbf{k} \cdot \mathbf{U}(t) = \mathbf{p} \cdot F(t) \quad (6)$$

in which $\mathbf{m} = \begin{pmatrix} \mathbf{m}_A & \mathbf{0} \\ \mathbf{0} & \mathbf{m}_B \end{pmatrix}$, $\mathbf{c} = \begin{pmatrix} \mathbf{c}_A & \mathbf{0} \\ \mathbf{0} & \mathbf{c}_B \end{pmatrix}$, $\mathbf{k} = \begin{pmatrix} \mathbf{k}_A & \mathbf{0} \\ \mathbf{0} & \mathbf{k}_B \end{pmatrix}$, $\mathbf{U} = \begin{pmatrix} \mathbf{U}_A \\ \mathbf{U}_B \end{pmatrix}$, \mathbf{m}_i , \mathbf{k}_i , \mathbf{c}_i and \mathbf{U}_i = mass matrix, damping matrix, stiffness matrix, and vector of nodal displacements of building i , respectively ($i = A, B$), \mathbf{p} = load distribution vector, $F(t)$ = scalar function describing the time-history of the external loading (input random process), and a superposed dot denotes differentiation with respect to time. It is noteworthy that connections between the two buildings (e.g., damping devices interposed between the building to mitigate seismic pounding risk) can be easily modeled by introducing the appropriate terms in matrix \mathbf{c} . The response process of interest $U_{rel}(t)$ can be related to the displacement response vector $\mathbf{U}(t)$ by means of a linear operator \mathbf{b} as $U_{rel}(t) = \mathbf{b} \cdot \mathbf{U}(t)$.

The probability of pounding conditional on $IM = im$ is given by

$$P_{p|IM} = 1 - P[U_{rel}(t=0) < \xi | IM = im] \cdot \exp \left\{ - \int_0^{t_{\max}} h_{U_{rel}|im}(\xi, \tau) d\tau \right\} \quad (7)$$

in which $P[U_{rel}(t=0) < \xi | IM = im]$ = probability that the random process $U_{rel}(t)$ is below the threshold ξ at time $t=0$, and $h_{u_{rel}|im}(\xi, \tau)$ = time-variant hazard function (i.e., up-crossing rate of threshold ξ conditioned on zero up-crossing before time t) conditional on $IM = im$. For systems with at rest initial conditions, $P[U_{rel}(t=0) < \xi | IM = im] = 1$.

To date, no exact closed-form expressions exist for the time-variant hazard function $h_{U_{rel}|im}(\xi, t)$. However, several approximate solutions are available in the literature, e.g., Poisson's (P), $h_{U_{rel}|im}^{(P)}(\xi, t) = \nu_{U_{rel}|im}(\xi, t)$, classical Vanmarcke's (cVM), $h_{U_{rel}|im}^{(cVM)}(\xi, t)$, and modified Vanmarcke's (mVM), $h_{U_{rel}|im}^{(mVM)}(\xi, t)$, approximations [22],[26]. These analytical approximations can be readily computed based on the closed-form expressions of the spectral characteristics of process $U_{rel}(t)$, as shown in Barbato and Vasta [25]. In addition, for linear elastic systems subjected to Gaussian loading, $P_{p|IM}$ can be efficiently and accurately estimated by using the Importance Sampling using Elementary Events (ISEE) method [27].

3.2 Linear systems with uncertain structural properties and separation distance

In addition to the uncertainty in the seismic input, significant uncertainty can be found in geometrical, mechanical, and material properties characterizing the structural systems and their models. Hereinafter, the uncertainty in geometrical, mechanical, and material properties of the structural models, as well as in their separation distance, Ξ , is referred to as model parameter uncertainty (MPU). MPU can significantly modify the structural performance and, thus, must be considered in the assessment of seismic pounding risk.

In order to include the effects of MPU, the total probability theorem is employed to compute the conditional probability of pounding as follows:

$$P_{p|IM} = \int_{\mathbf{X}} P_{p|IM,\mathbf{X}}(\mathbf{x}) \cdot f(\mathbf{x}) \cdot d\mathbf{x} = E_{\mathbf{X}} \left[P_{p|IM,\mathbf{X}} \right] \quad (8)$$

in which \mathbf{X} = vector of uncertain model parameters (including the uncertain separation distance Ξ) with joint probability density function $f_{\mathbf{X}}(\mathbf{x})$, and $P_{p|IM,\mathbf{X}}(\mathbf{x})$ = probability of pounding conditional on \mathbf{X} and IM .

MCS, or any variance reduction technique such as stratified sampling, can be employed to evaluate $P_{p|IM}$ in Eq. (8). For example, Latin hypercube sampling (LHS) can be employed for its computational efficiency [28]. The samples of \mathbf{X} generated by using LHS can be used to define a set of deterministic linear elastic models with deterministic separation distance, for which the conditional probability of pounding can be computed as in Eq.(7).

4 APPLICATION EXAMPLES

In this section, the proposed methodology is applied to: (1) compute the pounding risk for SDOF systems with deterministic model parameters, (2) evaluate the reliability of simplified design code formulae used to determine building separation distance, and (3) to evaluate the effectiveness of different retrofit solutions using viscous dampers in reducing the pounding risk for deterministic MDOF models of multistory buildings. In all the application examples considered here, the input ground acceleration is modeled by a time-modulated Gaussian process. The time-modulating function, $I(t)$, is represented by the Shinozuka-Sato's function [29], i.e.,

$$I(t) = c \cdot (e^{-b_1 t} - e^{-b_2 t}) \cdot H(t) \quad (9)$$

in which $b_1 = 0.045\pi \text{ s}^{-1}$, $b_2 = 0.050\pi \text{ s}^{-1}$, $c = 25.812$, and $H(t)$ = unit step function. A duration $t_{\max} = 30\text{s}$ is considered for the seismic excitation.

The power spectral density (PSD) of the embedded stationary process is described by the widely-used Kanai-Tajimi model, as modified by Clough and Penzien [30], i.e.,

$$S_{CP}(\omega) = S_0 \frac{\omega_g^4 + 4\xi_g^2 \omega^2 \omega_g^2}{\left[\omega_g^2 - \omega^2 \right]^2 + 4\xi_g^2 \omega^2 \omega_g^2} \cdot \frac{\omega^4}{\left[\omega_f^2 - \omega^2 \right]^2 + 4\xi_f^2 \omega^2 \omega_f^2} \quad (10)$$

in which S_0 = amplitude of the bedrock excitation spectrum, considered to be a white process, ω_g and ξ_g = fundamental circular frequency and damping factor of the soil, respectively, and ω_f and ξ_f = parameters describing the Clough-Penzien filter. The values of the parameters employed for all the applications are $\omega_g = 12.5\text{rad/s}$, $\xi_g = 0.6$, $\omega_f = 2\text{rad/s}$, and $\xi_f = 0.7$. The PSD function in Eq. (10) is shown in Fig. 2(a) for $S_0 = 1$.

The peak ground acceleration, PGA , is assumed as IM . In order to derive the fragility curves in terms of the selected IM , the relationship between the parameter S_0 of the Kanai-Tajimi spectrum and the PGA at the site is assessed empirically. A set of 500 synthetic stationary ground motion records are generated using the spectral representation method [31] based on the PSD function given in Eq. (10) with $S_0 = 1$. Each ground motion realization is then modulated in time using the function defined in Eq. (9). The peak ground acceleration corres-

ponding to $S_0 = 1$, $PGA_{S_0=1}$, is estimated as the mean of the $PGAs$ of the sampled ground motion time histories. The values of S_0 corresponding to different values of PGA are obtained as follows:

$$S_0 = \left(\frac{PGA}{PGA_{S_0=1}} \right)^2 \quad (11)$$

In this study, the site hazard curve is expressed in the approximate form used in Cornell et al. [32], i.e.,

$$v_{IM}(im) = P[IM \geq im | 1yr] = k_0 \cdot im^{-k_1} \quad (12)$$

in which k_0 and k_1 = parameters obtained by fitting a straight line through two known points of the site hazard curve in logarithmic scale. The site hazard curve is taken from Eurocode 8-Part 2 [33], assuming that, for the site of interest, $PGA = 0.3g$ corresponds to a return period of 475 years. Using $k_1 = 2.857$ [34], the site hazard curve becomes (see Fig. 2(b))

$$v_{PGA}(pga) = 6.734 \cdot 10^{-5} \cdot pga^{-2.857} \quad (13)$$

Fig. 2. Input ground motion: (a) PSD function of the embedded stationary process, and (b) site hazard curve.

4.1 Pounding risk for linear SDOF systems with deterministic model parameters

The first application example consists in the assessment of the pounding risk between two adjacent buildings modeled as deterministic linear elastic SDOF systems with periods t_A and t_B , and damping ratios $\zeta_A = \zeta_B = 5\%$. The conditional probability of pounding $P_{p|IM}$ is calculated using the approximate analytical hazard functions $h_{U_{rel}|im}^{(P)}(\xi, t)$, $h_{U_{rel}|im}^{(cVM)}(\xi, t)$, and $h_{U_{rel}|im}^{(mVM)}(\xi, t)$, for a deterministic distance between the buildings $\xi = 0.1m$ and for two different combinations of natural periods of the two systems, i.e., (1) $t_A = 0.5s$ and $t_B = 1.0s$, referred to as well separated natural periods (Fig. 3(a)), and (2) $t_A = 0.9s$ and $t_B = 1.0s$, referred to as close natural periods (Fig. 3(b)). The obtained conditional probabilities are presented in Fig. 3 as fragility curves and compared with the corresponding results obtained using ISEE method [27], which are assumed as reference solution.

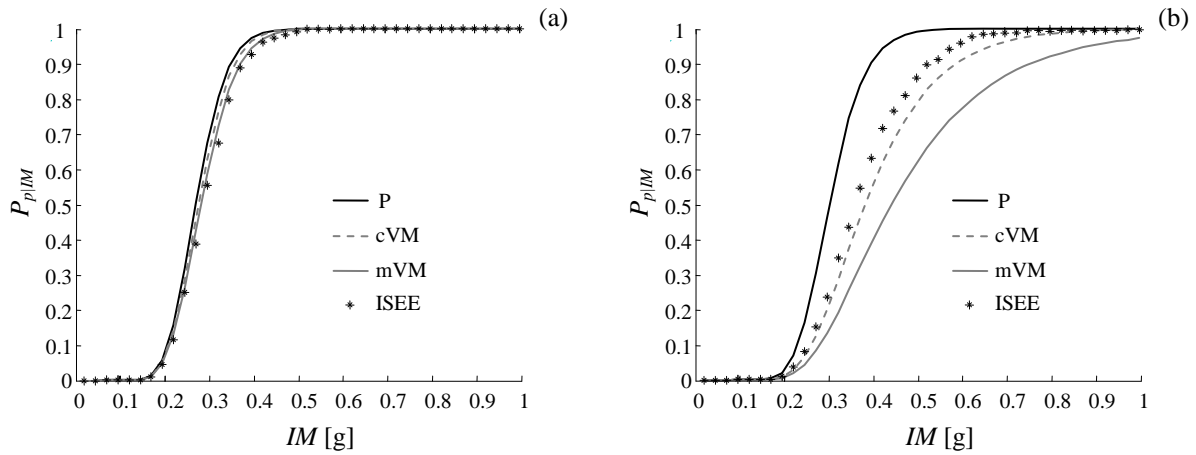

Fig. 3. Fragility curves for $\xi = 0.1\text{m}$: (a) $t_A = 0.5\text{s}$ and $t_B = 1.0\text{s}$, and (b) $t_A = 0.9\text{s}$ and $t_B = 1.0\text{s}$.

In the case of well separated natural periods for the structures (Fig. 3(a)), the fragility curves estimated using the P, cVM, and mVM approximations are very similar and close to the fragility curves obtained using the ISEE method. In the case of close natural periods (Fig. 3(b)), the fragility curves estimated with the approximate analytical methods show significant differences, and only the cVM approximation provides results that are close to the fragility curves estimated using the ISEE method. The observed result can be explained by recognizing that the relative displacement process $U_{rel}(t)$ can be interpreted as a response process of a two-degree-of-freedom system. This multi-modal characteristic of $U_{rel}(t)$ can significantly affect the accuracy of the different approximations of the time-variant hazard function $h_{U_{rel}|im}(\xi, t)$ [35]. In the case of well separated natural periods, the contribution of the higher period vibration mode to $U_{rel}(t)$ is significantly larger than the contribution of the lower period vibration mode. By contrast, in the case of close natural periods, both vibration modes provide a significant contribution to the response process.

Fig. 4 shows the MAF of pounding, v_p , as a function of the building separation distance ξ (in semi-logarithmic scale) for the cases of well separated natural periods (Fig. 4 (a)) and of close natural periods (Fig. 4(b)), respectively. The estimates of the MAF of pounding obtained using the analytical approximations (P, cVM, and mVM) of the hazard function are compared to the corresponding estimate obtained using the ISEE method. Fig. 5 plots (in semi-logarithmic scale) the pounding risk for a design lifetime of 50 years, evaluated according to Eq. (4), for the same two cases of well separated and close natural periods. Considerations similar to the ones made for the fragility curves can be made also for the MAF of pounding and the 50-year pounding risk, i.e., the analytical approximations provide very accurate results for the case of well separated natural periods and less accurate results for the case of close natural periods, with the exception of the cVM approximation, which is accurate in both cases.

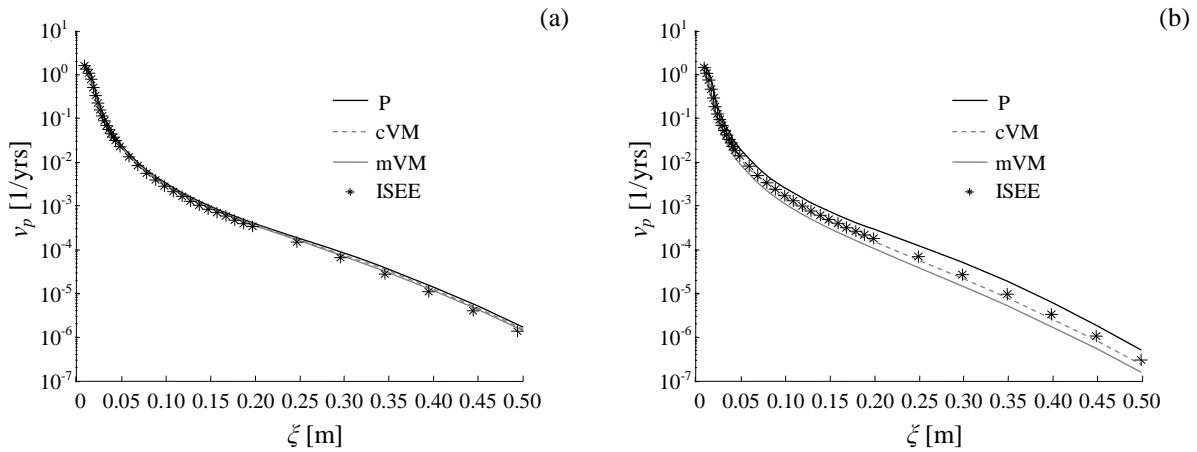

Fig. 4. MAF of pounding for varying separation distance: (a) $t_A = 0.5\text{s}$ and $t_B = 1.0\text{s}$, and (b) $t_A = 0.9\text{s}$ and $t_B = 1.0\text{s}$.

Fig. 5. 50-year pounding risk for varying separation distance: (a) $t_A = 0.5\text{s}$ and $t_B = 1.0\text{s}$, and (b) $t_A = 0.9\text{s}$ and $t_B = 1.0\text{s}$.

It is observed that the Poisson's approximation of the time-variant hazard function always yields conservative results, while the mVM approximation underestimates the risk computed using the ISEE method for the case of close natural periods. Similar results have been documented for the first-passage reliability problem of SDOF and MDOF systems subjected to time-modulated white and colored noise excitations [26].

4.2 Reliability of code formulae

The proposed methodology is applied here to evaluate the pounding risk corresponding to the separation distance prescribed by anti-seismic design codes. In order to avoid pounding between new adjacent buildings, current seismic design codes (e.g., [4],[33]) prescribe a minimum clearance to be provided between the structures. This minimum clearance between two adjacent buildings is assumed equal to the expected value of the peak relative displacement (or CSD), for a given site-specific earthquake action and a given value of the seismic intensity (hazard level). Given the seismic input, the peak relative displacement is obtained by combining (using simplified combination rules) the values of the peak displacements of the two adja-

cent structural systems, which are computed using (deterministic) structural analysis. The most commonly employed rules are the ABS method or the slightly more accurate SRSS method. The major limit of these approximate rules is that they neglect the response phase differences between the adjacent structures. In order to overcome this drawback, the use of the Double Difference Combination rule for determining the CSD has been proposed and investigated by several researchers [1], [2],[3].

In the application presented here, the values of the CSD according to the ABS, SRSS, and DDC rules are calculated following the procedure described in [5]. This procedure involves (1) generating a set of 500 samples of input ground motion time histories for the reference value of the peak ground acceleration, (2) computing the corresponding 500 peak displacement responses of systems A and B ($U_{A,\max}$ and $U_{B,\max}$), (3) computing the sample means $\bar{U}_{A,\max}$ and $\bar{U}_{B,\max}$ of $U_{A,\max}$ and $U_{B,\max}$, respectively, and (4) combining $\bar{U}_{A,\max}$ and $\bar{U}_{B,\max}$ using the ABS, the SRSS, and the DDC rule to derive estimate of the peak relative displacement $\bar{U}_{rel,\max}$.

Table 1 shows the values of the separation distance computed according to different combination rules and the corresponding 50-year probability of failure, computed based on the cVM approximation of the time-variant hazard function.

$t_A = 0.5\text{s}$ and $t_B = 1\text{s}$				$t_A = 0.9\text{s}$ and $t_B = 1\text{s}$			
	ABS	SRSS	DDC		ABS	SRSS	DDC
ξ [m]	0.1379	0.1049	0.1042	ξ [m]	0.1832	0.1298	0.0946
Pp	0.0620	0.1351	0.1376	Pp	0.0106	0.0334	0.0857

Table 1: Critical separation distance and corresponding 50-year pounding risk using different combination rules.

It is observed that the CSDs obtained using simplified combination rules yield inconsistent values of the failure probability, which are also strongly dependent on the natural periods of the two adjacent buildings. It is concluded that a methodology is still needed to determine the CSD between adjacent buildings corresponding to consistent safety levels for different combinations of the buildings' natural periods and location's seismic hazard.

4.3 MDOF models of multistory buildings retrofitted by means of viscous dampers

As a third application, the proposed methodology is employed to assess the risk of pounding between two adjacent multistory buildings modeled as linear MDOF systems, before and after retrofit with viscous dampers (Fig. 6). Different retrofit solutions are considered and their effectiveness in reducing the seismic pounding risk is compared (Fig. 6(b)). The considered buildings are steel moment-resisting frames with shear-type behavior. The properties of the buildings are taken from Lin [36]. Building A is a six-story building with story stiffness $k_A = 548,183\text{kN/m}$ (equal for every story) and floor mass $m_A = 454.545\text{tons}$ (equal for each floor), building B is a four-story building with story stiffness $k_B = 470,840\text{kN/m}$ and floor mass $m_B = 454.545\text{tons}$. A Rayleigh-type damping matrix \mathbf{c}_R is used to model the inherent buildings' damping and is built by considering a damping ratio $\zeta_R = 2\%$ for the first two vibration modes of each system. MPU is not considered in this application. The fundamental vibration periods of building A and B are $t_A = 0.751\text{s}$ and $t_B = 0.562\text{s}$, respectively.

The following six different retrofit solutions, based on the use of braces with purely viscous behavior [37], are considered: (1) braces located at each story of both buildings (retrofit scheme 1), (2) braces located at all stories of the tall building only (retrofit scheme 2), (3) braces located at all stories of the short building only (retrofit scheme 3), (4) braces located at

the lower four stories of the tall building only (retrofit scheme 4), (5) braces located at the lower four stories of both buildings, and (6) a single brace located at the first story of the tall building only. The two buildings before retrofit are shown in Fig. 6(a), while the six retrofit schemes are shown in Fig. 6(b). The viscous braces provide an additional source of damping, modeled by means of a damping matrix \mathbf{c}_v . The total damping matrix for the two buildings' systems becomes $\mathbf{c} = \mathbf{c}_R + \mathbf{c}_v$. The damping coefficient corresponding to the dampers at each floor of buildings A and B is $c_d = 10,000 \text{ kN}\cdot\text{s/m}$. The systems corresponding to retrofit schemes 4, 5, and 6 are non-classically damped and their analysis requires the use of the complex modal analysis technique [25].

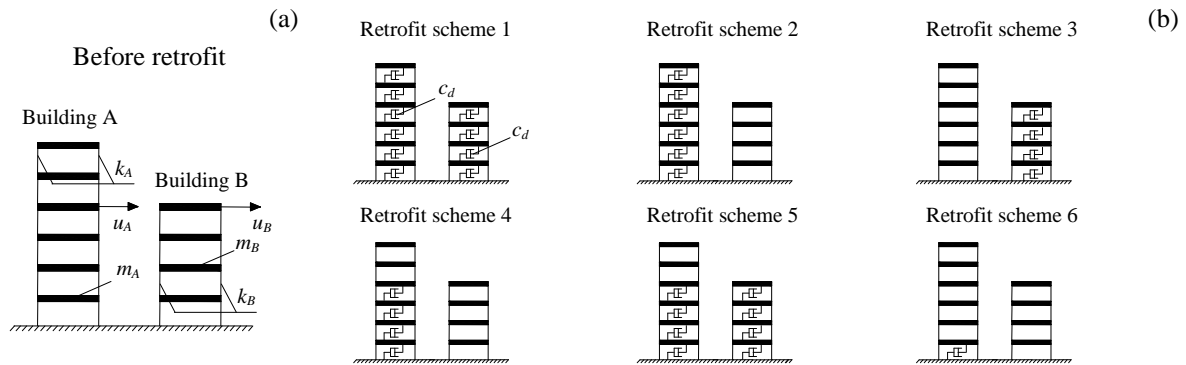

Fig. 6. Pounding between adjacent multistory buildings: (a) building A and B before retrofit, and (b) different retrofit schemes considered in this study.

Fig. 7(a) shows three different analytical estimates (P, cVM, and mVM approximations) of the 50-year probability of pounding between the two un-retrofitted buildings, for different values of the separation distance. Fig. also reports the 50-year probability of pounding obtained using the ISEE method, which is considered as reference solution. The analytical estimates provide a very good estimate of the pounding risk for a wide range of separation distances. In this particular case, the results obtained using the cVM hazard function give the best approximation of the ISEE results.

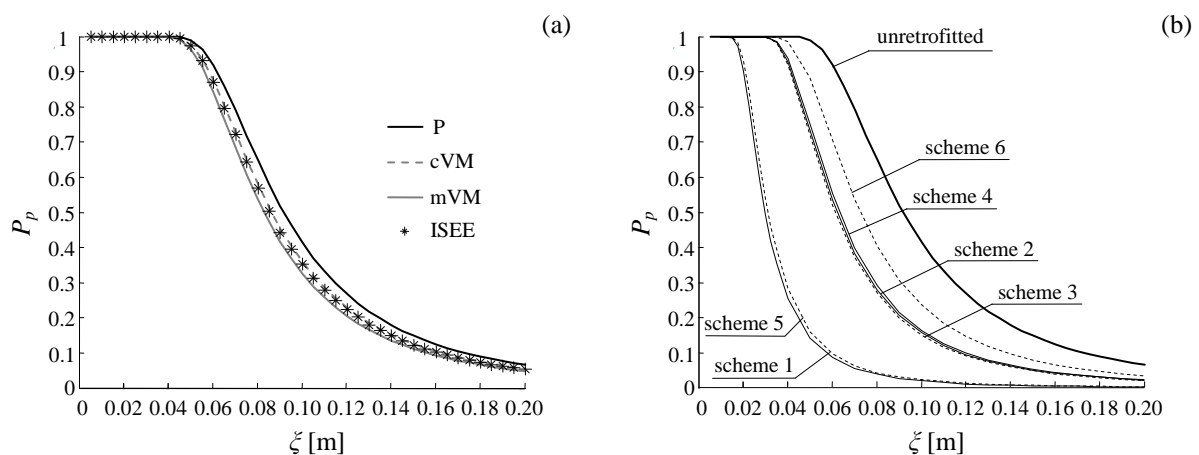

Fig. 7. Pounding risk between multistory buildings A and B: (a) comparison of different analytical solution and ISEE results, and (b) comparison of different retrofit schemes.

Fig. 7(b) shows compares the 50-year probability of pounding of the un-retrofitted buildings and of the buildings retrofitted following the six different retrofit solutions considered in this application example. The results presented in Fig. 7(b) are obtained using the cVM approximation of the hazard function.

It is observed that the use of viscous dampers can be very effective in reducing the risk of pounding between the two buildings. It is also found that the introduction of viscous braces according to scheme 3, scheme 5, and scheme 6 (corresponding to the dotted lines in Fig. 7(b)) is a very efficient retrofit solution, since it obtains a significant reduction of the pounding risk at a significantly lower retrofit cost when compared with other retrofit schemes. In particular, retrofit scheme 3 appears to achieve a very good compromise between retrofit cost and reduction of pounding risk.

CONCLUSIONS

This paper presents a fully probabilistic performance-based methodology for assessment of the seismic pounding risk between adjacent buildings. This methodology, which is consistent with the PEER PBEE framework, is able to account for all pertinent sources of uncertainty that can affect the pounding risk, e.g., uncertainty in the seismic input (i.e., site hazard and record-to-record variability) and in the parameters used to describe the structural systems of interest (i.e., material properties, geometry, damping properties, separation distance).

An efficient combination of analytical and simulation techniques is proposed for the calculation of the pounding risk under the assumptions of linear elastic behavior for the buildings and of non-stationary Gaussian input ground motion. The pounding problem is recast as a first-passage reliability problem, which is solved analytically by using the spectral characteristics (up to the second order) of the non-stationary stochastic process representing the relative displacement between the buildings. Three different analytical approximations of the time-variant hazard function are used: (1) the Poisson's approximation, (2) the classical Vanmarcke's approximation, and (3) the modified Vanmarcke's approximation. Results obtained by employing the importance sampling using elementary events method are assumed as reference solutions to evaluate the absolute and relative accuracy of the three analytical approximations considered here. The proposed formulation is very convenient in the case of linear elastic MDOF systems with both proportional and non-proportional damping, since the spectral characteristics of the relative displacement processes can be computed in exact closed form. The effects of uncertainty in the model parameters are efficiently included by means of the total probability theorem and the Latin hypercube sampling technique.

The proposed methodology is applied to investigate the risk of pounding between SDOF systems, both with deterministic and uncertain properties. With reference to this specific application example, the following observations are made. (1) The proposed combination of analytical and simulation techniques provides sufficiently accurate estimates of the pounding risk when the classical Vanmarcke's approximation is used to estimate the time-variant hazard function. (2) The accuracy of the analytical approximations of the time-variant hazard function depends on the ratio between the natural periods of the adjacent buildings. Higher accuracy is reached when the natural periods of the two buildings are well separated. (3) The Poisson's approximation of the time-variant hazard function yields always conservative estimates of the risk. (4) The design codes' simplified combination rules for calculating the critical separation distance yield inconsistent values of the pounding probability, which are also strongly dependent on the natural periods of the adjacent buildings.

In addition, the capabilities of the proposed method are demonstrated by assessing the effectiveness of the use of viscous dampers, according to different retrofit schemes, in reducing

the pounding probability of adjacent multi-story buildings modeled as linear elastic multi-degree-of-freedom systems. Based on the results presented, the following considerations are made. (1) The analytical approximations provide very accurate estimates of the pounding risk, due to the fact that the fundamental periods of the two buildings are well separated. (2) The use of viscous dampers can dramatically reduce the risk of pounding between the two systems for any given separation distance. (3) The use of viscous braces in the lower levels of the taller building is a very efficient and cost-effective technique for minimizing the pounding risk.

Based on the results presented in this paper, it is concluded that the proposed methodology can be efficiently employed (1) for the assessment of pounding risk of adjacent buildings exhibiting linear elastic behavior before pounding, (2) for the computation of the mean annual frequency of pounding between adjacent buildings in the context of performance-based earthquake engineering, and (3) for the rational evaluation of the absolute and relative effectiveness of different retrofit solutions for adjacent building with high risk of seismic pounding.

Keplerlaan 1, Noordwijk, The Netherlands
e-mail: Adriano.Calvi@esa.int

Keywords: Loads Analysis, Spacecraft Structure, Structural Dynamics, Standardization, ECSS, Handbook.

Abstract. *The handbook of the European Cooperation for Space Standardization (ECSS) E-HB-32-26 titled “Guidelines for Loads Analysis of Spacecraft and Payloads” is developed with the goal to harmonize methodologies, procedures and practices currently applied for the conduct of spacecraft and payloads loads analysis. The handbook will make available to the European Space Community a set of well proved methods and procedures for the calculation and assessment of structural design loads and for the evaluation of the test loads.*

The handbook is presently drafted by the “Loads Analysis Handbook Working Group” and contains a number of topics strictly related to computational structural dynamics. An overview of the proposed handbook, with a synopsis of some chapters, has been developed and it is here presented. It is planned that the handbook be published in the year 2012. Comments on the proposed handbook are solicited from the scientific community and industry.

1 INTRODUCTION

European Cooperation for Space Standardization (ECSS) [1] is an initiative established to develop a single set of consistent space documents for use by the entire European space community. The objective is to increase the effectiveness of all space programs in Europe through the application of the ECSS documents recognized by all potential European customers and equally accepted by industry. The ECSS documents have evolved from the previous 30 years of experience in the management and implementation of European space projects. ECSS is supported by several agencies and companies. The actual members of ECSS are the European Space Agency (ESA), the National Space Agencies of Canada, France, Germany, Italy, Norway, the Netherlands, the United Kingdom, and the European space industry represented by Eurospace.

The ECSS handbooks are nonnormative documents providing background information, orientation, advice or recommendations. A handbook therefore contains advice about how to properly do something important and useful information about a subject.

The ECSS E-HB-32-26 “Loads Analysis Handbook” [2] is developed with the goal to harmonize methodologies, procedures and practices currently applied for the conduct of spacecraft and payloads loads analysis. It will make available to the European Space Community a set of well proved methods and procedures for the calculation and assessment of structural design loads and for the evaluation of the test loads.

The handbook is presently drafted by the “Loads Analysis Handbook Working Group” and contains a number of topics related to computational structural dynamics. In particular, recent advances in the area of structural dynamics and vibrations, in both methodology and capability, have the potential to make spacecraft system analysis and testing more effective from technical, cost, and hardware safety points of view. However, application of advanced analysis methods varies among the Space Agencies and their contractors. Identification and refinement of the best of these methodologies and implementation approaches is an objective the Working Group. An overview of the proposed handbook, with a synopsis of some chapters, has been developed and it is here presented.

2 GENERAL CONTENT OF THE HANDBOOK

The handbook is organized in a number of chapters which cover the following topics:

1. Terms and definitions
2. General aspects of the loads verification
3. Loads combination
4. Launcher/spacecraft coupled loads analysis (CLA)
5. Static loads
6. Sine vibration environment
7. Random vibration and vibro-acoustic environments
8. Shock environment
9. Structural stability
10. Dimensional stability
11. Fatigue and fracture control
12. Microgravity and micro-vibration environment
13. Mathematical models

Some topics are briefly illustrated in the following sections.

3 SPACECRAFT FLIGHT ENVIRONMENTS AND DYNAMIC LOADS

There are three basic types of flight environments that generate dynamic loads on payload components [7]:

- a) The low-frequency dynamic response, typically from 0 to 100 Hz, of the launch vehicle/payload system to transient flight events.
- b) The high-frequency random vibration environment, which typically has significant energy in the frequency range from 20 Hz to 2000 Hz, transmitted from the launch vehicle to the payload at the launch vehicle/payload interfaces.
- c) The high frequency acoustic pressure environment, typically from 20 Hz to 8000 Hz, inside the payload compartment. The payload compartment acoustic pressure environment generates dynamic loads on components in two ways: (1) by direct impingement on the surfaces of exposed components, and (2) by the acoustic pressure impingement upon the component mounting structures, which induces random vibrations that are mechanically transmitted to the components.

Combinations of these loads may occur at different times in flight.

4 SPACECRAFT-LAUNCHER COUPLED LOADS ANALYSIS

The structural response of the spacecraft to transient flight events (low frequency mechanical environment) is simulated by spacecraft-launcher coupled dynamic analysis [3]. This is normally a transient analysis performed by using the finite element models (FEM) of the satellite and launcher, merged together, and by applying the forcing functions for the different launch events (figure 1).

The main objective of the CLA is to calculate the loads on the spacecraft, where the term “loads” refers to the set of internal forces, displacements and accelerations that characterise the structural response to the applied forces. The loads of the spacecraft derived from the analysis are taken as a basis to verify the dimensioning of the spacecraft itself. Spacecraft programs typically perform a number of analysis loops (called “loads cycles”), for example one each for preliminary design, final design, and final verification. The latter is done with “test verified” mathematical models.

The low frequency domain typically ranges from 0 to up 100 Hz and corresponds to the frequency content of the forcing functions used in the CLA. The excitation may be of aerodynamic origin (wind, gust, buffeting at transonic velocity) or may be induced by the propulsion system (thrust build up or tail-off transient, acoustic loads in the combustion chambers, etc.). Of primary interest are the spacecraft interface accelerations and interface forces. The interface accelerations can be used to derive an equivalent sine spectrum at the spacecraft interface. The interface forces can be employed to calculate the “equivalent accelerations” at the spacecraft centre of gravity. Of large interest is also the recovery of the internal responses which are used to verify the structural integrity of the spacecraft and its components. The computed responses and their deduced minimum and maximum levels can be employed within the design, verification and test phases of the spacecraft. For example, secondary structures and flexible components such as solar arrays, booms, instruments and propellant tanks must also be designed (and test verified) to withstand the dynamic environment induced at the base of the spacecraft. The dynamic loads (accelerations, forces, stresses, etc.) on these components can be verified directly by means of the CLA (apart from acoustic loads under the fairing which are analysed separately).

In the test verification phase of the spacecraft, the equivalent sine spectrum computed by means of CLA is used to locally reduce the prescribed spectrum from the launcher user's

manual at specific resonant frequencies. This might be required to avoid possible damage to the spacecraft structure itself or its components (solar arrays, booms, etc.).

The chapter on launcher/spacecraft coupled loads analysis includes:

- Description of load cases
- Methodology
- Static and dynamic contributions
- Generation of reduced mathematical models and output transformation matrices
- Damping modelling
- Uncertainty factors
- Output and results evaluation
- Sensitivity analysis
- Non-linearity

5 SINE VIBRATION ENVIRONMENT

In a number of situations sine-wave excitations are used for qualification and protoflight testing of space vehicle hardware, even though the “mission” dynamic excitation being simulated is not periodic [4]. In particular the low frequency transient is often simulated at the sub-system and system assembly level using a swept-sine vibration test over a frequency range up to about 100 Hz. The magnitude and sweep rate for the resulting vibration are selected supposedly to cause the hardware response to be similar to the response predicted for the transient. Some common procedures to derive such a test are reported in [2, 4].

The use of a swept-sine excitation to simulate a transient excitation can result in the unique situation of causing a simultaneous undertest and overtest of the hardware. The undertest is due to exciting only one hardware resonance at a time during the swept-sine test, as opposed to the simultaneous excitation of multiple resonances of the hardware, as would be induced by

the transient excitation. The potential overtest is due to applying a larger number of stress cycles to the hardware during the swept-sine test than occurs during the transient excitation. Of course, the amount of overtesting can be reduced by increasing the sweep rate.

However the main cause of potential overtesting is the difference in structure boundary conditions between test and flight configurations. During a vibration test, the test article is usually attached to a very rigid fixture and it is excited or driven along a single linear direction, with the structure being completely restrained along the other five degrees-of-freedom (DOF). This generates a response of the spacecraft in its “clamped natural modes” and not in the coupled launcher-spacecraft modes as exhibited during the flight [5, 6].

In the flight configuration the satellite is attached to a mounting structure (i.e. adapter and launcher) that normally exhibits some flexibilities in all six DOF in the frequency range of interest. The flexibility difference in the direction of excitation is the main contributor to the overtesting phenomenon. In the flight configuration, the acceleration at the interface between the mounting structure and the test article drops at certain frequencies, resulting in valleys in the acceleration spectra. These frequencies correspond to the resonance frequencies of the test article when attached to a rigid support (such as a shaker). This phenomenon is known as the vibration absorber effect. In other words, during a vibration test, the structure is excited with a specified input acceleration that is the envelope of the flight interface acceleration, despite the amplitude at certain frequencies drops in the flight configuration. This results in exaggerated amplification of input forces, and internal stresses, at the resonance frequencies of the test article. In practice, because the input spectrum does not consider the actual flight behaviour and excites the spacecraft modes, the structural response of the spacecraft would exceed the spacecraft design capability and the values encountered during the launch simulations.

To avoid such effects, the sine test input spectrum needs to be notched. However, it should be clear that the criteria used for notching do not have to generate an input spectrum that can jeopardize the flightworthiness of the spacecraft. For example this can happen if the testing levels are not coherent with the levels required by the CLA. As a general rule, the notching should be kept to a minimum and the input spectrum to be applied to the spacecraft as much as possible similar to the one requested by the launcher authority. The reason is that this spectrum provides robustness to the spacecraft design compliant with it since it covers a wide range of responses found in past spacecraft-launcher CLA and in addition it provides a sweep over the frequency band of interest, therefore covering possible deviations of local modes.

It should be noted that the dynamic environments for space vehicle hardware are typically multiple-axis, i.e., the excitations occur simultaneously along all three orthogonal axes of the hardware. Acoustic tests naturally simulate a multiple-axis excitation, but shock and vibration test facilities are commonly uniaxial (figure 2). Multiple axis test facilities designed to simulate low frequency shock and vibration environments (generally below 100 Hz) are available (figure 3). For space vehicle hardware, however, it is more common to perform shock and vibration tests using machines that apply the excitation sequentially along one axis at a time. The potential error caused by simulating a multiple-axis shock and/or vibration excitation with sequentially applied single-axis excitations is widely debated.

The chapter on sine vibration environment includes:

- Source of the sine environment
- Response analysis
- Environment and test specifications for instruments and components
- Methods and procedures for notching of the input spectrum in sine vibration test

6 RANDOM VIBRATION AND VIBRO-ACOUSTIC ENVIRONMENTS

Some load environments must be treated as random phenomena, when the forces involved are controlled by non-deterministic parameters [7]. Examples include high frequency engine thrust oscillation, aerodynamic buffeting of fairing, and sound pressure on the surfaces of the payload.

Random vibration analysis describes the forcing functions and the corresponding structural response statistically. It is generally assumed the phasing of vibration at different frequencies is statistically uncorrelated. The amplitude of motion at each frequency is described by a

power spectral density function. In contrast to transient analysis which predicts time histories of response quantities, random vibration analysis generates the power spectral densities of these response quantities. From the power spectral density, the root mean square (rms) amplitude of the response quantity is calculated. The root-mean-square (rms) acceleration is the square root of the integral of the acceleration PSD over frequency. Random vibration limit loads are typically taken as the 3- sigma load (obtained by multiplying the rms load by 3).

The most appropriate measure of the severity of a random vibration environment is the maximum PSD value or the PSD value at the frequency of the resonances of the structural item. It is a common mistake to use the rms value of the input as a measure of its severity. The problem with the rms value is that it depends strongly on the values of the PSD at very high frequencies and on the upper frequency limit, which are often irrelevant.

The chapter on random vibration and vibro-acoustic environments includes:

- Source of the environment
- Response analysis
- Environment and test specifications for instruments and components
- Notching of the input spectrum in random vibration test
- Methodology and procedures for vibro-acoustic analysis

7 MICRO-GRAVITY AND MICRO-VIBRATION ENVIRONMENT

One of the major goals for the future space utilization projects is conducting activities, experiments and processes in a very low gravity environment, the so-called micro-gravity environment [2]. This micro-gravity environment is usually made available in low-earth-orbiting spacecraft systems and pressurized module compartments over long period of days and months without interruptions. Consequently the spacecraft systems should be designed and should be operated such that limit acceleration levels are not exceeded during the performance of experiments and processes.

The chapter on microgravity and micro-vibration environment includes:

- General aspects related to the micro-gravity environment
- Identification of the microgravity disturbance sources
- Derivation of microgravity specifications
- Verification of the microgravity requirements

8 MATHEMATICAL MODELS

This chapter addresses the mathematical models of space structures with a special emphasis on the finite element models used for loads analysis. In particular it provides some guidelines for ensuring finite element analysis quality, i.e. the correct use of this specific technology, – the finite element method - and the acceptance of the results. The handbook promotes the verification and validation (V&V) guidance proposed in the ASME Guide for V&V [8].

The chapter includes the following topics:

- Requirements for structure mathematical models (e.g. [9, 10])
- Introduction to verification and validation in computational mechanics [8]
- Uncertainty quantification during design and verification loads cycles
- Model verification and quality assurance for spacecraft finite element analysis
- Mathematical model validation

9 CONCLUSIONS

Recent advances in the area of structural dynamics and vibrations, in both methodology and capability, have the potential to make spacecraft system analysis and testing more effective from technical, cost, and hardware safety points of view. However, application of advanced analysis methods varies among the Space Agencies and their contractors.

The ECSS Handbook for spacecraft loads analysis [2] is presently in the drafting phase and is developed with the goal to harmonize methodologies, procedures and practices currently applied for the conduct of spacecraft and payloads loads analysis. The handbook will make available to the European Space Community a set of well proved methods and procedures for the calculation and assessment of structural design loads and for the evaluation of the test loads. It is planned that the handbook be published in the year 2012. Comments on the proposed handbook are solicited from the scientific community and industry.

Acknowledgments

The work described in this paper was carried out by the members of the E-HB-32-26 Loads Analysis Handbook Working Group. Their contributions are gratefully acknowledged. The handbook is funded by the European Cooperation for Space Standardization.

Keywords: Modal Analysis, Nonlinearity, Aerospace.

Abstract. *The dynamic systems theory is well-established for linear systems and can rely on mature tools such as the theories of linear operators and linear integral transforms. This is why theoretical and experimental modal analysis, i.e., the computation of vibration modes from a mathematical model and from experimental data, respectively, is really quite sophisticated and advanced. Even though linear modal analysis served, and is still serving, the structural dynamics community for applications ranging from bridges to satellites, it is commonly accepted that nonlinearity is a frequent occurrence in engineering structures.*

Because linear modal analysis fails in the presence of nonlinear dynamical phenomena, the development of a practical nonlinear analog of modal analysis would be an extremely timely contribution; it is clearly missing in the structural dynamics literature. A new framework for nonlinear modal analysis of real-world structures, which includes the computation of nonlinear modes from finite element models, is introduced in this paper. This framework will permit a rigorous, yet understandable by the practicing engineer, analysis of nonlinear dynamical phenomena. It will also provide solid theoretical foundations for extending finite element model validation to nonlinear aerospace structures.

1 INTRODUCTION

Nonlinear normal modes (NNMs) offer a solid theoretical and mathematical tool for interpreting a wide class of nonlinear dynamical phenomena, yet they have a clear and simple conceptual relation to the LNMs [1, 2, 3]. However, most structural engineers still view NNMs as a concept that is foreign to them, and they do not yet consider NNMs as a useful concept for structural dynamics. One reason supporting this statement is that most existing constructive techniques for computing NNMs are based on asymptotic approaches and rely on fairly involved mathematical developments.

There have been very few attempts to compute NNMs using numerical methods [4, 5, 6, 7]. Algorithms for the continuation of periodic solutions are really quite sophisticated and advanced (see, e.g., [8, 9, 10]), and they have been extensively used for computing the forced response and limit cycles of nonlinear dynamical systems (see, e.g., [11]). Interestingly, they have not been fully exploited for the computation of nonlinear modes.

In this paper, we support that these numerical algorithms pave the way for an effective and practical computation of NNMs. The proposed algorithm, implemented in MATLAB, relies on two main techniques, namely a shooting procedure and a method for the continuation of NNM motions. The objective is to demonstrate that the numerical computation of the NNMs of complex real-world structures is then within reach. The application considered in this study is the airframe of the Morane-Saulnier Paris aircraft, whose ground vibration tests have exhibited some nonlinear structural behaviors.

2 Nonlinear Normal Modes (NNMs)

A detailed description of NNMs and their fundamental properties (e.g., frequency-energy dependence, bifurcations and stability) is given in [1, 2, 3]. For completeness, the two main definitions of an NNM are briefly reviewed in this section.

The free response of discrete conservative mechanical systems with n degrees of freedom (DOFs) is considered, assuming that continuous systems (e.g., beams, shells or plates) have been spatially discretized using the finite element method. The equations of motion are

$$\mathbf{M} \ddot{\mathbf{x}}(t) + \mathbf{K} \mathbf{x}(t) + \mathbf{f}_{nl} \{\mathbf{x}(t), \dot{\mathbf{x}}(t)\} = 0 \quad (1)$$

where \mathbf{M} is the mass matrix; \mathbf{K} is the stiffness matrix; \mathbf{x} , $\dot{\mathbf{x}}$ and $\ddot{\mathbf{x}}$ are the displacement, velocity and acceleration vectors, respectively; \mathbf{f}_{nl} is the nonlinear restoring force vector.

There exist two main definitions of an NNM in the literature due to Rosenberg and Shaw and Pierre:

1. Targeting a straightforward nonlinear extension of the linear normal mode (LNM) concept, Rosenberg defined an NNM motion as a *vibration in unison* of the system (i.e., a synchronous periodic oscillation).
2. To provide an extension of the NNM concept to damped systems, Shaw and Pierre defined an NNM as a two-dimensional invariant manifold in phase space. Such a manifold is invariant under the flow (i.e., orbits that start out in the manifold remain in it for all time), which generalizes the invariance property of LNMs to nonlinear systems.

At first glance, Rosenberg's definition may appear restrictive in two cases. Firstly, it cannot be easily extended to nonconservative systems. However, the damped dynamics can often be interpreted based on the topological structure of the NNMs of the underlying conservative

system [3]. Secondly, in the presence of internal resonances, the NNM motion is no longer synchronous, but it is still periodic.

In the present study, an NNM motion is therefore defined as a (*non-necessarily synchronous*) *periodic motion* of the conservative mechanical system (1). As we will show, this extended definition is particularly attractive when targeting a numerical computation of the NNMs. It enables the nonlinear modes to be effectively computed using algorithms for the continuation of periodic solutions.

3 Numerical Computation of NNMs

The numerical method proposed here for the NNM computation relies on two main techniques, namely a shooting technique and the pseudo-arclength continuation method. A detailed description of the algorithm is given in [12].

3.1 Shooting Method

The equations of motion of system (1) can be recast into state space form

$$\dot{\mathbf{z}} = \mathbf{g}(\mathbf{z}) \quad (2)$$

where $\mathbf{z} = [\mathbf{x}^* \quad \dot{\mathbf{x}}^*]^*$ is the $2n$ -dimensional state vector, and star denotes the transpose operation, and

$$\mathbf{g}(\mathbf{z}) = \begin{pmatrix} \dot{\mathbf{x}} \\ -\mathbf{M}^{-1} [\mathbf{K}\mathbf{x} + \mathbf{f}_{nl}(\mathbf{x}, \dot{\mathbf{x}})] \end{pmatrix} \quad (3)$$

is the vector field. The solution of this dynamical system for initial conditions $\mathbf{z}(0) = \mathbf{z}_0 = [\mathbf{x}_0^* \quad \dot{\mathbf{x}}_0^*]^*$ is written as $\mathbf{z}(t) = \mathbf{z}(t, \mathbf{z}_0)$ in order to exhibit the dependence on the initial conditions, $\mathbf{z}(0, \mathbf{z}_0) = \mathbf{z}_0$. A solution $\mathbf{z}_p(t, \mathbf{z}_{p0})$ is a periodic solution of the autonomous system (2) if $\mathbf{z}_p(t, \mathbf{z}_{p0}) = \mathbf{z}_p(t + T, \mathbf{z}_{p0})$, where T is the minimal period.

The NNM computation is carried out by finding the periodic solutions of the governing nonlinear equations of motion (2). In this context, the *shooting method* is probably the most popular numerical technique. It solves numerically the two-point boundary-value problem defined by the periodicity condition

$$\mathbf{H}(\mathbf{z}_{p0}, T) \equiv \mathbf{z}_p(T, \mathbf{z}_{p0}) - \mathbf{z}_{p0} = \mathbf{0} \quad (4)$$

$\mathbf{H}(\mathbf{z}_0, T) = \mathbf{z}(T, \mathbf{z}_0) - \mathbf{z}_0$ is called the *shooting function* and represents the difference between the initial conditions and the system response at time T . Unlike forced motion, the period T of the free response is not known a priori.

The shooting method consists in finding, in an iterative way, the initial conditions \mathbf{z}_{p0} and the period T that realize a periodic motion. To this end, the method relies on direct numerical time integration and on the Newton-Raphson algorithm.

Starting from some assumed initial conditions $\mathbf{z}_{p0}^{(0)}$, the motion $\mathbf{z}_p^{(0)}(t, \mathbf{z}_{p0}^{(0)})$ at the assumed period $T^{(0)}$ can be obtained by numerical time integration methods (e.g., Runge-Kutta or Newmark schemes). In general, the initial guess $(\mathbf{z}_{p0}^{(0)}, T^{(0)})$ does not satisfy the periodicity condition (4). A Newton-Raphson iteration scheme is therefore to be used to correct an initial guess and to converge to the actual solution. The corrections $\Delta \mathbf{z}_{p0}^{(k)}$ and $\Delta T^{(k)}$ at iteration k are found by expanding the nonlinear function

$$\mathbf{H}(\mathbf{z}_{p0}^{(k)} + \Delta \mathbf{z}_{p0}^{(k)}, T^{(k)} + \Delta T^{(k)}) = 0 \quad (5)$$

in Taylor series and neglecting higher-order terms (H.O.T.).

The phase of the periodic solutions is not fixed. If $\mathbf{z}(t)$ is a solution of the autonomous system (2), then $\mathbf{z}(t + \Delta t)$ is geometrically the same solution in state space for any Δt . Hence, an additional condition, termed the *phase condition*, has to be specified in order to remove the arbitrariness of the initial conditions. This is discussed in detail in [12].

In summary, an isolated NNM is computed by solving the augmented two-point boundary-value problem defined by

$$\mathbf{F}(\mathbf{z}_{p0}, T) \equiv \begin{cases} \mathbf{H}(\mathbf{z}_{p0}, T) & = 0 \\ h(\mathbf{z}_{p0}) & = 0 \end{cases} \quad (6)$$

where $h(\mathbf{z}_{p0}) = 0$ is the phase condition.

3.2 Continuation of Periodic Solutions

Due to the frequency-energy dependence, the modal parameters of an NNM vary with the total energy. An NNM family, governed by equations (6), therefore traces a curve, termed an NNM branch, in the $(2n + 1)$ -dimensional space of initial conditions and period (\mathbf{z}_{p0}, T) . Starting from the corresponding LNM at low energy, the computation is carried out by finding successive points (\mathbf{z}_{p0}, T) of the NNM branch using methods for the *numerical continuation* of periodic motions (also called *path-following methods*) [8, 9]. The space (\mathbf{z}_{p0}, T) is termed the continuation space.

Different methods for numerical continuation have been proposed in the literature. The so-called pseudo-arclength continuation method is used herein.

Starting from a known solution $(\mathbf{z}_{p0,(j)}, T_{(j)})$, the next periodic solution $(\mathbf{z}_{p0,(j+1)}, T_{(j+1)})$ on the branch is computed using a *predictor step* and a *corrector step*.

Predictor step

At step j , a prediction $(\tilde{\mathbf{z}}_{p0,(j+1)}, \tilde{T}_{(j+1)})$ of the next solution $(\mathbf{z}_{p0,(j+1)}, T_{(j+1)})$ is generated along the tangent vector to the branch at the current point $\mathbf{z}_{p0,(j)}$

$$\begin{bmatrix} \tilde{\mathbf{z}}_{p0,(j+1)} \\ \tilde{T}_{(j+1)} \end{bmatrix} = \begin{bmatrix} \mathbf{z}_{p0,(j)} \\ T_{(j)} \end{bmatrix} + s_{(j)} \begin{bmatrix} \mathbf{p}_{z,(j)} \\ p_{T,(j)} \end{bmatrix} \quad (7)$$

where $s_{(j)}$ is the predictor stepsize. The tangent vector $\mathbf{p}_{(j)} = [\mathbf{p}_{z,(j)}^* \ p_{T,(j)}]^*$ to the branch defined by (6) is solution of the system

$$\begin{bmatrix} \frac{\partial \mathbf{H}}{\partial \mathbf{z}_{p0}} \Big|_{(\mathbf{z}_{p0,(j)}, T_{(j)})} & \frac{\partial \mathbf{H}}{\partial T} \Big|_{(\mathbf{z}_{p0,(j)}, T_{(j)})} \\ \frac{\partial h}{\partial \mathbf{z}_{p0}}^* \Big|_{(\mathbf{z}_{p0,(j)})} & 0 \end{bmatrix} \begin{bmatrix} \mathbf{p}_{z,(j)} \\ p_{T,(j)} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ 0 \end{bmatrix} \quad (8)$$

with the condition $\|\mathbf{p}_{(j)}\| = 1$. The star denotes the transpose operator. This normalization can be taken into account by fixing one component of the tangent vector and solving the resulting overdetermined system using the Moore-Penrose matrix inverse; the tangent vector is then normalized to 1.

Corrector step

The prediction is corrected by a shooting procedure in order to solve (6) in which the variations of the initial conditions and the period are forced to be orthogonal to the predictor step. At iteration k , the corrections

$$\begin{aligned} \mathbf{z}_{p0,(j+1)}^{(k+1)} &= \mathbf{z}_{p0,(j+1)}^{(k)} + \Delta \mathbf{z}_{p0,(j+1)}^{(k)} \\ T_{(j+1)}^{(k+1)} &= T_{(j+1)}^{(k)} + \Delta T_{(j+1)}^{(k)} \end{aligned} \quad (9)$$

are computed by solving the overdetermined linear system using the Moore-Penrose matrix inverse

$$\begin{bmatrix} \frac{\partial \mathbf{H}}{\partial \mathbf{z}_{p0}} \Big|_{(\mathbf{z}_{p0,(j+1)}^{(k)}, T_{(j+1)}^{(k)})} & \frac{\partial \mathbf{H}}{\partial T} \Big|_{(\mathbf{z}_{p0,(j+1)}^{(k)}, T_{(j+1)}^{(k)})} \\ \frac{\partial h}{\partial \mathbf{z}_{p0}} \Big|_{(\mathbf{z}_{p0,(j+1)}^{(k)})} & 0 \\ \mathbf{p}_{z,(j)}^* & p_{T,(j)} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{z}_{p0,(j+1)}^{(k)} \\ \Delta T_{(j+1)}^{(k)} \end{bmatrix} = \begin{bmatrix} -\mathbf{H}(\mathbf{z}_{p0,(j+1)}^{(k)}, T_{(j+1)}^{(k)}) \\ -h(\mathbf{z}_{p0,(j+1)}^{(k)}) \\ 0 \end{bmatrix} \quad (10)$$

where the prediction is used as initial guess, i.e. $\mathbf{z}_{p0,(j+1)}^{(0)} = \tilde{\mathbf{z}}_{p0,(j+1)}$ and $T_{(j+1)}^{(0)} = \tilde{T}_{(j+1)}$. The last equation in (10) corresponds to the orthogonality condition for the corrector step.

This iterative process is carried out until convergence is achieved. The convergence test is based on the relative error of the periodicity condition:

$$\frac{\|\mathbf{H}(\mathbf{z}_{p0}, T)\|}{\|\mathbf{z}_{p0}\|} = \frac{\|\mathbf{z}_p(T, \mathbf{z}_{p0}) - \mathbf{z}_{p0}\|}{\|\mathbf{z}_{p0}\|} < \epsilon \quad (11)$$

where ϵ is the prescribed relative precision.

3.3 Sensitivity Analysis

Each shooting iteration involves the time integration of the equations of motion to evaluate the current shooting residue $\mathbf{H}(\mathbf{z}_{p0}^{(k)}, T^{(k)}) = \mathbf{z}_p^{(k)}(T^{(k)}, \mathbf{z}_{p0}^{(k)}) - \mathbf{z}_{p0}^{(k)}$. As evidenced by equation (10), the method also requires the evaluation of the $2n \times 2n$ Jacobian matrix

$$\frac{\partial \mathbf{H}}{\partial \mathbf{z}_0}(\mathbf{z}_0, T) = \frac{\partial \mathbf{z}(t, \mathbf{z}_0)}{\partial \mathbf{z}_0} \Big|_{t=T} - \mathbf{I} \quad (12)$$

where \mathbf{I} is the $2n \times 2n$ identity matrix.

The classical finite-difference approach requires to perturb successively each of the $2n$ initial conditions and integrate the *nonlinear* governing equations of motion. This approximate method therefore relies on extensive numerical simulations and may be computationally intensive for large-scale finite element models.

Targeting a reduction of the computational cost, a significant improvement is to use sensitivity analysis for determining $\partial \mathbf{z}(t, \mathbf{z}_0)/\partial \mathbf{z}_0$ instead of a numerical finite-difference procedure. The sensitivity analysis consists in differentiating the equations of motion (2) with respect to the initial conditions \mathbf{z}_0 which leads to

$$\frac{d}{dt} \left[\frac{\partial \mathbf{z}(t, \mathbf{z}_0)}{\partial \mathbf{z}_0} \right] = \frac{\partial \mathbf{g}(\mathbf{z})}{\partial \mathbf{z}} \Big|_{\mathbf{z}(t, \mathbf{z}_0)} \left[\frac{\partial \mathbf{z}(t, \mathbf{z}_0)}{\partial \mathbf{z}_0} \right] \quad (13)$$

with

$$\frac{\partial \mathbf{z}(0, \mathbf{z}_0)}{\partial \mathbf{z}_0} = \mathbf{I} \quad (14)$$

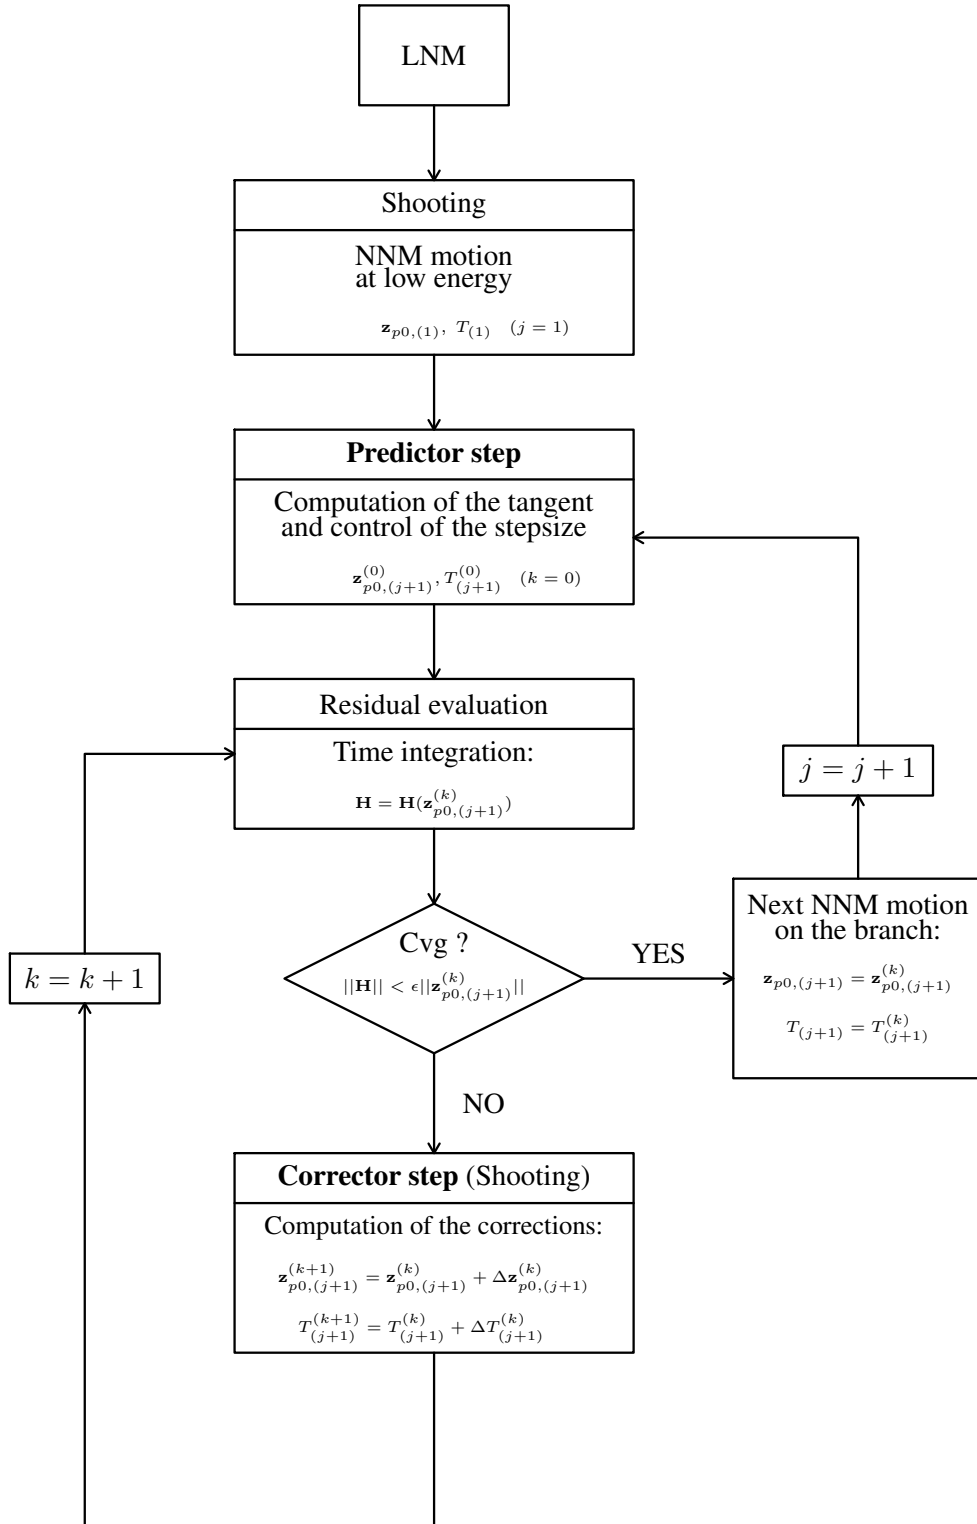

Figure 1: Algorithm for NNM computation.

since $\mathbf{z}(0, \mathbf{z}_0) = \mathbf{z}_0$. Hence, the matrix $\partial \mathbf{z}(t, \mathbf{z}_0)/\partial \mathbf{z}_0$ at $t = T$ can be obtained by numerically integrating over T the initial-value problem defined by the *linear* ordinary differential equations (ODEs) (13) with the initial conditions (14).

In addition to the integration of the current solution $\mathbf{z}(t, \mathbf{x}_0)$ of (2), these two methods for computing $\partial \mathbf{z}(t, \mathbf{z}_0)/\partial \mathbf{z}_0$ require $2n$ numerical integrations of $2n$ -dimensional dynamical systems, which may be computationally intensive for large systems. However, equations (13) are linear ODEs and their numerical integration is thus less expensive. The numerical cost can be further reduced if the solution of equations (13) is computed together with the solution of the nonlinear equations of motion in a single numerical simulation [13].

The sensitivity analysis requires only one additional iteration at each time step of the numerical time integration of the current motion to provide the Jacobian matrix. The reduction of the computational cost is therefore significant for large-scale finite element models. In addition, the Jacobian computation by means of the sensitivity analysis is exact. The convergence troubles regarding the chosen perturbations of the finite-difference method are then avoided. Hence, the use of sensitivity analysis to perform the shooting procedure represents a meaningful improvement from a computational point of view.

As the monodromy matrix $\partial \mathbf{z}_p(T, \mathbf{z}_{p0})/\partial \mathbf{z}_{p0}$ is computed, its eigenvalues, the Floquet multipliers, are obtained as a by-product, and the stability analysis of the NNM motions can be performed in a straightforward manner.

3.4 Algorithm for NNM Computation

The algorithm proposed for the computation of NNM motions is a combination of shooting and pseudo-arclength continuation methods, as shown in Figure 1. It has been implemented in the MATLAB environment. Other features of the algorithm such as the step control, the reduction of the computational burden and the method used for numerical integration of the equations of motion are discussed in [12].

So far, the NNMs have been considered as branches in the continuation space (\mathbf{z}_{p0}, T) . An appropriate graphical depiction of the NNMs is to represent them in a frequency-energy plot (FEP). This FEP can be computed in a straightforward manner: (i) the conserved total energy is computed from the initial conditions realizing the NNM motion; and (ii) the frequency of the NNM motion is calculated directly from the period.

4 Numerical Experiment - Full-Scale Aircraft

The numerical computation of the NNMs of a complex real-world structure is addressed. This structure is the airframe of the Morane-Saulnier Paris aircraft, which is represented in Figure 2. This French jet aircraft was built during the 1950s and was used as a trainer and liaison aircraft. The structural configuration under consideration corresponds to the aircraft without its jet engines and standing on the ground through its three landing gears with deflated tires. For information, general characteristics are listed in Table 1. A specimen of this plane is present in ONERA's laboratory, and ground vibration tests have exhibited nonlinear behavior in the connection between the wings and external fuel tanks located at the wing tip. As illustrated in Figure 3, this connection consists of bolted attachments.

Figure 2: Morane-Saulnier Paris aircraft.

Table 1: Properties of the Morane-Saulnier Paris aircraft

Length (m)	Wingspan (m)	Height (m)	Wing area (m ²)	Weight (kg)
10.4	10.1	2.6	18	1945

Figure 3: Connection between external fuel tank and wing tip (top view). Close-up of (a) front and (b) rear bolted attachments.

4.1 Structural Model of the Paris Aircraft

4.1.1 Finite Element Model of the Underlying Linear Structure

The linear finite element model of the full-scale aircraft, illustrated in Figure 4, was elaborated from drawings by ONERA [14]. The wings, vertical stabilizer, horizontal tail and fuselage are modeled by means of 2-dimensional elements such as beams and shells. The complete finite element model has more than 80000 DOFs. Three-dimensional spring elements, which take into account the structural flexibility of the tires and landing gears, are used as boundary conditions of the aircraft. At each wing tip, the external fuel tank is connected with front and rear attachments (see Figure 3). In this linear model, these connections between the wings and the fuel tanks are modeled using beam elements. The linear model, originally created in the Nastran software, was converted and exploited in the Samcef finite element environment for this study.

The natural frequencies of the underlying linear system in the [0-50Hz] frequency range are given in Table 2. The first nine modes correspond to aircraft rigid-body modes: six modes are modes of suspensions of the landing gear while the three others are associated to rigid-body motions of the control surfaces (i.e., the ailerons, elevator and rudder). The frequency range of the rigid-body modes is comprised between 0.09 and 3.57 Hz, i.e., noticeably lower than the first flexible mode located at 8.19 Hz. The modal shapes of different elastic normal modes of vibrations are depicted in Figure 5. Figure 5(a) represents the first wing bending mode. The first and second wing torsional modes are depicted in Figures 5(b) and 5(c). These two torsional modes correspond to symmetric and anti-symmetric wing motions, respectively. As shown thereafter, these modes are of particular interest in nonlinear regime since there is a significant deformation of the connections between the wings and fuel tanks. Indeed, the other modes mainly concern the aircraft tail and are consequently almost unaffected by these nonlinear connections.

4.1.2 Reduced-Order Model

The proposed algorithm for the numerical computation of NNMs is computationally intensive for the large-scale original model possessing more than 80000 DOFs. Since the nonlinearities are spatially localized, condensation of the linear components of the model is an appealing approach for a computationally tractable and efficient calculation.

A reduced-order model of the linear finite element system is constructed using the Craig-Bampton (also called component mode) reduction technique [15]. This method consists in describing the system in terms of some retained DOFs and internal vibration modes. By partitioning the complete system in terms of n_R remaining \mathbf{x}_R and $n_C = n - n_R$ condensed \mathbf{x}_C DOFs, the n governing equations of motion of the global finite element model are written as

$$\begin{bmatrix} \mathbf{M}_{RR} & \mathbf{M}_{RC} \\ \mathbf{M}_{CR} & \mathbf{M}_{CC} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{x}}_R \\ \ddot{\mathbf{x}}_C \end{bmatrix} + \begin{bmatrix} \mathbf{K}_{RR} & \mathbf{K}_{RC} \\ \mathbf{K}_{CR} & \mathbf{K}_{CC} \end{bmatrix} \begin{bmatrix} \mathbf{x}_R \\ \mathbf{x}_C \end{bmatrix} = \begin{bmatrix} \mathbf{g}_R \\ \mathbf{0} \end{bmatrix} \quad (15)$$

The Craig-Bampton method expresses the complete set of initial DOFs in terms of: (i) the remaining DOFs through the static modes (resulting from unit displacements on the remaining DOFs) and (ii) a certain number $m < n_C$ of internal vibration modes (relating to the primary structure fixed on the remaining nodes). Mathematically, the reduction is described by relation

$$\begin{bmatrix} \mathbf{x}_R \\ \mathbf{x}_C \end{bmatrix} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{K}_{CC}^{-1} \mathbf{K}_{CR} & \Phi_m \end{bmatrix} \begin{bmatrix} \mathbf{x}_R \\ \mathbf{y} \end{bmatrix} = \mathbf{R} \begin{bmatrix} \mathbf{x}_R \\ \mathbf{y} \end{bmatrix} \quad (16)$$

Figure 4: Finite element model of the Morane-Saulnier Paris aircraft.

Mode	Freq. (Hz)	Mode	Freq. (Hz)
1	0.0936	13	21.2193
2	0.7260	14	22.7619
3	0.9606	15	23.6525
4	1.2118	16	25.8667
5	1.2153	17	28.2679
6	1.7951	18	29.3309
7	2.1072	19	31.0847
8	2.5157	20	34.9151
9	3.5736	21	39.5169
10	8.1913	22	40.8516
11	9.8644	23	47.3547
12	16.1790	24	52.1404

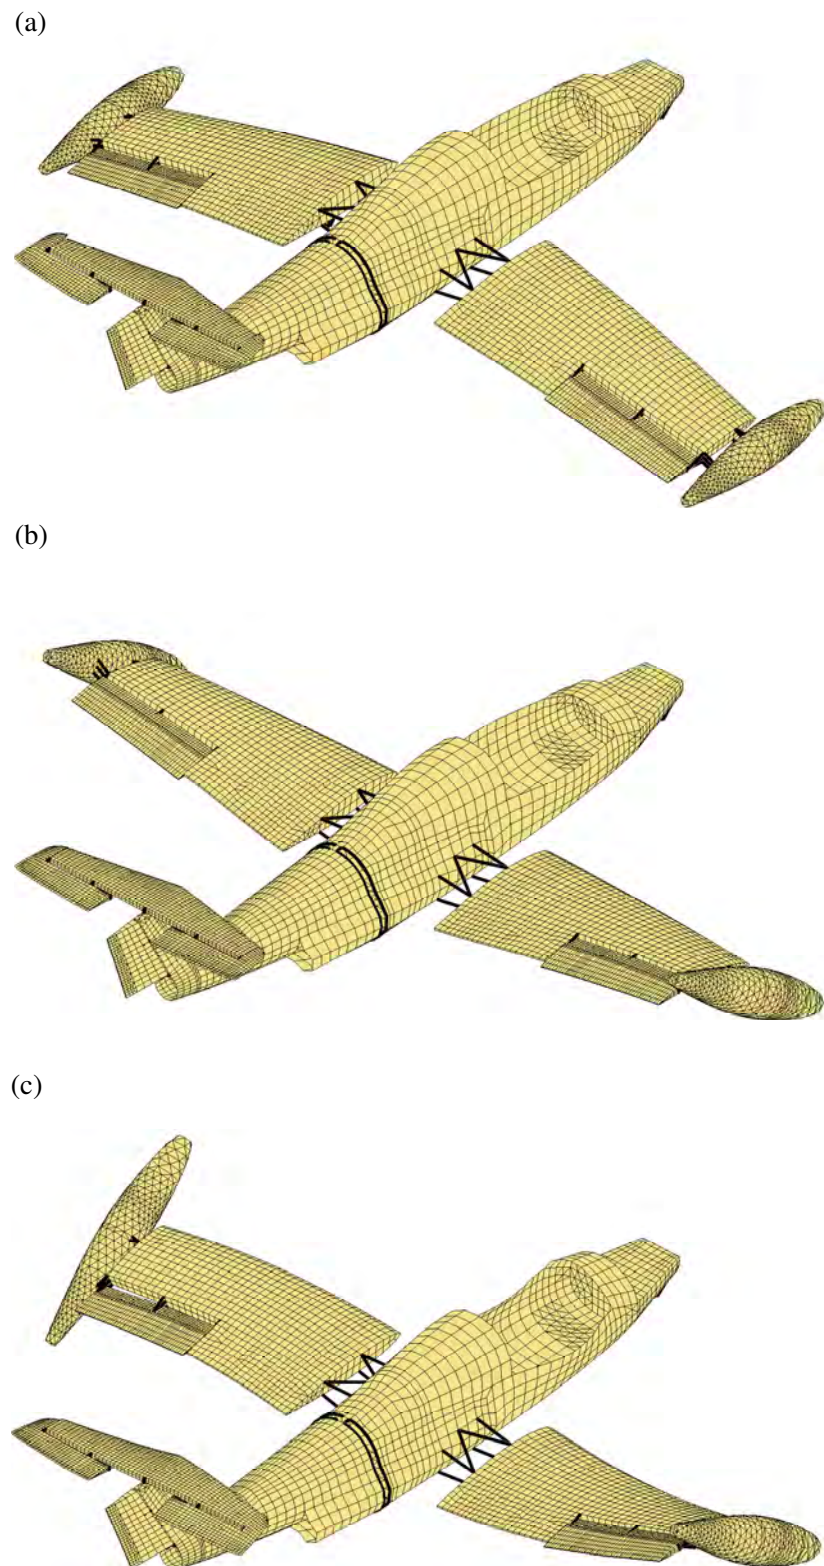

Figure 5: Normal modes of the linear finite element model of the Morane-Saulnier Paris aircraft. (a) First wing bending mode (8.19 Hz), (b) first (symmetric) wing torsional mode (31.08 Hz) and (b) second (anti-symmetric) wing torsional mode (34.92 Hz).

which defines the $n \times (n_R + m)$ reduction matrix \mathbf{R} . \mathbf{y} are the modal coordinates of the m internal linear normal modes collected in the $n_C \times m$ matrix $\Phi_m = [\phi_{(1)} \dots \phi_{(m)}]$. These modes are solutions of the linear eigenvalue problem corresponding to the system fixed on the remaining nodes

$$(\mathbf{K}_{CC} - \omega_{(j)}^2 \mathbf{M}_{CC}) \phi_{(j)} = \mathbf{0} \quad (17)$$

The reduced model is thus defined by the $(n_R + m) \times (n_R + m)$ reduced stiffness and mass matrices given by

$$\begin{aligned} \overline{\mathbf{M}} &= \mathbf{R}^* \mathbf{M} \mathbf{R} \\ \overline{\mathbf{K}} &= \mathbf{R}^* \mathbf{K} \mathbf{R} \end{aligned} \quad (18)$$

where star denotes the transpose operation. After reduction, the system configuration is expressed in terms of the reduced coordinates (i.e., the remaining DOFs and the modal coordinates). The initial DOFs of the complete model are then determined by means of the reduction matrix using relation 16.

In order to introduce the nonlinear behavior of the connections between the wings and the tanks, the reduced-order linear model of the aircraft is constructed by keeping one node on both sides of the attachments. For each wing, four nodes are retained: two nodes for the front attachment and two nodes for the rear attachment. In total, only eight nodes of the finite element model are kept to build the reduced model. It is completed by holding the first 500 internal modes of vibrations. Finally, the model is thus reduced to 548 DOFs: 6 DOFs per node (3 translations and 3 rotations) and 1 DOF per internal mode. The reduction is performed using the Samcef software. The generated reduced-order model is next exported in the MATLAB environment.

Before proceeding to nonlinear analysis, the accuracy of the reduced-order linear model is assessed. To this end, the linear normal modes of the initial complete finite element model are compared to those predicted by the reduced model. The deviation between the mode shapes of the original model $\mathbf{x}_{(o)}$ and of the reduced model $\mathbf{x}_{(r)}$ is determined using the Modal Assurance Criterion (MAC)

$$\text{MAC} = \frac{|\mathbf{x}_{(o)}^* \mathbf{x}_{(r)}|^2}{|\mathbf{x}_{(o)}^* \mathbf{x}_{(o)}| |\mathbf{x}_{(r)}^* \mathbf{x}_{(r)}|} \quad (19)$$

MAC values range from 0 in case of no correlation to 1 for a complete coincidence. In the [0-100Hz] range, MAC values between modes shapes are all greater than 0.999 and the maximum relative error on the natural frequencies is 0.2%. It therefore validates the excellent accuracy of the reduced linear model in this frequency range. It is worth noticing that less internal modes are sufficient to ensure such a correlation in the [0-100Hz] frequency range, which is typically the range of interest for aircrafts. However, a larger number of modes was deliberately chosen for two main reasons. On the one side, it serves to illustrate the ability of the numerical algorithm to deal with the NNM computation of higher-dimensional systems. On the other hand, due to nonlinearity, modes of higher frequencies may interact with lower modes of interest. In nonlinear regimes, higher internal modes should then be necessary to guarantee the accuracy of the model.

4.1.3 Nonlinear Model

The existence of a softening nonlinear behavior was evidenced during different vibration tests conducted by ONERA. In particular, FRF measurements reveal the decrease of resonant frequencies with the level of excitation. The connections between the wings and fuel tanks are assumed to cause this observed nonlinear effect.

To confirm this hypothesis, both (front and rear) connections of each wing were instrumented and experimental measurements were carried out. Specifically, accelerometers were positioned on both (wing and tank) sides of the connections and two shakers were located at the tanks. This is illustrated in Figure 6 for rear connection.

The dynamic behavior of these connections in the vertical direction is investigated using the restoring force surface (RFS) method [16]. By writing Newton's second law at the wing side of each connection, it follows

$$m_c \ddot{x}_c(t) + f_{r,c} = 0 \quad (20)$$

where $f_{r,c}$ is the restoring force applied to this point. The index c is related to the connection under consideration (i.e., either the rear or front attachment of the left or right wing). From Equation (20), the restoring force is obtained by

$$f_{r,c} = -m_c \ddot{x}_c(t) \quad (21)$$

Except the multiplicative mass factor m_c , the restoring force is then given by the acceleration $\ddot{x}_c(t)$. Nevertheless, this total restoring force does not consist only of the internal force related to the connection of interest, but also includes contributions from the linking forces associated to the wing elastic deformation. Provided that these latter do not play a prominent role, the measurement of the acceleration signal may still provide a qualitative insight into the nonlinear part of the restoring force in the connection between the tank and the wing.

The aircraft is excited close to the second torsional mode (see Figure 5(c)) using a band-limited swept sine excitation in the vicinity of its corresponding resonant frequency. In Figure 7, the measured acceleration at the wing side is represented in terms of the relative displacement x_{rel} and velocity \dot{x}_{rel} of the connection obtained by integrating the accelerations on both sides of the attachment. It is given for the rear connections of the right and left wings. A nonlinear softening elastic effect is observed from the evolution of these estimated restoring force surfaces. In particular, the detected behavior has a piecewise characteristic. This is more clearly

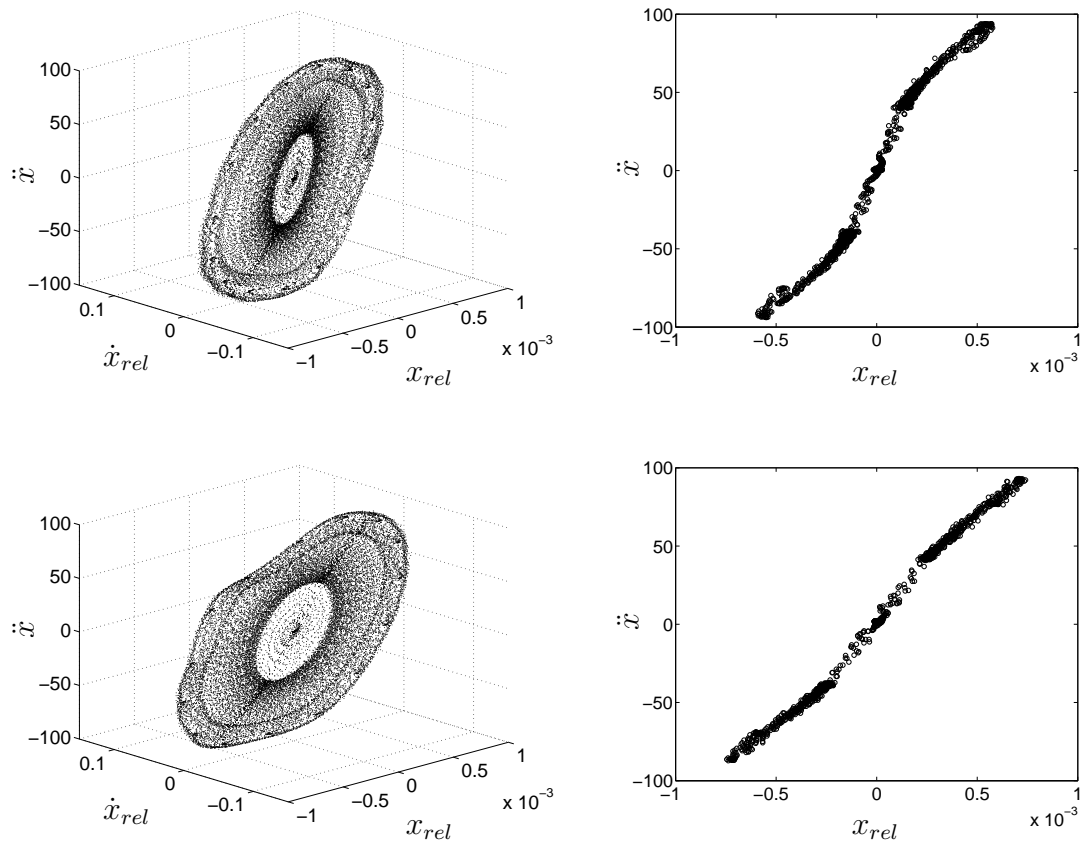

Figure 7: Estimated restoring force in the connections between tanks and wings. Left plots: measured acceleration in terms of the relative displacement (m) and velocity (m/s). Right plots: stiffness curve given by the measured acceleration for zero velocity. Top plots: rear tank connection of the left wing. Bottom plots: rear tank connection of the right wing.
